mixture. A DKK Model IOL-50 ion meter, a DKK Model EL7100 S^{2-} ion-selective electrode, and a DKK Model EL4083 double junction reference electrode (1M KNO_3 outer electrolyte, 3 M KCl inner electrolyte, Ag/AgCl inner electrode, glass sleeve junction) were used for monitoring of S^{2-} ion in making CdS-Ag_2S mixture in wet methods and for potential measurements of the Cd^{2+} ion-selective electrode. A Hitachi Model 208 atomic absorption spectrometer was used for the detection of cadmium, lead, copper and iron in the industrial waste water. Ag_2S of 99.99% purity, CdS of 99.9% purity and sulfur of 99.9% purity were obtained from Kojundo-kagaku (Tokyo, Japan). A silver disk, a silver wire and silver powder of 99.99% purity were obtained from Tokuriki (Tokyo, Japan), and silver paste SILVEST P-110 were obtained from Tokuriki Chemical (Tokyo, Japan).

Silver nitrate, cadmium nitrate, sodium sulphide, sodium acetate, disodium hydrogenphosphate, potassium nitrate, hydrogen nitrate, sodium hydroxide, salicylaldoxime and ethyl alcohol were obtained from Wako Chemicals (Osaka, Japan). All chemicals were of analytical reagent grade. Pure water obtained by a MILLI-Q SP Reagent Water System was used in this work. Argon cylinder gas and hydrogen sulphide cylinder gas were obtained from Nipponsanso (Tokyo, Japan).

2.2. Preparation of CdS-Ag_2S membrane by dry method

CdS-Ag_2S mixture was prepared the following two methods. The ratio between CdS and Ag_2S is 10:90 mol%, typically.

1. Stoichiometric amount of cadmium powder, silver powder and surfer powder was mixed well and was baked for 3 h at 700°C under hydrogen sulphide gas stream.
2. Stoichiometric amount of cadmium sulphide powder and silver sulphide powder and 5 mol% equivalent of surfer powder was mixed well and was baked for 3 h at 700°C under hydrogen sulphide gas stream.

The CdS-Ag_2S mixture produced was ground into powder (under 147 μm (100 mesh)) and was compressed under 200 kgf cm^{-1} in a 8 mm diameter die to form 2 mm thickness pellet or membrane. Furthermore the pellet was baked for 3 h at 700°C under hydrogen sulphide gas stream.

2.3. Preparation of CdS-Ag_2S membrane by wet method

CdS-Ag_2S mixture was prepared the following method. The ratio between CdS and Ag_2S is 10:90 mol%, typically. EL7100 sulphide ion-selective electrode and EL4083 reference electrode were soaked in solution of 0.1 M sodium sulphide. 1 M potassium nitrate was filled in outer chamber of the reference electrode not to outflow chloride ion from the liquid junction to the 0.1 M sodium sulphide. Solutions of 0.1 M cadmium nitrate and 0.2 M silver nitrate were mixed in 10:90 ratio. This mixed solution was added little by little in the 0.1 M sodium sulphide while the solution was strongly stirred and the change of the sulphide ion-selective electrode potential was measured. The co-precipitate reaction was stopped when the potential variation from the initial potential in the 0.1 M sodium sulphide reached at 116 mV, which the sulphide ion concentration became 10^{-4} of the initial concentration. After the solution kept being stirred for 1 h, the co-precipitate of CdS and Ag_2S was decanted and washed by sufficient amount of water for five times. Therefore the co-precipitate was filtered out and was washed by ethyl alcohol for three times and was dried at 80°C under argon gas stream. The final CdS-Ag_2S mixture powder was compressed under 200 kgf cm^{-1} in a 8 mm diameter die to form 2 mm thickness pellet or membrane not to touch the air so long time.

2.4. Electrode assembly

The structure of cadmium ion-selective electrodes fabricated is shown in Fig. 1. The CdS-Ag_2S membrane tablet is stuck in an epoxy resin body by epoxy bond. Two types of electrodes were measured. Type A electrode has inner solution (10^{-3} M cadmium chloride) and a Ag/AgCl inner electrode. The membrane of type B electrode is led out by a silver wire and a silver disk

which is stuck in opposite side of the membrane by silver paste. As these types of electrode were shown the same characteristics without the absolute value of the electrode potential, type B electrode was used throughout. The performance of the electrode was examined by measuring the e.m.f. against Model EL4083 reference electrode with a glass sleeve junction, 1M KNO_3 outer solution, 3M KCl inner solution and a Ag/AgCl inner electrode.

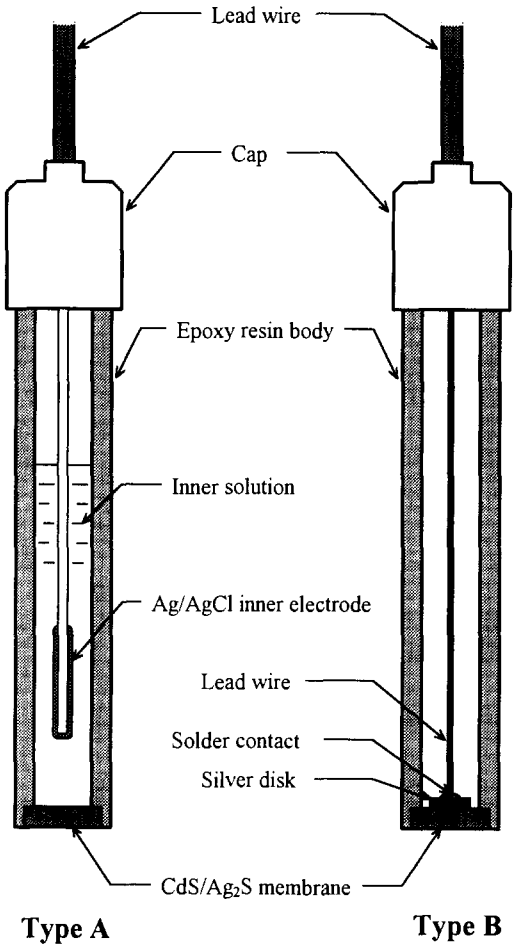

Fig. 1. Structure of Cd^{2+} ion-selective electrodes with CdS/Ag_2S solid state membrane.

2.5. Preparation of buffer solution

100 g of sodium acetate trihydrate, 100 g of disodium hydrogenphosphate 12 water, 100 g of potassium nitrate are dissolved in adequate quantity of water. The solution dissolved 10 g of salicylaldoxime in 50 ml of ethyl alcohol is added to the previous solution and adjusted in 6.15 pH by adding acetic acid using a pH meter and the whole quantity is adjusted by water in 1 l. When 1 vol.% of this buffer was added waste water of 5–8.5 pH it could be adjusted in about 6 pH.

2.6. Potential measurements and calibration curve

The Cd^{2+} ion-selective electrode fabricated and Model 4083 reference electrode were placed in 200 ml beaker. Sample of 100 ml in a beaker was stirred by a 300 mm length of magnet on a magnetic stirrer at about 400 rev min^{-1} during the measurement. The performance of the Cd^{2+} ion-selective electrode was examined by measuring the e.m.f. of the following electrochemical cell:

Ag |silver paste| CdS-Ag_2S |sample ‖1 M KNO_3‖ 3 M KCl |Ag/AgCl| Ag Each electrode was immersed in 10^{-9}–10^{-1} M l^{-1} Cd^{2+} standard solution of which the total ionic strength was adjusted with 0.1 M KNO_3 and calibration curves of each electrode were made. The electrode potentials were recorded after their values had stabilized within ± 0.1 mV min^{-1}. The potential-concentration curves were plotted as shown in Fig. 2.

2.7. Influence of pH

Each electrode was calibrated using standard solutions that changed pH from 2 to 11. The pH was adjusted by adding small volumes of HNO_3 or NaOH to the standard solution. The electrode potentials were recorded after their values stabilized, and were plotted as a function of pH values and Cd^{2+} concentration as shown in Fig. 3.

2.8. Influence of temperature

From 10^{-7}–10^{-1} M l^{-1} Cd^{2+} standard solution were prepared in a water bath at 5, 25 and

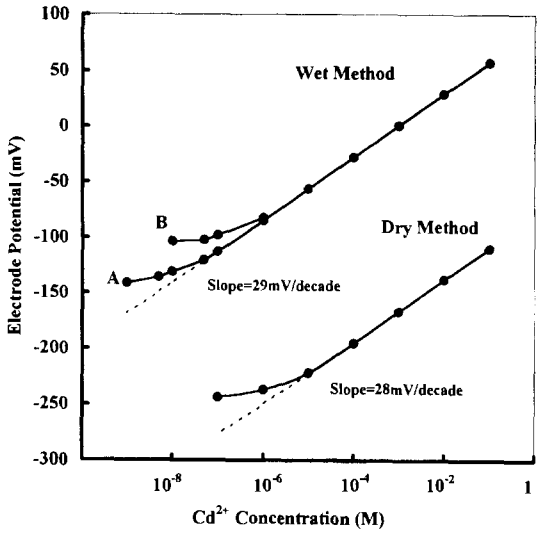

Fig. 2. Calibration curves for Cd^{2+} ion-selective electrodes with CdS/Ag_2S solid state membrane by a dry method and a wet method.

45°C, respectively. They were kept at a constant temperature within ±0.1°C. The calibration curves of the electrode were measured in standard solution at 5°C, and then, were measured at 25 and 45°C. The electrode potentials were recorded after their values stabilized, and were plotted as a function of temperature values and Cd^{2+} concentration.

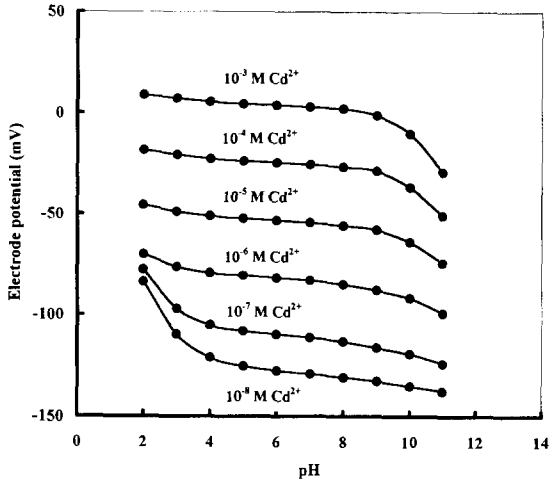

Fig. 3. Effect of pH on Cd^{2+} ion-selective electrodes with CdS/Ag_2S solid state membrane by a wet method.

2.9. Selectivity

Selectivity coefficients were determined by the mixed solution method, wherein the concentration of Cd^{2+} was fixed at 10^{-5} M l^{-1} of Cd^{2+} and the concentration of an interfering ion was varied. The selectivity coefficients, $K^{pot}_{A,B}$, were calculated according to the relation $K^{pot}_{A,B} = C_A^{(zB/zA)}/C_B$, where C_A and C_B are the total concentration of Cd^{2+} and that of an interfering ion obtained graphically in the sample solution, respectively. zA and zB are the charges of Cd^{2+} and the interfering ions, respectively.

3. Result and discussion

3.1. Detection limit of calibration curve

Calibration curves with the dry method membrane and the wet method membrane A and B are shown in Fig. 2. In the wet method, the membrane A is one that the co-precipitate reaction was stopped when the potential variation from the initial potential in the 0.1 M sodium sulphide reached at 116 mV, which the sulphide ion concentration became 10^{-4} of the initial concentration, the membrane B is one that the co-precipitate reaction was stopped when the potential variation reached at 38 mV, which the sulphide ion concentration became 5% of the initial concentration. Detection limits, which are the lowest point of Cd^{2+} concentration that their calibration curves showed Nernstian response, are 10^{-6}, 10^{-8} and 10^{-7} M l^{-1}, respectively. The characteristics of dry method electrodes on detection limit were varied between 10^{-5} and 10^{-3} M l^{-1} independently of whether departure materials of CdS-Ag_2S production were Ag-Cd-S or Ag_2S-CdS-S. This seems to be resulted from inhomogeneities of powder mixing, unequal heating, etc. In the wet method, the potential variation of S^{2-} ion-selective electrode became more, the detection limit of the membrane tended to be lower. However, as S^{2-} ion-selective electrode potential became unstable when the potential variation goes up to over 87 mV, which the sulphide ion concentration became 10^{-3} of the initial concentration,

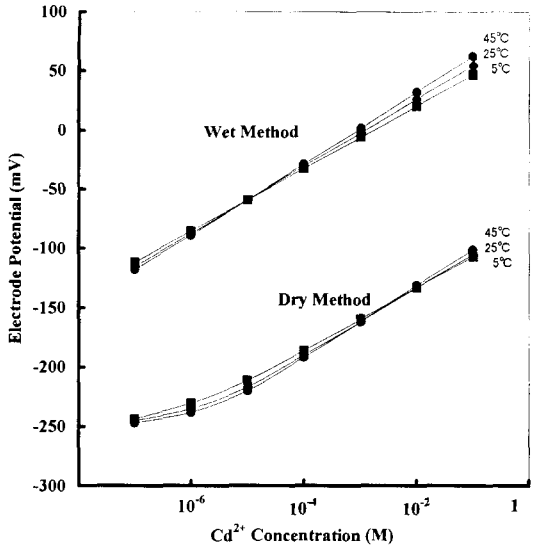

Fig. 4. Effect of temperature on Cd^{2+} ion-selective electrodes with CdS/Ag_2S solid state membrane by a dry method and a wet method.

it would be difficult to make the membrane with lower detection limit than the membrane A.

3.2. Effect of pH

pH dependence of the $CdS\text{-}Ag_2S$ membrane (the wet method membrane A) is shown in Fig. 3. There are not much differences between methods to make the membranes. Cd^{2+} ion-selective electrode potential is mostly independent of pH from 2 to 9. It is slightly interfered for pH values down to 4 for extremely low cadmium concentration (under 10^{-7} M l^{-1}). The detection limit comes to 10^{-7} M l^{-1} for pH 3 and 5×10^{-7} M l^{-1} for pH 2. However, as pH coefficient is calculated about -1.1 mV pH^{-1} (Cd^{2+} of 10^{-7}–10^{-3} M l^{-1}, pH of 2–9), calibration and sample measurement should be done at the same pH values.

3.3. Effect of temperature

Temperature dependencies of the $CdS\text{-}Ag_2S$ membrane (the dry method membrane and the wet method membrane A) at 5, 25 and 45°C were shown in Fig. 4. The isothermal point of the dry method membrane was calculated between 10^{-3} and 10^{-2} M l^{-1}. That of the wet method membrane was calculated at about 10^{-5} M l^{-1}. Although the slope (the electrode potential change per decade) increased according to Nernstian coefficient (0.0993 mV°C^{-1} at 25°C for divalent cation) when the temperature increased, detection limit became higher.

3.4. Effect of interfering compounds and its masking

Mercury (Hg^{2+}), silver ion (Ag^{+}), Cu^{2+}, Lead (Pb^{2+}), iron ion (Fe^{3+}) interfere with Cd^{2+} ion-selective electrode potential. Although under coexistence of interfering ions the Cd^{2+} ion-selective electrode potential is not stable and the selectivity coefficients could not be correctly measured, the interference of ions mentioned above were shown in Table 1. The approximate errors (S.D.) of the selectivity values were 50–200% in ten repeated measurements. These interfering result was independent of how to make the $CdS\text{-}Ag_2S$ membrane.

In the application for industrial waste water, practical selectivity could be improved by using masking reagents of interfering ions. By the use of 1% of the buffer solution (10 wet% of sodium acetate trihydrate, 10 wet% of disodium hydrogenphosphate 12 water, 10 wet% of potassium nitrate, 1 wet% of salicylaldoxime, pH 6.15), practical selectivity coefficients were obtained as shown in Table 1.

Table 1
Selectivity coefficients of Cd^{2+} membrane

Ions	Selectivity coefficients of Cd^{2+} membrane	
	In aqueous solution	In 1% buffer solution
Hg^{2+}	10^3	0.2
Ag^{+}	10^2	10^{-3}
Cu^{2+}	10	10^{-3}
Pb^{2+}	1	10^{-3}
Fe^{3+}	1	10^{-3}

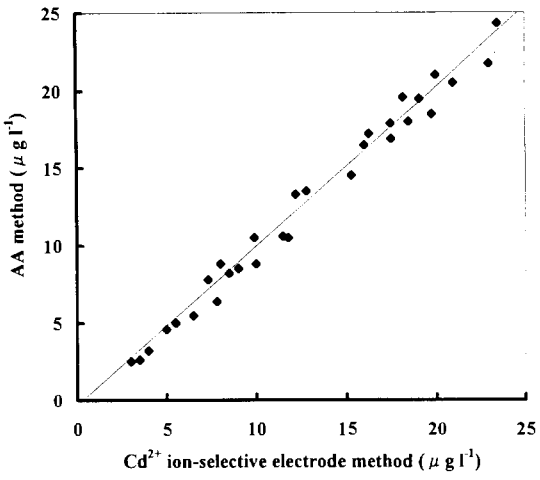

Fig. 5. Correlation between the value of Cd^{2+} ion-selective electrodes and that of AA in the industrial waste water.

4. Analysis of industrial waste water

We applied the present Cd^{2+} ion-selective electrode for the determination of the Cd^{2+} ion in the industrial waste water. Fig. 5 shows the correlation between the value of the Cd^{2+} ion-selective electrode and that of AA in the industrial waste water. The wet method membrane A was used in the analysis and 1% of buffer solution was added to sample solution for masking of Cu^{2+}, Pb^{2+} and Fe^{3+} ions. Concentrations of Cu^{2+}, Pb^{2+} and Fe^{3+} ions in the industrial waste water were 0.1–1, 0.1–0.5, and 0.2–2 mg l^{-1}, respectively. The values with Cd^{2+} ion-selective electrode are good agreement with those with AA ($r^2 = 0.984$, $y = 1.035x - 0.629$). In the analysis of industrial waste water under coexistence of 20–100 fold of Cu^{2+}, Pb^{2+} and Fe^{3+} ions against Cd^{2+} ion, low concentration range of 2.5–25 μg l^{-1} (2.5×10^{-8}–2.5×10^{-7} M) Cd^{2+} ion could be successfully measured. From these data, it is clear that the present Cd^{2+} ion-selective electrode was useful for the simple and speedy control of Cd^{2+} ion in the industrial waste water with sufficient sensitivity compared with AA.

5. Conclusion

New highly sensitive Cd^{2+} ion-selective electrode was developed by titration method using S^{2-} ion-selective electrode as the indicator electrode compared with the dry method. In the dry method, in the case S or H_2S was not used, the CdS-Ag_2S membrane was entirely not or little shown a Nernstian response. Also, in the wet method, in the case the sodium sulphide solution was added into Ag^+ and Cd^{2+} mixed solution and the co-precipitate reaction was stopped at about 400 mV of S^{2-} ion-selective electrode potential, which S^{2-} ion was not existed at all the CdS-Ag_2S membrane was entirely not shown a Nernstian response, too. Although Hirata et al. [6] reported to relationship between the electrode characteristics and the existence of intermediate phases: $Ag_{1.55}Cu_{0.45}S$, etc., in the study of ceramic copper (II) ion-selective electrode membrane in a X-ray microanalysis, we obtained good characteristics of the CdS-Ag_2S membrane without a heat treatment in the present wet method. As shown in Fig. 2, electrode potentials on the same concentration of Cd^{2+} standard solution are different the dry method membrane from the wet method membrane. Furthermore, as shown in Fig. 4, isothermal points are different each other. Because the each CdS-Ag_2S membrane obtained in dry method and in wet method has more or less different characteristics. However, it is sure that a sulphide in a CdS-Ag_2S procedure plays an important role for its good characteristic. As a result, we could make a Cd^{2+} ion-selective electrode of the best characteristics by titration method. Data by the present method was good agreement with those from AA.

Abstract

Sequential injection analysis (SIA) technique has been applied to anodic stripping voltammetry (ASV). The sample and reagent volumes can easily be controlled by SIA. The technique also allows plating of the mercury film on-line and therefore substantially reduces generation of mercury containing waste. Repeated sample passage through the detector was used during the deposition step to enhance the sensitivity. The way solution handling is done in SIA allows an easy and effective medium exchange procedure increasing the selectivity of the method. This has been demonstrated by changing the stripping medium and having different complexing agents in the stripping solution. The observed potential shifts of the stripping peaks could theoretically be explained in the cases where the complexation constants are known. Calibration and the standard addition methods are discussed and demonstrated by determining copper in tap water as a method of testing the procedure. © 1997 Elsevier Science B.V.

Keywords: Anodic stripping voltammetry; Copper; Mercury; Sequential injection analysis

1. Introduction

Sequential injection analysis (SIA) is a new generation of flow injection analysis (FIA) [1]. The method is based on the same principle as FIA i.e., controlled dispersion, reproducible injection of the sample and exact timing of the different operations. The way how solutions are handled makes SIA more versatile than FIA. The enhanced versatility of SIA is due to the instrumental units of the system. A precise, in reversal directions functioning and digitally controlled pump as well as a multiposition and digitally controlled valve are needed [2]. Timing has to be precise, accurate and easily adjustable and therefore the system requires computer control. Remaining parts of the system i.e., detector, tubing and additional arrangements are similar as in FIA. One additional requirement in SIA is the response time of the detector. In FIA the flow is continuously pumped through the detector. In SIA, however, the flow is stopped while the sample and reagents are aspirated into the holding coil. Therefore the detector in SIA has to reach a stable baseline very fast after the flow is again directed through the detector. This is especially

PII S0039-9140(96)02115-7

important when using potentiometric and voltammetric detectors where the response is based on interaction of the compounds in the flow and the sensor surface. The advantages of SIA are:

(i) reduced reagent consumption

(ii) easy and fast change of solutions and their handling: change of concentration and volume ratio, dilution, change of reagents

(iii) easy and fast change of system operating parameters: flow rate, number of reagents and their aspirated volumes

The last two points can easily be done by adjusting the proper parameters in the computer program.

The way how the sample and reagent solutions are handled in SIA makes the technique ideal for ASV at mercury film electrodes (MFE) in flow systems. ASV [3] is the method of choice for determination of heavy metals. Because the thin film electrode has a high ratio of surface area to volume, the mercury film electrodes exhibit a higher sensitivity than the bulk mercury electrode such as the hanging mercury drop electrode (HMDE) and its modern variants. Glassy carbon is an often used substrate for MFE, due to the lack of interaction between the substrate and mercury and the substrate and the deposited metals. Mercury, however, is not forming a real film on the glassy carbon substrate but the layer rather consists of very small drops of mercury. In contrast, metallic substrates such as silver, gold, platinum, copper, iridium give the possibility to obtain a real mercury film. However, depending on the metal substrate some interfering factors are possible such as: intermetallic compounds, substrate amalgamation or problems with mercury deposition because of an oxide film at the substrate surface. Two different electrochemical methods are normally used to generate a film of mercury on the substrate. One method is to preplate the mercury film during a separate plating step and in a separate mercury solution. Usually this method is used to make a thick film to be used in a number of subsequent analytical determinations. The second method is an 'in situ' preparation of the film where the mercury film is formed together with the metals to be determined [4].

The easy solution handling in FIA and the small sample volume used in assays have made FIA technique attractive also for anodic stripping voltammetry (ASV) [5–13]. The aim of the present paper is to show how the technique of SIA can be used with ASV in flow systems to improve the process of making a mercury film electrode, to enhance the sensitivity and selectivity of the method and how the analytical procedure can be carried out with reduced reagent consumption.

2. Experimental

2.1. The system

The SIA system used is shown in Fig. 1. The peristaltic pump is of type C4-V from Alitea, USA. The eight-ports multiposition valve with a home made controller of type MV-8 is from Pharmacia, Sweden. The whole system is controlled by a 486 PC computer (Compaq) with FIALab software (Alitea USA) via an ADA 1100 card (RTD, USA) and a home made connecting box. Parts of the flow system were connected together with PVC tubing with 0.8 mm i.d. and 4.0 mm o.d. Holding and auxiliary coils were fabricated by coiling up 1.5 m of tube on a plastic rod of 25 mm

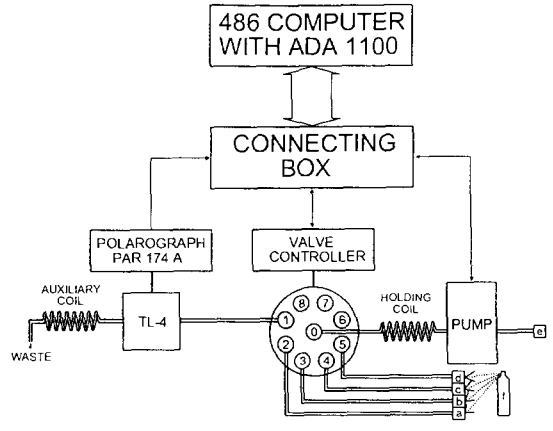

Fig. 1. Schematic diagram of the SIA system for ASV. Solutions: a, 0.1 M HCl; b, sample solution; c, Hg plating solution; d, stripping medium; e, carrier 0.1 M HCl. N_2 was used for deaeration of the solutions, f.

Table 1
Schedule of the medium exchange experiment

Event	Time s	Duration s	Pump speed %	Valve position	Potential V	Data acquisition	Operation
1	0	20	60	1	+0.5	Off	Cleaning
2	20	15	−30	5	+0.5	Off	Stripping medium

9	124	45	0	3	Scan −1→0	On	Stripping
10	166	30	30	1	+0.5	Off	Cleaning

o.d.. The detector was a thin layer cell TL-4 from BAS, USA, with glassy carbon working electrode, saturated silver–silver chloride 3 M NaCl reference electrode and the stainless steel upper body of the detector serving as the auxiliary electrode. Potential control and current measurements were done by the polarographic analyzer model 174A, PAR, USA. Data were collected from the polarograph by an ADA 1100 card, visualized and stored with FIALab software. Interpretation of data was carried out with MicroCal Origin (MicroCal Software, USA). Deaeration of the solutions (sample, mercury plating solution, stripping solution) was performed outside the flow system by purging the solutions with nitrogen. Carrier solution was not deaerated.

2.2. Reagents

Carrier solution was 0.1 M HCl (Merck). Metal ion stock solutions were: Cd(II) 1000 ppm—cadmium shot (Merck 7398) dissolved in nitric acid (Merck suprapur); Cu(II) 1000 ppm—copper shot (Riedel De Haan 12809) dissolved in nitric acid; Hg(II) 50 mM—$HgSO_4$ (Merck) in 5% H_2SO_4; In(III) 5 mM—$InCl_3 \cdot 4H_2O$ (Fluka AG, puriss) in 0.1 M HCl; Pb(II) 1000 ppm—$Pb(NO_3)_2$ (Merck) in 2% nitric acid; Sn(II) 5 mM—$SnCl_2 \cdot 2H_2O$ (Baker, pure) in 0.1 M HCl; Tl(I) 5 mM—CH_3COOTl (BDH, general purpose) in 0.1 M HCl. The stripping solutions were: ammonia buffer 0.01 M, pH 9.2 (NH_4Cl—Merck, ammonia solution 25%—Merck suprapur); 2M ethylenediamine (Merck, for synthesis) in 0.1 M HCl; 0.2 M citric acid (Merck) in 0.1 M HCl and 0.1 M EDTA (Merck–Titriplex III) in 1 M ammonia buffer pH 9.0. The mercury plating solution was 1×10^{-5} M $HgSO_4$ in 0.1 M HCl. In the experiments where a thicker mercury film was required 1×10^{-4} M $HgSO_4$ was used. If not stated otherwise, purity of reagents were of the quality 'pro analysis' and they were used without additional purification. All solutions were prepared using Millipore water.

2.3. Procedure

Whole flow system is operated under computer control via an ADA 1100 card and FIALab software. Table 1 shows the schedule for an experiment with medium exchange. The first and last events are flushing the flow system with carrier solution. In this case carrier is pumped through port 1 to the detector. Next five steps are subsequent aspirations of the stripping solution, deaerated HCl, the sample, the plating solution and again the deaerated HCl solution. These five steps prepare the system for the actual analysis. In the seventh event the electrode potential is switched to plating potential (usually −1.0 V) and the solutions stacked in the holding coil are then pumped via port 1 of the valve to the detector. Solutions reach the detector in a reverse sequence than when they were aspirated in the holding coil. Generation of the Hg film at the electrode is followed by deposition of the components in the

sample. Concentration profiles of the solutions as they pass the detector during the event # 7 are shown in Fig. 2. The profiles were determined by using 1 mM $K_3Fe(CN)_6$ in 1 M acetate buffer pH = 4.5 as the zone which profile was to be measured. In such experiment all the other zones injected were 0.1 M HCl. The current was measured amperometrically at + 0.2 V by using the differential pulse mode with 25 mV pulse amplitude. In the actual experiment with the sample the flow is stopped when the maximum concentration of the stripping solution has reached the detector. After a short rest and stabilization period, step # 8, the stripping step is started in the event # 9 where a differential pulse potential scan is initiated. The scan rate is 20 mV s^{-1} and the pulse amplitude 25 mV. The stripping current is measured with a data acquisition frequency of 5 Hz. Event # 9 is terminated when the electrode potential reaches 0 V. During event # 10 the carrier solution is pumped through the detector. Potential scan is still continued without data collection until the electrode potential reaches + 0.5 V. By this time the mercury film has been removed from the electrode, waste solutions are removed and the system has been washed. The system is then ready for the next cycle. Potential + 0.5 V is also applied to the working electrode during events # 1–# 6.

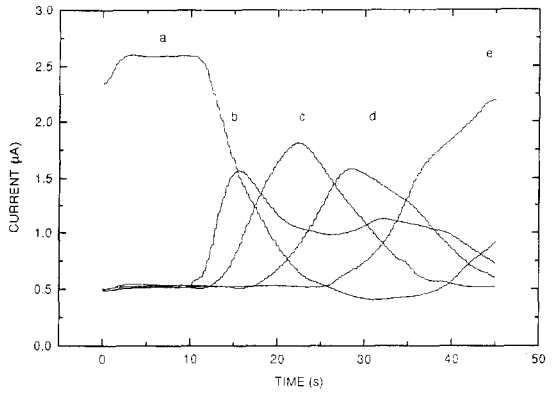

Fig. 2. Concentration profiles for the medium exchange experiment. Solutions: a, carrier 0.1 M HCl; b, deaerated 0.1 M HCl; c, Hg plating solution; d, sample; e, stripping medium. 1 mM $K_3Fe(CN)_6$ in 1 M acetate buffer pH = 4.5 was used as the solution for the zone which profile had to be measured.

Data collected by the FIALab software were stored in MATHLab format and after initial processing by MATHLab they were exported to Microcalc Origin, by which program the data were interpreted, graphically presented and archived.

3. Results and discussion

3.1. Reagent consumption

Increasing requirements on environment protection as well as economic reasons cause the demand to develop analytical methods with minimal reagent consumption and waste production. SIA is a technique that fulfils these requirements to a great extent. Even in comparison with FIA, a method of which one basic advantage is low reagent consumption, SIA shows substantial reagent savings.

3.2. Carrier solution

The role of carrier solution in SIA is to transfer the aspirated zones to the detector and flush the system. In most SIA application distilled water can be used as the carrier. By using distilled water as carrier not only the reagent consumption is reduced but the life time of the pump is also prolonged because in SIA only carrier is in contact with the pump. If peristaltic pumps are used the tubing will last longer lowering the maintenance costs of the system. In the present work it was necessary to assure a certain conductivity in the carrier solution and therefore 0.1 M HCl solution was used. During the entire experimental work required for this paper only 1.5 l of the carrier solution was consumed.

3.3. Sample

The main part of the sample consumed in a FIA system with injection valve goes to rinse the sample loop with a new sample prior to each new assay. Volume of the sample required is therefore 3–5 times higher than the actual volume of the sample loop. In a SIA system the sample is aspirated directly into the holding coil and therefore

only an exactly defined volume of the sample is used, minimizing the consumption of the sample. Assuming that a typical volume of sample in an ASV determination by SIA is 200 μl and three replicate determinations are done, SIA consumes only 0.6 ml, whereas consumption in FIA is 1.8–3.0 ml. Consumption during the sample change is similar in both flow methods and depends on the length of the tubing that delivers the sample to the valve.

3.4. Mercury plating solution

Reduction in consumption of the plating solution is especially important due to the toxicity of mercury salts. Direct comparison with FIA is not simple because in FIA mercury plating is done by a more complicated way. The consumption in FIA is low when the mercury film is generated in situ. In that case the sample is usually made to 50 μM in respect to the mercury salt. Then the consumption of the sample containing mercury salts for three replicate determinations is 1.8–3.0 ml plus the volume (about 2 ml) necessary to wash the delivery tube when the sample is changed. This makes it to 3.8–5.0 ml altogether. Assuming the same volume for cleaning the delivery tube, consumption in SIA is 2.6 ml. But when using the method of film generation as used in this work, i.e., the mercury solution is aspirated through a separate port, the consumption is only 0.6 ml. During the entire experimental work in this paper less than 100 ml of a 10 μM $HgSO_4$ solution was used. Other methods to generate a mercury film in FIA as well as in batch methods generally consume much more of the mercury salt.

3.5. Generation of mercury film

Generation of the mercury film electrode in a flow system needs usually a special procedure. Simplest way is the in situ generation [4]. In many cases, however, a preplated mercury film is used. In those cases the MFE is generated in batch conditions outside the flow system, or by a separate arrangement to deliver the mercury solution to the detector for plating. When a troublesome generation procedure has to be used the same film is then used for several assays. The principles of SIA allows an easy and versatile way to generate a thin mercury film electrode. In SIA it is possible to generate a MFE both by in situ and ex situ method without changing the system manifold.

The same procedure as in FIA can also be used in SIA to generate a mercury film electrode by the in situ method. The sample is made to 5×10^{-5} M with respect to a Hg(II)-salt and the mercury film is formed simultaneously with reduction and amalgam formation of the metals in the sample. Reproducibility of such an electrode was found to be 4.8% measured as the relative standard deviation in the lead stripping peak of a 1 μM Pb(II)-solution with deposition at −1.0 V for 40 s. In that time the leading plug of carrier, the sample and the second plug of carrier have passed the detector, so that the actual efficient deposition time was somewhat shorter.

Generation of a preplated film to be used in several determinations requires a separate SIA solution handling procedure. Mercury plating solution is aspirated first. The next step is deposition of the mercury film and exchange of the solution in the cell. Reproducibility of a preplated film measured with the same lead stripping procedure as mentioned earlier was found to be 5.3% with five determinations. The repeatability was slightly better, 4.3%. A preplated film could be used in generally in more than 15 determinations but the number varied and was difficult to predict in advance.

The third possibility is to generate a mercury film in each analytical run in combination of the metal deposition. As can be seen in Fig. 2 the zones of the mercury plating solution and the sample overlap each other resulting in a mixed zone where plating and deposition could be performed. Only mercury is deposited first and then both mercury and the metals and finally only the metals in the sample. The best results were obtained when the film was removed after each determination by anodic dissolution at +0.5 V and by keeping all the other conditions the same. With this procedure the reproducibility measured with 12 subsequent films was 4.2%. This is the procedure described in Table 1.

In some cases overlapping of the plating solution and the sample may be not advisable because of some possible chemical reactions with the components in the sample and the plating solution. In such cases a small volume of deaerated carrier may be aspirated between the sample and the plating solution. Reproducibility of such an electrode is the same as described above, but analysis time is naturally slightly longer.

3.6. Sensitivity

Sensitivity of ASV depends mainly on the deposition time and effectiveness of charge and mass transfer during the deposition step. In the injection techniques deposition takes place only during a certain effective time [6], i.e., the time during which the sample passes through the detector. With a constant sample volume the sensitivity can, to a certain degree, be enhanced by controlling the flow rate. By decreasing the flow rate the deposition time can be increased, but at the same time, unfortunately, transport of the metal ions from the sample to the electrode surface for amalgam formation is decreased due to increase in the thickness of the diffusion layer at the electrode. For each detector system there is an optimal flow rate which gives the maximal sensitivity. It is possible to improve the sensitivity further by increasing the sample volume or passing the same sample several times through the detector during the deposition step. Both approaches are easy to accomplish in a SIA system.

Sample volume can be increased by increasing the time of aspiration. Fig. 3 shows dpp stripping peaks of 0.5 μM lead and 0.48 μM cadmium in 0.1 M HCl for different aspiration times, i.e., sample volumes. The peak height is linearly dependent on the time of aspiration. The regression lines for both peaks go through the origin and the slopes are 0.204 and 0.153 μA s^{-1} for lead and cadmium, respectively. The correlation coefficient in both cases is 0.999.

Wang et al. demonstrated that when the sample plug in an ASV flow experiment was passed several times through an electrochemical detector with a cylindrical microelectrode the sensitivity could significantly be enhanced [9]. In their study

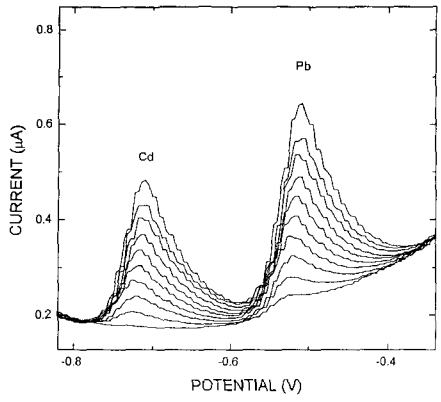

Fig. 3. Dpp stripping peaks of 0.5 μM lead and 0.48 μM cadmium in 0.1 M HCl for different times of aspiration: 0, 2, 4, 6, 8, 10, 12, 14, 16 and 20 s.

with a thin layer cell only 2.5-fold enhancement was reached even with 20 cycles of forward–backward sample passing. However, the following simple arrangement in the manifold used in the present work increased the sensitivity three times already after four forward–backward cycles. A second outlet was fabricated in the thin layer cell. An auxiliary coil of 1.5 m and i.d. of 0.8 mm was connected to this outlet. Flow through the original outlet where the reference electrode is sitting was stopped after the tubings were filled with the carrier solution. During the deposition step the sample was cycled between the auxiliary coil and the thin layer cell. Significant reduction of the sample dilution and dispersion could be achieved by this simple arrangement. Fig. 4A shows the deposition current and therefore also the concentration profiles during several passages of a 200 μl sample of 0.5 μM Pb(II) in 0.1 M HCl through the detector. Fig. 4B shows the dependence of the height of the lead peak on deposition time during which the sample has gone through the detector in both direction. The whole procedure of sample cycling is controlled by the computer and can therefore easily be modified, e.g., number of cycles can be changed depending on the sample. To take the maximum advantage of this repeated sample passage procedure the concentration profile of the sample in the cell has to be known in order to chose the best moment to reverse the flow and duration of each event.

3.7. Selectivity

3.7.1. Theory

Overlapping stripping peaks of different metals is a sever problem in ASV. Peak separation can sometimes be achieved by choosing a proper electrolyte. In ASV it is often enough to change the electrolyte only for the stripping step, a procedure usually referred to as the medium exchange method [14]. In a SIA system the solution in the cell can easily be exchanged. Stripping medium is aspirated as the first solution and the system timing must be organized in such a way that the flow is stopped for the stripping step exactly when the maximum concentration of the stripping medium is in the detector (Fig. 2).

During the stripping step the metal amalgam is oxidized:

$$M(Hg) \rightarrow M^{n+} + ne^- + Hg \quad (1)$$

If the stripping medium contains a ligand with which the metal forms a complex, the following reaction takes place:

$$M + pL \rightleftharpoons ML_p \quad (2)$$

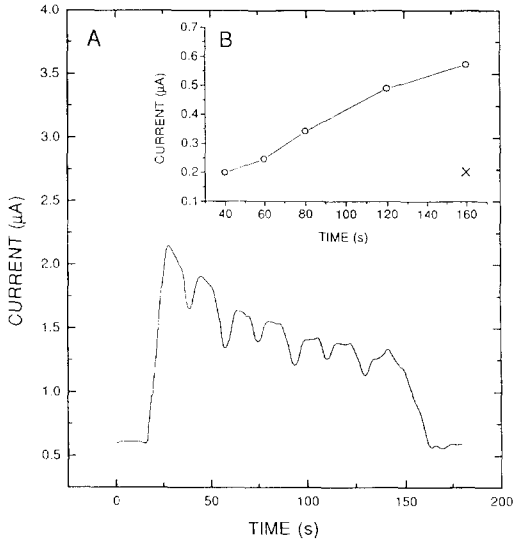

Fig. 4. Repeated sample passage procedure. A: concentration profile of the sample during multiple passages through the detector. B: dependence of the peak of lead on deposition time (during forward–backward cycles). Point 'x' represents the peak current with 160 s deposition time when the solution has flown in the forward direction only.

For simplicity the charges of the species are omitted. The notations to be used in this work are according to Ringbom [15]. The stability constant of the complex ML_p is given as:

$$K^{M,pL}_{ML_p} = \frac{[ML_p]}{[M][L]^p} \quad (3)$$

Potential and the current of a dc polarogram of the complex ML_p can approximately be expressed by the following equation [16]:

$$E = E^M_{1/2} - \frac{RT}{nF} \ln K^{M,pL}_{ML_p} - \frac{RT}{nF} p \ln[L] - \frac{RT}{nF} \ln \frac{i}{i_d - i} \quad (4)$$

$E^M_{1/2}$ denotes the half wave potential of the dc-wave of the free metal ion. As can be seen in Eq. (4), the half wave potential, which is approximately the same as the potential of the stripping peak, will be shifted due to complexation of the metal ion. The magnitude of the shift, ΔE, depends on the stability constant of the complex, coordination number of the metal ion and the concentration of the ligand:

$$\Delta E = -\frac{RT}{nF} \ln K^{M,pL}_{ML_p} - \frac{RT}{nF} p \ln[L] \quad (5)$$

The shift of the peak potential ΔE due to complexation of the metal ion may also be expressed as [15]:

$$\Delta E = -\frac{RT}{nF} \ln \alpha_{M(L)} \quad (6)$$

where $\alpha_{M(L)}$ is defined as:

$$\alpha_{M(L)} = \frac{[M']}{[M]} \quad (7)$$

where [M'] is the sum of the concentrations of the free metal ion and all the different species containing M and L. [M] is the concentration of the free metal ion. It can be shown that Eqs. (5) and (6) are practically equivalent.

If the metal ion, the ligand and the complex take part in some side reactions besides the main reaction Eq. (2), the stability constant according to Eq. (3) has to be recalculated to a conditional stability constant. This can be done by using the side reaction coefficients α_M, α_L and α_{ML_p}:

$$K'_{(ML_p)'} = \frac{\alpha_{ML_p} K^{M,pL}_{ML_p}}{\alpha_M (\alpha_L)^p} \quad (8)$$

where α_L is the side reaction coefficient for the protonation reaction of the ligand, i.e., $\alpha_{L(H)}$. The primed indexes indicate that side reactions of those species have been considered. The side reaction coefficient α_M is:

$$\alpha_M = \sum_{i=1}^{n} \alpha_{M(X_i)} + \alpha_{M(OH)} - n \quad (9)$$

where $\alpha_{M(X_i)}$ is the side reaction coefficient for the reaction where M reacts with ligands X_i and $\alpha_{M(OH)}$ is the side reaction coefficient for the reaction of the metal with hydroxide ions. The term $\alpha_{M(OH)}$ is presented here separately in order to emphasis the importance of the metal-hydroxide complexes. If the complex ML_p takes part in any side reactions, e.g., in forming acidic or basic complexes or any mixed ligand complexes α_{ML_p} should also be considered. In this work we assume that such complexes are not formed and therefore $\alpha_{ML_p} = 1$. When side reactions are considered Eq. (7) can be expressed in the following way:

$$\alpha_{M(L)} = \frac{[M']}{[M]} = 1 + \sum_{j=0}^{p} [L'] K^{M',jL'}_{ML_j} \quad (10)$$

where [L'] is the total concentration of the ligand in the solution. The values of the stability constants and the α-coefficients can be found in the reference [15] or can be calculates according to the theories presented in the same reference. If side reactions have to be considered the appropriate primed parameters should be introduced in Eq. (5).

3.8. Experimental

When 200 μl of a standard solution of 1.25 μM Cd(II) and 2.0 μM In(III) in 0.1 M HCl was aspirated in the SIA system and then processed according to the protocol in Table 1 the stripping peaks of Cd and In overlap each other and only one peak at ca 690 mV can be observed, Fig. 5A curve a. The stripping medium in this case was 0.1 M HCl. The peaks of the two metals could, however, be separated when the stripping medium was changed to 0.01 M EDTA in 2 M NaOH, Fig. 5B curve b. The cadmium peak is visible at ca

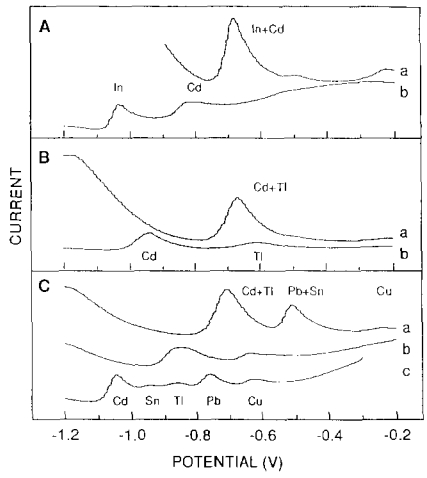

Fig. 5. Resolution of overlapping peaks by the medium exchange of 200 μl sample solution containing: A, 1.25 μM Cd(II) and 2.0 μM In(III), stripping in: (a) 0.1 M HCl; (b) 0.01 M EDTA in 2 M NaOH; B, 1.25 μM Cd(II) and 2.5 μM Tl(I), stripping in: (a) 0.1 M HCl; (b) 2 M ethylenediamine in 0.1 M HCl; C, 0.2 μM Cu(II), 1.0 μM Pb(II), 4.0 μM Tl(I), 10 μM Sn(II) and 2.0 μM Cd(II), stripping in: (a) 0.1 M HCl; (b) 0.1 M EDTA in 1 M ammonia buffer (pH = 9); (c) 0.05 M EDTA, 1 M ethylenediamine, 1 M ammonia buffer (pH = 9).

− 820 mV and the indium peak at − 1030 mV. A certain mixing of the stripping medium with the carrier solution is inevitable during the SIA procedure before the plugs reach the detector. Consequence of this is that concentrations in the stripping medium will be slightly changed. In the experiment shown in Fig. 5A and curve b the concentrations in the actual stripping media can be approximated to 0.008 M EDTA, 1.6 M NaOH and 0.02 M NaCl. The pH of such a mixture is ca 14.

The theoretical shifts of the peak potentials can be calculated by using Eqs. (6)–(10) and the values of the constants and α-coefficients as given by Ringbom [15]. Stability constants for Cd and In with EDTA are $10^{16.5}$ and $10^{25.0}$, respectively. These values have to be corrected for the side reactions of the metal ions and the ligand. At pH = 14 the ligand is completely deprotonated and $\alpha_{L(H)}$ is unity. The metal ions, however, form complexes with hydroxide ions. The following values, valid at pH = 14, can be found in [15]: lg $\alpha_{Cd(OH)} = 12.0$ and lg $\alpha_{In(OH)} = 7.0$. The metal complexes are assumed not to react further with

Table 2
Details of calculations of the potential shifts

Metal	p	lg $K_{ML}^{M,L}$	lg $\alpha_{L(H)}$	lg $\alpha_{M(OH)}$	lg $K_{ML}^{M',L}$	lg $\alpha_{M(L)}$	ΔE, mV calc.	ΔE, mV exp.
0.008 M EDTA, 1.6 M NaOH, pH = 14 Fig. 5A								
Cd	1	16.5	0	12.0	4.5	2.5	−75	−130
In	1	25.0	0	7.0	18.0	15.9	−320	−340

hydroxide ions to form any basic complexes and therefore the conditional stability constants for Cd-EDTA and In-EDTA complexes can be calculated according to Eq. (8) to $10^{4.5}$ and $10^{18.0}$, respectively. Concentration of EDTA is approximately 0.008 M and with this value and Eq. (10) the following values can be calculated: lg $\alpha_{Cd(L)} = 2.4$ and lg $\alpha_{In(L)} = 15.9$. When these values are used in Eq. (6), the theoretical shifts of the peak potentials can be calculated: −75 mV for cadmium and −340 mV for indium. The shift of the indium peak is the same as observed in Fig. 5A within the experimental uncertainties. There is, however, a larger discrepancy in the shift of the cadmium peak. This can be explained by the strong complexes cadmium forms with hydroxide ions. Even small variations in pH result in large changes in the $\alpha_{Cd(OH)}$ values. At pH = 13 the value is lg $\alpha_{Cd(OH)} = 8.1$ and would give $\Delta E = -190$ mV. The shift of the peak potential −130 mV, as experimentally found for cadmium, would be observed at pH 13.5. Such a change in pH in the vicinity of the electrode surface where the complex formation reaction takes place is quite possible. Indium, on the other hand, does not form as strong complexes with hydroxide ions as cadmium and pH 13.5 would give a shift of −330 mV in the peak potential. These calculations are presented in Table 2.

The stripping voltammogram for aspiration of 200 μl of a standard of 1.25 μM Cd(II) and 2.5 μM Tl(I) and the determination performed according to the protocol is shown in Fig. 5B. When the stripping medium is 0.1 M HCl only one peak can be observed at −680 mV, curve a. This peak has a small shoulder on the positive side. In 2 M ethylenediamine, En, and 0.1 M HCl, however, two separate peaks can be observed: cadmium at −940 mV and thallium at −610 mV. Thallium is not know to form any complexes either with hydroxide ions or ethylenediamine. Therefore the stripping peak of thallium is not shifted in this medium and the small shoulder observed on the peak on curve a in Fig. 5B is obviously the thallium peak. Cadmium forms a strong 1:3 complex with ethylenediamine with the stability product $10^{12.1}$. Concentration of ethylenediamine in the flow cell can be approximated to 1.6 M and pH of the solution to 11.7. At this pH ethylenediamine is totally deprotonated and therefore $\alpha_{En(H)} = 1$. The value of the side reaction coefficient for the reaction of cadmium with hydroxide ions can be calculated to lg $\alpha_{Cd(OH)} = 3.3$. With Eqs. (10) and (6) a ΔE value of −280 mV can be calculated. This value is in a good agreement with the experimentally found value of −270 mV. These calculations are also shown in Table 2.

The third example is the stripping analysis of 200 μl of a standard solution of 1.0 μM Pb(II), 2.0 μM Cd(II), 4.0 μM Tl(I), 0.2 μM Cu(II) and 10.0 μM Sn(II). When the stripping medium is 0.1 M HCl two peaks can be seen on the voltammogram, Fig. 5C curve a. The more positive peak is formed by overlapping of the peaks of lead and tin. The more negative peak is formed of cadmium and thallium peaks. When 0.1 M EDTA in 1 M ammonia buffer at pH = 9 is used as the stripping medium no further separation of the peaks could be accomplished. The overlapping peaks only shifted to more negative potentials but remained still overlapped. When the stripping medium was changed to a solution which in the

detector had the following concentrations: 0.04 M EDTA, 0.8 M ethylenediamine, 0.8 M ammonia buffer pH = 9.8, the stripping voltammogram c in Fig. 5C was observed. Five separate stripping peaks can be seen in the voltammogram showing that by selecting a proper stripping medium good separation of the individual peaks can be obtained even in such a complex mixture as in the experiment in Fig. 5C. Similar calculations of the shifts of the stripping peaks as done for the voltammograms in Fig. 5A and B and shown in Table 2 would give less good agreement between the theoretical and the experimentally found values. One of the reasons is that there is a possibility for formation of mixed ligand complexes because of the low concentration of the metal ions and the high concentration of the ligands: EDTA, ammonia and ethylenediamine. Constants of such mixed complexes are not known and therefore a number of approximations have to be made. Calculations of the α coefficients would therefore be difficult and give only too inaccurate values.

3.9. Analytical applications

Both the calibration curve and the standard addition method can be used with ASV with SIA. For determination of lead with a sample volume of 200 μl and by using forward flow with flow rate 0.85 ml min^{-1} during the deposition step, a linear calibration line was obtained in the concentration range 30–175 nM with the slope of 0.421 ± 0.016 nA nM^{-1}, intercept 71.9 ± 1.4 nA, limit of detection (by the error propagation method [17]) 25 nM and correlation coefficient $r = 0.9994$.

The standard in the standard addition method may be added directly to the sample, but it is also possible to do the standard addition in the flow system. The standard solution is connected to a separate port in the multiposition valve and aspirated into the holding coil either before or after the sample. The amount of the standard can be controlled by the aspiration time. This procedure has been shown to function well but the running parameters such as flow rate and deposition time have to be optimized separately for each case.

Calibration of the standard addition method in SIA is necessary to determine the correlation between the aspiration time of the standard solution, dispersion of the sample and the standard zones, mixing of the zones and the total amount of analyte in the zones. This can be done by aspirating different volumes of a standard, i.e., by using different aspiration times. In our work where 500 nM standard of lead was used, the correlation was found to be 180 ± 5 nM s^{-1}, i.e., aspiration of the standard for 1 s increased the concentration in the sample by 180 nM. Concentrations in this experiments were determined by comparing the stripping current observed with the current from a calibration plot. The shortest aspiration time that still gave reproducible results was 0.2 s. When this method was applied to a sample of 60 nM lead solution, standard addition with three aspirations gave a result of 56.4 nM, i.e., error of 6%.

In the procedure of repeated sample passage the standard addition method as described above is not convenient because the method requires that both the sample and the standard zones have to pass the detector entirely during each cycle. Therefore when ASV with SIA in the repeated sample passage mode was tested, a traditional standard addition method was used. Two additions of the standard was made in the sample prior to aspiration into the SIA system. The method was tested in determination of copper in tap water of the laboratory. The results were 12.2 ± 4.8 ppb and 63.0 ± 8.6 ppb in the cold and hot water, respectively.

4. Conclusions

SIA has shown to be a powerful technique in performing ASV experiments. SIA has several advantages over FIA in ASV. Solution handling in SIA is more simple than in FIA. It is easy to change the solutions in a SIA system and in that way to have the right solution zone in the detector during each step in the ASV protocol. In order to increase sensitivity the repeated sample passage method can easily be applied. The medium exchange procedure to increase the selectivity of the stripping method can also easily be performed. Generation of the mercury film on the substrate

electrode can be done more conveniently and effectively in SIA than in FIA. The same manifold can be used in SIA to perform different analyses. Change of the manifold is normally required in FIA when the analysis protocol is changed. Because only small volumes are used in SIA, consumption of reagents and the problem with waste solutions, such as mercury waste, are of less importance than in ordinary batch ASV experiments or when FIA is used. By improving the existing software it would be possible to automate the method even further and include all data collection and processing procedures in one run.

Announcement

MUACC: A 50 year heritage that continues to grow

Visionary analytical chemists strive to make enduring contributions to their field, contributions usually thought of as breakthrough research, innovative use of base elements, or improved testing and refining procedures.

As shown by the soon-to-be 50 year history of the Midwestern University Analytical Chemistry Conference (MUACC), enduring traditions sometimes are made of different stuff.

MUACC, an informal gathering of top chemistry faculty from throughout the Midwest, has clearly made its mark, changing lives, careers, teaching methods and research outcomes since 1947.

"It started out with Hobart Willard, an analytical chemistry professor from the University of Michigan and two of his very precocious students, G. Frederick Smith and Harvey Diehl", explains long-time MUACC attendee Professor Emeritus Carl Moore from Loyola University. "After Smith and Diehl earned their doctorates, the three kept a close, almost family relationship. Somehow, they got the idea to get together about once a year, visit, talk chemistry, talk about on-going work, talk 'blue sky' work, and engage in graduate student 'horse trading'".

Thus, MUACC was born. Its first meeting was held in December, 1947 at Northwestern University, with a dozen attendants from Syracuse to Iowa and in between. From the very beginning, MUACC separated itself from the multitude of other conferences available to academia.

The group differed, in part, because presentations must be informal discussions on research in progress. No slides or formal final work were permitted, just 'chalk talks'. Further, no specialized segments were held—all participants took part in the ongoing discussion, no matter their field of expertise.

"The topics covered were so broad, and all right on the forefront", explains retired professor A.A. Schilt who participated in MUACC for over 30 years. "Often, you would read the results of the research problems presented in the following year's research journals. We heard from people right on the fringe of scientific breakthroughs, detailing research problems in chromatography, mass spectrometry, polarimetry, all the different modifications in voltammetry, and a great deal in atomic spectroscopy".

Professor James Taylor from the University of Wisconsin, who has become known as the 'constant first', always volunteering to take the lead in presentations, explains:

"When you are asked to talk without slides about a project you have not finished, you are forced to go directly to the heart of why you are doing what you are doing. Sometimes, you end up with absolutely fabulous suggestions on how to resolve roadblocks from individuals working completely outside your subject area. When I first started, many presentations focused on electrochemistry. Now, it is shifted toward mass spectrochemistry. This field is so dynamic, and you can taste that at every MUACC meeting".

MUACC's emphasis on innovation does not stop at the lab door. It also enters the classroom.

PII S0039-9140(96)02128-5

"I am at an institution where we do not undertake a lot of research, but I have found MUACC as a group is wide-ranging, discussing problems that touch faculty and graduate students in all facets of their professional and academic life", says Professor Rod Olson at Hamline University in Minnesota. "Way back in the 1960s, I developed tape and slide curricula, something commonplace now but very different then. I shared preliminary versions of these materials with MUACC, and received enough positive feedback to keep me going on it. One segment was later published by the American Chemical Society".

"Everyone gave advice and encouragement, that is what I always remember about MUACC", notes Professor Bruno Jaselskis from Loyola University. "My first meeting was in the fall of 1995. Through the years, I have discussed issues like xenon chemistry, sometimes hilariously, some seriously. Xenon was very novel at one time, and while the analytical significance was not great, it did offer some very interesting characteristics. Some comments I received from founder G. Frederick Smith urged me to explore applications in an entrepreneurial nature".

MUACC participants mutually agree that the three founders of the group left a strong personal imprint upon it. Professor James Carr of the University of Nebraska has even spent time researching the "genealogy" of MUACC.

"In large measure, MUACC is comprised of the academic descendants of Hobart Willard's students and their students", he explains. "An enormous number trace their background to Willard, and subsequently to Diehl and Smith".

Schilt agrees. "MUACC is and was mainly built by Smith, Willard and Diehl. In one sense, though, the group flows back even further to critical research leaders like Fresenius. Like most family trees, it has just grown abundantly. We could probably tie it back to the first experiments of Adam".

Part of the imprint includes what group participants now jokingly call "their anonymous benefactor", G. Frederick Smith. Smith is one of a handful of academic chemists who successfully ventured into the commercial world. He founded G. Frederick Smith Chemicals with his brothers Allyne and Clarence Smith, in Columbus, Ohio, in 1928. As the company prospered, Smith and his brothers quietly financed all or a portion of MUACC's cost.

"Part of our success has always stemmed from making the meeting as affordable to participants as possible", says Dr Alexander Scheeline, Associate Professor of Chemistry at the University of Illinois, and host of the 1996 meeting. "Professor Smith, and now GFS Chemicals, assist with event costs, and help us achieve that goal".

MUACC also has extended far beyond just the "Midwest". Over its 50 year history MUACC meeting sites have included the University of Colorado, and the University of Alberta, in Edmonton, Canada.

"We stretch like a rubber band", notes Jaselskis". "We are very flexible and we have drawn people from Pittsburg, Mississippi and around the country".

Schilt remembers participants from places as far as Birmingham, England. He also notes that MUACC has spawned similar groups in the US, including SWAP, Southwest Analytical Professors, and SAC, Southeast Analytical Chemists.

What draws participants today to MUACC is the same draw created 50 years ago, says Steel Hutchinson, continuing event sponsor, grandson of Allyne Smith, and Vice President of Marketing for GFS Chemicals.

"The uniqueness of MUACC—and its number one reason for survival—is its ability to help participants step outside of their own paradigm, avoid myopic vision, and find a fresh approach to problem-solving in an atmosphere of openness and mutual support", says Hutchinson. "We believe in the spirit of MUACC's founders. Our business strives to carry on their traditions, by maintaining our independence as a privately-owned concern in a marketplace dominated by large corporations, by producing catalogs and other materials to educate and inform the industry, and by sponsoring MUACC, a group which clearly fosters great science".

"The informality remains, but the role of MUACC has expanded", summarizes Scheeline, who hosted the 1996 MUACC at the University

of Illinois. "We are a place where analytical faculty from both small colleges and large can go, where we can share our differences and our commonalities, whether an emphasis on classroom teaching or an emphasis on research, and we can meet and cross-fertilize".

With 50 years of cross-fertilization, it is no wonder that MUACC continues to grow.

Abstract

A liquid ion-selective membrane electrode containing a chloroform–acetonitrile (10:1) solution of the complex of In(III) with 1-benzyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP) and diphenylguanidine is described. The basic electrode performance characteristics were evaluated according to IUPAC recommendations. The slope of the calibration graph (electrode potential v. concentration) was 18.7 mV $(pIn)^{-1}$ in the pIn range 4.5–1 (pH 6). Direct potentiometric determination of In(III) showed an average recovery of 99.1% with a standard deviation of 1.2%. The method is recommended for the precise direct potentiometric assay of In(III) in metals and minerals without a prior separation.

Keywords: Indium(III); Liquid ion-selective membrane electrode

1. Introduction

A number of electrodes sensitive to Ca(II), Fe(II), Bi(III) and La(III) cations [1] have been developed and employed as indicator electrodes in potentiometric titrations. The commonly known electrodes sensitive to Indium ion feature low selectivity and the slope of calibration graphs is different from Nernstian slope [2].

In the present paper, a new electrode sensitive to In(III) ion is proposed, the liquid ion exchanger being a complex of In(III) with 1-benzyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP). PMBP with In(III) forms an $In(PMBP)_3$ complex, which is well extracted into the organic phase of choroform–acetonitrile in the presence of diphenylguanidine (DPG). These properties of the $In(PMBP)_3$ complex led us to develop a simple potentiometric method for In(III) with sufficiently high accuracy, selectivity and speed.

2. Experimental

2.1. Reagents and materials

All reagents were of analytical reagent grade. Doubly distilled water from a quartz still was used. The composition of the ion-exchange solu-

tion was 1×10^{-3} M $In(PMBP)_3$ and 1×10^{-4} M diphenylguanidine in choroform–acetonitrile (10:1). A solution of concentration 1×10^{-3} M $In(PMBP)_3$ was obtained by shaking a solution of indium salt with PMBP in the mixed solvent (in the ratio 1:3) [3,4].

2.2. Apparatus

The liquid membrane was stabilized on a porous circular plate. A silanized filter disc saturated with ion-exchange solution was used as the liquid membrane. The composition of the inner solution of electrode was 1.0×10^{-3} M In(III) and 1×10^{-2} M KCL.

An Ag/AgCl electrode (Orion 90-02), containing 10% (w/v) potassium nitrate in the outer compartment, was used as the reference electrode. An Orion Ross combination pH electrode (Model 81-02) was used for pH adjustment.

3. Results and discussion

3.1. Effect of pH

The effect of pH on the potential of the electrode system was studied. The response of this electrode is hardly affected by changes in pH in the range 5.0–7.0 (Fig. 1).

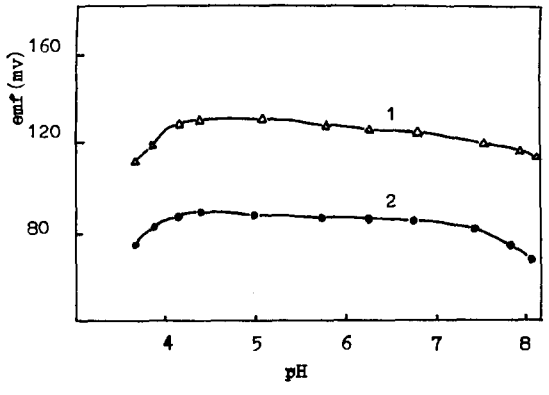

Fig. 1. Effect of pH on the Indium electrode. (1). 10^{-2} M; (2). 10^{-4} M.

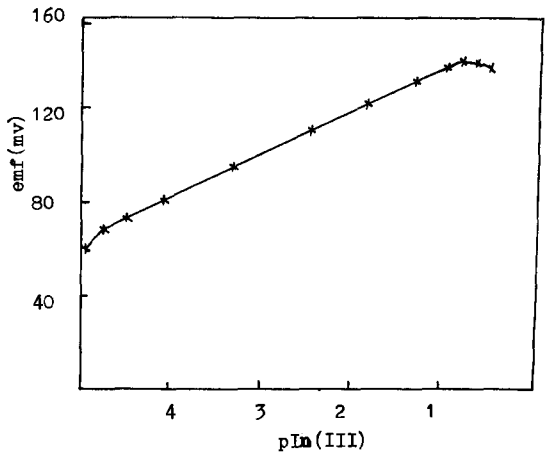

Fig. 2. Calibration graph for the indium-electrode.

3.2. Interference effects

The interference effect of different inorganic cations on the electrode response was evaluated. The potentiometric selectivity coefficients K^{pot} for the In(III) electrode was studied by the separate solutions method [5,6]. The selectivity coefficients were calculated using the extended Nernst equation:

$$\log K^{pot}_{In,M} = \frac{E_2 - E_1}{2.303RT/n_1F} + \left(1 - \frac{n_1}{n_2}\right) \log C_1 \qquad (1)$$

where E_1 and E_2 are the potential readings observed after 1 min due to the same concentration of In(III) and interferents, respectively, n_1 and n_2 are the charges of In and interferent ions, respectively, and C_1 is the concentration of In(III).

The values of the selectivity coefficients obtained are presented in Table 1. In most cases, up to a 100-fold excess of the interferent did not have a significant influence on the electrode performance. Electrodes sensitive to In(III) are not selective against Ga(III) and Ge(II) ions. However, they exhibit high selectivity against Ca(II), Al(III), Ni(II), Cu(II), Sn(II), La(III), Lu(III) and Nd(III).

3.3. Calibration graph

The calibration graph in Fig. 2 exhibits a Nernstian response for 3.2×10^{-5}–1×10^{-1} M In(III) with slope of 18.7 ± 0.5 mV per decade change in concentration. The dynamic response time of the electrode system was tested for the concentration range 1×10^{-1}–3.2×10^{-5} M In(III). The measurement sequence was from low to high concentration and back. The time required for the electrode to reach values within ± 0.2 mV of the final equilibrium potential after increasing the In(III) concentration level 10-fold is fairly short; it reaches 97% of its final steady potential after 30 s for In(III) $> 10^{-3}$ M and 1 min for In(III) $< 10^{-3}$ M.

The potential displayed by the In electrode did not vary by more than ± 1 mV ($n = 10$) on the same day. The calibration slope did not vary by more than ± 0.5 mV per decade change of concentration. The reproducibility and stability of the potential were evaluated over 2 months by constructing replicate calibration graphs ($n = 10$). The detection limit, linear range, response time and selectivity coefficients were almost constant for this liquid membrane electrode during this period. The critical response characteristics of the indium liquid membrane electrode are given in Table 2.

3.4. Analytical application

The direct potentiometric determination of In(III) using the indium liquid membrane electrode was performed by the standard addition method in a solution containing In(III) at concentrations of 10^{-2}–10^{-4} M in the presence of Cu(II), La(III) and Cd(II) at a concentration of 10^{-3} M. The results showed an average recovery of 99.1% and a standard deviation 1.2%.

A real sample was also analysed. A sample of Stannum (provided by the Metal Company, Human, China) were treated by the method in Ref. [7]. The method was compared by using the 5,7-dibromo-8-hydroxyquinoline (I) spectrophotometric method as follows:

The simulated or real sample solution was transferred into a 25 ml calibration flask, 2 ml of a chloroform solution of I and 10 ml of sodium acetate–acetic acid buffer solution (pH 4.0) were added and the volume was made up to the mark with water. The solution was transferred to a separating funnel, 10 ml of a chloroform solution of I were added twice and the organic layer was separated.

The absorbance of the organic extract was measured at 415 nm against the reagent blank using 1 cm glass cells. The results are given in Table 3.

The proposed electrode system was selected as it showed the most successful characteristics. This method is recommended for the precise direct potentiometric assay of In(III) in metals and minerals without a prior separation.

Abstract

The simultaneous determination of silver(I) and copper(II) is realized for the routine analysis of trace levels of these elements by anodic stripping voltammetry (ASV) at the carbon paste electrode (CPE). The electrochemical response is studied in 14 different supporting electrolytes, ranging from acidic solutions (pH 0.1) to neutral and basic (pH 9.7) media, and the parameters governing electrodeposition and stripping steps are characterized for each medium by the use of pseudo-voltammograms. Comparison between different modes of matter transport mechanisms is also given. The dynamic range of the method is 0.05 to 150 μg l^{-1} Ag(I) in the majority of the media studied and can be extended to 400 μg l^{-1} in selected media, with a general reproducibility in the ±2% range for five replicate measurements. The total analysis time lies between approximately 30 s and 10 min. Activation of the CPE surface has been studied, but this pretreatment is demonstrated to be unfavourable and is replaced by a simpler unique 'cleaning' procedure of dipping the CPE in diluted nitric acid. © 1997 Elsevier Science B.V.

Keywords: Anodic stripping voltammetry; Carbon paste; Copper; Silver; Trace element

1. Introduction

Stripping techniques are among the most frequently used enhancers of the key analytical parameters, namely sensitivity and selectivity [1]. Enhancements are achieved in the preconcentration step involved in such processes [2–4]. The most classical technique, i.e. stripping with a slow, linear potential scan (ASV), has recently be superseded by more modern methods [5]. Despite this, no potentiostatic method solves definitively the problem of the relatively poor selectivity of the measurement [3], and galvanostatic methods, including no-current methods [6,7] have been studied and applied to trace element analysis [8,9]. However, the classical ASV methodology remains the more practicable method used in routine analysis; it displays rapidity and feasibility, and uses relative low-cost commercial instrumentation that has been developed for non-electrochemists. Carbon paste electrode (CPE) takes a increasing importance in ASV [10]. On the other hand, the pyrolytic graphite electrode and the glassy carbon electrode are not suitable for the determination of small amounts of silver, as are wax-impregnated electrodes with a surface renewed on emery paper;

PII S0039-9140(96)02053-X

however carbon paste electrodes are used for this purpose, permitting 25 determinations without refilling [11]. Consequently, the main goal of this work is to improve a simple, rapid and efficient electrochemical method for the trace element determinations of Ag(I) and Cu(II) in routine analysis, based on CPE with commercial low-cost instrumentation and without the need for time-consuming sample/electrode pretreatment.

Silver does not normally occur in animal or human tissue but is found in different materials of general use [12]. The level of this metal in natural waters and in biological fluids is generally very low, so, analytical methods with great sensitivity are required. Electrochemical determinations of silver within the scope of this study has been reported in review articles: Vydra and co-workers [2] (until 1976), Mannino and Wang [13] and, more recently, Rivas and Ortiz [14]. In the recent literature, the use of modified carbon-based materials has attracted much interest [15]. However, the proper choice of the supporting electrolytes and of the parameters governing accumulation, electrodeposition and stripping are not always clearly defined and systematically studied. Furthermore, the necessity of time-consuming pretreatment, defining optimum electrode composition and the drift of signals observed over long-time use complicates the question of finding (for routine measurements) a simple, rapid and efficient technique, using a stable working electrode, in a wide concentration range, which can be used by non-electrochemists on low-cost instrumentation. Finally, the electrochemical measurement should be directly compatible with a variety of chemical dissolution media used in the analysis of real samples (water, effluents, sewage, minerals, biological fluids, alloys and metals).

2. Experimental

2.1. Reagents

All chemicals are AR quality and the solutions were prepared with Millipore MilliQ System's water. Stock solutions of silver nitrate and copper sulphate are checked weekly by classical volumetric analysis [16]. Supporting electrolyte solutions are checked by contamination tests developed for polarographic analysis [17].

2.2. Instrumentation

ASV measurements are made with a PAR EG and G scanning potentiostat coupled to a Phillips PM 9848 XY-t recorder. The electrochemical cell is the Radiometer TTA 80 and electrodes are Radiometer F 4551 (SCE) and Radiometer F 5155 (platinum counter electrode), respectively. For studies with a rotating CPE, the PAR EG and G Model 616 RDE is adapted to the configuration of the home-made CPE.

2.3. Carbon paste electrode

Despite the fact that the electrochemical characteristics of the CPE depend upon paste composition [18–21], for routine analysis we used the commercial Metrohm mixture (74 wt.% C, 26 wt.% mineral oil, abbreviated as CPE 74:26). Carbon paste sensors (tip configuration) are made as follows. The paste is packed under pressure into 1 ml polyethylene syringes (5 mm diameter), the tip of which is cut off in the conical region to obtain the desired geometric area (2–3 mm diameter); the electrical contact is established by a stainless steel wire, the diameter of which is chosen so it can be forced into the top of the syringe. The paste is furthermore compacted by polishing the tip of the CPE on filter paper (Whatman GF/C ultrafine glass fibre paper) and visualizing the final surface by microscopic examination to avoid edge effects. After an initial stabilization period (see below), the CPE can be used continuously for up to 2–3 weeks without alteration of its electrochemical response, if it is kept in 0.20 M HNO_3 between experiments and overnight. When working with metal ion concentrations in the ppm range, some memory effects [19,20] are observed; these are eliminated by dipping the CPE into 0.20 M HNO_3 for 15 min. and examining the background characteristics of the renewed CPE in the actual supporting electrolyte. We have not observed any significant differences between the signals obtained with and without oxygen removal

from the solutions; consequently, we consider that oxygen removal is not necessary for the present experiments.

The CPE is centred in the sample vessel and the stirring rod placed so that the angular velocity is zero but the circular motion maximum; the tip of the CPE is positioned close to the SCE. As previously demonstrated [21,22], the deposition current in stirred solutions obeys the semiempirical equation:

$$i_d = Knr_o^2 D^{\frac{2}{3}} C\,(\mathrm{RPM})^{\frac{1}{2}} + 4\pi r_o nFDC$$

where r_o is the CPE's radius, RPM is the velocity of stirring (rev min^{-1}) and n, F, D and C have their usual meaning [23]. The sensitivity of the method is thus related to cell geometry and stirring. Furthermore, the rest period required between the deposition and stripping steps is another parameter that affects the sensitivity [7–9,24]. To keep the results of this work within the scope of classical instrumentation, we choose a stirring rate of 3000 rev min^{-1} and a rest period of 30 s, which are compatible with conventional stirring devices and routine analysis times.

3. Results and discussion

3.1. Silver quantification

In 0.10 M $HClO_4$, by cycling between -0.40 and $+0.80$ V, a low cathodic current is observed from $+0.10$ to -0.40 V and, during the reverse scan, an oxidation peak appears in the anodic region at $+0.250$ V (E_{p_a}). A very high enhancement of the oxidation current (i_{p_a}) is observed if silver electrodeposition is made under potentiostatic control at a determined potential (E_d) during a fixed time (t_d) under stirring. In this work, the electrodeposition step will be conducted as follows: potentiostatic control at E_d during a time t_d under stirring, followed by the same potentiostatic control during a rest period of time ($t_r = 30$ s). In such conditions, the ASV signals appear as illustrated in Fig. 1, for a 0.10 M $HClO_4$, 30 μg l^{-1} Ag(I) solution.

Until now, stripping determinations of silver on carbon materials have been restricted to some definite media (0.15 M NH_3–0.15 M NH_4^+, 0.10 M KNO_3, 0.01 M H_2SO_4–0.05 M K_2SO_4 [2.5] despite the fact that such experiments can be conducted in a very wide variety of supporting electrolytes, ranging from acidic solutions to neutral media and basic pH buffers. In the majority of these media, the reproducibility and the magnitude of the oxidation current for low t_d values and Ag(I) concentration is such that silver quantification is predicted at the CPE. For instance, a relative standard deviation (RSD) of $\pm 0.2\%$ for i_{p_a} magnitudes is observed for five successive measurements in 0.018 M HAc–0.018 M NaAc for 30 μg l^{-1} Ag(I), where Ac stands for acetate. However, in identical electrodeposition conditions (E_d, t_d), the observed i_{p_a} values can be quite different from one medium to another, so that optimization of electrodeposition and stripping steps must be studied independently for each medium.

The only way to determine exactly the optimum electrodeposition potential and to see the influence of the nature and concentration of the supporting electrolyte on i_{p_a} is the observation of the corresponding ASV pseudo-voltammogram, e.g.

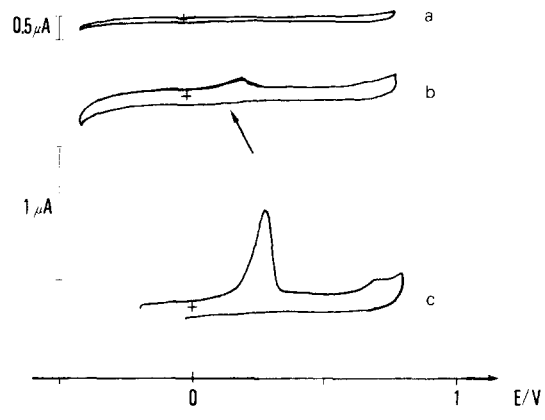

Fig. 1. (a) Cyclic voltammogram at the CPE in 0.10 M $HClO_4$; (b) cyclic voltammogram in 0.10 M $HClO_4$ + 30 μg l^{-1} Ag(I), same conditions as (a); (c) anodic portion of ASV voltammogram of medium (b), with $E_d = -0.20$ V, $t_d = 30$ s, $t_r = 30$ s, stirring rate: 3000 rev min^{-1}, same conditions as (a). The reduction wave (see arrow) is actually not detected but inferred by visualizing the corresponding reoxidation peak.

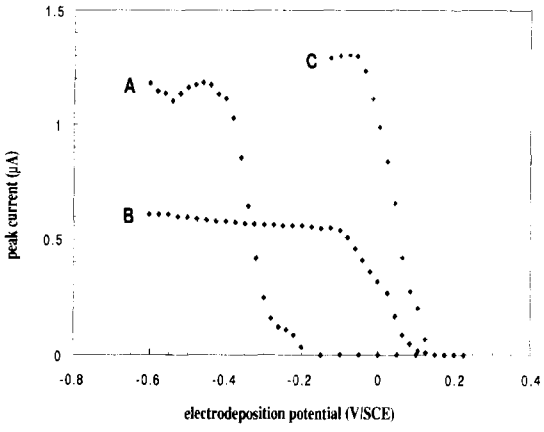

Fig. 2. ASV pseudo-voltammograms of 30 µg l^{-1} Ag(I) in various supporting electrolytes: (A) 0.10 M NH_3–0.10 M NH_4^+, pH = 9.7; (B) 0.10 M KNO_3, pH = 6.9; (C) 0.10 M $HClO_4$, pH = 1.1. Operating conditions: t_d = 60 s, t_r = 30 s, stirring rate: 3000 rev min^{-1}, scan rate: 50 mV s^{-1}.

the function $i_{p_a} = f(E_d)$ with all other parameters constant. Fig. 2 is an example of such ASV pseudo-voltammograms obtained in three typical media for a 30 µg l^{-1} Ag(I) concentrations and a low (60 s) electrodeposition time. One can see that the optimum electrodeposition potentials regions are rather different for each medium (− 0.010 V in 0.10 M $HClO_4$, − 0.45 V for 0.10 M NH_3: 0.10 M NH_4^+ and from − 0.20 to − 0.60 V for 0.10 M KNO_3) and that the corresponding i_{p_a} values differs by one order of magnitude depending upon the medium and the E_d selection. Furthermore, the optimum E_d values differ significantly from those given in the literature for the already studied media [2,5]. Selecting an E_d value of − 0.60 V for all media illustrated in Fig. 2 will, for instance, decrease the i_{p_a} value in 0.10 M $HClO_4$ because proton reduction is markedly altering the Ag(I) deposition. When interference problems are encountered, selection of E_d values from − 0.20 to − 0.60 V in 0.10 M KNO_3 medium can directly circumvent the problem (see below).

Table 1 gives a general overview of the ASV electrochemical responses of Ag(I) in 14 different supporting electrolytes. The choice of the media selected in Table 1 is governed by three reasons: (1) comparison with previous studies [2,5]; (2) a large pH range to correspond to the dissolution steps of the various materials containing silver; and (3) comparison of the ASV method with Ag(I) determinations observed in chemical potentiometric stripping analysis on CPE (with Fe(III) as the oxidizing agent) [23] or by adsorptive stripping voltammetry (media 5, 6 and 7, for instance) [18–20]. In identical operating conditions, a Ag(I) level of 30 µg l^{-1} gives oxidation currents ranging from 0.36 µA (0.10 M Na_2HPO_4) to 1.92 µA (0.08 M acetate buffer). Low differences in oxidation currents are observed with pH variations, but qualitatively, the method gives similar responses from pH 0.1 to pH 9.7 if the E_d value is correctly selected. These procedures avoid the use of exchange matrix solutions and the need for sample chemical pretreatment leading to contamination risks and time-consuming measurements. As a general conclusion, the choice of the correct electrodeposition potentials range is the primary problem to be solved for a determined supporting electrolyte. When the corresponding pseudo-voltammogram is determined, all the media selected in Table 1 can be used for Ag(I) analysis on a classical CPE. The position of the oxidation signal on the potential scale (E_{p_a}) is also dependent of the nature and pH of the supporting electrolyte and this last parameter must be considered for interference studies (see below).

Ag(I) quantification is also determined by the response of the oxidation signal with electrodeposition time, or more precisely, by the dynamic linear range of this response. We studied this parameter for a low concentration of Ag(I) (3 µg l^{-1}) in the media of Table 1. Typical responses are illustrated in Fig. 3, which gives the functions $i_{p_a} = f(t_d)$ in the two first media of Table 1. For 0.10 M NH_3–0.10 M NH_4^+, the linearity (equation order $N = 1$) is observed at this Ag(I) level for electrodeposition times up to 10 min. For a 0.10 M KNO_3 medium, apart from the fact that i_{p_a} is lower (Table 1), the function follows a second-order equation ($N = 2$) for the same electrodeposition times range. This is an illustration of the relative facility of metal electroplating from a medium where the metal ion is in a complexed form. When observing oxidation responses similar to those illustrated in Fig. 3, one can conclude that media 3, 4, 8, 9 and 10 of Table 1 offer a

14	$NaHCO_3$ 0.10 M	8.7	−0.20–0.65	0.93	+0.260

Operating conditions: 30 μg l^{-1} Ag(I); $t_d = 60$ s; $t_r = 30$ s; stirring rate: 3000 rev min^{-1}; scan rate: 50 mV s^{-1}.
[a] As selected from the corresponding pseudo-voltammograms.
[b] i_{p_a} values given for three successive measurements in the optimum electrodeposition potential range.

linear relationship, whereas all the other media selected in Table 1 give a second-order relationship, in the 0–10 min electrodeposition time range. As this conclusion is valid only for this Ag(I) level and for the actual CPE geometry and composition, it must be noted that, for routine quantitative analysis of Ag(I), the standard addition procedure is recommended.

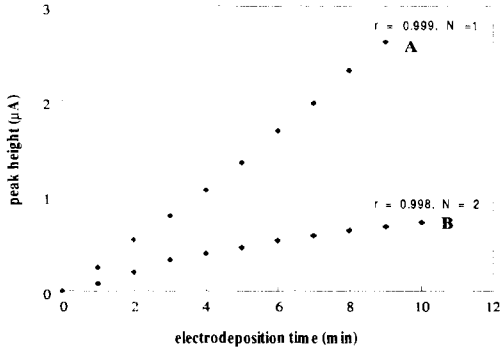

Fig. 3. Relationships between oxidation current and electrodeposition time in two supporting electrolytes: (A) 0.10 M NH_3–0.10 M NH_4^+, $E_d = -0.60$ V; (B) 0.10 M KNO_3, $E_d = -0.25$ V. [Ag(I)] = 3 μg l^{-1}; stirring rate: 3000 rev min^{-1}; cyclic voltammetry from E_d to +0.80 V at 50 mV s^{-1}. The oxidation current is corrected by subtracting the current component corresponding to $t_r = 30$ s in a quiescent solution from the observed value.

Calibration curves were established at different electrodeposition times for two modes of matter transport: linear diffusion (stationary electrode mode) and diffusion-convection, at a Ag(I) concentration of 12 μg l^{-1}. The oxidation currents observed, for diffusion during 90 s are practically similar to those obtained under diffusion-convection with an electrodeposition time three times lower. Currents corresponding to 30 s diffusion (0.037 μA) and 90 s diffusion-convection (0.323 μA), differ by a factor of approximately 10. At this Ag(I) concentration, all the calibration curves are linear, and the sensitivities of the ASV method (defined as the slope of a set of calibration curves corresponding to a defined matter transport, in μA s^{-1} μg^{-1} l Ag(I)) are 1.05×10^{-4} (linear diffusion) and 3.05×10^{-4} (diffusion-convection) respectively.

Fig. 4 indicates that, for a CPE used in normal electrodeposition conditions (say, stirring the medium during the electrodeposition time t_d), the linearity is respected in the range 0–400 μg l^{-1} Ag(I). This linearity range varies somewhat with the nature of the supporting electrolyte but, for all the media described in Table 1, the linearity is realized over a minimum concentration range 0–250 μg l^{-1} Ag(I). For comparison, the behavior

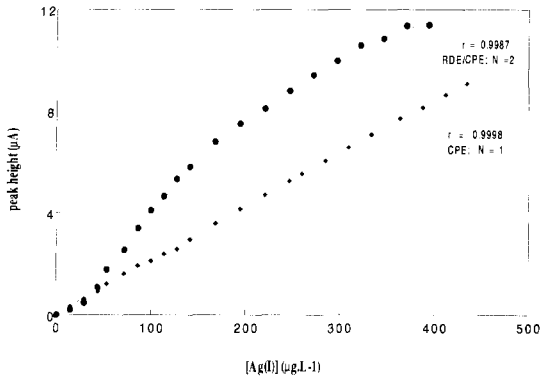

Fig. 4. Calibration curve for Ag(I) ions in 0.10 M KNO_3: high concentration range (0–450 μg l^{-1}). Operating conditions: $E_d = -0.25$ V; $t_d = 30$ s; $t_r = 30$ c; stirring rate: 3000 rev min^{-1} for the normal CPE; rotating rate: 5000 rev min^{-1} for the rotating CPE during t_d; cycling at 50 mV s^{-1}; number of measurements: 5.

of a rotating CPE (say, a CPE of the same geometrical area fixed at the rotating axis of a rotating disk electrode device) is also shown in Fig. 4, for identical electrodeposition conditions. This last electrode gives somewhat higher oxidation currents (by the fact that diffusion-convection is more efficient than forced convection in the deposition step), but the linearity region is narrower (0–150 μg l^{-1} Ag(I)) (electrode saturation more rapidly attained). The rotating CPE also permits the verification of the Levich's relation, indicating that diffusion is governing the electrodeposition of Ag(I). As the detection limit of both CPEs is approximately 0.05 μg l^{-1} (for measurements with a global duration of ±10 min, a value considered as compatible with routine analysis), the dynamic range of the method is approximately stated at 0.05–250 μg l^{-1} Ag(I). Such results can be compared with corresponding measurements made on chemically modified carbon paste electrode (CMCPEs): for instance, Yeom and co-workers [19] obtained a linear response up to 100 mg l^{-1} Ag(I) by linear sweep voltammetry and 1 μg l^{-1} Ag(I) by differential pulse polarography with a CPE modified by 2-imino-cyclopentane-dithiocarboxylic acid.

The question of the reproducibility of the CPE for quantitative analysis of metal ions by a (direct) preconcentration step has been tested [24,25]. It has been claimed that such a sensor needs electrode pretreatment or conditioning as a necessary preliminary step before it can offer reproducible electrochemical signals. Yet such pretreatment annuls the general gain in analysis time which is possible by direct electrodeposition. Applying a pretreatment will place this procedure among time-consuming measurements, such as needed by chemically modified electrode [2,5,25] or by adsorptive stripping voltammetry [18–20] (where pretreatment of the CMCPE or accumulation of the adsorbed species enhance the measurement duration).

The way to obtain a satisfying repeatability of the CPE (same electrode) without the need for tedious pretreatments that are incompatible with routine analysis is demonstrated as follows. First, the CPE is cycled in the studied supporting electrolyte at 50 mV s^{-1} during 3 min and the background curve is determined (as, for instance, in Fig. 1a). After this, the supporting electrolyte is subjected to electrodeposition/stripping cycles in the same manner as in the presence of metal ions (Fig. 5a) for 3–4 cycles. The metal concentration is finally spiked in the medium and electrodeposition/stripping steps are repeated: the oxidation signal is enhanced during the first cycles (Fig. 5b) (behavior already mentioned for modified CPEs) [2,5,30] and reaches a reproducible value after 8 to

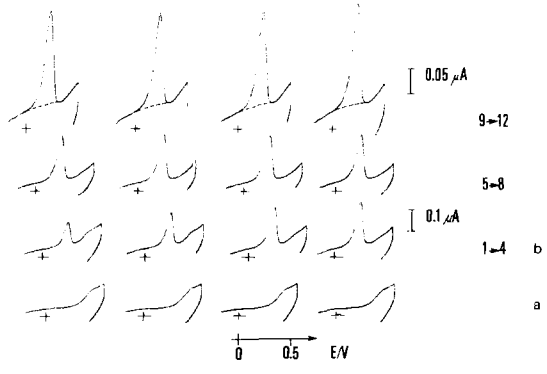

Fig. 5. Stabilization procedure of a freshly prepared CPE for Ag(I) analysis, in 0.10 M KNO_3 supporting electrolyte and operating conditions as in Fig. 4. (a) 0.10 M KNO_3 background curves; (b) same solution spiked with 14.2 μg l^{-1} Ag(I). The last eight electrodeposition/stripping cycles of Fig. 5b correspond to the first calibration point of Fig. 4.

12 cycles. In Fig. 5 the last eight cycles are considered to be reproducible (note the different current scales) and the mean of the i_{pa} values is the first point of the calibration curve of Fig. 4 (0.314 ± 0.008 μA, the RSD value considered to be acceptable for the corresponding Ag(I) concentration, 14.2 μg l^{-1}). Once this initial stabilization procedure is finished, further measurements can be made by repeating the first five electrodeposition/stripping cycles. Continuous measurements can be made with the same electrode for up to two to three weeks, the first alteration of the CPE behavior being suggested by an enhancement of the background curve (Fig. 1a). The reproducibility of different new CPEs, submitted to the described procedure, give, in a standard Ag(I) solution, a RSD of $\pm 2.1\%$ (five independent measurements, five electrodes). This value is mostly attributed to the difficulty in obtaining the same electrode geometric area (cutting pipette tips) than to the inherent behavior of the CPE itself. As the stabilization step is completed within ± 20 min, the question of the reproducibility of classical CPEs for quantitative analysis of metal ions by a direct preconcentration step does not seem to be a major problem for routine analysis.

The detection limit is related to a number of operational parameters (electrode surface, electrodeposition potential and time, stirring mode of solution and/or electrode, coulometric or amperometric recording). Consequently, considering that the maximum measurement time that can be devoted to low metal ions levels (< 1 μg l^{-1}) in routine analysis is of the order of 10–15 min, the corresponding concentration level has been measured: the current value (0.026 μA) corresponds, in such conditions, to the 50 ng l^{-1} Ag(I) level. For comparison, Yeom and co-workers [19] obtained, with CM-CPEs, a detection limit of 1×10^{-7} M and 1×10^{-9} M Ag(I) at 20 min deposition in linear sweep voltammetry and differential pulse polarography, respectively, with an electrode body made of 1 ml polyethylene syringes (5 mm diameter), the tip of which had been cut off.

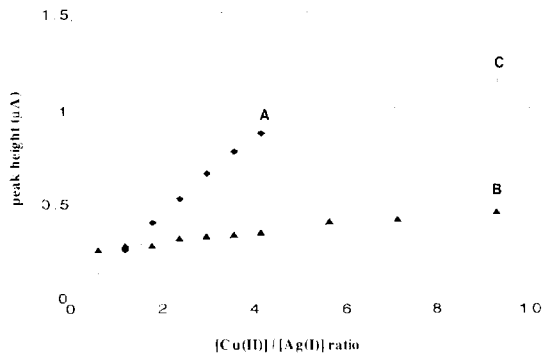

Fig. 6. Effect of Cu(II) interference on Ag(I) analysis in various supporting electrolytes: (A) 0.10 M KNO_3, [Ag(I)] = 8 μg l^{-1}, $E_d = -0.25$ V, $t_d = 60$ s, $t_r = 30$ s, stirring rate: 3000 rev min^{-1}; (B) 0.10 M Na_2HPO_4, [Ag(I)] = 8 μg l^{-1}, $E_d = -0.550$ V, $t_d = 60$ s, $t_r = 30$ s, rotating rate: 3000 rev min^{-1}; Ag(I) oxidation current at $E_{p_a} = +0.080$ V; (C) same conditions as (B): Cu(II) oxidation current at $E_{p_a} = +0.295$ V.

3.2. Interferences

The interference effects of other metal ions as Cd(II), Mg(II), Zn(II), Ni(II), Co(II), Fe(II), Pb(II), Bi(III) and Cu(II) was also studied.

Only Cu(II) and Bi(III) interfere during Ag(I) analysis. In the majority of the media described in Table 1, Ag(I) and Cu(II)/Bi(III) oxidation peaks appear close together, despite the selection of the proper E_d value: direct determination of mixtures of Ag(I), Cu(II) and Bi(III) is thus impossible. In basic media (Table 1, media 2, 12 and 14), where the different complexation characteristics of Cu(II), Bi(III) and Ag(I) with NH_3 and OH^- can be taken into account (as it can experimentally be visualized by the pseudo-voltammograms), the two oxidation signals appear at different E_{p_a}, values and the Cu(II)/Bi(III)-Ag(I) interference drops out. This is the case, for instance, for the 0.10 M Na_2HPO_4 supporting electrolyte, and, more generally, for the basic media of Table 1 (media 2, 12 and 14). In 0.10 M Na_2HPO_4, for $E_d = -0.50$ V, where both metal ions are reduced at the optimum reduction current (Table 1), the Ag(I) oxidation current is approximately independent of the Cu(II) concentration (Fig. 6b) and the Cu(II) signal presents a normal relationship with the metal ion content (Fig. 6c). Unfortunately, in this medium, the Ag(I) signal is somewhat lower

than in acidic electrolytes (Table 1) and this fact can be attributed to a partial precipitation of Ag(I) as Ag_3PO_4 ($K_s = 2.6 \times 10^{-18}$) or Ag_2O ($K_s = 3.8 \times 10^{-18}$) [26]. Nevertheless, the method remains applicable to the simultaneous determination of both ions in one analysis step. Cu((II)–Bi(III) interference must, for its part, be eliminated by specific complexation of one metal. The classical CPE sensor shows here its lack of specificity vs. the chemically modified carbon paste or adsorptive stripping mode [5,18–20].

3.3. Activation of the carbon paste surface

Among the various activation procedures, we select the method of Motta and Guadalupe used for biosensors [27] (cycling the electrode throughout the oxidative potential region at a relatively high scan speed during a determined time (t_a, activation time)) because this procedure is compatible with the requirements of routine analysis. The procedure was made directly in the supporting electrolyte, and the potential scan was extended by 0.9 V more positive than the actual anodic potential limit. Processing activation in basic solutions can appear quite surprising: however, recent studies [10,28] have demonstrated that electrochemical graphitic oxide can be formed in basic solutions, but is unstable only in highly basic media (pH > 12); furthermore, different potential regions must also be considered [28]. Considering the results of recent studies [10], the model developed by McCreery [29] thus needs to be reconsidered for a more effective understanding of the activation process. In such conditions, it is not unusual to examine the effect of activation on CPE in the various electrolytes studied in Table 1, whose pH values range between 0.1 and 9.3.

Upon activation, the equilibrium potential of the electrode becomes more positive, the reduction current is enhanced and the reversibility of the Ag(I)/Ag system increases. However, as indicated by Fig. 7, the silver oxidation signals show enhancements of i_{p_a} and back-ground currents, so that the signal/noise ratio is lowered. A possible explanation is that the electrochemically oxidized CPE is reduced at E_d and that the corresponding reoxidation component (quinone formation), the paraffin removal, porosity and edge effects enhancements more greatly affect the background signal than the silver one. The same conclusion is obtained with some variations, for the various (acidic, neutral and basic) electrolytes studied in Table 1; the value of the signal-to-background ratio depends upon the nature of the medium and the value of the activation time. Consequently as a general conclusion, the activation (as used in the conditions mentioned) of the CPE surface is unnecessary and quite unfavourable in the ASV technique, by opposition with chemical reoxidation as visualized by, f.i., potentiometric stripping analysis [23].

3.4. Method validation

The method is evaluated by determining the Ag(I) and Cu(II) contents of two NBS reference materials: the gelatine multicomponent Trace Element Reference Materials TEG 50 B and TEG 50 C. Observing the NBS recommendations, a sample aliquot ($\geqslant 250$ mg, dried) is treated with 6 ml

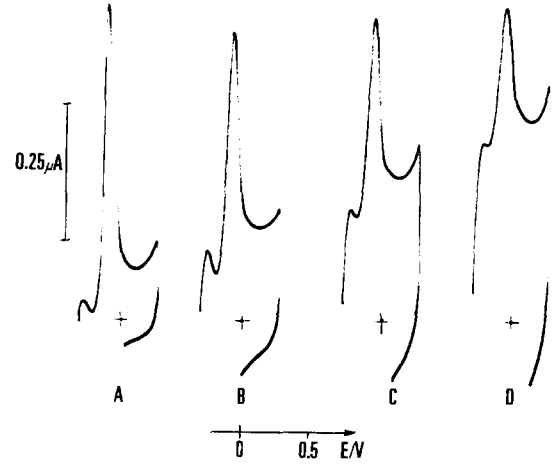

Fig. 7. Partial cyclic voltammetric measurements for [Ag(I)] = 8 μg l^{-1} in 0.10 M NH_3–0.10 M NH_4^+: (A) without activation; (B) after activation of 30 min; (C) after an additional activation time of 240 min; (D) after another additional activation time of 240 min. Activation: cycling between + 0.30 and + 1.20 V at 0.5 V s^{-1}, stationary conditions. ASV conditions: $E_d = -0.550$ V, $t_d = 60$ s, $t_r = 30$ c, stirring rate: 3000 rev min^{-1}.

Table 2
Comparison between measured and certified Ag(I) and Cu(II) concentrations in reference materials

Material	Element	Certified value (ppm)	Measured values (ppm)[a]					Mean (ppm)	RDS (ppm)
TEG 50 B	Cu	49 ± 2	51	52	53	50	50	51.2	1.9
	Ag	56 ± 7	61	61	60	58	56	59.2	3.3
TEG 50 C	Ag	51 ± 2	50	52	53	49	48	50.4	2.8

[a] Operating conditions: CPE 74:26; $E_d = -0.550$ V; $t_d = 45$ s; $t_r = 30$ s; stirring rate: 3000 rev min^{-1} 1.0×10^{-4} M $HClO_4$.

of a 2:1 volume mixture of HNO_3 (Ultrapure Grade, Merck): water at ± 80°C under reflux for approximatively 1 h; after cooling the solution is diluted to 10 ml and 2 ml aliquots are mixed with the supporting electrolyte ($HClO_4$) and analysed by the standard addition method.

Table 2 illustrates the results obtained; the correlation between the certified and measured Ag(I) and Cu(II) concentrations is good, for a total measurement time of ± 10 min. The final value was the mean of five replicate measurements.

4. Conclusion

Trends in electrochemical stripping analysis today make great use of CMCPEs and ASV. However, few applications appear in the routine determination of trace elements. By widening the choice of supporting electrolytes and selecting more precisely the electrochemical parameters by pseudo-voltammograms, a classical CPE is comparable in many ways with the more elaborate sensors and methodologies. If this electrode shows an inherent lack of selectivity, the direct (potentiostatic) preconcentration mode still presents unique advantage in routine analysis: low analysis time, low-cost instrumentation, friendly procedure and avoidance of matrix exchange and/or exotic electrolytes (as is generally the case for CMCPE and adsorptive stripping). The dynamic range of the method is 0.05 μg l^{-1} and this can be extended to 400 μg l^{-1} for a total analysis time between 30 s and 10 min. The reproducibility lies between 2 and 5% for five replicate measurements. Activation of the CPE appears unnecessary and only a first stabilization period of 20 min maximum is needed.

Received 22 April 1996; received in revised form 23 July 1996; accepted 8 August 1996

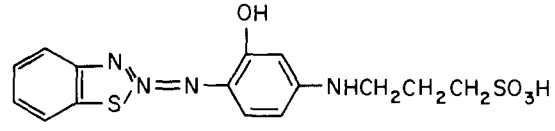
Abstract

The separation and determination of Co(III), Ni(II), V(V) and Fe(III) chelates with 2-(2-benzothiazolylazo)-5-(3-sulfopropyl)aminophenol (BTASPAP) by reversed-phase ion-pair HPLC was investigated. In the presence of the oxidant potassium iodate, BTASPAP reacts with Co(III), Ni(II), V(V) and Fe(III) to form stable, negatively charged, water-soluble chelates. The chelates were separated on a C_{18} siloxane bonded phase and eluted within 7 min with acetonitrile-acetate-water (36:1:63 v/v) containing 0.2 mol l^{-1} acetic acid-sodium acetate buffer (pH 3.0) and 1.0 mmol l^{-1} tetrabutylammonium bromide. The detection limits of Co(III), Ni(II), V(V) and Fe(III) at 565 nm are 0.3, 0.8, 0.3 and 1.0 ng (signal-to-noise ratio = 2), respectively. The method was applied to the determination of Co, Ni, V and Fe in four samples of standard alloys. © 1997 Elsevier Science B.V.

Keywords: Metal chelates; Reversed-phase ion-pair high-performance liquid chromatography

1. Introduction

Precolumn derivation HPLC is not only a sensitive but also a selective and rapid method for the separation and determination of metal ions. Many spectrophotometric reagents have been widely used in HPLC, such as 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol(5-Br-PADAP) [1], 4-(2-pyridylazo)resorchinol (PAR) [2], 2-pyridyl-β-azonaphthol (PAN) [3] and others [4–6]. However, the use of thiazolazo reagents for the separation and determination of metal ions by means of HPLC has seldom been reported [7]. 2-(2-benzothiazolylazo)-5-(3-sulfopropyl)aminophenol (BTASPAP) is a sensitive spectrophotometric reagent.



which can react with many metal ions, such as Fe, Co, Ni, V, Cu and Zn [8,9] to form stable, nega-

* Corresponding author.

PII S0039-9140(96)02061-9

tively charged, water-soluble, purplish red complexes, has been used in spectrophotometric determinations of these metal ions [8,10]. The spectrophotometric determination of any one of these metals ions is difficult when they are present together in a mixture, as a result of the spectral overlap of the BTASPAP complexes of these metal ions. The selectivity of BTASPAP is poor in the determination of metal ions by spectrophometry. Precolumn derivatization HPLC, which combines the high sensitivity of spectrophotometric reagents with the selectivity of HPLC, is a highly sensitive and selective method for the simultaneous determination of some metal ions. This paper reports for the first time the use of BTASPAP as a precolumn derivatization reagent to separate and determine Co(III), Ni(II), V(V) and Fe(III).

The reported reversed-phase HPLC methods for the separation and determination of heavy metals using chelating reagents such as PAR, 5-Br-PADAP and 2-(2-thiazolylazo)-5-dimethylaminophenol (TAM), have the disadvantage that they require the mobile phase to contain a high proportion of an organic solvent or surfactant owing to the poor water solubility of their chelates. In contrast, the BTASPAP chelates of metal ions are very water soluble, and therefore they can be separated from each other with a mobile phase containing a lower proportion of organic solvent. The BTASPAP chelates approach described here has the advantages of high sensitivity, good resolution in a short analytical time and good column efficiency.

2. Experimental

2.1. Apparatus

A Pye Unicam PU4015 HPLC system (Philips, Cambridge, UK) with a Spherisorb ODS C_{18} column (5 μm particle size, 250 × 4.6 mm i.d.), equipped with a PU 4025 UV-Visible detector and an SP4290 integrator (Beijing, China) was used.

2.2. Chemicals

Stock solutions of Co(III), Ni(II) and Fe(III) in 1 mol l^{-1} nitric acid were prepared from their pure metals (99.99%). Stock solution of V(V) was prepared by dissolving the desired amount of divanadium pentoxide (V_2O_5) (99.99%) in water containing few drops of nitric acid. Working solutions of Co(III), Ni(II), V(V) and Fe(III) of 5.00 mg l^{-1} each by dilution. Solution 1.0 mmol l^{-1} of BTASPAP (synthesized as desented earlier [11]) was prepared in water containing 40% (v/v) acetonitrile. The mobile phase was acetonitrile-acetate-water (36:1:63, v/v) containing 0.2 mol l^{-1} acetic acid–sodium acetate buffer (pH 3.0) and 1.0 mmol l^{-1} tetrabutylammonium bromide (TBA Br). All reagents used were of analytical-reagent grade and doubly distilled water was used for all solution preparations.

2.3. Procedure

2.3.1. Preparation of standards

A set of solutions containing different concentrations of Co(III), Ni(II), V(V) and Fe(III) ions were prepared in 10 ml volumetric flasks with 2.0 ml of acetic acid–sodium acetate buffer solution (pH 3.0), 1.0 ml of 0.4% (w/v) potassium iodate (KIO_4) solution and 3.0 ml of 1.0 mmol l^{-1} BTASPAP solution, then heated for 7 min at 70°C and, after cooling, diluted to volume with doubly distilled water. After thorough mixing, the solutions were allowing to stand for 20 min and filtered through a 0.45 μm filter membrane. At a column temperature of 40°C, 20 μl of the prepared test solution were injected on to the column and the complexes were eluted with acetonitrile-acetate-water (36:1:63 v/v) containing 0.2 mol l^{-1} acetic acid–sodium acetate buffer (pH 3.0) and 1.0 mmol l^{-1} TBABr at a flow-rate of 1.0 ml min^{-1}. The peak heights were measured at a detection wavelength of 565 nm.

2.3.2. Sample preparation

A known amount of accurately weighed alloy sample (0.1 g) was dissolved in about 15.0 ml of hydrochloric acid (1:1), the resulting solution was evaporated nearly to dryness, a few drops 37.5% nitric acid were added and the excess of nitric acid was removed by heating. The solution was trans-

ferred in to a 100 ml volumetric flask and diluted to the mark with water, then the experiments were continued in the same manner as for the preparation of standards.

3. Results and discussion

3.1. Precolumn derivatization conditions and detection wavelength

In the requisite medium in the presence of the oxidant KIO_4, BTASPAP reagent reacts with Co(III), Ni(II), V(V) and Fe(III) to form stable, negatively charged, water-soluble, purplish red chelates. The ratios of Co(III), Ni(II), V(V) and Fe(III) to BTASPAP are 1:2, 1:2, 2:3 and 1:2, respectively. The negative charges of the chelates for Co(III), Ni(II), V(V) and Fe(III)-BTASPAP are 1, 2, 4, and 1, respectively.

The optimum conditions for chromogenic reactions of BTASPAP with these metal ions were studied in detail by the spectrophotometric as shown in Table 1. We found by experiment that Co(III) reacted initially with BTASPAP to form the Co(II)-BTASPAP complex in the presence of only air at room temperature, the Co(II)-BTASPAP complex was gradually oxidized by oxygen in air to form the stable Co(III)-BTASPAP complex and strong oxidants and higher temperature could accelerate the oxidation. Under optimum HPLC conditions, Co(II)-BTASPAP and Ni(II)-BTASPAP complexes could not be separated. If the Co(II)-BTASPAP complex was oxidized to the stable Co(III)-BTASPAP complex, the complete separation of Co(II)-BTASPAP and Ni(II)-BTASPAP complexes could be achieved by changing the HPLC separation conditions.

For precolumn derivatization reactions, the optimum conditions were 5.0 ml of acetic acid-solium acetate buffer (pH 3.0), 3.5 ml of 1.0 mmol l^{-1} BTASPAP, 1.0 ml of KIO_4 solution and 3 μg each of the four metal ions per 10 ml. After the solution had been heated for 7 min at 70°C, all the metal ions complexes were stable for at least 24 h.

The absorption spectra of the four complexes are shown in Fig. 1. The wavelength of maximum absorption for the Co(III), Ni(II), V(V) and Fe(III) complexes and the reagent were 570, 560, 585, 580

and 528 nm, respectively. A optimum wavelength of 565 nm was chosen for the determination.

3.2. Chromatographic separation conditions

3.2.1. Selection of organic solvents in mobile phase

The effects of acetonitrile–water and methanol–water as mobile phases on the separation of Co, Ni, V and Fe were studied. It was found that acetonitrile–water was the most suitable mobile phase. The effect of the ratio of acetonitrile to water on capacity factor (k') is shown in Fig. 2.

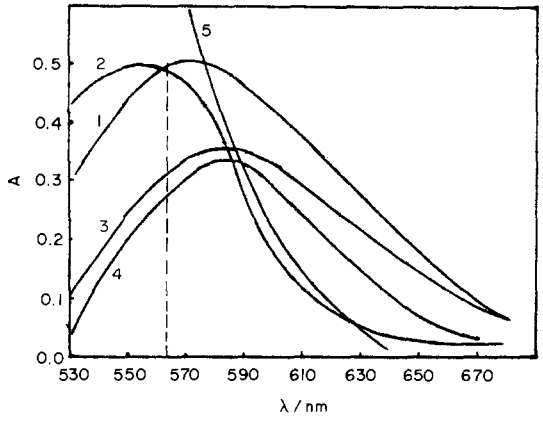

Fig. 1. Absorption spectra. Derivatization conditions: 10.0 ml HAc-NaAc buffer (pH 3.0), 5 ml 1.0 mmol l^{-1} BTASPAP, 1.0 ml KIO_4/25 ml. (1) 5.0 μg/25 ml Co(III); (2) 5.8 μg/25 ml Ni(II); (3) 5.0 μg/25 ml V(V); (4) 7.0 μg/25 ml Fe(III); (5) BTASPAP. Spectra 1–4 measured vs. reagent blank and 5 vs. water blank.

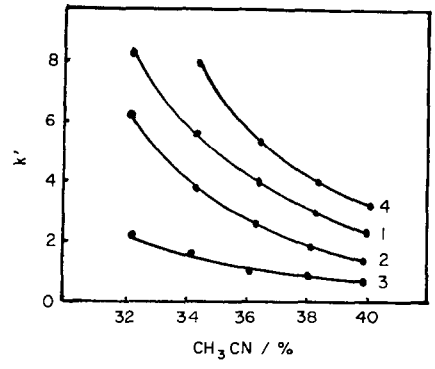

Fig. 2. Effect of content of acetonitrile on capacity factor, k' (1% acetone, 0.8 mmol l^{-1} TBABr and pH 3.0 were fixed). (1) Co-BTASPAP; (2) Ni-BTASPAP; (3) V-BTASPAP; (4) Fe-BTASPAP. Concentration of metal ions = 3.5 μg/10 ml.

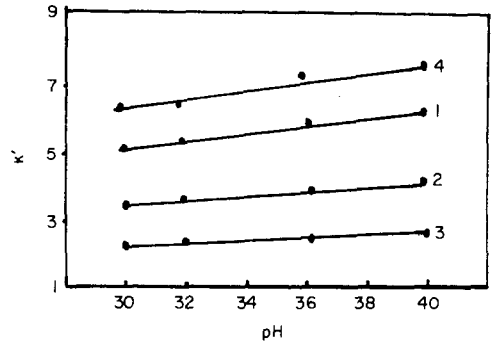

Fig. 3. Effect of pH of the mobile phase on k' (acetonitrile-water-acetone (36:63:1 v/v), 0.8 mmol l^{-1} TBABr, 20% HAC-NaAC buffer). (1) Co-BTASPAP; (2) Ni-BTASPAP; (3) V-BTASPAP; (4) Fe-BTASPAP.

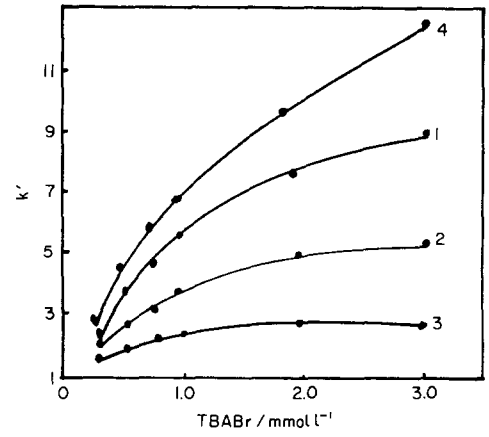

Fig. 4. Effect of the concentration of TBABr in the mobile phase on k' (acetonitrile-water-acetone (36:63:1, v/v), pH 3.0 20% HOAC-NaOaOAC buffer). (1) Co-BTASPAP; (2) Ni-BTASPAP; (3) V-BTASPSP; (4) Fe-BTASPAP.

The k' values of the four metal ion complexes decreased gradually with increase in the content of acetonitrile in the mobile phase. A 1% addition of acetone to the mobile phase was the most favorable for improving the chromatographic peak shapes and enhancing the peak heights. Acetonitrile–acetone–water (36:1:63, v/v), separated the Co(III), Ni(II), V(V) and Fe(III) complexes in the least time.

3.2.2. Effect of the pH of mobile phase

To prevent the four complexes from decomposing on the column, the mobile phase had to contain requisite amount of inorganic buffer. When the pH of the mobile phase was much lower than 3.0, it

would destroy the column, and if the pH was higher than 5.0 or lower than 3.0, the complexes would be unstable and decompose, with a decrease in chromatographic peak heights. With an increase in the pH of mobile phase, the k' values of the four metal ions only showed small changes. We examined the effect of the pH of the mobile phase on the retention volumes of the complexes only over a small pH range, as shown in Fig. 3. Based on the results we adopted pH 3.0 in subsequent work.

3.2.3. *Effect of added ion-pair reagent*

For better separation of the four metal ion complexes, an ion-pair reagent was added to the mobile phase. Three ion-pair reagents, tetramethylammonium bromide (TMABr), cetyltrimethylammonium bromide (CTMABr) and tetrabulylammonium bromde (TBABr) were examined for improving the separation of the complexes. The results showed that TMABr could not improve the separation of the chelates and the use of CTMABr could extend the retention times of the chelates. It was found that TBABr was the most suitable ion-pair reagent. The k' values of the four complexes increased slowly with increasing content of TBABr, as shown in Fig. 4. The optimum concentration range of TBABr was 0.8–1.0 mmol l^{-1}.

[a] Average of five determinations.
[b] Relative standard deviation ($n = 5$).

0.3, 0.3, 0.8 and 1.0 ng, respectively (signal-to-noise ratio = 2).

3.4. Effect of foreign ions

The potential interference of numerous ions was studied by spectrophotometry. Different amounts of ionic species were added to a mixture of Co, Ni, V and Fe containing 3 μg/25 ml of each. The starting amount of each foreign ion added was 100 mg, and if interference occurred the amount of the foreign ion were gradually reduced until interference ceased to occur. The tolerated limits were taken as the concentrations within which the errors caused were not greater than $\pm$ 5% in the determinations.

The tolerance limits are given in Table 3. All of the foreign ions in Table 3 have higher allowable amounts by the spectrophotometric method. In fact, none of the foreign ions gave a peak at 565 nm, but they consumed more BTASPAP reagent.

3.5. Analyses of some standard samples

The method was applied to the determination of Co, Ni, V and Fe in four standard alloys. The results are given in Table 4 together with the certified values, and demonstrate the good accuracies and precisions of the results obtained with the procedure proposed.

Abstract

A modified graphite electrode was produced by adsorption the bis(diisopropyloxythiophosphone)disulphide {(i-PrO-)$_2$P(S)S-}$_2$ under vacuum. Its electrochemical characteristics in flowing stream were described. The modified electrode has been used for simultaneous determination of Cu(II), Ag(I) by flow injection anodic stripping voltammetry. © 1997 Elsevier Science B.V.

Keywords: Anodic stripping voltammetry; Chemically modified electrode; Copper; Flow injection analysis; Silver

1. Introduction

Chemically modified electrodes enlarge the scope of electroanalytical determinations. They improve the selectivity and the sensitivity of analysis. This is due to different ligands immobilized on their surfaces by various methods [1–3]. Different organic ligands have been used for graphite electrodes modification aiming at the simultaneous determination of inorganic ions (for example copper and silver).

Some authors have immobilized dithiocarbamate ligands on platinum and graphite electrode [4,5], but they have determined only copper in the presence of nickel, lead and zinc. It is proposed a paste graphite electrode for simultaneous determination of copper and silver [6]. The poor reproducibility of the electrode's surface is the main problem here.

It is known from the literature that the organic ligands which have a disulphide group (–S–S–) extend amazingly by the selectivity of extractive spectrophotometrical determination of Cu(II) and Ag(I) [7]. Their synthesis was described for the first time in [8,9]. There the alkaline salts of the ditiophosphonate acids are oxidized by slight oxidizers according to the equation:

$$2(RO_2)P(S)SK + Ox_2 = (RO)_2P(S)S - S(S)P(RO)_2 + 2\mathrm{Red} \quad (1)$$

where R is alkyl or aryl.

A modified graphite electrode produced by adsorption of bis(diisopropyldithiophosphate) disulfide is described. Its application to flow

injection analysis (FIA) of metal ions is presented as well.

The equipment used includes a potentiostat-galvanostat 'Bi-Pad'; a generator of lineal voltage 'Servovit'; a recorder 'Sefram' (Tacussel, France), a peristaltic pump (P-1 Sweden), a flow voltammetric cell (home made [10]) and an injection valve (home made [13]). It is important to underline that the working part of the graphite electrode is of 0.6–0.8 mm diameter and its length is of 1.4–1.8 mm.

The following reagents were used: potassium diisopropyldithiophosphate $\{(i\text{-PrO})_2\text{P(S)SK}\}$ p.a., and bis(diisopropyloxythiophosphone)disulphide $\{(i\text{-PrO-})_2\text{-P(S)S-}\}_2$ which has been triply recrystallizated from ethyl alcohol. The concentration of the standard solution of Cu(II) and Ag(I) are of 1 g l^{-1}. All other reagents used were of an analytical grade (Merck). Doubly distilled water was used for solutions preparation and dilution.

1.1. Procedures

1.1.1. Preparation of a reagent for modification.

It has been prepared, according to the described Eq. (1), by dissolving potassium diisopropyldithiophosphate in doubly distilled water and has been oxidized with iodine solution. In this way the synthesizing disulphide has been recrystallisated into ethyl alcohol to get a product with a purity p.a. which has been controlled by chromatographic analysis.

1.1.2. Graphite electrode production.

The graphite electrode was prepared from spectroscopically pure graphite manufactured by Czechoslovak Ceramics Corporation, Praha, Czehia. The electrode's body was shaped to fit the dimensions pointed above by metal cutting machine and then glued to plastic holder.

1.1.3. Electrode modification.

The prepared electrode was placed in a vacuum vessel where a definite amount of the modifying reagent had been initially introduced. The system was then sealed and put into a water bath which was heated up to $T = 90$–95°C. At this temperature range the reagent was melted, the vacuum pump was turned on and a residual pressure of 13.3 HPa was created. In this way the thermal destruction of the modifier was avoided. The modification was carried out for 3 h at the same pressure and the same temperature. The electrode was then taken out of the melt and left over it at the same temperature and pressure for 30 min for homogenization of the coating.

2. Design of the analytical module

The flow injection system, created in our laboratory, is shown in Fig. 1. The electrochemical characteristics of the modified electrode were studied on varying of the type of the flow carrier and its rate and the parameters of electrochemical apparatus. The experiments were carried out in a flowing stream of a solution (0.2 M $KNO_3/10^{-3}$ M HNO_3).

3. Results and discussion

Cyclic voltammetry has been applied Fig. 2 shows cyclic voltammograms of graphite electrodes modified in different ways.

The electrode modified under vacuum (curve 1) is characterized by the widest working range (− 0.6– + 0.7 V) and the least residual current. It can be used for quantitative determination of ions of the precious metals because their anodic peaks appear in this range of potentials. The modified reagent favours the electrode's properties (curve 1) by decreasing the value of the residual current

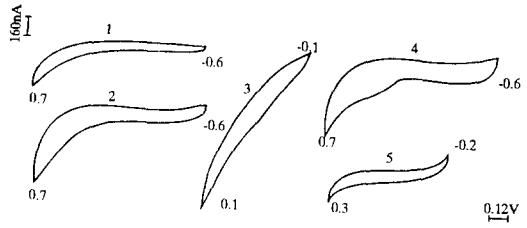

Fig. 2. Polarization curves for graphite electrode. (1) Graphite electrode modified under vacuum; (2) modified by dipping in a melt of the reagent; (3) modified by glycerine solution of the reagent; (4) pure graphite electrode in a flow carrier 0.2 m KNO_3; and (5) a graphite electrode modified in vacuum, in a flow carrier 0.1 M HNO_3; flow rate 1.3 ml min^{-1}; linear sweep potential rate 1 V min^{-1}.

when compared with that of a pure graphite electrode (curve 4). Curve 5 corresponds to a graphite electrode modified under vacuum, but the flow carrier used is 0.1 M HNO_3. Curve 5 shows also that the cathodic range becomes more narrow which is due to the disulfide reduction in presence of H^+.

3.1. Selectivity and sensitivity

The electrochemical behaviour of bis(diisopropyloxythiophosphone)disulphide $\{(i\text{-PrO-})_2P(S)S\text{-}\}_2$ on a mercury dropping electrode was described in detail [11]. It is reasonable to assume that the disulphide immobilized of the graphite electrode will have the same behaviour in the process of the electrochemical analysis in accordance with the following scheme:

$$\{(i\text{-PrO})_2P(S)S\}_{2ads} + 2e = 2\{(i\text{-PrO})_2P(S)S\text{-}\}_{ads} \quad (2)$$

$$2\{(i\text{-PrO-})_2P(S)S^-\}_{ads} + Me^{n+} = 2\{(i\text{-PrO})_2P(S)S\}Me_{ads} \quad (3)$$

$$\{(i\text{-PrO-})_2P(S)S\}Me_{ads} - 2e = Me^{n+} + \{(i\text{-PrO-})_2P(S)S\text{-}\}_{2ads} \quad (4)$$

The capabilities of modified graphite electrode (MGE) in respect to its sensitivity and selectivity, under the conditions of the flow injection analysis by anodic stripping voltammetry were tested by injections of samples containing the metal ions of interest. The results of those determinations are shown in Fig. 3.

Curves 1 and 2 show the sensitivity of a modified and unmodified graphite electrodes, respectively in the anodic stripping voltammetry analysis of the mercury ions present in the sample. The difference sensitivity in this is obvious. The modified electrode's sensitivity is two and a half times that of the unmodified electrode under the same experimental conditions. It is due to the complexation effect of the modifier which provides a stronger analytical signal than that observed at the unmodified graphite electrode. Curve 3, in the same figure can be treated as an anodic stripping voltammetric characteristics obtained on the oxidation of the products deposited upon the MGE during the electrolysis of the sample solution containing copper and silver ions. The two well outlined peaks, at potentials of -0.23 V for copper and -0.09 V for silver, coincide with values for the single peaks of copper or silver ions, correspondingly on the same MGE under identical experimental conditions. Curve 4 refers to the oxidation of the products deposited on the unmodified graphite electrode during the electrolysis of the sample containing copper and silver ions. An intensive peak with a maximum at a potential of -0.2 V is observed here. This intermediate value indicates that the separation under the conditions of FIA ASV is impossible. It follows that the modified graphite electrode shows a high selectivity towards this couple and a joint determination of both elements is possible. Thus, it can be used for quantitative analysis.

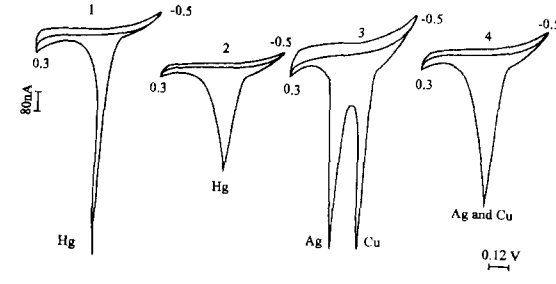

Fig. 3. ASV polarization curves of graphite electrodes. $E_{dep} = -0.5$ V; Carrier flow rate {0.2 M KNO_3/10^{-3} M HNO_3}-0, 13 ml min^{-1}; sample volume injected—800 μl; t_{dep}—10 min; concentration of the elements, 1 ppm.

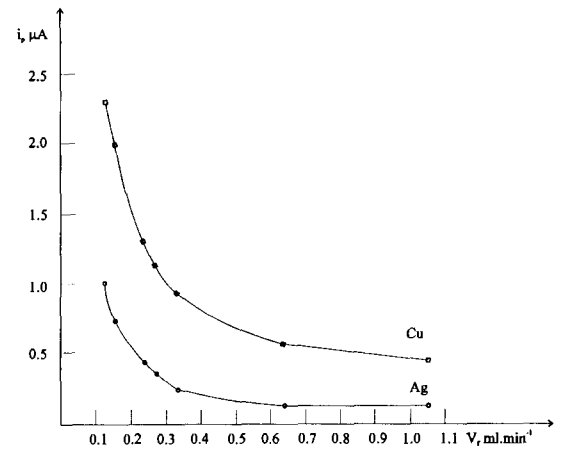

Fig. 4. Dependence of stripping peak on flow rate of copper and silver. $E_{dep} = -0.5$ V; $t_{dep} = 10$ min; $s_v = 800$ μl; $V_E = 33.3$ mV min^{-1}; flow carrier—0.2 M $KNO_3/10^{-3}$ M HNO_3; concentration of analyzed ions 1 ppm.

3.1.1. Optimization parameters of the FIA by modified graphite electrode

The basic parameters which may be optimized allow to find the most suitable conditions for a quantitative analysis. The analytical signal depending on the flow carrier rate should be followed. Fig. 4 shows analytical signals at different flow carrier rates.

The analytical signal is optimal for both analyzed cations at low flow carrier rates (0.10–0.25 ml min^{-1}). The reasons for the signal decrease with the flow carrier rate increase, is explained in the following way. The amount of the electrolysis products decreases practically with the increase of the flow rate because most of it is carried away by the flow prior to the electrolysis itself. Another factor of the FIA is the analytical signal dependence on the injection sample volume. For the anodic stripping voltammetric analysis the sample volume which will be injected in to the system depends on the analyte concentration, flow carrier rate and the time of electrolysis. For our determinations the injection sample volume is between 800 and 1000 μl the deposition time is of 10 min, the electrolysis potential is of -0.5 V, flow carrier rate is of 0.13 ml min^{-1}, linear sweep rate is of 33.3 mV s^{-1}.

The range used was determinated in the following way: a series of standard solutions containing both of the analyzed ions with different concentrations (0.10, 0.25, 0.50, 0.75 and 1 ppm) were prepared. The volume of the sample injected was 800 μl, the flow carrier rate (0.2 M $KNO_3/10^{-3}$ M HNO_3) was kept constant at 0.13 ml min^{-1} so that the electrolysis time was within of 10 min and the deposition potential was -0.5 V (SCE). After this period the flow carrier rate was increased to 1.3 ml min^{-1} and the linear sweep potential with rate of 33.3 mV s^{-1} was performed. The obtained anodic peaks are in the interval from -0.5 to 0.7 V. Their height was measured in μA and the dependence of the current on the analyzed elements concentration was followed. From time to time an empty sample solution was injected to the system aiming at the elimination of the hindering effect. Each analysis was carried out five times. Then the data for the calibration line were treated statistically [12]. The obtaining correlation coefficients of both curves are $r = 0.999$ for the copper and $r = 0.998$ for the silver. The equations of each line are $i_p = 0.044 + 3.42\ C_{Cu}$ and $i_p = 0.022 + 2.20\ C_{Ag}$, respectively $L.O.D._{Cu} = 0.05$ ppm and $L.O.D._{Ag} = 0.06$ ppm.

Application of modified graphite electrode to flow injection stripping voltammetry analysis of synthetic mixtures, containing copper and silver ions.

The synthetic mixture analysis was carried out in the following way. Three samples of different contents of side ions were prepared from an initial standard solution which had a concentration of 1 g l^{-1}.

The modified graphite electrode was inserted into the flow cell, the flow carrier was started (0.13 ml min^{-1} rate) and the cyclic voltammogram in the interval from -0.6 to 0.7 V was recorded. Then the indicator electrode potential was reduced to -0.5 V, the sample solution was injected and electrolysis was conducted for 10 min. After the corresponding deposition time linear sweep potential with a rate of 33.3 mV s^{-1} was applied. The anodic peaks recorded were measured in μA and the analyzed ions concentration was found from the calibration plot. The results are given in Table 1.

The hindering elements studied were selected because they could deposit and give respective

Table 1
A FI ASV with MGE of synthetic mixture containing 250 ppb silver ions and 250 ppb copper ions ($n = 5$; $P = 95\%$)

Added	Silver			Copper

20 ppm from each elements	250 ± 16.5	6.7	2.7	250 ± 10.3	4.2	1.6
30 ppm from each elements	250 ± 17.0	6.8	2.7	250 ± 13.1	5.3	2.1

peaks in the potential range of interest. Table 1 shows that the modified graphite electrode did not react with them and therefore both metal ions can be simultaneously determined in their presence. The modified graphite electrode was tested in the determination of silver ions content in shampoos. The results are compared with the data from emission spectral analysis with inductively couple plasma—Table 2.

It is seen from Table 2 that both methods have one and the same precision and reproducibility.

4. Conclusion

A modified graphite electrode was prepared using a new reagent bis(diisopropyloxytiophosphone)disulphide. A method for its modification by heat treatment under vacuum was applied. A firm, homogeneous film of a modifier was obtained on the graphite surface. The advantages of the modified electrode when compared with the unmodified one, in respect to its electrochemical characteristics and behaviour towards the copper–silver couple were shown. The modified graphite electrode was used for champoo analysis and the results obtained were compared with those from ICP-AE.

Solubility of metal chelates and their extraction from an aqueous environment via supercritical CO_2

Mehdi Ashraf-Khorassani [a,*], Michael T. Combs [b], Larry T. Taylor [b]

[a] *Analytical Division, Durability Inc., Blacksburg, VA 24060, USA*
[b] *Department of Chemistry, Virginia Tech, Blacksburg, VA 24061, USA*

Received 21 May 1996; received in revised form 20 August 1996; accepted 20 August 1996

Abstract

Solubility of nickel(II), copper(II), and chromium(III) hexafluoroacetylacetone and chromium(III) acetylacetone chelates was measured in supercritical CO_2 at two different pressures (200 and 400 atm) and 60°C. Solubility of fluorinated acetylacetone chelates was at least an order of magnitude higher than the non-fluorinated complexes. These pre-formed metal chelates as well metal diethyldithiocarbamate (DDC) and metal bis(trifluoroethyl)dithiocarbamate (FDDC) have also been extracted from aqueous environment using pure supercritical CO_2. It was demonstrated that metal HFA chelates while exhibiting higher solubility in supercritical CO_2 compared with metal FDDC chelates, exhibited lower extraction efficiency using the same extraction conditions. This behavior of metal HFA chelates is related to their stability in an aqueous environment. Direct extraction of Ni^{+2} and Cu^{+2} from an aqueous matrix was also achieved via in-situ chelation using diethyldithiocarbamate and bis(trifluoroethyl)dithiocarbamate as the ligands. Bis(trifluoroethyl)dithiocarbamate proved to be a more effective ligand for direct extraction of metal ions from aqueous environment using supercritical CO_2. © 1997 Elsevier Science B.V.

Keywords: Aqueous environment; Extraction; Metal chelates; Solubility; Supercritical CO_2

1. Introduction

Metal ions and metal-ligand complexes are usually extracted from liquid matrices via formation of a neutral chelate combined with solvent extraction [1]. After complexation using a suitable ligand, toxic organic solvents are required to extract the complex. The toxic organic solvent, often in relatively large volume, usually causes a hazardous environment in terms of both solvent handling and solvent disposal.

Supercritical fluids have become an alternate solvent for extractions in the past decade. The high diffusivity, low viscosity and variable solvent strength as a function of density (P, T) are some of the attractive features of supercritical fluids [2]. Extraction of hydrated metal ions using pure supercritical CO_2 is not feasible due to the weak interaction of ionic solute and non-polar fluid [3]. However, metal ion extractions can be obtained via binding of the positive metal ion to an anionic

* Corresponding author. Fax: + 1 540 2313327.

PII S0039-9140(96)02075-9

organic ligand which forms a stable neutral metal complex provided the metal complex exhibits reasonable solubility in supercritical CO_2.

The literature regarding solubility of metal chelates in supercritical CO_2 is very limited. Recently, Wai et al. [4,5] measured the solubility of different metal (Ni^{+2}, Co^{+3}, Cu^{+2}, Na^{+}, Bi^{+3}, and Hg^{+2}) diethyldithiocarbamate (DDC) and bis(trifluoroethyl)dithiocarbamate (FDDC) chelates in supercritical CO_2. It was demonstrated that metal FDDC chelates have approximately 2–3 orders of magnitude higher solubility than metal DDC chelates in supercritical CO_2. Also it was demonstrated that the solubility of $Cu(FDDC)_2$ increased significantly as the density of the supercritical CO_2 increased at constant temperature [4]. They also measured solubility of $Hg(FDDC)_2$ and $Hg(DDC)_2$ in methanol modified CO_2. It was demonstrated that 5% methanol modified CO_2 enhanced the solubility of $Hg(FDDC)_2$ and $Hg(DDC)_2$ by an order of magnitude [5].

Knowing this information, Laintz et al. [6] were able to extract quantitatively Cu^{+2} ion from both a solid sorbent and an aqueous matrix using supercritical CO_2 saturated with LiFDDC as a chelating agent. Extraction efficiency of Cu^{+2} ion from both matrices was greater than 95% at density above 0.35 g/ml and 35°C. The same group also reported extraction of other divalent and trivalent metal ions from aqueous and solid matrices. Extraction efficiencies of greater than 90% were reported for Cd^{+2}, Pb^{+2}, Pd^{+2}, Zn^{+2}, As^{+3}, Au^{+3}, Ga^{+3} and Sb^{+3} from sand and filter paper using LiFDDC ligand [9]. Similar recovery was also obtained for extraction of Cd^{+2}, Pb^{+2} and Zn^{+2} from aqueous solution [9]. Wai et al. have reported [5] extraction of mercuric ion (Hg^{+2}) from cellulose-based filter paper using LiFDDC as a chelating agent. Extraction efficiency of Hg^{+2} was less than 12% from the dry filter paper. The low extraction efficiency of mercury ion was reportedly due to strong interaction of Hg^{+2} with the cellulose matrix. However, by addition of a small amount of water (10 μl) directly to the matrix, extraction efficiency of mercury increased to 84%. When using 5% methanol modified CO_2, the extraction efficiency of Hg^{+2} was increased from 84 to 95%. This increase in extraction efficiency was mostly due to enhanced interaction between the solute and the modified solvent.

Extraction of similar heavy metals from different matrices has been achieved using again supercritical CO_2 saturated with LiFDDC. Liu et al. [8] reported extraction of Co^{+3}, Cd^{+2}, Zn^{+2} and Cu^{+2} from solid matrices (sand, soil and filter paper). Recovery of ions ranged from 70 to 100%. They reported that metal impurities in the stainless steel extraction vessel can form a metal chelate with the ligand and positively affect percent recovery of analytes. They suggested using a non-metal containing apparatus such as polyether ether ketone (PEEK). Recently Wang et al. [10] used different dithiocarbamates such as tetrabutylammonium dibutyldithiocarbamate (TDBDTC), tetrabutylammonium diethyldithiocarbamate (TDEDTC), sodium diethyldithiocarbamate [Na(DEDTC)] and ammonium pyrollidinecarbamate (APDTC) ligands for in-situ chelation and SFE of Zn^{+2}, Cd^{+2} and Pb^{+2} from aqueous media. It was demonstrated that extraction efficiency of Zn-DBDTC is much greater than Zn-DEDTC or Zn-PDTC. The high extraction efficiency of Zn-DBDTC was related to the high solubility of the chelate. Solubility ratios of Zn-DBDTC/Zn-DEDTC and Zn-SDDTC/Zn-PDTCin SF CO_2 were measured to be 20 and 139, respectively.

Beside dithiocarbamates, other ligands such as tetra-butyl-substituted dibenzobistriazolo-crown ether have been used for extraction of similar heavy metal ions (Cd^{+2}, Co^{+3}, Pb^{+2}, Ni^{+2}, Mn^{+2}, Au^{+3} and Zn^{+2}) from sand and filter paper [7]. Extraction efficiency of most metal ions, except Au^{+3}, from wet matrices was less than 4% using 5% methanol modified CO_2. The efficiency of extracted Au^{+3} from wet filter paper using 5% methanol modified CO_2 was 79%. Bistriazol-crown ether was also used for extraction of Hg^{+2} [7]. It was demonstrated that 5% methanol modified CO_2 saturated with a bistriazol-crown ether can extract only 78% of Hg^{+2} from sand, while the same fluid after addition of 10 μl water to the sample improved extraction efficiency to more than 95%.

The objective of our study was first to measure solubility of different metal acetylacetone and metal hexafluoroacetylacetone complexes in supercritical CO_2. Second, obtain extraction efficiency of different pre-formed metal acetylacetone, metal hexafluoroacetylacetone, metal diethyldithiocarbamate, and metal bis(trifluoroethyl)dithiocarbamate chelates from an aqueous environment using pure CO_2. No results have been reported regarding solubility or extraction efficiency of Cr^{+3}, Ni^{+2}, and Cu^{+2} acetylacetone or hexafluoroacetylactone chelates from an aqueous environment using supercritical CO_2. Finally we were interested to learn if metal ions (Ni^{+2}, and Cu^{+2}) could be extracted from an aqueous environment via in-situ chelation using supercritical CO_2.

2. Experimental

2.1. Apparatus

A Suprex (Pittsburgh, PA) Prepmaster equipped with an Accutrap™, variable flow restrictor, and a 10 ml extraction vessel modified for use with aqueous samples [11–13] was used for all extractions. The stainless steel frits which were part of the fitting seals were removed in order that 1/16 inch stainless steel tubing (0.01 inch i.d.) could pass through either end of the vessel. The stainless tubing inserted through the top of the vessel extended to within 1 cm of the bottom, and vice versa. Standard 1/16 inch fittings and ferrules (Valco, Houston, TX) were used to obtain reliable seals.

A Suprex 200A supercritical fluid chromatographic pump, Waters (Milford, MA) 6000 high performance liquid chromatographic pump, a Micropump (Concord, CA) recirculating pump, a 6 port-2 position valve, a 4 port-2 position valve, and Kratos Spectroflow 757 UV absorbance detector were used for all on-line solubility measurement. A 0.5 ml stainless steel extraction vessel was used for solubility determination.

2.2. Reagents

Bis(acetylacetonato)nickel(II) $Ni(AcAc)_2$, tris(acetylacetonato)chromium(III) $Cr(AcAc)_3$, bis(acetylacetonato)copper(II) $Cu(AcAc)_2$, bis(hexafluoroacetylacetonato)nickel(II) $Ni(HFA)_2$, bis(hexafluoroacetylacetonato)copper(II) $Cu(HFA)_2$, copper nitrate hydrate, chromium nitrate hydrate, nickel nitrate hydrate, and sodium diethyldithiocarbamate (NaDDC) were purchased from Aldrich (Milwaukee, WI). Lithium bis(trifluoroethyl)dithiocarbamate (LiFDDC) was prepared according to a procedure outlined in the literature [14]. Bis(diethyldithiocarbamato)nickel(II) $Ni(DDC)_2$, bis(diethyldithiocarbamato)copper(II) $(Cu(DDC)_2$, and bis(bis(trifluoroethyl)dithiocarbamato)nickel(II) $Ni(FDDC)_2$ and bis(bis(trifluoroethyl)dithiocarbamato)copper(II) $Cu(FDDC)_2$ were synthesized according to a procedure outlined in the literature [6]. HPLC grade methanol and chloroform were purchased from EM Science (Gibbstown, NJ). SFE/SFC grade CO_2 (helium head pressure) was used for both supercritical fluid extraction and solubility studies and was obtained from Air Products and Chemical Co. (Allentown, PA).

2.3. Solubility measurement apparatus

Fig. 1 shows the apparatus and positions of valves at each step for measuring solubility of organic and inorganic compounds under supercritical conditions. In each measurement, the 0.5 ml extraction vessel was filled with metal chelate. Next, the system was pressurized to 200 atm using pure CO_2. After pressurization of the system, the three way valve was closed and the recirculating pump was activated (A). The function of the recirculating pump was to ensure complete saturation of supercritical fluid with the chelate of interest. After 30 min of equilibration, the 4 port-2 position valve with 1 μl sample loop was rotated such that the solubilized chelate in supercritical CO_2 was directed from the 1 μl loop to the liquid chromatographic (LC) system (B). The LC flow then washed the chelate from the injection loop

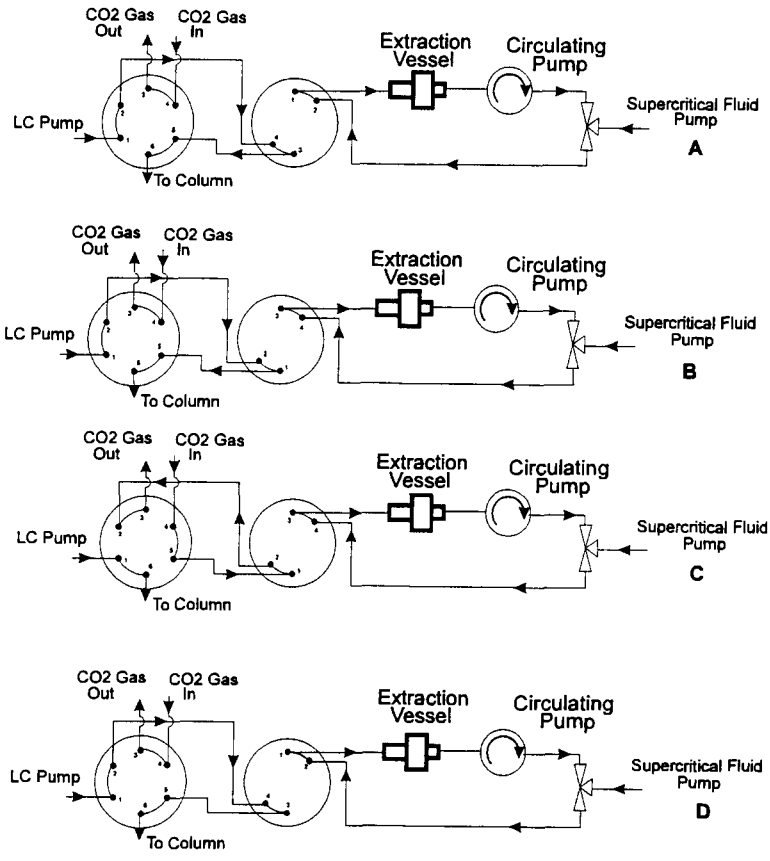

Fig. 1. Schematic diagram of apparatus for measuring solubility of inorganic compound in supercritical fluid.

through the column to a multi-wavelength UV absorbance detector operated at 280 nm for AcAc and HFA complexes and at 416 nm for DDC and FDDC complexes. By employing a second valve (6 port-2 position valve), a stream of carbon dioxide could then be passed through the sample loop to remove the chromatographic mobile phase from the loop, thus avoiding modification of supercritical fluid composition (C). Next, the 4 port-2 position valve was rotated to the load position and the procedure was repeated (D). Replicate determinations were made on each metal chelate to ensure reproducibility of the system. After measurement of analyte solubility at 200 atm, the system was pressurized to 400 atm and the same experiments were repeated.

2.4. SFE procedure

For each extraction, 5 ml of distilled water was added directly to the modified extraction vessel. Next, 200 μl of individual metal chelate standard with a concentration range of 15–22 μg μl^{-1} was spiked directly in to the distilled water. The system was operated at either 200 or 400 atm and 60°C for 10 min static and 30 min dynamic period using pure supercritical CO_2 at flow of 2 ml min^{-1}. For studies of in-situ chelation, 200 μl of metal salt standard with a concentration range of 6–8 μg μl was spiked into the vessel containing 5 ml of distilled water saturated with chloroform followed by addition of excess chelating ligand. The sample was then extracted under the same

Table 1
Solubility of different metal β-diketone and metal dithiocarbamate chelates in supercritical CO_2 at different conditions

Chelate	Mole l^{-1}, 200 atm, 60°C	Mole l^{-1}, 400 atm, 60°C	[a]Mole l^{-1}, 100 or 150 atm, 60°C
$Ni(HFA)_2$	$(8.0 \pm 0.1) \times 10^{-3}$	$(9.9 \pm 0.2) \times 10^{-3}$

conditions specified previously. The extracts were then collected in 5 ml of a 50/50 mixture of methylene chloride/methanol at ambient temperature. The analysis of the sample extracts for each metal was performed by atomic absorption spectroscopy (using either a nitrous oxide or acetylene flame) by REIC Laboratory (Beaver, WV).

3. Results and discussions

3.1. Solubility measurements

Solubility of $Ni(HFA)_2$, $Cu(HFA)_2$, $Cr(HFA)_3$, and $Cr(AcAc)_3$ was determined using the apparatus described in the Section 2. Table 1 shows the solubility of each analyte in CO_2 at 200 and 400 atm and 60°C. Due to low solubility of $Cu(AcAc)_2$ and $Ni(AcAc)_2$ in supercritical CO_2 and their poor chromatographic behavior [15], solubility measurements of these chelates via our system were not feasible. Even, increasing pressure from 200 to 400 atm did not drastically effect solubility of $Ni(AcAc)_2$ or $Cu(AcAc)_2$. It is important to note here that solubility of $Cr(HFA)_3$ in supercritical CO_2 was very high. It is believed that during our solubility measurement saturation of fluid was not achieved (due to limited mass of $Cr(HFA)_3$) since no chelate remained in the extraction vessel upon completion of the experiment. Therefore it is expected that solubility of $Cr(HFA)_3$ is greater than or equal to that reported here. The solubility of $Cr(HFA)_3$ in pure CO_2 at either 200 or 400 atm was at least an order of magnitude higher than the corresponding non-fluorinated complex. Also results showed that solubility of all metal HFA chelates was at least two order of magnitude higher than solubility of those metal FDDC chelates ($Ni(FDDC)_2$, $Cu(FDDC)_2$, $Co(FDDC)_3$, NaFDDC, $Bi(FDDC)_3$, and $Hg(FDDC)_2$) reported previously by Wai et al. [4,5].

Table 2
Percent recovery of different metal acetylacetone complexes from an aqueous environment using supercritical CO_2. Extraction period: 10 min static and 30 min dynamic with flow of 2 ml min^{-1}

Metal complex	% Recovery, 200 atm	% Recovery, 400 atm
$Ni(AcAc)_2$	2 (55)[a]	1.5 (3)
$Cu(AcAc)_2$	12 (66)	9 (18)
$Cr(AcAc)_3$	66 (10)	82 (1)

Extraction temperature: 60°C.
[a] % RSD for triplicate extractions are noted in parentheses.

3.2. Recovery of metal acetylacetone complexes from water

Extraction efficiency of Ni^{+2}, Cu^{+2}, and Cr^{+3} acetylacetone complexes from an aqueous matrix was obtained at two different pressures (200 and 400 atm) at 60°C. Table 2 shows the recovery of each analyte at the different pressures. Recovery of $Ni(AcAc)_2$ from water at either 200 or 400 atm was less than 2%, while recovery of $Cu(AcAc)_2$ from water using the same extraction conditions was less than 12%. The low recoveries and poor precision in extraction efficiency of chelates can be explained by either the low solubility of metal chelates in supercritical CO_2 or changes in composition of the chelates at low pH's caused by CO_2 passing through water thus producing carbonic acid. Hedrick et al. have demonstrated extraction of phenols and organic bases from aqueous matrices. They observed strong interaction of basic compounds with aqueous acidic matrices [16–18]. Similar results were reported by Combs et al. [13] on a series of phenols in buffered aqueous solutions. $Ni(AcAc)_2$ and $Cu(AcAc)_2$ are known as kinetically labile complexes. Therefore, it is possible that these labile complexes lose one of the anionic ligands bonded to the metal and which makes the resulting cationic complex less extractable in supercritical CO_2 as shown below.

$$[ML_n]^0 \Leftrightarrow L^- + [ML_{(n-1)}]^+$$

Recovery of $Cr(AcAc)_3$ increased from 66 to 82% by increasing CO_2 pressure from 200 to 400 atm. The $Cr(AcAc)_3$ exhibited higher solubility in supercritical CO_2 compared with $Ni(AcAc)_2$ and $Cu(AcAc)_2$, thus, accounting for the higher extraction efficiency from an aqueous environment. Also, $Cr(AcAc)_3$ is known as a kinetically inert complex which means that the complex is not prone to hydrolysis or ligand displacement.

3.3. Recovery of metal hexafluoroacetylacetone complexes from water

Table 3 shows the extraction efficiency of $Ni(HFA)_2$, $Cu(HFA)_2$, and $Cr(HFA)_3$ samples from an aqueous environment. Percent recovery of $Ni(HFA)_2$ at either 200 or 400 atm was less than 12%. Recovery of $Cu(HFA)_2$ and $Cr(HFA)_3$, however, increased to above 50% at both pressures. The higher percent recovery of HFA complexes, compared with AcAc complexes, is due to enhanced solubility of fluorinated complex compared with non-fluorinated complex in supercritical CO_2. It was expected that full recovery of all chelates from water could be obtained since all of the HFA complexes in this study exhibited high solubility in supercritical CO_2. However, it was concluded from our solubility measurement and extraction efficiency results that the stability of these complexes was very much dependent on the extraction environment. It is believed that carbonic acid produced during the extraction promotes partial dissociation of the HFA complexes to yield less soluble species via acid catalyzed hydrolysis. Similar factors may have also caused poor precision in the extraction recovery. Further studies are being pursued to show these effects.

Table 3
Percent recovery of different metal hexafluoroacetylacetone complexes from aqueous environment at different pressures using supercritical CO_2

Metal complex	% Recovery, 200 atm	% Recovery, 400 atm
$Ni(HFA)_2$	6.4 (35)[a]	11 (40)
$Cu(HFA)_2$	49 (1)	51 (9)
$Cr(HFA)_3$	61 (10)	52 (9)

Extraction conditions: same as Table 2.
[a] % RSD for triplicate extractions are noted in parentheses.

3.4. Recovery of metal diethyldithiocarbamates from water

The results from extraction of both pre-formed $Ni(DDC)_2$ and $Cu(DDC)_2$ chelates from an aqueous environment and the recovery of Ni^{+2} and Cu^{+2} from an aqueous matrix by in-situ chelation using supercritical CO_2 under various conditions are given in Table 4. Extraction efficiency of $Ni(DDC)_2$ from water after 30 min at both pressures was 5.9 and 8.4% respectively, which was lower than the extraction efficiency of $Cu(DDC)_2$ using the same extraction conditions

(e.g., 10% at 200 atm and 38% at 400 atm). The low recovery and poor precision in the extraction efficiency of metal DDC complexes from water can be explained by the low solubility of DDC chelates in supercritical CO_2. $Ni(DDC)_2$ and $Cu(DDC)_2$ possess solubility of 8.5×10^{-7} and 1.1×10^{-6}, M respectively, in supercritical CO_2 at 100 atm and 50°C [4]. The higher extraction efficiency of $Cu(DDC)_2$ maybe due to its higher solubility in supercritical CO_2. A stepwise extraction for 120 min of $Cu(DDC)_2$ and $Ni(DDC)_2$ chelates spiked separately into water is shown in Fig. 2. The profiles obtained for the extraction of $Cu(DDC)_2$ and $Ni(DDC)_2$ suggest a solubility limited process. Therefore, an extended extraction time was deemed necessary to achieve a quantitative extraction of these chelates.

Similar results were obtained when excess DDC ligand was added to the water for direct in-situ chelation and extraction of Ni^{+2} and Cu^{+2}. Extraction efficiencies of Ni^{+2} and Cu^{+2} via in-situ chelation were less than 20% after 30 min of extraction (Table 4). A stepwise extraction profile of both $Ni(DDC)_2$ and $Cu(DDC)_2$, at 400 atm and 60°C, formed by in-situ chelation can be observed in Fig. 3. Total extraction of each in-situ chelate after 120 min equalled 48% for $Ni(DDC)_2$ and 42% for $Cu(DDC)_2$, while total recovery of spiked pre-formed $Cu(DDC)_2$ from water after 90 min was 109%. The lower recovery and poor precision in the supercritical CO_2 extraction of $Ni(DDC)_2$ and $Cu(DDC)_2$, obtained by in-situ

Table 4
Percent recovery of $Ni(DDC)_2$ and $Cu(DDC)_2$ pre-formed complexes and Ni^{+2} and Cu^{+2} via in-situ chelation from aqueous environment using supercritical CO_2

Metal DDC	% Recovery, 200 atm	% Recovery, 400 atm
$Ni(DDC)_2$	6 (97)[a]	8 (37)
$Ni(DDC)_2$, in-situ	—	11 (18)
$Cu(DDC)_2$	10 (26)	38 (6)
$Cu(DDC)_2$, in-situ	5.6 (35)	20 (20)

—No measurement was obtained.
[a] % RSD for triplicate extractions are noted in parentheses.

chelation can be explained by the fact that diethyldithiocarbamate ligand may decompose to produce CS_2 at low pH's. Our previous studies have demonstrated that the pH of aqueous solutions can easily drop to below 4 by continuous

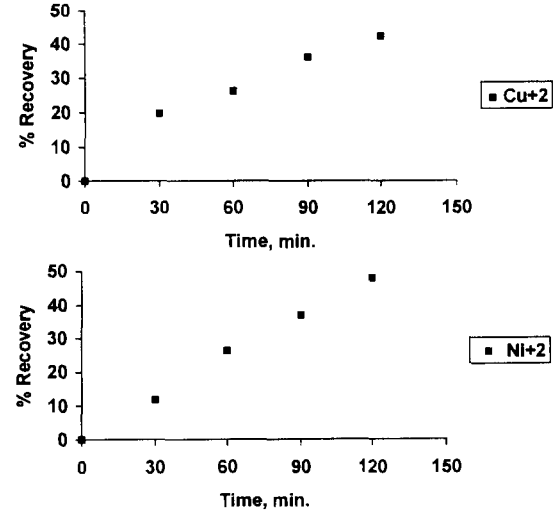

Fig. 3. Extraction profile for Cu^{+2} (A) and Ni^{+2} (B) ions via DDC in-situ chelation from water. Extraction conditions: 400 atm, 60°C, 2 ml min^{-1} liquid CO_2.

Table 5
Percent recovery $Ni(FDDC)_2$ and $Cu(FDDC)_2$ pre-formed complexes and Ni^{+2} and Cu^{+2} via in-situ chelation from an aqueous environment using supercritical CO_2

Metal FDDC	% Recovery, 200 atm	% Recovery, 400 atm
$Ni(FDDC)_2$	93 (7)[a]	103 (9)
$Ni(FDDC)_2$, in-situ	—	101[b]
$Cu(FDDC)_2$	95 (6)	94 (8)
$Cu(FDDC)_2$, in-situ	—	90[b]

—No measurement was obtained.

[b] Only two measurements were obtained due to limited mass of ligand.

bubbling of SF CO_2 through water [13]. Thus, if a large portion of the ligand in solution has decomposed during extraction, quantitative recovery of metal ion will not be possible since all metal ion would have not been fully chelated. As evidence for decomposition of DDC, a strong odor of CS_2 was noticed during extraction.

3.5. Recovery of bis(trifluoroethyl)dithiocarbamate complexes from water

Table 5 shows the recovery of both pre-formed metal FDDC complexes and Ni^{+2} and Cu^{+2} via in-situ chelation from water. Quantitative recovery of both pre-formed $Ni(FDDC)_2$ and $Cu(FDDC)_2$ at both 200 and 400 atm and 60°C was obtained. The increased metal complex solubility allowed quantitative recovery to occur in a short time period. Laintz et al. [6] have reported similar results. They concluded that high extraction efficiency of metal FDDC was related to large solubility of metal FDDC complexes in supercritical CO_2 and their high formation constant. In-situ chelation studies were performed by adding excess FDDC ligand directly to the aqueous extraction vessel containing Ni^{+2} or Cu^{+2}. After 30 min of extraction at either 200 or 400 atm, quantitative recovery of the metals was obtained. It was demonstrated that bis(trifluoroethyl)dithiocarbamate is the most effective ligand tested in this study for extraction of Ni^{+2} or Cu^{+2} from water. Unlike extraction of metal ions via in-situ chelation using DDC as a ligand, no decomposition of FDDC occurred during in-situ chelation of metal ions.

4. Conclusion

Solubility of Ni^{+2}, Cu^{+2}, and Cr^{+3} hexafluoroacetylacetone, and Cr^{+3} acetylacetone were measured in pure supercritical CO_2. Solubility of fluorinated chelates (e.g. $Cr(HFA)_3$) was at least an order of magnitude higher than the non-fluorinated (e.g., $Cr(AcAc)_3$) complexes and two orders of magnitude higher than metal FDDC complexes. Due to the low solubility of $Ni(AcAc)_2$ and $Cu(AcAc)_2$ in supercritical CO_2 and their poor chromatographic behavior, solubility measurements of these chelates was not feasible. Results from extraction efficiency of metal chelates from water demonstrated that fluorination of the ligand improved extraction efficiency by increasing volatility and solubility of the complex. However, stability of the ligand under supercritical conditions and aqueous acidic environments is very important. Extraction efficiency of metal DDC and metal FDDC showed quantitative recovery of chelate is feasible. However, longer extraction time is required to obtain quantitative recovery of metal DDC complexes. Also it was demonstrated that metal ions dissolved in aqueous solution can be extracted by supercritical CO_2 via in-situ chelation. However the extraction efficiency of ions is very much dependent on the type of ligand used as the chelating agent. Finally it was demonstrated that higher solubility of metal chelates in pure CO_2 does not necessarily mean a higher extraction efficiency of chelates. Extraction efficiency of chelates not only depends on their solubility in supercritical CO_2, but also depends on the matrix in which the chelates are located and the stability of the chelates in the surrounding environment.

Abstract

A spectrophotometric flow-injection method for determining copper(II) has been developed. It is based on the catalytic effect of copper(II) on the oxidative coupling of *N*-phenyl-*p*-phenylenediamine with *m*-phenylenediamine in the presence of hydrogen peroxide. Pyridine and ammonia as activators increased the absorbance for the copper(II)-catalyzed coloration, and the dye formed was stabilized by adding a non-ionic surfactant. The working range of the method was 0.1–2.0 ng ml^{-1} of copper(II) with a relative standard deviation 2.4% at a sampling rate of 30 h^{-1}. Interference from iron(III) was effectively suppressed by citric acid. Copper in natural water samples can be determined easily. © 1997 Elsevier Science B.V.

1. Introduction

The application of catalyzed reactions to the trace analysis of metal ions is very attractive. By using an appropriate indicator reaction, nanogram and/or subnanogram amounts of a metal ion acting as a catalyst can be determined. The presence of ligands as activators increases the rate of the catalyzed reaction. High sensitivity and/or selectivity of catalytic methods can be achieved [1,2]. Furthermore, a surfactant having the ability to form organized assemblies can control reaction pathways and change reaction mechanisms [3]; its addition to the reaction system can improve sensitivity.

There have been many batchwise methods for the catalytic determination of copper, based on catalysis of various redox reactions [4–18]. These methods are able to determine the element at sub- and/or nanogram per ml levels; especially, by oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone (MBTH) with *N*-ethyl-*N*-(2-hy-

PII S0039-9140(96)02096-6

droxy-3-sulphopropyl)-3,5-dimethoxyaniline which, in the presence of hydrogen peroxide, allowed as little as 2 pg ml^{-1} of copper(II) to be determined [18]. However, their analytical conditions should be strictly controlled and the procedures are time-consuming.

Flow-injection analysis is an important technique in the development of kinetic-based methods, because control of the reagent addition and the reaction time is easy [2]. Thus, catalytic methods offer better reproducibility and sampling frequency as well as higher sensitivity by the aid of flow-injection mode. Some indicator reactions catalyzed by copper(II) were applied to flow-injection systems [19–21]. The oxidation of thiosulfate with iron(III) was employed for the determination of 0–180 ng ml^{-1} of copper [19]. Satoh et al., [20] reported a flow-injection determination for copper based on the catalytic effect on the oxidative coupling of MBTH with *N,N*-dimethylaniline by hydrogen peroxide. The detection limit of this method was 0.05 ng ml^{-1} of copper(II). A chemiluminescent reaction of 1,10-phenanthroline with hydrogen peroxide was adapted to the flow-injection determination of ultratrace levels of copper(II) [21].

In the previous paper [22], we have developed a catalytic flow- injection method for the determination of 0.5–30 ng ml^{-1} of iron using an oxidative coupling of *N*-phenyl-*p*-phenylenediamine (PPDA) with *m*-phenylenediamine (PDA) in the presence of hydrogen peroxide and polyoxyethylene(20) sorbitan monooleate (Tween 80) as a surfactant. This indicator reaction was also catalyzed by trace amounts of copper(II). Furthermore, pyridine and ammonia acted as activators in the copper(II)-catalyzed reaction system. This paper describes the highly sensitive flow-injection photometric determination of copper(II) based on catalysis of the coloration system of PPDA, PDA and hydrogen peroxide. In order to obtain higher sampling frequency and prevent the adsorption of the reaction product on the inner wall of the reaction coil, Tween 80 was also added to the present system. The interference of iron(III) was effectively eliminated with citric acid as a masking agent. Copper(II) in the range 0.1–2.0 ng ml^{-1} can be determined with a sampling rate of 30 h^{-1}.

2. Experimental

2.1. Reagents

All solutions were prepared from analytical grade reagents and deionized water purified with a Millipore Milli-Q system.

A copper(II) standard solution (1.0 mg ml^{-1}) was obtained from Wako Junyaku, Japan. The working standard solutions were prepared daily by diluting the standard solution with 0.1 mol l^{-1} hydrochloric acid.

N-Phenyl-*p*-phenylenediamine hydrochloride (PPDA) obtained from Aldrich was used as received. A 1.0×10^{-3} mol l^{-1} PPDA solution containing 0.5% w/v polyoxyethylene(20) sorbitan monooleate (Tween 80) was prepared. *m*-Phenylenediamine dihydrochloride (PDA) was purified by recrystalization from hydrochloric acid and a 1.0×10^{-2} mol l^{-1} PDA stock solution was prepared. A hydrogen peroxide solution (0.5 mol l^{-1}) was prepared by dilution of a commercial solution (30%, Mitsubishi Gasu Kagaku) with water. Acetic acid (1.0 mol l^{-1}), pyridine (1.0 mol l^{-1}), ammonia (2.0 mol l^{-1}) and citric acid (0.1 mol l^{-1}) stock solutions were also prepared.

A working mixed solution of PDA (3.0×10^{-3} mol l^{-1}), acetic acid (0.1 mol l^{-1}), ammonia (0.5 mol l^{-1}) and citric acid (2.0×10^{-3} mol l^{-1}) was prepared by mixing the stock solutions; the pH of the mixed solution was adjusted to about 5.6 with 1.0 and 0.1 mol l^{-1} hydrochloric acid.

2.2. Apparatus

A schematic diagram of the flow-injection system used for the determination of copper(II) is shown in Fig. 1. All connecting lines and reaction coil were made from 0.5 mm i.d. Teflon tubing. Carrier and reagent solutions were propelled by two double-plunger micropumps (Sanuki Kogyo, DMX-2400T). Sample solutions were introduced into the flow-line by a sixway injection valve (Sanuki Kogyo SVM-6M2) with a loop. The reaction coil was immersed in a circulating thermostated bath (Toyo LH-l000C). A spectrophotometer (Soma Kougaku S-3250) with

a 10-mm micro flow-cell (8 μl) and a recorder (Nippon Denshi Kagaku V1250) were used for detecting and recording the absorbance of the reaction product. An Hitachi 200–10 double-beam spectrophotometer with 10-mm cells and a Toa Model HM-5S pH meter were also used.

2.3. Procedure

Carrier (R1, 0.1 mol l^{-1} hydrochloric acid) and reagent solutions in the reservoirs R2 (hydrogen peroxide), R3 (PPDA and Tween 80) and R4 (PDA, acetic acid, pyridine, ammonia and citric acid) were pumped into the analytical line at a flow rate of 1.0 ml min^{-1} (Fig. 1). An aliquot of the sample solution (215 μl) was introduced into the carrier stream by a loop-valve injector (*S*), and then merged in the reagent solutions. The color formation of PPDA with PDA took place in the reaction coil (RC, 8 m) submerged in the thermostated bath at 55.0 ± 0.1°C. The absorbance of the colored product was continuously monitored at 620 nm.

3. Results and discussion

PPDA reacts with PDA to form a blue dye in the presence of hydrogen peroxide. The dye produced is thought to be *N*-phenyl-*N*′2′,4′-diaminobenzene-1,4-benzoquinone diiminonium ion and has a absorption maximum at 620 nm in the presence of Tween 80, as described previously [22]. The rate of coloration is catalytically accelerated by trace amounts of copper(II) in the slightly acidic medium.

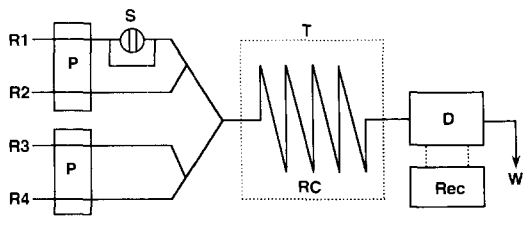

Fig. 1. Flow diagram for the determination of copper(II). R1, carrier (0.1 mol l^{-1} HCl); R2, 0.5 mol l^{-1} H_2O_2; R3, mixture of 1.0×10^{-3} mol l^{-1} PPDA and 0.5% w/v Tween 80; R4, mixture of 3.0×10^{-3} mol l^{-1} PDA, 0.5 mol l^{-1} ammonia, 0.2 mol l^{-1} pyridine and 2.0×10^{-3} mol l^{-1} citric acid; P, micropump (1.0 ml min^{-1}); S, sample injector valve (215 μl); RC, reaction coil (8 m); T, thermstated bath (55°C); D, detector (620 nm); Rec, recorder; and W, waste (pH 4.6–4.7).

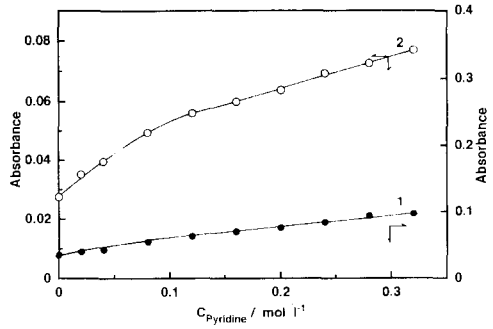

Fig. 2. Effect of pyridine concentration on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1 except for pyridine concentration. $C_{Cu(II)}$, 2.0 ng ml^{-1}.

3.1. Choice of activator and surfactant

The catalytic action of metal ion can be modified with an activator. It yields better sensitivity and lower limit of detection in a catalytic method [1,2]. Ammonia was used as an activator and an alkaline in the present system, because it is known as an activator for the copper(II)-catalyzed reaction [5]. By using the present flow system, the effect of other ligands such as pyridine, 2,2′-bipyrine (bpy) and 1,10-phenanthroline (phen) on the catalyzed reaction were examined in the presence of ammonia; these ligands enhanced the catalytic activity of copper(II). However, bpy and phen acted as activators for iron(III) which interfered with the copper(II) determination. Thus, pyridine was chosen as an activator for the copper(II)-catalyzed reaction. Fig. 2 and Fig. 3 show the effect of pyridine and ammonia concentrations on the uncatalyzed and catalyzed reactions. The peak heights increased with increasing the concentrations of these ligands. The concentrations of pyridine and ammonia were fixed at 0.2 and 0.5 mol l^{-1}, respectively.

As descried previously [22], the presence of a surfactant at concentrations above the critical micelle concentration (CMC) accelerated the catalyzed reaction and stabilized the dye produced. In

addition, the surfactant suppressed the adsorption of the dye on the inner surface of Teflon tubing. It led to higher sensitivity and sampling frequency. Cationic and non-ionic surfactants were examined since sodium dodecylsulphate (SDS) was observed to precipitate from the reaction system. The tested surfactants were tetradecyltrimethylammonium bromide (TTAB), tetradecyldimethylbenzylammonium chloride (zephiramine, TDBAC), hexadecyltrimethylammonium bromide (HTAB), hexadecylpyridinium chloride (HPC), polyoxyethylene(23) dodecanol (Brij-35), polyoxyethylene(9.5)p-1,1,3,3,-tetramethylbutylephenol (Triton X-100), polyoxyethylen(20) sorbitane monolaurate (Tween 20) and Tween 80. In the presence of cationic surfactants such as TTAB, TDBAC, HTAB and HPC, peak heights for the catalyzed reaction were almost constant and/or decreased with increasing surfactant concentration. On the other hand, the presence of non-ionic surfactants such as Brij-35, Triton X-100, Tween 20 and 80 at concentrations above the CMC increased peak heights and decreased peak tailing. In the present copper(II)-catalyzed coloration system, 0.5% w/v of Tween 80 was used.

3.2. Effect of reaction variables

The flow manifold and chemical variables were optimimized for the determination of copper(II). The baseline and the peak height increased with longer reaction time, i.e., lower flow rates and longer coil. The baseline was due to the uncatalyzed reaction and the peak height was due to the catalyzed reaction. The higher the height of baseline, the poorer its stability. The flow rate of streams and the reaction coil length were selected as 1.0 ml min^{-1} and 8 m, respectively, for the procedure. The peak height and peak width increased with increasing sample volume. A 215-μl sample solution was injected into the flow-line. As the reaction temperature was elevated, the higher rates of uncatalyzed and catalyzed reactions were observed. Considering sensitivity and baseline stability, the reaction coil was kept at 55°C.

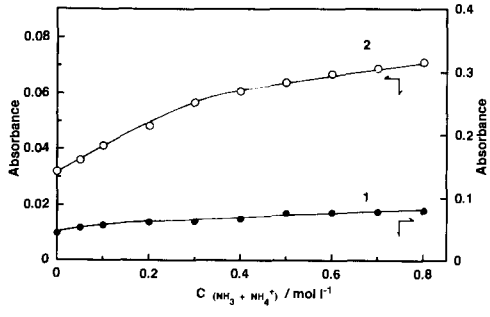

Fig. 3. Effect of total ammonia concentration on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1 except for ammomia concentration. $C_{Cu(II)}$, 2.0 ng ml^{-1}.

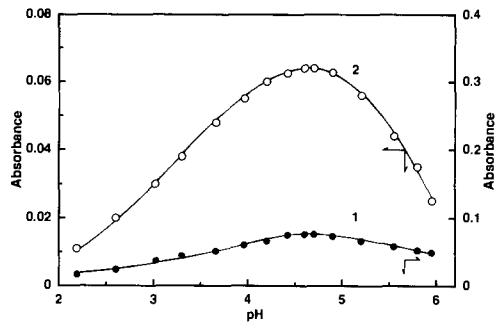

Fig. 4. Effect of pH on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1 except for reaction pH. $C_{Cu(II)}$, 2.0 ng ml^{-1}.

Fig. 4 shows the effect of pH on the copper(II)-catalyzed reaction over the range 2–6; a maximum peak height is obtained in the pH range 4.6–4.7. The reaction mixture in the coil was adjusted in this pH range. Acetic acid was chosen as a buffer because the acid up to 0.2 mol l^{-1} did not affect the peak heights. The concentration of acetic acid was fixed at 0.1 mol l^{-1} for the procedure.

The effects of PPDA, PDA and hydrogen peroxide concentrations were examined. An increase in the PPDA concentration caused an increase in the rate of uncatalyzed and catalyzed reactions. The concentration of PPDA was selected at 1.0×10^{-3} mol l^{-1} because of baseline stability due to the uncatalyzed reaction. With the increase in the PDA concentration, the rate of the catalyzed reaction increased, but it reached its maximum at concentrations above 2.0×10^{-3} mol l^{-1}. A 3.0×10^{-3} mol l^{-1} of PDA solution was used. As

the hydrogen peroxide concentration increased, the heights of baseline and peak also increased. A 0.5 mol l^{-1} of hydrogen peroxide concentration was selected being considered with the height of baseline.

3.3. Calibration graph

The calibration graphs for copper(II) were prepared by the recommended procedure. The relationship between peak height and copper(II) concentration was linear from 0.1 to 2.0 ng ml^{-1}. The detection limit for a signal to noise ratio of two was 0.05 ng ml^{-1}. The reproducibility was satisfactory; the relative standard deviations for ten determinations of 1.0 and 2.0 ng ml^{-1} of copper(II) were 2.4 and 1.6%, respectively. The sample throughout was about 30 h^{-1}.

3.4. Effect of diverse ions

Iron(III) also catalyzed this indicator reaction described previously [22]. Some complexing agents such as citric acid, diphosphate and malonic acid, which did not act as activators for iron(III), were examined in order to eliminate the interference of the element. Among them, citric acid was found to be the most effective masking agent for iron(III). At citric acid concentrations above 1.0×10^{-3} mol l^{-1}, 100 ng ml^{-1} iron(III) can be effectively masked in the determination of 1.0 ng ml^{-1} copper(II). A concentration of 2.0×10^{-3} mol l^{-1} citric acid was used as a masking agent for iron(III).

Table 1 summarizes the tolerance limits of other diverse ions on the determination of 1.0 ng ml^{-1} copper(II) in the presence of citric acid; an error of 5% are considered. Most of ions examined did not interfere with the copper(II) determination in concentrations up to at least 100-fold excesses. Chromium(VI) at the amount of 100 ng ml^{-1} gave positive interference; it did not interfere at amounts below 10 ng ml^{-1}. The levels of these metal ions normally presented in the natural water samples were tolerable.

3.5. Application

To evaluate the applicability of the proposed flow-injection method, it was applied to the determination of copper in river, lake and seashore water samples. These samples were filtered through a 0.45-μm Millipore filter and then concentrated hydrochloric acid was added to the filtrates (about pH 1). These filtrates were injected into the flow line after appropriate dilution; both calibration curve and standard addition methods were carried out. The results are summarized in Table 2. The values obtained from the calibration curve and the standard addition methods are in good agreement with each other. For the filtrates except for seashore waters, an aliquot of 50 ml was digested with nitric and perchloric acids because some copper species in the samples did not catalyze the indicator reaction [5]. As can be seen in Table 2, the copper contents in the digested samples were larger than those without digestion; reactive and non-reactive copper species in the fresh water samples could be found.

4. Conclusions

A simple and rapid catalytic flow-injection method is proposed for the determination of copper(II) at levels as low as 0.05 ng ml^{-1}, based on

its catalytic effect on the color-forming system of PPDA, PDA and hydrogen peroxide. The presence of pyridine, ammonia and Tween 80 in the reaction system led to higher sensitivity and sampling frequency. The selectivity of the method was improved by adding citric acid. The method was successfully used for the determination of reactive and non-reactive copper species in natural water samples with and without acid digestion. Due to easy operation and inexpensive instrumentation, the present method should be useful for monitoring natural water.

Received 15 April 1996; received in revised form 12 September 1996; accepted 12 September 1996

Abstract

Analysis of the total antimony in plant material was unsuccessful using the electrothermal atomic absorption spectrometry (ETAAS) conditions recommended by the instrument manufacturer. For this reason, an optimisation procedure utilising the Plackett–Burman method, simplex optimisation and visualisation of the generated response surface via principal components analysis, was carried out. The Plackett–Burman method was used to eliminate four of the initial variables chosen. Four variables (atomisation temperature, atomisation time, ash temperature and modifier concentration) were subsequently optimised using the composite modified simplex method and the results were visualised as a contour diagram, after reduction to two principal components. The optimised conditions were used for the analysis of both an acid digested pine needle standard reference material (NIST 1575) and a pond weed sample, collected from a contaminated site at Yellowknife Bay, Yellowknife, NWT, Canada. The total concentration of antimony present in the pine needles was statistically indistinguishable from the non-certified value, as was the value for the pond weed sample, compared with a value determined by neutron activation analysis (NAA). The results for the analysis of the pond weed sample by ETAAS agreed with those obtained from a subsequent analysis by inductively coupled plasma-mass spectrometry. © 1997 Elsevier Science B.V.

1. Introduction

Antimony has been found in biological, geological and water samples [1–4], and its toxicity has led the United States Environmental Protection Agency (US-EPA) to consider it and its compounds priority pollutants [5]. Common techniques for determining the total amount of antimony include: inductively coupled plasma mass spectrometry (ICP-MS) or atomic emission spectroscopy (ICP-AES) and hydride generation, followed by different atomisation methods such as electrothermal or flame heated quartz tube atomic

absorption spectroscopy (HG-QT-AAS) [1–3]. The preconcentration of antimony hydride in a graphite furnace, followed by atomisation has recently been developed as another method of analysis [6,7].

All these methods give low detection limits, but ICP based methods are expensive for routine analysis. Hydride generation may not give 100% recovery when non-hydride forming species are present in the sample and is labour intensive. Electrothermal atomic absorption spectroscopy (ETAAS) is a widely used analytical tool for the determination of many trace metals, including antimony, in a wide variety of sample matrices [8–11]. The use of ETAAS for the determination of total antimony is cost effective and simple, but no formal optimisation of conditions has been reported for plant samples.

The very first studies [12] on the graphite furnace technique showed that the sample matrix has a pronounced effect on the absorbance signal observed for a particular element. These effects often lead to systematic errors when determining metals in complex organic matrices and result from substances not being fully volatilised prior to atomisation of the metal. Optimisation of instrumental conditions is therefore a prerequisite for development of an environmental analytical protocol using electrothermal AAS.

Until recently it was usual to optimise a system using a one-factor-at-a-time-approach, in which each variable but one is held at a low level and

the response is evaluated at the lower and the upper level of the factor being tested. Each variable is treated in turn, until the response is maximised or minimised, depending on the system. This approach is far from adequate because there is no guarantee that an optimum response will be found, it requires a large number of experiments to be carried out and the presence of inter-relationships between the variables (e.g., modifier concentration and ash temperature) means that the optimum obtained will depend on the initial conditions chosen. Factorial experiments, in which all the factors are varied simultaneously according to a pre-set design, have also been used to optimise analytical systems. However, this approach is highly dependent on the levels of each factor and thus, it works best when some prior knowledge of the system is available. It also requires a large amount of experimentation when more than three variables are investigated.

Simplex optimisation is a highly efficient, multifactor, empirical feedback, optimisation procedure, that does not require the large number of experiments nor the initial variable information that is necessary with the two methods outlined above. This procedure 'homes in' on the optimum response region by driving the experiments in the direction of steepest ascent of the response surface. The optimum thus obtained is generally a local optimum, but some assurance that it is the overall optimum can be obtained by repeating the search from different starting conditions to see if the same conditions are reached.

Simplex optimisation is now routinely used as a method of maximising a response [13,14] or reducing interferences [15,16] in the analysis of trace elements. In the present work the use of the instrument manufacturer's recommended operating conditions [17] for the determination of antimony by ETAAS were completely unsuccessful, yielding no absorbance maximum. These conditions were: dry at 75°C for 5 s, then at 90°C for 60 s, then at 120°C for 10 s, hold at 120°C for 2 s, ramp to 2000°C in 1 s (maximum ramp rate), atomise at 2000°C for 3 s, clean at 2000°C for 1 s.

A two stage approach was used to optimise the experimental conditions used for the determination of antimony in plant material. The first part

Table 3
Range and stepsize of the variables being optimised by the composite modified simplex method

Variable	Lower limit	Upper limit	Stepsize[a]
Atomisation temperature (°C)	1400	2700	100
Atomisation time (s)	0	4	1
Ash temperature (°C)	800	1600	50
Modifier concentration (mg l^{-1})[b]	100	900	100

of the investigation involved the use of the Plackett–Burman method to screen a number of potential variables to select the most appropriate to optimise using the composite modified simplex method [18,19]. The principle advantages of this approach are that information concerning the significance of each variable is obtained (Plackett–Burman method) and the optimum conditions are efficiently reached, with less experimentation than would be necessary if none of the variables had been eliminated. Additionally, visualising the response surface eliminates the need for univariate searches around the optimum, which are often carried out to check that the optimum is correct. These goals are not possible using a one-step-at-a-time-approach, or a factorial experiment.

To check the accuracy of the developed methodology the concentration of antimony in a pine needle standard reference material (SRM), NIST 1575, was determined. The pond weed sample was acid digested and methanol extracted and these samples were statistically compared with results obtained by ICP-MS, as well as by neutron activation analysis (NAA).

2. Experimental

2.1. Reagents

Concentrated nitric and hydrochloric acids (both double sub-boiling distilled, Seastar Chemicals Inc., Sidney, BC), concentrated sulphuric acid (Analytical grade, BDH Chemicals, Toronto, ON), and glacial acetic acid (Reagent grade, Fisher Scientific, Nepean, ON). Hydrogen peroxide (30%) (Assurance grade, BDH Chemicals, Toronto, ON), D-tartaric acid (Reagent grade, Allied Chemical Canada Ltd., Canada), palladium nitrate ($Pd(NO_3)_2.2H_2O$, Reagent grade, Sigma Chemical, St. Louis, MO), citric acid (Certified, Fisher Scientific, Fairlawn, NJ).

Water was purified to a final resistivity of better than 1 M ohm (Barnstead Mega-Pure system, Barnstead/Thermolyne, Dubuque, IA). Methanol (HPLC grade, Fisher Scientific, Nepean, ON). A methanol/water (1/1 v/v) solvent mixture was used to extract the aqueous antimony species. Antimony metal (Certified, Fisher Scientific, Fair Lawn, NJ) and 1000 mg l^{-1} indium (Spectroscopy standard, High-Purity Standards, Charleston, SC).

The freeze dried pine needle standard reference material 1575, was obtained from the National Institute of Standards and Technology (NIST, Washington, DC). The pond weed sample (*Potomogetan pectinatus*) was collected from a site contaminated with mine tailings (Yellowknife Bay, NWT, Canada) as described previously [20] and freeze dried. The pine needle SRM (NIST 1575) was chosen as a representative standard reference material because it contains an uncertified antimony concentration of 0.2 mg kg^{-1}.

2.2. Preparation of samples and standards

The pine needles (1575), and pond weed were dried to constant weight and then acid digested. Acid digestions were carried out in duplicate by adding 3 ml of concentrated nitric acid, 3 ml of 30% hydrogen peroxide, and 1 ml of concentrated sulphuric acid to a 250 ml round bottom flask containing pine needles (0.5 g) or pond weed (0.25–0.40 g) and refluxed for 3 h as described

elsewhere [21]. An additional pine needle digestion was carried out by heating 1 g of material with the above acid/hydrogen peroxide mixture, in a vial on a hot plate, at 90°C for 3 h. After the digestions were complete, the partially evaporated samples were diluted to 5 ml (pine needles) and 10 ml (pond weed) using deionised water.

Extraction of the pondweed was carried out by sonicating 0.5 g dry material with 10 ml methanol/water (1/1 v/v) for two samples, and 10 ml 0.2 M acetic acid for one sample. The sample and solvent were sonicated for 20 min, the mixture was centrifuged at 3000 rpm for 10 min. and the supernatant was decanted. This was repeated five times and the combined extracts were evaporated under reduced pressure to dryness and made up to 5 ml with water.

A stock solution of 1000 mg l^{-1} antimony solution was prepared by dissolving 0.1000 g antimony metal in aqua regia and diluting to 100 ml with 1% D-tartaric acid. The 50 and 25 μg l^{-1} solutions for use in the standard additions determinations were prepared fresh daily from the stock.

The palladium modifier solution was prepared by dissolving 0.1083 g palladium(II) nitrate dihy-

drate in 0.5 ml of concentrated nitric acid and diluting to 100 ml with 2% citric acid solution to give a 1000 mg l^{-1} Pd solution. This stock solution was then diluted further with 2% citric acid solution to give the various concentrations needed for the experiments.

Indium solution was used as an internal standard in the ICP-MS determinations and was prepared by diluting an appropriate volume of a 200 μg l^{-1} standard solution so that the final concentration was 10 μg l^{-1} in each sample.

2.3. Instrumentation

An atomic absorption spectrometer (Varian Techtron Model 1275, Australia) fitted with an auto-sampler, graphite furnace and programmer (GTA-95) was used throughout this work. The antimony hollow cathode lamp (SpectrAA, Varian, Australia) was operated at 10 mA with a slit corresponding to a spectral bandwidth of 0.2 nm and the 217.9 nm line was monitored. Continuous background correction was by a deuterium lamp (Varian, Australia). Pyrolytically coated graphite tubes (Varian, Germany) were used.

The ICP-MS measurements were carried out using a VG PlasmaQuad 2 turbo plus instrument (VG Elemental, Fisons Scientific Equipment, Winsford, Cheshire, UK), operated at 1350 W RF power. Cooling, auxiliary and nebulizer gases (Ar) were at flow rates of 13.82, 0.69 and 1.00 l min^{-1}, respectively. Masses were monitored in the peak jumping mode by using m/z 115 (In) and 121 (Sb).

A real sample (pond weed digest diluted four times with deionised water) was used for the optimisation procedure outlined below. This sample was chosen, rather than an antimony standard, so that matrix and species dependent effects could be minimised and the antimony signal maximised.

The OPTIMA3 computer program [18,19] was used for the simplex calculations and the generation of experimental conditions. The principal components analysis was carried out by using Systat® 5.03 for windows (SYSTAT, Inc.). Both of these programs were run under Windows® 3.1, on a DELL 466/M personal computer.

NAA was carried out as described elsewhere [20,22].

2.4. Plackett–Burman experiments

The initial variables chosen to be screened using the Plackett–Burman method were: dry time (Dt), dry temperature (DT), ash time (At), ash temperature (AT), atomisation ramp (AtR), atomisation time (Att), atomisation temperature (AtT) and modifier concentration (MC). This allowed for the use of three dummy variables and so had 3 df (see Table 1). Initial experiments carried out using longer ash and atomisation times (up to 15 and 7 s, respectively) resulted in a short graphite tube lifetime (60 firings), thus limits for these variables were chosen to minimise tube deterioration. The limits for all the variables were chosen so as to show a change in measured absorbance, which was the response measured, rather than to reflect conditions usually used for ETAAS.

After the first design was carried out, three variables (atomisation ramp, atomisation time and modifier concentration) were kept constant, whilst the effect of the other five variables were investigated using a $n = 8$ design (two dummy variables, 2 df) (see Table 2). The matrix designs, adapted from the method of Jones et al. [23], accompany the designations of variables in Table 1 and Table 2.

2.5. Simplex optimisation

The composite modified simplex (CMS) optimisation method described previously [18,19] was employed during this work. Having screened out the variables that did not have a significant effect on the response, the remaining four factors (atomisation temperature, atomisation time, ash temperature and modifier concentration) were optimised to provide the maximum antimony absorbance signal from a pond weed digestate. The upper and lower limits used in the CMS procedure as well as the stepsize for each variable are given in Table 3.

Five initial experiments were conducted and the conditions for each factor, as well as the resulting absorbance, were entered into the OPTIMA3 computer program. The next set of experimental conditions were generated and carried out, and the response was entered. The simplex progressed via a series of reflections, expansions, contractions or fit points, towards the optimum absorbance (see Table 4). The process was continued until the S.D. of the five highest responses was less than the value of the stepsize of the absorbance (0.010), three times sequentially. To prove that the optimum values determined were not due to a local region of maximum response, the procedure was repeated with different starting conditions; the same optimum conditions were found.

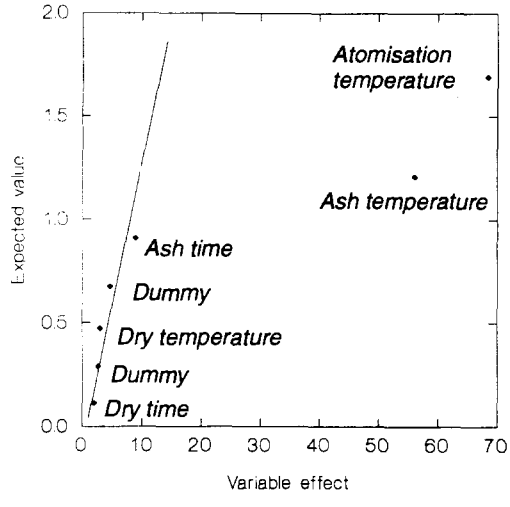

Fig. 1. Birnbaun plot for the second Plackett–Burman, showing the significance of the two variables atomisation temperature and ash temperature.

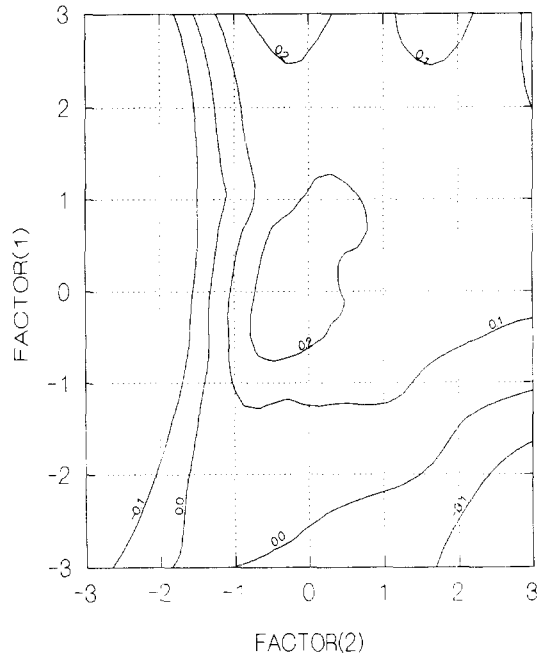

Fig. 2. Contour diagram showing the response surface for the first optimisation.

2.6. Visualisation of the response surface

The experimental results were analysed by using principal components analysis, as described in detail and with examples by Molinero [24]. Briefly, principle components analysis was used to reduce the four variables from the simplex optimisation to two new variables (principle components 1 and 2). The scores of these principle components give coordinates for all the experimental vertices. Thus, the vertices of the simplex previously represented by n variables, are now represented by two variables, and the responses are plotted against these variables, to generate the response surface. The relative significance of the effects of the original variables on the reponses can be evaluated by considering the loading of each variable on each principle component, which indicates to what degree each principle component is influenced by each of the original vari-

Table 6
The optimised furnace program, used for quantitation of antimony in plant samples (400 mg l^{-1} or 4 μg Pd as modifier was used)

Step no.	Temperature (°C)	Duration (s)	Gas flow (l min^{-1} Ar)	Function
1	90	30	3	Dry/ramp
2	120	10	3	Dry/ramp
3	1350	1.9	3	Ash/ramp
4	1350	2	3	Ash/hold

7	2200	3	3	Clean

[a] 2000°C s^{-1} ramp from 1350 to 2200°C, integration during this step.

ables. This approach provides visual information on the optimum and the response surface, which is not possible with the simplex search alone. The response surface can be studied to determine more information such as the presence or absence of ridge features or local maxima. It also helps to show other factor levels that could provide better experimental conditions in terms of lower temperature operating conditions, or less modifier, thus resulting in a more cost effective procedure.

3. Results and discussion

3.1. Plackett–Burman experiments

The results for the first Plackett–Burman experiment were used to obtain a minimum t value of 3.18 for a 95% confidence interval. Only the atomisation time and modifier concentration give t values above this and so are the only significant variables at this confidence level (Table 5). Birnbaun plots can be used to confirm or help clarify results obtained from such experiments, as explained in more detail elsewhere [23]. Briefly, deviance of points from a straight line indicate large variable effects [14]. In this instance, the Birnbaun plot (not shown) gives essentially a straight line and therefore does not help with the further interpretation of this experiment.

The second Plackett–Burman experiment was carried out by holding three factors constant and hence utilised five of the original variables and two dummies (2 df). The atomisation time and modifier concentration shown to be important by the first experiment were held constant at 0 s and 500 mg l^{-1}, respectively, in the hopes that any other significant variables might be revealed. The ramp rate was observed in these and preliminary experiments to give maximum results at higher speeds, as noted by Pergantis et al. [11] in their optimisation for arsenic. Instrumental constraints limited the ramp to 2000°C s^{-1} and this value was used for all subsequent experiments.

The results for the second experiment produced a minimum t value at the 95% confidence interval of 4.3 and the t values for the two variables, ash and atomisation temperature were greater, indicating that these variables have a significant effect on the antimony response. The Birnbaun plot in Fig. 1 shows that the ash and atomisation temperatures deviate from a straight line because of large variable effects, which confirms the significance of these variables.

[e] Four analytical replicates.
[f] No replication.

Four variables: atomisation time, atomisation temperature, ash temperature and modifier concentration, were subsequently optimised by using the composite modified simplex procedure (CMS).

3.2. Simplex optimisation

A total of 29 experiments were carried out and the maximum response was reached after 23 experiments (see Table 4). The optimum parameters were found to be: atomisation temperature, 2200°C; atomisation time, 0 s; ash temperature, 1350°C; and modifier concentration, 400 mg l^{-1}. The simplex analysis was repeated from different initial conditions and the maximum response was: atomisation temperature, 2200°C; atomisation time, 0 s; ash temperature, 1450°C; and modifier concentration, 400 mg l^{-1}. These conditions were reached after 22 experiments from a total of 27. The conditions from the first optimisation are considered to be better for routine use, because the lower ash temperature is less destructive to the graphite cuvette.

The response surfaces generated from both searches are not identical, but the characteristic ridge feature of high absorbance is present in both (see Fig. 2 for the response surface generated from the first simplex). The results for the principle components analysis (PCA) indicate that the first and second principle components (PC) retain 43.8 and 31.5%, respectively of the original variance of the data. This is similar to values reported in previous work [24]. The results also demonstrate that the atomisation temperature and modifier concentration have the greatest influence on the first PC, whereas ash temperature has the greatest influence on the second PC. Generation of the response surface also eliminates the need to carry out univariate searches around the optimum to establish that it is correct.

Therefore, after carrying out the simplex optimisation twice, from two different starting conditions and then analysing each response surface using principle components analysis, it was felt that further univariate investigates of the optimum were unnecessary.

3.3. Analysis of samples by using the optimised temperature program

The optimised procedure (Table 6) was used to determine the antimony concentration in pine needle SRM and pond weed, by using ETAAS and the method of standard additions. The results obtained for analysis of the pine needles are shown in Table 7, along with a comparison to the reference value. The concentrations for pine needles, with an average observed concentration of 0.220 mg kg^{-1}, do not differ significantly from the non-certified concentration of 0.2 mg kg^{-1}.

The pond weed sample is from a contaminated site near a gold mine in the Northwest Territories, Canada. The concentration of antimony in this sample was determined by ICP-MS to verify the

values obtained by ETAAS and the results are given in Table 8. The results for the two methods do not differ significantly, as shown by the statistical comparison. The concentration of antimony for each digestion does not differ significantly (95% level) from the value determined by neutron activation analysis of 41.2 mg kg^{-1}.

The aqueous phase soluble antimony species were extracted from the pond weed sample with 1/1 methanol/water (V/V), so that further analysis by speciation techniques such as HPLC-ICP-MS or HG-GC-MS [24] can be carried out. However, prior to this it is important to establish the total antimony concentration, both hydride and non-hydride forming, present in the extract. Although the values obtained for the methanol/water extracts after analysis by ETAAS and ICP-MS do not differ statistically, consistently lower values for the ICP-MS results were observed. This is probably due to matrix or solvent effects, as the ETAAS analyses were carried out by using the method of standard additions, whereas the ICP-MS analyses were carried out using external calibration with aqueous standards.

By the analysis of the SRM and the methanol/water extract the optimised ETAAS procedure for the determination of antimony has been shown to overcome any interferences due to the sample matrix and any differences due to the different antimony species present. In addition, the method can be used for any total antimony determinations in samples of plant origin.

Acknowledgements

The authors would like to thank Dr M. Dodd for provision of the pond weed samples and NAA results, Mr B. Mueller for help with ICP-MS analysis, Ms M. Winters for assistance with sample preparation and Dr A. Wade for comments on the manuscript. We would like to acknowledge Dr K.J. Reimer, Environmental Sciences Group, Kingston, Ontario and the Natural Sciences and Engineering Research Council of Canada for financial assistance.

Europium complexation by an aquatic fulvic acid - effects of competing ions

Maria Nordén, James H. Ephraim, Bert Allard

Department of Water and Environmental Studies, Linköping University, S-581 83 Linköping, Sweden

Received 15 December 1995; received in revised form 10 September 1996; accepted 16 September 1996

Abstract

Effects of competing ions, Fe^{2+}/Fe^{3+} and Al^{3+}, on Eu^{3+} complexation with an aquatic fulvic acid (FA), have been investigated using an ion exchange technique. The influence of different concentrations (10^{-6}, 10^{-4} M) of the competing ions on the distribution coefficient for Eu was measured, and the overall complex formation function, β_{ov}, was resolved for the Eu systems with Fe and Al. All systems showed pH-dependent β_{ov}-functions. The presence of 10^{-4} M concentration of competing ion reduced the resolved complex formation function ($\log \beta_{ov}$) for Eu complexation with fulvic acid by 0.6 and 0.4 log units at pH 5 for Fe and Al, respectively. This indicates that Fe has a more perturbing effect on Eu–FA complexation than Al. In similar competition studies Sr and Eu were found not to perturb each others complexation with fulvic acid, suggesting therefore that the two metals probably bind to different sites on the fulvic acid molecule. © 1997 Elsevier Science B.V.

Keywords: Competing ions; Europium; Fulvic acid; Ion exchange technique

1. Introduction

Humic substances are ubiquitous in natural waters and have significant effects on metal speciation and mobility in aquatic environments [1]. The metal complexes formed with humic substances are influenced by pH, ionic strength, concentrations of metal and humic matter and presence of competing ions. Few studies that investigate the effects of competing metals have been carried out [2–5]. The influence of Ca^{2+} [2–4], Mg^{2+} [2,3] and Cd^{2+} [5] on Cu^{2+} binding by naturally occurring dissolved organic matter are some of the few investigations where competition effects are considered. Usually in these studies only minor effects are observed. In a more recent work Al^{3+} was found to compete with Cu^{2+} for binding sites in a fulvic acid [6].

The overall objective of this study has been to quantify the perturbing effects of Fe, Al and Sr on the Eu-FA complexation. Europium was chosen as a model element for trivalent radionuclides that might be released into the environment from, e.g. radioactive waste in geologic deposits [7]. Aluminium and Fe are common metals in the environment, and therefore likely competitors. Aluminium can be found in fresh waters in the concentration range of 10^{-6}–10^{-4} M and Fe in the concentration range of 10^{-7}–10^{-4} M [1]. Strontium is present in radioactive waste and its

PII S0039-9140(96)02102-9

competition with Eu is therefore of interest. The conditions of the experiments (e.g. FA concentration, ionic strength) were chosen to resemble the experimental conditions in an earlier paper [8] in order to facilitate a meaningful comparison (Table 1). It has not been the goal to determine the selectivity coefficients for Eu, Al and Fe over the ion-exchange resin.

2. Experimental

2.1. Materials

A well-characterised aquatic fulvic acid (FA), extracted from the surface water of a bog area (Bersbo, Sweden), was used in all experiments. The potentiometric properties of the FA molecule have previously been described by assuming five predominant acid sites [9]. The Fe and Al content of the Bersbo FA was 0.18 and 1.87 mg g^{-1}, respectively (by Atomic Absorption Spectrophotometry). Other characteristics of the Bersbo FA are given elsewhere [8,9].

Radionuclides (^{152}Eu and ^{85}Sr; from Amersham) and analytical grade chemicals with Milli-Q water were used for all solutions. The non-radioactive Eu and Sr were prepared from Eu_2O_3 and $Sr(NO_3)_2$ (Merck), respectively, and the Al and Fe mixtures from $AlC_3 \times 6H_2O$ and $FeCl_2 \times 4H_2O$. The sodium form of a Dowex 50WX8 (mesh 50–100) cation exchange resin was used as adsorbent (see below). A radiometer pHM 82 standard pH-meter (precision ± 0.02 pH units) and a pH-combination glass electrode, GK 2401C, were employed for pH determinations. Calibration was carried out with two buffer solutions and the pH values are given as concentrations. Radioactivity measurements were made using a LKB (Wallac) 1282 Compugamma counter.

2.2. Procedures

The ion exchange distribution experiments were carried out batch-wise by a radiotracer technique (^{152}Eu and ^{85}Sr). The additional competing ions (Fe, Al, Eu or Sr) were non-active (no radiotracer), and the activities in the solutions with and without competing ions were compared. The ion exchange procedure for studies of metal complexation with humic substances, and the mode of computation of the overall complex formation function, β_{ov}, from the distribution coefficient, D, have been outlined in a previous work [8].

Constant ionic strength (0.10 M $NaClO_4$), constant total concentration of FA (120 mg l^{-1}, corresponding to a total acid capacity of 5.6×10^{-4} eq l^{-1} and 6.9×10^{-5} M with $M_n = 1750$) and constant concentrations of the complexed elements Eu and Sr were selected. The competing elements (Fe, Al, Eu or Sr) were added without absolute exclusion of air, and therefore some of the Fe would be oxidised to the trivalent state in the absence of FA and consequently Fe(III) hydrolysis products will form with increasing pH. Since FA is known to reduce Fe(III) to Fe(II) it is expected that the Fe(II) will be maintained in the divalent state in the FA systems, even in the presence of air [10–14]. The metal and metal-FA solutions were pH adjusted with $HClO_4$ or NaOH and left to equilibrate for 20 ± 3 h prior to addition to the ion exchange resin. This mode of pH adjustment is different from the one used in an earlier paper [8], where the pH was adjusted after aliquots of bulk solutions had been added to the resin. The pH adjustment was altered to accomplish an equilibrium between metal ions and ligands before the ion exchange reaction with the resin. The pH values that were determined after the equilibrium with the resin were used in calculations of log D and log β_{ov}. Samples of 5 ml were

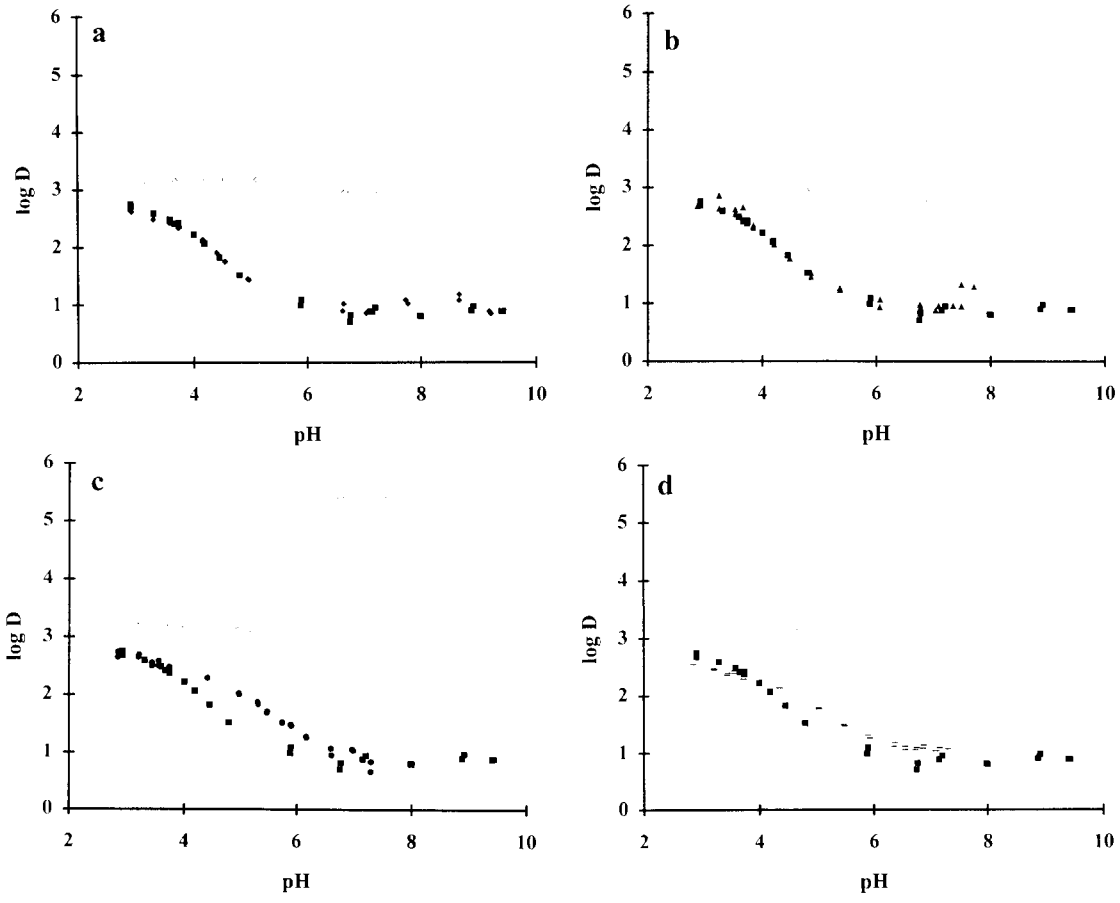

Fig. 1. The effect of different Fe and Al concentrations on the distributions of Eu over a cation exchange resin in the absence and presence of FA. □ Eu; ■, Eu + FA; (a) Fe(10^{-6} M), ◇ Eu; ◆ Eu + FA; (b) Al(10^{-6} M), △ Eu; ▲ Eu + FA, (c) Fe(10^{-4} M), ○ Eu; ● Eu + FA; and (d) Al(10^{-4} M), + Eu; − Eu + FA.

transferred from each container to three tubes (duplicate samples and one control with no resin). The tubes were equilibrated for 20 ± 3 h on a shaking-table (~ 110 rpm) at ambient temperature (20 ± 1°C). After equilibrium, the pH of each metal-resin mixture was determined. The mixture was centrifuged for about 10 min at 2000 rpm (~ 350 g), and 1 ml of the clear solution was withdrawn for radioactivity measurement. Duplicate samples were taken. The experimental systems are summarised in Table 1.

3. Results and discussion

The distribution of Eu over the ion exchange resin is illustrated in Fig. 1. Data from the Eu and Eu + FA series (without competing ions) are given in all diagrams for comparison. The distribution coefficient, D, was independent of pH in the pH-range 3–9 for Eu in the absence of FA. This observation differs form an earlier observation where log D decreased with an increase in pH [8]. The discrepancy in the results is attributable to the difference in the method of pH adjustment.

In the Eu + FA series the distribution coefficient decreased from 2.8 log units in the pH range 3–6 to a constant value of 0.8 log units at pH > 6.

3.1. The effects of Fe on the Eu distribution

The effects of Fe at 10^{-6} and 10^{-4} M, respectively, are shown in Fig. 1a and c. In the presence of 10^{-6} M Fe the distribution coefficient of Eu was the same as in the absence of Fe in the pH range of 3 to 5.5. However, at pH > 5.5 the decrease in log D (0.1 to 0.4 log units) was increasing with an increase in pH (Fig. 1a); i.e. more Eu stayed in solution in presence of 10^{-6} M Fe at pH > 5.5. The Fe would be present predominantly in the trivalent state, and the decrease may be caused by the formation of colloidal $Fe(OH)_3$ that can adsorb Eu and keep it in solution. Studies of Eu adsorption on colloidal $Fe(OH)_3$ have previously shown a pronounced Eu adsorption at pH > 5 [15]. The present centrifugation procedure to separate the ion exchange resin from the solution would not be sufficient to completely separate colloids from the true solution [15].

For the higher Fe concentration (10^{-4} M) the distribution coefficient was increasing at pH > 5–6 (Fig. 1c). This increase reached a maximum of 2.2 log units at a pH around 7. This would be due to aggregation of colloids and the formation of solid $Fe(OH)_3$ which together with the resin can serve as the adsorbing surface for Eu. Additionally, the increase in log D at higher pH could be attributable to the interaction of the solid $Fe(OH)_3$ with the ion exchange resin to produce a new surface with a higher affinity for Eu. Calculations of the amount of solid $Fe(OH)_3$ at the two total concentrations (10^{-6} and 10^{-4} M Fe) indicate that at the low concentration the solid phase would be only approximately 0.01% (pH-range 5–9) of the weight of the ion exchange resin, while at the higher concentration the corresponding value would be 1.0% for the same pH range (assuming $K_{sp} = 4 \times 10^{-38}$) [16].

3.2. The effects of Al on the Eu distribution

Aluminium seemed to influence the adsorption of Eu on the resin in a similar way as Fe (Figs, 1b and d). In absence of FA 10^{-6} M Al decreased log D of Eu by 0.3 log units in the pH interval 3 to 9. At the higher Al concentration (10^{-4} M) a sharp increase in the distribution coefficient was obtained at pH > 6 (Fig. 1d), with a maximum of 2.1 log units at a pH around 7.5. The effect was similar to that of Fe(10^{-4} M). A plausible explanation to the increase can be the formation of solid $Al(OH)_3$ (similar to the formation of $Fe(OH)_3$) that can act as an adsorbent for the Eu. Calculations indicate that the formation of solid $Al(OH)_3$ at the low Al concentration would be up to 0.007% (pH-range 5.5–9) of the weight of the ion exchange resin. For the higher concentration in the same pH range the formation of $Al(OH)_3$ would be 0.7% of the resin weight (assuming $K_{sp} = 2 \times 10^{-32}$) [16].

3.3. The effects of competing metals on Eu-FA and Sr-FA complexation

No difference in distribution coefficient was discernible for the Eu-FA system in the presence of 10^{-6} M Fe (Fig. 1a). This could imply that 10^{-6} M Fe does not affect the complexation of Eu with FA. However, it could also imply that since there is excess of FA both Fe and Eu can be complexed without effecting each other. At the higher concentration of Fe (10^{-4} M) there was a slight increase in log D (0.1 to 0.6 log units) between pH 4 and 7 which may be explained by the competition of Fe for the FA binding sites (Fig. 1c).

In the presence of FA at the lower Al concentration (10^{-6} M) no influence was discernible (Fig. 1b), just as for Fe at the same concentration. With FA and 10^{-4} M Al in the system there was a slight increase in log D (0.1 to 0.4 log units) in the pH range 4–7 (Fig. 1d).

In another competition study the influence of Sr on the Eu-FA complex, but also the influence of Eu on the Sr-FA complex, were investigated (Fig. 2). In one set of experiments inactive Sr^{2+} was added to active Eu^{3+} plus FA solution, in a typical ion exchange experiment as described earlier [8]. In the other set inactive Eu^{3+} was added to active Sr^{2+} plus FA solution, in a similar ion exchange distribution experiment. In the case of

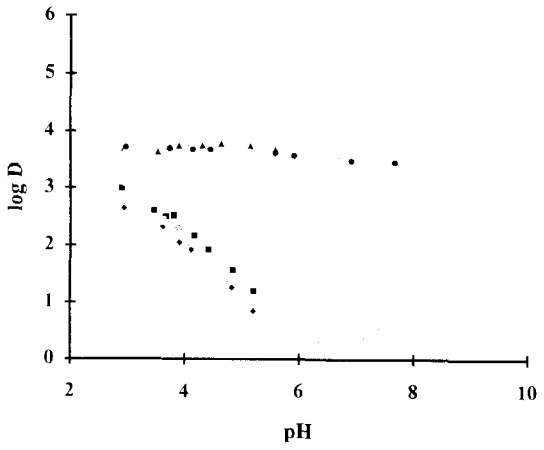

Fig. 2. The effect of different Sr concentrations on the distribution of Eu and the effect of different Eu concentrations on the distribution of Sr, over a cation exchange resin in the presence of FA. ◇ Eu + FA; ◆ Eu + Sr(10^{-8} M) + FA; □ Eu + Sr(10^{-6} M) + FA; ■ Eu + Sr(10^{-4} M) + FA; ○Sr + FA, ● Sr + Eu(10^{-8} M) + FA; △ Sr + Eu(10^{-6} M) + FA; ▲ Sr + Eu(10^{-4} M) + FA.

Eu-FA complexation Sr affected the observed log D of Eu only when its concentration was increased to 10^{-4} M, suggesting that competition was only significant at that concentration level. When Eu acted as the competing ion no effects of increasing concentration were noticed for the distribution of Sr on the ion exchange resin. This indicates that neither Eu nor Sr influences the others complexation with FA.

The relationship between the overall complex formation function, β_{ov}, and pH, calculated from distribution data are summarised in Table 2. Iron

Table 3
Comparison of formation constants for iron, aluminium and europium fulvic acid complexes

at 10^{-4} M disturbs the Eu-FA binding more than Al at the same concentration in the pH interval 4 to 6, e.g. log $\beta_{ov} = 4.60$ for Fe and 4.86 for Al, as compared with the original value of 5.22. At a concentration of 10^{-6} M both Fe and Al seem to disturb the Eu-FA binding to an equally low degree, log $\beta_{ov} = 5.03$ and 5.04 for Fe and Al, respectively.

It is difficult to make a meaningful comparison of the stability constants of Fe, Al and Eu complexes with fulvic acids because of a number of

Table 2
The overall complex formation function, β_{ov}, for five Eu + FA systems described by polynomials (120 mg l^{-1} FA, I = 0.10 M $NaClO_4$ M)

System	pH	r	n	log β_{ov} (pH)[b]	log β^{c}_{ov} (pH = 5)

factors, e.g. pH, ionic strength, method, mode of computation and the origin of the FA. However, in Table 3 an attempt is made to compare literature values for Fe^{2+} and Al^{3+} fulvic acid complexes with the Eu-FA complexation data. The conditional stability constants for the Eu-FA complex are in general apparently greater than the constants for the Fe^{2+} and Al^{3+} complexes.

The conditional stability constant for Fe^{2+} yields a mean value of 5.5 in the pH interval 3.5–6.0, which is considerably lower than most values for Eu-FA in the same pH interval (Table 3). However, the concentration of Fe (10^{-4} M) in the present study is much greater than for Eu (5×10^{-9} M) which can explain the observed competition from Fe.

4. Conclusions

The experimental results from this work corroborate the observation that an increased pH augments the complexation between FA and Eu, but that the Sr complexation is insensitive to pH (in the pH range 3–8) [8].

Iron and Al exhibited some influence on the Eu-FA complexation. However, the effect was minor at 10^{-6} M. The concentration 10^{-4} M gave a clear effect (e.g. reduction of log β_{ov} by 0.6 and 0.4 log units at pH 5 for Fe and Al, respectively). Known formation constants for FA with Fe^{2+}, Al^{3+} and Eu^{3+} suggests that Eu^{3+} forms stronger complexes with FA than Fe^{2+} and Al^{3+}. This may explain why as much as 10^{-4} M of the competing ions is needed to affect a clear disturbance of the Eu-FA complex. Another feasible conclusion for the high concentration of competing ions required is that Eu and, Fe and Al, do not necessarily complex to the same site on the FA molecule. Since Sr did not influence the Eu-FA complex, nor did Eu influence the Sr-FA complex, it is also postulated that Sr and Eu probably bind to different sites on the FA molecule. However, these conclusions need to be supported by further experiments, e.g. investigation of the effect of different FA concentrations. Such exercises are in progress.

Acknowledgements

This work was supported by the Swedish Nuclear Fuel and Waste Management Company and the Swedish Natural Science Research Council. The assistance by Mr Anders Düker in performing the metal analysis of the fulvic acid is gratefully acknowledged.

Complexometric determination of some toxic mixtures of ions using bromo-cresol orange with visual endpoint indication

Medhat A.H. Hafez *, Magdi E. Khalifa

Chemistry Department, Faculty of Science, Mansoura University, El-Mansoura, Egypt

Received 10 April 1996; received in revised form 22 August 1996; accepted 17 September 1996

Abstract

A rapid and simple general complexometric method was presented for the determination of lead, cadmium and thallium or mercury or arsenic(V) in laboratory synthesized mixtures similar to those of some ores, minerals and alloys of such metals. The precision and accuracy attainable in successive titrations of Pb^{2+}, Cd^{2+} and Tl^{3+} or Hg^{2+} or AsO_4^{3-} (As^{5+}) with 0.05 and/or 0.01 mol l^{-1} solutions of disodium ethylenediaminetetraacetate (Na_2EDTA) and standard $Pb(NO_3)_2$ of the same concentration using Bromo-Cresol Orange (BCO) as a new metallochromic indicator with visual endpoint indication were studied. For the analysis of a three component mixtures of the aforementioned ions, Tl^{3+} was at first directly titrated with Na_2EDTA at pH 0.5–1 (HNO_3) using BCO as indicator. At the thallium endpoint an excess of Na_2EDTA was added and the pH was adjusted at pH ~ 4.8 using hexamine-HNO_3 buffer (solution A). The excess EDTA was back-titrated with standard solution of $Pb(NO_3)_2$. 1,10-Phenanthroline (1,10-phen) was added to release the EDTA combined with Cd^{2+}, while thiosemicarbazide (TSC) was used to liberate the EDTA from the mercury-EDTA chelate. To determine AsO_4^{3-} ion in such type of mixtures the pH of (solution A) was raised to a value of 10 using ammonia buffer. Excess standard Mg^{2+} solution was added and the formed precipitate of $MgNH_4AsO_4$ was separated, dissolved and its magnesium content equivalent to AsO_4^{3-} was determined complexometrically using Eriochrome Black-T (EBT) indicator. The interference caused by different anions, cations and organic acids was investigated. A comparison of the indicators BCO and Xylenol Orange (XO) for successive titration of the studied metal ions was carried out. The proposed successive titration method was applied successfully to some real samples of ores, minerals and alloys of the studied metal ions and the results were satisfactory and agreed with those obtained by AAS. © 1997 Elsevier Science B.V.

Keywords: Bromo-cresol orange (BCO); Cadmium; Lead; Mercury and arsenic determination; Thallium; Visual complexometric titration

1. Introduction

The toxicity of most of the investigated cations are due to the retardation of the brain growth and damage of the nervous system e.g., Pb^{2+} and Hg^{2+} [1–6]. Some of them accumulate in liver and kidneys e.g., Cd^{2+} [7–10]. Other metal ions combine with cell membrane altering the permeability of the membrane [6]. Some of such metals

* Corresponding author.

PII S0039-9140(96)02106-6

have also been shown to produce dangerous breaks in chromosomes of somatic cells, thus, causing mental retardation for children born to mothers exposed to excessive amounts of such metals [6] e.g., Hg^{2+}. Arsenate compounds find extensive use in agriculture as herbicides for weeds and pest control. The use of arsenic compounds is however limited because most of arsenicals are poisonous.

Although Tl^{3+}, Hg^{2+}, Cd^{2+}, Pb^{2+} and AsO_4^{3-} are very toxic ions, yet very little methods have been used for the determination of some of them together [20]. Usually rapid and simple general methods for their analysis have encountered difficulties especially in presence of AsO_4^{3-} ion. The selection of specific physical conditions for carrying out such an analysis complicates the determination by the use of a group of reagents for separating mixtures and for the determination of such individual ions. Körbl and Přibil [11] in 1957 prepared BCO (I) as a new metallochromic indicator by condensation of formaldehyde, iminodiacetic acid and bromo phenol red. No further work was reported to such indicator until 1970. Cherkesov et al. [12,13] in 1971 prepared the indicator again named it Bromo-phthalexon-S and studied its complexes with few metal ions. In 1977 Vytřas determined some values of its acid-dissociation constants potentiometrically and spectrophotometrically [14]. From that time until now no further detailed work was reported either for Bromo-Cresol Orange (BCO), (I) or its semi-form (II).

The aim of this work is to present a rapid and simple general complexometric method for the determination of Pb^{2+}, Cd^{2+} and Tl^{3+} or Hg^{2+} or AsO_4^{3-} if only three of such ions are present together in one aliquot solution successively with high precision and accuracy. At first some artificial solution mixtures similar to those of such ores, minerals and alloys were determined by visual endpoint indication using BCO as a metallochromic indicator followed by an application of the proposed procedures for real naturally occurring samples containing one or some of such metals.

II Y=H

2. Experimental

2.1. Reagents and solutions

A 0.05 mol l^{-1} solution of disodium ethylenediaminetetraacetate (Na_2EDTA) was prepared by dissolving the required mass of $Na_2EDTA.2H_2O$ (analytical reagent grade, BDH, Poole, Dorset, UK) in redistilled water and diluting to the necessary volume. Standard Hg(II), Cd(II) and Pb(II) nitrate solutions were prepared by dissolving highly pure (99.99%-BDH) carbonates of such metals in concentrated nitric acid (BDH) and diluting to the necessary volume with 0.5 mol l^{-1} nitric acid. AsO_4^{3-} solution was prepared by oxidizing the corresponding mass of Na_3AsO_3 (BDH) with bromine water in 1 mol l^{-1} nitric acid. The excess bromine was removed by heating the solution on a steam bath for 15 min until the appearance of faint green colour of AsO_4^{3-} ion. Tl(III) nitrate solution was prepared by boiling the corresponding mass of Tl_2O_3 (BDH) in concentrated nitric acid and diluting to the necessary volume with 1 mol l^{-1} nitric acid. Na_3AsO_4 was standardized by precipitation as $MgNH_4AsO_4$ using standard $Mg(NO_3)_2$ solution and back titrating the excess Mg^{2+} with Na_2EDTA using Erichrome Black-T (EBT) as indicator (pH 10). The Na_2EDTA solution ($\sim$ 0.05 mol l^{-1}) was standardized by the spectrophotometric titration of 0.005 mol l^{-1} Pb(II) nitrate using XO as indicator in hexamine–HNO_3 buffer solution (pH 5, 520 nm). All other salts were prepared by dissolving the calculated mass of each salt (BDH) in the required

volume of redistilled water. In this work highly purified sample of the free acid form of BCO indicator obtained by liquid-liquid extraction procedures was used [17,18]. The product formed by Mannich condensation at 55°C (10 h) of bromophenol red, iminodiacetic acid and paraformaldehyde was extracted several times with pure *n*-butanol (organic phase) and 0.1 mol l^{-1} $NaHCO_3$ (aqueous phase). The component in the aqueous-phase (Semibromo-Cresol Orange (SBCO), and Bromo-cresol orange (BCO)) were extracted several times using n-butanol (organic phase) and 0.1 mol l^{-1} hydrochloric acid (aqueous phase). SBCO was isolated in the organic phase (raffinate) and BCO was extracted into the aqueous one. Further details of separation of SBCO and BCO have been described elsewhere [18]. The purity of the obtained BCO indicator was ascertained using HPLC (LKB-Bromma-Switzerland) instrument using *n*-butanol-acetic acid–water (4:1:2) by volumes as a mobile phase. For freshly preparing a 0.01 mol l^{-1} solution of the BCO indicator, the corresponding masses of the free acid form of the indicator was dissolved in redistilled water. 0.05 mol l^{-1} solution of 1,10 phen and TSC (Merck, Germany) were prepared by dissolving the required mass of reagent in pure methanol. Computation of experimental data and its statistical evaluation were as reported earlier [15,16]. If necessary, some outlier statistical tests such as *Q*-test were used to eliminate values of the determined metal ions, x_i, showing a statistically significant deviation from other experimentally determined values [15,16].

2.2. Decomposition of samples

The process of crushing, grinding (150 mesh), decomposition with different fusion mixtures and dissolution of various real samples were carried out as described earlier [19,20]. Some samples were fused with an approximately 0.5–1 g of Na_2CO_3 at 800°C for 1.5 h in an electric muffle furnace and dissolved after the described pretreatment in a 100 ml calibrated flask. Silica must be completely removed in each case by treating the fused ore in platinum crucible with an excess of hydrofluoric acid and small volume of concentrated sulphuric acid. The silica was expelled as volatile silicon tetrafluoride. The different cations present in the ore were first converted into the fluorides, which passed into the sulphates in contact with the less volatile sulphuric acid. Subsequent brief ignition at 700°C for 15 min converted the sulphates back into the oxides. The latter oxides were boiled with concentrated nitric acid nearly to dryness, cooled and diluted to 100 ml in a volumetric flask. The sulphate ores e.g., anglesite ($PbSO_4$) was treated in the same way after its fusion at 850°C for 30 min to convert the sulphate ore into PbO. The sulphides ores of some metals e.g., cinnabar (HgS), greenockite (CdS), realgar (As_4S_4) and orpiment (As_2S_3) were boiled with aqua regia and hydrofluoric acid until near dryness, cooled, diluted with redistilled water, filtered from the suspended sulphur and completed to the necessary volume with redistilled water. Other experimental procedures and apparatus were described earlier [21–24]. The proposed successive back-titration method for the determination of the elements under investigation was compared with the atomic absorption spectrometry (AAS). A Perkin-Elmer Model 2380 atomic absorption spectrometer (USA) was used with Pye Unicam (England) hollow-cathode lamps for Pb, Cd, As, Hg and Tl. Absorbance values were taken after an average integration time of 1 s. The optimum conditions used for the determination of the investigated elements were described elsewhere [25].

3. Results and discussion

3.1. Successive titrations of Cd^{2+}, Pb^{2+} and Tl^{3+} or Hg^{2+} or AsO_4^{3-} by visual endpoint indication using BCO

Different series of samples containing different proportions of Cd^{2+}, Pb^{2+} and Tl^{3+} or Hg^{2+} or AsO_4^{3-} were analysed. The same procedure was used for real samples of ores and alloys. In one of such series (series I_a), 5 ml of 0.1 mol l^{-1} Tl^{3+}, 5 ml of 0.1 mol l^{-1} Cd^{2+} and 5 ml of 0.1 mol l^{-1} Pb^{2+} solutions were transferred into a 250 ml conical flask containing about 85 ml of doubly distilled water. The mixture was adjusted to pH 0.5–1 (according to Tl^{3+} concentration) by dropwise addition of HNO_3 solution (5 mol l^{-1}). A few drops of BCO indicator (10^{-3} mol l^{-1}) to allow

the endpoint to be easily detected visually were added. The whole mixture was titrated with 0.05 mol l^{-1} Na_2EDTA solution. At the endpoint the colour changed from bright red to lemon yellow. This step gave Tl^{3+} only. At the Tl^{3+} endpoint 30 ml of 0.05 mol l^{-1} Na_2EDTA were added and the excess Na_2EDTA was back-titrated versus 0.05 mol l^{-1} $Pb(NO_3)_2$ solution after controlling the pH of solution to ~4.8 (hexamine–HNO_3 buffer). At the endpoint the colour reversibly changed from lemon yellow to red. 1,10-phen (25 ml of 0.05 mol l^{-1} solution) was added to the latter endpoint and the liberated EDTA equivalent to Cd^{2+} was titrated against the same $Pb(NO_3)_2$ solution. The process of addition of 1,10-phen and continuous stirring of solution should be repeated several times until permanent endpoint i.e., permanent existance of red colour. Pb^{2+} was found by difference. The feasibility of the proposed successive titration (ST) method for one aliquot sample containing Tl^{3+}, Cd^{2+} and Pb^{2+} was studied using different ratios of the components. Five series of titrations (series a) were done with different molar ratios of the investigated metal ions. The results for five series of parallel determinations of Tl^{3+}, Cd^{2+} and Pb^{2+} using the proposed ST method are given in Table 1 (series a). In another mixture containing Hg^{2+}, Cd^{2+} and Pb^{2+} (series 2_b), 1 ml of 0.1 mol l^{-1} Hg^{2+}, 9 ml of 0.1 mol l^{-1} Cd^{2+} and 5 ml of 0.1 mol l^{-1} Pb^{2+} solution were transferred into 250 ml conical flask and the whole solution was completed to about 100 ml with redistilled water. An excess of 40 ml of Na_2EDTA of concentration 0.05 mol l^{-1} were added and the excess Na_2EDTA was indirectly titrated against 0.05 mol l^{-1} $Pb(NO_3)_2$ solution using BCO indicator after adjusting the pH to ~4.8 (hexamine–HNO_3). At the endpoint thiosemicarbazide (TSC), 4 ml of 0.1 mol l^{-1} solution, were added to release the EDTA equivalent to Hg^{2+}. The released EDTA was titrated with $Pb(NO_3)_2$ again until the same endpoint. The process of addition of TSC should be done many times with continuous stirring until permanent endpoint.

At the Hg^{2+} endpoint 1,10-phen was added to release the EDTA combined with Cd^{2+}. Lead in the mixture was found by difference. The feasibility of the suggested ST method for one aliquot sample containing Hg^{2+}, Cd^{2+} and Pb^{2+} was studied using five series and the results are shown in Table 1 (series b).

For a third mixture containing AsO_4^{3-} (As^{5+}), Cd^{2+} and Pb^{2+} (series 3_c), 5 ml of 0.1 mol l^{-1} AsO_4^{3-}, 9 ml of 0.1 mol l^{-1} Cd^{2+} and 1 ml of 0.1 mol l^{-1} Pb^{2+} were transferred into 250-ml conical flask and the whole solution was diluted in the usual manner. An excess of 30 ml of 0.05 mol l^{-1} of Na_2EDTA was added. The pH of the solution was adjusted to pH 10 ($NH_4OH + NH_4Cl$ buffer) and an excess of 10 ml of standard 0.1 mol l^{-1} $Mg(NO_3)_2$ was added. The solution was boiled for 15 min, cooled and filtered. The white precipitate of $MgNH_4AsO_4$ was washed several times with doubly distilled water. AsO_4^{3-} was determined by directly titrating the magnesium equivalent to AsO_4^{3-} in the precipitate after its dissolution in boiling dilute nitric acid, controlling the pH to 10 (NH_4OH) using EBT indicator and adding both hydrazine hydrochloride and KBr to reduce the arsenic (V) to (III). The pH of the filtrate solution after the complete separation and determination of AsO_4^{3-} was lowered to pH ~4.8 using concentrated nitric acid and hexamine buffer. Both Cd^{2+} and Pb^{2+} were determined by the usual proposed procedure. The presence of Mg^{2+} ions do not cause interference at such lower pH. The feasibility of the proposed ST method for one aliquot sample containing AsO_4^{3-}, Cd^{2+} and Pb^{2+} was studied using five series and the results are shown in Table 1 (series c). Generally it was necessary to determine the value of the blank by titrating the same volume of a solution containing all the constituents with the exception of the metal ions at the selected pH value.

3.2. Interference of foreign species

It was found that NO_3^- and ClO_4^- at molar concentration of up to 1000 times that of Tl^{3+}, Hg^{2+}, Cd^{2+}, Pb^{2+} or AsO_4^{3-} did not interfere. SO_4^{2-} and Cl^- at 100-fold molar concentration of Pb^{2+} did not interfere. Iodide at the same molar concentration led to the complete reduction of Tl^{3+} to Tl^+ and converts Hg^{2+} to HgI_4^{2-} complex. PO_4^{3-} started to interfere when present at a molar concentration at least 100 times that of any of the metal ions studied. Higher concentrations of PO_4^{3-} (more than 100-fold) led to the formation of

Table 1
Statistical evaluation and tests of experimental data for five series of successive titrations of Cd^{2+}, Pb^{2+}, and Tl^{3+} or, Hg^{2+} or AsO_4^{3-} by visual detection of end-point using BCO and/or EBT indicators, pH = 0.5–1 for Tl^{3+}, 4.8 for Hg^{2+}, Cd^{2+} and Pb^{2+} and 10 for AsO_4^{3-} $C_{Na_2EDTA} = C_{Pb(NO_3)_2} = 0.05$ and/or 0.01 mol l^{-1}. The number of titrations in a series (n) = 5

turbidity that spoiled the titration completely. Citric, tartaric and acetic acid at molar concentrations of up to 1000 times that of Tl^{3+}, Hg^{2+}, Cd^{2+}, Pb^{2+} and AsO_4^{3-} did not interfere. Formic acid at the same concentration interfered owing to the complete reduction of Tl^{3+} to Tl^{+} and Hg^{2+} to Hg^{+}. Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+} did not interfere at such lower pH. Zn^{2+}, Co^{2+}, Mn^{2+}, Al^{3+}, Ni^{2+}, Cu^{2+} and Fe^{2+} interfere at equal molar concentration to Cd^{2+} in the mixture. Fe^{3+}, Zr^{4+}, Bi^{3+}, Ti^{4+}, Th^{4+} and Sc^{3+} interfere at equal molar concentration to Tl^{3+} in the mixture. Fortunately most of interfering cations are rarely found in Tl^{3+}, Hg^{2+}, Cd^{2+}, and Pb^{2+} mineral, but iron is only sometimes present with As^{5+} ores and minerals and could be easily masked by triethanolamine (pH 10).

3.3. Successive titrations of Cd^{2+}, Pb^{2+} and Tl^{3+} or Hg^{2+} or AsO_4^{3-} by visual endpoint indication using XO

As for BCO, five series of successive titrations were performed with molar ratios of Tl^{3+}:Cd^{2+}:Pb^{2+}, Hg^{2+}:Cd^{2+}:Pb^{2+} and Cd^{2+}:Pb^{2+}:AsO_4^{3-} of 1:5:9, 5:9:1, 9:1:5 and others for each mixture using XO as indicator in order to obtain a reasonable comparison of the accuracy, precision and detection limits with the two indicators. The experimental procedure was the same for both indicators. The results of five series of parallel determinations for each mixture of the three investigated ions are shown in Table 2. The statistical evaluation showed that the detection limit (2s + blank) [26,27] is nearly the same for both indicators. The detection limit per 100 ml of solution is 2 mg for Tl^{3+}, 1.2 mg for Cd^{2+}, 3 mg for Pb^{2+}, 2.8 mg for Hg^{2+} and 1.4 mg for As^{5+}. Comparison between the experimental mean value of each metal ion (for both indicators) with the given standard value, μ, by applying the null hypothesis of $|t|_1$ for $P = 0.05$ and $n = 5$ in order to estimate systematic error was carried out.

From Table 1, it is found that for BCO indicator $|t|_1 = 0.00–2.68$ for all the three metals with the exception of mercury and cadmium in series 5b, and arsenic in series 4c for which have $|t|_1 = 3.13, 3.9$ and 3.73, respectively. This means that mercury and cadmium in series 5b and arsenic in series 4c are subjected to systematic error (the null hypothesis of $|t|_1$ for $P = 0.05$ and $n = 5$ for the specified metals in these series are rejected). For all the other metals ions the null hypothesis of $|t|_1$ for $P = 0.05$ and $n = 5$ is retained where the calculated experimental values of $|t|_1$ are less than the tabulated value ($|t|_1 = 2.78$) [16]. From Table 2, it is found that for XO indicator $|t|_1 = 0.00–2.48$ for all three metals in different series with the exception of lead in series 4a and 1b and cadmium in series 5b. This means that these metals ions in these series are the only determinations subject to systematic error. For all other metal ions determined the null hypothesis of $|t|_1$ for $P = 0.05$ and $n = 5$ is retained, which can be explained as mentioned before.

Comparison between the experimental means for the two studied indicators was carried out using the null hypothesis of $|t|_2$ for $P = 0.05$ and $n = 10$ (Table 2). It was found that for both indicators $|t|_2 = 0.0–2.20$ for all the three metals ions with the exception of thallium in series 4a, lead in series 4a, 5a, 1b and 2b. This means that the observed experimental values of $|t|_2$ are less than the tabulated value ($|t|_2 = 2.31$) [16] and $|t|_2$ is retained for all determinations with the exception of the referred to series for thallium and lead. In the latter series the null hypothesis of $|t|_2$ for $P = 0.05$ and $n = 10$ is rejected and the determined metals in these cases have unacceptable means or recoveries compared with the other accepted series (Table 2).

Comparison between the experimental means for the two studied indicators to estimate random errors of the two sets of data (Table 1 and Table 2) was carried out using the two-tailed F-test [16]. From Table 2, it is clear that all the experimental $F_{4,4}$ values are between 0.16 and 5.06 for all the series of determinations. These values are less than the tabulated value of $F_{4,4}$ for $P = 0.05$ and $n = 10$ (9.6) [16]. This proves that there is no significant difference between the two standard deviations at $P = 0.05$ for both BCO and XO indicators or that the two indicators give the same precision have in such determinations. In addition, all series are not subject to random errors for both investigated indicators.

The success of this ST method depends on the fact that Pb^{2+} ion does not react with neither 1,10-phen nor TSC and can be determined easily by difference. Also, Cd^{2+} ion does not react with TSC in case of

Hg^{2+} determination. The se quence of determination of metal ions should be adopted exactly to have perfect results. Trials to determine Hg^{2+} using KI instead of TSC as demasking reagent for EDTA did not succeed specially in presence of 1,10-phen in the second step for the determination of Cd^{2+} where a white turbidity was found. The use of $Pb(NO_3)_2$ instead of $Zn(NO_3)_2$ as titrant proceeded easily because it was found that Zn^{2+} ion reacted with 1,10-phen present in the titrating solution and no endpoint was observed or the solution was over titrated. The ST method is preferred for AAS in the fact that, it is relatively rapid, has no standard curves and conditions and of little interference.

3.4. Application of the proposed successive titration method

The results of the determination of Pb^{2+}, Cd^{2+} and Tl^{3+} or Hg^{2+} or As^{5+} in a series of naturally occurring ores, minerals and alloys containing one or any of three ions either together or with other metals are shown in Table 3. These results (average of three determinations of two different weighed samples) are in a good agreement with the values obtained by AAS. The relative standard deviation estimated using the range method [16] was found to be 1–2.5% for the proposed ST method. From the results obtained, it is clear that the titration of any of the three metal ions in different real samples is simple and reliable and can be used with good reproducibility.

Acknowledgements

We express our sincere gratitude to Mr Mohamed Salah El-Din Zaki, Chief of the Geological Museum, Geology Department, Faculty of Science, Mansoura University, for providing the real ore and mineral samples investigated and for constructive comments.

Abstract

The evidences of spontaneous oxidation of Mn(II) by the dissolved oxygen in azide buffer medium, which is dependent on the N_3^-/HN_3 concentration, suggested a formation of stable Mn(III) complexes due to marked colour changes. Spectrophotometric studies combined with coulometric generation of Mn(III), in presence of large excess of Mn(II), showed a maximum absorbance peak at 432 nm. The molar absorptivity increases with azide concentration (0.44–3.9 mol l^{-1}) from 3100 to 6300 mol^{-1} l cm^{-1}, showing a stepwise complex formation. Potential measurements of the Mn(III)/Mn(II) system in several azide aqueous buffers solutions: 1.0×10^{-2} mol l^{-1} HN_3, (0.50–2.0 mol l^{-1}) N_3^- and 5.0×10^{-2} mol l^{-1} Mn(II) and constant ionic strength 2.0 mol l^{-1}, kept with sodium perchlorate, leads to the conditional potential, $E^{0'}x$, in several azide concentrations at 25.0 ± 0.1°C. Considering the overall formation constants of Mn(II)/N_3^-, from former studies, and the potential, $E^{0'}s = 1.063$ V versus SCE, for Mn(III)/Mn(II) system in non-complexing media, it was possible to calculate the Fronaeus function, $F_0(L)$, and the following overall formation constants: $\beta_1 = 1.2 \times 10^5$ M^{-1}, $\beta_2 = 6.0 \times 10^8$ M^{-2}, $\beta_3 = (2.4 \pm 0.7) \times 10^{11}$ M^{-3}, $\beta_4 = (1.5 \pm 0.5) \times 10^{11}$ M^{-4} and $\beta_5 = (9.6 \pm 0.8) \times 10^{11}$ M^{-5} for the Mn(III)/N_3^- complexes. These data give important support to understand the importance of Mn(II) and Mn(III) synergistic effect on the analytical method of S(IV) determination based on the Co(II) autoxidation. © 1997 Elsevier Science B.V.

Keywords: Azide; Manganese; Stability constants

1. Introduction

It is well known that some ligands are able to stabilize Mn(III) complexes. Analytical applications, for instance, come from the use of pyrophosphates in manganese determination due to its formation of manganese(III) complexes [1]. The reaction of permanganate with the reducing agent oxalate is an interesting example of participation of Mn(III) as an intermediate in such redox reaction [2,3].

Former studies of manganese(II) in azide buffers solutions, N_3^-/HN_3, have shown a tendency to change colour of the solution with a possible formation of brownish manganese(III) azide complexes [4,5]. Spontaneous oxidation by

PII S0039-9140(96)02112-1

dissolved oxygen takes place specially at azide concentrations higher than 1.0 mol l^{-1} and it is markedly dependent on HN_3 concentration. We are concerned about the stabilization of Mn(III) in azide medium in order to better understand the role of the Mn(III)/Mn(II) system in previous kinetics studies on the autoxidation of Mn(II) induced by S(IV) and its synergistic effect on the similar studies of Co(II) and Fe(II) ions. These studies are of special relevance in environmental chemistry [5–10].

The synergistic effect of the Mn(II) and Mn(III) ions on the autoxidation of Co(II) induced by S(IV) allowed the development of an alternative analytical determination method of S(IV) in environmental samples [6,7]. The concentration of Co(III) azide complex formed was a linear relationship with the initial S(IV) concentration. As the molar absortivity of Co(III) in 365 nm is high ($\epsilon \approx 22\,000$ mol^{-1} l cm^{-1}), it was possible to determined S(IV) in the range of 10^{-6}–10^{-4} mol l^{-1}.

The present study deals with some spectrophotometric characteristics of Mn(III) azide complexes. The Mn(III) was generated by anodic oxidation of Mn(II) in azide medium at constant ionic strength. The parallel potentiometric measurements allowed to obtain the redox potential of Mn(III)/Mn(II) system at some azide concentrations in which stabilization of Mn(III) takes place. The potentiometric measurements in the $MnO_2/H^+/Mn^{2+}/Mn^{3+}$ system, by combination with data on the Fe(III)/Fe(II) system, were used to estimate the conditional potential, $E^{0'}s$, of the Mn(III)/Mn(II) in non complexing medium at the same ionic strength. Analysis of the potentiometric data led to the equilibrium constants in the Mn(III)/N_3^- system.

2. Experimental

2.1. Reagents and standard solutions

All reagents were from AR or CP specification from Merck or Fluka A.G.

Sodium azide was prepared directly from the salt. Standardization was carried out by adding a known volume of standard sulfuric acid solution, boiling to remove volatile hydrazoic acid, HN_3, followed by back titration of the remaining strong acid with standard sodium hydroxide solution.

Manganese(II) perchlorate solution was prepared from direct reaction of excess carbonate with 6.0 mol l^{-1} perchloric acid, under stirring for 2 days at room temperature. After filtering, free perchloric acid was added to adjust pH to 5.5, in order to avoid hydrolysis. Standardization was carried out by complexometric titration with EDTA [11].

Sodium perchlorate solution 5.0 mol l^{-1} utilized to make up the ionic strength of working solutions was standardized by taking small volume solution and dried in an oven at 120°C until constant weight.

Standard perchloric acid solution was added to the working solutions to displace hydrazoic acid from the azide ions.

2.2. Working solutions

The working solution for preparation of Mn(III) consisted of 100 ml of 1.0×10^{-2} mol l^{-1} HN_3, 5.0×10^{-2} mol l^{-1} Mn(II) and NaN_3 ranging from 0.50 to 2.0 mol l^{-1}. Electrolysis was performed at constant current (10 mA) as a function of time. After each period of applied current, the potential measurements of platinum indicator electrode, versus the Hg/Hg_2Cl_2 electrode, were done as described in former work [12]. Simultaneously UV-visible absorption spectra were recorded with a HP-8452 spectrophotometer equipped with a thermostatic cell holder. All measurements were performed at 25.0 ± 0.1°C.

3. Results and discussion

3.1. Evidences of the spontaneous oxidation of Mn(II) in azide medium

Fig. 1 shows the spectra changes, due to the spontaneous oxidation of Mn(II), by dissolved oxygen, in azide solutions containing Mn(II) in presence of some air and a small and constant hydrazoic acid concentration. The higher the

azide concentration the faster and more effective is the oxidation. In solutions previously bubbled with nitrogen the oxidation is almost non existent such small HN_3 concentration, such as 5.0×10^{-2} mol l^{-1}. The concentration of hydrazoic acid is also an important parameter in such oxidation, as the lowering pH favours the process. The following redox systems can well explain the oxidation power of hydrazoic acid [13]:

$$HN_3 + 3H^+ + 2e^- \rightleftharpoons N_2 + NH_4^+ \quad E^0 = 1.96\ V \tag{1a}$$

$$HN_3 + 11H^+ + 8e^- \rightleftharpoons 3NH_4^+ \quad E^0 = 0.695\ V \tag{2a}$$

These reactions can be better considered in the adequate form for the azide buffer:

$$4HN_3 + 2e^- \rightleftharpoons N_2 + NH_4^+ + 3N_3^- \tag{1b}$$

$$12HN_3 + 8e^- \rightleftharpoons 3NH_4^+ + 11N_3^- \tag{2b}$$

3.2. Determination of the potential of the Mn(III)/Mn(II) in non complexing medium

An important data to calculate the equilibrium constants of $Mn(III)/N_3^-$ complex is the value of the conditional potential, $E^{0'}s$, of the Mn(III)/Mn(II) system in non complexing medium at 2.0 mol l^{-1} ionic strength in perchlorate medium. The difficulties to obtain it are the tendencies of the trivalent cation to hydrolyze [14] and to disproportionate Eq. (3) at lower acidity medium [15], so it is required studies at high acidic medium.

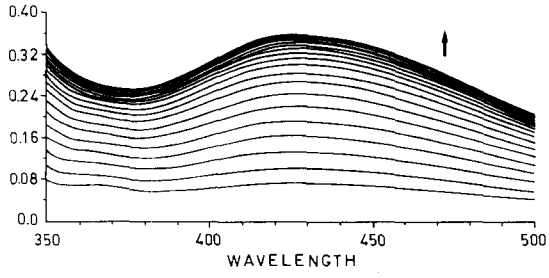

Fig. 1. Successive spectra, every 60 s, of $Mn(II)/N_3^-$ solutions in presence of dissolved oxygen with Mn(III) spontaneous formation. $Mn(II) = 1.0 \times 10^{-1}$ mol l^{-1}, $HN_3 = 5.0 \times 10^{-2}$ mol l^{-1}, $N_3^- = 1.6$ mol l^{-1} (path length = 1.00 cm).

$$2Mn^{3+} + 2H_2O \rightleftharpoons Mn^{2+} + 4H^+ + MnO_2$$
$$K \sim 10^9 \tag{3}$$

The literature refers to 1.5 V versus N.E.H. as the conditional potential of the Mn(III)/Mn(II) system in 3.0 mol l^{-1} perchloric acid or 7.5 mol l^{-1} sulfuric acid medium [16,17]. These data, in virtually non complexing medium, can not obviously be used in combination with the present potentiometric data in azide medium due to the very different experimental conditions of both experiments, such as ionic strength and acidity.

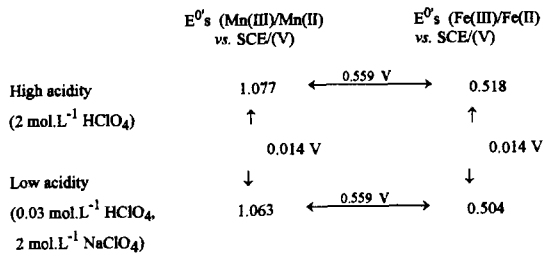
To calculate the conditional potential value, measurements were carried out initially in the following cell:

$$Hg|Hg_2Cl_2, NaCl(sat): 2.0M\ HClO_4, 5.0 \times 10^{-1}\ M\ Mn(ClO_4)_2, z[Mn^{3+}]|Au \tag{4}$$

The Mn^{3+} concentration was initially generated by coulometric oxidation up to 10^{-3} mol l^{-1} order. Measurements of the potential in several solutions led to non reproducible $E^{0'}$ data due to the low current electrode efficiency and slow oxidation of water by the trivalent cation formed.

Another way to obtain the conditional potential value of Mn(III)/Mn(II) system at this acidity medium was performed by reversion of the disproportioning Eq. (2a) by adding to a solution of 2.0 mol l^{-1} $HClO_4$ and 5.0×10^{-1} mol l^{-1} Mn(II) a large excess of manganese dioxide in order to form about 10^{-3} mol l^{-1} of Mn(III). To evaluate the Mn(III) concentration in the final solution, an excess of I^- was added and the I_2 formed was titrated with standard solution of $Na_2S_2O_3$. Measurements of the potential of the cell (4) led to the conditional potential value of 1.077 0.003 V versus the saturated calomel electrode (SCE). Gold electrode is more inert than the platinum one and is preferentially used for measurements in highly oxidizing medium as happens in this Mn(III)/Mn(II) system.

The evaluation of the conditional potential at 2 mol l^{-1} $NaClO_4$ and lower acidity was done by using the Fe(III)/Fe(II) redox system as a potentiometric pilot system. Equivalent experiments were performed with a solution having a similar cell compartment, described by cell (4): 2 mol l^{-1}



Scheme 1. Estimation of the conditional potential value, $E^{0'}s = 1.063$ V, for the Mn(III)/Mn(II) system, in 2.0 mol l^{-1} perchlorate medium based on the Fe(III)/Fe(II) system used as a potentiometric pilot system.

$HClO_4$ 0.5 mol l^{-1} Mn(II), and both Fe(III) and Fe(II) at 5.0×10^{-3} mol l^{-1} level, led to a conditional potential of Fe(III)/Fe(II) system equal to 0.518 V versus SCE. Further experiment at lower acidity solution, 3.0×10^{-2} mol l^{-1} $HClO_4$ 5.0×10^{-1} mol l^{-1} Mn(II) and both Fe(III) and Fe(II) at 5.0×10^{-3} mol l^{-1} and $NaClO_4$ to make up the ionic strength 2.0 mol l^{-1}, gave the value of 0.504 V versus SCE. This datum differs only 0.014 V from the other condition of higher acidity and different ionic medium, a difference that could be used as a correction to estimate the $E^{0'}s$ for the Mn(III)/Mn(II) system.

As both redox systems are constituted by the ratio of metal ion(III)/metal ion(II), a reasonable assumption is to attribute the same ratio of activity coefficients, γ_{III}/γ_{II} for both trivalent/divalent cations. On this basis, the Fe(III)/Fe(II) system can be used as a potentiometric pilot system which permits to estimated $E^{0'}s$ value of Mn(III)/Mn(II) at the 2.0 mol l^{-1} ionic strength ($NaClO_4$) by discounting 0.014 V from the 1.077 V value, becoming 1.063 V versus SCE. The Scheme 1 shows the estimation of this conditional potential by using the Fe(III)/Fe(II) redox system as a potentiometric pilot system. As there is a marked change in the potential of the Mn(III)/Mn(II) system in azide medium, compared with a non complexing medium, an uncertainty of even 10 mV resulting from this artifice is relatively small.

3.3. Determination of the conditional potential of the Mn(III)/Mn(II) in azide medium

Fig. 2 shows the spectrophotometric data of the average molar absortivity at 432 nm of Mn(III) azide complexes generated coulometrically in increasing azide concentration solutions. The Mn(III) concentration was calculated by Faraday's law.

The results suggest that a mixture of stepwise complexes are formed. The average molar absortivity tends to a constant value ranging from 3100 to 6300 mol^{-1} l cm^{-1}, in azide solutions from 0.439 to 3.85 mol l^{-1}. At this wavelength the average molar absortivity Mn(II) azide complexes is very small and can be neglected.

The potentiometric measurements data in the complexing medium were carried out with the following cell:

$$Hg|Hg_2Cl_2, NaCl(sat)5.0 \times 10^{-2}\ M\ Mn(ClO_4)_2, y\ M\ NaClO_4, x\ M\ NaN_3, 1.0 \times 10^{-2}\ M\ HN_3, z[Mn(III)]|Pt \quad (5)$$

The measured potential, E_x, is related to the conditional potential, $E^{0'}x$, and the Mn(III)/Mn(II) concentration ratio by the following Nernst equation, at fixed free ligand concentration:

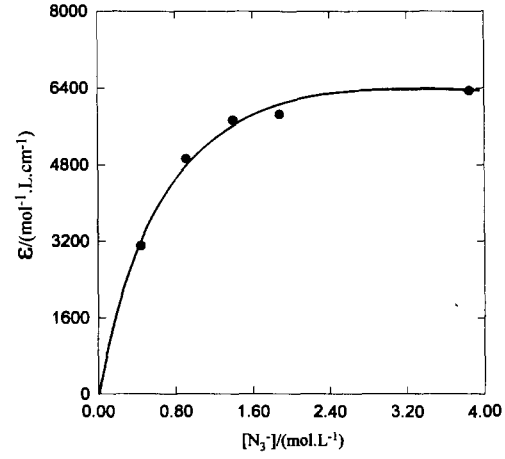


Fig. 2. Average molar absortivity of the Mn(III)/N_3^- complexes, at 432 nm, as a function of free azide concentration ($HN_3 = 1.0 \times 10^{-2}$ mol l^{-1}).

$$E_x = E_x^{0'} + 0.05916 \log \frac{[Mn(III)]}{[Mn(II) - Mn(III)]} \quad (6)$$

The data treatment was done, as described in a previous work, in order to obtain the conditional standard potential of the Mn(III)/Mn(II) system at different free azide concentration, $E^{0'}x$, due to the formation of different complexes in the two oxidation states [4].

Measurements in lower than 0.4395 mol l^{-1} free azide concentrations were not considered as the Mn(III) complexes system becomes unstable, the brownish colour fades and the potentiometric data drift to lower values.

In similar experiments carried out at high acidity (0.1 mol l^{-1} HN_3), the data treatment was not possible due to the high contribution of the spontaneous oxidation of Mn(II) by the HN_3 and by dissolved oxygen.

3.4. Determination of the equilibrium constants of the Mn(III)/N_3^- complex

Equilibrium data can be obtained by the Fronaeus function, $F_0(L)$, for several ligand concentrations [18] Eq. (7):

$$F_0(L) = 1 + \sum_{n=1}^{n} \beta_n [N_3^-]^n \quad (7)$$

The $F_0(L)$ values, for each free azide concentration, can be related to the change of $E_s^{0'}$, in non complexing perchlorate medium, to a less positive $E_x^{0'}$, in presence of the ligand Eq. (8). When the element is in two oxidation states, as Mn(III/Mn(II) or in a similar Co(III)/Co(II) system [12], the $E^{0'}$ refers to a ratio of the $F_0(L)$ values. Table 1 presents several experimental potentiometric data of $-\Delta E^{0'} = -(E^{0'}x - E^{0'}s)$ of the Mn(III)/Mn(II) system, in the range from 0.4395 to 1.936 mol l^{-1} of free azide concentration at 2.0 mol l^{-1} constant ionic strength in $NaClO_4$.

$$-\Delta E^{0'} = -(E_x^{0'} - E_s^{0'}) = 0.05916 \log \frac{F_0(L)_{ox}}{F_0(L)_{red}} \quad (8)$$

The $F_0(L)_{red}$, referred to the complexes of Mn(II) with azide, can be calculated for the several azide concentrations with the overall formation constants of the four stepwise complexes, β_n, determined in our previous work [19]:

Table 1
Potentiometric data of $-E^{0'} = -(E^{0'}x - E^{0'}s)$ of the Mn(III)/Mn(II) system, at different free azide concentration at ionic strength 2.0 mol l^{-1} ($NaClO_4$) and 25.0 ± 0.1°C

0.6867	1.936	66.96	2712

$E^{0'}s$ = 1.063 V.

$$F_0(L)_{red} = 1 + 4.15[N_3^-]^1 + 6.61[N_3^-]^2 + 3.33[N_3^-]^3 + 0.63[N_3^-]^4 \quad (9)$$

The $F_0(L)_{ox}$ at the same free ligand concentration, corresponding to the Mn(III) complexes, can be calculated by introducing in the Eq. (8) the $F_0(L)_{red}$, $E^{0'}x$ and $E^{0'}s$ data.

Average ligand number estimation for manganese(III), n_{III}, is based on $\Delta E^{0'}/\Delta \log[N_3^-]$, where potentials $E^{0'}x_1$ and $E^{0'}x_2$ refer to the ones in solutions with small increments in azide concentrations, $[N_3^-]_1$ and $[N_3^-]_2$, respectively, as described by Eq. (10). The average ligand number for manganese(II), n_{II}, can be calculated with de β_n for Mn(II)/N_3^- system [19]. The n_{III} values are in the range from 3.6 to 4.4 ligands and indicates that at least five stepwise complexes are formed.

$$n_{III} = (E^{0'}x_2 - E^{0'}x_1) / 0.05916(\log[N_3^-]_2 - \log[N_3^-]_1) + n_{II} \quad (10)$$

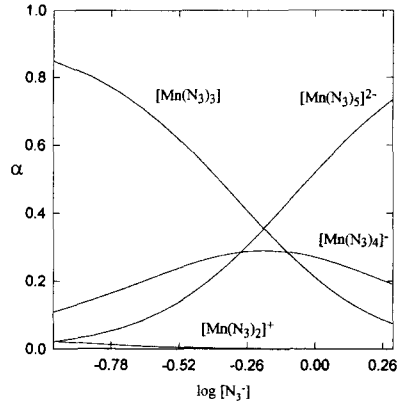

Fig. 3. Distribution diagram of the Mn(III)/N_3^- complexes calculated with the equilibrium constants.

The potentiometric data obtained in this concentration range of the azide ions are inadequate to permit the equilibrium data calculation for the species with less than three ligands. The reason for that is the instability of Mn(III) complexes in azide concentration lower than 0.4 mol l^{-1} azide concentration.

The conventional graphic treatment of $F_0(L)$ data could not be applied for the present system [18]. Matrix solution of the weighed simultaneous equations indicated only five ligands, neglecting a solution for six ligands [20]. These experimental data were also inadequate for the direct calculation of β_1 and β_2, because there were no potentiometric data at lower than 0.44 mol l^{-1} ligand concentration, due to experimental problems of Mn(III) stabilization. The limited concentration range of the ligand led to exclude the terms referred to β_1 and β_2, in the matrix of simultaneous equations. A set of weighed simultaneous equations was prepared and solved in a sophisticated computer program written in Quick BASIC-4.50—Microsoft®: the matrix solution gave the following data for the overall formation constants with 95% of confidence: $\beta_3 = (2.4 \pm 0.7) \times 10^{11}$ M^{-3}, $\beta_4 = (1.5 \pm 0.5) \times 10^{11}$ M^{-4} and $\beta_5 = (9.6 \pm 0.8) \times 10^{11}$ M^{-5}.

A reasonable estimation of β_1 and β_2 was taken by extrapolation in a linear plot of the $(\log \beta_n)/n$ versus $n (n = 3–5)$. This procedure is based on the proportionality of the average free energy with the ligand number attachment to the higher complexes. Data of β_1 and β_2 were found to be 1.2×10^5 M^{-1} and 6.0×10^8 M^{-2}, respectively.

Fig. 3 shows the distribution diagram of the Mn(III)/N_3^- complexes. The contributions of the $[Mn(N_3)]^{2+}$ and $[Mn(N_3)_2]^+$ complexes are negligible at free azide concentration of 0.5 mol l^{-1}.

The role of selected cations in the formation of pseudomicelles in aqueous humic acid

R. von Wandruszka *, C. Ragle, R. Engebretson

Department of Chemistry, University of Idaho, Moscow, Idaho, ID 83844-2343, USA

Received 1 August 1996; received in revised form 7 October 1996; accepted 7 October 1996

Abstract

The fluorescence intensity enhancement of a pyrene probe in aqueous humic acid solutions was assessed in terms of added lanthanide and thorium cations. Among the trivalent ions it was found that size played a role, with the small Lu^{3+} ion producing the greatest increase in pyrene emission. This was attributed to its superior ability to cause pseudomicellization in the humic acid polymer. Slow kinetic effects were observed, leading to substantial fluorescence enhancement over a period of 7 h. This was ascribed to a continuous aggregation process in aqueous humic acid, leading to ever more viscous microenvironments for the probe molecule. © 1997 Published by Elsevier Science B.V.

Keywords: Cations; Humic acid; Pseudomicelles

1. Introduction

Recent investigations conducted in this laboratory [1–5] have shown that aqueous solutions of certain soil humic acids respond to the addition of cations by the formation of molecular microdomains of relatively low polarity [6–8]. These domains, which can be looked upon as intramolecular aggregates, are referred to as pseudomicelles in view of their similarity to detergent micelles with regard to structure and polar character. It was found that humic acid molecules consisting of long flexible polymers, have a tendency to coil up in the presence of cations, especially metals. This is thought to be due to a combination of charge neutralization and functional group bridging. The former arises because the humic acid molecule, which requires neutral to basic conditions for solubilization, contains numerous carboxyl and hydroxyl groups that are negatively charged in these solutions. Mutual repulsion among these functional groups causes the humic acid polymers to adopt a stretched configuration, providing few association sites for nonpolar species in solution. Upon the addition of cations this effect is minimized and they fold and shorten, forming compact structures with relatively hydrophobic interiors and hydrophilic surfaces. Functional group bridging is considered to enhance this effect, especially with multivalent cations, by drawing together various groups on the humic acid chain. It should also be noted that all humic acid solutions are polydisperse, and that

PII S0039-9140(96)02116-9

the interaction of segments of different sizes leads to a degree of intermolecular aggregation that further augments pseudomicellization.

Evidence for the model described above was derived from the fluorescence behavior of small nonpolar species such as pyrene and diphenyloxazole which were added to humic acid solutions. As would be the case with detergent micelles, these molecules were found to partition into the hydrophobic domains of the humic acid structure. Sequestered in this manner, they are protected from solution borne fluorescence quenchers (e.g., bromide ion) and are unaffected by the presence of these species. It was also found that the increased microviscosity of the humic acid pseudomicelles strongly reduced dynamic quenching of the encapsulated fluorescent probe, producing an increase in fluorescence intensity upon the addition of salts. This is reminiscent of the effect of metal ions on fluorescent probes in bile salt solutions [9]. Fluorescence anisotropy measurements were consistent with these observations, showing that the rotational diffusion of humic acid/probe aggregates was directly linked to the degree of sequestration of the latter. When the ability of humic acids to coil up was reduced by photolytic cleavage of the chains, the effects described above disappeared. Likewise, when aquatic humic acids were used, which size exclusion chromatography showed to be considerably smaller than soil humic acids, the effects were absent or greatly diminished.

2. Experimental

The pyrene excitation and emission wavelengths used in this work were 240 and 373 nm, respectively. The former was chosen to minimize interference by humic acid fluorescence. Typical humic acid excitation extends from 250 to 420 nm, while emission is strong from 380 to beyond 500 nm [10,11]. The emission of pyrene dissolved in a humic acid solution will therefore be attenuated and must be appropriately corrected. While humic acid fluorescence can be subtracted from the total fluorescence by the use of a blank, the inner filter effect remains operative and requires additional treatment. A correction developed by Gauthier et al. [12] which incorporates the absorbances at the wavelengths in question was implemented:

$$\frac{F_{corr}}{F_{obsd}} = 2.3\frac{dA_{ex}}{1-10^{-dA_{ex}}}\,10^{gA_{em}}\,\frac{2.3sA_{em}}{1-10^{-sA_{em}}} \qquad (1)$$

Here F_{obsd} is the observed intensity, F_{corr} the corrected intensity, A_{ex} the absorbance at the excitation wavelength per cm of solution, A_{em} the absorbance at the emission wavelength cm^{-1} of solution, d the distance between the edge of the excitation beam and the inside wall of the cuvette, and s the width of the excitation beam (all in cm). The treatment corrects for absorption at both the excitation and emission wavelengths.

The humic acid used in this study was deashed Latahco silt-loam humic acid, extracted in our laboratory from a local soil (Argiaquic Xeric Argialbolls) by the procedure outlined by the International Humic Substances Society (IHSS, 1985). Its elemental analysis and characterization have been reported previously [2]. The humic acid was dissolved in 0.01 M NaOH (Fisher Scientific) to give a 1000 ppm stock solution. A subsequent dilution to 10 ppm was made with doubly deionized water. Pyrene was purchased from Sigma (98%), recrystallized from ethanol, and twice sublimed onto a cold finger. Aqueous pyrene solutions at 1×10^{-7} M were prepared by introducing an aliquot of a 0.01 M pyrene solution in cyclohexane into a volumetric flask, evaporating the cyclohexane, adding water, and sonicating for 2–3 h. The resulting solutions were stored in the dark at room temperature. Magnesium chloride (Baker), the hexahydrates of lanthanum chloride (Strem Chemicals), samarium chloride (Aldrich), lutetium chloride (Strem), and thorium nitrate (Spectrum Chemical) were used without further purification. The deionized water used for all solutions were brought to a resistivity of 18 MΩ cm by passing through a 0.22 μm Millipore filter system.

Fluorescence measurements were taken with a Hitachi F-4500 fluorescence spectrophotometer equipped with a thermostatted cell holder. Slits were set at a 5 nm bandpass. The data reported as a function of salt concentration were obtained by adding consecutive aliquots of a concentrated salt

solution to a known volume of humic acid solution containing pyrene [2]. A blank was also measured, which consisted of an aqueous humic acid solution (not containing pyrene) to which the same aliquots of salt solution were added. Dilution of the humic acid was insignificant over the range studied. The solutions were held at 19°C, open to the air. They were stirred with a magnetic stirrer using a stainless steel stir bar for 2 min after each addition of salt, and then left to equilibrate in the dark for 5 min before the fluorescence was measured.

3. Results and discussion

One of the central observations in previous studies [2,5] was the pyrene fluorescence enhancement obtained when salts were added to aqueous solutions containing soil humic acids. The effect of the cation followed the order $Na^+ < K^+ < Cs^+ < Mg^{2+}$, while the anion had no observable influence. In the present study, cations of the lanthanide series were investigated to evaluate the impact of more highly charged species and assess the role of ionic size. For comparison, Th^{4+} was included as a tetravalent species. Kinetic aggregation effects were also measured.

Fig. 1. shows the change in pyrene fluorescence intensity upon the addition of three lanthanide ions in comparison with mono- and divalent cations. It is clear that higher ionic charge generally leads to greater fluroescence enhancement,

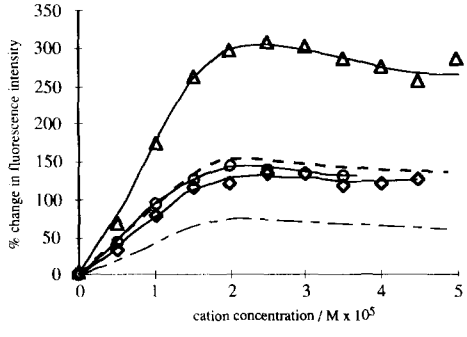

Fig. 1. Variation of pyrene fluorescence intensity in a 10 ppm humic acid solution containing salts. ○, $SmCl_3$; ◇, $LaCl_3$; △, $LuCl_3$; – – –, $MgCl_2$ (Ref. [2]); — — —, KCl (Ref. [2]).

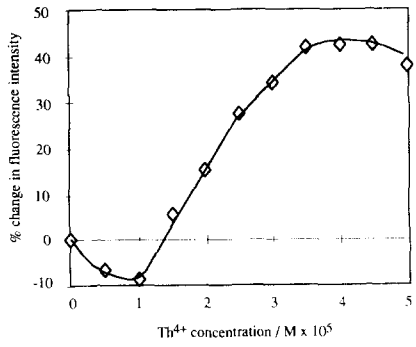

Fig. 2. Variation of pyrene fluorescence intensity with Th^{4+} concentration in a 10 ppm humic acid solution.

which must be ascribed to a tighter, more viscous interior of the humic pseudomicelles. Interestingly, however, La^{3+} and Sm^{3+}, the larger lanthanides (ionic radii 1.016 and 0.964 Å, respectively) [13] produced effects that were little different from each other and from Mg^{2+}. Lu^{3+} (radius 0.85 Å), on the other hand, gave a pyrene emission intensity twice as large as that of Sm^{3+}. In a separate experiment it was shown that aqueous pyrene solutions containing the various metal ions but no humic acid, produced no discernible trends in emission intensity. This indicates that neither cation quenching, nor metal-probe sensitization was responsible for the variations in fluorescence in the presence of humic acid. The effect of Th^{4+} (radius 1.02 Å) is shown in Fig. 2. It is evident that the extent of pyrene fluorescence enchancement is considerably less, and that there is an initial slight decrease in intensity when the salt is added. To assess the possible influence of the anion (thorium nitrate was used here, while all the other salt were chlorides), a side-by-side comparison of $MgCl_2$ and $Mg(NO_3)_2$ was carried out. Pyrene fluorescence enchancement was found to be virtually identical for the two salts.

It was found in earlier work that the kinetics of humic acid configurational adjustments can be slow. To evaluate the role this may play in the behavior of the Th^{4+} containing solution, extended measurements were carried out for 16 h. In this, a single addition of $Th(NO_3)_4$ was made to a humic acid/pyrene solution, bringing the salt concentration to 5×10^{-5} M. Repeated measure-

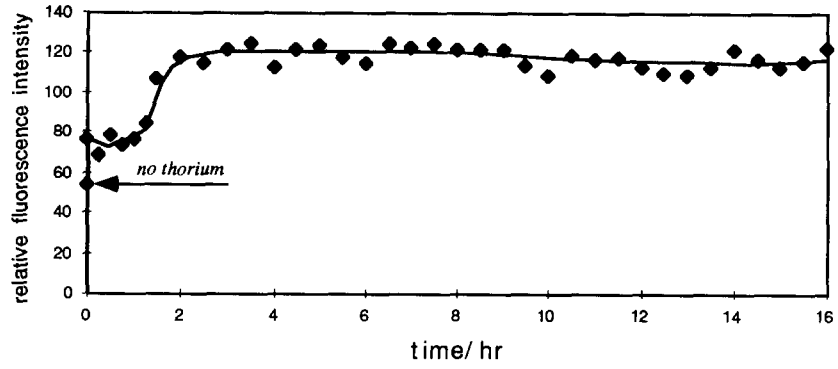

Fig. 3. Variation of pyrene fluorescence with time in a solution containing 10 ppm humic acid and 5×10^{-5} M $Th(NO_3)_4$.

ments were then carried out as shown in Fig. 3. These indicated that the initial rise in pyrene fluorescence intensity occurred as expected and persisted for approximately 90 min. After this period, a further rise in emission intensity was observed, reaching a maximum level after about 2 h. The conclusions drawn from this result are two-fold: (1) slow kinetics are indeed operative, and the pyrene probe finds a stable environment only after 7 h; and (2) the initial decrease in pyrene fluorescence intensity (Fig. 2) is unlikely to be affected by this. Comparisons with lanthanide salt kinetics were made to shed light on the long-term fluorescence enhancement (vide infra).

In the above discussion it was implied that ionic size is a factor in the cation-assisted pseudomicellization of humic acid. The information available on the lanthanide ions provides their crystalline radius (cf. the familiar lanthanide contraction), and as the prime distinguishing feature it is reasonable to invoke this to explain their different behavior vis-à-vis humic acid. It may be suggested that the small, densely charged Lu^{3+} (albeit hydrated) is most effective in pulling the humic acid into a structured cage. La^{3+} and Sm^{3+} are large and similar in size, especially when hydrated, and consequently interact in a similar fashion with humic acid. Comparison with Mg^{2+} and Th^{4+} is more tenuous since charge becomes a distinguishing factor with these ions. The crystal ionic radius of Mg^{2+} is 0.82 Å, similar to that of Lu^{3+}, but its lower charge renders its interactions with humic acid similar to those of the larger but more highly charged La^{3+} and Sm^{3+}. Th^{4+} is about the same size as La^{3+}, but carries an additional charge. It is possible that it is set apart from the others by its very large hydrated radius [14] of 11 Å. The singly charged potassium ion clearly has a much smaller effect.

The kinetics of pyrene fluorescence in a humic acid solution to which Sm^{3+} was added provided an interesting insight. Shown in Fig. 4, the time profile appears similar to that of the Th^{4+} solution in Fig. 3. Again the initial rise in fluorescence intensity after the addition of 5×10^{-5} M $SmCl_3$ and its persistence for about 2 h are evident. Then, over a period of another 2 h, a further doubling of the emission intensity was observed. In this case, however, this was accompanied by the gradual formation of a visible precipitate in the cell. Because of the optical configuration of the Hitachi 4500 fluorimeter, which excites a horizontal cross-section of solution near the bottom of the cell, the precipitate settling under gravity in that region gave rise to the increased fluorescence. This indicates that the macroscopic humic acid aggregates carry the (already microscopically sequestered) pyrene down with them, lending further credence to the association model. Furthermore, a parallel can be drawn between the precipitation process and the results shown in Fig. 3. No visible precipitate was observed with Th^{4+}, but it must be remembered that the coagulation process of dissolved humic acid should be viewed as a continuum of aggregation events, starting with intramolecular coiling of the polymer chains. It is therefore reasonable to suggest that the aggregation of humic acid under the influence of

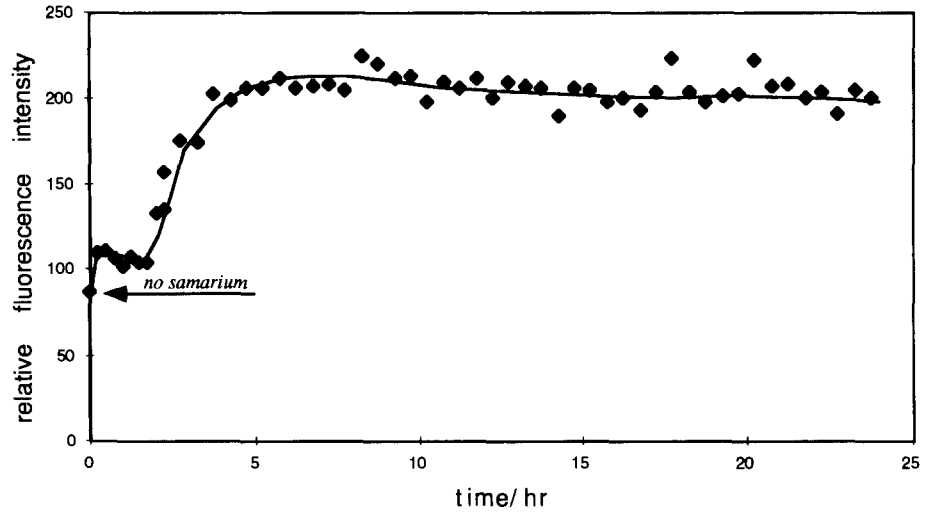

Fig. 4. Variations of pyrene fluorescence with time in a solution containing 10 ppm humic acid and 5×10^{-5} M $SmCl_3$.

Th^{4+}, while producing no precipitate, proceeded to an intermediate stage. The aggregates thus formed slowly settled to the bottom of the cell, like their larger counterparts, concentrating the sequestered pyrene in that region.

4. Conclusions

Ionic size and charge appear to exert a combined effect on the ability of cations to cause pseudomicellization in dissolved humic acid, with higher charge densities being more effective. Macroscopic and microscopic coagulation processes proceed slowly, taking 7 h to reach a final state of aggregation.

Zirconium and hafnium determination by energy dispersive X-ray fluorescence with solid phase preconcentration

Patricio Peralta-Zamora *, Lorena Cornejo-Ponce, Maria Izabel Maretti S. Bueno, José Walter Martins

Universidade Estadual de Campinas, Instituto de Química, CP. 6154, CEP 13083-970, Campinas-SP, Brazil

Abstract

Two preconcentration methods has been developed for simultaneous determination of zirconium and hafnium by energy dispersive X-ray fluorescence (EDXRF). The first method is a liquid–solid extraction procedure with the use of an anionic exchange resin modified with xylenol orange. The second is a precipitation procedure carried out in the presence of lanthanum. Both methods permit significant enhancement of sensitivity in comparison with direct measurement in the aqueous phase. The applicability of both procedures for the preconcentration of Zr and Hf prior to their determination by EDXRF was demonstrated by analyzing synthetic mixtures and a sample of zirconium ore. The results obtained with the use of the modified resin show relative standard deviation of about 4% and good agreement with those obtained by spectrographic analysis. © 1997 Published by Elsevier Science B.V.

Keywords: Hafnium; Preconcentration; X-ray fluorescence; Zirconium

1. Introduction

The simultaneous determination of zirconium and hafnium is one of the most difficult problems of analytical chemistry, because the close similarity of their chemical properties hinders the use of classical analytical methods [1–5]. Colorimetric techniques do not have any interesting application due to unavailability of specific chromogenics agents. The principal contribution of these techniques is reduced to the existence of several differential methods, based on differences between zirconium and hafnium complexes under different acidic conditions [6] or in the presence of specific masking agents [7].

The classic configuration of flame atomic absorption or emission techniques shows little application for this determination due to the heat-resistant characteristics of both species and the high complexity of the emission spectra [1–4]. The use of more energetic atomization systems (i.e., plasma, arc and spark) permits more suitable results only for determination of the concentration ratios [1]. Absolute determinations can be performed by using special calibration methods, typically chemometric tools for correction of mutual spectral interferences [1]. The individual de-

termination of zirconium in silicate rocks by inductively-coupled plasma emission spectrometry were reported by Uchida et al. [8]. However, the results show poor precision (relative standard deviation, RSD, between 14 and 38%).

Due to the great spectral resolution of the instrumental system, energy dispersive X-ray fluorescence permits the determination of Zr-Hf mixtures without important interference problems. However, the low sensitivity of the technique can be resolved only by the use of preconcentration methods [9–21]. The determination of a great number of metallic species by EDXRF is usually preceded by concentration steps which involve the use of ion exchange resins [9,10,12,16], activated charcoal [9,10,17], naphthalene [14], polyurethane [15], modified silica [21] and coprecipitation procedures using ferric hydroxide as a collector [18–20]. The great selectivity reached by the use of chelating resins [22] has contributed to its popularization as solvents system. Xylenol orange has been used for modification of ionic exchanger resins, and for determination of zirconium by solid phase spectrophotometry [23–25].

In this work we propose the use of an ion exchange resin modified with xylenol orange or a lanthanum coprecipitation procedure for preconcentration and simultaneous determination of zirconium–hafnium mixtures by EDXRF.

2. Experimental

2.1. Instrumental

Spectrophotometric determinations were performed with an Intralab DMS-100 UV-Vis Spectrophotometer. X-ray fluorescence measurements were executed on a Spectrace 5000 Energy Dispersive X-ray Fluorescence Spectrometer, equipped with a rhodium tube and a Si(Li) semiconductor crystal detector (irradiation time, 60 s; tube voltage, 30 kV; tube current, 0.20 mA; atmosphere, air; filter, 0.127 mm rhodium film). The measurements were realized at 15.744 KeV for Zr (Kal) and 7.898 KeV for Hf (Lal). The samples were introduced on a cylindrical plastic device from Chemplex, of about 2 cm of height and 3 cm of internal diameter, using a X-ray Mylar film as sample support.

Spectrographic measurements were carried out on Carl Zeiss PGS-2 Emission Spectrometer, equipped with a linear array of photodiodes [26].

2.2. Chemicals and solutions

The zirconium standard solution was prepared by direct dissolution of $ZrOCl_2 . 8H_2O$ (99.5%, Riedel-de Haen) in H_2SO_4 (1:5 v/v). Zirconium hydroxide was precipitated with an aqueous solution of NH_3. The solid was recovered by filtration, thoroughly washed with deionized water and dissolved in HCl (final concentration of HCl, about 2 mol l^{-1}). The hafnium standard solution was prepared from HfO_2 (Specpure, Johnson, Mathey and Co.). The oxide was dissolved with a HF-H_2SO_4 (1:1 v/v) mixture, heating several times almost to dryness with successive additions of concentrated H_2SO_4. The solid residue was dissolved in H_2SO_4 and the hydroxide precipitated with an aqueous solution of NH_3. The solid was recovered by filtration, thoroughly washed with deionized water and dissolved in HCl (final concentration of HCl, about 2 mol l^{-1}). Both solutions were standardized by a gravimetric procedure using mandelic acid [27].

The lanthanum standard solution (40 g l^{-1}) was prepared from La_2O_3 (99%, Carlo Erba). Amberlite IRA-400 anion resin (Koch-Light Laboratories, 100–200 mesh) and Xylenol orange (Fluka A.G., Bucks S.G.) were used without further purification.

The natural sample, purchased from the Energetic and Nuclear Research Institute (IPEN, São Paulo-Brazil), corresponds to a mixture of zirconium and hafnium hydroxides obtained by physical and chemical treatment of a zirconium ore.

2.3. Preparation of modified resin

Dried resin, 40 g, were added to 400 ml of an aqueous solution of xylenol orange (4.3×10^{-3} mol l^{-1}, pH 7.0) and the mixture was vigorously stirred for 6 h. After this impregnation time, the

solid mass was filtered, thoroughly washed with deionized water, dried at 60°C and stored in amber glass flasks.

2.4. Extraction with modified resin

Suitable volumes of solution of Zr and Hf were placed in 200 ml beakers, diluted up to 50 ml with deionized water and adjusted to adequate pH values with aqueous solutions of HCl or NH_3. To these solutions were added 0.5 g of the modified resin. The mixture was stirred for a convenient time and the solid was recovered by filtration in Whatman 41 filter paper, washed with deionized water and dried at 60°C for 2 h. In preliminary studies, the Zr and Hf recuperation was evaluated by colorimetric determination [28] of the remained amounts in the filtrate. For this determination, the filtrate (approximately 50 ml) was led to almost dryness in a water bath, dissolved in 3.0 ml of 0.3 mol l^{-1} HCl, and added of 2.0 ml of xylenol orange 0.05% in HCl 0.3 mol l^{-1}. The concentration of zirconium or hafnium was determined spectrophotometrically at 550 nm, using analytical curves obtained between 0.2 and 2.0 mg l^{-1}. Further determinations were carried out by direct analysis of the solid mass by EDXRF. The concentration of Zr and Hf was determined through external calibration using standard solutions submitted to analogous extraction procedures.

2.5. Preconcentration by precipitation in the presence of lanthanum

Aqueous solutions, 50 ml, containing adequate amounts of Zr and Hf were added to 10 ml of the standard lanthanum solution. The hydroxides were precipitated by addition of an aqueous ammoniacal solution. After 5 min of stirring the precipitate was recovered by filtration and dried at 100°C for 2 h. The recuperation degree was evaluated by colorimetric analysis in the filtrate. Further determinations by EDXRF were directly carried out on the solid fraction.

3. Results and discussion

3.1. Impregnation of the resin

Colorimetric determination of the remaining amount of xylenol orange after the impregnation procedure verified that the efficiency of the impregnation process is very close to 100%. Relating the amounts used of resin (0.5 g) and the xylenol orange amount present in this solid fraction (0.043 ml mol), it is possible to estimate a maximum extraction capacity of about 2000 μg for Zr or 3500 μg for Hf.

3.2. Extraction with modified resin

The extraction of both species is almost complete at similar pH values (pH 4.0–8.0). Although the zirconium and hafnium hydrolysis is favored at these pH values, precipitation was not observed probably due to the low concentration of the analytes used in this study (approximately 2 μg ml^{-1}) and due to the presence of large amounts of sulfate ion, which can displace the hydroxyl groups from hydrolyzed species [1]. The procedure is not selective in this pH region, a result resembling those obtained by the application of other extraction procedures [29,30]. For subsequent determinations, a pH of 7.0 was selected. A X-ray fluorescence spectrum of zirconium and hafnium on the xylenol orange modified resin is presented in Fig. 1.

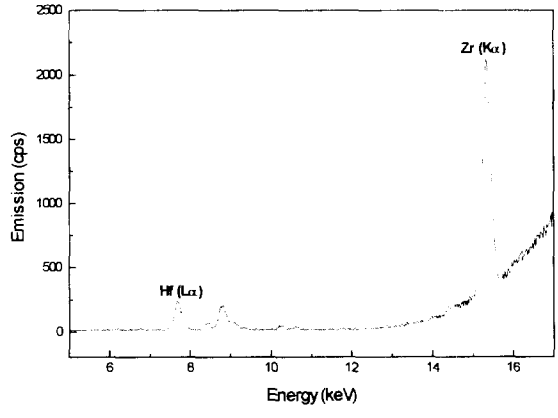

Fig. 1. X-ray fluorescence spectrum of zirconium and hafnium on the xylenol orange modified resin.

100.0	300.0	101.9(1.9)	303.1(1.0)
500.0	100.0	497.3(0.5)	105.9(5.9)
Average difference		1.5%	3.4%
RSD ($n = 5$)		3.0%	4.0%

The quantitative recuperation of Zr and Hf is completed with stirring times of about 15 min. The complete extraction of the analytes in a short time like this, and the great convenience of the involved operations, implies a very important economy of time, mainly when compared with the times required for other preconcentration procedures. Liquid–liquid extraction procedures and liquid–solid methodologies executed in column systems, for example, are slower techniques because of the difficulty in reaching equilibrium conditions and long time elution stages, respectively. For posterior determinations stirring times of 20 min were selected.

Using sample volumes between 50 and 200 ml, the extraction of Zr and Hf is quantitative. With higher volumes the recuperation of the analytes is decreased, presumably due to excessive dilution of the solid extractor and consequently inefficient contact of the phases during the selected stirring time. If we consider the complete transference of the Zr or Hf amounts present in this high volume of aqueous phase for a small mass of resin, it is possible to perceive the great preconcentration potentiality of the proposed method. For subsequent determinations maximum volumes of 200 ml were selected.

Is known that the particle size have a great importance on the X-ray fluorescence measurements, nevertheless preliminary studies shown that for ours experimental conditions insignificant differences are obtained by using resin of size equivalent to 41–60 or 150–190 mesh.

Executing the extraction procedure in the optimized conditions and measuring the EDXRF emission directly on the solid mass, linear calibration curves are obtained for a large concentration range (10–800 μg for zirconium, and 50–800 μg for hafnium) with typical correlations higher than 0.999. Considering the sensibility of the determination as a function of the inclination of the analytical curves, we observed that the proposed method permits sensitivity increases of about 25 times for Zr and 40 times for Hf, in relation to direct measurement in the aqueous phase.

3.3. Analysis of synthetic samples

The results obtained for synthetic mixtures of diverse composition (Table 1) indicate high concordance between added and found amounts. The precision of the methodology, expressed as relative standard deviation for five determinations (about 3% for Zr and 4% for Hf), is very similar to that obtained by other techniques [9,10].

3.4. Precipitation in the presence of lanthanum

This method appears as a very simple alternative for preconcentration of metallic species because it depends on but a few experimental variables. The added amount of lanthanum, for example, is not a critical parameter. The selected value was defined only to facilitate the filtration and transference operations and as a function of the capacity of the sample compartment. Prelimi-

Table 2
Zr-Hf determination from synthetic samples by precipitation in the presence of lanthanum

Added (mg)		Found (mg)	
Zr	Hf	Zr (difference, %)	Hf (difference, %)
100.0	100.0	100.8(0.8)	101.2(1.2)
100.0	150.0	98.7(1.3)	150.9(0.6)
100.0	200.0	99.5(0.5)	201.9(1.0)
300.0	200.0	297.4(0.9)	203.4(1.7)
500.0	200.0	498.7(0.3)	205.6(2.8)
Average difference		0.8	1.5%
RSD ($n = 5$)		4.0%	4.0%

nary experiments indicated 300 ml as a maximum sample volume; with higher volumes the recuperation of the metallic species is incomplete.

The calibration curves show good linearity ($r > 0.999$) over a large concentration range (300–1000 μg ml^{-1}). However, the sensitivity is lower than that obtained by extraction on the modified resin. In any case, the sensitivity is enhanced about 4 times in relation to the directly measurement in the aqueous phase.

The results for the Zr-Hf determination from synthetic mixtures (Table 2) show high coherence with the added amounts, with typical standard deviations of about 4%. The accuracy of the proposed method is better than those obtained by Ricci [18] (5–10%) through a coprecipitation procedure using ferric hydroxide as a collector agent.

3.5. Zr-Hf determination from natural samples

Both proposed preconcentration procedures were evaluated for determination of Zr-Hf mixtures from natural samples, which result from physical and chemical treatments of zirconium ore. The results for zirconium determination using the modified resin and the coprecipitation procedure (Table 3) show a high coherence with those obtained by spectrographic analysis. By applying the statistical Student's test for 95% of confidence, we verify that for hafnium determination, only the modified resin provides comparable results. The results obtained by the coprecipitation procedure shows significant differences with those obtained by spectrographic analysis and by using the modified resin.

4. Conclusions

Both preconcentration procedures permit the quantitative recuperation of Zr and Hf from large volumes of aqueous samples. For this motive they represent a potential and simple alternative for determination of metallic species by EDXRF. The procedure based on the use of a modified resin permits a significant increase of the sensitivity of

Table 3
Zr-Hf determination from zirconium ore using the proposed methods

Run	Extraction with modified resin (%)		Precipitation (%)		Spectrography (%)	
	Zr	Hf	Zr	Hf	Zr	Hf
1	95.4	4.6	96.5	3.5	95.0	5.0

the determination and can be used in analyses of low concentration samples. The non-selectivity of the extraction procedure with the use of modified resin is not a significant inconvenient, because can be compensate for the great selectivity presented for the EDXRF technique.

Determination of tin in canned foods by UV/visible spectrophotometric technique using mixed surfactants

Xirong Huang *, Wenjuan Zhang, Shuhan Han, Xinqian Wang

Department of Chemistry, Shandong University, Jinan 250100, People's Republic of China

Received 11 June 1996; received in revised form 23 September 1996; accepted 27 September 1996

Abstract

The complex of tin(IV) with bromopyrogallol red (BPR) in the presence of nonyl phenoxy polyethoxyethanol (OP) and cetyltrimethylammonium bromide (CTAB) has a sensitive absorption peak at 304 nm. Under the optimal conditions, Beer's law is obeyed over the range 0.1–2.5 μg ml^{-1} Sn(IV) with molar absorptivity being 8.2×10^4 l mol^{-1} cm^{-1} and detection limit 0.018 μg ml^{-1}. As compared with the visible method which also uses BPR as chromogenic reagent ($\lambda_{max} = 550$ nm), our method is sensitive and selective because of the complex's high, sharp absorption peak. In addition, the present method is simple and rapid, no heating or standing is needed. By means of the mixed surfactants the precipitation caused by the ion association of cetyltrimethylammonium cation and I_3^- anion is avoided if iodide is used for separating micro amounts of tin(IV) from a sample matrix. An application of the proposed method to the determination of Sn(IV) in a canned food was made with satisfactory results. © 1997 Elsevier Science B.V.

Keywords: Spectrophotometry; Tin determination; Bromopyrogallol red; Surfactant; Canned food

1. Introduction

It is of great importance to establish a method for the determination of the inorganic tin at μg or sub μg levels. Because micro amounts of tin have an adverse effect on deep-drawing steels [1], the amount of tin present in these steels must be monitored. In addition, studies on marine antifouling coatings also need a method for tin determination in seawater [2]. If a tin-plated iron can is used for package, the content of tin in food is indicative of the quality of the food in storage although inorganic tin is nontoxic for living systems. It is also worth a mention that a sensitive method for inorganic tin determination could be used as an alternative for organic tin (toxic)determination after proper modifications.

To date, there are many spectrophotometric methods for tin determination such as extraction spectrophotometry [3], solid phase spectrophotometry [4,5] and micelle spectrophotometry [6–14]. In the case of micelle spectrophotometry, each chromogenic system has its advantages and disadvantages with respect to sensitivity, selectivity and rapidity due to using different chromogenic reagents and surfactants. As the chromogenic

reagents used for tin determination are almost all anionic dyes, and, hence, the surfactants are only cationic ones such as cetyltrimethylammonium bromide (CTAB) and cetylpyridinium bromide (CPB), precipitates often occur, especially at low room temperature [13] or after heating, due to the interaction of anionic dyes with cationic surfactants (CSF). In view of the properties of mixed surfactants such as low critical micelle concentration (CMC) (ion-association, and hence sensitisation, occurred only above CMC [1,15]), we substituted a mixed surfactant solution composed of CTAB and nonyl phenoxy polyethoxyethanol (OP) for single CTAB (Systems in the presence of CTAB and sodium dodecylsulfate (SDS) were turbid even if not heated). Preliminary tests showed that the use of the mixed surfactant solution could not only get rid of the drawbacks occurred when single CSF was used, but also enhance the sensitivity. In this paper, we developed a spectrophotometric method for Sn(IV) determination with bromopyrogallol red (BPR) in the presence of OP and CTAB as well as applied it to the determination of tin in canned foods.

2. Experimental

2.1. Apparatus

The UV-vis absorption spectra were recorded on a Shimadzu UV-240 spectrophotometer using a matched pair of 1 cm quartz cuvettes. The pHs of solutions were measured using a model PHS-2 pH meter.

2.2. Reagents

Unless otherwise stated, all reagents used were of analytical grade and their solutions were prepared by weighing with distilled water as solvent.

The concentration of each reagent was as follows:

(1) bromopyrogallol red (BPR), from Merck, 0.01%,

(2) cetyltrimethylammonium bromide (CTAB), from Jining Institute of Chemical Industry, China, 0.1%,

(3) nonyl phenoxy polyethoxyethanol (containing approximately 10 moles of ethylene oxide) (OP), from Wuhan Tongxing Chemical Reagent Plant, China, 0.2%,

(4) tin(IV) stock solution, 100 μg ml^{-1}, prepared by dissolving 0.1000 g of granulated tin metal (Baker) in 10 ml of concentrated H_2SO_4, and then diluting to 1 l with concentrated H_2SO_4 and water so that the concentration of H_2SO_4 was 0.1 mol l^{-1}; tin(IV) working solution, 10 μg ml^{-1}, prepared fresh, when required, by diluting 10 ml of 100 μg ml^{-1} tin(IV) stock solution to 100 ml with water.

2.3. Procedure

Pipette to a 10 ml colorimetric tube 3.0 ml of 0.01% BPR, 0.8 ml of 0.2% OP, 0.2ml of 0.1% CTAB, 2.0 ml of 95% ethanol, in that order. After mixing, add a portion of the working solution, (or sample solution) and dilute to the mark with 0.10 mol l^{-1} H_2SO_4. Finally, transfer the resulting solution to the quartz cuvettes and record the absorption spectrum using corresponding blank as reference.

3. Results and discussion

3.1. Absorption spectra

The complex of Sn(IV) with BPR in the presence of OP + CTAB had two sensitive absorption peaks in the UV/Visible zone (see Fig. 1). Under any circumstances, the peak height and half-band width of each ultraviolet absorption peak were better than those of corresponding visible absorption peak, respectively. So we chose the ultraviolet peak for tin determination. It is worth mentioning that in the visible range the absorption peak of Sn(IV)-BPR complex in the presence of single CTAB was much similar in peak position and half-band width to that in the presence of cetylpyridinium bromide (CPB) [6].

3.2. Selection of experimental conditions

3.2.1. Composition of mixed surfactant solution and its volume

Let the total volume of 0.2% OP + 0.1% CTAB be equal to 1.0 ml and change the relative volumes of the OP and the CTAB (other conditions as in Fig. 1). We found that 0.8:0.2 (0.2% OP:0.1% CTAB) was the optimum volume ratio and 1.0 ml was none other than the optimum volume of the mixed surfactant solution prepared in the optimum ratio. The peak under such conditions was the highest with its position being at 304 nm.

3.2.2. Effect of acidity

With the decrease of the pH of the system (conditions as in Fig. 1(1) except the volume of 0.1 mol l^{-1} H_2SO_4), the absorbance of the system at 304 nm first increased gradually (pH = 2.3–1.6) then changed little (pH = 1.6–1.0). After that, it decreased by a big margin (pH = 0.8–0.5). For the above system, maximum absorbance occurred at 1.42 (pH of the final solution) where 1.3 ml of 0.10 mol l^{-1} H_2SO_4 was added for adjusting the acidity of the system. Owing to the effect of pH on the absorbance of the system was very small over the pH range 1.0–1.6, we controlled the final pH of each system used for the calibration curve of tin(IV) simply by diluting with 0.1 mol l^{-1} H_2SO_4 to the mark (strong acid (pH < 2) itself is a buffering agent).

By the way, ionic strength, adjusted with up to 1.0 ml of 1.0 mol l^{-1} KCl, had almost no influence on the absorbance (if 2 ml of 0.1 mol l^{-1} H_2SO_4 was added, then the ionic strength from the solution itself to which the standard procedure was applied was roughly 0.06). A detailed investigation into the influence was not made.

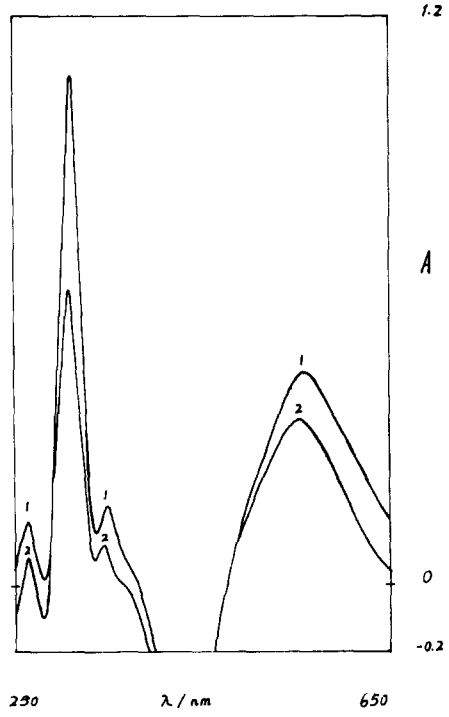

Fig. 1. Absorption spectra of Sn(IV)-BPR complex in the presence of OP + CTAB(1) and CTAB(2). Conditions: 3.0 ml of 0.01% BPR + 1.0 ml of a mixed surfactant solution (V_{OP}/V_{CTAB} = 8/2)(1) or 1.0 ml of 0.1%CTAB(2) + 2.0 ml of 95% ethanol + 15 μg Sn(IV) + 1.3 ml of 0.1 mol l^{-1} H_2SO_4.

3.2.3. Volume of 0.01% BPR

For a system containing 20 μg Sn(IV) (conditions as in the procedure except the volume of 0.01% BPR), with the increase of the volume of 0.01% BPR, the absorbance increased first rapidly then very slowly. After that, it dropped slowly. The optimal volume of 0.01% BPR was 3.0–4.0 ml. Taking into account the absorption of corresponding reagent blank at 304 nm, we chose 3.0 ml as optimum (the molar ratio of BPR to Sn was ca. 3.5:1).

3.2.4. Effect of ethanol

Ethanol had a sensitizing effect on the determination of Sn. For the system composed of 3.0 ml of 0.01% BPR, 1.0 ml of the mixed surfactant solution, 1.0 ml of 0.10 mol l^{-1} H_2SO_4 and 20 μg Sn(IV), the absorbance of the system increased rapidly with the increase of the volume of ethanol followed by remaining almost unchanged. The optimum amount of 95% ethanol was 2–3 ml. An excess of alcohol over the optimum could cause the absorbance to decrease. It was reported [6] that CPB was the optimal one among several cationic surfactants. However, we found that both CPB and CTAB have almost the same effects. This discrepancy lies in the solvent used for the

preparation of CSF (In Ref. [6], the solvent for CPB was 20% methanol in water, while that for CTAB was pure water).

Ethanol also had a stabilizing effect on the micellar system used for tin determination [16]. This effect is the reason their system [6] was not turbid even if heated in a water bath at 80–90°C (if alcohol was not added in CPB, we found their system would be turbid especially when a slight excess of Sn(IV) was present). In our system, however, this effect became insignificant because of the presence of OP (when heated our system was not turbid even if ethanol was not added).

3.2.5. The order of addition of the reagents

The order of addition of the reagents was studied. Results demonstrated that the order has a great effect on the absorbance. The chromogenic reagent and the surfactants must be added before the Sn(IV) or sample solution (see Procedure in Section 2).

3.2.6. Stability of the complex

The chromogenic reaction completed immediately after all reagents were added in the given order, and the chromogenic system could stabilize for at least 4 h.

3.3. Composition of the complex

The composition ratio of the Sn(IV)-BPR complex obtained using the mole-ratio method and the method of continuous variations was 1:3 (Sn(IV):BPR). We did not obtain the 1:1 ratio even if small amounts of BPR were added, which was not in accord with the results in Ref. [6]. A possible explanation for this difference was that the polyoxyethylene ether chains of OP molecules in a micelle could form a 'cage' like a crown ether molecule to capture Sn(IV) [17].

3.4. Analytical characteristics

Under the optimal conditions, Beer's law was obeyed over the range 0.1–2.5 μg ml^{-1} Sn(IV) with molar absorptivity being 8.2×10^4 l mol^{-1} cm^{-1} and detection limit (based on three times the standard deviation ($n = 11$) of the blank solution) being 0.018 μg ml^{-1}. For 15 μg Sn(IV), the relative standard deviation (R.S.D.) of seven replicate determinations was 1.6%.

3.5. Interference study

Under the optimal conditions, the effects of various foreign ions on the determination of 10 μg Sn(IV) were examined separately. With a relative error being less than ± 3%, the tolerance limits (μg) for various metal ions were as follows: Ca(II), Mg(II), As(III), Fe(II), Cr(III), Pb(II)(1000); Ni(II), Zn(II), Cu(II), Co(II), Mn(II)(200); Fe(III), W(VI), V(V)(10); Mo(VI), Sb(III), Cr(VI)(5). The tolerance limits for anions (used as complexing or reducing agents or media): lactic acid, oxalic acid, ascorbic acid, citric acid, NH_2OH HCl (2 g); iodide (13 mg)(26 mg (if 1.0 ml of 2% ascorbic acid was added)); chloride (100 mg); sulfate (200 mg). Nitrate and EDTA caused serious positive and negative interferences, respectively. Incidentally, when the volume of 0.1 mol l^{-1} EDTA exceeded 1.0 ml, the system became turbid (the white precipitate may be the ion-association complex of EDTa with CTAB). Sn(II), as $SnCl_2$ $2H_2O$, had almost the same results as Sn(IV) with respect to peak shape and peak position; for equal amounts of tin, however, the peak height of Sn(II) was a little lower than (ca. 93%) that of Sn(IV).

The interferences caused by Cr(VI), Fe(III), Sb(III), W(VI), Mo(VI) and V(V) could be reduced by reduction with 1 ml of 2% ascorbate (for Cr(VI) from 5 to 1000 μg and Fe(III) from 10 to 1000 μg) and by masking with 1 ml of 2% citrate (for Sb(III) from 5 to 20 μg and W(VI) from 10 to 30 μg [8]) as well as 1 ml of 2% lactate (for Mo(VI) from 5 to 30 μg and V(V) from 10 to 30 μg [1]).

3.6. Sample analysis

An application of the proposed method to canned meat, produced by Jinan Meat Packing Plant was made. It was told that the packing material was tin-plated iron sheet; so the main interferent was Fe(III), which could be eliminated readily by its reduction with 1.0 ml of 2% ascorbic acid.

Table 1
Recovery assays of Sn(IV) in canned foods

Added (μg)	Found[a] (μg)	R.S.D. (%)	Recovery (%)
0	11.3 (10.9)[b]	2.7	—
5	16.7	2.1	108.0
10	21.6	1.9	103.0
15	26.1	2.3	98.7

[a]Mean of five replicate determinations.
[b]Datum in parentheses was the value obtained by hydride generation [9]-atomic absorption spectrometry [18].

Prior to the determination, the sample was pretreated in the following way:

Weigh ca. 2.0 g of the meat; dry and ash it at 600°C. After that, dissolve the ash with 10 ml of concentrated HCl and dilute to 50 ml with distilled water and 1 mol l^{-1} NaOH so that the final pH was ca. 1. Pipette 1.0 ml of the digest for the determination.

The tin content (mean of five replicate determinations) obtained was 282.5 mg kg^{-1} (R.S.D. = 2.7%).

In order to check the accuracy of the proposed method, a recovery study was carried out on 1.0 ml of the digested solution. The average recovery was 103.2% (see Table 1), which is acceptable.

Usually, the iodide extraction method was used for separating micro amounts of Sn(IV) from interfering matrices. However, this sample pretreatment method could hardly be combined with other micelle spectrophotometric methods, in which a single CSF was used, owing to the precipitation of CSF by I_3^- introduced from extract. Probably because of the solubilization of the mixed micelles composed mainly of OP [16], the present method could preclude the precipitation even if no ascorbic acid was added (it was reported that ascorbic acid could preclude this phenomenon [1,11,19]).

In order to demonstrate that the proposed method could be compatible with the iodide extraction method, we digested the ashed sample, according to Ref. [1], first with concentrated HCl then concentrated H_2SO_4 (to drive off remaining HCl because chloride interfered in the extraction of SnI_4). As the contents of Cu(II) and Pb(II) were very low, their interferences (due to reactions with iodide) were not significant. After digestion, Sn(IV), as SnI_4, was extracted into toluene, then back-extracted into 0.2 mol l^{-1} HCl (a detailed procedure see Ref. [1]). Prior to the determination, no ascorbic acid was added to the extracts to preclude iodine (not Fe(III)). The amount of Sn(IV) found in this method was 11.0 μg ml^{-1}, which was satisfactory to us.

3.7. Conclusions

First, the proposed method is simple and rapid. The chromogenic reaction completed immediately after all reagents were added. No heating [6] or standing [1,2,14] was needed.

Second, the proposed method is sensitive. Its molar absorptivity at 304 nm was nearly three times as much as that in Ref. [6] ($\varepsilon = 3.0 \times 10^4$ l mol^{-1} cm^{-1} at 550 nm), which also used BPR as chromogenic reagent, more than five times as much as that in Ref. [3] ($\varepsilon = 1.6 \times 10^4$ mol^{-1} cm^{-1}), which was lately obtained by extraction spectrometry, and comparable to the latest result reported in Ref. [14] ($\varepsilon = 1.03 \times 10^5$ l mol^{-1} cm^{-1}). In terms of detection limit, the result of our method was as good as that obtained by hydride generation-flame AAS [20].

Third, the selectivity of our method is high because of its narrow half-band width. In addition, the linear range of our method is about three times as wide as that in Ref. [6].

Last but not the least, difficulties (precipitation of CSF by I_3^-) experienced by other researchers [11,16] in combining the proposed method with the selective extraction of SnI_4 have been overcome by means of the mixed surfactants.

Received 15 April 1996; received in revised form 11 September 1996; accepted 26 September 1996

Abstract

A differential pulse voltammetric enzyme-linked immunoassay for the determination of *helicobacter pylori* (*H. pylori*) specific IgG antibody in human serum has been developed. The method is based on coupling the oxidation reaction of 3,3′,5,5′-tetramethylbenzidine (TMB)-H_2O_2 that is catalysed by horseradish peroxidase-IgG(HRP-IgG) conjugate with the electro-reduction of the enzymatic product to measure the activity of HRP-IgG. The latter reaction exhibits a sensitive differential pulse voltammetric response at 0.1 V (versus Ag/AgCl) in pH 4.0 acetate buffer solution. So, the *H. pylori* specific IgG antibody could be detected. The detection limit of present method for *H. pylori* specific IgG antibody was 1.0 units ml^{-1}, which was about seven times lower than that obtained by traditional spectrophotometric ELISA procedure. © 1997 Elsevier Science B.V.

Keywords: *Helicobacter pylori*; Immunoglobulin G (IgG) antibody; Serum

1. Introduction

H. pylori is a curved bacillus in close contact with gastric epithelium in biopsy samples from patients showing active chronic gastritis. *H. pylori* can cause acute gastritis and may lead to chronic gastritis [1]. The determination of *H. pylori* is valuable in diagnosis of gastritis and peptic ulcers. The current method for the determination of *H. pylori* is enzyme-linked immunosorbent assay (ELISA). In the ELISA, antibody production against *H. pylori* is studied, the presence of high IgG titer specific to *H. pylori* may show active *H. pylori* infection. Antibodies in the serum sample are allowed to react immunologically with the purified *H. pylori* antigens that are immobilized on the microwells. After washing off the unbound materials, the bound antibodies are quantitated by an enzyme labelled second antibodies specific to human IgG. A substrate is added and the intensity of the color generated is directly proportional to the concentration of the specific IgG that reacted with the *H. pylori* group specific antigens. Although ELISA is a popular assay in clinical examination, the relatively

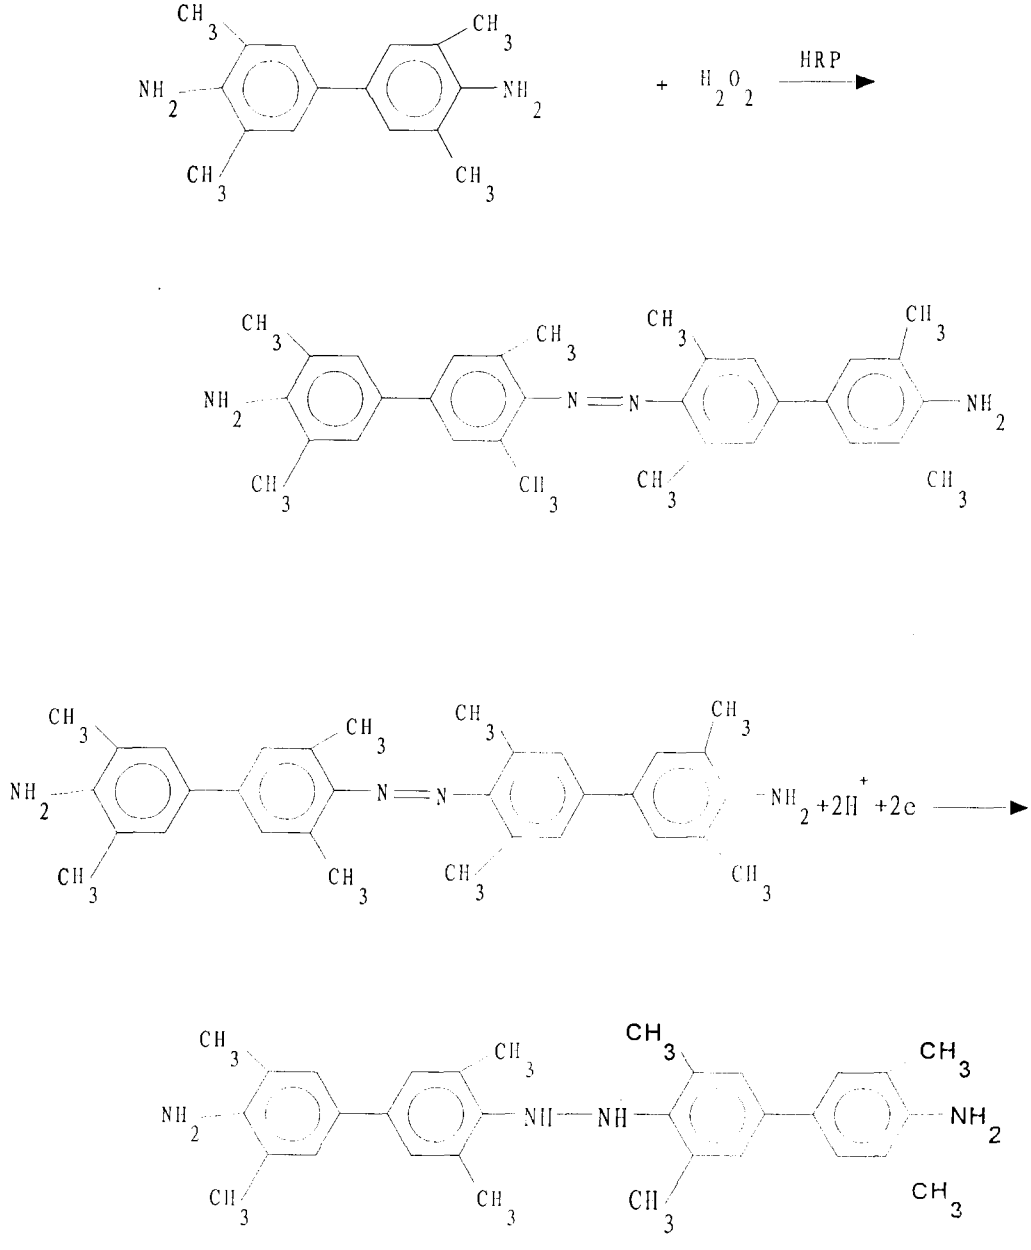
poor detection limit with absorbance spectrophotometry is one cause of its lack of sensitivity [2,3].

Immunoassay with electrochemical detection appears to have some inherent advantages over the more widely used spectrophotometric techniques [4]. Lower detection limits and wider working detection range can be achieved with Morden electrochemical techniques. One approach used in such techniques is to employ an enzyme label that generates an electrochemically active product. Many of the recent studies have utilized amperometric detection of electroactive species, as *p*-aminophenol [5], the reduced form to 2,6-dichloroindophenol [6], 1-naphthol [7] and NADH [8] generated catalytically by an enzyme label. But to our knowledge, voltammetric immunoassay method was reported much less than amperometric immunoassay method.

In this paper, we established a voltammetric enzyme-linked immunoassay for *H. pylori* specific IgG antibody using HRP as labeled enzyme and TMB-H_2O_2 as substrate. The enzymatic product 4,4′-di(3,5-dimethyl-4-amino),2,2′,6,6′-tetramethylazobenzene is electroactive and can be detected by differential pulse voltammetry. The assay shows high sensitivity and accuracy, and the electrochemical detection can be done within half a minute.

The enzymatic coupling reaction scheme and the electrochemical reaction scheme are as follows.



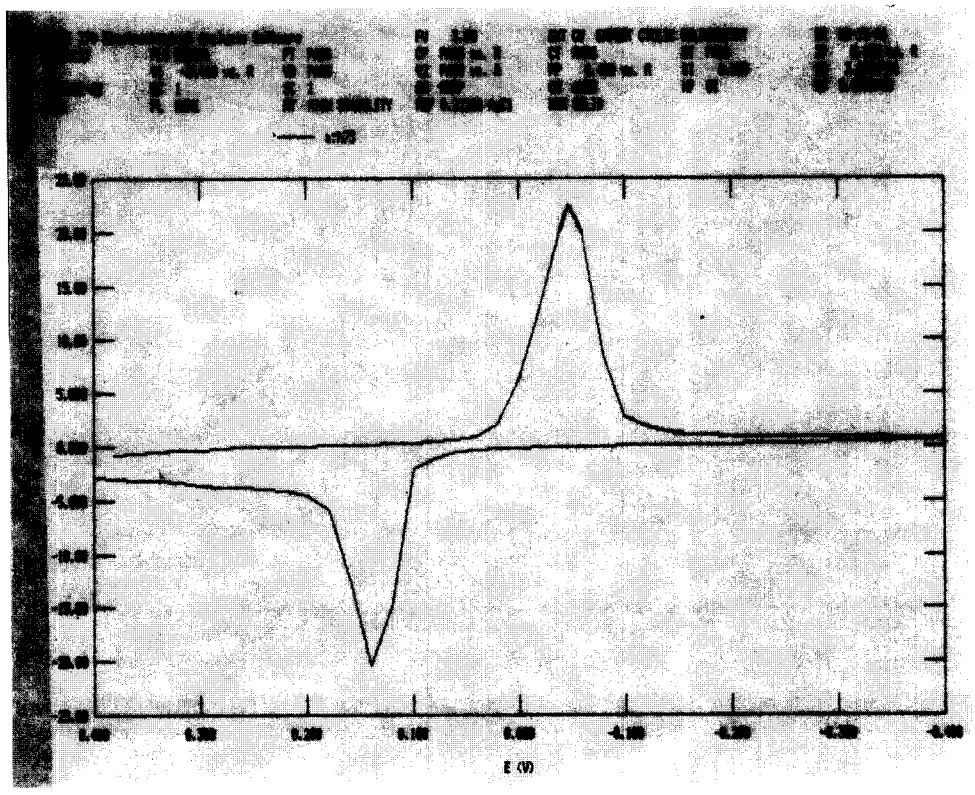


Fig. 1. Cyclic voltammogram of the enzymatic product in 0.2 mol l^{-1} pH 4.0 acetate/DMSO buffer solution. TMB: 0.5×10^{-3} mol l^{-1}, H_2O_2: 0.8×10^{-3} mol l^{-1}, HRP-IgG: $1{:}5.0 \times 10^{6}$ scan rate: 300 mV/S.

2. Experimental

2.1. Reagents and apparatus

A ELISA test kit for *H. pylori* specific IgG antibodies measurement was purchased from BIO-RAD laboratories (USA) and was used accordance with manufacture instructions [9]. In the kit, the serum diluent concentrate was pH 7.4 phosphate saline with PEG, Tween, 0.002% Thimerosal and 0.01% sodium azide. The substrate solution was TMB-H_2O_2 in pH 5.0 acetate/DMSO buffer solution. The ratio of the DMSO to the acetate buffer was 1%, and it was constant in all the experiments. The wash buffer concentrate was pH 7.4 phosphate buffered saline with Tween 20, 0.02% Thimerosal and 0.01% Gentamicin. The stop solution was 1 mol l^{-1} H_2SO_4. The voltammetric determination was done with an electrochemical system (Model 270, EG and G, USA). The working electrode was a home made gold disk electrode. The diameter of it was 0.5 mm. The counter electrode was a platinum wire and the reference electrode was a Ag/AgCl electrode with 0.1 mol l^{-1} KCL. Before use, the electrode was prepared as follows: first, polish the electrode by rough and fine sand paper, respectively. Then, polish it to a mirror smoothness on silk by successively fine grade of alumina, the final diameter of which was 0.05 μm. Finally, clean the electrode by ultrasonic waves.

The absorbancies were detected by a DYNATECH MR7000 microplate readers (USA).

2.2. H. pylori specific IgG antibody immunoassay

A series of human serum *H. pylori* specific IgG

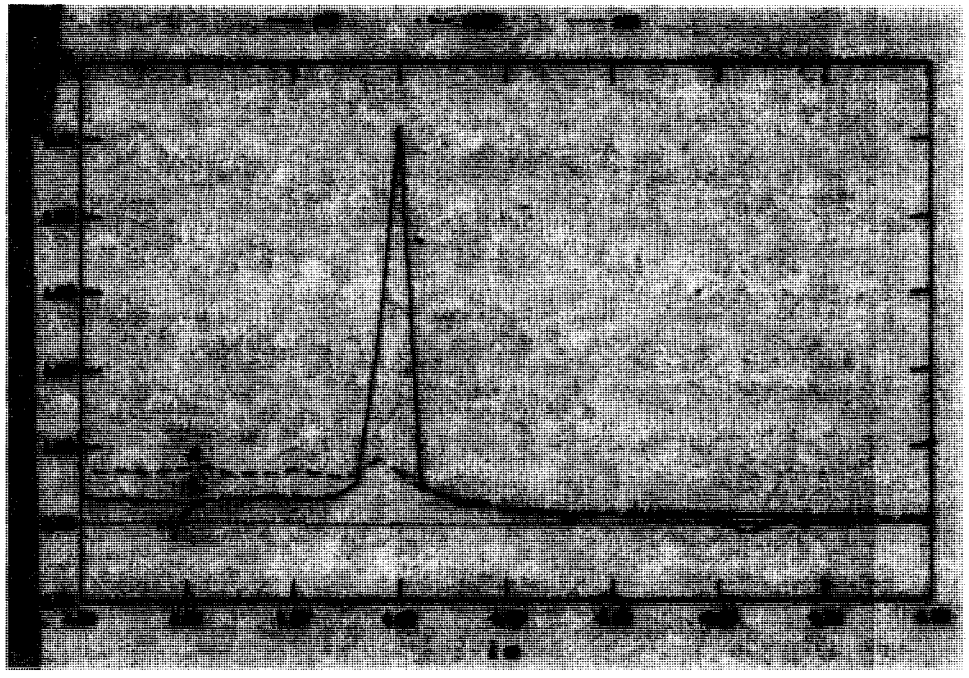

Fig. 2. Differential pulse voltammogram of the enzymatic product. 1. 0.2 mol l^{-1} pH 4.0 acetate/DMSO buffer solution. 2. $1 + 0.5 \times 10^{-3}$ mol l^{-1} TMB + 0.8×10^{-3} mol l^{-1} H_2O_2. 3. 2 + HRP-IgG($1:5.0 \times 10^6$). Pulse height: 60 mV, pulse width: 0.05 S, scan rate: 300 mV/S.

antibody calibrators that covered the clinically relevant range (0–100 units ml^{-1}) was supplied with the ELISA test kit. A standard curve for the spectrophotometric procedure was produced by following manufacture's protocol. Concentrations of *H. pyroli* specific IgG antibody were detected spectrophotometrically by measuring absorbance changes at 450 nm.

2.3. Voltammetric H. pylori specific IgG antibody immunoassay

After the H_2SO_4 termination in the ELISA procedure, 22 ul 2 mol l^{-1} NaOH was added to the well of an ELISA plate to return its pH to 4.0. Without separation, the small three-electrode system was directly inserted in the well for voltammetric determination. The scan rate was 300 mV/S,the initial potential was 0.40 V, the final potential was −0.40 V. For DPV detection, the pulse height was 60 mV, the pulse width was 0.05 S.

3. Results and discussion

3.1. Cyclic voltammetry of the enzymatic product

Fig. 1 is a cyclic voltammogram of the enzymatic product formed by H_2O_2 oxidizing TMB catalysed by HRP in 0.2 mol l^{-1} pH 4.0 acetate/DMSO buffer solution. It shows that enzymatic product could give a quasi-reversible current response. A pair of well-defined cathodic and anodic peaks appeared. E_{pc} and E_{pa} were −0.04 V and 0.14 V, respectively. The existence of the anodic peak suggests that the product of electroreduction of the enzymatic product can be oxidized again at the electrode when the scan direction is reversed. The influence of scan rate on the peak current was studied, the response of peak current was linear with respect to the scan rate between 50 and 300 mV/S, suggesting the adsorption of the enzymatic product and the electroreduction process of the enzymatic product is adsorption controlled [10].

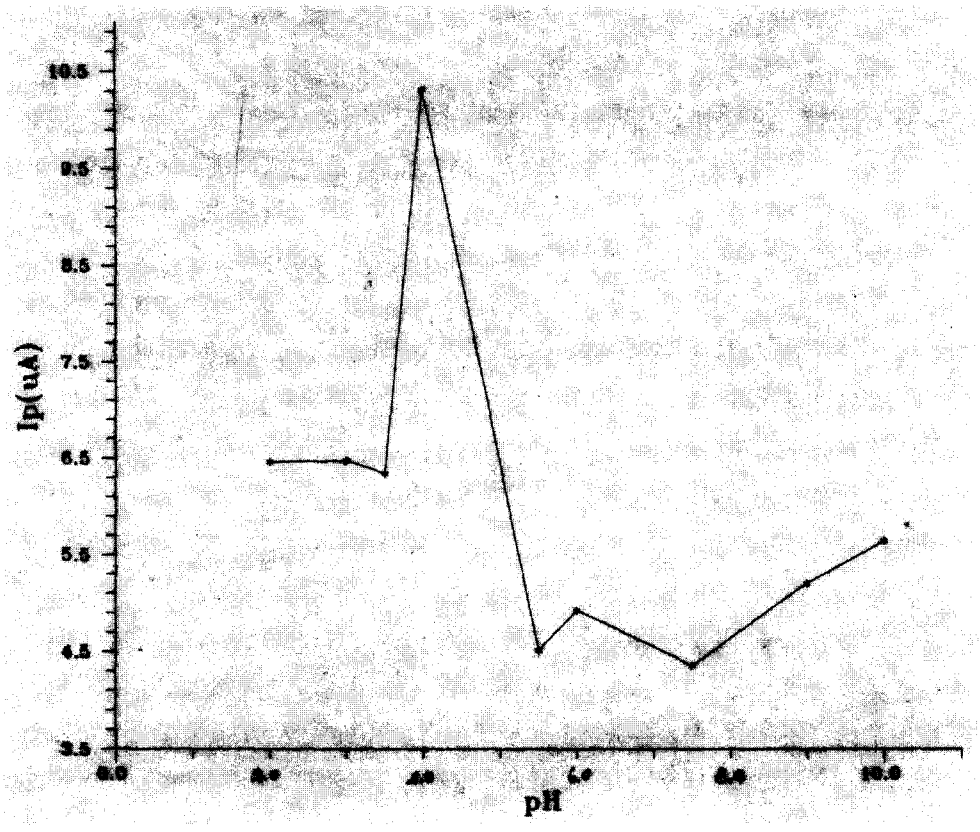

Fig. 3. Effect of pH on differential pulse voltammetric response of the enzymatic product. Conditions are the same as Fig. 2.

3.2. *Differential pulse voltammetric response of the enzymatic product*

The linear sweep voltammetry, the modern square wave voltammetry, the normal pulse voltammetry and the differential pulse voltammetry (DPV) all have excellent voltammetric peaks in the detection of the enzymatic product. Among these methods, DPV has the advantages of the highest sensitivity and the lowest detection limit. Fig. 2 shows the result of the differential pulse voltammetry. Curve 1 shows the situation that in the coupling reaction process there is nothing but acetate buffer solution that has no DPV response. Curve 2, which presents a lower DPV peak at 0.1 V (versus Ag/Ag CL) potential, shows the situation that the coupling reaction process has acetate buffer solution + TMB + H_2O_2. There is a blank peak that is due to a slow oxidation of TMB by H_2O_2 and the high sensitivity of this method. Curve 3 shows the situation at the time when HRP was added to the former solution. Owing to the addition of HRP, the product of the enzymatic reaction produced a high well-shaped DPV peak. Comparing curve 3 with curve 2, we could find that the peak potential did not move practically, but the peak current increased sharply. This means that HRP could highly speed up the oxidizing reaction of TMB by H_2O_2. With this electroreduction peak, free HRP and different labelled HRP can be detected. By means of immunoassay, different antibodies and antigens can also be identified.

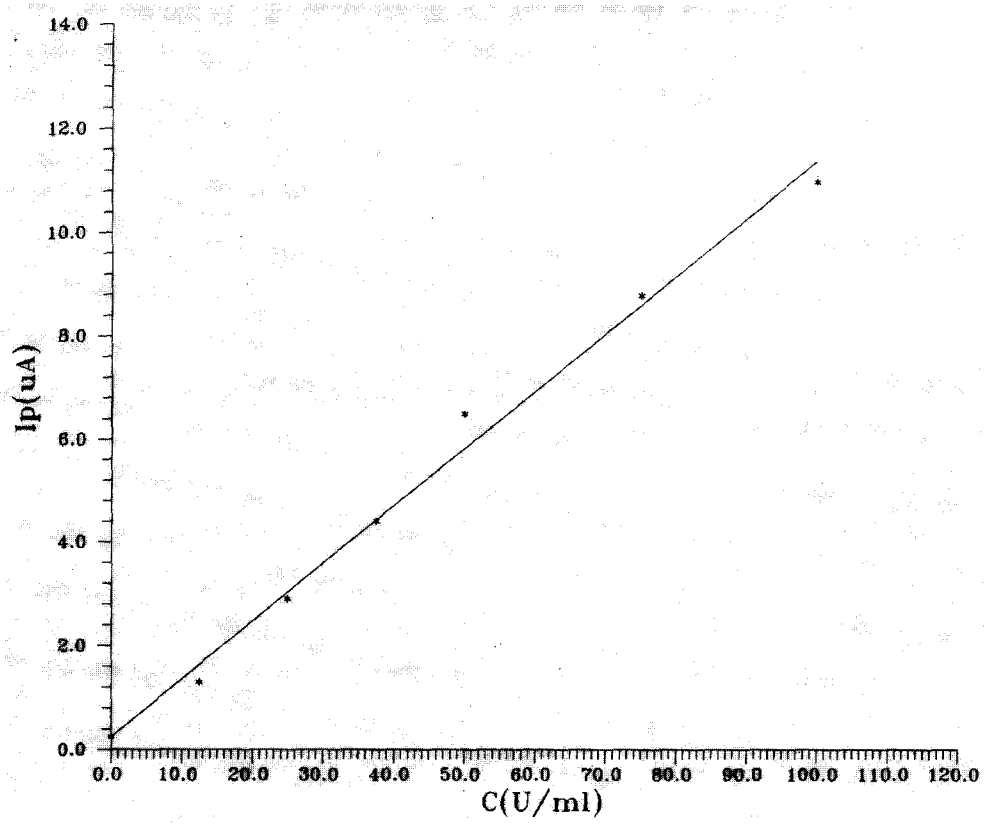

Fig. 4. Calibration curve for the determination of *H. pyroli* specific IgG antibody by differential pulse voltammetry. Conditions are the same as Fig. 2.

3.3. Optimum conditions for the determination of the enzymatic product

To check the effect of pH on the DPV response of the enzymatic product, successively increased volume of 2 mol l^{-1} NaOH was added to adjust the pH of the determination system after the enzymatic product formation and H_2SO_4 termination in the ELISA procedure. As shown in Fig. 3, the peak current I_p remains relatively low value between pH 1.5–3.5 and 5.5–10.0, but I_p increases sharply in pH 3.5–4.0, and reaches maximum value at pH 4.0, then it decreases at higher pH. So, pH 4.0 was selected as the working pH considering the response sensitivity.

DPV parameters were adjusted to optimize the instrument condition. Although I_p was greater for higher pulse height between 10–100 mV, a sharper peak was found at 60 mV using pulse width 0.05 S. A scan increment of 20 mV and a step time of 55 mS were selected.

3.4. Quantitative test for the detection of H. pylori specific IgG antibody

Under the selected conditions described above, the DPV response of the enzymatic product is proportional to the concentration of *H. pylori* specific IgG antibody in the serum. A linear calibration curve for the detection of *H. pyroli* specific IgG antibody in serum was produced over the range of 0–100 units ml^{-1} as shown in Fig. 4. The linear regression equation was $C_{HP} = 8.88\ I_p - 1.57$ with the linear relation coefficient (r) 0.996. The relative standard deviation (RSD) for the determination of 25 units ml^{-1} *H. pylori*

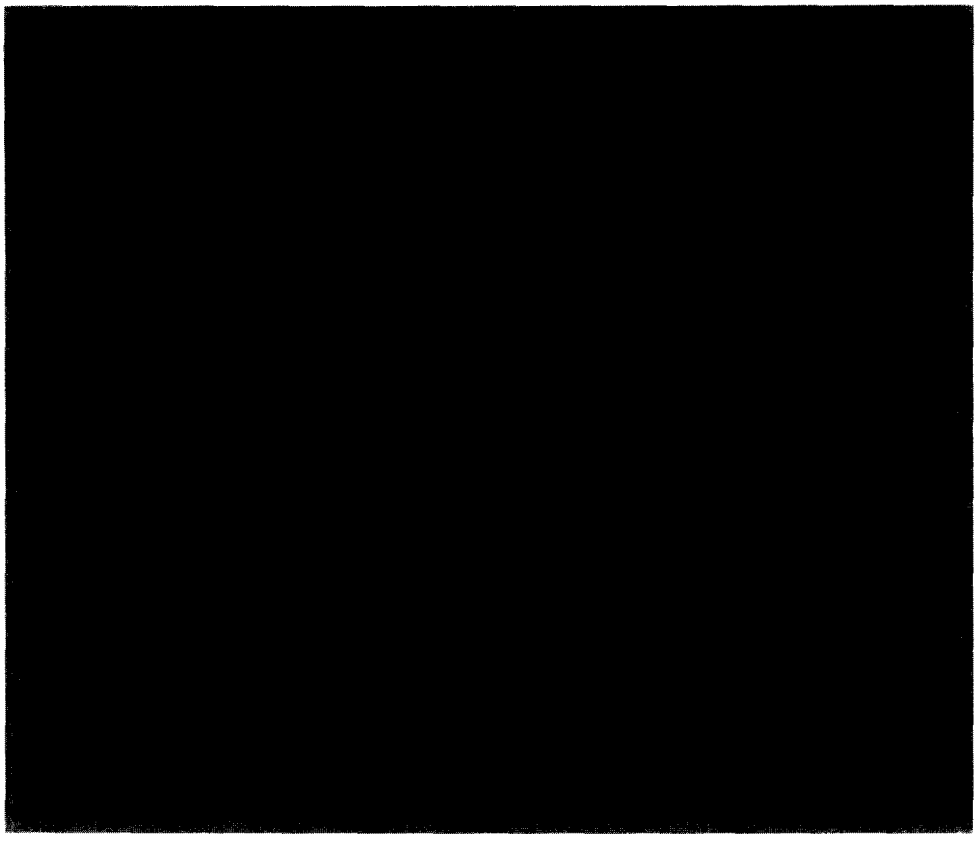

Fig. 5. Calibration curve for the determination of *H. pyroli* specific IgG antibody by ELISA.

specific antibody was 7.6% (eight replicates).

The ELISA procedure was also carried out as described, absorbance changes were plotted against the corresponding *H. pylori* specific IgG antibody concentration and a calibration curve was constructed. (Fig. 5, $C_{HP} = 54.03\ A - 9.16$, $r = 0.980$), the RSD for the determination of 25 units ml^{-1} *H. pylori* specific antibodies was 8.4% (eight replicates).

From Fig. 4 and Fig. 5, we could observe that DPV immunoassay has wider detection range than ELISA procedure in the higher and lower IgG concentration range. Taking the detection limit to be the concentration that gives a signal three times the standard deviation (S.D.) of the blank, we could calculate the detection limit from the calibration curve of these two methods. The S.D. of the blank for DPV and ELISA was 0.095 and 0.10, respectively (eight replicates). So, the calculated detection limit for DPV and ELISA procedure is 1.0 and 7.1 units ml^{-1}, respectively.

This result shows that DPV detection limit is about seven times more sensitive than that of the spectrophotometric method.

Direct electrochemical redox of tyrosinase at silver electrodes

Baoxian Ye, Xingyao Zhou *

Department of Chemistry, Wuhan University, Wuhan 430072, People's Republic of China

Received 30 April 1996; received in revised form 18 September 1996; accepted 26 September 1996

Abstract

The direct electron transfer reactions between tyrosinase and silver electrode were investigated by using cyclic voltammetry and potential-step chronoamperometry as well as current-step chronopotentiometry techniques. The kinetics of these reactions is quasi-reversible with two electron transfer reactions and 0.030 s^{-1} apparent electrode reaction rate constant. The results demonstrate that neither electrode surface modification nor the inclusion of mediators is necessary to study the electron transfer reactions of tyrosinase at silver electrodes. Moreover, both the anodic and the cathodic currents are linear relationship with the tyrosinase concentration in the range of $1 \times 10^{-9} \sim 5 \times 10^{-8}$ mol l^{-1}. It is possible to be used as a method of analyzing tyrosinase concentration. © 1997 Elsevier Science B.V.

Keywords: Direct electrochemistry; Silver electrode; Tyrosinase

1. Introduction

The electrochemical behavior investigations of biomacromolecules, such as proteins and enzymes, have been a major research area in recent years [1,2]. These investigations are important not only for fundamental reasons but also for the development of electroanalytical methodology [3]. It is because some analogies exist between the reactions of biomacromolecules at electrodes and their interaction in biological redox system [4]. However, although many proteins and enzymes possess functional groups that can be readily oxidized or reduced by chemical redox agents, it is rare for the biomacromolecules to undergo facile redox at electrodes, for reasons ascribed both to their extended three-dimensional structure and the resulting inaccessibility of the electroactive centers as well as their strong adsorption onto electrode surface for subsequent passivation. Most biomacromolecules exhibit so slow electron transfer reactions at electrode surface that no useful currents appear even when rather large overpotentials are applied. For our knowledge, only a few proteins with quasi-reversible redox are obtained at some chemically modified electrodes or by the presence of some promoters so far [5–10]. Few of these redox reactions could be used for analytical possibility.

A few papers about electrochemical redox of blue copper proteins were reported previously. Gray et al. [11,12] reported the direct electro-

chemistry of *Bean plaslocyanin*, *Rhus vernicifera stellacyanin* and *Pseudomonas averuginosa azurin* at modified gold electrodes. The direct electrochemistry of *Spinach plaslocyanin* at graphite electrodes promoted by $Pt(NH_3)_6^{4+}$ were studied by Hill et al. [13]. Tyrosinase (Tyr) is one of blue copper proteins. It is an important enzyme with biofunction for catalyzing oxidation of Tyrosine and Catechol. The only report about the direct electrochemical behavior of Tyr was by Kelly et al. [3]. They modified glass carbon electrodes using Nafion mixed with copper chelate and obtained the redox reactions of Tyr. In our experiments, we found that Tyr occurred quasi-reversible redox reactions at bare silver electrodes with two electron transfer and 0.030 s^{-1} apparent reaction rate constant. More importantly, both the anodic currents and the cathodic currents are linear relationship with the concentration of Tyr in the range of $1 \times 10^{-9} \sim 5 \times 10^{-8}$ mol l^{-1}.

2. Experimental

2.1. Reagents and materials

Tyrosinase was obtained from Sigma with purity of 99% and without further purification. Tyr solid was stored under 0°C. Tyr solution, prepared fresh everyday, was stored under 5°C. Other reagents were of analytical grade and were used as received. All solutions were prepared using distilled water.

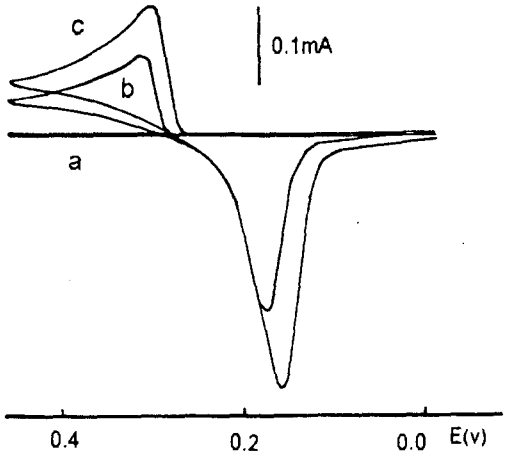

Fig. 1. The voltammograms of Tyr on bare Ag electrode (a) 0.50 mol l^{-1} KH_2PO_4; (b) (a) + 5×10^{-9} mol l^{-1} Tyr; (c) (a) + 1×10^{-8} mol l^{-1} Tyr v = 20 mV s^{-1}; pH = 5.0.

2.2. Apparatus and procedures

Model 270 electrochemical system (EG and G Princeton Applied Research, USA) was employed along with an IBM 386 computer to control and treat data for cyclic voltammetry, potential-step chronoamperometry and current-step chronopotentiometry. A standard three-electrode electrochemical cell was used for all electrochemical experiments. The electrodes consist of bare silver electrode (area of 3.14 mm^2) as working electrode, platinum slice (area of 1.0 cm^2) electrode as counter electrode and SCE as reference electrode. The Ag electrodes were polished to a mirror smoothness on silk impregnated with 0.3 μm alumina powder suspension and then cleaned with ultrasonic waves. All experiments were performed under undeoxygen at room temperature.

3. Results and discussion

3.1. The direct electrochemical behavior of tyrosinase on silver electrodes

Fig. 1 shows the cyclic voltammograms of Tyr on bare silver electrodes. In medium of 0.5 mol l^{-1} KH_2PO_4 (pH = 5.0), with potential range of 0.00 ~ +0.5 V(versus SCE) and scan rate of 20 mV s^{-1}, the silver electrode does not occur redox reaction itself [Fig. 1(a)] and a pair of redox peaks are obtained when 5×10^{-9} mol l^{-1} Tyr is added in the medium with $E_{pc} = 171$ mV and $E_{pa} = 346$ mV ($\Delta E_p = 175$ mV) respectively [Fig. 1(b)]. Increasing Tyr concentration to 1×10^{-8} mol l^{-1}, both anodic currents I_{pa} and cathodic currents I_{pc} are multiplied with $E_{pc} = 155$ mV and $E_{pa} = 335$ mV ($\Delta E_p = 180$ mV). It is clear that the peak potentials (E_{pa} and E_{pc}) are related to Tyr

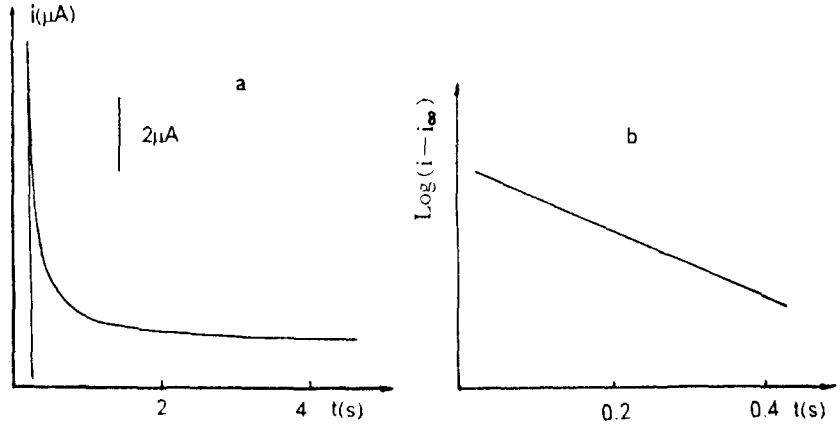

Fig. 4. Potential step experiment (ΔE = 5 mV). (a) $I \sim t$ curve; (b) $\mathrm{Log}(i - i_\infty) \sim t$ curve.

Table 2
The relationship between adsorbance and Tyr concentration ($\Delta i = 0.1$ mA)

Tyr(mol l^{-1})	Adsorbance(mol mm^{-2})
1.0×10^{-9}	7.7×10^{-13}
5.0×10^{-9}	1.1×10^{-12}
1.0×10^{-8}	2.57×10^{-12}
1.5×10^{-8}	3.71×10^{-12}
2.0×10^{-8}	4.64×10^{-12}
2.5×10^{-8}	5.56×10^{-12}

concentration. Both E_{pa} and E_{pc} are shifted negatively with increasing Tyr concentration. But the E_{pc} is shifted more quickly than that of E_{pa}, which results in the multiplication of ΔE_p, for reason ascribed to the I_{pc} larger than I_{pa} ($I_{pc} \cong 2I_{pa}$). The peak currents (I_{pa} and I_{pc}) are linear relationship with scan rate in range of $10 \sim 200$ mV s^{-1}[Fig. 2]. This exhibits that both Tyr and its redox product are adsorbed on electrode surface. In fact, if we immerse an Ag electrode in a solution containing Tyr for a moment and then put it in 0.5 mol l^{-1} KH_2PO_4 solution for cyclic scan, the redox peaks of Tyr are obtained still. Moreover, we had a silver electrode adsorbed Tyr on its surface be exposed in air for 30 min and then performed cyclic scan in background solution. The same voltammograms were obtained as that of performing in containing Tyr solution. This result suggests that the redox reactions of Tyr possess good stability. For this consideration, we performed the cyclic scan in a solution containing Tyr 1×10^{-8} mol l^{-1} for continuing 30 min [Fig. 3]. The electrode reactions exhibit so good a stability that the peak currents change by less than 8.0% (cathodic current)and 6.5% (anodic current), respectively.

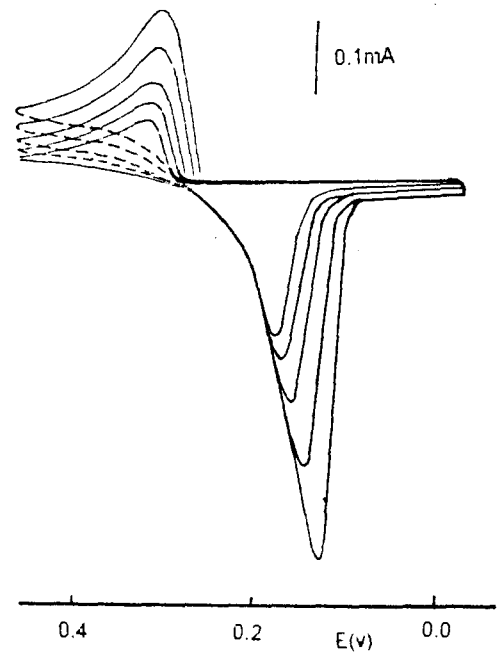

Fig. 6. The relationship between peak currents and Tyr concentration (from inner to exterior) 1×10^{-9}; 5×10^{-9}; 1×10^{-8}; 2×10^{-8}; 3×10^{-8} mol l^{-1}, $[KH_2PO_4] = 0.5$ mol l^{-1}, pH = 5.0, v = 20 mV s^{-1}.

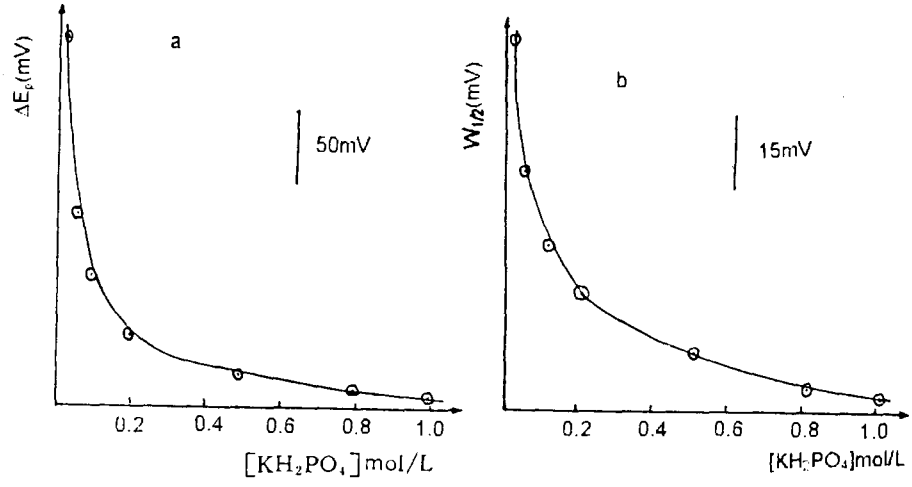

Fig. 5. The effect of KH_2PO_4 concentation on ΔE_p(a) and peak half – width $W_{1/2}$(b). [Tyr] = 1×10^{-8} mol l^{-1}, v = 20 mV s^{-1}.

3.2. The reaction rate of Tyr on bare silver electrodes

Cyclic voltammetric technique was employed to study the redox reactions between Tyr and bare silver electrodes. According to Laviron's theory [14], when the adsorption obeys the langmuir isotherm, the peak currents are linear relationship with scan rate. That is:

$$I_p = n^2F^2A\Gamma v/4RT = nFQv/4RT$$

Γ is the total surface concentration of electrode reaction substance (mol cm^{-2}). A is the electrode area(cm^2) and Q is the peak area of voltammogram (coulomb). I_p is here expressed in unit of amperes. n, F, R, T have their usual significance. The above equation shows that as long as Q is obtained under certain v, then n can be calculated. Table 1 shows the results on this basis. So, the redox of Tyr at bare silver electrodes is a two electron transfer reaction. The electrode reaction rate constant k_s was calculated using the method demonstrated by Laviron [15]. The transfer coefficient α can be obtained with $E_p \sim f(\log v)$ relation. Here when scan rate is 20 mV s^{-1}; $\Delta E_p = 175$ mV, that is $\Delta E_p > 200\ n^{-1}$ mV. K_s can be obtained with following equation:

$$\log k_s = \alpha\log(1-\alpha) + (1-\alpha)\log\alpha - \log(RT/nFv) - \alpha(1-\alpha)nF\,\Delta E_p/2.3RT$$

From this, we figured out $\alpha = 0.61$ and $k_s = 0.030\ s^{-1}$. It shows a quasi-reversible reaction.

3.3. The electrode reaction parameters R_r, C_d and electrode surface adsorbance

For an electrode reaction controlled by electrochemical step, when a low amplitude potential step ($\Delta E < 10$ mV) exerts on the electrode and continues for a short time, the concentration polarization will not occur. The controlling potential transient technique can be used to detect solution resistance R_l (including electrode inner resistance), electrode reaction resistance R_r and electrical double layer capacitance C_d. For this system, we used $\Delta E = 5$ mV as potential step to exert on electrode and record $i \sim t$ curves (Fig. 4). At this condition, we can consider that the R_r is not relation to potential, that is R_r = constant. According to Macdonald's [16] theory:

$$i_{max} = \Delta E/R_l$$

$$i = i_\infty + A\,e^{-t/R_{ll}C_d}$$

(R_{ll} is the parallel combination of R_r and R_l)

$$\mathrm{Log}(i - I_\infty) = \mathrm{Log}\,A - t/2.3\,R_{ll}\,C_d$$

If the i_∞ is selected suitably, the $\mathrm{Log}(i - i_\infty) \sim t$ curve is a straight line (Fig. 4b.) So: /slope/ = $(1/R_l + 1/R_r)/2.3\,C_d$ and $R_r = \Delta E/i_\infty - R_l$ We obtained $R_l = 1442\ \Omega$; $R_r = 8408\ \Omega$; and $C_d = 12.8\ \mu F$. The real electrode surface is $S_{real} = C_d/C_N = 12.8/20 = 0.64\ cm^2$. It is much larger than its apparent surface.

The electrode surface adsorbance have been investigated using transient current-step chronopotentiometry technique. In different Tyr concentration solutions, a fixed current-step exerted on electrode and different transitional times τ were obtained. Then, the charges (Q) were calculated from $Q = \tau \times t$ and the adsorbance were calculated from $\Gamma = Q/nFA$. Table 2 shows the results on this basis.

From the results, we know that the adsorbance are enhanced with increasing Tyr concentration. It predicts that it may possesses a linear relationship between electrode reaction currents and Tyr concentration. This has been confirmed by following experiments. We also know that there is an adsorption equilibrium between adsorbed Tyr molecules and Tyr molecules in solution. For reasons ascribed that Tyr molecule is a macromolecule. The adsorbed Tyr molecules impede the further adsorption of dissolved Tyr molecules. Although the adsorbance on electrode surface does not reach saturation, it cannot be enhanced further, unless the Tyr concentration be increased. This may be explained that the adsorbance are linearly multiplied with increasing Tyr concentration.

3.4. The relationship between peak currents and Tyr concentration

Several salts have been examined as electrolyte. The results indicate that the KH_2PO_4 is the best choice. The solution pH and KH_2PO_4 concentration have been carefully tested for affecting I_p and E_p. The results are that pH do not affect I_p but affect the E_p. Both E_{pa} and E_{pc} are shifted negatively (about 12 mV pH^{-1}) with decreasing pH, but the ΔE_p is a constant at different pH (ΔE_p = 180 mV with 1×10^{-8} mol l^{-1} Tyr). This suggests that the H^+ ions do not participate in the reaction. Fig. 5 shows the affect of ΔE_p(a) and the peak half-width $W_{1/2}$(b) by KH_2PO_4 concentration. Both ΔE_p and $W_{1/2}$ are decreased with increasing KH_2PO_4 concentration. This suggests that the KH_2PO_4 concentration affects the Tyr conformation and reaction activation energy. Fig. 6 is the voltammograms of different Tyr concentration. Both the anodic currents and cathodic currents are multiplied with increasing Tyr concentration and linear relationship with it in the range of $1 \times 10^{-9} \sim 5 \times 10^{-8}$ mol l^{-1}. The linear regression equations are:

$$I_{pa(A)} = 4.64 \times 10^{-5} + 2434.7C(\text{mol}\,l^{-1})$$

$$I_{pc}(A) = 9.77 \times 10^{-5} + 5514.4C(\text{mol}\,l^{-1})$$

with correlation coefficients $\Upsilon_a = 0.9960$ and $\Upsilon_c = 0.9976$. The detection limit is up to 5×10^{-10} mol l^{-1} estimated by signal/noise = 1.

4. Conclusion

The existence of Tyr are of tetramers, each of which contains an electroactive center (copper) and may be experiencing electron transfer individually. The tetramers are negatively charged at pH 5. Some kind of 'adsorption bond' may be formed between Tyr and the 5s orbit of Ag atom (a half-full orbit of Ag). But the tetramers are a macromolecules with molecular weight of 119 000 (from mammal tissues). One side of the tetramers is adsorbed on the electrode surface and exchanges two electrons with the electrodes. Essentially, the redox reactions of Tyr in the process are the redox between Cu^{2+} and Cu^+.

Spectrophotometric determination of palladium after solid–liquid extraction with 1-(2-Pyridylazo)-2-naphthol at 90°C

Jinzhang Gao *, Bo Peng, Haiyan Fan, Jingwan Kang, Xudong Wang

Department of Chemistry, Northwest Normal University, Lanzhou, 730070, People's Republic of China

Received 26 February 1996; received in revised form 17 September 1996; accepted 27 September 1996

Abstract

An effective spectrophotometric determination of palladium with 1-(2-pyridylazo)-2-naphthol (PAN) using molten naphthalene as a diluent has been studied. A green complex of palladium with PAN is formed at 90°C. In the range of pH 1.5–7.5, the complex is quantitatively extracted into molten naphthalene. The organic phase is anhydrously dissolved in $CHCl_3$ to be determined spectrophotometrically at 678 nm against the reagent blank. Beer's law is obeyed over the concentration range of 0.5–10 ppm. The molar absorptivity and Sandell's sensitivity are 1.2×10^4 l mol^{-1} cm^{-1} and 0.0070 mg cm^{-2}, respectively. The optimum conditions for determination are obtained. The interferences of various ions are observed in detail. The method has been applied to the determination of palladium in synthetic samples. © 1997 Published by Elsevier Science B.V.

Keywords: Molten naphthalene; Palladium; Spectrophotometric

1. Introduction

Solvent extraction of precious metals is widely employed in chemistry and industry for many years. Normally, it is difficult for metals such as palladium, platinum, rhodium, etc., to form complex with extractant at the room temperature, while at a high temperature the water-insoluble complex can form easily and rapidly. In 1969, Fujinaga et al. [1] developed a method involving the extraction of the complex at high temperature followed by the solid–liquid separation at room temperature. In recent years, much work was done on the solid–liquid extraction in our lab [2–4]. In this technique, organic substances which are solid at room temperature such as naphthalene, biphenyl and paraffin waxes are used as a diluents. The water-insoluble complex is extracted into the molten diluent at the high temperature to achieve distribution equilibrium. The phase separation is obtained by cooling the extraction system to room temperature. This technique is also applied for the concentration and separation of precious metals. Solid–liquid extraction spectrophotometric determination of palladium [5], platinum [6], rhodium [7], iridium [8], osmium [9] and ruthenium [10] are reported. The organic extractants used are mainly focused on 8-hydroxyquinolines, oximes and dioximes, cuprals and xanthates [5].

PII S0039-9140(96)02122-4

For the solid–liquid extraction spectrophotometric analysis of platinum group metals, there are some shortages. The sensitivities of some system are lows and molar absorptivity are usually around 10^{-3} level [11,12], others have a relatively high sensitivities, but are not suitable to be extracted and detected for a wider acidity [13,14].

As a highly sensitive and selective indicator of polydentate organic reagents, PAN forms intensively coloured and water-insoluble complexes with many metals [15] which can be extracted into an organic solvent. However, there is no application of PAN for solid–liquid extraction of platinum group metals at a high temperature. The liquid–liquid extraction of palladium with PAN into $CHCl_3$ has been reported [16,17], but it has a narrow pH range for the determination and is time consuming.

In this paper, PAN is first used for the solid–liquid extraction of palladium (II) into molten naphthalene. High sensitivity of detection and a wider pH range of extraction are obtained. Time consumption is decreased and procedures are more convenient.

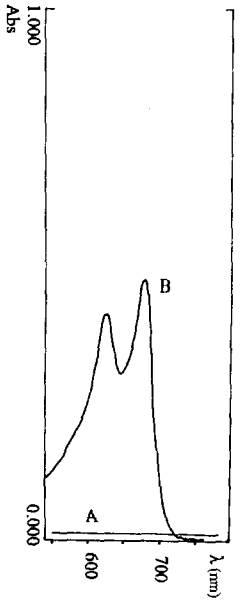

Fig. 1. Absorption spectra of PAN-Pd(II) complex and PAN in naphthalene–chloroform solution. (A) reagent against naphthalene–chloroform, (B) PAN-Pd(II) complex against reagent.

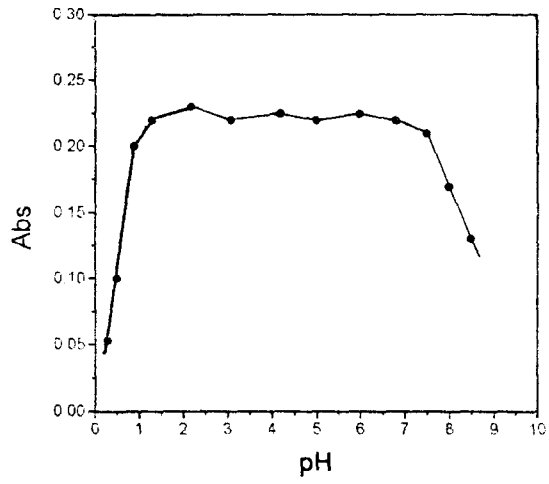

Fig. 2. Effect of pH on the extraction. Pd(II): 20 μg, PAN(1×10^{-3} M): 0.5 ml, V_{aq}: 20 ml, naphthalene:1.0 g (1.3 ml), $I = 0.1$ M $NaClO_4$.

2. Experimental

2.1. Apparatus

A model U-3400 Hitachi spectrophotometer (Japan), a Model pHS-10A digital acidity/ionometer (Xiaoshan, China) and a Model HHS21-4 super thermostatic water bath (Beijing, China) were used in this study.

2.2. Reagents

2.2.1. Standard palladium solution

A standard palladium solution was prepared by dissolving 0.08866 g of palladium chloride (99.99%) in 10 ml of concentrated hydrochloric acid and diluting to 500 ml with water. The content of palladium was also standardized gravimetrically by the method reported elsewhere [18]. The solution contains 106.4 μg ml^{-1} of palladium. Solutions of lower concentration required were prepared by diluting standard solution.

2.2.2. (2-pyridylazo)-2-naphthol solution (PAN)

A 1×10^{-3} M solution in acetone is prepared by dissolving 0.02490 g PAN (Baker Analyzed) in 100 ml pure acetone and stored in an amber bottle.

2.2.3. Buffer solution

0.1 M of solution acetate–acetic acid and 0.1 M of ammonium chloride–ammonia are used for the experiment.

2.2.4. Naphthalene (m.p. 80–82°C)

The purity of naphthalene is checked spectrophotometrically before use in the range 300–800 nm.

Distilled-deionized water was used throughout. All other reagents are of analytical reagent grade.

2.3. General procedure

All solid–liquid extractions were carried out at 90 ± 0.1°C as follows: a certain amount of standard palladium solution was pipetted into a 250 ml Erlenmeyer flask. 5.0 ml of NaAc–HAc buffer solution and 1.0 ml of 1×10^{-3} M PAN-acetone solution were added sequentially. The total volume of the aqueous phase was diluted to 20 ml with water. The mixture in the flask was warmed on a water bath of 90 ± 0.1°C for 3 min after addition of 1.0 g of naphthalene and continued to be warmed until naphthalene melted completely. The flask was shaken vigorously for 30 s, cooled to room temperature until naphthalene coagulated completely. The solid phase was collected dried at 50°C dissolved in 10 ml chloroform. Palladium was determined spectrophotometrically by measurement of the colour complex of 678 nm against a reagent blank.

3. Results and discussion

3.1. Absorption spectra

The absorption spectra of the palladium complex in naphthalene–chloroform are measured against a reagent blank, that of the reagent, treated in a similar manner against a chloroform–naphthalene blank (Fig. 1). The palladium complex has two absorbance peaks at 678 and 625 nm, respectively, where the absorbance of the reagent is negligible. The intensity of the peak at 625 nm is slightly smaller than that at 678 nm. Therefore, the following determinations performed at 678 nm.

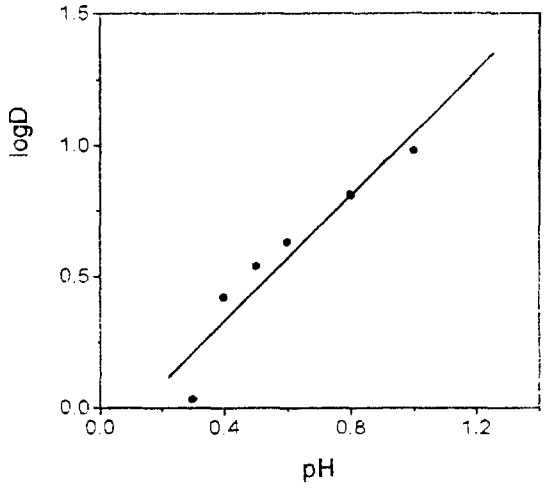

Fig. 3. Relationship between log D and pH value; conditions shown are the same as in Fig. 2.

3.2. Effect of pH value

The effect of pH value in aqueous phase on the absorbance is examined and showed in Fig. 2. In the pH value range from 1.5–7.5, quantitative

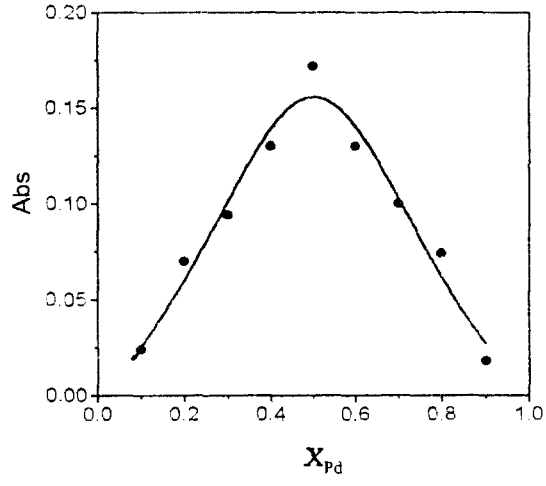

Fig. 4. Plot of composition of the extracted species by Job's continuous variation method. Pd(II): 1×10^{-4} M, PAN: 1×10^{-4} M, pH:4.40, total content of Pd(II) and PAN: 0.4×10^{-6} mol, V_{aq}: 20 ml, naphthalene: 1.0 g (1.3 ml), I = 0.1 M $NaClO_4$.

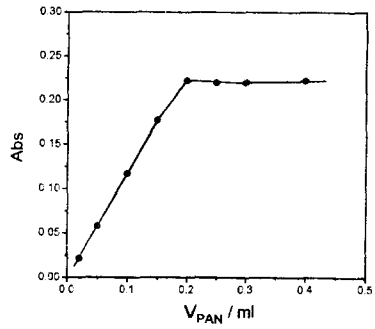

Fig. 5. Plot of composition of the extracted species by Molar ratio method. Pd(II): 20 μg, PAN: 1×10^{-3} M, pH: 4.40, V_{aq}: 20 ml, naphthalene: 1.0 g (1.3 ml), I = 0.1 M $NaClO_4$.

extraction of palladium occurs and the absorbance is found to be constant. Although PAN in the aqueous solution displays different colours at different acidity, no interference is found for the measurement. A NaAc–HAc buffer of pH 4.40 is employed for the following experiments.

3.3. Effect of volume of the aqueous phase and naphthalene

When the volume of the aqueous phase is varied from 10–150 ml, the absorbance remains constant up to 45 ml. Above this volume, it begins to decrease due to excessive ratio of two phases and incompleted extraction of palladium occurs. Thus, in the following experiments a volume of 20 ml was maintained. It was found that the absorbance has a slight increase when the amount of naphthalene was varied from 0.2–2.0 g. Excessive naphthalene was detrimental to the determination of palladium because of its low solubility in chloroform and volatilization. An optimum of 1.0 g of naphthalene is employed for this work.

3.4. Effect of heating, shaking and standing times

The extraction system is heated about 3–4 min at the temperature of the experiment. After naphthalene is completely molten, 30 s of vigorous shaking can achieve extraction equilibrium. The absorbance of the palladium complex in naphthalene–chloroform solution is constant for more than 24 h.

3.5. Mechanism of extraction

As a weak organic acid, the degree of dissociation of PAN increases with the decreasing acidity in the aqueous phase. At the given acidity, the metal ion Pd (II) reacts with PAN (HL) in the presence of anion A^-, giving an uncharged chelate which is distributed between two phase according to the equation:

$$Pd^{2+} + nHL_{(o)} + (2-n)A \rightleftharpoons PdL_nA_{(2-n)(o)} + nH^+ \quad (1)$$

the equilibrium constant of the above reaction is defined as:

$$K_{ex} = [PdL_nA_{(2-n)}]_{(o)}[H^+]^n/[HL]^{n(o)}[Pd^{2+}][A^-]^{(2-n)} \quad (2)$$

Assuming that the species of Pd(II) in the aqueous phase and $PdLnA_{2-n}$ in the organic phase mainly exist respectively, there is:

$$K_{ex} = D[H^+]^n/[HL]^n[A^-]^{(2-n)} \quad (3)$$

where D is the distribution ratio of the palladium between two phase as defined by Eq. (4),

$$D = [PdL_nA_{(2-n)}]/[Pd^{2+}] \quad (4)$$

Expressing Eq. (3) in the equivalent logarithmic form, there is called:

$$\log D = \log K_{ex} + npH + n\log[HL]_{(o)} - (2-n)\log[A^-] \quad (5)$$

Under the conditions of experiments, the relationship between the distribution ratio D and absorbance A is expressed as:

$$D = [A_i/(A_{max} - A_i)](V_{aq}/V_o) \quad (6)$$

Eq. (6) may be simplified into the form:

$$D = A_i/(A_{max} - A_i) \times r \quad (7)$$

where A_{max} denotes the mean maximum absorbance of determination, A_i denotes the absorbance of single determination, r denotes the ratio of to phase.

Log D at different pH values keeping $[HL]_o$ and $[A^-]$ constant are obtained. The plot log D versus

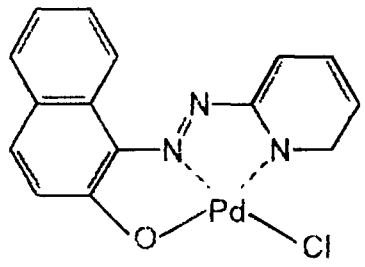

Fig. 6. A suggested structure of palladium complex.

pH (Fig. 3) gives a straight line with a slop of 1, i.e., $n = 1$. One proton is released in the extraction reaction.

The composition of the extraction species is studied by means of Job's method (Fig. 4) and the Molar Ratio method (Fig. 5). The results show that the molar ratio of Pd (II) to PAN in the extracted species is 1:1. The palladium and PAN in the extracted species is demonstrated to be [Pd(PAN)]Cl in the presence of large amount of Cl. Fig. 6 shows a possible structure. Therefore, the extraction reaction can be rewritten as follow:

$$PAN_{(o)} + Pd^{2+} + Cl^{-} \overset{463K}{\rightleftharpoons} Pd(PAN)Cl_{(o)} + H^{+} \quad (8)$$

3.6. Beer's law and sensitivity

Under the optimum conditions described above, Beer's law is obeyed over the concentra-

tion range from 0.5–10.0 ppm. The molar absorptivity and Sondell's sensitivity are 1.2×10^4 l mol^{-1} cm^{-1} and 0.0070 μg cm^2, respectively.

3.7. Effect of coexisting ions

Tolerance limits of various cations and anions were investigated on the extraction of palladium. The results are listed in Table 1. It is found that large amount of NO_3^{-1}, Cl^{-1}, CO_3^{2-}, tartrates and citrates do not interfere in the determination. I^{-1}, SCN^{-1} have positive effects on the absorbance. This implies that sensitivity can be improved by choosing I^- or SCN^{-1} as diverse ion in a suitable system. But the reducibility of I^- and chelation of SCN^{-1} also produce disadvantageous at the same time.

Cations were tested by comparing in the presence/absence of masking agents EDTA and citrate sodium. It is found that Pt(IV), Rh(III), Au(III), Ag(I) do not interfere. Ni(II), Fe(II), Fe(III) interfere seriously. However their interferences are masked efficiently by addition of 0.5 ml of 0.1 M EDTA and 1 ml 0.05 M sodium citrate.

3.8. Applications

The propose method was applied to the determination of palladium in synthetic mixtures. A suitable aliquot of synthetic mixture was analyzed by the procedure described above and the results displayed in Table 2.

Extraction and separation of mercury(II) using triisobutyl phosphine sulfide (TIBPS/Cyanex 471X) as an extractant and its application to industrial effluent

Rashmi Singh, S.N. Tandon *

Department of Chemistry, University of Roorkee, Roorkee-24766, India

Received 1 April 1996; received in revised form 20 September 1996; accepted 27 September 1996

Abstract

Studies have been carried out on the extraction of Hg(II) along with Cr(III), Fe(III), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Pb(II) and Ag(I), from mineral acid media using TIBPS. The effect of different variables influencing extraction of Hg(II), such as, mineral acid used, nature of diluent, concentration of metal ion and extractant has been investigated. Based on the partition data some binary separations from Hg(II) have been achieved. The potential of the extractant for decontaminating Hg from paper industry effluent has been assessed. © 1997 Elsevier Science B.V.

Keywords: Extraction; Paper industry effluent; Mercury; Triisobutyl phosphine sulfide

1. Introduction

Mercury is one of the most toxic elements and has a tendency to concentrate in the human system because of its affinity to the sulphydryl group. Thus the removal of Hg from waste streams assumes a paramount importance. Also Hg readily forms amalgams with a number of metals and therefore its separation from them has been a subject of great analytical interest. Over the years a number of sulfur containing ligands have been proposed as extractants for Hg(II). Most of these reagents lack selectivity and for separations a strict control of aqueous phase conditions, namely pH [1–6] and/or the presence of masking reagents are required [7–11]. In the recent past, triisobutyl phosphine sulfide (TIBPS) has been marketed under the trade name Cyanex 471X. Because of a lower pKa value it will be able to extract metal ions at a higher acidity than trioctyl phosphine oxide (TOPO). Moreover, the branching in the chain may introduce selectivity in extraction. It is a soft Lewis base and will readily complex with soft acids e.g., Ag(I), Au(III), Hg(II) and Pd(II). Salvado et al. [12] have employed TIBPS for the extraction of gold from chloride solutions. A number of workers have recovered silver by using this reagent [13–15]. Mathur et al. [16] have reported the probable Pd(II)–TIBPS extracting species. Employing this extractant, Baba et al. [17] reported the extraction of Hg(II) from hydrochloric acid solutions.

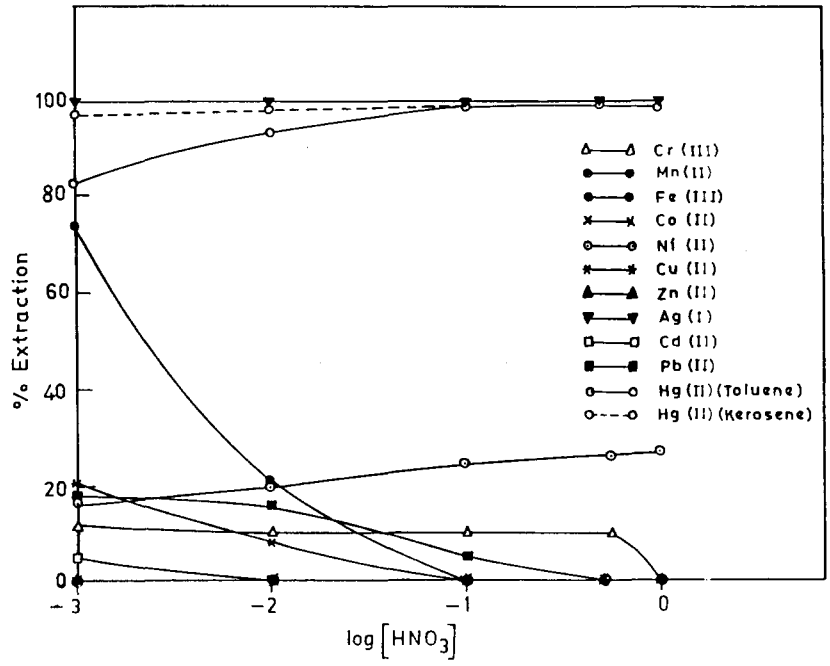

Fig. 1. Extraction behaviour of some metal ions (1.0×10^{-4} M) in toluene solution of 0.10 M TIBPS.

In view of the reported extractability by TIBPS of Hg(II), a detailed study has been planned. The present paper reports the extraction behaviour of Hg(II) in TIBPS from mineral acid media. The effect of various parameters, namely type of mineral acid used, nature of diluent, concentration of metal ion and extractant has been investigated. The probable extracting species has been identified by log–log plot of distribution ratio versus extractant concentration and mole ratio method. The behaviour of other metal ions namely Cr(III), Fe(III), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Pb(II) and Ag(I) has been studied to achieve separations. Based on the distribution data the separation of Hg(II) from other metal ions is reported. Hg(II) is recovered quantitatively from the organic phase by various stripping agents. The method has been used successfully to quantitatively remove Hg(II) from paper industry waste effluent.

2. Experimental

2.1. Instruments and reagents

The nitrates/chlorides of Cr(III), Fe(III), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Pb(II), Hg(II) and Ag(I) were used to prepare the stock solutions which were standardised by the usual complexometric titrations. TIBPS was procured from American Cyanamid, USA and used after purification [18]. The purity was checked by GC. The distribution studies were carried out by solutions labelled with ^{51}Cr, ^{54}Mn, ^{58}Co, ^{59}Fe, ^{65}Zn, ^{110m}Ag and ^{203}Hg radioisotopes. A well type NaI(Tl) scintillation counter was used for the measurement of gamma activity of ^{51}Cr, ^{54}Mn, ^{58}Co, ^{59}Fe, ^{65}Zn, ^{110m}Ag and ^{203}Hg. ICP-AES (8040 PLASMA LABTAM, Australia) and AAS (Perkin Elmer 3100) were used for obtaining the distribution data of Ni(II), Cu(II), Cd(II) and

Pb(II), checking the yield in the separations and analysis of the industrial waste.

Equal volumes of aqueous phase (metal ion in mineral acid) and organic phase (Cyanex 471X in an appropriate diluent) were shaken at room temperature (25 ± 3°C) for 5 min to ensure complete equilibration. The two phases were separated and suitable aliquots of each phase were removed to determine the concentration of the metal ion by the assay of radioactivity or using ICP-AES/AAS.

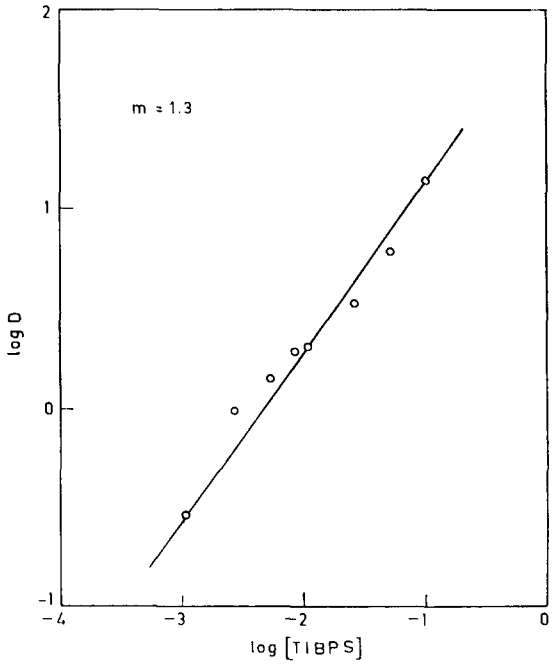

Fig. 2. Effect of concentration of TIBPS on the distribution of Hg(II) in 0.010 M HNO_3.

3. Results and discussion

3.1. Extraction behaviour

The extraction behaviour of different metal ions in toluene solution of TIBPS from nitric acid solution is shown in Fig. 1. Ag(I) and Hg(II) are more or less quantitatively extracted over the entire investigated range of acid molarity. Mn(II), Co(II), Zn(II) and Cd(II) show negligible extraction (< 5%) while Cr(III), Ni(II), Cu(II) and Pb(II) show poor extraction with a maximum of ~ 20%. In the case of Fe(III), the percentage extraction increases with decreasing acid molarity reaching a value of ~ 70% at 1.0×10^{-3} M HNO_3. Thus Hg can be quantitatively separated from almost all the metal ions except Ag(I) with a high decontamination factor. It was observed that the extraction behaviour of Hg(II) remains practically the same (within ± 3%) on changing the aqueous phase from nitric acid to hydrochloric or sulfuric acid. All further studies regarding the effect of different variables were carried out with nitric acid as the aqueous phase. The results of the change in the nature of diluent are shown in Table 1. The extraction increased with the increase in the dielectric constant of the diluent; kerosene being an exception. The extraction of Hg(II) is > 90% with toluene, kerosene (160–200°C), chloroform and cyclohexanone whereas it shows poor or negligible extraction when xylene and *n*-hexane are used as diluents. Further studies were carried out using nitric acid as aqueous phase and toluene as diluent.

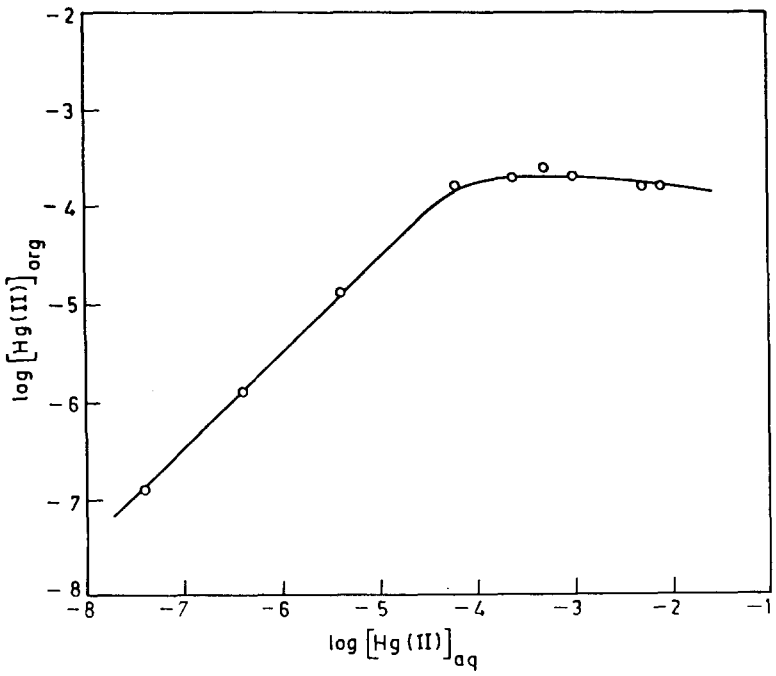

Fig. 3. Extraction isotherm of Hg(II) (1.0×10^{-7} to 5.0×10^{-3} M) from 0.10 M HNO_3 by TIBPS in toluene (1.0×10^{-3} M).

3.2. Effect of the concentration of metal ion

The effect of the concentration of the metal ion as studied in the range 1.0×10^{-7} to 5.0×10^{-3} M shows that the distribution is more or less independent of the concentration. This suggests that the extracting species is not changing in this metal ion concentration range. For subsequent studies on identification of extracting species the metal ion concentration was confined to this range. In most of other experiments 1.0×10^{-4} M was chosen as the working concentration.

6.	Sodium sulfite	0.0
7.	Sodium thiosulfate	99.9
8.	Sodium citrate	0.0
9.	Thiourea	99.5
10.	Thiosemicarbazide	0.0

3.3. Nature of the extracted species

The effect of concentration of the TIBPS (1.0×10^{-3} to 0.10 M) as studied for Hg(II) from 0.010 M HNO_3 is shown in Fig. 2. There is an increase in extraction with the increase in the concentration of the extractant. The variations of distribution ratio with the concentration of the extractant can be utilized for the identification of the extracting species. A straight line with a slope of around one suggests the involvement of one molecule of the extractant in the formation of the Hg(II) complex. The results of loading the extractant (TIBPS) with varying concentration of Hg(II) are shown in Fig. 3. The concentration of Hg in the organic phase first increases linearly with the increase in the aqueous phase but as the extrac-

[a] Average of three determinations.
[b] Hg(II) was recovered from the organic phase by washing with 5% NH_4Cl in 1:10 NH_3.

tant gets saturated, the Hg content in the organic layer tends to assume a constant value. This result clearly indicates a 1:1 stoichiometric ratio of metal ion to extractant which is in conformity with the slope analysis data. The extracting species can be proposed as $Hg(NO_3)_2$ (TIBPS). This is similar to the one reported by Mathur et al. for palladium, i.e. $Pd(NO_3)_2$ (TIBPS) [16].

3.4. Stripping agent

Various stripping agents of different concentrations were examined for the back-extraction of the metal ion from the organic phase (Table 2). Hg(II) is stripped almost quantitatively by DL-pencillamine, thiourea, sodium thiosulfate and 5% NH_4Cl in 1:10 NH_3.

3.5. Separations

Partition data indicate that separation of Hg(II) from metal ions such as Cr(III), Fe(III), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) can be easily achieved by carrying out extraction with 0.10 M TIBPS at 0.10 M HNO_3. Under these conditions Hg(II) is quantitatively extracted in the organic phase, leaving other metal ions in the aqueous phase. The results of separation of Hg(II) from other metal ions are shown in Table 3. Due to the similar extraction behaviour and response to stripping reagents it was not possible to separate Hg(II) from Ag(I).

3.6. Determination of Hg(II) in industrial effluent

The proposed method was applied for the removal and recovery of Hg(II) from paper industry wastewater (0.75 ppm Hg). 50.0 ml Sample was boiled with 5.0 ml HNO_3 and evaporated on a hot plate to reduce the volume and then finally made up to 50.0 ml [19]. 10.0 ml Of the prepared sample were extracted with 10.0 ml of 0.10 M TIBPS in toluene. Hg was quantitatively removed from the aqueous phase and subsequently recovered from the organic phase by washing it with 5% NH_4Cl in 1:10 NH_3 and determined by ICP-AES.

The investigations reveal that the reagent offers a convenient method for the separation of Hg(II) from a number of metal ions. Since the extraction of Hg is more or less quantitative over the entire acidity range of different mineral acids it does not require a rigid control of aqueous phase conditions for separation. Moreover, Hg(II) can be recovered quantitatively by a variety of reagents depending upon the need for its further processing. Kerosene (160–200°C) can replace toluene as diluent without any change in the extraction behaviour of Hg (Fig. 1) thereby offering a possibility to reduce the cost of the separation process.

Acknowledgements

The authors are grateful to American Cyanamid, USA for providing the samples of the extractant. The financial assistance from Council of Scientific and Industrial Research (CSIR) and Society for Participatory Research in Asia (PRIA), New Delhi, India is gratefully acknowledged.

Consecutive thin-layer chromatographic separation of Zr(IV), Hf(IV) and many other ions on silica gel in nitric acid–hydrogen peroxide media

Yoichi Takeda, Koji Ishida *

Laboratory of Chemistry, Nippon Medical School, Kosugi, Nakahara-ku, Kawasaki, Kanagawa 211, Japan

Received 5 April 1996; received in revised form 4 October 1996; accepted 8 October 1996

Abstract

The thin-layer chromatographic (TLC) behaviour of 64 ions including Zr(IV) and Hf(IV) has been surveyed on systems composed of silica gel and of nitric acid and nitric acid–hydrogen peroxide media. In the 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution, only Hf(IV) adsorbed very strongly, whereas Zr(IV) and many other ions showed no or weak adsorption. Stepwise development with diluted nitric acid and subsequently with nitric acid–hydrogen peroxide solution allowed the consecutive separation of three-component mixtures consisting of Zr(IV), Hf(IV) and one of many other accompanying elements, such as Mo(VI), Nb(V), Th(IV), Ti(IV), U(VI) and rare earths(III), to be conducted simply and effectively. © 1997 Elsevier Science B.V.

Keywords: Hydrogen peroxide; Nitric acid; TLC separation; Silica gel

1. Introduction

Considerable data regarding the thin-layer chromatographic (TLC) separation of Zr(IV) and/or Hf(IV) from other metals have been compiled [1–3], though most of these data have been obtained only within systematic investigations of the chromatographic behaviour of inorganic ions on a number of systems composed of various combinations of stationary and mobile phases. Little has, however, been reported about the simultaneous separation of Zr(IV) and Hf(IV), because of the remarkable similarity in the chemistry of both elements, based on their similar outer electronic configurations and ionic radii.

Several TLC methods [4–7] for separating Zr(IV) and Hf(IV) have been proposed, but they are often time-consuming, and/or applicable only to mixtures containing limited amounts of both metals and a few or no other ions. The best resolution for the separation of both metals has been obtained by Olsina et al. [6] in the system composed of silica gel and of an HCl–H_3PO_4–H_2O (10:1:9, v/v/v) mixture, in which Zr(IV) remains near the starting point and Hf(IV) migrates up to the solvent front. However, this TLC method of separation requires some experience and special care in preparing the sample solutions.

Furthermore, the separation of Zr(IV) and/or Hf(IV) from other metals has not been demonstrated, whereas the R_f data of 41 ions are given on silica gel and cellulose in the same solvent. Recently, we [7] have also revealed that the systems composed of silica gel and of mineral acid–hydrogen peroxide media provide separation factors large enough to resolve Zr(IV) and Hf(IV) from each other, present in large amounts and ratios, though the adsorption sequence is reversed from that in the system developed by Olsina et al. [6]. However, the TLC behaviour of other metals has not been investigated. Thus, effective methods for the separation of Zr(IV) and Hf(IV) from each other and from other ions are still lacking.

In this paper, the TLC behaviour of a number of inorganic ions including Zr(IV) and Hf(IV) is surveyed in systems composed of silica gel and of nitric acid–hydrogen peroxide media, and simple and useful procedures for the specific separation of three-component mixtures of Zr(IV), Hf(IV) and another inorganic ion by means of one-dimensional, stepwise development with nitric acid and subsequently with a nitric acid–hydrogen peroxide solution are presented.

2. Experimental

2.1. Materials

2.1.1. Stock solutions

Stock solutions of Zr(IV) and Hf(IV) were prepared from their oxychlorides (99.99% purity) similarly to that described earlier [7], so as to give a concentration of 0.05 mol metal l^{-1} of 6 mol l^{-1} HNO_3. For most other metals, appropriate amounts of their nitrates were dissolved in 0.1 mol l^{-1} HNO_3 to give a concentration of 0.01 to 0.1 mol metal l^{-1}. For Au(III), Bi(III), Ir(IV), Os(IV), Pd(II), Pt(IV), Rh(III), Ru(III), Sb(III), Sn(II) and Tl(III), their chlorides were dissolved in 3 mol l^{-1} HCl to give a 0.01 to 0.1 metal l^{-1} solution. For As(III), As(V), Mo(VI), Re(VII), Se(IV), Se(VI), Te(IV) and W(VI), their oxysalts were dissolved in distilled water to give a 0.005 to 0.01 mol l^{-1} solution. For V(IV), the oxychloride was dissolved in 1 mol l^{-1} HCl to give a 0.1 mol l^{-1} solution. For Ge(IV), the oxide was dissolved in a 1 mol l^{-1} NaOH solution, and the resulting solution was acidified with 1 mol l^{-1} HCl and then diluted with distilled water to a 0.005 mol l^{-1} solution. For Nb(V) and Ta(V), their chlorides were dissolved in hydrofluoric acid and a small amounts of H_2SO_4, and the resulting solutions were evaporated until sulfur trioxide fumes were evolved. The residues were taken up with a 1 to 2 mol l^{-1} tartaric acid solution to give a 0.005 mol l^{-1} metal solution. For Ti(IV), the sulfate was dissolved in 0.5 mol l^{-1} H_2SO_4 to give a 0.02 mol l^{-1} solution.

Test solutions for the measurement of R_f values were prepared, if necessary, by diluting the respective stock solutions with 6 mol l^{-1} HNO_3 or with the solvent used for the preparation of each stock solution. Sample solutions used for the separation were prepared by mixing appropriate amounts of the respective stock solutions of Zr(IV), Hf(IV) and another ion, or by diluting the resulting mixtures with 6 mol l^{-1} HNO_3. The concentrations of Zr(IV) and Hf(IV) in the test and the sample solutions were adjusted to 0.005 mol l^{-1} with respect to each metal. When the sample solution contained Sn(II), oxychloride solutions of Zr(IV) and Hf(IV), dissolved in 6 mol l^{-1} HCl, were used to prevent the production of metastannic acid.

2.1.2. Preparation of thin-layer plates

A 20-g portion of silica gel without binder (Wakogel B-0; Wako, Osaka, Japan) was thoroughly blended with 41.5 ml of distilled and deionized water. The slurry was spread to a thickness of 0.375 mm on glass plates (20×20 cm^2) with an applicator. The plates were allowed to stand for 30 min at room temperature and then dried in an oven at approximately 70°C for 30 min.

In order to remove inorganic impurities from the silica gel, the plate was thoroughly washed by developing up to the upper edge of the plate by means of the ascending technique with 30 ml of a 1 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution, using a sandwich type chamber made of plastic. Subsequently, the plate was dried on a hot-plate at approximately 90°C for 20 min. After cooling, the

plate was stored in a desiccator containing a saturated sodium chloride solution, until ready for use.

2.2. Procedure

A 0.5 μl portion of the test solution was applied to each plate by means of a microcap (Drummond, Broomall, PA) at a point 2.5 cm from one edge, and the spots were dried in air for 10 min. The plate was placed in a chromatographic chamber ($20 \times 10 \times 22$ cm^3) equipped with a small tank ($21 \times 5 \times 4$ cm^3) containing 30 ml of a developing solvent, and developed up to 10 cm from the starting point by the ascending technique at room temperature. It took about 20 min to develop with the solvent. The solvents used were 0.5 mol l^{-1} HNO_3 and a 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution. In the case of the sample solution containing Sn(II), a 0.5 mol l^{-1} HCl–3% (w/v) H_2O_2 solution was also used as a solvent.

For the separation of the sample solutions of the three-component mixtures, a new developing technique was applied. The plate, on which a 0.5 μl portion of the sample solution was spotted, was immersed first in 0.5 mol l^{-1} HNO_3 in a similar manner to that described above, and developed up to a distance of 3 cm from the starting point (development time approximately 4 min). Immediately, the plate was transferred to a different chromatographic chamber with a tank containing 30 ml of a 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution, and developed up to a distance of 10 cm from the first starting point by the ascending technique (development time approximately 16 min). When the sample solution contained Ti(IV), nitric acid of 2 mol l^{-1} was used as the first developing solvent to prevent the hydrolysis of the metal during chromatography.

2.3. Detection

After the second development, the plate was dried on a hot-plate at approximately 90°C, and the locations of the respective ions were visualized by spraying with various solutions of chromogenic reagents, as indicated in Table 1.

3. Results and discussion

3.1. Adsorption behaviour

HNO_3 system: The R_f values of all of the ions tested on silica gel in 0.5 mol l^{-1} HNO_3 are summarized in Table 2. Most of the ions did not show any adsorption, because of specific adsorption of protons on silica gel in the acidic solution [8]. Contrarily, Zr(IV) and Hf(IV) adsorbed very strongly, as noted previously [7]. Oxyanions, such

[b] Average of $R_f \times 100$ values of 56 ions.
[c] Developed with 0.5 mol l^{-1} HCl–3% (w/v) H_2O_2 (10 cm run).
[d] Developed with 2 mol l^{-1} HNO_3 (3 cm run) and then with 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 (7 cm run).

as As(III), Ge(IV) and Mo(VI), adsorbed to a moderate extent, probably owing to the anion exchange of silica gel in the strong acidic solution [8]. Sn(II) and W(VI) showed long tailing, due to the formation of insoluble species, metastannic acid and tungustic acid, respectively. Furthermore, Ti(IV) also showed long tailing, because of the hydrolysis of the metal during chromatography. It is clear that the nitric acid system is suitable for the separation of both Zr(IV) and Hf(IV) from many other ions except Sn(II) and Ti(IV).

HNO_3-H_2O_2 system: The R_f values of the ions tested are also given in Table 2. Zr(IV), Mo(VI), Ti(IV) and W(VI), which easily produce peroxso complexes, migrated up to the solvent front, and furthermore almost all of the others (56 ions) showed no adsorption, so that Hf(IV) could be separated from all the ions, except for Sn(II) which exhibited long tailing. This system is not favorable for the separation of Zr(IV) from many other ions, but is suitable for the separation of three-component mixtures consisting of Zr(IV), Hf(IV), and As(III) or Ge(IV). In addition, As(III) gave somewhat higher R_f values in this system than in the nitric acid system, because of the oxidation of As(III) to As(V) during chromatography.

Stepwise development: Inspection of the adsorption behaviour of a large number of ions tested in the nitric acid and the nitric acid–hydrogen peroxide media suggests that many effective procedures for the consecutive separation of Hf(IV), Zr(IV) and another inorganic ion in the described order can be established by a combination of these two solvents. In order to separate three-component mixtures of Zr(IV), Hf(IV) and another ion from each other, the stepwise development first with 0.5 mol l^{-1} HNO_3 (3 cm run) and then with a 0.5 mol l^{-1} HNO_3–3% H_2O_2 solution (7 cm run) was attempted as a new technique. The results are summarized in Table 2. The R_f data indicate that this technique enables the complete separation of three-component mixtures containing Zr(IV), Hf(IV), and one ion among 56 ions other than Ge(IV), Sn(II), and Ti(IV). It should be noted that in applying this developing technique, the plate should not be dried on a hot-plate just after the first development, because Zr(IV), if dried, gives irregular and long tailing.

3.2. Separation

Typical chromatograms of three-component mixtures, obtained by the stepwise development,

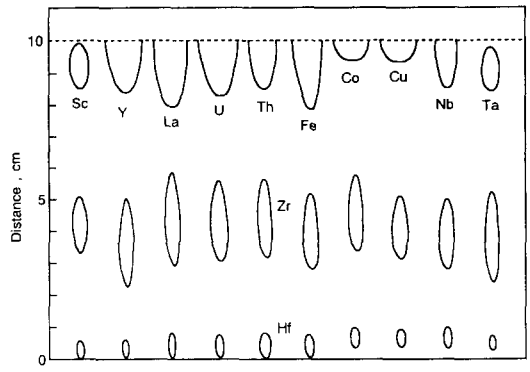

Fig. 1. Separation of Zr(IV), Hf(IV) and other metals (Zr(IV): the middle spot; Hf(IV): the lowest spot). Solvent: 0.5 mol l^{-1} HNO_3 for the first development (3 cm run); 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 for the second development (7 cm run), Loading amount: 2.5×10^{-9} mol for Zr(IV), Hf(IV), Nb(V) and Ta(V); 5.0×10^{-7} mol for Sc(III), Y(III), La(III), U(VI), Th(IV), Fe(III), Co(II) and Cu(II), - - -: solvent front.

are given in Fig. 1. As expected from the R_f data, Zr(IV) and/or Hf(IV) were easily and simultaneously separated from 56 ions except Ge(IV), Sn(II), and Ti(IV). For the separation of Zr(IV), Hf(IV), and Ge(IV) or Sn(II), the stepwise development technique was not applied. The three-component mixture containing Ge(IV) or Sn(II) was simply separated by developing upwards to 10 cm with the 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution, or with the 0.5 mol l^{-1} HCl–3% (w/v) H_2O_2 solution, respectively. The R_f values of each metal are given as numerical values in parentheses in Table 2. Furthermore, the complete separation of the three-component mixture containing Ti(IV) was achieved by the stepwise development first with 2 mol l^{-1} HNO_3 (3 cm run) and subsequently with the 0.5 mol l^{-1} HNO_3–3% (w/v) H_2O_2 solution (7 cm run). The first developing solvent was effective in preventing the formation of long tailing. The R_f values of each metal, obtained with this development, are also given in Table 2.

Hence, the present TLC systems composed of silica gel and of nitric acid and/or hydrogen peroxide enabled the specific separation of Zr(IV) and/or Hf(IV) from many other accompanying elements, such as Mo(VI), Nb(V), Th(IV), Ti(IV), U(VI) and rare earths(III), present in natural ores, reactor materials, and fission products. In addition, it can be expected that the present systems will offer a number of useful procedures effective for the separation of three-component mixtures, and furthermore will be applicable not only to TLC separation, but also to the column separation of three-component mixtures coexisting in a wide range of amounts and ratios.

Abstract

Fluorescent reaction between ascorbic acid (AA) and 2,3-diamino-naphthalene (DAN) was studied. The experimental results showed that AA could react with DAN at pH = 10.2–10.5, and form the fluorescent heterocyclic condensation products which emitted strong fluorescence. The fluorescence intensity was measured in a 1 cm quartz cell with excitation and emission wavelengths of 400 and 520 nm, respectively. The relationship was obtained between the fluorescence intensity and AA concentration in the range of 2–300 μg ml^{-1}, the regression coefficient is 0.9993. The detection limit (signal-to-noise = 2) is 0.4 μg ml^{-1}. © 1997 Elsevier Science B.V.

Keywords: Ascorbic acid determination; Fluorescent reaction

1. Introduction

Many different methods for the determination of ascorbic acid (AA) have been reported in the literature. They concentrated on spectrometry [1], redox reaction [2], derivatization reaction [3], electrochemical method [4], enzymatic method [5], and chromatographic method [6], but few fluorometric estimation methods of AA were reported. A classic fluorometric method with *o*-phenylenediamine (OPDA) as fluorescence reagent was used to determine AA [7]. This method needed to treat with redox reagent beforehand and then reacted AA with OPDA, its detection limit was 2 μg ml^{-1}. Our experiments indicated that at the pH = 10.2–10.5, AA could react with 2,3-diaminonaphthalene (DAN) which didn't need pretreatment, its detection limit was 0.4 μg ml^{-1}. So the proposed method is more simple and sensitive than OPDA method.

2. Experimental

2.1. Apparatus

All fluorescence intensities were measured on a 850 fluorescence spectrophotometer (Hitachi, Japan).

* Corresponding author.

PII S0039-9140(96)02129-7

2.2. Reagents

1. 2,3-diaminonaphthalene (DAN) solution (0.1%, v/v): it is prepared by dissolving 0.1 g DAN in 100 ml 0.1 mol l^{-1} HCl, then treated with cyclohexane, rejected organic phase, the remained water phase repeated 2–3 times with cyclohexane according to the above procedure.
2. Ascorbic acid solution: it is prepared by dissolving 0.100 g AA in 100 ml distilled water. The stock solution was 1.00 mg ml^{-1}.
3. Aminoacetic acid buffer solution: it is prepared by dissolving 3.8 g aminoacetic acid in 100 ml distilled water and adjusting pH to 10.3 with 6 mol l^{-1} NaOH.

2.3. Procedure

To a 25 ml test tube, solutions were added according to the following order: AA solution, 0.5 ml 0.5 mol l^{-1} NaOH, 1 ml 0.1% DAN solution, 2 ml aminoacetic acid buffer. The mixture was diluted to 10 ml with distilled water, thoroughly mixed by shaking and then allowed to stand for 40 min. The fluorescence intensity was measured in a 1 cm quartz cell with excitation and emission wavelengths of 400 and 520 nm, respectively.

3. Results and discussion

3.1. Fluorescence spectra

The excitation and emission spectra of AA-DAN-aminoacetic acid (1), DAN-aminoacetic acid (2) are shown in Fig. 1. From Fig. 1, it can be seen that the wavelength of emission peak is 520 nm, the wavelengths of excitation peak are 370, 400 nm. Since DAN itself is a strong fluorephore with excitation and emission wavelengths of 340 and 390 nm, if the excitation wavelength is 370 nm, the excess of DAN in the reaction will interfere with the emission of the fluorescence products, therefore, the excitation wavelength of 400 nm was chosen in our experiments and a low and stable reagent blank was obtained.

3.2. Effect of pH

The effect of pH on fluorescence intensity of the system was shown in Fig. 2. From Fig. 2, it can be seen that the fluorescence intensity is the strongest and remains stable in the range of pH = 10.2–10.5.

In this paper, the following buffers were examined: Na_2CO_3, borax–NaOH, NH_3–NH_3Cl, K_2HPO_4, aminoacetic acid. The results showed that 2 ml of 0.5 mol l^{-1} aminoacetic acid buffer was the most suitable.

3.3. Effect of DAN concentration

The effect of DAN concentration on fluorescence intensity of the system was studied. The results were shown in Fig. 3. From this figure we can see that the suitable concentration of DAN was 0.01%.

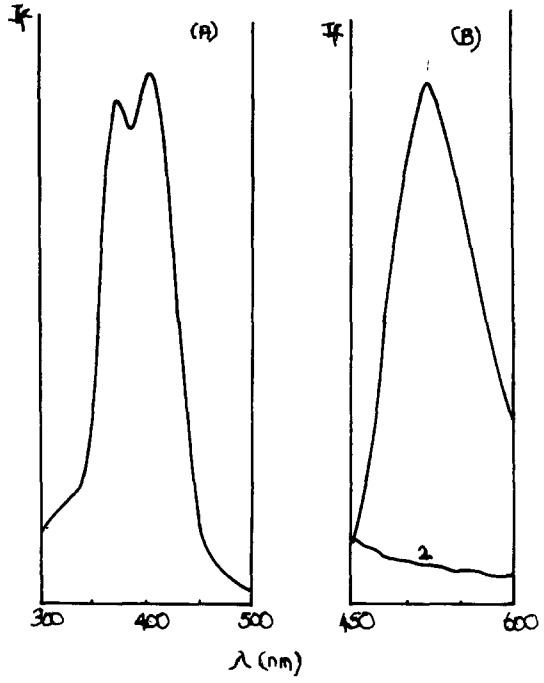

Fig. 1. Fluorescence spectra (a) excitation spectrum (λ_{em} = 520 nm), (b) emission spectrum (λ_{ex} = 400 nm). (1) AA-DAN-aminoacetic acid, (2) DAN-aminoacetic acid conditions: ascorbic acid: 0.2 mg ml^{-1}, DAN: 0.01%; aminoacetic acid: 0.5 mol l^{-1}, 2 ml, pH = 1.03.

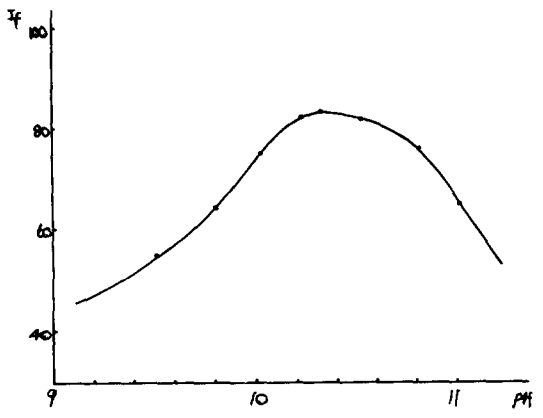

Fig. 2. Effect of pH. Conditions: ascorbic acid: 0.05 mg ml^{-1}, DAN: 0.01%; aminoacetic acid: 0.5 mol l^{-1}, 2 ml.

3.4. Effect of temperature

High temperature could destroy the structure of AA and quench the fluorescence of the system. Our experiments indicted that when the temperature was higher than 50°C, the fluorescence intensity of the system was completely quenched. The suitable temperature was 30°C or so.

3.5. Stable tests

The experiments indicated that at room temperature the fluorescence intensity of the system reached a maximum after 40 min and remained stable at least for 1 h. In addition, effect of surfactants of fluorescence intensity of the system was examined, the results showed the enhancement effect was not obvious.

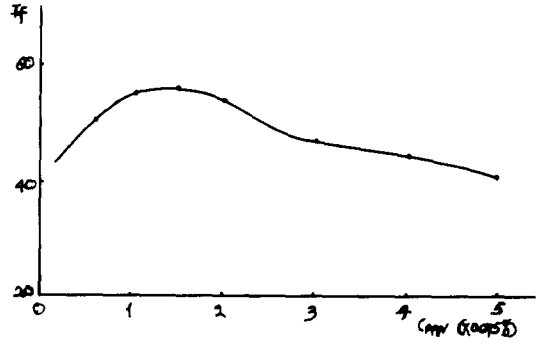

Fig. 3. Effect of DAN concentration. Conditions: ascorbic acid: 0.25 mg ml^{-1}; aminoacetic acid: 0.5 mol l^{-1}, 2 ml, pH = 10.3.

3.6. Calibration curve and detection limit

The calibration curve was made according to the procedure in the optimum conditions. The results indicated that the fluorescence intensity of the system was a linear function of AA concentration in the range of 2–300 μg ml^{-1}, the regression coefficient is 0.9993, the detection limit (S/N = 2) is 0.4 μg ml^{-1}.

3.7. Recovery test

In the serum, recovery tests of AA were made. The results were shown in Table 1. From Table 1, it can be seen that recovery ratios were upwards of 90% and serum didn't need complicated biological treatment. Therefore, the proposed method for determining AA was satisfactory.

3.8. Sample determination

The proposed method was used to determine AA in Vc tablets (Jilin Tonghua Baishan Medicine Factory of China) and compared with the most commonly used OPDA method [8]. The results were shown in Table 2. From Table 2, it can be seen that the accuracy and precision of the method are satisfactory.

3.9. The characteristics of the proposed method

In comparison with the most commonly used OPDA method, the proposed method possesses the following characteristics:

1. The detection limit is 0.4 μg ml^{-1}, which is obviously lower than that of OPDA method [8]. so the sensitivity of the proposed method is higher.

2. In OPDA method, the redox reagent, such as norit (carbon), 2,6-dichloroindophenol, *N*-Bromosuccinimide and iodone, must be used to oxidize AA to DHAA, while in this method it is unnecessary to add a redox reagent to the reaction system. We think that AA will not be transferred to DHAA in the absence of the oxidizer

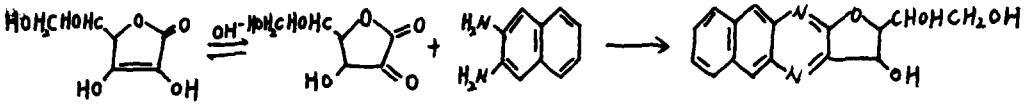
Table 1
Recovery test in the serum

Added Vc (μg ml^{-1})	Found Vc (μg ml^{-1})	$\bar{X} \pm S$	Recovery (%)
20.0	18.92, 17.95, 18.33, 18.92, 18.95	18.6 ± 0.45	93.1
100.0	94.8, 96.1, 94.3, 93.4, 95.2	94.8 ± 1.01	94.8

Table 2
Determination of samples

The proposed method		OPDA method (8)	
Found Vc (%)	$\bar{X} \pm S$	Found Vc (%)	$\bar{X} \pm S$
52.3, 50.9, 54.6		52.4, 50.5, 50.9	
50.9, 52.3	52.2 ± 1.5	53.4, 54.2	52.3 ± 1.6

and there is a tautomeric between enediol and 2-hydroxy carbonyl groups in the alkaline medium. Therefore, the possible mechanism is illustrated as follows.



Since the conjugate π-bond system of the condensate product in the proposed method is larger than that in the OPDA method, the sensitivity of the proposed method is higher than that of OPDA method.

Abstract

A new method of physically immobilizing a biomolecule of analytical interest in poly(vinyl alcohol) cryogels was developed to obtain suitable biosensors. An amperometric glucose sensor was constructed using glucose oxidase immobilized on membranes obtained by a freezing-thawing cyclic process. No chemical cross-linking agent was used. Sensor behaviour was evaluated electrochemically with a hydrogen peroxide electrode. The glucose content in standard solutions was determined and linear calibration curves in the 5×10^{-5}–3×10^{-3} mol l^{-1} range were obtained. Temperature and pH effects on the electrochemical response were described and kinetic parameters in the immobilized system were evaluated. © 1997 Elsevier Science B.V.

Keywords: Biosensors glucose oxidase; Physical immobilization; PVA cryogels

1. Introduction

Amperometric enzyme-based biosensors continue to generate much interest in clinical, environmental and quality control analyses. The performance of enzyme electrodes are strongly dependent on enzyme immobilization techniques. Generally, entrapment of enzyme molecules in polymeric membranes is considered an attractive procedure because it is regarded as a mild coupling method that preserve quaternary protein structure and most of its activity, even if in some cases it can be reversible.

A method has been developed for the physical immobilization of enzymes in poly(hydroxyethylmethacrylate)(HEMA) membranes and glucose [1] and choline [2] sensors have been studied and characterized. The immobilization procedure, based on low-temperature γ induced polymerization of an aqueous solution of monomer and enzyme, produced a matrix characterized by a porous cross-linked structure, with both features of hydrophilicity and biocompatibility.

Pursuing our interest for biocompatible membrane electrodes with good electrochemical performances, we immobilized glucose oxidase (GOD) in poly(vinyl alcohol)(PVA) cryogels obtained by freezing-thawing cyclic processing.

PII S0039-9140(96)02130-3

Poly(vinyl alcohol) is a biocompatible polymer [3], that is considered an appropriate matrix for sensor preparation. Lactate oxidase was incorporated in a PVA network prepared by cross-linking the reactive nucleophilic groups (as hydroxyl and amino) with aromatic tri-isocyanates [4]. Other authors demonstrated the possibility of immobilizing glucose oxidase [5] and lactate oxidase [6] in a PVA matrix on platinized graphite electrodes by γ irradiation, obtaining an enzyme layer sandwiched between two polymer layers. Enzymes were entrapped in a PVA membrane that was cross-linked by means of UV light [7]. Immobilization of microorganisms with phosphorylated PVA gel was also reported [8]. Recently a mixture of PVA and polyhydroxy cellulose was used to immobilize tyrosinase on a glassy carbon electrode [9] and a glucose sensor was realized by immobilizing glucose oxidase in a composite membrane of silk fibroine and PVA [10].

Acetogenium kivui cells were immobilized in PVA cryogels [11] to obtain biocatalytic reduction of CO_2 and *Pseudomonas sp.* cells were immobilized to construct an L-Proline biosensor [12].

The proposed method of enzyme immobilization in PVA hydrogels is characterized by the absence of chemical cross-linking agents that could compromise its biocompatibility or of physical agents, such as γ radiation that could deactivate the biological substrates, due to damage caused mostly by the indirect effect of water radiolysis.

The exposition of aqueous PVA solutions to several freezing-thawing cycles leads to reinforced gels owing to a densification of the macromolecular structure [13,14], that is function of the cycling time and temperatures. After the freezing-thawing process, the chains are physically cross-linked by semipermanent entanglements, molecular associations or crystallites. These novel networks are of significant interest in the biomedical field because they are nontoxic for organisms, contain no impurities and their water content matches that of biological tissue.

In this paper, GOD immobilized in PVA cryogel was used to assemble an amperometric sensor measuring hydrogen peroxide produced in the enzymatic reaction. The parameters that could affect the electrode performances were evaluated and the electrochemical features of the system are also described.

2. Experimental

2.1. Reagents

Glucose oxidase (EC 1.1.3.4, type II-S from *Aspergillus niger*, 18 000 units g^{-1} solid), peroxidase (POD, EC 1.11.1.7, type VI from Horseradish, 250 purpurogallin units mg^{-1} solid), o-dianisidina dihydrochloride (ODA) and β-glucose were obtained from Sigma Chemical (St. Louis, USA). Stock solutions were prepared in bidistilled water or buffer solution and stored in the dark at 4°C. Glucose solutions were allowed to mutarotate overnight at room temperature before use.

PVA with an average Mw = 50 000 and Mw = 124 000–186 000 both with a degree of hydrolysis of 99% were purchased from Aldrich Chemie (Stenheim, Germany) and used without further purification. All others analytical grade chemicals were purchased from Carlo Erba (Milano, Italy) or Merck (Darmstadt, Germany).

Control serum was manufactured by Technicon Instruments (Tarrytown, USA) and marketed by Bayer Diagnostics (Oreq-Tournai, Belgium).

2.2. GOD immobilization and sensor preparation

PVA solutions in 0.1 M phosphate buffer at pH 6 were heated in an oven at 90°C for a time no longer than 5 h to achieve complete polymer dissolution. When the solution had cooled to 30–35°C the appropriate amounts of GOD dissolved in few μl of buffer was added. The viscous honey-like solution was carefully mixed and then sonicated to remove air bubbles at a temperature below than 37°C. After partial filling with PVA solutions, polyethylene vials (5 mm i.d.) were sonicated again and left at −25°C for 12 h. After this first freezing process, they were allowed to thaw at 4°C for up to 12 h. Five freezing-thawing cycles were used for the PVA gel preparation. The sponge-like material obtained with this procedure

was cooled at −20°C and sliced into about 120 micron discs with a microtome. The discs were carefully washed six times with a phosphate buffer (20 ml, pH 6) for 12 h at 4°C.

The apparent GOD activity was determined by dipping a membrane in a 0.1 M glucose solution (2.8 ml, 0.1 M in phosphate buffer, pH 6) and incubating for 1 min, with stirring at 25°C. After removal of the membrane, a solution of 100 μl POD (50 purpurogallin units ml^{-1}) and 20 μl ODA (1% m/v in water) was added and the solution transferred to a glass cells to read the absorbance value at 460 nm.

The working electrode was a platinum wire (0.5 mm diameter) sealed in a glass tube and polished with alumina powder to ensure a flat surface. A membrane disc, placed on the electrode surface and fixed with a teflon cap having a 3 mm hole, gave the active sensor. When not in use the membranes were stored at 4°C in 0.1 M phosphate buffer at pH 6.

2.3. Apparatus

The determination of hydrogen peroxide was performed in an electrochemical cell with a working volume of 20 ml, in a three-electrode configuration. The three electrodes were connected to an AMEL (Milano, Italy) 559 model potentiostat. A saturated calomel electrode and a platinum foil with large surface area were used as the reference and counter electrode, respectively. All the experiments were carried out in a temperature-controlled cell using a Haake F3-C thermostatic bath.

Spectrophotometric measurements were carried out with a Hitachi U-3200 spectrophotometer equipped with a 1 cm thermostated cell.

The scanning electron microscopy was performed with a Cambridge Stereoscan 250 (Cambridge, UK) operating at a 20 kV accelerating voltage.

2.4. Electrochemical measurements

Glucose determination was carried out electrochemically by measuring the hydrogen peroxide production as a result of the enzymatic reaction. This was done by immersing the sensor in stirred 0.1 M phosphate buffer at pH 6 and applying an oxidative potential of +600 mV against a saturated calomel electrode. When the backround current had stabilized, an appropriate amount of glucose solution was introduced to give a preselected concentration. All measurements were carried out using a thermostated bath at 25°C, unless otherwise mentioned.

3. Results and discussion

The procedure described produces a matrix of a physically cross-linked polymer containing uncrossed-linked polymer and water. The porous, hydrophilic and permeable membranes had interesting mechanical characteristics and can be handled easily. The properties of this gel depended, under the same conditions of temperature and freezing time and number of cycles, on the molecular weight of the uncrossed-linked polymer and its concentration in an aqueous solution.

In fact, the characteristics of hydrogels are determined by the size of particles that make up the supermolecular structure and these small spheres increased in diameter with each freezing-thawing cycle. Freezing time and freezing temperature are very important in determining the cryogel structure. The stability and strength of gels increased with an increase in freezing time. Stable gels were formed even when solutions were frozen at −20°C for only 1 h, but the strongest gels resulted after 24 h. When the freezing temperature was changed to 0°C, the ensuing gel could not hold their weight even after four freezing-thawing cycles. Thawing temperature was not very important for the final structure of gel, provided it is above 0°C.

In water, the PVA gel is essentially insoluble, but undergoes significant swelling [15]. Experimental measurements related to swelling behaviour of the gel demonstrated that a significant densification of the structure was obtained after five freezing-thawing cycles and with a thawing time of approximately 4 h [14]. The increase of mechanical strength as the number of cycles increased was probably due to the increased degree of crystallinity [16].

Although even a solution of 10% wt of PVA led to a gel formation, stronger structures with high stability were obtained from solutions of at least 15% wt.

The features of two kinds of polymers were examined: *A*, obtained from an aqueous solution of 24% wt of PVA with an average Mw = 50 000 and *B*, from a solution of 15% PVA (highest solubility grade) with an average Mw = 124 000–186 000.

Fig. 1 shows the scanning electron micrographs of these two matrices. Although both PVA solutions led to stable polymers, stronger gels were obtained with the higher molecular weight. The structure looked closer and the pores were smaller.

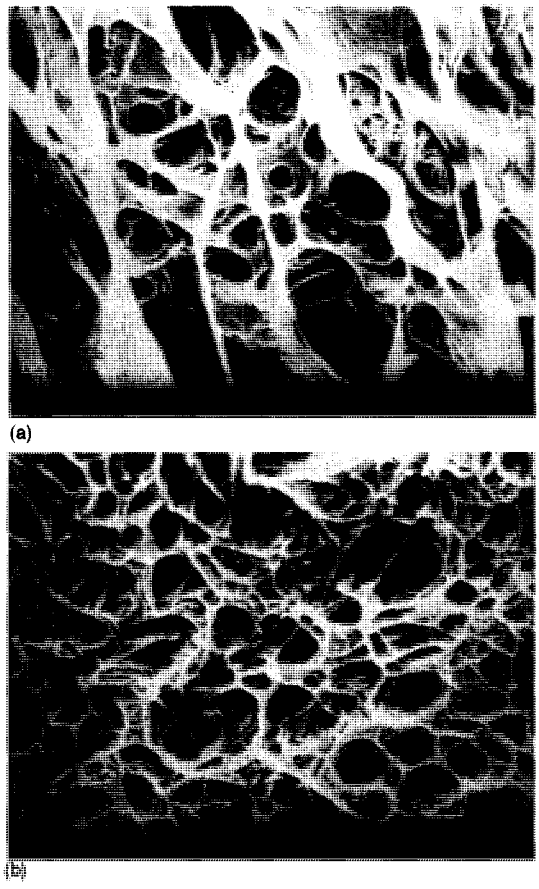

Fig. 1. Scanning electron microphotographs of PVA membranes. *A*, 24% PVA with an average Mw = 50 000; *B*, 15% PVA with an average Mw = 124 000–186 000.

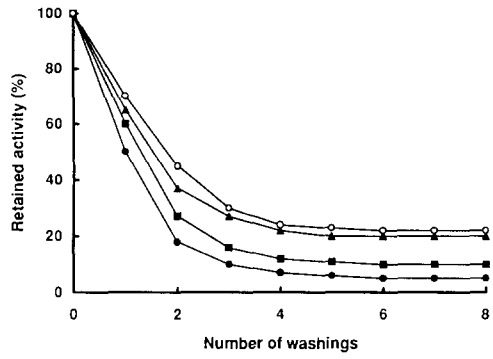

Fig. 2. Activity retention curves for the immobilized enzyme after repeated washings. (●) Membrane *A* with a 6 mg g^{-1} enzyme loading; membrane *B* with a (■) 6 mg g^{-1}, (△) 3 mg g^{-1} and (○) 1.5 mg g^{-1} enzyme loading.

In order to measure the apparent activity truly fixed, important to forecast its analytical performance as a sensor, and to determine the percentage leakage from the gel, the following method was used. Several pieces with a total weight of about 1 g were washed with a phosphate buffer (20 ml, pH 6) for 12 h, then the washing solution was assayed for enzyme activity. This process was repeated eight times, using the same matrix sample. After the last washing, the matrix was also assayed for apparent enzyme activity. The results are shown in Fig. 2. With an enzyme loading of 6 mg g^{-1} of monomer solution, the greater part of the total activity introduced passed into the solution in the first three washings and only 5–6% and 9–10% for polymer *A* and *B*, respectively were really fixed permanently. In order to verify the effect of the enzyme loading on the amount of activity truly fixed, the specific activity of polymer *B* was also measured using initial amounts of 1.5 and 3 mg g^{-1} of solution. The detected activity corresponded to a percentage immobilization of up to 22 and 20%, respectively. As shown in Fig. 2, this means that the percentage of fixed activity with respect to the introduced amount became less upon increasing the enzyme loading, whereas the specific activity seemed to increase very little for values higher than 3 mg g^{-1}. Moreover it is important to evaluate either the total weight of enzyme introduced or its molecular weight because these are all important factors in the understanding of the immobilization process.

All the following measurements were carried out with membranes obtained from an enzyme loading of 6 mg g^{-1} and washed six times with buffer solutions and so that all not fixed GOD had been rinsed out.

The apparent activity of immobilized GOD in measured membranes (120 μm thickness and 5 mm diameter) used for the amperometric analysis were found to be about 90 and 150 mU cm^{-2} for the polymers *A* and *B*, respectively. The enzyme was retained in the network of the polymer *B* in larger amounts than *A* and this was compatible with the stronger structure observed for the hydrogel obtained from the kind of PVA with higher molecular weight.

Typical calibration graphs for GOD-modified *A* and *B* polymer electrodes, measured by anodic oxidation of H_2O_2, are shown in Fig. 3. The response to glucose gave linear patterns in the 5×10^{-5}–3×10^{-3} M range with a linear regression equation of $y = 0.099x + 0.003$, $R^2 = 0.9992$ for electrode *A* and $y = 0.141x + 0.004$, $R^2 = 0.9994$ for electrode *B*, where y was the current (μA) and x was the substrate concentration (mmol l^{-1}). A detection limit of 3×10^{-5} M was estimated with a signal-to-noise ratio > 3. The relative standard deviation for five replicate determinations of 1 mM glucose solution was 2.5%.

As expected, the response increased with the amount of apparent enzyme activity immobilized in the membrane. These changes, however, were not directly proportional to the enzyme content. In fact, the slopes of the resulting calibration

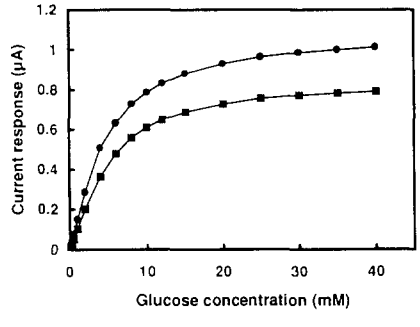

Fig. 3. Calibration graphs for glucose obtained at pH 6 and 25°C. (■) sensor with membrane *A* (lower Mw); (●) with membrane *B* (higher Mw).

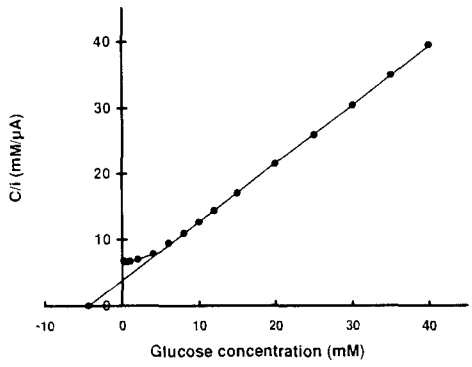

Fig. 4. Hanes plot of the calibration data for a glucose oxidase electrode with membrane *B*.

graphs in the linear range, and hence the sensitivities, were 0.099 and 0.141 μA l $mmol^{-1}$ for the electrodes *A* and *B*, respectively.

The glucose response curves can be described by the Michaelis–Menten equation, expressed in the electrochemical Hanes form:

$$C/i = (C + Km_{(app)})/i_{max}$$

where C = glucose concentration, i = steady-state current, i_{max} = maximum steady-state current and $Km_{(app)}$ = apparent Michaelis-Menten constant.

The linear portion of the curve (Fig. 4), corresponding to the response in the kinetic regime for electrode *B*, gave values of 4.5 mM for $Km_{(app)}$ ($-x$ intercept) and 1.126 μA for i_{max} (reciprocal of the slope). The response for electrode *A* gave the same value for $Km_{(app)}$ and 0.890 μA for i_{max}.

Surprisingly, the apparent Michaelis–Menten constant calculated was very low. Generally, an increase in K_m value for immobilized enzyme systems was observed, owing to the effect of conformation changes in the enzyme as a result of the chemistry of cross-linking and the effect of the diffusion of substrate towards the active sites. The gel material obtained through the process of freezing-thawing cycles is a physically cross-linked polymer containing uncrossed-linked polymer and water [13]. The enzyme is retained in the network but it behaves as it were freely soluble and maintained the same active conformation. Moreover the presence of a high water content and hydroxyl groups in the polymer provides microenvironmental conditions particularly favorable for glucose

oxidase. The structure of this matrix and its hydrophilicity reduces the mass-transport resistance to the diffusion of a substrate.

The poor linearity observed in Fig. 4 seems to imply diffusional limitations for lower glucose concentrations. An attempt was made to analyse the same data with the method proposed by Albery, Bartlett and coworkers [17–19], even though Albery's theoretical model does not take into consideration the concentration polarization in the enzyme layer and therefore these conclusions should to be considered correct as regards mass-transport limitations, but only approximate as regards the real experimental situation.

From this model, the k'_S/k'_{ME} ratios were calculated, where k'_S was the mass-transport rate constant for the substrate diffusion through the membrane and k'_{ME} was the effective electrochemical rate constant for the enzyme electrode. Values of 1.4 and 1.3 for electrodes *A* and *B* were obtained respectively, indicating that transport of glucose through membrane was partially rate limiting, mostly at low substrate concentration [20].

A low value for the apparent Michaelis–Menten constant implies more favorable conditions for GOD activity, but lowers the upper limit of the linear response range.

The pH influence on the sensor *B* was also investigated and Fig. 5 shows the sensor response to glucose solution in the pH range of 4–8. It can be seen that the optimum pH was found at 5.5, the same value reported for the free enzyme [21,22]. The lack of the typical shift toward more alkaline values upon immobilization procedures, confirmed the hypothesis that GOD in this matrix behaved as if it were free.

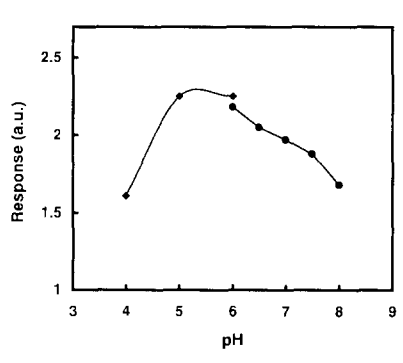

Fig. 5. Biosensor *B* response dependence on pH in 1 mM glucose solution at 25°C. (■) 0.1 M citrate buffer; (●) 0.1 M phosphate buffer.

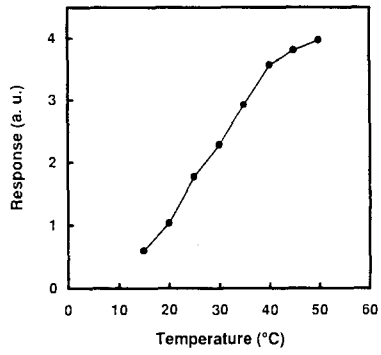

Fig. 6. Biosensor *B* response dependence on temperature in 1 mM glucose solution, pH 6.

Fig. 6 shows the trend of the electrode *B* response as a function of temperature. The response increased with a temperature increase from 15 to 50°C. In this range there were no irreversible modifications to the system; measurements carried out at 25°C with the same electrode again showed the original signal.

Response is modulated by the mass-transport through the membrane and therefore the electrode signal is considerably influenced by the thickness of the enzyme layer. Hence this parameter must be carefully controlled. The electrode signal of ten membranes with the same diameter, average weight and presumably the same thickness showed a relative standard deviation less than 5%.

The response time, for the examined biosensors *A* and *B*, was within 120 s and it remained unchanged for the entire life of the membranes.

The long term stability of the GOD modified polymer was good. In order to examine the effect of storage, the membranes were detached and washed after each assay in buffer solutions and kept at 4°C. After 2 months the electrode signal decreased by about 10% in comparison with the initial value measured at a single concentration in the linear response range.

Physical immobilization procedures are always connected with protein leaking on long term storage or exposures over large volumes, mainly if there are modifications of ionic strength or pH values.

Some membranes of an interesting batch (about 0.5 g) in buffer solution (25 ml) for a 2 months period were kept under control and an enzyme leaking of about 1–2% with respect to the original enzyme loading, corresponding to a 5–10% respect to the activity measured in the membranes after six washings, was actually observed.

From our results it could be claimed that this kind of leakage has no effect on normal, analytical biosensor performances, but it could otherwise be a problem when proposing the biocompatibility of the system.

The electrode *B* was used to determine glucose in a real sample and the results, relative to the analysis of a control serum, were compared with those obtained for the same sample by the enzymatic-spectrophotometric method which is generally used in routine biomedical analysis.

Nominal value of serum = 4.17 mmol l^{-1} (scattering range 3.67–4.67 mmol l^{-1}); mean value found by spectrophotometric method (triplicate) = 3.87 ± 0.04 mmol l^{-1}; mean value found by amperometric method (triplicate) = 3.95 ± 0.08 mmol l^{-1}.

4. Conclusions

This work supports the results that PVA cryogel produced by a cyclic freezing-thawing process is a suitable material for the immobilization of GOD on electrode surfaces and has some advantageous characteristics over other immobilization methods. The hydrogel membranes resulting from this treatment have interesting mechanical properties and the immobilization is achieved without use of chemical or reinforcing cross-linking agents.

In particular, the following considerations may be made.

(a) The PVA cryogel with higher molecular weight offers better performances owing to the closer structure, higher amount of immobilized enzyme and magnitude of the electrode signal.

(b) The data obtained indicate that the PVA hydrogel provides very favorable environmental conditions for glucose oxidase and the enzyme behaves as if it were virtually free.

(c) The low $Km_{(app)}$ value of the system limits the linear range and the possibility of extending the upper limit to higher values should be investigated.

(d) The response time and the long term stability of this glucose sensor are good.

(e) The immobilization method needs to be further improved so as to prevent all the enzyme leaking.

Flow injection determination of Pb and Cd traces with graphite furnace atomic absorption spectrometry

M. Colognesi, O. Abollino, M. Aceto, C. Sarzanini, E. Mentasti *

Department of Analytical Chemistry, University of Turin, Via P. Giuria n. 5, 10125 Turin, Italy

Received 14 May 1996; received in revised form 14 October 1996; accepted 15 October 1996

Abstract

The preconcentration and recovery of lead and cadmium traces at ng l^{-1} level were evaluated in standard solutions and natural aqueous samples using a FIAS (Flow Injection Atomic Spectrometry) apparatus. The method is based on retention of the complex formed between Pb or Cd and 1,2-dihydroxy-3,5-benzendisulphonic acid (Tiron) on a macroporous anion-exchange resin. The recovery of the analytes was obtained by elution with 0.1 M HCl and their determination was performed by Graphite Furnace Atomic Absorption Spectrometry (GFAAS). The detection limits were 9 and 7 ng l^{-1} for Pb and Cd respectively. The effects of sample solution pH and composition and of interfering agents as well as reagent purity are discussed. The technique was applied to the analysis of natural waters. © 1997 Elsevier Science B.V.

Keywords: Cadmium; Flow injection atomic spectrometry; Lead; Natural waters; Preconcentration; Tiron

1. Introduction

Two important features distinguish heavy metals from other toxic pollutants: they are not biodegradable and their toxicity is controlled by their physico-chemical form. Heavy metals can be found in waters (fresh, sea, lake, waste), food (fruit, fish, milk), soils, sediments and biological samples [1].

Several studies concerning determination of ultratraces of metal ions in water samples with preconcentration and/or separation of the analyte from its matrix have been reported [2–7].

The aim of this study was to determine very low concentrations of metal ions, namely lead and cadmium, in liquid samples. Lead and cadmium commonly occur in the environment due to the contribution of anthropogenic sources, such as waste incineration and combustion of coal and oil, and are among the most toxic heavy metals for human health.

Fang et al. [5,6] and Sperling et al. [7] determined cadmium and lead in sea-water and drinking water with a preconcentration system based on on-line sorbent extraction. A micro-column packed with silica C-18 and sodium diethyldithiocarbamate (DDTC) as ligand were used in conjunction with a flame atomic absorption spectrometer.

A flow injection preconcentration technique and atomic spectrometry were coupled in this study; this allows several advantages such as minimised interference effects, enhanced sensitivity, ease of automation and matrix removal [8]. The method is based on the complexation of Pb and Cd with Tiron, 4,5-dihydroxy-1,3-benzendisulphonic acid, which forms negatively charged complexes, then retained by a macroporous anion-exchange resin. Metal complexation with Tiron takes place via the two hydroxylic moieties which allow a reversible chelation, whereas the two sulphonic groups allow the retention of the complex on the anion exchange resin. The total metal recovery from the resin was then obtained with a small volume of 0.1 M HCl, which was immediately analysed using graphite furnace atomic absorption spectrometry (GFAAS). Alternatively, it is possible to drive the eluate to the nebulizer of a flame atomic absorption spectrometer.

An advantage of the proposed method is the use of an anion exchange resin, which has a wider operating pH range (0–14) with respect to the C-18 sorbent (2–8) and allows the use of an acidic eluent, more suitable than an organic one in GFAAS determinations. In fact we verified in our laboratory that the measured metal concentrations in ethanol media decreased with time, probably due to absorption on the walls of the vessel. Moreover Tiron has a greater stability than DDTC and can be stored for a long time without degradation.

The method proposed in this paper is one of the approaches developed in our laboratory [3,4,9,10] for trace metal preconcentration. Advantages of the present technique over previous systems [9,10] coupled to inductively coupled plasma atomic emission spectrometry (ICP-AES) are slightly lower detection limits, reduced sample and reagents consumption and lower running costs (in the case of ICP-AES, the torch is powered during all the analysis cycle).

On the other hand the formerly developed GFAAS preconcentration technique [3], which was based on the direct insertion of the enrichment column in the autosampler arm, has lower detection limits than the present one and reasonable running costs. Anyway the alignment of the column tip with the graphite furnace is a delicate task and requires frequent readjustments. The present method based on FIAS system is more straightforward, does not require trained operators or expensive consumables.

2. Experimental

2.1. Instrumentation

A Perkin-Elmer Model 5100 atomic absorption spectrophotometer with Zeeman-effect background correction was used for Pb and Cd determinations. Pyrocoated graphite furnaces with L'Vov platforms were used and measurements were performed at 283.3 nm Pb and 228.8 nm Cd analytical lines with a 0.7 nm slit. The heating cycle programs are reported in Table 1 and Table 2.

The preconcentration manifold used (Fig. 1(a)), a Perkin-Elmer FIAS-200, is composed of two peristaltic pumps and a four-way switchable valve.

The pump rate (range 1–12 ml min^{-1}) and valve position are completely software-controlled. Tygon pump tubings were used (i.d. 1.40 mm for Tiron and sample solutions and i.d. 0.76 mm for HCl).

UV-VIS Absorption measurements were performed with a double-beam spectrophotometer Hitachi 150–200.

A Mettler Delta 320 pH-meter equipped with a combined glass-calomel electrode was used for pH measurements.

High-purity acids and ammonia were obtained with a sub-boiling quartz still (K. Kurner).

All polyethylene labware was washed by immersion in 1 M HNO_3 for 48 h and stored in 1×10^{-2} M HCl until the moment of use.

Eppendorf dispensers or Gilson micropipets were used to prepare solutions. The accuracy of the dispensed volumes was periodically checked by weighing.

All sample manipulations were performed under a laminar flow hood in a laboratory provided with filtered air.

2.2. Reagents and materials

Analytical grade 100–200 mesh, macroporous anion-exchange resin AGMP-1(Bio-Rad) was used in Cl^- form for preconcentration.

Analytical grade 100–200 mesh, iminodiacetic functionalised resin Chelex-100 (Bio-Rad) and silica RP-C18 (40–63 μm, Merck) were used for reagent purification.

The microconic column used for preconcentration, loaded with 0.03 ml of AGMP-1 (Fig. 1(b)), was prepared by filling the column with a suspension of resin dispersed in 1 M HCl, using the slurry technique. Two 75-mesh Teflon filters were placed on both ends of the column.

The columns used for purification were prepared by filling short Tygon tubes (1.5 cm; i.d. 3.90 mm) with a suspension (total weight 0.05 g) in 1 M NH_4OH for Chelex-100 and in methanol for silica RP-C18 respectively, using the slurry technique. The particles were kept in place with two plugs of Teflon net inserted at the ends of the column.

High-purity water (HPW) was produced with a Milli-Q system and used to dilute all reagent solutions.

4,5-dihydroxy-1,3-benzendisulphonic acid (Tiron), monohydrate disodium salt (Merck) was dissolved in water at the desired pH and used after purification (see below).

Ammonium acetate buffer (prepared by mixing the appropriate amounts of concentrated acetic acid and ammonia previously purified by sub-boiling distillation) at pH values in the range 4.0–6.0 was used. Concentrated ammonia and a 3×10^{-2} M ammonium borate buffer were employed in pH range 7.0–9.0. For pH lower than 4.0 a 0.1 M trichloroacetic acid solution was used.

Lead and cadmium standard solutions were prepared from 1000 mg l^{-1} stock solutions of $PbCl_2$ and $CdCl_2$ (Merck) and diluted as required with HPW.

A matrix modifier for Cd and Pb AAS determinations (prepared by mixing 0.2 g $NH_4H_2PO_4$ and 0.01 g $Mg(NO_3)_2$ in 10 ml of HPW) was used.

Drinking water was collected from the hydric distribution of the city of Turin. Lake and sea-water were collected in Antarctica during the X

expedition within the Italian Antarctica Project. The samples were immediately filtered through 0.45 μm filters and kept frozen during transportation and storage.

2.3. Procedure

The method is based on retention on a macroporous anion-exchange resin of the negatively charged complex formed between Pb or Cd and Tiron; elution is obtained with 0.1 M HCl.

Proper volumes of sample, buffer solution and Tiron were pre-mixed and fluxed through a microcolumn filled with the resin; since a subsequent washing with buffered HPW only gave reduced recoveries ($73.0 \pm 0.5\%$ for Pb; $64 \pm 6\%$ for Cd), due to a partial retention of Pb and Cd on the surface of tubings; this step was modified and for the optimised procedure 1 ml of 1×10^{-2} M Tiron solution was used. Finally buffered HPW was loaded in order to drive the sample and Tiron through the column. The metal was eluted in countercurrent with 0.1 M HCl. The column was washed with 6 M HCl and conditioned with HPW buffered at the pH of the following experience. The eluate (0.5–1.0 ml) was directly collected in a sampling cup for GFAAS determination. The autosampler of the GFAAS was programmed to inject 20 μl of sample and 10 μl of matrix modifier for each analysis.

In order to load the desired sample volume through the column and elute the retained metal, a FIAS program consisting of eight steps was designed (see Table 3).

3. Results and discussion

The preconcentration procedure was optimised evaluating the percentage recoveries of each metal (10 μg l^{-1} Pb, 1 μg l^{-1} Cd) as a function of the pH of sample solution (that is pre-mixed ligand, buffer and metal solutions), of ligand concentration and of eluent type.

All these experiments were carried out with a sample and eluent volume of 1 ml, i.e., a preconcentration ratio of 1, in order to obtain a high sample throughput. In each determination the loading and elution volumes may slightly change (and usually do) and their values strongly depend upon the wear of the tubings. These factors were controlled, by weighing the sample bottle before and after loading and weighing the elution cup before and after elution. After calculating the loaded and eluted volumes a correction factor was applied to the percentage recovery. The formula used was:

$$\{(A/B \times C) - (A1/B1 \times C1)\}/D \times 100$$

where:

A and A1 are the volumes of the sample and blank eluates;

B and B1 are the loaded volumes of the sample and blank;

C and C1 are the concentrations of the sample and blank eluates;

D is the metal standard concentration.

3.1. Recovery as a function of type of eluent

Two different eluents, namely 0.1 M HCl and 1 M HNO_3, gave the best results for metal ion recoveries. The recovery was higher when eluent was 0.1 M HCl (Pb: 94 ± 4%, Cd: 76 ± 2%), since Cl ions have a greater affinity for Pb and Cd than NO_3 (Pb: 87 ± 12%, Cd: 74 ± 3%).

The presence of chloride influenced the subsequent GFAAS determination of lead. In fact when lead is vaporised and atomised from a chloride matrix, the presence of $PbCl_2$ (g) has been observed [11] prior to the appearance of Pb (g); a small amount of chlorine in the graphite furnace will bind lead to form $PbCl_2$ (c) or $PbCl_2$ (g). The proposed mechanism of atomisation is as follows:

$$PbCl_2(ad) \rightarrow PbCl_2(g) \rightarrow Pb(g) + Cl_2$$

where 'ad' stands for 'adsorbed' in agreement with [11]. Chloride matrix interference is due to the formation and loss of volatile lead chloride species (PbCl (g) and $PbCl_2$ (g)) in the gas phase.

This effect was taken into account by evaluating sample concentrations with standards prepared in 0.1 M HCl and using a matrix modifier which inhibits sample volatility (see Fig. 2(a) and (b)). The same modifier was used for cadmium determination as advised in the literature.

3.2. Recovery as a function of loading and elution flow-rate

The recovery yield of analytes was investigated for several loading and elution flow-rates; while the loading rate was kept constant to 1 ml min^{-1} and then 2 ml min^{-1}, the elution rate was varied from 1 ml min^{-1} to 3 ml min^{-1}. The best recoveries (Pb: 94 ± 4%; Cd: 76 ± 2%) were found at a loading and elution rate of 1 ml min^{-1} (Fig. 3 and Fig. 4), because it allows for a long contact period between resin and solution (metal-Tiron complex in the load step and 0.1 M HCl in the elution step).

3.3. Effect of pH and Tiron concentration

Using a load and elution rate of 1 ml min^{-1} the pH range of 3.0–9.0 was tested. The recovery increases with increasing pH in accordance with the values of the conditional stability constants for the metals, and pH 9.0 gave the highest recoveries.

Different ligand concentrations were investigated (5×10^{-3}–5×10^{-6} M). The recovery increases with increasing ligand concentration, since the equilibrium is shifted toward complex formation. Higher Tiron concentrations were not tested in order to avoid competition between complex and free ligand for the exchange sites on the resin.

Figs. 5–8 show the recovery behaviour (%) of Pb and Cd respectively as a function of the above cited parameters. The reduced recovery of Cd in respect to Pb is essentially due to a lower stability constant, which in turn is related to the presence of negatively charged oxygen-donor groups in Tiron molecule. The effect of these groups on complex stability

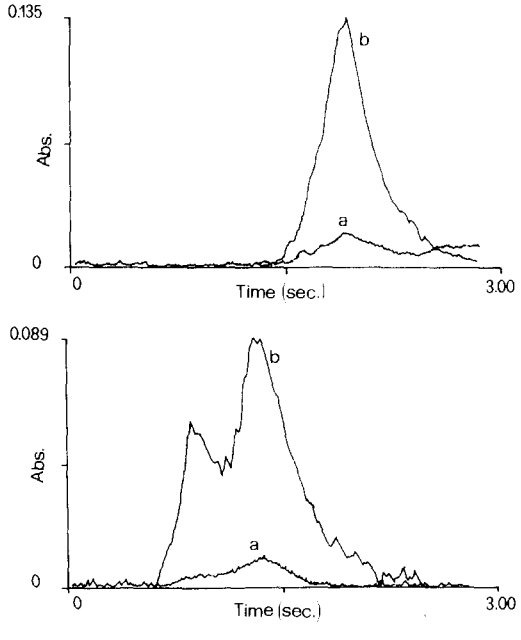

Fig. 2. (a) Atomic absorption spectrometry signal of lead in the presence of matrix-modifier. a, background; b, analyte. (b) Atomic absorption spectrometry signal of lead in the absence of matrix-modifier. a, background; b, analyte.

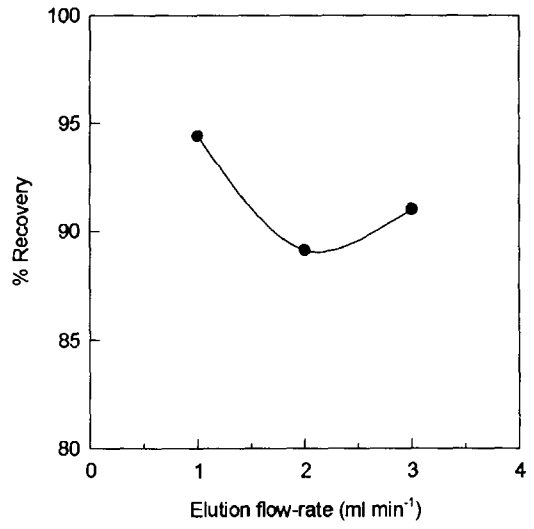

Fig. 3. Percentage recovery of lead as a function of elution flow-rate (ml min^{-1}) at a constant loading-rate (1 ml min^{-1}).

appears to depend on the acidity of the metal ion concerned. When acidity increases, the affinity of the metal ion towards negative O^--donor ligand, e.g., the OH^- ion, is also increased [12]. Anyway the recovery of cadmium is reproducible and the procedure can be used for analytical purpose.

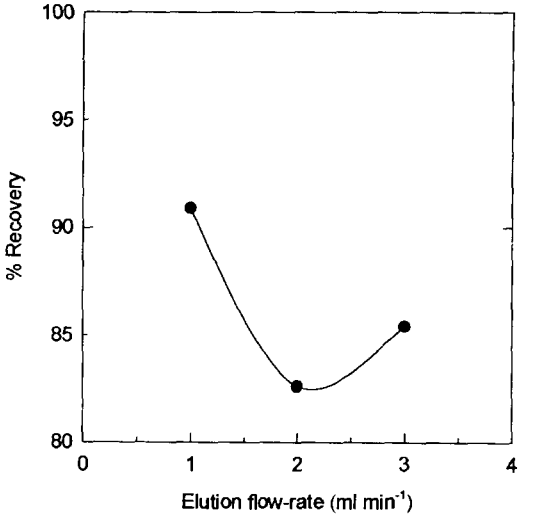

Fig. 4. Percentage recovery of lead as a function of elution flow-rate (ml nim^{-1}) at a constant loading-rate (2 ml min^{-1}).

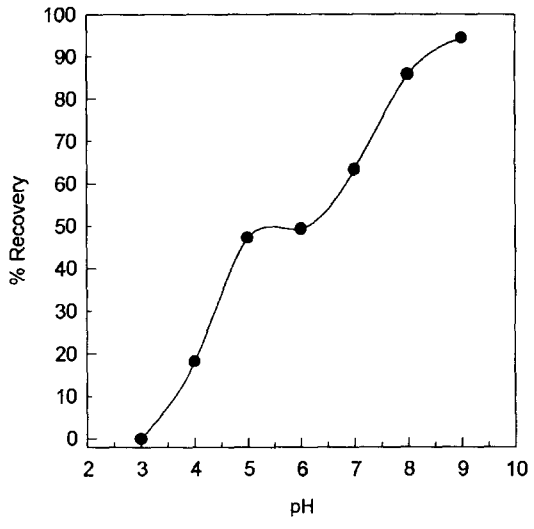

Fig. 5. Percentage recovery of lead as a function of pH (Tiron concentration 5×10^{-3} M).

3.4. Interfering agents

The effects of ionic strength (0.5 and 1.0 M NaCl), surfactants (10 and 100 mg l^{-1} polyoxyethylene-23-laurylether (Poly) and the concomitant presence of 20 mg l^{-1} Ca and 2 mg l^{-1} Mg were investigated. The chosen interferents are those likely to be present in natural waters. The

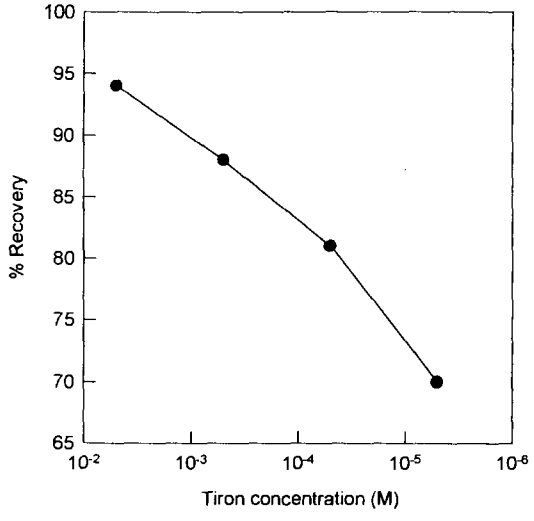

Fig. 6. Percentage recovery of lead as a function of Tiron concentration (pH = 9.0).

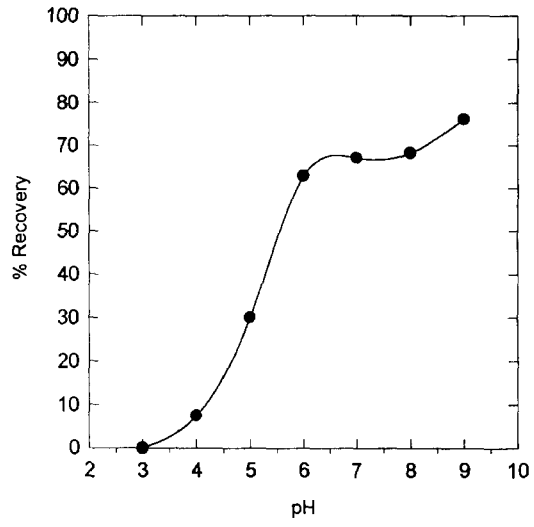

Fig. 7. Percentage recovery of cadmium as a function of pH (Tiron concentration 5×10^{-3} M).

experiments were carried out at pH 9.0, at a ligand concentration of 5×10^{-3} M and a flow rate of 1 ml min^{-1} corresponding to the maximum recovery. A 2 M NaCl solution (pH 9.0) was purified from Pb and Cd impurities (about 1.5 μg l^{-1}), before preconcentration and then diluted to the desired concentrations: NaCl solution was eluted through a microcolumn packed with Chelex-100 in NH_4^+ form.

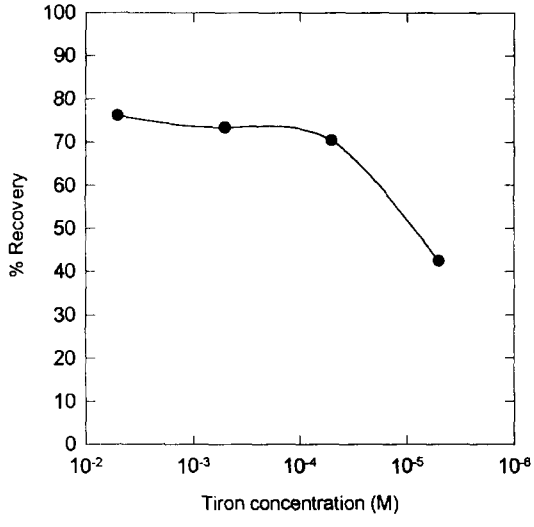

Fig. 8. Percentage recovery of cadmium as a function of Tiron concentration (pH = 9).

Table 4
Effect of different interfering agents on lead and cadmium recovery

Interfering agent	Recovery %	
	Pb	Cd
1 M NaCl	83 ± 1	52 ± 2
0.5 M NaCl	93.4 ± 0.9	70.8 ± 0.7
10.0 mg l^{-1} Poly	90.4 ± 0.9	73 ± 3
100.0 mg l^{-1} Poly	78 ± 3	60 ± 7
20.0 mg l^{-1} Ca + 2.0 mg l^{-1} Mg	82 ± 2	78 ± 2

Three replicates.

Table 4 shows recoveries obtained in the presence of the different interfering agents. The trend of the recoveries in the presence of NaCl is due to a competition between Cl^- and the metal complexes for the exchange sites of the resin, whereas Ca and Mg compete with the analytes for complexation. For all the agents considered the recovery was lower at higher interferent concentrations, but the interferences were not so large to hinder the use of the method for natural samples. In particular the method can be used for the analysis of sea water, whose ion strength is approximately 0.5 M.

3.5. On line procedure

The former experiments were performed by batch mixing ligand and sample. On-line mixing of sample and Tiron solutions allows a satisfactory recovery (92.7 ± 0.4%) of lead, but very low recoveries for Cd (28 ± 1%). This fact could be explained by considering the low kinetic of reaction for Cd-Tiron.

3.6. Enrichment and detection limits

Lead enrichments were initially evaluated for a preconcentration ratio of 10 (from 1 to 10 μg l^{-1} Pb). The recovery was highly satisfactory (95 ± 2) for this kind of samples and blank signals were under the detection limit. Recovery for a preconcentration ratio of 50 was also evaluated. Solutions containing 50 ng l^{-1} of Pb were preconcentrated up to 2.5 μg l^{-1} and the recovery

resulted 95.5%. In this case the blank levels were at 13 ng l^{-1} before preconcentration.

A similar approach was considered for Cd. Solutions (100 ng l^{-1}) were preconcentrated to 1 μg l^{-1} and gave a satisfactory recovery (76.0 ± 0.4%). The recovery percentage in solution containing 50 ng l^{-1} Cd and preconcentrated to 2.5 μg l^{-1} was slightly inferior: 69.1%.

For these enrichment procedures the blanks were purified using a method below detailed.

The detection limits of the technique, evaluated as three times the standard deviation of the blank (for the experiments with a preconcentration ratio of 50), were 9 ng l^{-1} for Pb and 7 ng l^{-1} for Cd.

3.7. Analysis of real samples

This preconcentration method was used for the analysis of Antarctic lake water and Turin drinking water. For these experiment the preconcentration ratio was 50 and purified Tiron was used (see below).

Pb and Cd were determined with the standard addition method in drinking water to be 218 ± 6 and 51 ± 2 ng l^{-1}, respectively. In Antarctic lake water (Carezza Lake, Ross Bay) Pb was found to be 22 ± 1 ng l^{-1} for Pb, while Cd resulted lower than the detection limit.

The accuracy of the method was checked by analysing a sample of uncontaminated sea-water from Antarctica spiked with 1 μg l^{-1} of Pb and 250 ng l^{-1} of Cd. The analysis was performed by standard addition method. The signal given by the original metal content, which is in the order of few tenths of ng l^{-1}, was subtracted as a blank signal.

The concentrations found were 950 ± 87 ng l^{-1} of Pb and 281 ± 6 ng l^{-1} of Cd, in good agreement with the expected values. The deviations (− 5.0% for Pb, + 12.4% for Cd) could be due to the sum of errors occurring during the procedure, i.e., in metal standard dilution, in loaded and eluted volumes and in the GFAAS measurements. Anyway the results are satisfactory, especially if the low concentration levels involved are taken into account.

These data confirm the applicability of the method to the determination of ultra-traces of metal ions in natural samples.

3.8. Tiron purification

The main source of contamination was found to be the impurity content of Tiron. Therefore the following methods for its purification were investigated: (1) crystallisation; (2) Chelex-100 treatment; (3) elution through silica RP-C18 after addition of 1 M 8-hydroxyquinoline to Tiron solution; and (4) elution through AGMP-1 functionalised with Tiron.

The crystallisation of Tiron was obtained taking advantage of its lower solubility in an acid medium. Concentrated HCl was gradually added (1 ml every day) to a saturated solution of Tiron (2.5 g in 6 ml of HPW) in order to obtain long thin crystals and to facilitate purification. In fact a flock precipitate would not be suitable for purification because of co-precipitation phenomena.

By the second method the metal impurities were bound to the resin owing to iminodiacetic groups.

Method (3) is based on the ability of 8-hydroxyquinoline to form neutral complexes with the metal ions which could be removed from Tiron solution by retention onto a C-18 microcolumn.

In the AGMP-1 method the resin exchange sites were saturated with Tiron. The saturation of the resin (10 ml of 1×10^{-2} M Tiron for 0.05 g resin) was evaluated spectrophotometrically by monitoring (at 290 nm) the concentration of Tiron in the effluent. Since the stability constants for metal-ligand complexes are greater for Tiron bound onto the resin than for the free one (solution) [13], it was possible to remove metal ions impurities by fluxing the solution of Tiron through a microcolumn filled with the so modified AGMP-1 resin.

These purification methods were formerly studied in our laboratory for the preconcentration of iron (see results in Table 5).

Table 5
Purification percentage efficiency

	Method 1	Method 2	Method 3	Method 4
% Efficiency	94.3	68.9	100	100

The last method was chosen because it is quick, simple, it does not require the addition of any reagent, it could be performed on-line and gives the best performance.

For this reason it was used also for Pb and Cd, whose concentrations in 1×10^{-2} M Tiron were about 5–6 μg l^{-1} (after 50-fold enrichment); using the last method the metal impurities in Tiron were reduced below the detection limit.

4. Conclusions

The preconcentration method developed to determine traces and ultratraces of Cd and Pb allows a precise and accurate determination of metal ions at low concentration (ng l^{-1}) in natural samples, and in the presence of interfering agents. Blanks are very low and detection limits are satisfactory.

The time required for preconcentration and determination of lead and cadmium levels close to the detection limit is about 30 min; the sample throughput increases if there is no need to reach such low concentrations. For instance it is possible to analyze nine samples in an hour at 100 ng l^{-1} level by loading 2.5 ml of the sample and eluting the analyte in 0.25 ml. This small volume is enough for several GFAAS determinations.

The method described can be used for several applications, not only for natural water samples but also for environmental or industrial samples. The procedure has been adapted in our laboratory also for the determination of aluminium [4] and iron.

Abstract

A combined method for the preconcentration and selective spectrophotometric determination of both valencies of iron, i.e., Fe(II) and Fe(III), down to 0.4 μg l^{-1} has been developed. Iron(III) from synthetic and natural water samples has been concentrated on a melamine-formaldehyde resin at pH 5; iron(II) was not retained under identical conditions. The oxidized iron was concentrated on a second resin column. The iron in both columns was eluted with 1 M HCl solution and separately analyzed by the 1,10-phenanthroline-citrate spectrophotometric method. The effect of pH, adsorption and elution rates, and interferences on the developed procedure were investigated. Metal ions that can be retained by the resin at moderate concentrations, e.g., Al^{3+}, do not cause interference in more dilute solutions encountered in natural water samples. At least 160-fold volume enrichment can be easily obtained using an adsorption flowrate of 50 ml min^{-1}. A hydrothermal water sample was analyzed by the recommended procedure and by a literature method, and the results were statistically compared by *t*- and *F*-tests. © 1997 Elsevier Science B.V.

Keywords: Iron(II) and iron(III); Melamine-formaldehyde resin; Preconcentration; Separation

1. Introduction

Spectrophotometric determination of iron in different oxidation states in water has been a matter of concern in analytical chemistry since the mid 1950s [1]. The low concentration of iron present in natural waters (at mg l^{-1} levels) necessitates the selection of a suitable preconcentration procedure [2].

Most of the published spectrophotometric methods for the simultaneous determination of Fe(II) and Fe(III) involve the measurement of either valency in one sample portion, and of total iron, after oxidation or reduction, in another sample portion; the concentration of the other species is obtained by difference [3]. Such a procedure requires the usage of a selective photometric reagent capable of determining one of the valencies, usually the lower valency, of iron.

1,10-Phenanthroline has been shown to be a reliable colorimetric reagent for Fe(II) [4], but errors can arise in the presence of Fe(III) which can form a yellow complex with phenanthroline [1]. In this case, the absorbance of the Fe(II)-com-

PII S0039-9140(96)02132-7

plex is not stable due to the slow reduction of the ferric complex [5]. However when phenanthroline is used along with citrate, the latter as the masking reagent for Fe(III), both ferrous ion and total iron (after reduction with hydroxylamine or ascorbic acid) can be determined using this procedure [6].

Another reagent which selectively forms a coloured complex with Fe(II) but not with Fe(III) is ferrozine [3-(2-pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4-triazine] [7]. On the other hand, a ferric ion-specific reagent is tiron which may also enable the determination of total iron after catalyzing the autooxidation of Fe(II) to the ferric state in aerated solution [3].

On-line separation and preconcentration of both valencies of iron by a rapid and selective procedure is very important in flow injection analysis (FIA) which has received considerable attention in recent years [8,9]. For example, the Fe(II)-specific ferrozine may be used in this regard, enabling direct feeding of Fe(III) contained in the sample to AAS while the Fe(II)-ferrozine formed in-line is temporarily retained on a C_{18}-modified silica column and subsequently eluted with methanol [9]. This work aims to utilize the inexpensive and conventional phenanthroline–citrate reagent in conjunction with a melamine–formaldehyde preconcentrating resin column for developing a FIA-compatible spectrophotometric procedure for the simultaneous determination of Fe(II) and Fe(III) in natural waters.

The preconcentration and separation of elements by the use of chelating resins have been extensively reported and recently summarized [10]. Polyacrylonitrile [11], epoxypropyl methylacrylate grafted into a polyvinyl fiber with tannin [12], polyether foam [13], and polyether-type polyurethane foam [14,15] have been utilized as effective preconcentration agents for selectively retaining Fe(III) from water.

Melamine–formaldehyde resins having the methylol melamine functional groups [16], which have been used for long in textile-finishing and leather tanning operations [17] have recently been utilized in Cr(VI) preconcentration [18] and Cr(III)/Cr(VI) separation prior to AAS analysis [19]. Preliminary experiments showed that this resin could serve the purpose of selective preconcentration of the higher valency of iron, thereby giving rise to this work.

2. Experimental

2.1. Reagents

All chemicals used were of analytical grade (E. Merck), and distilled water was used throughout.

The melamine–formaldehyde resin was prepared from formaldehyde, NaOH and melamine according to the procedure set by Gams et al. [20], washed with 0.1 M HCl, 0.1 M NaOH and sufficient water in this order, dried, grounded, and classified to a particle size range of 500–600 mesh as described elsewhere [18]. The IR Spectrum of the resin was compared with that of the literature, and essential band assignments were made from the observed wavenumbers.

The stock solutions were prepared as follows:

Fe(III), 1000 ppm: 4.320 g of ammonium ferric alum was dissolved in 10 ml concentrated HCl and some water, and diluted to 500 ml with water.

Fe(II), 1000 ppm: 3.510 g Mohr's salt, i.e., $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, was dissolved in 2 ml concentrated HCl and some water, and diluted to 500 ml with water. (Deaerated water purged with N_2 was used for the Fe(II) solution) The Fe(II) stock solution was freshly prepared every week, and stored in the dark for inhibiting oxidation to Fe(III).

Both solutions were standardized by EDTA titration [21].

Phenanthroline, %0.2 (w/v): 0.2 g of 1,10-phenanthroline hydrochloride was dissolved in 100 ml hot water and cooled to room temperature.

2.2. Procedure for the preconcentration of iron(III) and iron(II) ions

A double-column procedure was used for preconcentrating iron(II) and iron(III) from synthetic and natural water samples. Two grams of the resin suspended in water was slurry-packed in each glass column (i.d. 1.0 cm) at a height of 8 cm and rinsed thoroughly before use.

The water sample containing up to 2 ppm of ferric ion and adjusted to an optimal pH of 5.0 (using acetic acid/sodium acetate buffer) was passed through the first column at a rate of 20–25 ml min^{-1}. The sample volume was usually taken as 250 ml. To the effluent of the first column were added several drops of concentrated (14 M) HNO_3 and concentrated H_2O_2 in hot solution so as to oxidize the Fe(II) to Fe(III) [22].

After oxidation, the pH was readjusted to five with sodium acetate and acetic acid, and the solution was passed through the second column as before. The originally present Fe(III) and Fe(II), the latter after oxidation, was retained by the first and second columns, respectively.

The iron retained in each column was eluted with 25 ml of 1.0 M HCl at a flow rate of 3 ml min^{-1} and analyzed by the phenanthroline method. The used resins were washed with water, 0.1 M NaOH, and finally with sufficient water until neutral prior to next use.

The effects of possible interferent ions were investigated under identical conditions with those of iron uptake. The interferent ions were added in varying amounts to 250 ml of 2 ppm Fe(III) solution, and the final mixture was passed through the resin column with subsequent analysis. The effect of the essential interferent, i.e., Al^{3+}, was further studied as a function of total metal concentration and pH. The dependence of iron recovery on pH, and on solution flowrates at adsorption and desorption were separately analyzed while keeping the other parameters constant.

2.3. Procedure for the simultaneous determination of iron(II) and iron(III) in synthetic and natural samples

The spectrophotometric method developed by Nigo et al. [6] was followed for determining both ferrous and total iron in a sample. To the acidic column eluate containing preferably 1–50 mg iron, 5 ml of 10% NH_2OH. HCl was added and the mixture was titrated dropwise with 5 M NH_3 solution until a pH of 2–3 was reached. After letting stand for 2 min, 10 ml of 25% diammonium hydrogen citrate solution was added to bring the pH to ~ 5. After the addition of 5 ml of 0.2% phenanthroline solution, dilution to a final volume of 50 ml was made. The absorbance at 512 nm of the resulting solution was measured against a reagent blank within 30 min. The acidic eluates of the first and second columns, when analyzed by this procedure, yielded the Fe(III) and Fe(II) concentrations, respectively, originally present in the water sample. All spectrophotometric analyses were accompanied by flame AAS for confirmation using the analytical wavelength of Fe at 248.3 nm; a spectral bandpass of 0.5 nm and a lamp current of 10 mA was selected with an air-acetylene flame for atomization.

The real sample containing both valencies of iron was collected from Yalova Termal hydrothermal water reserves, acidified with HCl (10 ml concentrated HCl to 1 l of water) before being brought to the laboratory, and immediately analyzed on the day of sample collection. An independent analysis for confirming the Fe(III) and Fe(II) results of the developed method was carried out by ion-exchanger colorimetry using the procedure set by Nigo et al. [6]. For this purpose, the phenanthroline–citrate reagent was used without and after the addition of hydroxylamine hydrochloride for the determination of Fe(II) and total Fe in two different sample aliquots, respectively, using Dowex 50W-X2 resin as the iron-concentrating medium from relatively large volumes of water. In the case of Fe(II) analysis alone where NH_2OH. HCl addition was omitted, dropwise neutralization of the acidic water sample with 5 M NH_3 solution was made after the addition of the citrate buffer so as to prevent any local hydrolytic iron precipitation possibilities.

2.4. Procedure for measuring the batch capacity of the resin for iron

Iron(III) solutions of concentration $(2.0–10.0) \times 10^{-4}$ M were contacted batchwise with the resin at a liquid-to-solid ratio of 200, i.e., 10 ml of solution per 50 mg of resin, in stoppered flasks placed in a thermostatic (25 ± 0.1°C) shaker/water bath for 4 h. The highest (saturation) amount of iron bound per unit mass of resin was noted.

2.5. Instruments

A Perkin-Elmer 300 atomic absorption spectrometer and a Hitachi 220 A UV-Visible spectrophotometer were used for iron determinations. The pH measurements were made with a Metrohm Herisau E-512 pH-meter equipped with a glass electrode. The infrared spectrum of the resin in KBr pellet was recorded with a ATI Unicam (Mattson 1000) FT-IR spectrometer within the wavenumber range of 4000–500 cm^{-1}.

3. Results and discussion

3.1. The resin functional groups and Fe(III) uptake

The IR-spectral band assignments (in cm^{-1}) showing the presence of—NH CH_2OH groups bound to carbon atoms of the resin were made as follows:

–O–H (OH bending): 1346.1 (s), C–OH (C–O stretch): 1061.5 (s), NH: 3346–3360 (m), NH: 1500 (w).

The selective uptake of Fe(III) over Fe(II) by the resin may partly be associated with the fact that ferric iron is a harder acid in the sense of HSAB Theory [23] showing a higher affinity to the hard O– and N– donor Lewis bases of the trimethylolmelamine structural units of the resin molecule. It has been well established in the literature that transition metal ions in high oxidation state tend to coordinate to hard σ donor-π donor ligands, and that in selective adsorption, inner-sphere complex formation may be preferred over ion-exchange [24]. Considering the predominantly hydrolytic complex environment of Fe(III) at the working pH (i.e., pH 5), the capability of mixed complex formation of Fe(III) (e.g., some Schiff-base-type bidentate N,O–donor ligands (L) form mixed hydroxo-complexes with ferric iron having the formula Fe^{III} $L(OH)_2$ constituting the predominant species in the neutral region) may reasonably explain the selective uptake of Fe(III) over Fe(II) on the resin having N– and O–donors [25]. Due to the complex nature of the melamine-formaldehyde polymer, it is quite difficult to exactly identify the mechanism of Fe(III) uptake, as in the case of polyether-type polyurethane foam where ether-like solvent extraction, ligand addition or exchange, anion exchange and cation chelation mechanisms could be involved [14,15,26].

3.2. Selection of optimal pH of preconcentration

The optimal pH of iron preconcentration was chosen in regard to both prevention of hydrolytic precipitation of Fe(III) at the ppm level and of Fe(II) oxidation to the ferric state. The percentage recovery of iron achieved when 250 ml of 1 ppm Fe(III) at various pH was passed through 2.0 g of resin in column is shown in Fig. 1. On the other hand, the non-retention of Fe(II) was clearly demonstrated where Fe(II) was not held by the resin between pH 2.0 and 5.9 (tested at 0.5 pH unit intervals). The influent and effluent pH were the same at pH 5 (where 100% Fe(III) recovery was observed) which was selected as the optimal pH in the successive experiments. Since the conjugate acid of the trimethylol melamine moiety has a pK_a of ~ 4 [16], the amine group should be available for iron binding at this pH.

The species distribution diagrams for the hydrolytic Fe(III) complexes, i.e., $FeOH^{2+}$, $Fe(OH)^{2+}$ and $Fe_2(OH)_4^{4+}$ in the heterogeneous

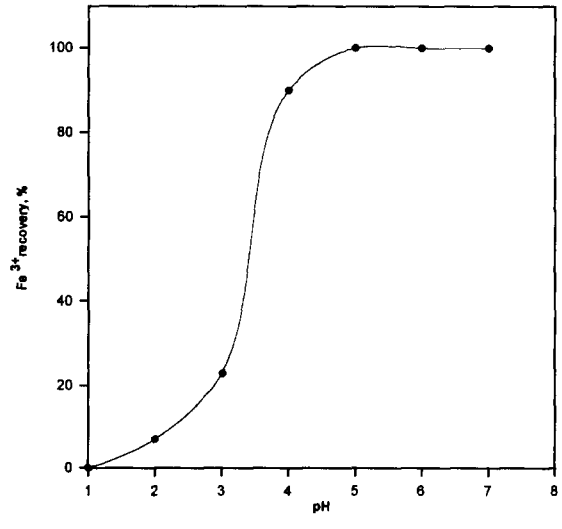

Fig. 1. Percentage recovery of iron as a function of pH.

system show that the solution becomes oversaturated with respect to solid amorphous $Fe(OH)_3$ over most of the pH range. However, additional polynuclear hydrolysis species occur as kinetic intermediates in the usually slow transition to $Fe(OH)_3$ (s) in the weakly acidic pH range [27]. Moreover, the upper limit of Fe(III) concentration that can remain in solution at a predetermined pH is also a function of total iron concentration. Thus, due to the slow character of the phase transition and to the additional iron complexation effect of acetate [28] used in the buffer for adjusting the pH of synthetic solutions, the uptake of Fe^{3+} ions at several ppm level from aqueous solutions of pH 5 could be investigated free from interference of hydrolytic precipitation within the relatively short time period of the experiments. Furthermore, iron(III), but not iron(II), has a tendency to form mixed hydrolysis complexes with N, O–donor ligands [25], which may also apply for the uptake by the resin. Besides hydrolytic equilibrium expectations, the selected pH is suitable from a kinetic standpoint as the oxidation of Fe(II) is very slow below pH 6 [27]. The rate of oxidation of Fe(II) in solutions of pH ≥ 5 has been reported to be first-order with respect to the concentrations of both Fe(II) and O_2 [27], and second-order with respect to the OH^- ion concentration [29]. Therefore Fe(II) present in a water sample may be safely determined along with Fe(III). However, it is still advisable to add at least ten-fold NH_2OH. HCl to the ferrous analyte solutions to prevent its oxidation to Fe(III) before the addition of phenanthroline [21] when the analyte does not originally contain Fe(III).

3.3. The flowrate at iron adsorption and elution, and eluant acid concentration

The uptake of ferric ions is very rapid as observed from nearly 100% recoveries with flow rates up to 50 ml min^{-1}. A precautious value of 25 ml min^{-1} was chosen as the adsorption flowrate in further experiments.

It was seen that 25 ml of 1.0 M HCl could effectively elute (with 100% recovery) the 250 mg Fe (III) retained in the column using a flowrate of 3 ml min^{-1}. In order to find out an optimal concentration factor (of iron from natural waters), two different eluant volumes, i.e., 10 and 25 ml, were selected using 0.1–2.0 M HCl as the eluant (Fig. 2). The effect of elution rate on recovery (Table 1) was tested using 25 ml of 1.0 M HCl as eluant; a precautious value of 3 ml min^{-1} was adapted in further experiments. As a conclusion, it may be deduced that iron(III) from relatively large amounts of natural water may be concentrated on the resin and eluted as described above with a high volume reduction factor useful for increasing analytical sensitivity.

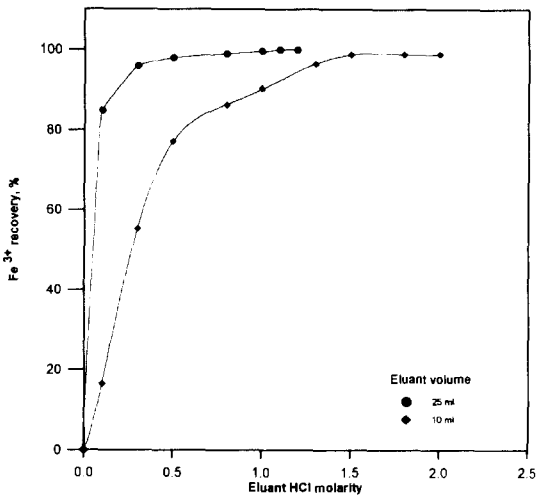

Fig. 2. Percentage recovery of iron as a function of eluant acidity.

Table 1

1.0/0.5	98.7/100	0.2/4.0[a]	95.8/98.4
0.5/3.0	100/100.3	0.2/0.2	96.0/97.1
0.5/0.5	100/100	4.0/0.2	98.7/97.2
RSD = 0.7%		RSD = 1.3%	

[a] A ratio of 1:20 Fe(II)/Fe(III) is meaningful in simulated natural water samples [9].

3.4. Preconcentration/analysis of Fe(II)-Fe(III) synthetic mixtures and precision

The analysis results of synthetic Fe(II)-Fe(III) mixture solutions at moderate and dilute concentrations are depicted in Table 2 using 250 ml^{-4} l infiltrate and 25 ml eluate volumes. The precision data for 8 determinations of Fe(II) + Fe(III) mixtures (at varying proportions) between 0.5–2.0 mg l^{-1} concentrations yielded an average relative standard deviation (RSD) of 0.7%, whereas the RSD was ca. 1.3% for mixture solutions between 0.2–20 μmol l^{-1}. At least 160-fold volume enrichment (from 4 l to 25 ml) could be easily achieved without serious loss of recovery efficiency and precision.

3.5. Calibration and precision

The calibration curves were perfectly linear, and when the factors of molar absorptivity, recovery and volume enrichment were taken into account, these calibration equations were found as:

$A_{512\ nm} = 1.94 \times 10^{-3}$ C for 500 ml

$A_{512\ nm} = 1.51 \times 10^{-2}$ C for 4 l samples, where C is the concentration of iron in the sample solution in μg l^{-1}. These curves were essentially identical for column-retained 'original' Fe(III) and first oxidized, then column-retained or 'converted' Fe(II). When the standard deviation of blank absorbance, calibration sensitivity (i.e., slope of the calibration equation) and literature coefficients [30] were considered together, the detection and quantification limits for 4 l samples were 0.4 and 1.3 μg l^{-1}, and for 500 ml samples 2.8 and 9.3 μg l^{-1} , respectively. Although adsorption from water volumes greater than 4 l was not employed, it is envisaged that lower detection limits may be attained. The developed method is probably capable of determining iron in most spring and coastal [31] waters, but not sensitive enough as required by oceanographic environments [29]. Since a preconcentration step is involved, the precision of the method is better than those of a great many direct spectrophotometric procedures [3,7].

3.6. Batch capacity of the resin for Fe(III) ions

The resin exhibited a Langmuir-type adsorption isotherm for iron (not shown). The saturation capacity was 7.2 mg Fe/g-resin. Naturally saturation would not be attained even with relatively large volumes of natural waters passed through the resin column.

3.7. Interferent ions and analysis of a real (hydrothermal water) sample

The following cations did not interfere at 100 ppm concentrations in the preconcentration and determination of 1 ppm Fe^{3+} ion: Mg^{2+}, Ca^{2+}, Cr^{3+}, Ni^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+}, Cd^{2+}, Pb^{2+}. Aluminium(III) at 5 ppm level interfered, but

could be masked with phosphate or fluoride, necessitating higher concentrations of the latter (See Table 3). Probably Al^{3+} was retained in a similar binding mode as Fe^{3+}. The excessive amounts of Cl^-, NO_3^-, ClO_4^-, SO_4^{2-}, PO_4^{3-} and CH_3COO^- did not interfere provided that the pH did not exceed 5. Thus, most ions that bear the potential of accompanying iron in natural waters were either interference-free or could be masked easily without prolonging the time required for the recommended procedure.

Since Al^{3+} showed the potential of being the essential interferent in natural waters, it needed special treatment. Batch equilibration tests carried out by agitating 100 mg resin in 50 ml aqueous solution at pH 5 for 2 h yielded different results for iron and aluminium uptake whereas equilibration could not be attained under dynamic conditions. According to batch results, the ratio of the distribution coefficients (D) of Fe(III) and Al(III) on the resin, i.e., selectivity defined as D_{Fe}/D_{Al},determined separately, in binary mixtures and in ternary mixture solutions containing 3.6 ppm Fe^{3+}, 1.8 ppm Al^{3+} and 12.5 ppm F^- were 12.0, 10.2 and 38.4, respectively. When the initial metal concentrations were reduced prior to batch contact, i.e., to 0.4 ppm Fe^{3+} and 0.05 ppm Al^{3+}, either in separate solutions or in combination, iron retained its uptake efficiency on the resin while aluminium was not retained at all probably due to the increased abundance of the chemically inert polyhydroxo complexes in Al speciation [32].

Table 3
Aluminium interference and its elimination by masking (amount of iron(III) taken: 2 ppm)

Ion added, ppm			Fe recovery %
Al^{3+}	PO_4^{3-}	F^-	
1	—	—	70.0
2	—	—	69.5
5	—	—	69.5
10	—	—	57.7
—	100	—	100.0
—	—	100	100.0
5	100	—	100.0
5	—	100	100.0

Column experiments showed a different picture since 0.5 ppm Al^{3+}, either alone or in the presence of 10 ppm F^-, was not retained on the resin. When 0.4 ppm Fe^{3+} alone, in combination with 0.05 ppm Al^{3+}, or in a ternary mixture containing 0.05 ppm Al^{3+} and 0.35 ppm F^-, were passed through the resin, iron uptake was 100% in all three cases, and Al^{3+} did not pose any problems. These observations lead to a hypothesis capable of explaining the competition of Al^{3+} on the selective resin sites responsible for Fe^{3+} uptake and of the elimination of Al interference: ferric iron forms the more stable hydroxo-complexes while Al^{3+} forms the more stable fluoride complexes ($\log \beta_3$ values of F^- are 12 and 15 for Fe^{3+} and Al^{3+}, respectively. Moreover the Al^{3+}-F^- system has a $\log \beta_4$ value of 17.8) [28]. In batch experiments, iron uptake is slightly increased in the presence of fluoride as Fe(III) gets undersaturated with respect to the colloidal ferric hydroxide precipitation, and as polyhydroxo-iron(III) complex formation is diminished as a result of F^- complexation. Iron most probably binds to the resin-methylolamine moieties in the form of mixed complexes, and one or two sites around its coordination sphere are sufficient to anchor iron to the resin even if the other sites are preoccupied by OH^- or fluoride. Al^{3+} interference, normally observed at elevated concentrations, is eliminated with F^- due to selective complexation with this anion. On the other hand, Al^{3+} may not compete at reduced concentrations—without necessitating F^- - due to coordinative saturation and kinetic inertness of its polyhydroxo-complexes [32]. Aluminium should also form less stable complexes with N– and O–donor groups of the resin, because the complexing affinity of Fe(III) toward such donors involves the use of d-electrons (e.g., d^5) while Al(III) lacks such valence electrons. Considering the reduced concentration levels of Fe(III) and Al(III) in natural waters and similar samples, no interference from Al was expected (and actually observed) under dynamic column conditions; 100% iron recoveries were easily recorded without a secondary aid such as fluoride.

Hydrothermal water as the real sample was selected because of its known Fe (II) content[27],

which may sometimes be as high as 0.5 μM. This water was analyzed in 5 l volumes both by the recommended procedure and by ion-exchanger colorimetric literature method [6] yielding Fe^{3+}: 21.5 μg l^{-1}, Fe^{2+}: 34.4 μg l^{-1}, and total iron: 56.1 μg l^{-1} as the mean values ($n = 8$). The population means and standard deviations were compared by two-tailed t- and F-tests within 95% confidence limits [33]. The two procedures were not essentially different in precision and accuracy.

Abstract

Based on self-assembled biotinylated disulfide derivative monolayer on gold electrode, the sensors immobilized monolayer or multilayer membranes composed of avidin and biotinlabeled glucose oxidase (B·GOD) or of avidin-B·GOD complex (ABC) and B·COD were prepared. The present technique may be useful for controlling the enzyme content of the sensors in molecular level by repeating the deposition of enzyme layers. The sensors have the characteristics of shorter response time, higher sensitivity. The linear range is from 6.0×10^{-6}–5.0×10^{-3} M. The sensor can be used for more than 1 month and can be reactivated. The sensor was used to determine glucose in human blood serum, and the results are satisfactory. © 1997 Elsevier Science B.V.

Keywords: Avidin; Biotin; Enzyme sensors; Glucose oxidase; Immobilization; Self-assembled monolayer

1. Introduction

In order to fabricate enzyme sensors, considerable effort has been devoted to the development of various techniques for immobilizing enzymes. Recently, much attention has been devoted to molecular-level modification of electrode surface with enzymes [1–3]. Self-assembled monolayers are widely used to modify solid electrode surface in molecular-level [4–6]. We have recently reported to prepare multilayer enzymes based on self-assembled aminoethanethiol monolayer and the advantage of strong affinity between avidin-biotinlabeled enzyme on ITO electrode [7,8]. In this paper we present that based on self-assembled biotinylated disulfide derivative monolayer on gold electrode monolayer or multilayer enzyme membranes composed of avidin and biotinlabeled glucose oxidase (B·GOD) or of avidin and B·GOD complex and B·GOD (ABC-B·GOD) are prepared. The sensors have the characteristics of shorter response time, and higher sensitivity.

2. Experimental section

2.1. Materials

Biotinlabeled glucose oxidase (B·GOD, 200 units mg mg^{-1} protein, biotin content: 5.1 mol

* Corresponding author. Fax: +86 21 2576217.

PII S0039-9140(96)02133-9

mol^{-1} protein) were purchased from Sigma Chemical (St. Louis, USA). Avidin (13.2 units mg^{-1}, from chicken egg white) was obtained from Calzyme Lab. (Csan Luis Obispo, USA). Bis(*N*-biotinylhydrazidoethyl) disulfide (BDS) obtained from Dojindo Chem. Lab. (Japan). Glucose was obtained from Wako (Japan). Dulbecco's phosphate buffer saline (PBS) (PH = 7.4) was used throughout. 0.1 M BDS solution was prepared with DMSO, and diluted to 1.0×10^{-4} M with ethanol.

2.2. Electrode preparation

Gold electrodes (0.7 mm diameter, 0.5 cm length, 0.11 cm^2 area). The Gold electrode was washed with 1: HNO_3, acetone and water in ultrasonic waves, then was pretreated by electrocycling in 1.0 M H_2SO_4 (1.7 V–(−0.2)V versus Ag/AgCl) with scan rate of 10 V/S for 5 min [9]. The procedure for the modification of the surface of gold electrodes is schematically illustrated in Fig. 1. The gold electrode was immersed in 1.0×10^{-4} M BDS/ethanol for 14 h for electrode 1. Electrode 2 was prepared by immersing electrode 1 in avidin (50 mg ml^{-1}) and B·GOD (50 mg ml^{-1}) alternately for 30 min. For the construction of electrodes 3–6, a multiple Avidin-B·GOD Complex (ABC) solution which was prepared by mixing an equal volume of avidin (50 mg ml^{-1}) and B·GOD (25 mg ml^{-1}) solution was used. Electrode 3 was prepared by immersing the electrode 1 in ABC solution for 2 h. Electrodes 4, 5 and 6 were prepared by the modification of electrode 1 with ABC for 2 h and then B·GOD (50 mg ml^{-1}) for 30 min alternately each.

2.3. Determination method

All electrochemical measurements were made with Model 173 potentiostat/Galvanostat and Model 175 Universal Programmer (EG and G Princeton Applied Research). A conventional three electrode setup was employed with the enzyme modified gold electrode as the working electrode, Pt wire as auxiliary electrode, and Ag/AgCl as the reference electrode. The oxidation current of H_2O_2 produced by enzyme reaction was measured at 0.65 V versus Ag/AgCl. All measurements were performed at room temperature. When checking the long-term stability of the sensors, the sensors were stored in PBS buffer at 4°C if not use.

3. Results and discussion

3.1. Electrochemical characteristic of electrode 1

The biotin-functionalized self assembled monolayers on gold can change the property of the electrode surface [10]. Fig. 2 shows the cyclic voltammograms of $Fe(CN)_6^{3-}$ ions at bare gold electrode and electrode 1. The biotin-functionalized self-assembled monolayer can increase the electrode reaction of $Fe(CN)_6^{3-}$ ions at gold electrode surface. This is different from self-assembled *n*-alkylthiol monolayers which prevent the electrode reaction of $Fe(CN)_6^{3-}$ ions at the electrode surface [11]. Fig. 3 plots the oxidation current of the bare and electrode 1 at 0.65 V versus Ag/AgCl as a faction of H_2O_2 concentration. The results show that the biotin functionalized self-assembled monolayer also increase the transport of H_2O_2 molecules to gold electrode surface where H_2O_2 should oxidized. It suggests that electrode 1 is useful for construction of enzyme sensors which detect H_2O_2 produced by the enzyme reaction.

3.2. The responses of electrodes 2–6 to glucose

We and other groups have recently reported the use of an avidin-biotin complexation technique for immobilizing enzymes on the electrode surface [7,8,12–14]. Electrodes 2–6 were prepared by utilizing the strong affinity among avidin, biotinlabeled enzyme and biotin monolayer which was self assembled on gold electrode surface. Fig. 4 shows a typical response of electrodes 2–6–10 mM glucose. Electrode 2 which has a single layer of B·GOD bridged by avidin layer exhibited evident current response to glucose. However, the response was low because of monolayer of B·GOD. In order to enhance the response, a much large amount of B·GOD can be expected to be immobilized directly in the form of ABC.

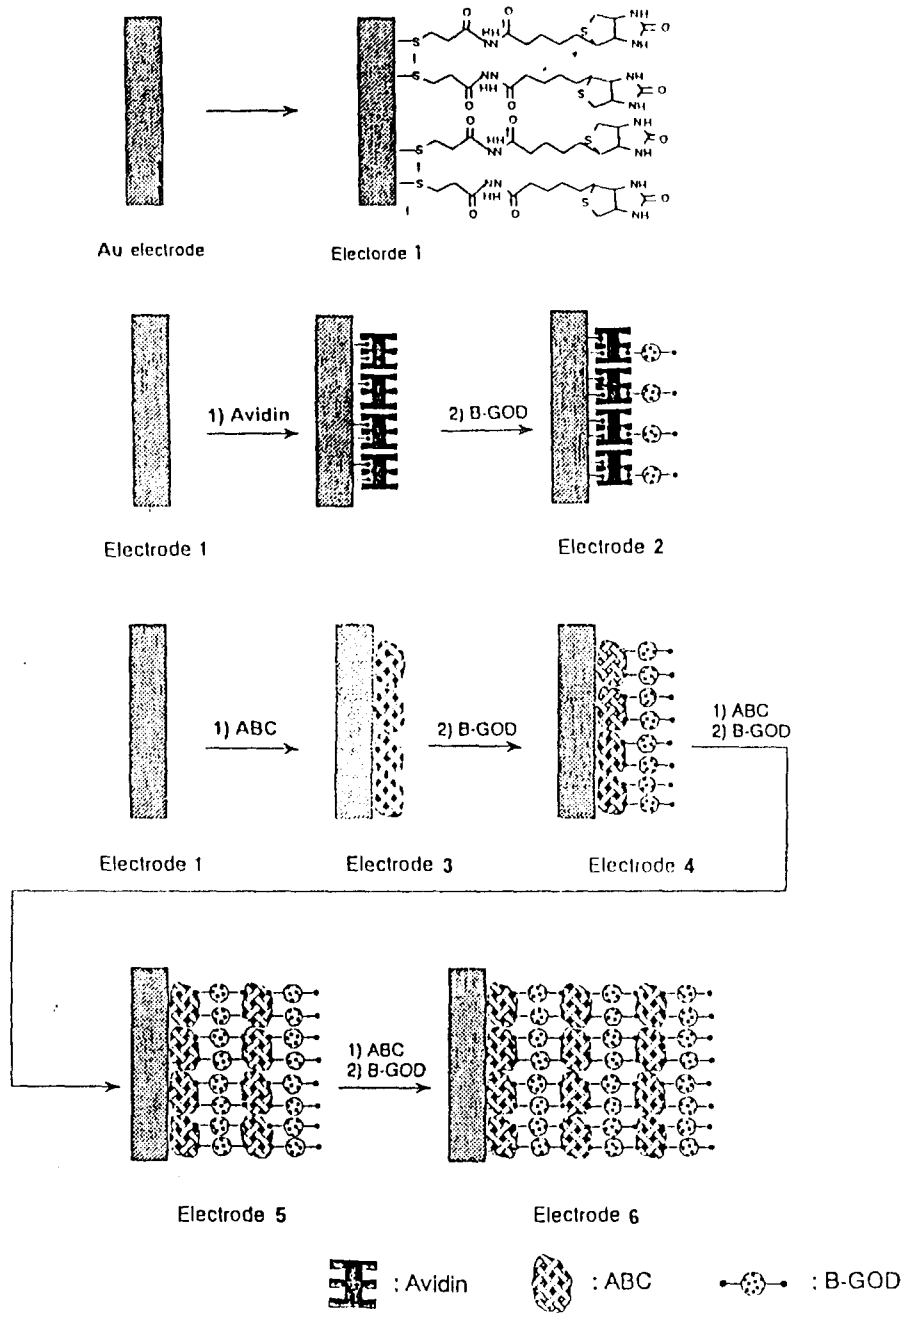

Fig. 1. Preparation of electrodes 1–6.

Electrode 3, which was prepared by immobilizing ABC membranes through complexation with biotin monolayers of electrode 1, showed a higher current response to glucose than electrode 2 (see Fig. 4b), indicated that more enzyme molecules were immobilized on gold electrode surface. On

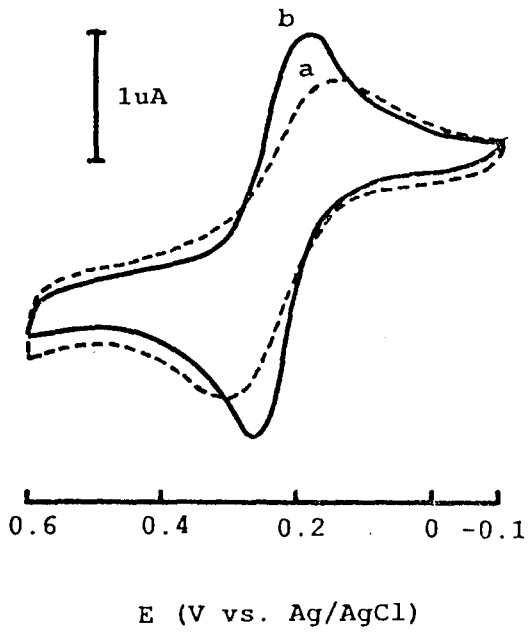

Fig. 2. Cyclic voltammograms of 1.0×10^{-3} M $K_3[Fe(CN)_6]$ on the bare gold electrode (a) and the electrode 1 (b). Scan rate: 100 mV s^{-1}.

the other hand, because each avidin protein contains four sites to biotin and the B·GOD used is substituted with an average 5.1 biotin residues per molecule, in principle, ABC membrane surface

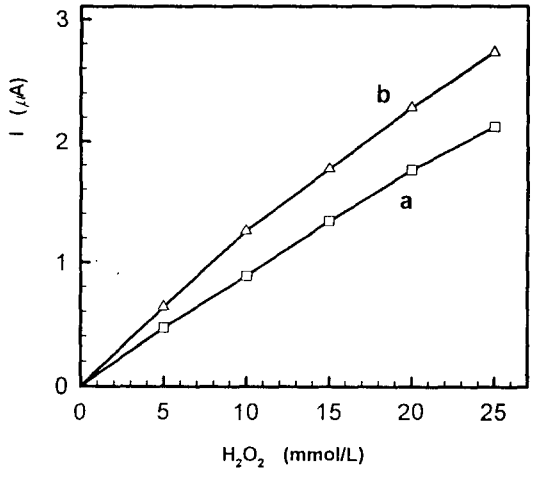

Fig. 3. Current response of bare gold electrode (a) and electrode 1 (b) to H_2O_2. Applied potential: 0.65 V (versus Ag/AgCl).

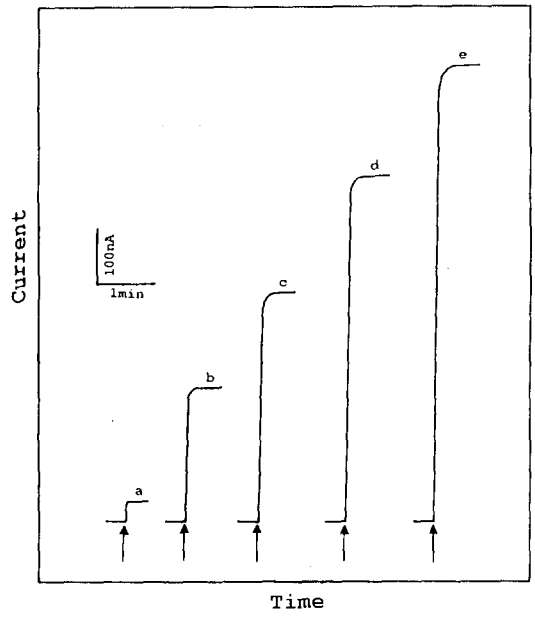

Fig. 4. Typical respone of electrode 2(a), 3(b), 4(c), 5(d), and 6(e) to 10 mmol l^{-1} glucose. Glucose was added to the sample solution at the time indicated by arrow.

can further load B·GOD. When electrode 3 was immersed in B·GOD solution, more B·GOD was immobilized on the electrode surface. Therefore, the current response of electrode 4 to glucose was further increased (as shown Fig. 4c). Electrode 5 and electrode 6 were prepared by depositing ABC and B·GOD alternately on the electrode for 2 times and 3 times, respectively. As shown in Fig. 4(d, e) the current values of the electrodes depend linearly on the number of ABC-B·GOD layers. For the reason, the alterant and repeated deposition of ABC and B·GOD thus provides a useful method for regulating the response sensitivity of enzyme sensors.

Fig. 5 shows the calibration curves for electrodes 2–6. The electrode 6 was most sensitive among the electrodes and the linear range of glucose was $6.0 \times 10^{-6} - 5.0 \times 10^{-3}$ M. On the other hand, although the electrodes 2–5 showed less sensitive than did electrode 6, the linear range of glucose was higher. The useful calibrations were over more than 30 mM which covers the blood glucose level of diabetic patients. This means that the technique may be useful for con-

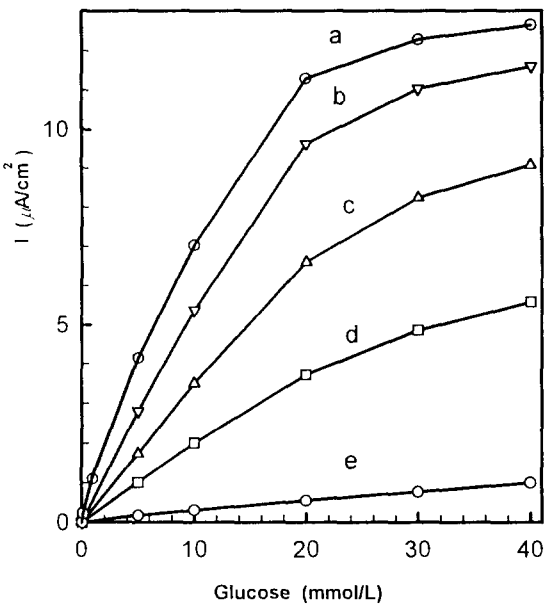

Fig. 5. Calibration curves of electrodes 2–6. Electrode: 6(a), 5(b), 4(c), 3(d) and 2(e).

trolling the performance characteristics of enzyme sensors such as low and up detection limit and magnitude of the output current by simply changing the number of deposition of the enzyme layer on the electrode surface.

3.3. Response time of electrodes

Table 1 shows the response time of electrodes 2–6–10 mM glucose. The results confirm that for all sensors the amperometric response are very rapid and response time is independent of the amount of B·GOD on the electrode surface.

3.4. Stability

In order to evaluate the long-term stability of the sensors, we measured the current response of

Table 1
Response time to glucose of electrodes 2–6

Electrodes	2	3	4	5	6
Response time(s)	2.1	3.1	2.8	3.7	3.0

Table 2
Comparison of response to glucose between before and after reactivation for electrodes 4–6

Electrodes	Beginning (nA)	After 2 weeks (nA)	
		No reactivation	Reactivation
4	385	294	404
5	589	437	570
6	782	571	758

the sensors to 10 mM glucose for 35 days. Although decrease in out-put current was observed in the first 5 days, after that period, the current values remained almost constant. This tendency in long-term stability was common to all electrodes 2–6. Meanwhile, the sensitivity of sensors preserved for long-term or/and used for many times could be recovered by immersing in 50 mg ml^{-1} avidin and 25 mg ml^{-1} B·GOD mixed solution for 30 min. In Table 2 comparison with the current values between before and after reactivation for the electrodes 4–6 which were preserved for 2 weeks conforms that the electrodes can be repeatedly reactivated.

3.5. Determination of glucose in blood serum

Human blood serum, 100 ml, was added in 8 ml PBS solution, and the current response of glucose at electrode 6 was determined. The results of glucose in three human blood serum samples are shown in Table 3. They are approached by the results determined by spectroscopic method and the recovery is among 90–110%.

4. Conclusion

We have demonstrated that the self-assembled biotinylated disulfide derivative monolayer is useful for constructing monolayer or multilayer enzyme membranes through avidin–biotin complexation. The method for the enzyme immobilization in molecular-level has the characteristics of fabricating enzyme sensors which have fast

Table 3
The determination results of glucose in blood serum

response to glucose, simply regulating the response sensitivity of the enzyme sensors by changing the number of deposition of the enzyme layers, and repeatedly recovering the sensitivity of sensors with avidin and biotinlabeled enzyme complex solution. The sensors were used to determine glucose in human blood serum and the results are quite satisfactory.

Potentiometric study of the protonation equilibrium of Tris(Hydroxymethyl) aminomethane in aqueous sodium perchlorate solutions at 25°C: construction of a thermodynamic model

R. Gil, M.S. Corbillón, M.A. Olazabal *, J.M. Madariaga

Kimika Analitikoaren Departamentua, Euskal Herriko Unibertsitatea, 644 P.K., E-48080, Spain

Received 15 December 1995; received in revised form 10 September 1996; accepted 17 October 1996

Abstract

The protonation equilibrium of the Tris(Hydroxymethyl)aminomethane (TRIS) has been studied using an automated potentiometric system. The temperature was kept constant at 25°C and the ionic strength was 0.1, 0.5, 1.0, 2.0 and 3.0 mol dm^{-3} in $NaClO_4$. The experimental constants, obtained at different ionic strengths, were correlated by means of the modified Bromley methodology (MBM) and the thermodynamic protonation constant found to be $\log {}^0\beta = 8.07 \pm 0.01$. Those values together with some others for NaCl medium were used to construct a thermodynamic model on both molal and molar scales for the protonation equilibrium of TRIS. © 1997 Elsevier Science B.V.

Keywords: Acid-base equilibria; Bromley's parameters; Ionic medium influence; TRIS

1. Introduction

A previous work [1] about fluoride determination by ion selective electrode in samples with high Al^{3+} concentrations has shown the high stability of aluminium-Tris(hydroximethyl)aminomethane (TRIS) complexes, although such complexes are not quantitatively described in the literature.

Metal-ligand complexes have been studied by the potentiometric technique using glass electrodes when the acid-base behavior of both, the metal and the ligand, is well established, i.e., when a proper chemical model (thermodynamic stability constant values and an estimation method for the activity coefficients computation of all the species) is defined. Such model is available for aluminium in pure sodium perchlorate using an approach developed by Baes and Mesmer [2] to estimate the ionic medium effects. Other approach used to estimate activity coefficient values is the Modified Bromley Methodology (MBM) [3,4] used by our working group for the last 5 years, that requires the knowledge of the interaction parameters of all the cations and anions present in the solution.

* Corresponding author.

PII S0039-9140(96)02134-0

In relation to the protolysis equilibrium of Tris(hydroxymethyl)aminomethane some works have been found in the literature but their results are not useful enough for our study. The use of single NaCl medium is reported in two papers [5,6], giving stoichiometric formation constant values which coincide within their random errors. From other papers, the thermodynamic constant value seems to be well defined [7,8]. However values in $NaClO_4$ medium reported by several authors are not enough information to have knowledge of the behavior of the system in our experimental conditions.

In order to define this system, i.e., to confirm the thermodynamic constant and calculate the Bromley's interaction parameters in a pure ionic medium, a systematic potentiometric study of the protonation constant of tris(hydroxymethyl)aminomethane at different ionic strengths has been performed using $NaClO_4$ as the ionic medium.

The protonation constants obtained in this work, together with data found in the literature will be used to build up a chemical model by the Bromley's methodology which will explain the behavior of this acid–base system in perchlorate and chloride media.

2. Experimental

2.1. Reagents and solutions

The chemicals used were all of analytical grade and used without further purification. Sodium perchlorate monohydrate (Fluka p.a.) was employed as the ionic medium. A stock solution of $NaClO_4$ was prepared and its concentration was tested gravimetrically after evaporation of an aliquot at 110°C. All solutions of this study have been prepared in a single $NaClO_4$ medium.

The following stock solutions were prepared and used as titrants:

$$C_{T1} = A_1 \text{ mol dm}^{-3} HClO_4 + (I - A_1) \text{ mol dm}^{-3} NaClO_4$$

$$C_{T2} = A_2 \text{ mol dm}^{-3} NaOH + (I - A_2) \text{ mol dm}^{-3} NaClO_4$$

where I is the total ionic strength. The ionic strengths studied were 0.1, 0.5, 1.0, 2.0 y 3.0 mol dm^{-3}. The C_{T2} solutions were prepared in N_2 atmosphere to avoid CO_2 contamination.

These solutions were standardized against tris(hydroxymethyl)aminomethane [9] and potassium acid phthalate [10], respectively.

The test solution were prepared with the following general composition:

$$C_B = B \text{ mol dm}^{-3} \text{ tris(hydroxymethyl) aminomethane} + I \text{ mol dm}^{-3} NaClO_4$$

where the values of B were 10^{-1}, 5×10^{-2}, 10^{-2} or 5×10^{-3} mol dm^{-3}.

2.2. Apparatus and experimental technique

The experiments were carried out as potentiometric titrations with constant ionic strength using an automated system developed in our laboratory which can control up to three titrations at the same time [11].

The titration cell with magnetic stirring was immersed in a thermostatic bath at 25.0 ± 0.1°C. The titrations were performed in a N_2 atmosphere to avoid CO_2 contamination during the experiments. The glass electrode (Methrom 6.0101.100) and the double-junction reference electrode [Ag-AgCl(s), Methrom 6.0726.100] were connected to an operational preamplifier in order to adapt the electric signal to the voltmeter. The electromotive force measurement was carried out with a Hewlett-Packard VXI E1326B voltmeter (resolution of six decimal digits and accuracy of 0.008% of the read + 15 μV) connected to a computer. The titrant additions were performed with a Metrohm Dosimat 665 burette with a precision of ± 0.01 ml. The potentiometric measurements were made with the following galvanic cell:

$$\text{Ag, AgCl(s)}/I \text{ mol dm}^{-3} NaClO_4 \text{ sat} \in \text{AgCl//Test solution/Glass electrode} \quad (1)$$

where I is the ionic strength of the solutions. As can be seen reference electrode has been designed including $NaClO_4$ as inert solution to minimize liquid junction potential.

Each titration took around 15 h and at least three different concentration were carried out for each ionic strength studied. Each titration was repeated at least twice in order to ensure the reproducibility of the data. For each titration it was considered that equilibrium was reached when the electromotive force measurement was kept constant during 5 min in a $\pm$ 0.05 mV interval.

2.3. Determination of h

The free hydrogen ion concentration, $[H^+] \cong h$, was determined by measuring the emf. of cell Eq. (1) in the course of the titrations. At 25°C the emf of the cell may be expressed as in Eq. (2) and Eq. (3).

$$E = E_0 + g \log h + E_j(h) \quad (2)$$

$$E_j(h) = j_{ac}\, h + j_{bas}\, k_w\, h^{-1} \quad (3)$$

E_0 value is specific for each titration carried out and is calculated in the first points (acid plateau) of each titration where no TRIS equilibrium is present. The value of the autoprototolysis constant of water (k_w) was determined previously for each ionic medium by means of potentiometric ionic media titrations. These parameters (E_0 and k_w) were calculated using a derivation of Gran's method and numerically refined by the non linear least squares computer program Model Function version [12] of Letagrop.

Acid and basic liquid junction potential coefficients (j_{ac} and j_{bas}, respectively) were determined from potentiometric ionic media titrations [13] as well. As liquid junction potential values depend only on the ionic strength, they can be considered as constant for each ionic strength in the latter potentiometric titrations with tris(hydroxymethyl)aminomethane.

3. Results

The protonation equilibria of tris(hydroxymethyl)aminomethane can be written as in Eq. (4)

$$H^+ + Tr \rightleftharpoons HTr^+ \quad (4)$$

and the corresponding stoichiometric protonation constant for a given medium of constant ionic strength can be expressed as in Eq. (5) where the superscript indicates the ionic strength.

$$^I\beta = \frac{[HTr^+]}{[H^+][Tr]} \quad (5)$$

The data were treated by means of graphical and numerical methods.

In a first approach to know the value of the protonation constant and to search some possible systematic errors in the total concentration of the reagents used, a graphical treatment was carried out [14]. The experimental $\bar{n}$ values ranged between 0 and 1 in the interval $1 < pH < 11$, which confirm the presence of one protonation step and the absence of systematic errors in the experiments. As an example, Fig. 1 shows an example of $\bar{n}$ function when $I = 2$ M.

The values obtained in the graphical treatment were numerically refined with two different programs the Nytit version [15] of the Letagrop program and Bstac11 program [16], minimizing the absolute square error sum of the measured

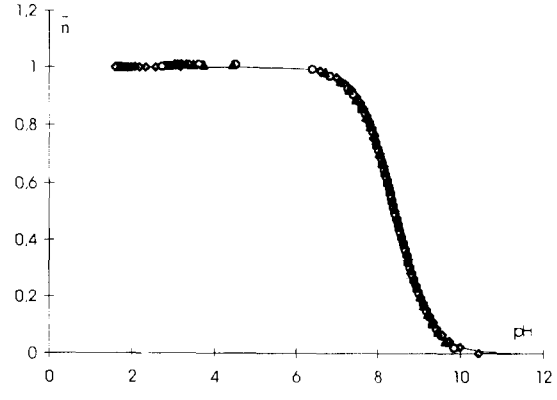

Fig. 1. Experimental $\bar{n}$ values plotted as a function of pH in 2 M $NaClO_4$ medium at different tris(hydroxymethyl)aminomethane concentrations levels.

Table 1
Stoichiometric protonation constant for tris-(hydroxymethyl)aminomethane protonation at different ionic strengths in $NaClO_4$ medium, obtained by the different numerical methods

Ionic strength (mol dm^{-3})	$\log {}^0\beta$		
	NYTIT	BSTAC	Proposed values
0.1	$8.06_5 \pm 0.01$	8.056 ± 0.008	8.06 ± 0.01
0.5	8.04 ± 0.05	8.091 ± 0.004	8.091 ± 0.004
1.0	8.199 ± 0.004	8.216 ± 0.002	8.207 ± 0.008
2.0	8.422 ± 0.002	8.418 ± 0.001	8.420 ± 0.002
3.0	8.64 ± 0.01	8.650 ± 0.006	8.65 ± 0.01

potential (U_E). Both programs have different minimization algorithms and different systematic error detection strategies.

The values obtained by this two numerical treatment programs are compared in Table 1. As it can be seen, the values from the different numerical treatments are equal within the limits of experimental error. The proposed value of the stability constants for $I = 0.1$, 1, 2 and 3 M ionic strengths have been calculated averaging the values obtained by the two numerical treatment programs (Nytit and Bstac). However for $I = 0.5$ M the error associated to the formation constant value was completely different with the two programs. As precision with Nytit is more than ten times larger, only the result obtained by Bstac has been considered. Fig. 1 also shows the fit between the experimental curves $\bar{n} = f(-\log h)$ and the theoretical plot of $\bar{n}$ versus $(-\log h)$ constructed with the protonation constant in $NaClO_4$ at the different ionic strengths, proposed in this work and listed in Table 1.

4. Discussion

As stated in the introduction, one of the aims of this work is to develop a thermodynamic model in order to explain the behavior of the protolysis of tris(hydroxymethyl)aminomethane in single $NaClO_4$ media. There are several literature references to the protonation constant of tris(hydroxymethyl)aminomethane at 25°C in $NaClO_4$ and NaCl media [5,6].

The chemical model has been constructed by means of the Modified Bromley Methodology, MBM [3,4]. In this method, it is necessary the knowledge of at least three stoichiometric constant values, in the same media, at different ionic strengths in order to calculate the thermodynamic constant value of the equilibria and the corresponding interactions parameters for each species taking part in the equilibrium.

The thermodynamic constant ${}^0\beta_i$ for the protonation equilibria of tris(hydroxymethyl)aminomethane can be expressed as Eq. (6):

$$ {}^0\beta_i = \frac{\{HTr+\}}{\{Tr\}\{H^+\}} = \frac{[HTr^+]\gamma_{HTr+}}{[Tr]\gamma_{Tr}[H^+]\gamma_{H+}} \quad (6) $$

where γ is the molar activity coefficient and $\{\}$ indicates activity. Combining Eq. (5) and Eq. (6), the expression to correlate the stoichiometric protonation constant can be written as:

$$ \log {}^0\beta = \log {}^I\beta + \log \gamma_{TrH+} - \log \gamma_{H+} - \log \gamma_{Tr} \quad (7) $$

The individual activity coefficients on the molar scale of the charged species, γ_i, can be substituted using the Bromley function, Eq. (8), where $A = 0.5111$ $dm^{3/2}$ $mol^{-1/2}$, I is the ionic strength on the molar scale, z_M the ionic charge of M, z_M the charge of the ionic species with the opposite sign to M and C_X its molarity.

$$ \log \gamma_M = -\frac{Az_M^2 I^{1/2}}{1+I^{1/2}} + \sum \mathring{B}_{MX}(|Z_M| + |Z_X|)^2 \frac{C_x}{4} \quad (8) $$

The parameter $\mathring{B}_{MX}$ can be expressed as in Eq. (9), where B_{MX} is the interaction parameter of the ion pair MX on the molar scale.

$$\mathring{B}_{MX} = \frac{(0.06 + 0.6B_{MX})|z_M z_X|}{[1 + (1.5I/|z_M z_X|)]^2} + B_{MX} \quad (9)$$

In the case of uncharged species the activity coefficient is expressed by means of the molar salt coefficient S by using an expression similar to that proposed by Long and Mc Devit (Eq. (10)) [17]:

$$\log \gamma_{MX} = S_{MX,\text{ionic medium}} I \quad (10)$$

Rearranging Eq. (7) and making use of Eq. (8) Eq. (9) Eq. (10) it is possible to obtain expression Eq. (11) to correlate the protonation constant at different ionic strength

$$\log^0\beta = \log^I\beta + \mathring{B}_{TrH^+,ClO_4^-} I + \mathring{B}_{H^+,ClO_4^-} I + S_{Tr,NaClO_4} I \quad (11)$$

This expression depends only on the value of the thermodynamic constant for the equilibrium taking place and the interaction parameters (B) or salt coefficient (S) of the different ionic or neutral species.

The value of $B_{H^+,ClO_4^-} = 0.1815 \pm 0.0005$ was previously determined [3] while the thermodynamic constant and the rest of the interaction parameters have to be calculated. The correlation of our proposed values in Table 1 was made by means of the program Model Function version [12] of Letagrop The results obtained from Eq. (11) are the following:

$$\log^0\beta = 8.07 \pm 0.01,\ B_{TrH^+,ClO_4} = 1.02 \pm 0.02 \text{ and } S_{Tr,NaClO_4} = 1.05 \pm 0.02$$

Fig. 2 shows the fit between our proposed $\log^I\beta$ values and the theoretical curve obtained with these results. The obtained thermodynamic constant value coincide with the values reported by Bates and Hetzer [7] (8.069) and by Datta et al. [8] (8.074).

The data collected in Table 1 and those bibliographic stoichiometric constants reported for NaCl [5,6] were finally used to define the thermodynamic model in Cl^- as well as ClO_4^- medium, by correlating both systems at the same time [14]. The results on both molal and molar scales are collected in Table 2 and the fit for molar data can be observed

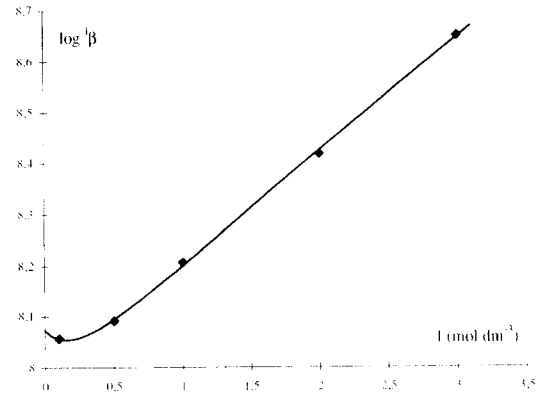

Fig. 2. Variation of log β with ionic strength together with the theoretical function.

in Fig. 3. With this model the stoichiometric constant for the protonation of TR1S can be obtained in both Cl^- or ClO_4^- salt medium or mixture of both at any ionic strength lower than 3 mol dm^{-3}. The uncertainty in the B and S parameters is similar for both media (NaCl and $NaClO_4$) although their values are quite different.

As it can be observed in Fig. 3, even if the stoichiometric values proposed in both media could be considered similar, the general shift of both system is different, showing a slight convex distribution for NaCl medium and a concave one in the $NaClO_4$ medium. The behavior of this system is similar to those obtained for other compounds having a amine group in their structure, as can be seen in the diethanolamine case [18].

Table 2
Thermodynamic protonation constant and Interaction parameters on molal and molar scales obtained with the Modified Bromley Theory in $NaClO_4$ as well as NaCl media

$\log^0\beta \pm 3\sigma(\log^0\beta)$	Molar scale 8.071 ± 0.006	Molal scale 8.067 ± 0.007
$NaClO_4$ medium	$B_{TrH^+,ClO_4} = 1.01 \pm 0.06$	$B_{TrH^+,ClO_4} = 0.77 \pm 0.06$
	$S_{Tr,NaClO_4} = 1.04 \pm 0.06$	$S_{Tr,NaClO_4} = 0.76 \pm 0.06$
NaCl medium	$B_{TrH^+,Cl} = -0.06 \pm 0.06$	$B_{TrH^+,Cl} = -0.23 \pm 0.04$
	$S_{Tr,NaCl} = -0.02 \pm 0.06$	$S_{Tr,NaCl} = -0.19 \pm 0.04$
U	6.47×10^{-4}	4.52×10^{-4}

Where U is the square cuadratic errors.

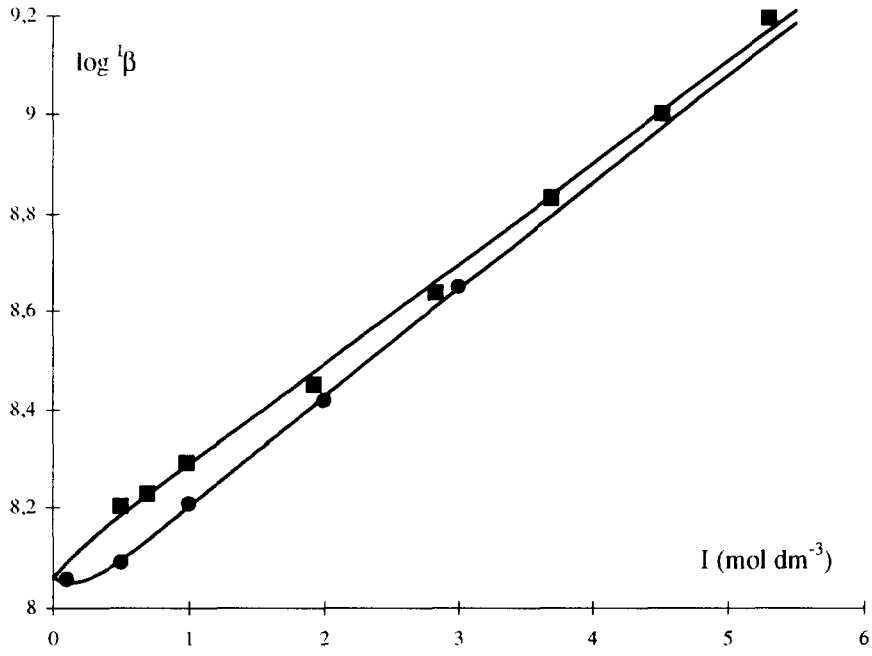

Fig. 3. Graphical representation of the experimental values of the constants in NaCl (■) and $NaClO_4$ (●) media together with the theoretical function.

Although somebody can argue the small difference between the two lines in Fig. 3, especially at high ionic strengths, the different behavior is important from the methodological point of view. For example we have observed that a convex shape is directly related with low or even negative values of the interaction parameters (B or S). A concave shape is always obtained with positive B and S values for all the species playing the equilibrium; as the B values increase, the concavity of the $\log \beta/I$ plot is more pronounced. A near linear shape seems to be related with similar values of the B and S parameters, where the corresponding estimated γ_i values of the different species are nearly equal at high ionic strengths; in such situations the slope of the $\log \beta/I$ plots is directly related to the activity coefficient of the third species participating in the equilibrium.

Divalent cations speciation with three phosphonate ligands in the pH-range of natural waters

Véronique Deluchat, Jean-Claude Bollinger *, Bernard Serpaud, Claude Caullet

Laboratoire des Sciences de l'Eau et de l'Environnement, Faculté des Sciences, 123 avenue Albert Thomas, 87060 Limoges, France

Received 11 April 1996; received in revised form 18 October 1996; accepted 21 October 1996

Abstract

AMP and HEDP complexation constants for seven divalent cations (Ca, Cu, Cd, Fe, Ni, Pb and Zn) have been determined by acid–base titrations at 25 ± 0.5°C, at constant ionic strength (0.1 M KNO_3) with Martell and Motekaitis's computer programs. Speciation diagrams enable us to compare AMP, HEDP and TPP complexing properties. AMP complexes more strongly all seven divalent cations than HEDP and TPP, which have similar ligand behavior. Among the divalent cations studied here, the ligands have lowest affinity with calcium and usually higher with copper. In all the cation/ligand systems, the major species are ML and MHL which are charged species. The uncharged ionic species Ca_2Y^0, CaH_4X^0 and CdH_2Y^0 (H_6X = AMP and H_4Y = HEDP) which can potentially exist in solid phase, cannot be neglected. Moreover hydroxide complexes have to be taken into consideration in the complexation constant determinations and in the environmental impact. © 1997 Elsevier Science B.V.

1. Introduction

Common washing powders contain surfactants, builders, peroxides and enzymes. Sodium tripolyphosphate (TPP) is the oldest builder, but phosphorus is now known to be a major factor in the eutrophication of lakes and rivers. The phosphorus in TPP detergents can account for 50% of the phosphorus in natural waters [1]. To combat eutrophication, the phosphate content in natural waters must be decreased and the most effective way to do this would be to decrease the amount of phosphorus in detergents.

The main TPP substitutes are zeolites, nitrilotriacetic acid, citrate, phosphonates and polycarboxylates [1,2]. Phosphonates or polycarboxylates improve the action of zeolites and other detergent compounds by their complexing behavior, especially with calcium and heavy metal cations. This is of interest because calcium deactivates the surfactants, and heavy metal cations catalyse peroxide decomposition. The EEC has recently established ecological criteria (decision no. 95/365/CE [3]) for the attribution of an 'Ecolabel' to formulations for textile detergents. In this study, we determine protonation and complexation constants with various cations for two phosphonic acids frequently encountered in detergent formu-

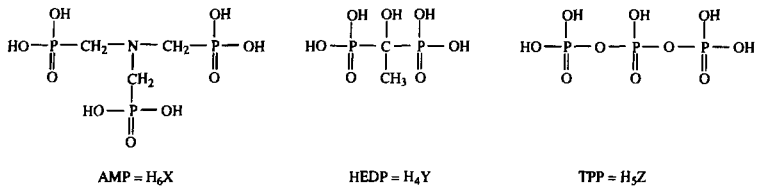

Scheme 1. Phosphonic acid formulas.

lations: nitrilotris(methylenephosphonic acid) AMP and 1-hydroxyethane-1,1′-diphosphonic acid HEDP (see Scheme 1).

Like TPP, these compounds will enter the ecosystem with domestic waste waters. Although AMP and HEDP have a very low biodegradability, HEDP is almost totally decomposed in surface waters when exposed to sunlight [4] and AMP is totally decomposed into various primary products [5]. However, before this abiotic degradation process begins, they are able to participate in cation mobilisation from river sediments. Thus we determine AMP and HEDP complexing properties with cations normally present in natural waters (Ca(II), Fe(II)), and with heavy metal cations (Cu(II), Zn(II), Ni(II), Cd(II), Pb(II)) able to come from industrial wastes. Some complexation constants have been previously published, and in some cases with a great number of figures, however most authors do not indicate precisely the nature of all complexed species taken into account in their calculations. The present study was carried out to determine these equilibrium constants paying special attention to the reproducibility of the calculated values and with a special emphasis on the computational process.

Stability constants were used to draw up speciation diagrams indicating major species present in natural waters (pH range from 5 to 9), thereby enabling us to determine the interference of hydroxide ligands. AMP and HEDP complexing behaviors are compared with that of TPP, in order to evaluate their environmental impact. In fact if the complexing properties of these compounds have already been studied with some cations, a forecast of their complexing behavior in the natural media has never been done.

2. Materials and methods

Equilibrium constants were calculated from data obtained by potentiometric titrations. pH titrations were done with a Metrohm 716-DMS automatic titrator. The combined glass electrode (Ag-AgCl, Metrohm 6.0233.100) was calibrated by hydrochloric acid titration with sodium hydroxide. Martell and Motekaitis [6] computer programs were used to analyse the pH data. Our stability constants were determined according to IUPAC recommended procedure [7] for testing the potentiometric apparatus and its technique for the pH measurement of metal-complex equilibrium constants with the glycine/nickel(II) system ($I = 1$ mol l^{-1} NaCl, 25°C). Experiments were carried out twice, and in duplicate by two manipulators (eight experiments with each system, protonation and complexation). Our protonation constants coincide exactly with IUPAC values. Taking into account standard deviations, our values for complexation constants are in good agreement with, though always slightly higher than, IUPAC values.

AMP and HEDP are pure grade Fluka products. Metal salts (nitrate) are pure grade compounds. The cation salt solutions were standardised with EDTA according to classic methods. The phosphonic acid and cation concentrations were 2.10^{-3} mol l^{-1}.

All the potentiometric titrations were performed at 25 ± 0.5°C in 0.1 mol l^{-1} KNO_3 solution and under purified nitrogen stream. Each

experiment was carried out at least three times, each one in triplicate.

3. Determination of equilibrium constants

When determining equilibrium constants various data must be taken into consideration:

- experimental data: concentrations, volume, pH,
- theoretical data: water ionic product, activity coefficients.

The protonation and complexation constants are obtained using an iterative method. The computer program calculates a pH value as close as possible to the observed pH:

$pH_{calc} = f$(experimental and theoretical data, equilibrium constants) = experimental pH.

The main difficulty is deciding when the iteration should stop, because in most cases the values of the calculated equilibrium constant keep varying but at levels not significant with respect to the uncertainty on the pH measurements.

The uncertainty of each one of these parameters leads to the uncertainty of equilibrium constants. The main problem is caused by the pH because it is difficult to calibrate precisely the electrode, especially at $pH \geq 10.5$. Water ionic product in 0.1 mol l^{-1} KNO_3 medium at 25°C is taken as $10^{-13.78}$ [8].

The data treatment is carried out according to the following systematic procedure:

- first, the data are analysed considering every species (phosphonate or hydroxyde complexes) which might exist;
- secondly, speciation diagrams are drawn up to show the complexed species present in solution;
- finally, the data treatment is performed again considering only the interfering species, and in the pH-range where phosphonate complexed species are present.

The use of this procedure allows to obtain reliable stability constants. Moreover, the treatment of more than ten experiments contributes also to determine a reliable standard deviation ($\sigma_{(n-1)}$) of the calculated stability constants.

Protonation constants were determined with the PKAS computer program [6] (Table 1). Considering i as the number of acid functions, we define

$$K_i = [H_iL]/\{[H^+][H_{i-1}L]\}$$

for the equilibrium

$$H^+ + H_{i-1}L \rightleftarrows H_iL$$

where the charges are omitted for easier printing.

There is good agreement between calculated and experimental pH, and between literature and present protonation constants values. The high uncertainty in $\log K_1$ is linked to the pH uncertainty in basic media. Whole protonated species represent a very low amount in the pH-range of the experiments, thus it is difficult to determine precisely their stability constants. Anyway, Grenthe [9] considers stability constant uncertainty of 0.05 (in log units) as a very high precision.

Complexation constants were determined with the BEST computer program [6] (Table 2). For each equilibrium:

$$MH_{(i-1)}L + H^+ \rightleftarrows MH_iL$$

Table 2
Complexation constants ($I = 0.1$ mol l^{-1} (KNO_3), 25 ± 0.5°C), $K_{MH_iL}^{MH_{(i-1)}L} = [MH_iL]/\{[MH_{(i-1)}L][H^+]\}$ $\beta_{MH_iL} = [MH_iL]/\{[M][L][H^+]^i\}$

[a] Taken from [10,11].
[b] Occurrence of the insoluble complex species $CdH_2L_{(s)}$ [12].
[c] Immediate formation of an insoluble compound $Pb_2L_{(s)}$ [12].

we define a stepwise formation constant:

$$K_{MH_iL}^{MH_{(i-1)}L} = [MH_iL]/\{[MH_{(i-1)}L][H^+]\}$$

and an overall stability constant:

$$\beta_{MH_iL} = [MH_iL]/\{[M][L][H^+]^i\}$$

Although omitted, the electrical charges on MH_iL species are not the same depending on the ligands X^{6-}, Y^{4-} and Z^{5-} (see Scheme 1).

The greater interference of hydroxide/cation complexes with HEDP than with AMP might explain the better agreement obtained with AMP. There is a higher disagreement between experimental and calculated pH at basic pH, especially with Cu, Zn and Pb. This might be due to difficulties in the pH calibration at basic pH and uncertainties concerning the hydroxide/cations formation constants (which were not determined from our experimental data, but taken from the literature [10,11]). It is difficult to estimate constants for species representing less than 18% for the whole pH-range.

During our previous study [12], hydroxide/cation formation constants were also calculated, which explains the gap between complexation constant values. The Zn/HEDP complexation constants determined then are not fully reliable because of a zinc solution purity problem.

Sawada et al. [13,14] neglected the interference of hydroxide/cation/phosphonic acid ternary complexes and also the presence of higher complexes such as M_2L or ML_2, but such species can perturb the pH adjustment. It is very difficult to evaluate the contribution of such complexes under our experimental conditions. We usually worked only with ratio M/L = 1, and therefore could precisely determine the stability constants of the common species such as ML, MHL...

Since the concentrations of calcium cations are probably higher than those of phosphonic acids in natural waters, we also studied the complexation behavior for a ratio Ca/L = 2, thus enabling us to determine M_2L complexation constants. We also studied the possibility of CO_2 interaction with the Ca^{2+}/phosphonic acid system [15]. Atmospheric CO_2 does not lead to pertubations on the complexation properties.

4. Discussion

Our values of complexation constants with AMP confirm previous observations by Sawada et al. [13,14]:

- In the case of transition-metal complexes, the K_{MHX} constants for Cu, Zn and Pb are similar and always smaller than the second protonation constant of AMP (7.22), but Ni and Cd data do not follow such a rule.
- In the case of calcium complexes, K_{MHX} is higher than K_{HX} and K_{MX}.

The M–N bond of the transition metal complexes would be strong and not affected by the first protonation of the complex which would occur on the O^- of the phosphonate group. On the other hand, the M–N bond of the alkaline earth metal complexes would be mainly ionic and thus, very weak, therefore the first protonation of the complex would rupture this weak bond and occur on the nitrogen atom [13,14].

In any case, differences between MH_iX and $MH_{i-1}X$ logarithmic constants ($i \geq 1$ with Cu, Zn, Cd and Pb; $i \geq 2$ with Ca and Ni) are close (1– 2 log units), indicating that they correspond to a protonation on a free O^- of the phosphonate group. This is confirmed since this is also observed for HEDP cations stability constants. The gap from 1 to 2 log units between these differences can be explained by electrostatic interactions occurring during the various protonations.

The HEDP hydroxyl group might interfere in the cation complexation [16,17], explaining the higher difference between MY^{2-} and MHY^- logarithmic constants with Cu, Zn and Fe. This interference is also used to explain the special behavior of HEDP with calcium where $K_{MHY} > K_{MY}$ [18,19].

4.1. Ligand affinity towards various cations

Complexing classification was estimated by considering the total fraction of cation linked to the ligand, calculated from our AMP and HEDP stability constants. TPP stability constants were taken from studies [20,21] with similar experimental conditions (temperature and ionic strength). The ligand complexation properties with the various cations are determined in the pH-range of natural waters (5–9), with ligand and cation concentrations corresponding to our experimental conditions (2.10^{-3} mol l^{-1}), and also with phosphonate concentrations nearer to those encountered in natural media (2.10^{-7} mol l^{-1}), always with a cation/ligand ratio M/L = 1.

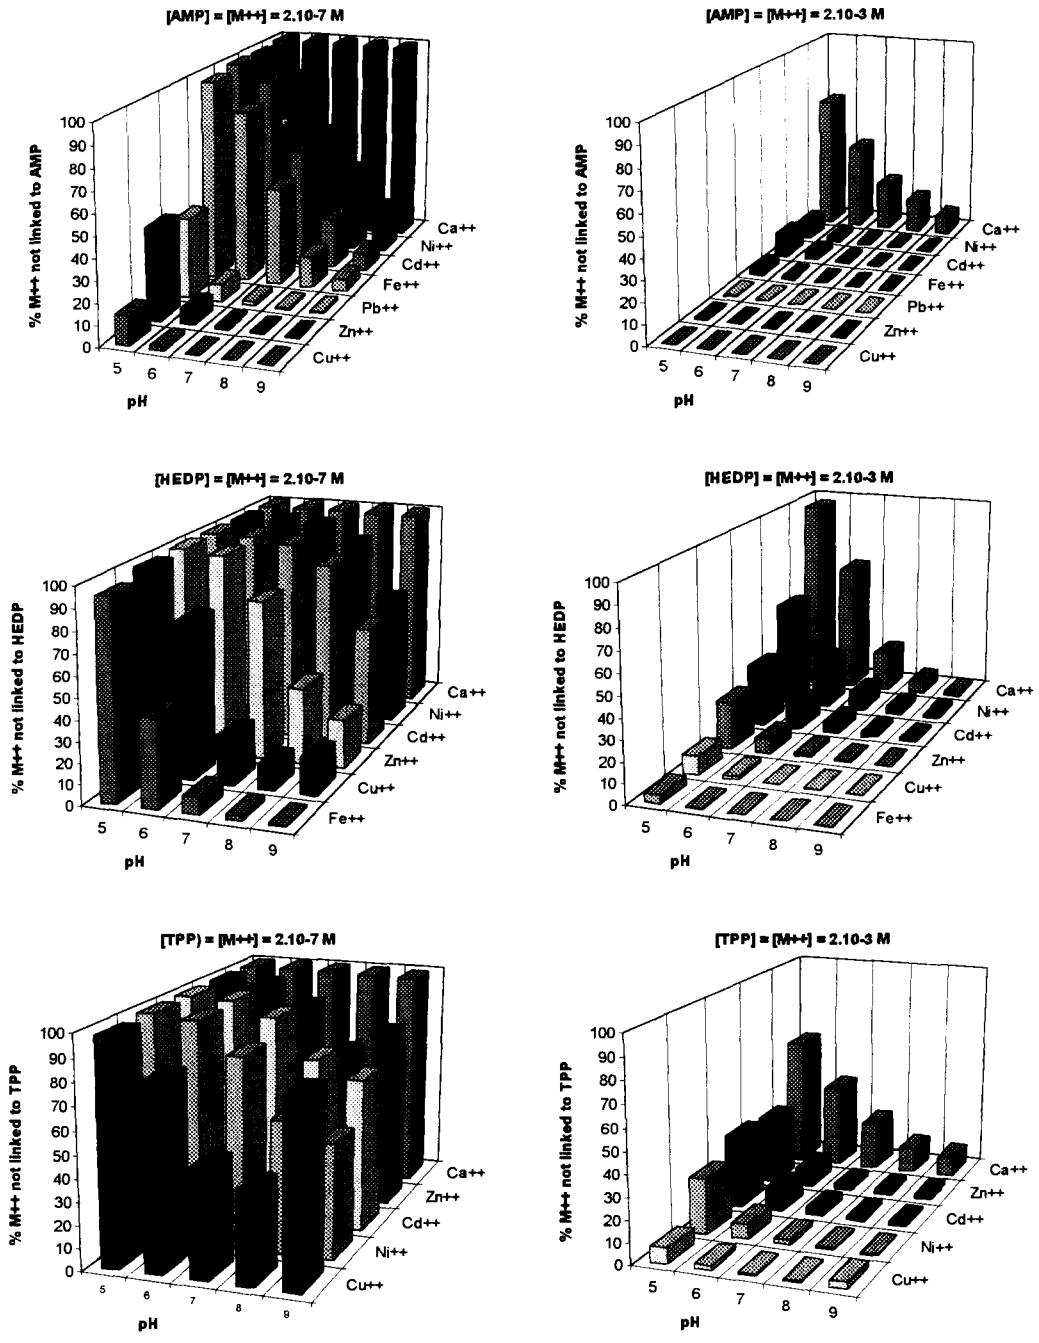

Fig. 1. Comparison of the ligands affinity classification with the various cations.

Fig. 1 shows the fraction of cations not linked to the ligand (= free cation + cation linked to hydroxide ions) at various pH. The following classifications can be made:

AMP Cu(II) > Zn(II) ≈ Pb(II) > Fe(II) > Cd(II) ≈ Ni(II) ≫ Ca(II)

HEDP Fe(II) > Cu(II) ≫ Zn(II) > Cd(II) > Ni(II) ≫ Ca(II)

TPP Cu(II) > Ni(II) ≈ Zn(II) ≈ Cd(II) > Ca(II)

The decrease of complexed cation at low concentrations is coherent with equilibrium rules. This phenomenon is less marked with AMP, but much more so with HEDP and TPP. At basic pH, with all the cations except Ca, 99% of the metal cations are linked to AMP at high concentrations, whereas at low concentrations only Cu, Zn and Pb complexes represent at least 98%. In the same pH range, at high concentrations 98% of Cu, Fe and Zn cations are linked to HEDP and 97% of all metal cations except Ca are complexed by TPP. At low concentrations these percentages decrease to 23% for Zn and 92% for Fe with HEDP, and to 47% for Cu and to 93% for Cd with TPP at pH 7.

Complexing classifications are similar at high and low concentrations. There is usually an increase in the complexed cation level with pH. TPP with Cu and Zn and HEDP with Cu do not follow such a rule. The percentage of cation linked to the ligand decreases from pH 8. This indicates that hydroxide complexation properties with these cations are stronger than those of TPP and HEDP at pH 9. This hydroxide complexes interference appears from pH 7 at low concentrations and makes affinity classification with TPP difficult. The three ligands, however, have the lowest complexing properties with Ca and usually highest with Cu. AMP has similar complexation properties with Cd, Ni and Fe, somewhat lower than those of Zn and Pb. The same is true of TPP with Ni, Zn and Cd. We cannot distinguish a family of cations with similar behavior with HEDP.

This classification is very similar to the Irving-Williams series of stabilities for chelates formed by metal ions with ligands [22]:

Zn < Cu > Ni > Co > Fe > Mn

In electrostatic terms, we would expect that the smaller the size of the metal ion, the greater the stability of the complex species. For Fe(II), Zn(II), Cu(II) and Ni(II), we did not obtain such a correlation with any of the three ligands studied, but observe that Zn always has higher complexing properties than Cd. This concept has been verified for alkaline-earth cations with HEDP [16] and AMP [13]. This phenomenon could be easily evaluated only with cations from a same column in the periodic table but is difficult to observe with cations from the same line, because the ionic radii are closer.

4.2. Complexation property classification of ligands

AMP is a stronger complexing agent than HEDP and TPP. We verified this with three typical cations of great interest in natural media. Ca is a major cation in water. Cu is often present in water because of its extensive use in farming, and its wide range of toxicological effects increases its interest. Both Ni and Cd have an intermediate behavior, but cadmium has a greater environmental impact because it is highly toxic. Furthermore, although Ni ore consumption is greater than that of Cd (18 000 and 800 000 tons year^{-1}, respectively), Cd concentrations in nonpolluted waters are of the same order of magnitude than those of Ni (ca. 1, and 2–13 μg l^{-1}, respectively) [23]. Zn and Fe complexing behaviors are similar with those of Cu and Cd.

Fig. 2 shows the complexation property classification of the three ligands with Ca, Cu and Cd at a molar ratio M/L = 1, in the pH-range of natural waters (5 to 9) at two concentration levels, 2.10^{-3} and 2.10^{-7} mol l^{-1}.

The complexation behaviors of HEDP and TPP are similar and much lower than that of AMP with copper and cadmium. HEDP has slightly stronger complexation properties than TPP, except at pH 5 with copper and for pH ≥ 6 with cadmium at high concentrations. AMP, HEDP and TPP have similar behaviors with calcium. This ligand classification is affected by pH only at high concentrations (2.10^{-3} mol l^{-1}).

AMP therefore appears to be the stronger ligand, the evolution of the complexation level with pH makes it difficult to draw a classification

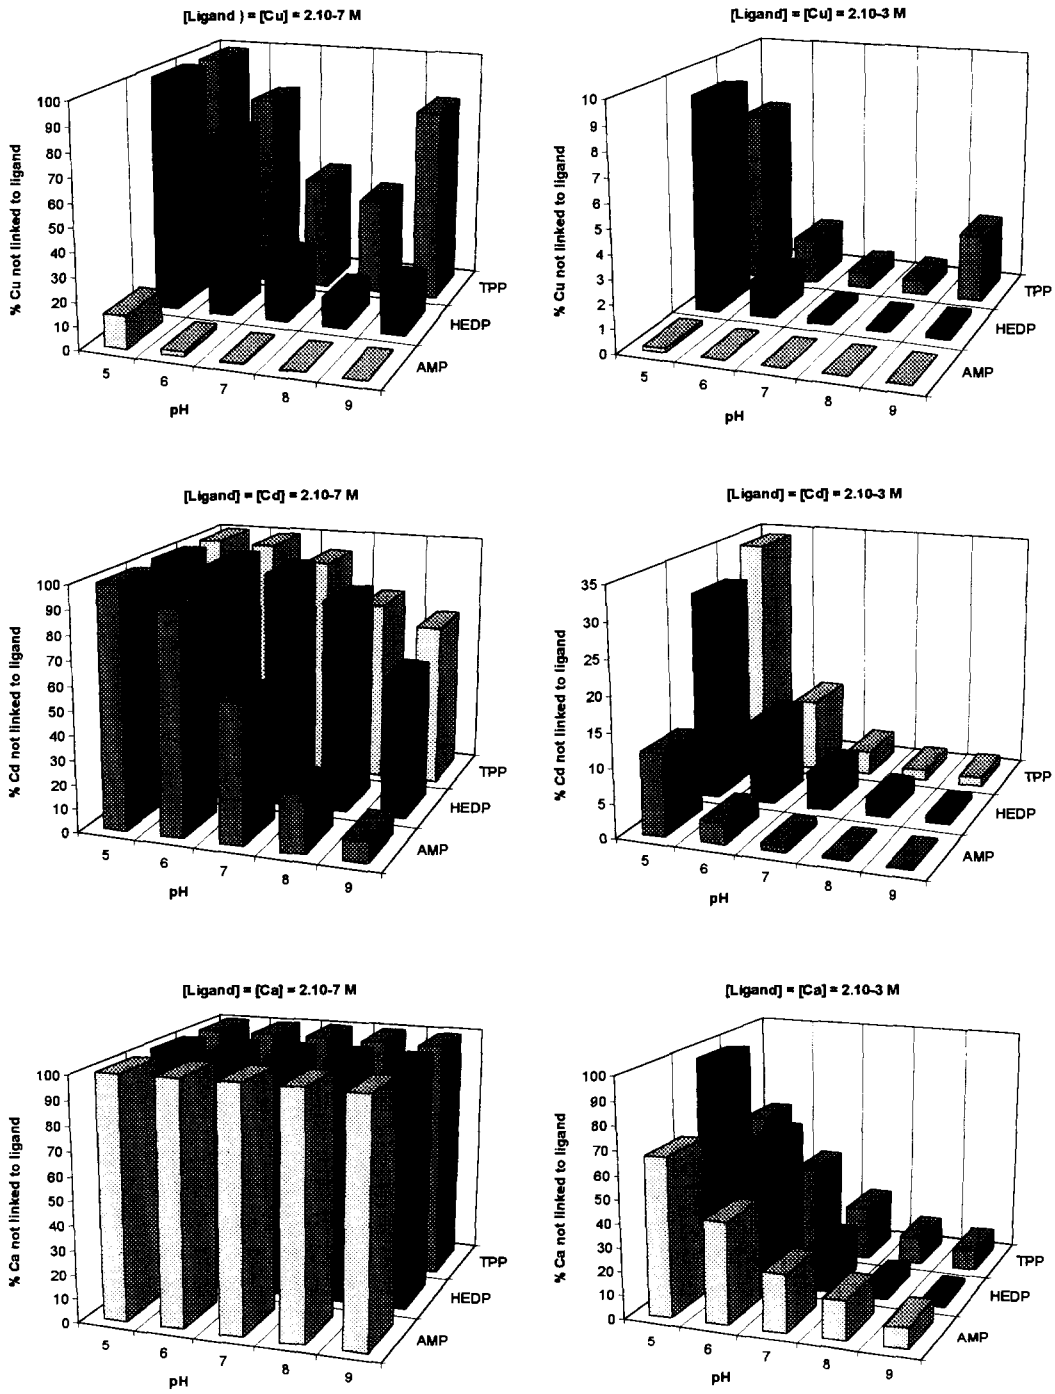

Fig. 2. Complexation properties classification of ligands.

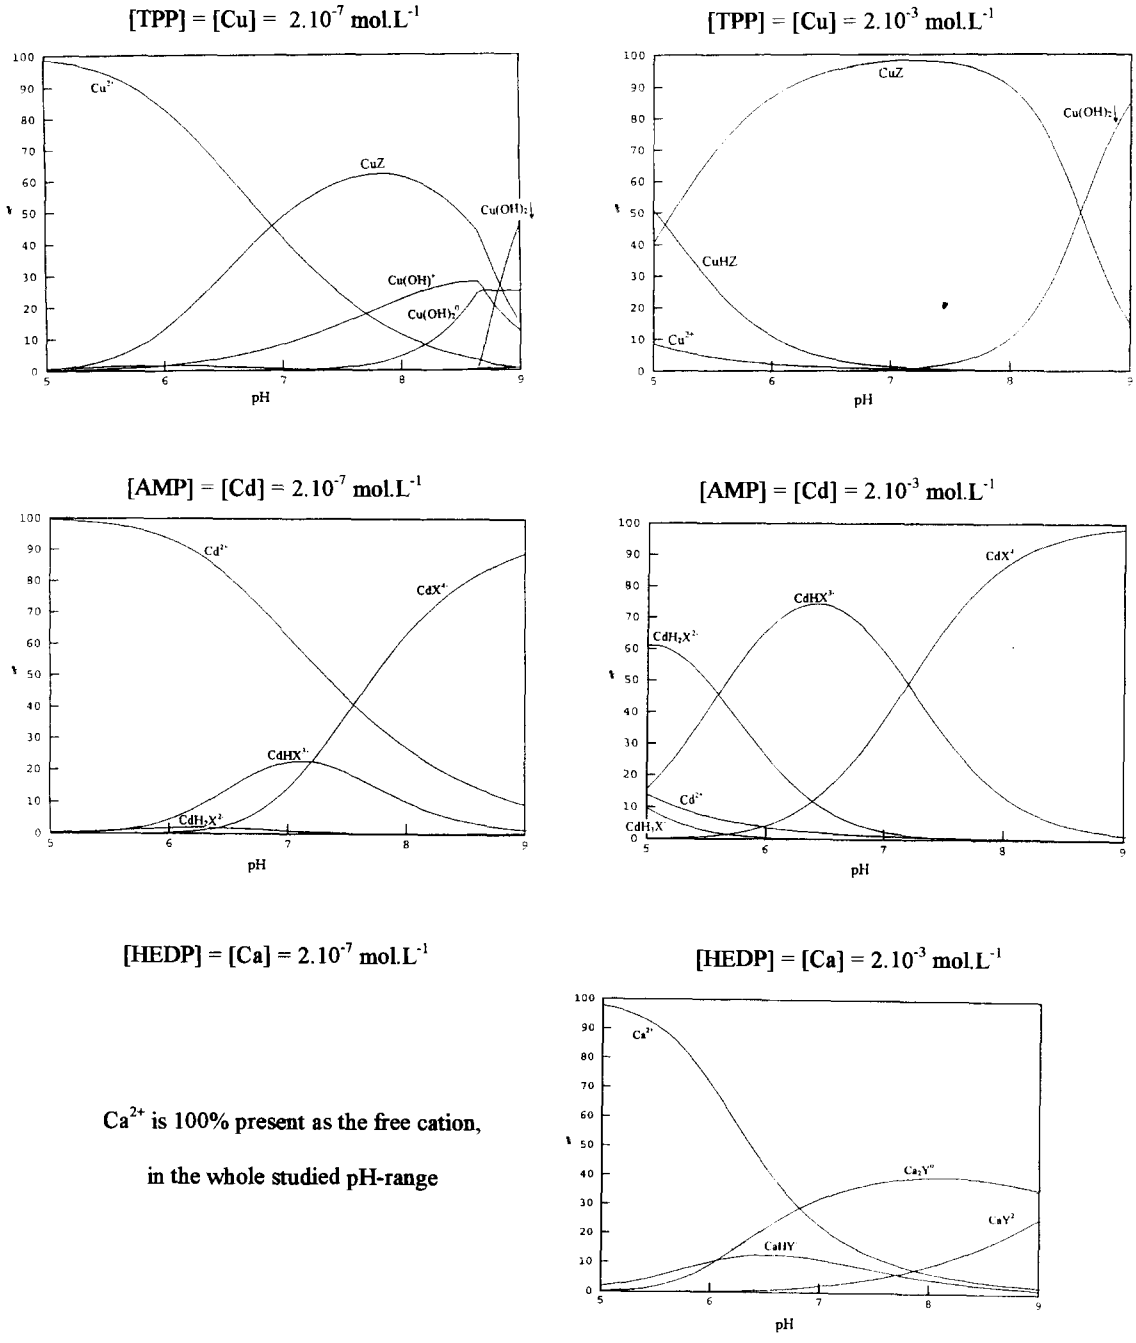

Fig. 3. Cation/ligand speciation diagrams determined with SPE computer program [6], calculated with our stability constants.

between HEDP and TPP. Therefore AMP might modify the heavy metal cations speciation in natural medium, more than HEDP and TPP.

4.3. Speciation diagrams

In natural aquatic and geological environments, the mobility and toxicity of a metal are determined by the thermodynamic activity of the species causing the toxic effect and not by the total soluble concentration of the metal [23,24]. A complete knowledge of speciation is therefore essential in order to assess the total environmental impact. Speciation diagrams were calculated with the SPE computer program [6] (Fig. 3). They are representative of ligand behavior with each cation.

At high concentrations, in our pH range, all the complexed species studied occur, except CaH_2Y^0, CdH_4X^0, CuH_4X^0, CuH_3X^- and CuH_2Y^0. The major species are $CaHX^{3-}$, Ca_2Y^0 and CaZ^{3-} in the Ca/ligand systems. CuL and CdL with $CdHX^{3-}$ and $CdHY^-$ are the major species in the Cu/ligand and Cd/ligand systems, respectively. Free cations are significant in every system except Cu/AMP. Hydroxide complex species are negligible at high concentrations, but $CdOH^+$, $CuOH^+$, $Cu(OH)_2^0$ and $Cu(OH)_3^-$ are present with HEDP and TPP at low concentrations ($[M] = [L] = 2.10^{-7}$ mol l^{-1}). At such concentrations, ligand interference decreases sharply. The percentage of free cations is higher, and it is the only metallic species in the Ca/ligand system. With each ligand, ML is the major species with Cu and Cd. Lamson et al. [25] studied the Ca/HEDP system in physiological conditions (pH 5.5–7.0, 25°C, $I = 0.1$ mol l^{-1}). They calculated speciation diagrams which are similar to ours, the same complexed species are present with similar proportions.

There is a high probability that all the charged species will stay in the liquid phase. Moreover in the natural water pH-range, all these phosphonate complexed species are anionic, as are natural ligands (such as humic substances, clays...), thus, no electrostatic adsorption phenomena will occur. Uncharged ionic species such as Ca_2Y^0, CaH_4X^0 and CdH_2Y^0 can potentially exist as a solid phase.

5. Conclusion

AMP is a stronger complexing agent with the seven divalent cations than HEDP and TPP which have similar ligand behavior. These phosphonic acids have higher affinity with Cu and lowest with Ca. HEDP will not modify heavy metal cations speciation more than TPP, whereas AMP might contribute to mobilize cations from sediments. A toxicologic study of MX^{4-}, MHX^{3-}, MH_2X^{2-}, MY^{2-} and MHY^- should be done to estimate AMP and HEDP potential harm to aquatic fauna and flora. Speciation diagrams, at low concentrations, confirm the hydroxide complexes significance in the HEDP and TPP systems with Cu and Cd. This is why hydroxide species have to be taken into consideration when determining complexation constants and, moreover, for an assessment of the impact of toxic cations on ecosystems.

Comparative voltammetric studies of immunoglobulins and DNP-labelled immunoglobulins

M.D. Sánchez-Suárez, A. Costa-García *

Departamento de Química Física y Analítica, Universidad de Oviedo, 33006 Oviedo, Asturias, Spain

Received 2 April 1996; received in revised form 18 October 1996; accepted 21 October 1996

Abstract

A comparative electrochemical study of human immunoglobulins IgG_1 and IgG_3 carried out at a hanging mercury drop electrode shows that mechanisms other than the reduction of interchain disulphide linkages are responsible for the cathodic peaks observed for such proteins. Considering that the nature of the electrochemical process observed for immunoglobulins are poorly defined and not fully understood, a new approach to the electrochemical determination of such proteins, involving the use of 2,4-dinitrophenol (DNP) as a label, has been developed. Dynamic linear ranges of nearly two magnitudes and detection limits below 10^{-10} M were achieved. © 1997 Elsevier Science B.V.

Keywords: DNP-labelled immunoglobulins; Hanging drop mercury electrode; Immunoglobulins; Voltammetry

1. Introduction

The immunoassay is a technique that exploits an antibody as an analytical reagent capable of selective determination of an antigen species. Because of the advantages associated to immunoassay as high selectivity, low detection limits, speed, simplicity and relatively low cost these analytical methods are currently used in clinical chemistry.

The trend away from radioimmunoassays has resulted in a proliferation of immunoassays using a wide range of non-radioisotopic labels. The use of either electroactive species or enzymes as labels have been two different approaches to developing electrochemical immunoassays. A more direct method, involving no label, has been reported based on monitoring the changes in the electrochemical response of an antibody (or antigen) when its specific binding partner is added to the solution [1,2].

Studies of the electrochemical behaviour of antibodies on mercury electrodes are important for the development of new electroanalytical techniques which use antibodies, immunoglobulins, as analytical reagents.

Proteins are adsorbed on mercury electrodes because of the interaction of disulphide bonds with the mercury surface. This adsorptive behaviour has been used by several authors [1–4] for the electrochemical determination of proteins by adsorptive stripping voltammetry (AdSV).

PII S0039-9140(96)02137-6

The reduction currents observed for proteins containing disulphide linkages in their structure have always been ascribed solely to the reduction of this bond [5–14]. Some results more recently reported [15,16] make difficult to agree with the assumption usually made in the literature, and other possible mechanisms as conformational changes of the adsorbed protein or reorientation of the molecule leading to some perturbation of the double layer have been suggested [17,18].

Following the controversy about the nature of the voltammetric behaviour reported for such proteins, as well as the bad definition of these peaks, Costa et al. [19] proposed a different approach to the electrochemical determination of proteins by means of the use of electroactive species as labels for these macromolecules. The 2,4-dinitrophenol (DNP) was studied. Several reasons were supporting this choice, first the DNP can be easily covalently bound to proteins by nucleophilic substitution achieving a high substitution grade (which leads to a significant increase in sensitivity). Moreover, the DNP presents a suitable electrochemical behaviour, its reduction involving a great number of electrons.

The starting point of this investigation was a comparative study of the electrochemical behaviour of two human immunoglobulins, which differ in the number of interchain disulphide linkages, to elucidate the role these bonds play in the electrochemistry of this type of proteins. A second stage involved the labelling of a mouse immunoglobulin with DNP, the DNP-labelled immunoglobulin electrochemical behaviour was studied and also was its ability to undergo an immunochemical reaction with anti-DNP and anti-mouse IgG_1 antibodies.

2. Experimental

2.1. Apparatus

Differential pulse voltammetric experiments were performed with a Metrohm Polarecord E-506. The working electrode was a hanging mercury drop electrode (HMDE), the surface of the mercury drop was 0.32 mm^2. A platinum wire was used as auxiliary electrode and all potentials were measured versus an Ag/AgCl/saturated KCl reference electrode.

A magnetic stirrer (Selecta Asincro) and a stirring bar (7 × 4 mm) provided the convective transport during the accumulation step, the rotation speed was 300 r.p.m.

2.2. Reagents

All compounds used were of analytical reagent grade. The electrolyte solution was 0.01 M phosphate buffer, pH 7.2, prepared by using phosphoric acid and sodium hydroxide in deionized water (obtained by passing distilled through a Milli-Q Millipore water purification system).

Human IgG_1 and IgG_3 were purchased from Sigma (St. Louis, MO, USA) and both proteins were reconstituted in 0.01 M phosphate buffer, pH 7.2 and stored at 4°C.

Mouse IgG_1 (clon: 8.4a9.13), was a gift from Dr Juan Toyos (Dpto. Biología Funcional, Universidad de Oviedo, Spain) and was supplied as 1 mg ml^{-1} stock solution in 0.01 M phosphate buffer saline (PBS) with 0.1% sodium azide as preservative.

2,4-dinitrobenzenesulfonic acid, sodium salt (DNBS) was purchased from Aldrich (Gillingham-Dorset, UK).

Goat anti-mouse IgG_1 (clon: LO-M61-2) was obtained from ICN Biomedicals, and rat anti-DNP (clon: 04-8300) was purchased from Zymed Laboratories.

Nitrogen N-48 (SEO) was used to remove dissolved oxygen.

2.3. Procedures

Before each voltammetric experiment the electrolyte was purged with oxygen-free-nitrogen for 30 min. After addition of the sample the solution was purged for a further 5 min. A preconcentration is carried out for the required accumulation time (t_{acc}) at open circuit, with stirring at 300 rpm. The stirring was stopped and, after 10 s equilibration time, the potential was scanned in the differential pulse (DP) mode in the cathodic direction, with a pulse amplitude of -50 or -100 mV and a scan-rate of 10 mV s^{-1}. All experiments were carried out at room temperature.

2.3.1. DNP-labelling reaction of proteins

The conjugation of DNP to a mouse IgG_1, was carried out according to the procedure described by Little et al. to obtain 2,4-dinitrophenylproteins [20]. The conjugate was purified by dialysis against ultrapure water using cellulose membrane (MW 12 400). The Bio-Rad micro-Bradford assay [21] was used for measuring total protein concen-

tration in the solutions obtained from dialysis. DNP-mouse IgG_1 solutions were stored at 4°C in the dark.

2.3.2. ELISA procedure

The enzyme-linked-immunosorbent-assay (ELISA) plates were precoated with 100 μl of the antigen (10 μl ml^{-1}) diluted in 50 mM bicarbonate buffer, pH 9.6 and incubated during 3–4 h at 37°C. They were washed (× 4) in PBS, pH 7.3, containing 0.05% Tween 20. the plates were blocked by incubation with 1% (w/v) BSA in 10 mM PBS, pH 7.3, 0.1% NaN_3, for 1 h at 37°C and overnight at 4°C. The plates were rewashed as before. Dilutions of mouse IgG_1 (1 μg ml^{-1}), used as positive control and DNP- labelled mouse IgG_1 (1 μg ml^{-1}) were then made up and incubated in the wells for 3–4 h at 37°C. The plates were washed and then 100 μl of HRP-conjugated goat anti-mouse (Sigma) are incubated in the wells for 3–4 h at 37°C. The substrate used for HRP was 100 μl of *o*-phenylendiamine dihydrochloride (Sigma) and H_2O_2 (0.3% (v/v)) in 0.1 M citrate buffer, pH 4. Absorbance was read at 492 nm.

3. Results and discussion

3.1. Electrochemical behaviour of human IgG_1 and IgG_3

To elucidate the role disulphide linkages play in the electrochemical behaviour described for this type of protein on mercury electrodes, the electrochemistry of two human immunoglobulins G, which differ in the number of interchain disulphide bonds, has been compared. Immunoglobulin G_1 (IgG_1) and immunoglobulin G_3 (IgG_3) contain, respectively, 2 and 15 interchain disulphide bonds in their structure [22].

This investigation was carried out by differential pulse voltammetry (DPV) on a HMDE in the potential range -0.2– -0.7 V. The IgG_1 and IgG_3 concentrations were varied from 10^{-9} to 10^{-7} M and the voltammograms obtained for them under the same experimental conditions (pulse amplitude (ΔE) -50 mV, scan-rate (v) 10 mV s^{-1}, and accumulation time at open circuit (t_{acc}) 300 s) are shown in Fig. 1. Both human immunoglobulins gave rise to a badly defined cathodic peak at -0.5 V versus Ag/AgCl as reported in the literature.

Because of the considerable difference in the number of interchain disulphide linkages, a higher current intensity would be expected for IgG_3 than for IgG_1 if the voltammetric response were due to the reduction of these linkages. Actually, the IgG_1 peak current is slightly higher than that obtained for IgG_3. From this and other studies [15,16], it follows that the voltammetric peaks obtained for these immunoglobulins on mercury electrodes are due to processes other than the simple reduction of disulphide linkages.

3.2. Electrochemistry of the DNP-mouse IgG_1

Considering that the electrochemical processes giving rise to those peaks are still not fully understood, the electrochemistry of the immunoglobulins was studied by using an electroactive molecule as a label for immunoglobulins. The 2,4-dinitrophenol (DNP), which had been proposed by Costa et al. [19] as label for proteins, was used. The procedure followed to obtain DNP-mouse IgG_1 has already been described in the experimental section.

Reaction parameters as DNBS, K_2CO_3 concentrations and temperature were varied to study their influence on the substitution grade achieved in the labelling reaction, and the specificity of the DNP-mouse IgG_1 to the antigen.

It was observed that the substitution grade increases by increasing DNBS and K_2CO_3 concentrations and better results were obtained using 37°C than room temperature. Regarding to the specificity of the DNP-mouse IgG_1, the ability of the conjugate to undergo an immunochemical reaction with the antigen was evaluated by comparison of the absorbance readings obtained for this molecule with those obtained for the mouse IgG_1 in an ELISA. According to these readings, high substitution grades in the labelling reaction were associated with more significant loss of specificity to the antigen.

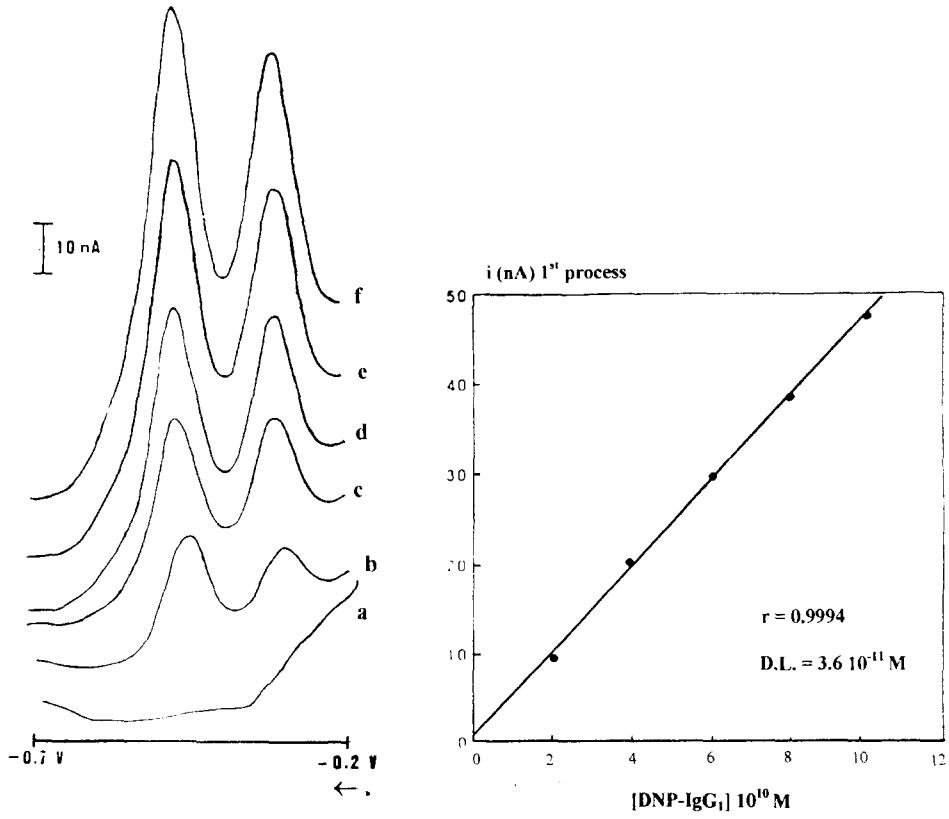

Fig. 4. Effect of concentration on the DP voltammetric current for DNP-mouse IgG_1: (a) background electrolyte, (b) 2×10^{-10} M, (c) 4×10^{-10} M, (d) 6×10^{-10} M, (e) 8×10^{-10} M, (f) 1×10^{-9} M DNP-mouse IgG_1; $\Delta E = -100$ mV, $v = 10$ mV s^{-1}, $t_{acc} = 600$ s at open circuit.

The DNP-immunoglobulin used in the following studies was obtained under that reaction conditions leading to higher substitution grade, i.e., 6.4 mg DNBS and 22.8 mg K_2CO_3, dissolved in 1 ml of 1 mg ml^{-1} mouse IgG_1, kept in the dark at 37°C for 48 h. The fact that its specificity is lost is not significant as the labelled immunoglobulin do not take part as an antibody in any of those immunochemical reactions described further on.

The electrochemical behaviour of the DNP-mouse IgG_1 was studied by differential pulse voltammetry (DPV) on a HMDE and the results have been compared with those obtained under the same conditions for the mouse IgG_1. The voltammograms recorded for 1×10^{-8} M solutions of each species, using $\Delta E = -50$ mV, $v = 10$ mV s^{-1} and $t_{acc} = 240$ s, are shown in Fig. 2. The mouse IgG_1 yields a poorly defined cathodic peak at -0.5 V versus Ag/AgCl, meanwhile the DNP-mouse IgG_1 gives rise to two peaks at -0.32 and -0.46 V versus Ag/AgCl. It is clear that those peaks obtained for the conjugate are analytically more useful signals than the one obtained for mouse IgG_1.

The accumulation curves for increasing concentrations of DNP-mouse IgG_1 (Fig. 3) were obtained by varying the preconcentration time from 0 to 1200 s and plotting this parameter against peak currents. The accumulation was carried out at open circuit under constant stirring. As expected, for each concentration, peak currents increase with accumulation time until saturation of the electrode was reached.

The analytical signal was optimized with respect to pulse amplitude as foreseen, increasing pulse amplitude gave rise to better analytical sig-

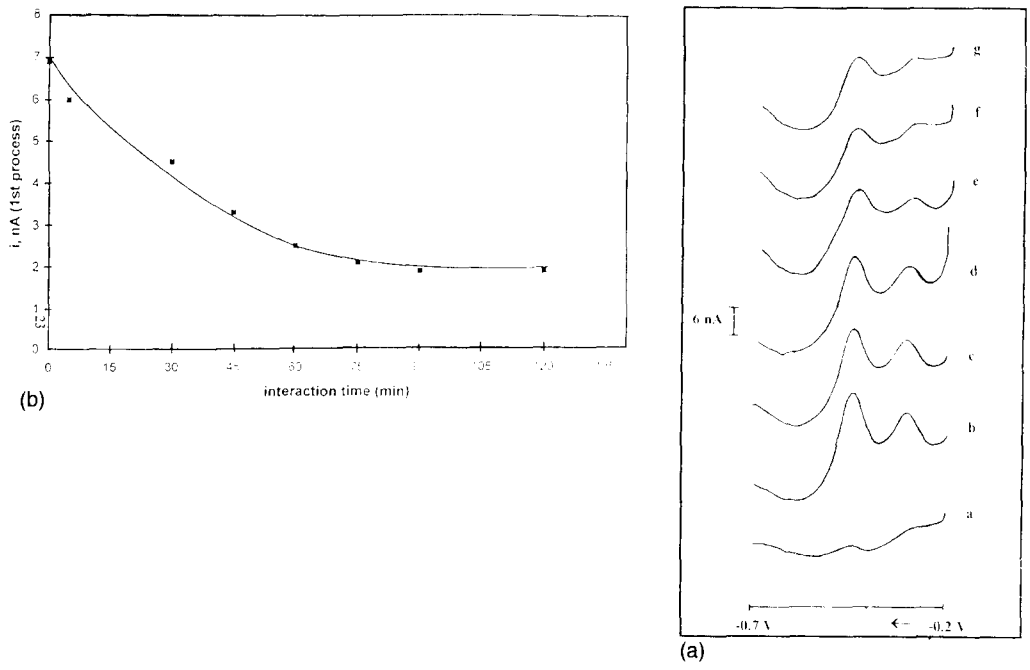

Fig. 5. Electrochemical response of 1×10^{-9} M DNP- mouse IgG_1 in the presence of 2×10^{-9} M anti-DNP: (a) background electrolyte, (b) 1×10^{-9} M DNP-mouse IgG_1, (c) 5 min (d) 30 min, (e) 1 h, (f) 1 h 30 min, (g) 2 h 15 min, anti-DNP and DNP-mouse IgG_1 interaction times. $\Delta E = -100$ mV, $v = 10$ mV s^{-1}, $t_{acc} = 240$ s at open circuit.

nals. A pulse amplitude of -100 mV was used for the remainder of the study.

The repeatability of the analytical signal was calculated for DNP-mouse IgG_1 from successive measurements ($n = 10$) of a 1×10^{-9} M solution, using a 240 s accumulation time at open circuit. The relative standard deviation was 2.6% for the first electrochemical process and 2.3% for the second one Fig. 4.

The DNP-immunoglobulin gave rise to current responses that increased linearly with respect to increasing concentration. Using an accumulation time of 600 s, the curve for the first electrochemical process was found to be linear between 2×10^{-10} M and 1×10^{-9} M ($r = 0.999$, $n = 5$). The detection limit achieved ($\sigma = 3$) was 3.6×10^{-11} M.

3.3. Interaction of DNP-mouse IgG_1 with anti-DNP and anti-mouse IgG_1 antibodies

The interaction in solution, at room temperature, of DNP-mouse IgG_1 and rat anti-DNP was monitored by DPV on a HMDE, using a pulse amplitude of -100 mV, a scan-rate of 10 mV s^{-1} and an accumulation time at open circuit of 240 s. The cell and the electrodes were equilibrated with the appropriate DNP-mouse IgG_1 solution for 2 h, so changes in the electrochemical response of the DNP-immunoglobulin could not be ascribed to a bulk concentration change by adsorption of DNP-mouse IgG_1 on the cell walls or salt-bridge tips, etc. A voltammogram of a 1×10^{-9} M DNP-mouse IgG_1 was recorded under the conditions indicated above. The solution was deareated for 5 min before each potential scan and the changes experimented by this signal, when the rat antibody anti-DNP was added at a concentration of 2×10^{-9} M to that solution, are monitored at different interaction times. It can be observed (Fig. 5A) that the peak currents of both first and second processes, registered for the DNP-immunoglobulin, decrease gradually with interaction time until a steady signal, (unvarying with reaction time), is obtained after 1 h 30 min (Fig. 5B).

When goat anti-IgG_1, instead of rat anti-DNP, was added at a concentration of 1×10^{-9} M no change in peak currents was observed in the different voltammograms recorded at different interaction times during a 4 h study. However, if the interaction was performed at 37°C the first and second reduction peaks both decrease with reaction time and after 2 h disappear.

Anti-DNP antibodies show a high affinity constant for DNP, this could be the reason these antibodies undergo immunochemical reaction at room temperature, meanwhile for an anti-mouse IgG_1 a 37°C temperature is necessary.

4. Conclusions

From the comparative study of the electrochemistry of human immunoglobulins IgG_1 and IgG_3 it can be concluded that the cathodic process observed for immunoglobulins on mercury electrodes involves some mechanism other than reduction of interchain disulphide linkages.

Immunoglobulins can be electrochemically determined by labelling these proteins with DNP using DPV dynamic linear ranges of nearly two orders of magnitude and detection limits below 10^{-10} M have been achieved.

The decrease in peak currents observed for DNP-labelled mouse IgG_1 in presence of anti-DNP and anti-mouse IgG_1 antibodies could support the monitoring of immunochemical reactions using electrochemical techniques.

Differential derivative spectrophotometric determination of phenobarbitone and phenytoin sodium in combined tablet preparations

C.V.N. Prasad, A. Gautam, V. Bharadwaj, P. Parimoo *

Department of Pharmacy, Birla Institute of Technology and Science, Pilani- 333031, India

Received 12 March 1996; received in revised form 16 October 1996; accepted 18 October 1996

Abstract

A pH-induced differential derivative spectrophotometric procedure has been developed for the simultaneous determination of Phenobarbitone (PBT) and Phenytoin sodium (DPH Na) in tablet preparations. The method comprized of measurement of difference absorptivities derivatized in second order(ΔD_2) of a tablet extract in 0.01 N NaOH relative to that of an equimolar solution in 0.01 N HCl at wavelengths of 244.8 and 252.8 nm respectively. The presence of identical zero-crossing points for pure drug and tablet extract solutions established the non-interference of the excipients in the absorption at these wavelengths. The compliance of Beer's law was adhered over a concentration range of 7.5–25 μg ml^{-1} for both PBT and DPH. © 1997 Elsevier Science B.V.

Keywords: Phenobarbitone; Phenytoin sodium; Spectrophotometric

1. Introduction

Derivative spectrophotometry has received increased attention in recent years in the assay of drugs alone or in combination from their formulations [1–3]. The procedure has been found to be successful in resolving two overlapping spectra, in the identification and quantification of drugs with low absorptivity values and in eliminating non-specific interferences from formulation matrix [4–6].

Difference spectrophotometry based on pH changes has also been reported to be useful in the determination of binary mixtures [7]. In our earlier work, we have described the successful application of later technique for the determination of combination preparations [8–10].

There are few reports on utilization of the above two combined techniques for the estimation of individual drug substances [11] and for combined preparations [12]. In the present work an effort has been made to utilize the combined techniques for simultaneous determination of phenytoin (DPH) and phenobarbitone (PBT) in the presence of each other as well as the excipients.

The combination of PBT and DPH Na in the form of tablet preparation is widely used for major epilepsy and psychomotor seizures. The official monographs describe the procedure for individual assay of PBT and DPH Na [13]. A differential titrimetric method [14] and a derivative compensation technique [15] has been reported for simultaneous determination of above mixtures.

2. Experimental

2.1. Apparatus

A JASCO model 7800 double beam UV-visible autoscan spectrophotometer with 1 cm quartz cells was used. Suitable settings were scan speed of 480 nm min^{-1}, chart speed of 10 nm min^{-1}, ordinate maximum and minimum were adjusted to the magnitude of derivative values.

2.2. Standard solutions

The stock solutions of pure PBT and DPH Na (Anglo-French, Bangalore, India) were prepared by dissolving 25 mg each of the pure drugs in 50 ml of methanol. Appropriate volume aliquots of the stock solution were transferred to 25 ml volumetric flasks in duplicate. The volumes were made up with 0.01 N HCl and 0.01 N NaOH to give a series of equimolar solutions containing 7.5–25 μg ml^{-1} of both PBT and DPH. Similarly three series of 25 ml each of equimolar solutions of mixtures of PBT and DPH Na in 0.01 N HCl and 0.01 N NaOH were also prepared by using the stock solutions. The first series contained a constant concentration of PBT (7.5 μg ml^{-1}) and a varying concentration of DPH Na (7.5–25 μg ml^{-1}).

The second and third series contained a constant concentration of DPH Na (15/25 μg ml^{-1}) and a varying concentration of PBT (7.5–25 μg ml^{-1}). The absorbance of the solutions were taken within 3 h of their preparation. All reagents used were of analytical grade.

2.3. Sample preparation

Tablets, 20, of Phenytal 30 (Intas, India) labeled to contain 30 mg of PBT, 100 mg of DPH Na and excipients, 20 tablets of Phenytal (Intas, India), labeled to contain 50 mg of PBT, 100 mg of DPH Na and excipients, were accurately weighed, well powdered and a weight of the powder equivalent to 25 mg of DPH Na(corresponding amount of PBT 7.5 or 12.5 mg depending on the chosen marketed preparation) was dissolved in methanol by thorough mixing and made up to volume in a 50 ml volumetric flask. The sample solution of 25 ml each in 0.01 N HCl and 0.01 N NaOH were prepared by using 0.375 ml aliquots of the filtrate so as to obtain concentration 7.5 μg ml^{-1} of PBT and corresponding amount of DPH Na (15 or 25 μg ml^{-1} depending on the chosen preparation). The difference spectra between the acidic solution and equimolar 0.01 N NaOH solution of pure drugs and sample were recorded from 230–275 nm by placing the acidic solution in the reference compartment and the 0.01 N NaOH solutions in the sample compartment. A second derivative spectrum of each of the differential curves was subsequently recorded. The solutions were measured at 252.8 and 244.8 nm for DPH Na and PBT, respectively.

3. Results

The zero order spectrum of pure PBT (7.5 μg ml^{-1}) and DPH Na (15.0 μg ml^{-1}) either in 0.01 N NaOH or in 0.01 N HCl were very similar (Fig. 1). However, the difference absorption spectrum of two drugs and a mixture of PBT and DPH Na (7.5 and 15 μg ml^{-1}, respectively) showed significant alteration (Fig. 2).

The second derivative differential curves of both the drugs (Fig. 3) offered an advantage for their simultaneous determination by having zero crossing points. In particular absorbance at 244.8 nm for PBT and at 252.8 nm for DPH were considered as the optimum working wavelengths for their determination. The derivative differential curves showed the best linear response to analyte concentrations used at these wavelengths.

The proportionality of the ΔD_2 values and concentrations of PBT and DPH were found by measuring ΔD_2 of ten pairs of solutions of each containing 7.5–25 μg/ml of PBT at 244.8 nm and for DPH Na solutions at 252.8 nm, respectively. The linear regression equations were obtained by using the method of least squares. The linear regression for PBT was

$$Y = 0.001066X - 0.00041 \quad (1)$$

with a correlation coefficient of $r = 0.9999$ at 244.8 nm. The linear regression equation for DPH Na was as

$$Y = 0.000124X - 0.00013 \quad (2)$$

with a correlation coefficient of $r = 0.9999$ at 252.8 nm.

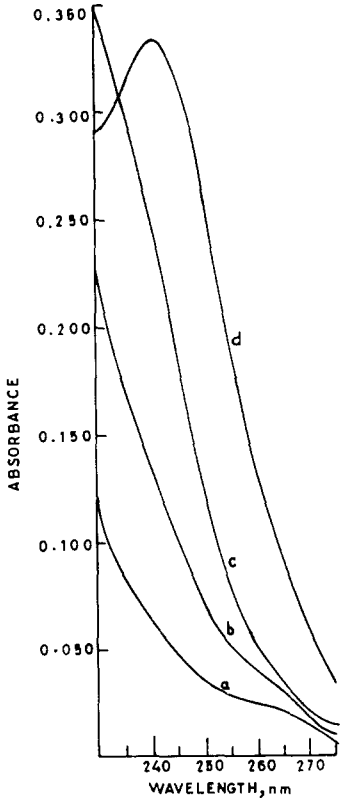

Fig. 1. Absorption spectra of (a) Phenobarbitone (7.5 μg ml^{-1}), (b) Phenytoin Na (15 μg ml^{-1}) in 0.01 N HCl and (c) Phenytoin Na (15 μg ml^{-1}), (d) Phenobarbitone (7.5 μg ml^{-1}) in 0.01 N NaOH, respectively.

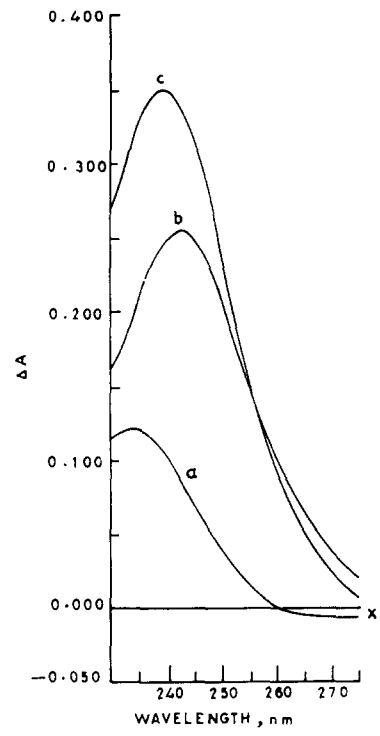

Fig. 2. Difference spectra of (a) Phenobarbitone (7.5 μg ml^{-1}), (b) Phenytoin Na (15 μg ml^{-1}) and (c) mixture of Phenobarbitone (7.5 μg ml^{-1} and Phenytoin Na 15 μg ml^{-1}) in 0.01 N HCl versus 0.01 N NaOH.

For establishing the specificity of the method for drug samples, three series each of ten solutions as mentioned under standard preparation were examined at the zero crossing wavelengths. The solution of the first series gave a regression equation of

$$Y = 0.000123X - 0.00018 \quad (3)$$

with a correlation coefficient of $r = 0.9999$ at 252.8 nm. The detection limit (LOD) [16] was 1.5 μg ml^{-1} and with a quantitation limit (LOQ) [16] of 2 μg ml^{-1}. The similarity of Eq. (3) with Eq. (2) and with a distinct isosbestic point at 244.8 nm (Fig. 4) suggested that the presence of PBT didn't affect the absorptivity of DPH Na at 252.8 nm.

The linear regression equations for second series was

$$Y = 0.001067X - 0.00019 \quad (4)$$

with a correlation coefficient of $r = 0.9999$ at 244.8 nm. The detection limit was 0.32 μg ml^{-1} and quantitation limit of 1 μg ml^{-1}. Similarly, the regression equation for third series was

$$Y = 0.001074X - 0.00001 \quad (5)$$

with a correlation coefficient of $r = 0.9999$ at 244.8 nm. The detection limit was 0.49 μg ml^{-1} and quantitation limit of 1 μg ml^{-1}.

The similarity of Eq. (4) and Eq. (5) with Eq. (1) and the presence of distinct isosbestic point at 252.8 nm (Fig. 5 and Fig. 6), the zero crossing point of PBT suggested a non-interference of absorptivity of DPH with that of PBT at 244.8 nm. The ΔD_2 values of standard solutions of PBT (7.5 μg ml^{-1}) and DPH Na (15 or 25 μg ml^{-1}) relative to ΔD_2 of tablet sample solution were used for the determination of PBT and DPH in the tablet preparation. The results are given in the Table 1.

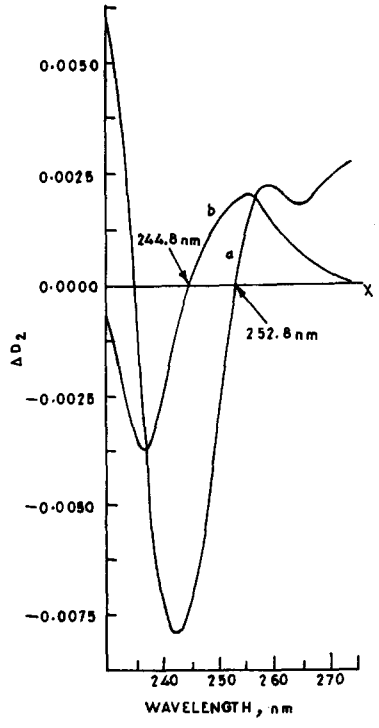

Fig. 3. Differential derivative spectra of (a) Phenobarbitone (7.5 μg ml^{-1}) and (b) Phenytoin Na (15 μg ml^{-1}) in 0.01 N HCl versus 0.01 N NaOH.

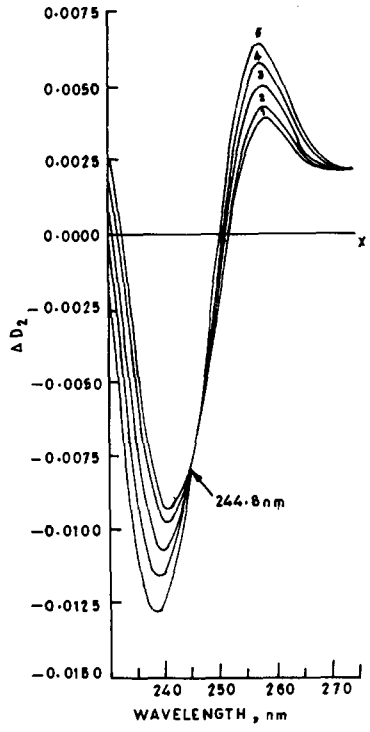

Fig. 4. Differential derivative spectra of Phenobarbitone (7.5 μg ml^{-1}) and Phenytoin Na (7.5, 10, 15, 20 and 25 μg ml^{-1}) in 0.01 N HCl versus 0.01 N NaOH in curves 1–5, respectively.

4. Discussion

The application of difference spectroscopy for the quantification of two component formulations depends on the fortuitous juxtaposition of the isosbestic points. As already pointed out in the text, the difference spectroscopy alone didn't produce the required isosbestic points. However, derivatization of the difference curves resulted in zero crossing points, which enabled the successful determination of both the drugs. The second derivative difference curves were relatively better for the estimation of drugs compared with the first derivative difference curves. In the latter, the zero crossing point of DPH Na had fallen closer to the 230 nm, which is the boundary limit of selected wavelength range. Hence the second derivative difference curves were chosen. The combined technique offers a distinct advantage as it involved refinement of spectra at two levels and

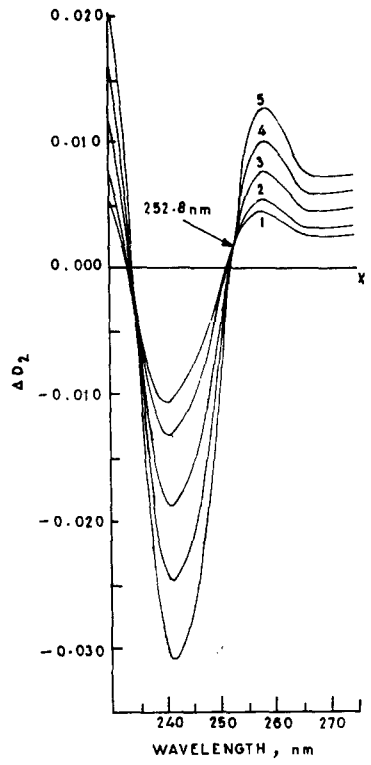

Fig. 5. Differential derivative spectra of Phenobarbitone(7.5, 10, 15, 20 and 25 μg ml^{-1}) and Phenytoin Na (15 μg ml^{-1}) in 0.01 N HCl versus 0.01 N NaOH in curves 1–5, respectively.

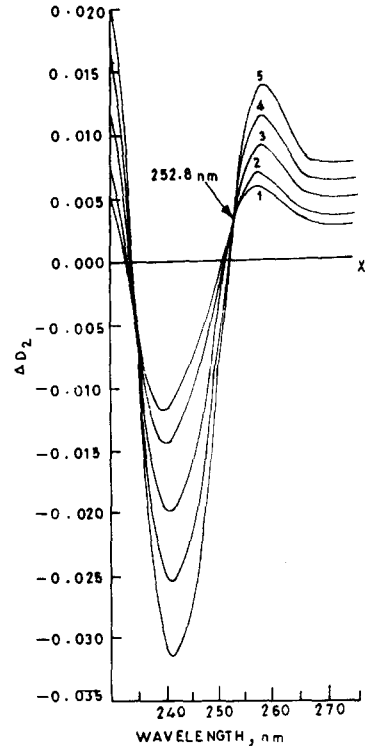

Fig. 6. Differential derivative spectra of Phenobarbitone (7.5, 10, 15, 20 and 25 μg ml^{-1}) and Phenytoin Na (25 μg ml^{-1}) in 0.01 N HCl versus 0.01 N NaOH in curves 1–5, respectively.

the interference from formulation matrix if any, will be at its minimum. The similarities between the linear regression equation, the detection and quantitation limits demonstrated the usefulness of derivative difference spectrophotometry in the quantitation of drug mixtures with overlapping spectra.

The procedure developed is simple and reproducible. In the absence of an official method for the simultaneous determination of PBT and DPH Na, the proposed method, if properly used can prove to be useful for routine analysis of the two drug combined formulations.

Acknowledgements

The authors express their gratitude to M/s The Anglo-French Drug Co (Eastern) Ltd, Bangalore, India for samples of pure DPH Na and PBT.

A linear regression method for the study of the Coomassie brilliant blue protein assay

Yong-ju Wei, Ke-an Li *, Shen-yang Tong

Department of Chemistry, Peking University, Beijing 100871, People's Republic of China

Received 11 June 1996; received in revised form 16 September 1996; accepted 18 October 1996

Abstract

The interactions of Coomassie brilliant blue G-250 (CBB) with bovine serum albumin (BSA) and γ-globulin at low pH are investigated by a spectrophotometric method. It is considered that the binding of CBB to protein is because of the weak interactions (ionic, van der Waals, hydrogen bonding, and hydrophobic). The solution equilibria involving the binding of three dye species (blue, green, and red) to protein are treated in the same way as Ringbom model used in the treatment of complexation in analytical chemistry. Based on this treatment, the formation of an isosbestic point in the absorption spectra of CBB-BSA mixtures is discussed, two mathematical models for the description of the CBB protein assay are developed. The first model is a nonlinear equation which is rigorous in theory but unreliable in use because of its optimization procedure. The second model based on an approximation is a linear equation, it allows to estimate apparent binding constant, maximum binding number, and molar absorptivity of bound dye from assay data by a linear regression method. The results of the linear regression operations are reasonable and in agreement with experimental findings. Factors which influence the sensitivity of the CBB protein assay are studied using this method. Ionic strength and acidity are found to have significant effect on the binding of CBB to protein. © 1997 Elsevier Science B.V.

Keywords: Coomassie brilliant blue protein assay; Solution equilibria; Spectrophotometry

1. Introduction

The Coomassie brilliant blue G-250 (CBB) protein assay [1] has been commonly used in biochemical and clinical laboratories because of its high sensitivity and convenience. In practice, the assay is conducted by adding a protein sample to a fixed quantity of dye reagent and measuring the increase in absorbance at 595 nm as a blue dye-protein complex forms. Though the performance of the assay is simple, its mechanism and solution equilibria are still under investigation [2–8]. A further theoretical study on the assay should be beneficial not only with regard to the quantitation of proteins but also to a deep understanding of the interactions between macrobiomolecules and small ions or molecules.

Previous authors have made great efforts in the study of the nature of the CBB protein assay. Compton and Jones [2] pointed out that CBB

* Corresponding author.

PII S0039-9140(96)02140-6

exists in three forms at the usual pH of the assay: cationic (red), neutral (green), and anionic (blue). A spectral study made by Chail et al. [4] shows that the three dye forms have markedly different visible spectra from one another and that none of these spectra correspond exactly to the spectrum of the dye-protein complex. The blue dye form is generally considered to be the form that complexes with protein [2,4,5], since its negative charge argues in favor of electrostatic attraction to arginine and lysine side chains on protein. However, there are indications of the existence of nonelectrostatic interactions between CBB and proteins in addition to the electrostatic interactions. Compton and Jones [2] estimated that the nonionic binding energies account for about 58% of the total binding energy of the CBB-protein complex. Therefore, Atherton et al. [8] recently proposed a dye-binding scheme in which it is assumed that all the three dye species can bind to protein to form dye-protein complexes.

The determination of binding constant and number of dye-binding sites on protein is a major difficulty in the theoretical study of dye-binding protein assays. The Scatchard equation [9] has long been considered to be a basic equation for the study of the interactions between macrobiomolecules and small ions or molecules. But there are reports pointed out that the Scatchard equation is not suitable for the description of some interactions between proteins and acid–base indicators such as T-azo-R [10], Chromazurol S [11], bromophenol blue [12], and bromocresol green [13] in acidic solutions. Though modified Scatchard equation was used to study high-affinity dye binding sites of the CBB protein assay at very large protein/dye molar ratios [6], there is no report on the use of this equation in the study of the CBB protein assay under normal conditions.

The number of dye-binding sites on protein could be estimated from the slope of the CBB protein assay plot [5,7], but binding constants cannot be found by this way. Recently, Atherton et al. [8] developed a mathematical model for the description of the CBB protein assay under normal conditions. Assay data may be fit to this model using curve-fitting techniques and thereby values of binding constant and number of binding sites could be estimated simultaneously for a particular protein. This model is quite rigorous in theory, but it seems that the optimization (curve-fitting) procedure is somewhat inconvenient in use.

In Ref. [12], the interaction of bromophenol blue with proteins in acidic solution is studied theoretically. As proposed by Kaler and Gavrilov [14], both dye species, protonated and deprotonated forms, are considered to be able to combine with protein by intermolecular forces (mainly electrostatic force). Two conditional constants, apparent binding constant and maximum number, are defined to express the binding ability of the dye to protein under a given set of conditions. These two parameters can be estimated by a linear regression method developed in that paper.

In the present work, the linear regression method proposed in reference [12] is extended to the study of the CBB protein assay. All the three dye species are treated to be able to combine with protein by weak interactions (ionic and nonionic) though their binding abilities are different. The solution equilibria are treated in the same way as Ringbom model [15] which is familiar to analytical chemist. A linear regression equation based on this treatment is developed to estimate apparent binding constant and maximum binding number from spectral data measured under normal conditions. The results obtained are in agreement with experimental findings.

2. Experimental

2.1. Reagents

BSA, 99%, was obtained from Sigma (fraction five, essentially fatty acid free). All calculations reported for BSA are in terms of a molecular weight of 65 000. The BSA solution (1.52×10^{-6} mol l^{-1}) was prepared by dissolving 0.100 g BSA reagent in 1000 ml deionized water. γ-Globulin human (γ-G) was obtained from Serva (Germany). Calculations reported for γ-G are in terms of a molecular weight of 160 000. The γ-G solution (6.2×10^{-7} mol l^{-1}) was prepared by dis-

solving 0.100 g γ-G reagent in 1000 ml deionized water. CBB was purchased from Fluka and purified by following a procedure reported by Wilson [6,16]. The CBB stock solution (1.17×10^{-3} mol l^{-1}) was prepared by dissolving 0.100 g purified dye in 50 ml 95% ethanol, and then diluting to 100 ml with deionized water. The operating solution of CBB was prepared by diluting the stock solution with water properly. All other reagents were of analytical or guaranteed reagent grade.

2.2. Apparatus

A Shimadzu Model UV-265 double-beam spectrophotometer was used for recording absorption spectra, and a Shimadzu UV-120-02 spectrophotometer for the measurement of absorbance at a given wavelength.

2.3. Method

Aliquots of 5% NaCl solution, phosphoric acid (7.3 mol l^{-1}) or standard HCl solution, and CBB operating solution were transferred into a series of 25 ml volumetric flasks, and then protein solution was added to each flask in different amounts. The mixtures were diluted to the mark with water and mixed thoroughly. After 20 min, spectra or absorbances of these solutions were measured with reference to water. The pH values of these solutions were calculated according to the concentrations of the acid used, ignoring activity effect.

3. Results and discussion

3.1. Absorption spectra and binding equilibria

Fig. 1 shows the absorption spectra of CBB at various pH values [4]. As the pH is raised a red form of the dye ($\lambda = 470$ nm) is replaced by a green form ($\lambda = 650$ nm) in the vicinity of pH 1. Further pH elevation results in a shift of the dye species from green form into a blue form ($\lambda = 585$ nm) at about pH 2. No isosbestic point is formed, indicating that three distinct dye species are present:

$$H_2L + \rightleftharpoons HL + H^+ \quad HL \rightleftharpoons L^- + H^+ \qquad (1)$$

with dissociation constants $pK_{a1} = 1.15$, and $pK_{a2} = 1.82$ [4].

Fig. 2 shows the absorption spectra of CBB-BSA mixtures [3]. They were obtained by keeping the CBB concentration and pH constant and changing the BSA concentration. With the increase in BSA concentration, the absorption peaks at 470 and 650 nm are replaced by a new absorption peak at 595 nm. An isosbestic point is formed at 530 nm. This spectral feature indicates that the free dye species are transformed into bound ones.

According to the study made by previous workers [2–6], the formation of CBB-BSA complexes is because of the weak (noncovalent) interactions (ionic, van der Waals, hydrogen bonding, and hydrophobic), all the three dye forms are being able to combine with protein although their binding abilities are different [8]. But, on account of the anion L^- has an advantage in binding to positively charged amino acid residues on protein by electrostatic force, we take this form as the main binding species and use the Ringbom model [15] for the description of the dye-binding equilibria (omitting electrical charges):

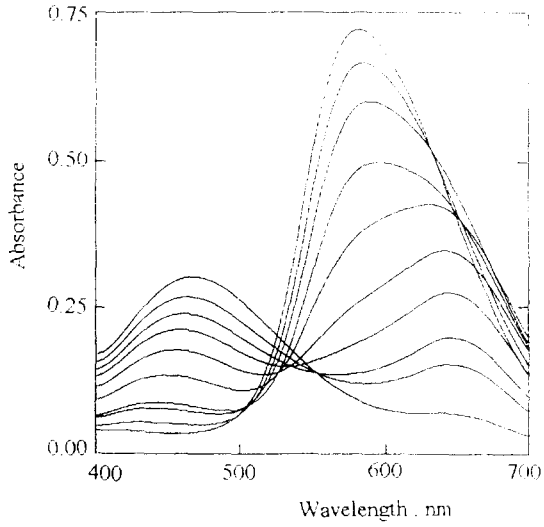

Fig. 1. CBB absorption spectra at various pH values. CBB concentration constant at 1.46×10^{-5} mol l^{-1}. In order of increasing absorbances at 595 nm, pH values are 0.27, 0.65, 0.80, 1.00, 1.17, 1.35, 1.65, 1.80, 2.17 and 2.65.

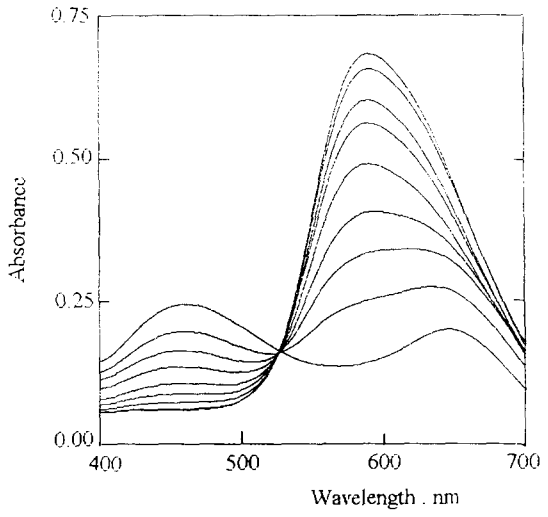

Fig. 2. Absorption spectra of CBB–BSA mixtures. 0.158 mol l^{-1} HCl medium, pH 0.80, CBB concentration constant at 1.46×10^{-5} mol l^{-1}. In order of increasing absorbances at 595 nm, BSA concentrations are 0.0, 3.0×10^{-8}, 6.0×10^{-8}, 9.1×10^{-8}, 1.5×10^{-7}, 2.1×10^{-7}, 2.7×10^{-7}, 3.6×10^{-7} and 4.6×10^{-7} mol l^{-1}.

$$\begin{array}{ccccc} L & + & P & \rightleftharpoons & L' \\ H\downarrow\uparrow & & A\downarrow\uparrow & & H\downarrow\uparrow \\ HL & & A' & & HL' \\ H\downarrow\uparrow & & & & H\downarrow\uparrow \\ H_2L & & & & H_2L' \end{array} \quad (2)$$

where P represents dye-binding sites on protein, A refers to co-existing anion(s) having unfavorable effect on the binding of dye to protein, the primed symbols, A′, L′, HL′, and H_2L' refer to bound A, L, HL, and H_2L, respectively. These equilibria may be described by proton dissociation constants for free and bound dye species and by binding constants for dye-protein and anion-protein complexes equilibria, as follows.

$$K_{a1} = [H][HL]/[H_2L];\ K_{a2} = [H][L]/[HL] \quad (3)$$

$$K'_{a1} = [H][HL']/[H_2L'];\ K'_{a2} = [H][L']/[HL'] \quad (4)$$

$$K_{L'} = [L']/[L][P] \quad (5)$$

$$K_{A'} = [A']/[A][P] \quad (6)$$

where [P] represents the total concentration of free dye binding sites on all protein molecules.

3.2. Explanation of the formation of the isosbestic point

The formation of the isosbestic point in Fig. 2 can be explained based on model Eq. (2). Define {L} as the total concentration of free dye, {L′} as the total concentration of bound dye, and c_L as the analytical concentration of dye, that is:

$$\{L\} = [L] + [HL] + [H_2L] \quad (7)$$

$$\{L'\} = [L'] + [HL'] + [H_2L'] \quad (8)$$

$$c_L = \{L\} + \{L'\} \quad (9)$$

The absorbance of the dye-protein mixture is (with 1 cm cell)

$$A = \epsilon_L[L] + \epsilon_{HL}[HL] + \epsilon_{H_2L}[H_2L] + \epsilon_{L'}[L'] + \epsilon_{HL'}[HL'] + \epsilon_{H_2L'}[H_2L'] \quad (10)$$

where ϵ_L, ϵ_{HL}, ϵ_{H_2L}, $\epsilon_{L'}$, $\epsilon_{HL'}$ and $\epsilon_{H_2L'}$ are molar absorptivities (mol^{-1} 1 cm^{-1}) of L, HL, H_2L, L′, HL′, and H_2L', respectively.

Define distribution coefficients as

$$\delta_L = [L]/\{L\} \quad (11)$$

$$\delta_{HL} = [HL]/\{L\} \quad (12)$$

$$\delta_{H_2L} = [H_2L]/\{L\} \quad (13)$$

$$\delta_{L'} = [L']/\{L'\} \quad (14)$$

$$\delta_{HL'} = [HL']/\{L'\} \quad (15)$$

$$\delta_{H_2L'} = [H_2L']/\{L'\} \quad (16)$$

Substituting Eq. (7) and Eq. (3) into Eq. (11) gives:

$$\delta_L = [L]/([L] + [HL] + [H_2L]) = K_{a1}K_{a2}/(K_{a1}K_{a2} + [H]K_{a1} + [H]^2) \quad (17)$$

Similar substitution leads to

$$\delta_{HL} = [H]K_{a1}/(K_{a1}K_{a2} + [H]K_{a1} + [H]^2) \quad (18)$$

$$\delta_{H_2L} = [H]^2/(K_{a1}K_{a2} + [H]K_{a1} + [H]^2) \quad (19)$$

$$\delta_{L'} = K'_{a1}K'_{a2}/(K'_{a1}K'_{a2} + [H]K'_{a1} + [H]^2) \quad (20)$$

$$\delta_{HL'} = [H]K'_{a1}/(K'_{a1}K'_{a2} + [H]K'_{a1} + [H]^2) \quad (21)$$

$$\delta_{H_2L'} = [H]^2/(K'_{a1}K'_{a2} + [H]K'_{a1} + [H]^2) \quad (22)$$

Note that distribution coefficients are merely the functions of pH and are independent of dye concentration. Substituting Eq. (11) Eq. (12) Eq. (13) Eq. (14) Eq. (15) Eq. (16) into Eq. (10) gives:

$$A = (\epsilon_L\delta_L + \epsilon_{HL}\delta_{HL} + \epsilon_{H_2L}\delta_{H_2L})\{L\} + (\epsilon_{L'}\delta_{L'} + \epsilon_{HL'}\epsilon_{HL'} + \epsilon_{H_2L'}\delta_{H_2L'})\{L'\} \quad (23)$$

Let

$$\epsilon = \epsilon_L\delta_L + \epsilon_{HL}\delta_{HL} + \epsilon_{H_2L}\delta_{H_2L} \quad (24)$$

$$\epsilon' = \epsilon_{L'}\delta_{L'} + \epsilon_{HL'}\delta_{HL'} + \epsilon_{H_2L'}\delta_{H_2L'} \quad (25)$$

where ϵ and ϵ' are the mean (distribution coefficient-weighted) molar absorptivities of free and bound dye at the assay pH. They are constants when pH and measuring wavelength are given. So Eq. (23) may be simplified as

$$A = \epsilon\{L\} + \epsilon'\{L'\} = \epsilon c_L + (\epsilon' - \epsilon)\{L'\} \quad (26)$$

Where ϵc_L is the absorbance of the CBB blank solution.

Fig. 2 shows that the maximum values of ϵ and ϵ' are at 470 nm and 595 nm, respectively. We could deduce that there should be a wavelength between 470 and 595 nm where ϵ equals ϵ'. As we can see from Fig. 2 this particular wavelength is 530 nm. It is at this wavelength that $\epsilon = \epsilon'$, Eq. (26) becomes $A = \epsilon c_L$, which is a fixed value, unchanging with increase of BSA concentration, so the isosbestic point appears.

The above discussion gives an explanation to the appearance of the isosbestic point in Fig. 2. The appearance of the isosbestic point in Fig. 2, in reverse order, provides an evidence for the above theory. And furthermore, based on the above discussion two mathematical models for the description of the CBB protein assay could be developed, as follows.

3.3. A nonlinear equation for the description of the CBB protein assay

In Eq. (26), both A and ϵc_L can be measured, ϵ' and ϵ are constants under certain conditions. Let

$$\Delta A = A - \epsilon c_L \quad (27)$$

$$\Delta\epsilon = \epsilon' - \epsilon \quad (28)$$

then Eq. (26) may be written as

$$\{L'\} = \Delta A/\Delta\epsilon \quad (29)$$

where ΔA is measurable, $\Delta\epsilon$ is a constant under certain conditions.

The total concentration of free dye binding sites [P] may be expressed as

$$[P] = (Nc_P - \{L'\}) \quad (30)$$

where c_P is the analytical molar concentration of protein, N the total number of binding sites per protein molecule. Substituting Eq. (30), Eq. (11) and Eq. (14) into Eq. (5) gives

$$K_{L'} = \delta_{L'}\{L'\}/[\delta_L\{L\}(Nc_P - \{L'\})] \quad (31)$$

Since $\delta_{L'}$ and δ_L have fixed values under certain conditions, we can define a new constant

$$K = K_{L'}\delta_L/\delta_{L'} = \{L'\}/[\{L\}(Nc_P - \{L'\})] \quad (32)$$

Substituting Eq. (29) and Eq. (9) into the above equation gives

$$K = (\Delta A/\Delta\epsilon)/[(c_L - \Delta A/\Delta\epsilon)(Nc_P - \Delta A/\Delta\epsilon)] \quad (33)$$

Rearranging this equation yields

$$\Delta A = K\Delta\epsilon^{-1}(\Delta\epsilon c_L - \Delta A)(\Delta\epsilon N c_P - \Delta A) \quad (34)$$

If the experiment is conducted by keeping the dye concentration c_L and other conditions constant and changing the protein concentration c_P, a group of $c_P \sim \Delta A$ data can be measured. These data may be fit to Eq. (34) using optimization method and, at the same time, the values of K, $\Delta\epsilon$, and N can be calculated.

But, unfortunately, in our experiment the optimization results are not satisfactory. Although Eq. (34) is a theoretically rigorous equation, its mathematical properties require further investigation. In the following section, a simple linear regression equation based on an approximation is proposed for studying the CBB protein assay.

3.4. A linear regression method for the study of the CBB protein assay

Define distribution coefficient of P as

$$\delta_P = [P]/Nc_P \quad (35)$$

Suppose δ_P is a constant over the entire c_P range studied when c_L and other conditions are fixed (this supposition is not rigorous in theory, but it leads to an easy mathematical treatment and it practically holds under normal conditions). Substituting Eq. (35), Eq. (11) and Eq. (14) into Eq. (5) gives

$$K_{L'} = \delta_{L'}\{L'\}/(\delta_L\{L\}\delta_P N c_P) \quad (36)$$

Under a given set of experimental conditions, $\delta_{L'}$, δ_L, δ_P and N are constants. Thus, we can define a new constant:

$$K_c = NK_{L'}\delta_L\delta_P/\delta_{L'} = \{L'\}/\{L\}c_P \quad (37)$$

K_c is a conditional constant. It is a measure of the CBB binding ability of a protein under certain conditions. We call K_c the apparent binding constant [12].

Substituting Eq. (29) and Eq. (9) into Eq. (37) gives

$$K_c = (\Delta A/\Delta\epsilon)/[(c_L - \Delta A/\Delta\epsilon)c_P]$$

Rearranging this equation yields

$$\Delta A = \Delta\epsilon c_L - K_c^{-1}\,\Delta A/c_P \quad (38)$$

where K_c and $\Delta\epsilon$ are conditional constants. If the experiment is conducted by keeping c_L constant and changing c_P, there should be a linear relationship between ΔA and $\Delta A/c_P$. From the slope ($-K_c^{-1}$) and the intercept ($\Delta\epsilon c_L$) of the regression line, K_c and $\Delta\epsilon$ (then $\epsilon' = \Delta\epsilon + \epsilon$) can be calculated.

Using the data measured at 595 nm in Fig. 2, a linear regression equation was obtained:

$$\Delta A = 0.771 - 1.78 \times 10^{-7}\Delta A/c_P \quad R = 0.9973$$

From the slope and the intercept of above equation, $K_c = 5.62 \times 10^6$, and $\Delta\epsilon = 5.28 \times 10^4$ mol^{-1} l cm^{-1} were obtained.

This example demonstrated that the linear regression method proposed above is feasible in the study of the CBB protein assay. This feasibility will be examined further in the following sections.

3.5. Maximum binding number and the Sandell index

The maximum binding number n and the Sandell index s (μg cm^{-2}) can be calculated respectively by the following equations [12]:

$$n = K_c c_L \quad (39)$$

$$s = F/n\,\Delta\epsilon \quad (40)$$

where F is the molecular weight of the protein assayed.

Using the K_c and $\Delta\epsilon$ values obtained above, $n = 82$, and $s = 0.015$ μg cm^{-2} were calculated. Both n and s values are reasonable.

3.6. Influence of experimental conditions on the binding of CBB to protein

The influence of ionic strength on the binding of CBB to protein is shown in Table 1. An increase in salt concentration causes a significant decrease in K_c and n values, thus decreasing the sensitivity of the CBB protein assay. This effect can be explained as a competition between anions and dye species for the same binding sites on BSA, see reaction model (2).

The influence of acidity on the binding of CBB to protein is shown in Table 2. From this test we can see that in the pH range studied a decrease in acid concentration causes an increase in K_c and n values, thus, increasing the sensitivity of the assay. This effect is due to the fact that an increase in pH causes an increase in L^- concentration thereby promoting the main reaction in model (2). But, the assay pH cannot be too high because a decrease in $\Delta\epsilon$ value occurs when pH is higher than pH 1.13. From Table 2 we can see that the best acidity for the CBB protein assay is at about pH 1.13 (0.73 mol l^{-1} H_3PO_4), which is slightly different from the acidity suggested by earlier workers (pH 0.97, 1.46 mol l^{-1} H_3PO_4) [1,3].

Table 1
Effect of sodium chloride concentration on binding of CBB on BSA

NaCl (%)	$\Delta\epsilon$	K_c	n	s	R
0	3.0×10^4	5.0×10^6	82	0.026	0.997
0.1	3.1×10^4	4.0×10^6	65	0.032	0.997
0.3	3.0×10^4	3.5×10^6	56	0.038	0.997
0.5	2.5×10^4	3.3×10^6	53	0.048	0.996
0.8	2.1×10^4	3.1×10^6	51	0.059	0.998

$c_L = 1.63 \times 10^{-5}$ mol l^{-1}, $c_{H_3PO_4} = 1.46$ mol l^{-1}, pH = 0.98, at 595 nm.

Table 2
Effect of acidity on binding of CBB on BSA

H_3PO_4 (mol l^{-1})	pH	$\Delta\epsilon$	K_c	n	s	R
1.46	0.98	2.5×10^4	3.3×10^6	53	0.048	0.996
1.02	1.06	4.6×10^4	3.9×10^6	64	0.021	0.999
0.88	1.09	4.6×10^4	4.5×10^6	73	0.019	0.993
0.73	1.13	5.2×10^4	5.2×10^6	85	0.014	0.991
0.58	1.18	5.1×10^4	5.4×10^6	88	0.014	0.997

$c_L = 1.63\times10^{-5}$ mol l^{-1}, 0.5% NaCl, at 595 nm.

Table 3 shows the influence of CBB concentration on the binding reaction. From this test we can see that an increase in dye concentration causes an increase in n values, while $\Delta\epsilon$ and K_c remain practically constant. Therefore an increase in dye concentration makes a higher sensitivity. This is an obvious result since more binding sites would be bound when the dye concentration increases. But the dye concentration cannot be too high in assay practice because of the restriction of spectral measurement.

3.7. Binding of CBB on γ-globulin

The binding of CBB on γ-globulin was investigated by using the linear regression method. Some results are listed in Table 4.

4. Conclusions

The combination of CBB with proteins at low pH is due to the weak interactions (ionic, van der Waals, hydrogen bonding, and hydrophobic). All the three dye forms (red, green, and blue) are able to combine with protein by nonelectrostatic forces. The anionic blue form of the dye has an advantage over other two forms in binding to protein by ionic attraction, which is the key point of the entire binding and color changing process.

Table 3
Effect of CBB concentration on CBB protein assay

c_L (mol l^{-1})	$\Delta\epsilon$	K_c	n	s	R
1.31×10^{-5}	2.3×10^4	3.2×10^6	42	0.068	0.990
1.63×10^{-5}	2.5×10^4	3.3×10^6	53	0.048	0.996
1.96×10^{-5}	2.6×10^4	3.9×10^6	78	0.032	0.994

$c_{H_3PO_4} = 1.46$ mol l^{-1}, pH = 0.98, 0.5% NaCl, at 595 nm.

The Ringbom model [15] used in the treatment of the complexation between metal ions and ligands is suitable in the expression of the dye-binding equilibria of the CBB protein assay. In this model, the influence of side reactions (dye's protonation and the competition of co-existing anions for the dye-binding sites on protein) on the main reaction (binding of the anionic blue form of the dye to protein) is expressed explicitly. By this model, the effects of acidity and ionic strength on the binding of CBB to protein are easier to understand.

The concepts of mean molar absorptivities defined in Eq. (24) and Eq. (25) for free and bound dye (ϵ and ϵ') are different from the usual concept of molar absorptivity for single species. They are distribution coefficient-weighted parameters, so that they are functions of pH. The sensitivity of the CBB protein assay depends greatly upon the difference of these two parameters ($\Delta\epsilon$). If the assay pH is higher than pH 1.2, its sensitivity will decline due to the decrease in $\Delta\epsilon$ value although more dye species may be bound to protein under such conditions.

The linear regression equation is able to give a reasonable description of the CBB protein assay. Both the apparent binding constant and the maximum binding number are conditional constants, so their values vary along with experimental conditions. The maximum value of the maximum binding number determined in this paper ($n = 88$) is about the same as that determined previously ($n = 82$–105) [5–8]. This value is consistent with the total number of arginine and lysine side chains on BSA ($n_{arg} + n_{lys} = 86$), lending credence to the

Table 4
Binding data of CBB on γ-globulin at different pH

H_3PO_4 (mol l^{-1})	pH	$\Delta\epsilon$	K_c	n	s	R
1.46	0.98	2.4×10^4	4.9×10^6	81	0.082	0.995
0.88	1.09	4.4×10^4	8.7×10^6	141	0.025	0.995

$c_L = 1.63\times10^{-5}$ mol l^{-1}, 0.5% NaCl, at 595 nm.

idea that arginine and lysine residues are the primary binding sites for CBB.

To use this method, one should first prepare a series of dye-protein mixtures containing the same amount of dye and having the same pH and ionic strength but different in protein concentration. Then measure the absorbances of these mixtures at a given wavelength (595 nm, for example). Finally, do a linear regression operation according to Eq. (38) and calculate $\Delta\epsilon$, K_c, n, and s, respectively. Compared with other methods used before, this new method is simple to use.

Voltammetric study of ketorolac and its differential pulse polarographic determination in pharmaceuticals

J.C. Sturm, H. Canelo, L.J. Nuñez-Vergara, J.A. Squella *

Bioelectrochemistry Laboratory, Chemical and Pharmaceutical Sciences Faculty, University of Chile, P.O. Box 233, Santiago 1, Chile

Received 15 July 1996; received in revised form 18 October 1996; accepted 18 October 1996

Abstract

A differential pulse polarographic method for the quantitative determination of ketorolac is described. Ketorolac is an antiinflamatory-analgesic agent that is directly electroreducible at the mercury electrode. The polarographic reduction is due to the reduction of the benzoyl moiety in the ketorolac molecule. For analytical purposes, a very well resolved diffusion controlled differential pulse polarographic peak obtained at pH 9 was selected. This peak was used to develop a new method for the determination of ketorolac in pharmaceutical dosage forms. Recovery study shows that the method is sufficiently accurate and precise to be applied in the individual tablet assay of commercial samples.

Keywords: Differential pulse polarography; Drug analysis; Ketorolac; Voltammetry

1. Introduction

Ketorolac tromethamine, (±)-5-benzoyl-2,3-dihydro-1H-pyrrolizine-1-carboxylic acid (Fig. 1), is a nonsteroidal anti-inflammatory analgesic agent [1]. Its rapid onset of action, effectiveness, lack of opiate action and safety make it an attractive agent for general purpose analgesia. Ketorolac is a non narcotic analgesic of great efficiency, that does not produce lateral effects on the central nervous system and does not provoke dependency [2–4]. It also possesses antipyretic properties, being indicated that it is 20 times more potent than the aspirin [5]. Furthermore some studies of its inhibitor action of the plaquelet aggregation have been described [2]. The mechanism of action consists of inhibiting the enzyme cyclooxygenase, involved in the synthesis of derivatives of the arachidonic acid, that is translated to a decrease in the metabolic products that trigger the inflammatory processes [6].

Ketorolac is manufactured as the tromethamine salt for enhanced solubility in form of tablets and intramuscular injectables. The recommended initial loading dose is 30–60 mg given via intramuscular injection, followed by additional doses of 15 or 30 mg every 6 h [2]. When ketorolac tromethamine is absorbed after oral ingestion, or following intravenous injection, it is rapidly dissociated into the anion form of ketorolac at neutral pH. The major metabolic pathway in humans is glucuronic acid conjugation. The products appear in the urine, but not in the plasma.

Several analytical techniques for the determination of ketorolac tromethamine from the bulk drug are described. These include non-aqueous titration, TLC, UV spectrophotometry and HPLC methods [7,8]. Ketorolac has been determined in blood after a solid-phase extraction, by gas chromatography-mass spectrometry after derivatization using diazopropane [9]. Other studies in human serum have been performed by HPLC [10,11]. A flow injection analysis (FIA) method with spectrophotometric detection after derivatization with dichloronitrophenol in pharmaceutical formulations was published recently [12].

However, to our knowledge no information about the electrochemical redox properties of ketorolac and its analytical application have appeared in the literature. In this work we have carried out a study of the electrochemical reduction behavior of ketorolac by differential pulse(dpp) and tast polarography and cyclic voltammetry.

A dpp method is recommended for the quantitative determination of the pure drug and for commercial preparations.

2. Experimental

2.1. Apparatus

Differential pulse polarography (DPP), tast polarography and cyclic voltammetry (CV) were carried out in an Inelecsa® assembly containing a pdc1212 potentiostat-scan generator attached to an Acer® 500 + PC with suitable software for totally automated control of the experiments and data acquisition. A 25 ml capacity Metrohm® thermostated cell equipped with a three-electrode system was used. The working electrodes were a dropping mercury electrode (DME) and a hanging mercury drop electrode (HMDE), Metrohm® model EA-290, for polarographic and cyclic voltammetric experiments, respectively. As reference electrode, a silver–silver chloride electrode and a platinum wire counter-electrode were used.

Spectrophotometric measurements were carried out with a UV–Vis Spectrophotometer (Unicam® model UV-3) using 1 cm quartz cells and equipped with a 486 computer with a Vision® acquisition and treatment program (Unicam®).

2.2. Reagents and drugs

Ketorolac tromethamine standard (100% pure drug) was obtained from Laboratorio Saval® (Santiago, Chile). Stock solutions 2×10^{-3} M were prepared in distilled water. Netaf® tablets containing 10 mg of ketorolac tromethamine (Lab.Chemopharma S.A., Santiago, Chile) were commercially obtained.

All reagents employed were of analytical grade.

2.3. Buffer solutions

The solutions under study were buffered using Britton–Robinson buffer (0.04 M phosphoric acid/0.04 M acetic acid/0.04 M boric acid) adjusted with NaOH to the desired pH. The ionic strength was kept constant at 0.3 M with KCl.

2.4. Working solutions

An aliquot (1.25 ml) of the drug stock solution was diluted to a final volume of 25 ml with buffer (pH 9.0) to obtain a final concentration of 1.0×10^{-4} M.

3. Methods

3.1. Cyclic voltammetry

For obtaining cyclic voltammetric curves a 1×10^{-3} M, pH 9 KT solution was used. Scan rates

were varied between 0.1 and 10 V s^{-1}. Potential range was −1300 mV (initial potential) to −1800 mV (switching potential) versus Ag–AgCl.

3.2. Calibration curve

A calibration curve was produced adding different volumes of standard solution to 20 ml of buffer solution (pH 9.0) within the polarographic cell. The concentrations ranged between 4.9×10^{-5} and 4.2×10^{-4} M.

3.3. Synthetic samples

Synthetic samples for recovery studies were prepared by weighing 10 mg ketorolac tromethamine standard plus suitable excipients according to the manufacturer's batch formulas for 10 mg tablets. The excipients tested were. Lactose, magnesium stearate, hydroxy-propylmethyl-cellulose, polyethylenglicol, titanium dioxide, starch and microcrystaline cellulose. All the components were suspended in 6 ml distilled H_2O and sonicated for 3 min, then diluted to 100 ml with pH 9, 0.04 M Britton–Robinson buffer, obtaining a final concentration of 2.7×10^{-4}. Prior to the spectrophotometric experiment each sample was centrifuged at 4000 rpm for 10 min. The samples were assayed by polarography and spectrophotometry.

Tablet assay procedure.

3.4. Polarography

Ten series of one tablet of Netaf®, Lab.Chemopharma S.A. Santiago, Chile (declared amount 10 mg per tablet) were suspended in 5 ml of distilled water and then diluted to a final volume of 100 ml with Britton–Robinson Buffer pH 9.0.

Then, not less than 10 ml of each solution was transferred to a dry polarographic cell and a deaeration performed for 5 min with nitrogen. The DP polarogram is then recorded at the DME between −1200 and −1700 mV. The current is measured at the peak potential of ketorolac at ca. −1530 mV and the amount of ketorolac in the sample solution calculated from prepared standard calibration curve.

3.5. Spectrophotometry

Ten series of one tablet of Netaf® (declared amount of ketorolac per tablet, 10 mg) were suspended in 5 ml of distilled water and diluted to a final volume of 100 ml. A portion of this solution was centrifuged at 4000 rpm for 10 min, then an aliquot of 2 ml was taken and diluted up to 25 ml with pH 9.0 buffer. Then, the sample solution absorbance was measured at 324 nm using buffer solution as a blank. The amount of ketorolac in the sample solution was calculated from a prepared standard calibration curve.

4. Results and discussion

Ketorolac trometamine (KT) appears to be an electroactive drug. Specifically, the drug is capable to be both, oxidable and reducible. However, tromethamine did not shows neither reduction waves nor oxidation peaks when submitted to a voltammetric experiment. Consequently we can conclude that the electroactivity was not due to the tromethamine moiety. As a first step KT was subjected to a polarographic study in the tast and differential pulse modes, and to a cyclic voltammetric study with the aim of characterizing its electrochemical reduction behavior. When KT was subjected to reduction in the differential pulse polarographic mode (dpp), three well-defined peaks were observed (Fig. 2, peaks I, II, and III). The appearance of these peaks was pH-dependent and the evolution of the DPP signals between pH 1.8 and 11 are shown in the E_p versus pH graph in Fig. 3. Peak (I) appears between pH 1.0 to 3.0, peak II is present between pH 1.0 and 7.0 while peak III is seen between pH 7.0 to 12.0. A totally analogous behavior is observed by tast polarography (Fig. 2) and the corresponding i_l versus pH graph is showed in the insert of Fig. 3. The limiting current of peak I (or wave I), that appears only at acidic pHs, is strongly dependent on pH and appears just before the signal of the supporting electrolyte. This characteristic suggests a catalytic wave due to the catalytic proton discharge, commonly found in compounds with heterocyclic nitrogen in the molecule [13]. Considering

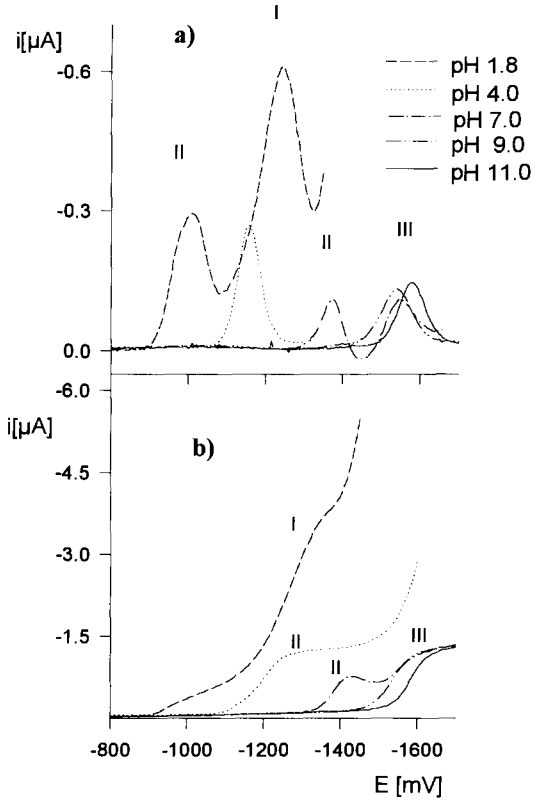

Fig. 2. Differential pulse (a) and Tast (b) polarograms of 1×10^{-4} M ketorolac at different pH values.

the molecular structure of KT the only possibility of obtaining a polarographic reduction signal is the reduction of the carbonyl group close to the benzene ring and the heterocyclic moiety. Consequently, peaks (or wave) II and III are due to the well-known two-electron carbonyl group reduction [14]. Peaks (or wave) II appears between pHs 1.8 and 6, shifting towards more negative potential values when pH increases. In Fig. 4 is clearly appreciated as the wave II that is observed at pH 5 is unfolded at pH 7 to be converted into a new wave III at pH 9. Between pHs 6 and 8 both waves II and III are present indicating the presence of two different reducible species. As can be seen the ratio of the wave heights (II and III) change with pH, however, the total height of these waves (II + III) remains constant. This phenomena is a very clear example of the general pattern that has been well-described by Zuman [15]. This

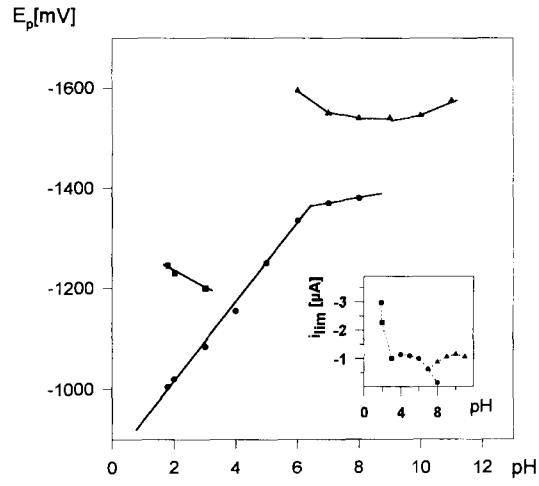

Fig. 3. Potential peaks and limiting current dependence with pH for 1×10^{-4} M ketorolac solutions. ■, peak (or wave) I; •, peak (or wave) II; and ▲, peak (or wave) III.

general pattern is described with the following scheme:

$$R + H^+ \rightleftharpoons RH^+ \quad (1)$$

$$RH^+ + n_1e^- \rightarrow P_1 \quad (2)$$

$$R + n_2e^- \rightarrow P_2 \quad (3)$$

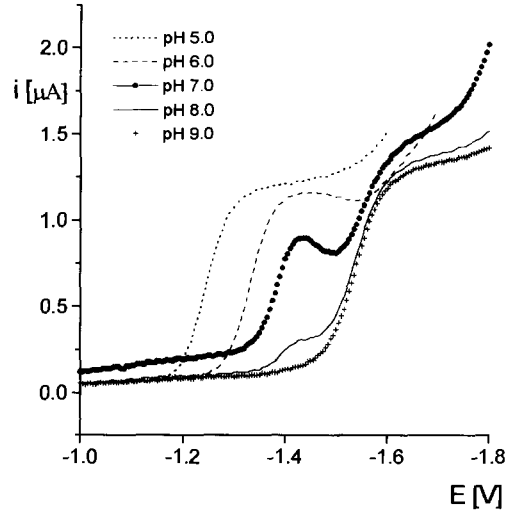

Fig. 4. Tast polarograms showing the unfolding of the benzoyl reduction wave of ketorolac between pHs 5 and 9.

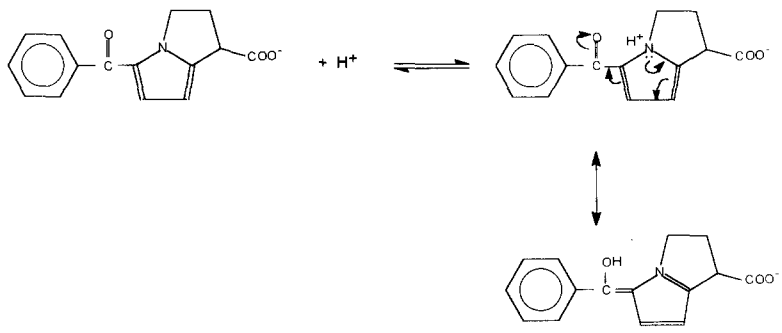

Scheme 1. Antecedent acid–base reaction and keto-enolic equilibria affecting the benzoyl reduction in ketorolac molecule.

At pH values $< pK_a$ the reduced specie would be RH^+ at the potential E_1, meanwhile at pH $> pK_a$ the non-protonated form is reduced at a more negative potential, E_2. In the zone ± 2 pH units around the pK_a, the two species coexists giving two polarographic signals. In our case, R is the KT molecule and RH^+ is the protonated KT. Specifically, the RH^+ specie corresponds to the KT molecule with the heterocyclic nitrogen protonated Scheme 1). The protonation on the heterocyclic nitrogen affect the reduction of the neighboring carbonyl group due to the existence of the keto-enolic equilibria as is shown in Scheme 1. According to the i_l versus pH behavior the pK_a value, that is defined as the pH value at which the heights of the waves II and III are equal. was 6.5. Consequently, at acidic pH the reduction occurs via Eq. (2) and at basic pH, the reducible specie is the non-protonated according to Eq. (3). Furthermore, the acid–base reaction can be qualified as a surface reaction. The phenomena that allows us to distinguish the surface character of the acid–base process involved is a decrease of the limiting current (pH 7 curve in Fig. 4) similar to that described for this type of surface processes [16].

We found that between pH 4.0 and 5.0 and at pH higher than 9.0 there is only one wave present, which is well resolved and appears suitable to be investigated for analytical use. But by comparing the electrocapillary curves (Fig. 5), it is observed that only the pH 9 condition did not show adsorption interferences in the potential range where the drug is reduced. Consequently, a pH of 9.0, buffered with the Britton–Robinson buffer, is selected to develop an analytical procedure. Furthermore, considering that tromethamine (TRIS buffer) was a normal constituent of the pharmaceutical form, the possibility of using TRIS buffer also was evaluated. However this buffer is ade-

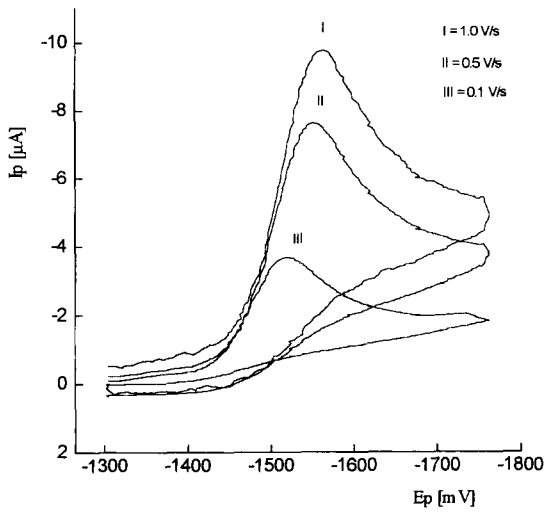

Fig. 6. Linear sweep cyclic voltammograms of 1×10^{-3} M, pH 9 ketorolac solution at different sweep rates.

quate only at physiological conditions (around pH 7.4).

In order to clarify the nature of the limiting current we have obtained a linear relationship between the limiting current and the height of the mercury column. From the dependence between the limiting current and the temperature a temperature coefficient of 2%°C^{-1} was obtained. Both of these results are indicative of a diffusion control of the limiting current. Moreover, also we have obtained a linear relation between the limiting current and the concentration of KT (linear range 2×10^{-3}–6×10^{-6} M) also showing a diffusion control.

From the cyclic voltammograms observed in Fig. 6, we can confirm that the reduction of KT at pH 9, appears to be irreversible with a linear relation between i_p and the square root of the sweep rate confirming a diffusion controlled process.

In order to develop a polarographic methodology for determining the drug, we have selected the differential pulse mode. For quantitation the calibration curve method, with concentrations ranging between 4×10^{-5} and 4×10^{-4} M, was used. The calibration curve is described by the following regression curve:

$$i_p(\mu A) = 1104.47C(M) - 0.00574 \quad (4)$$

(correlation coefficient = 0.999, $n = 10$, pH = 9, $T = 25$°C), where i_p is the peak current and C is the KT concentration. The repeatability (intra-day) and the reproducibility (inter-day) of the measurement was calculated from ten independent runs of a 1×10^{-4} M KT solution obtaining a RSD of 0.5 and 0.8%, respectively. The detection and quantitation limits were 4.04×10^{-6} and 6.15×10^{-6} M, respectively. The detection or quantitation limits were calculated as the blank response plus three times or ten times, respectively the blank standard deviation divided by the slope of the calibration curve. In order to check the accuracy and precision of the developed method, we have also carried out a recovery study (Table 1), obtaining a recovery of 98.25% with a RSD of 0.94%, concluding that the proposed method is sufficiently accurate and precise in order to be applied to pharmaceutical forms. The result for the individual tablet assay (Table 2) for commercial tablets containing 10 mg ketorolac tromethamine shows a mean of 9.81 with a RSD of 1.85% for ten individual tablets.

Furthermore, to obtain comparative results an UV spectrophotometric method was also applied. This spectrophotometric method was very similar to that described the U.S. Pharmacopeia [17] for the analysis of KT tablets. However, in order to

use the same sample that in the polarographic analysis we have performed the spectrophotometric analysis at pH 9. KT absorption spectra exhibit two well—resolved maxima at 250 and 324 nm in pH 9.0 solution. The maxima at 324 nm presents better absorbility and shows a linear dependence with the KT concentration. For analytical determination the calibration curve method, with concentrations ranging between 6.46×10^{-6} and 4.04×10^{-5} M, was used. This curve is described by the following regression line:

$$A = 21038.82C(M) + 5.014 \times 10^{-3} \quad (5)$$

(correlation coefficient = 0.9999, $n = 10$), where A is the absorbance of pH 9.0 solution of KT at 324 nm. The results of the recovery study (97.39, 0.5% RSD) and the individual tablet assay (9.54 mg tablet^{-1}, 1.49% RSD) are in accord with the polarographic results.

Although both, polarographic and UV spectrophotometric, showed similar accuracy and precision, the principal advantage of the proposed polarographic method over the spectrophotometric one is that the excipients do not interfere and the separation procedure is not necessary. Consequently, the above presented method is a good analytical alternative for determining ketorolac in tablets.

Dialysis membrane to prevent cadmium ion specific electrode fouling

Susan J. Fish, Pierre Brassard *

Abstract

We present a simple method of protecting a Cd(II) ion-selective electrode from fouling using a dialysis membrane. Drift due to fouling is inevitable during continuous exposure of the electrode to the bulk solution. It presents a major problem in the case of automated titrations because recalibration is not possible. The drift is due to natural organic matter present in the sediment, and the membrane prevents its accumulation on the electrode surface. This was verified by calibrating a Cd electrode exposed to sediment for varying times, both with and without a membrane covering. There are two types of time dependent biases. A primary drift occurs without exposure to sediments and is probably caused by oxidation of the surface. A more important effect due to natural organic matter accumulation causes additional drift and deteriorates the Nernstian response of the electrode. From these results, it is possible to predict the uncertainty associated with measurements of binding constants and surface site densities for a Langmuir model. In general, the biased electrode overestimates the total metal concentration, reduces the value of the stability constants and increases estimates of maximum surface site densities. © 1997 Elsevier Science B.V.

1. Introduction

The interference of organic matter with electrode response is not a new phenomena. In 1931, Heyrovsky developed the 'adsorption analysis' technique, which takes advantage of the natural adsorption or organics to a mercury electrode. This adsorption of natural surface active organics suppresses the streaming maxima around a mercury drop electrode, and can be quantified. Some difficulties with this technique were noted by Pleše and Žutic [1], who attributed irregular surfactant aggregates with the mercury electrode/aqueous solution interface.

More recently, Ochs et al. [2] studied the extent of adsorption of humic substances onto a hydrophobic mercury electrode surface by measuring directly the change in double layer capacitance due to adsorption. They determined that these humic substances adsorbed significantly to both hydrophobic and hydrophillic surfaces, over varying pH. It was suggested that the adsorbed mate-

rial could influence the chemical characteristics and reactivity of a surface, and therefore, its affinity for metal ions.

A silver based ion-selective electrode (ISE) is biased by complexones such as EDTA [3] and also by humic acids [4]. But even in the absence of organic matter, it will undergo ion exchange reactions in the presence of light which causes silver halide crystal growth on, and out of the membrane [5]. Scanning electron microscopy has also identified metallic silver on the active surface. This metallic silver leads to silver sulphide or silver oxide deposits on the electrode [6].

With the advent of automatic titrators, constant monitoring is required. Since the electrodes are not removed between readings, no recalibration is possible and some drift or fouling, due to contact with humic substances, is inevitable. These interferences can cause significant bias which could be removed by preventing natural organic matter (NOM) from contacting the electrode surface and, at the same time, allowing metal ions to react with the electrode.

We present here a series of experiments to evaluate the use of a dialysis membranes as a shield to isolate the electrode surface from NOM of high molecular weight. This approach is similar in concept but opposite in application from using dialysis membranes to retain enzymes near the electrode surface, as was done recently in the development of enzyme specific electrodes [7].

2. Experimental

2.1. Titrations

All titrations were done under CO_2 free air, obtained by filtering incoming instrument air through an ascarite column and followed by a water wash bottle. The reactor consisted of a 150 ml pyrex beaker. A plexiglass lid held reference and pH electrodes with also the tubing required for titrant addition and CO_2 free air. This method allowed rapid insertion and removal of electrodes to the reactor and thus, minimized exposure to ambient CO_2.

The following procedure was followed for all titrations. The electrode assembly was first calibrated against standard buffers immediately before the titration. The titration vessel was then filled with the titration solution and lowered in a constant temperature jacket (25°C) held over a magnetic stirrer. The titration was carried out after a 30 min equilibration time. After recalibration, blank titrations without cadmium and/or sediment followed. Because titration profiles for the blanks did not necessarily fall on the same pH points as the analyte, blank titration data were interpolated to the corresponding pH value of the analyte using cubic spline method. The difference between analyte and interpolated blank titrant addition at the same pH values yielded charge excess in the suspension.

Titration profile was controlled by a computer driven titrimeter (Tanager Scientific Systems, model 8901) and done at equal 0.1 pH intervals, based on estimates of the buffer capacity obtained from the previous titration point.

2.2. Sediment samples

Surficial sediments from Coote's Paradise (Cootes sediments) were collected with a square dredge from the deck of a scow in the western part of Hamilton Harbour at a depth of less then 3 m. The shallow depth of the embayment and strong winds maintain oxic conditions year round. Cootes sediments consist of erosion debris, mostly clays, coated with a small layer of organic matter arising from the very active algal and bacterial populations. Previous work on these sediments and at other locations in the harbour are given in Brassard et al. [8]. Loadings in Coote's Paradise come mainly from creek erosion (47 050 kg day^{-1} in 1987) and farming operations.

Surficial sediments were stored in polyethylene bottles at 4°C until decanted. We used a settling procedure designed to remove the coarse particulates, a necessary step to prevent grinding in the reactor and wear of electrode surfaces. Raw sediment, 50 g, was diluted in 500 ml water, stirred vigorously and then allowed to settle for 1 min. The top 1.5 cm was collected. The volume was replaced with water and the process repeated until

approximately 1 l of solution was collected. The concentration was determined by filtering an aliquot on 0.45 μm (Millipore) and weighing the dried filter until constant weight. A 1 g l^{-1} suspension was prepared by performing the appropriate dilution of the stock. Calculations from Stoke's settling equations predict the size distribution of the collected suspension to be less than 16 μm.

2.3. Electrodes

The Cd(II) ISE membrane was formed by thoroughly blending an equimolar ratio of CdS and Ag_2S powders under argon. A 6 mm die was loaded with this blend and subjected to 8000 kg cm^{-2} pressure [9,10]. A temperature controlled jacket held the die at 150 ± 5°C during a 16 h curing period. The resulting pellet was mounted at the end of a glass tube and sealed with a thermoplastic sleeve. A strip of platinum mounted at the end of a small spring established electrical contact between the inner surface of the pellet and a copper wire.

The Cd(II) ISE was polished before every use with 1.0 μm followed by 0.5 μm Al_2O_3 powder on a felt pad. A Radiometer pH glass electrode and Fisher Scientific Calomel reference electrode were calibrated with standard buffers before every use. The Cd(II) ISE was calibrated both automatically, and manually with standard $Cd(NO_3)_2$ solutions, ranging from $10^{-5.5}$ M to 10^{-3} M.

2.4. The membrane

Regenerated cellulose (viscose process) dialysis tubing (Viskase Canada) with a molecular weight cutoff of 12 000–16 000 Da was cut into 10 cm strips, three times boiled (30 min), and rinsed in deionized H_2O. The wet tubes were slip open and stored in deionized H_2O and used within 3 days. After cleaning the electrode, a square of tubing was pulled tightly over the end of the Cd electrode and an O-ring was rolled over it from one end, up to the edge of the tubing to hold the membrane in place. The arrangement is stable and the membrane could maintain a tight contact with the membrane surface for a week.

2.5. Exposure to sediment

The response of the electrode with and without membrane were examined under three operational conditions: (1) a pH edge titration where the amount of metal sorbed on the sediment was measured over a range of pH conditions; (2) drift of electrode potential with time due to NOM accumulation on the surface; and (3) offset in Nernstian calibration due to NOM accumulation.

For pH edge experiments, 1.1 g l^{-1} sediment was resuspended in 100 ml containing about 10^{-4} M Cd in 0.05 M KCl and brought to pH 3 by addition of 0.1 M HCl. The mixture was equilibrated in the titration reactor for 30 min in presence of precalibrated pH and ISE electrodes. Titration commenced with addition of 0.1 M NaOH at equal pH intervals until pH 10 where precipitation of Cd hydroxides dominated the system.

Eight experiments were performed in order to determine electrode drift. In each case, an ionic strength of 0.01 M $NaNO_3$ and a pH of 4.5 were maintained. The value of pH was determined from previous exposures to NOM and corresponds to the point of maximum electrode bias. Sediment were monitored, both with 10^{-4} Cd and without, and both with and without a membrane. Control solutions containing deionized H_2O in place of the sediment suspension were also monitored under the same conditions.

For offset in Nernstian calibration, the electrode was placed in a sediment solution, prepared as described above, and the suspension was adjusted to a particular pH, ranging from 4 to 6. This range corresponds to the greatest deviation in electrode response from the edge experiments. The total exposure time ranged from 0 to 3 h. The 'fouled' electrode was then placed in a series of $Cd(NO_3)_2$ standards at the same pH as the sediment and the Cd responses were measured. A similar series of experiments were performed with the electrode covered with the membrane.

3. Results and discussion

3.1. pH edge titrations

At low pH, sediment exists in a protonated form. As the pH of a sediment and metal suspension increases, protons on the sediment exchange with metal ions in solution and the total free metal concentration should decrease. However, free cadmium concentration appeared to increase with pH during a pH edge titration and suggested that more cadmium was present in the system than was originally added (Fig. 1a,b). In this experiment the exposure of the electrode to NOM was controlled by increasing the time interval between titrant addition. This additional cadmium did not come from the sediment since ICP-MS analysis of the sediment indicated cadmium at 14 μg g^{-1} [8], which is equivalent to 0.0485 μmol $^{-1}$ l and is not significant. A control experiment without cadmium (not shown) resulted in a similar increase in electrode potential for the same pH range, indicating electrode bias. In contrast (Fig. 1a,b), the membrane-coated electrode showed Cadmium to be free until pH 6.7 and progressively bound afterwards.

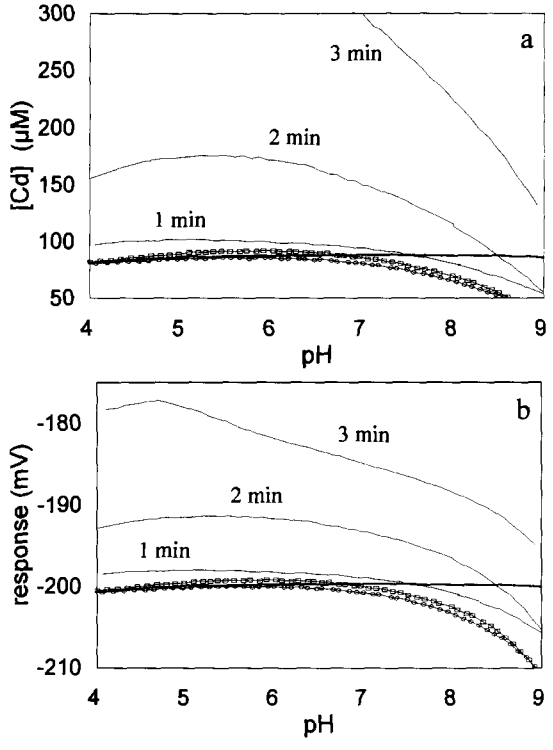

Fig. 1. Distortion of pH edge profile for Cd adsorption on 1 g l^{-1} suspended sediments. (a) Concentration expressed as molarity; and (b) concentration as electrode potential. Titrations were done with both an unprotected, and a membrane protected electrode. Thin lines: unprotected electrode at the indicated time interval. Symbols: membrane protected electrode at [○], 2 min, and [□], 5 min intervals. The thick line is a control without membrane and without sediments. Parameter optimization for Langmuir fit is shown in Table 1.

Similar results by Qi et al. [3] for Cd ISE exposed to complexing agents showed an enhanced electrode response above the total amounts added. Exposure to the complexones EDTA, EDTA and NTA without Cd addition showed a Nernstian response to ligand concentration. But the response did not work with weaker ligands such as citrate, tartrate or NH_3, suggesting that the Cd binding constant of the ligand must be very high to produce a bias. Sekerka and Lechner [4] found the same Nernstian behaviour using Cu ISE exposed to the above three complexones and also with humic acids. Gulens [11] proposed that the artificially high Cu concentration is caused by the ligand inducing dissolution of the electrode surface. In our case, for Hamilton harbour suspended sediments, the low molecular weight NOM that would pass through the membrane is either absent or, if present, would not be a ligand strong enough to produce the Nernstian response observed for complexones.

3.2. Drift

Our results show two distinct alteration processes occurring at the membrane surface. The first one is possibly oxidation of the exposed surface and occurs any time the electrode is exposed to molecular oxygen [6]. The drift is constant in time (Fig. 2) and shows a small increase in drift slope when Cd concentration is increased ten-fold.

The second process arises from exposure of the electrode to NOM. In Fig. 2, both solutions with and without sediments containing 10^{-4} M cadmium show a linear increase in electrode response with time. In the sediment suspension, the drift is

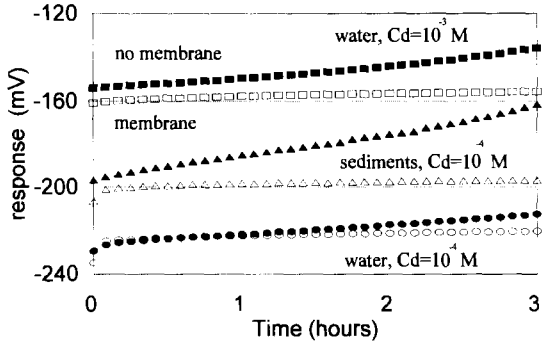

Fig. 2. Effect of drift on the Cd(II) ISE for water and sediment solutions at 10^{-4} M Cd, both with and without a dialysis membrane. [●], water blank without membrane; [○], water blank with membrane; [▲], sediment suspension without membrane; [△], sediment suspension with membrane; [■], 10^{-3} M Cd standard without membrane; and [□], 10^{-3} M Cd standard with membrane. The 10^{-4} M water blank was shifted by −30 mV for clarity.

more extreme, the difference owing entirely to the presence of NOM. Drift due solely to NOM is estimated to be 6.4 mV h^{-1} by difference from the water control. Since this offset disappears when the membrane is in place, the interference to the electrode surface can be attributed to colloidal NOM, above the 12 000–16 000 MW cut-off of the dialysis tubing.

Organic matter affecting the surface of the electrode would alter the Nernstian response as well. Fig. 3 demonstrates the degradation of the Nernstein response after exposing the Cd(II) ISE to

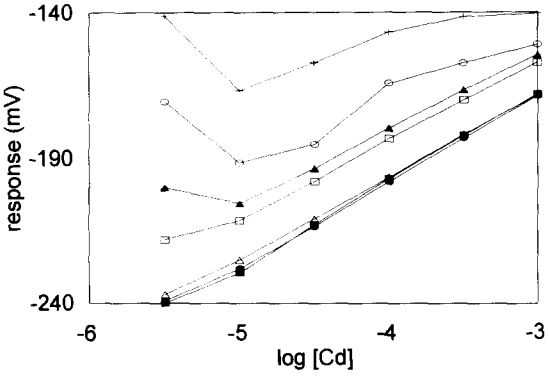

Fig. 3. Calibration without dialysis membrane. Exposure conditions: [+], pH 4, 3.5 h exposure; [○], pH 6, 3 h exposure; [▲], pH 5, 2 h exposure; [□], pH 4, 1.25 h exposure; [●], natural pH, 5 min exposure; [△], no exposure, with membrane; and [■], no exposure, no membrane.

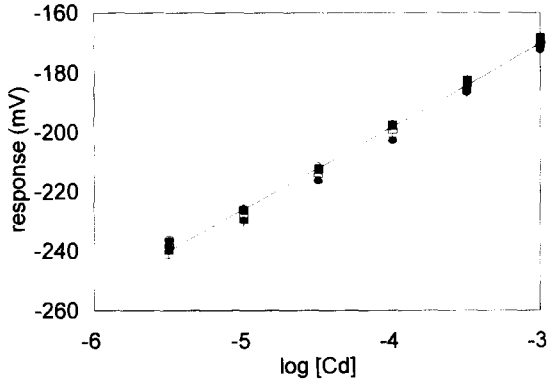

Fig. 4. Calibration with the dialysis membrane. Exposure conditions: [■], no exposure, no membrane; [●], no exposure, with membrane; [▲], pH 4, 2 h; [+], pH 4, 0.5 h; [□], pH 6, 1.25 h; [○], pH 6, 3.5 h; and [△], pH 5, 2 h.

sediment for extended periods of time, without membrane protection. As both exposure time and pH increase, the deviations from the expected Nernstian response increase. In contrast, Fig. 4 demonstrates that the membrane prevents NOM contamination regardless of solution pH or exposure time.

If we assume that the electrode surface is an adequate model for the surface of a resuspended natural sediment particle, it follows that only large molecular NOM, presumably humic acids, can significantly alter surface properties of aquatic suspensions. This effect is important since coatings of NOM on suspended particles are recognized as an important agent in metal exchange with the bulk solution and in controlling surface charge [12–14].

Generally, the membrane appears to reduce significantly the drift due to oxidation and NOM fouling. We do not know how this occurs. It is also unclear what kind of binding occurs between the organic matter and the surface but the fact that only colloidal substances have an effect suggests that NOM act as surfactant on natural particles.

3.3. *Effect on adsorption parameters*

Electrode drift during a continuous titration can introduce unaccounted biases in the profile

causing erroneous parameter evaluation. For pH edge titrations, adsorption on surfaces is generally a Langmuirian exchange between protons and free metal. Fu and Allen [15] have tested adsorption models based on 1:1 and 2:1 exchanges and found the predominant sites to follow a 1:1 exchange. Similar conclusions were reached by Bourg and Mouvet [16]. We therefore assume:

$$\equiv SOH + H^{2+} = \equiv SOM^{+} + H^{+} \quad (1)$$

and ignore the electrostatic terms associated with surface charge. The profile for adsorbed metal, Γ, is therefore:

$$\Gamma = M_T - [M^{2+}] = \frac{\Gamma_{MAX}[M^{2+}]}{\frac{[H^{+}]}{K} + [M^{2+}]} \quad (2)$$

where Γ_{MAX} is the total available surface site concentration (M), K is the stability constant for the equation I, M_T is the total exchangeable metal, and H^{+} is the proton concentration.

Of interest is how this function is distorted when we introduce a drift in the measurement of metal concentration. To do so, Eq. (2) is expressed as a function of the free metal:

$$[M^{2+}] = M_T - \frac{\Gamma_{MAX}[M^{2+}]}{\frac{[H^{+}]}{K} + [M^{2+}]} \quad (3)$$

We then adjust Eq. (3) to a series of pH edge titration data of suspended sediments (Fig. 1), under an increasing time interval, and for both electrode conditions. Non-linear curve fitting (Levenberg-Marquard minimization method) was used to obtain optimized values for $[M_T]$, Γ_{MAX} and K (Table 1). In spite of our lower sediment concentration (1 g l^{-1} versus 50 g l^{-1}), K and Γ_{MAX} in this experiment are both greater by about two orders of magnitude than the samples analyzed by Fu and Allen [15]. We attribute this difference to the air-drying step they used to remove reduced materials. We think that drying of the sediment could have decomposed some of the organic matter and/or forced the floc structure of the sediment particles to collapse. This would cause a reduction in the available surface sites for metal binding.

Fig. 3 shows that a greater time interval increases the duration of titration and, therefore, allows a greater bias due to fouling. Thus, although the unprotected electrode at 3 min time interval shows distorted estimates for M_T (Table 1), the protected electrode can still match the control at 5 min interval. The results are consistent with Fig. 1 and Fig. 2.

3.4. Sensitivity analysis

Adjustment of parameters by the Levenberg-Marquard method returns a sensitivity analysis useful for determining the pH range where a particular parameter is more important. Fig. 5 expresses sensitivity as a dimensionless ratio of the change in Eq. (3) resulting from a unit change in the value of the parameter. The binding function is essentially dominated by estimates for total metal at pH values lower than the binding constant. Past this point, its influence decreases somewhat and the other two parameters increase their influence only at a pH near 9. However, the titration would loose its value at that point since the precipitation of cadmium oxides becomes a

factor. Fig. 5 nevertheless shows why large uncertainties in Γ_{MAX} and K (Table 1) can still arise in spite of a good overall fit. This analysis exemplified the false security in using goodness of fit or correlation as sole indicators of the suitability of a parameter.

4. Conclusions

Metal binding studies using ISE electrodes as indicators of free metal are biased by a drift in potential probably caused by oxidation of the surface and by NOM coating the surface. The drift increases linearly in time and causes serious distortions to estimates from binding models. Effects are small if the electrode is inserted in the suspension only for short periods of time, and if regularly cleaned and calibrated between measurements.

The impact is severe when the electrode is part of an automated titration procedure since recalibration and cleaning are no longer possible. In this case, the use of a membrane to protect the electrode surface reduces both kinds of drift. The membrane probably prevents the first kind by hindering the flow of oxidant from the bulk solution to the electrode surface. In the second case, the membrane protects the electrode surface from contact with the high molecular weight colloidal fraction. The low molecular weight NOM has no effect and, presumably, does not coat the surface. By analogy, results suggest that only organic matter greater than 12 000–16 000 Da in size would be found on the surface of natural aggregates.

Short communication

Use of dichloromethane with dithizone as an alternative solvent to carbon tetrachloride restricted by Montreal Protocol

A.M. Kiwan

Received 24 June 1996; received in revised form 17 October 1996; accepted 21 October 1996

Abstract

The spectral characteristics of dithizone and its metal complexes were measured in dichloromethane as an alternative solvent to carbon tetrachloride which will be illegal to manufacture by the year 2000, according to the revised Montreal Protocol. The extraction equilibria of its metal complexes were also reported and discussed. Dichloromethane was found to enhance the sensitivity of dithizone towards Co(II), Cu(II), Hg(II), Pb(II), Zn(II), Bi(III), Ag(I), In(III) and Tl(I). It was also found to be a better solvent than carbon tetrachloride for the separation of Cd(II) from Zn(II) and for the separation of Co(II) from Ni(II). © 1997 Elsevier Science B.V.

Keywords: Dithizone; Dichloromethane; Extraction; Metal Complexes

1. Introduction

In view of its unique position among organic analytical reagents, dithizone, (Ph–N=N–C(=S)–NH–NH–Ph); 3-mercapto-1,5-diphenylthiocarbazone; phenyl azothioformic acid 2-phenylhydrazide as is listed in the Chemical Abstracts, is a well known S, N chelating ligand. There is a very rich literature comprising over 3000 published articles, extended reviews and special chapters in books [1–8]. Two special books are also devoted to its wide applications in analytical chemistry [9,10].

Dithizone reacts with 20 metals and several organometals to form highly coloured chelate complexes [8,9]. As dithizone and its metal complexes are insoluble in water but soluble in organic solvents, carbon tetrachloride was extensively used with dithizone in liquid–liquid extraction techniques for the separation and spectrophotometric determination of trace metals and organometals in various matrices [6–10].

Although other analytical techniques such as atomic absorption, inductively coupled plasma, atomic fluorescence spectrometry are used due to their higher sensitivities and certainly require less technical skill and experience for successful operation, this tendency will continue. At the same time, however, the use of dithizone for preconcentration of trace metals prior to their determina-

PII S0039-9140(96)02135-2

tion by highly sensitive methods is continuing [11–15].

In view of its ozone-depleting property, carbon tetrachloride was included among the compounds controlled by the revised Montreal Protocol which was agreed upon in London revision meeting of 1990 [16]. According to the terms of agreement, the production of carbon tetrachloride was to be frozen at 1989 level starting 1991 and to be cut by 85% from 1995 and to become completely banned from 2000.

The present paper reports our results on the use of dichloromethane as an alternative safer solvent to carbon tetrachloride for analytical applications with dithizone. The environmental safety of dichloromethane may be attributed [16] to its very short atmospheric lifetime, so it does not rise into the atmosphere and cause the same problems as carbon tetrachloride or the CFC's.

The spectral characteristics of dithizone and its metal complexes in dichloromethane are described. The extraction equilibria and $pH_{1/2}$ values of metal dithizonates are also reported and discussed in comparison with the corresponding data in carbon tetrachloride.

2. Experimental

2.1. Reagents and materials

Dithizone, dichloromethane, sodium perchlorate, sodium acetate and metal salts were A.C.S. (Aldrich) reagent quality. Solutions of dithizone in dichloromethane were purified by applying a similar procedure to that used for purifying solutions of dithizone in carbon tetrachloride or chloroform [7,18,19]. Deionized water was used throughout. Buffered (pH < 7) sodium perchlorate solutions were purified from traces of metals by scrubbing with solutions of dithizone in dichloromethane prior to use.

2.2. General procedures

The spectral characteristics (λ_{max} and ε_{max}) of both dithizone in dichloromethane were determined, as was done with chloroform and carbon tetrachloride [7,20,21]. The visible spectra of dithizone and its metal complexes were recorded on a Shimadzu double-beam UV-visible scanning spectrophotometer model UV-2101 PC. Metrohm 691 pH-meter was used for pH measurements.

The extraction constants (K_{ext}) of metal complexes were determined by equilibrating 5 cm^3 aliquots of dichloromethane containing known amounts of dithizone in stoppered glass tubes with equal volumes of sodium perchlorate (0.5 M) sodium acetate (0.02 M) mixture at different pH values in the presence of known amounts of metal ions. Preliminary experiments showed that the equilibrium was attained in ca. 30 min for Ni(II) complex and ca. 15 min for the rest of metal complexes. The extraction constants of $Hg(HDz)_2$ and $Cu(HDz)_2$ were carried out in presence of potassium iodide and EDTA, respectively, according to methods suggested by Takei and Kato [17]. The equilibrium concentrations of the dithizone and its metal complexes were determined spectrophotometrically, whereas the concentrations of metal ions in aqueous solutions were determined by difference; $[H^+]$ was calculated from the pH of the aqueous phase.

3. Results and discussion

Dithizone dissolves readily in dichloromethane (12.6 g l^{-1}, 30°C) [9] to give green solution with two distinct absorption bands with maxima at 609 and 445 nm, respectively (Table 1). These λ values agree with those reported by Koskinen [22], but our values of ε_{max} (Table 1) are slightly higher. Both bands are slightly shifted to lower wavelengths compared to the corresponding λ_{max} values of 620 and 450 nm, respectively, in carbon tetrachloride [9,10]. The solution of dithizone in dichloromethane was found to be stable for at least six days if kept refrigerated.

The spectral data summarized in Table 1 indicate that ε_{max}, 1 and ε_{max}, 2 of dithizone are considerably higher than the corresponding values in carbon tetrachloride. These findings suggest also that dichloromethane is a superior solvent to carbon tetrachloride since it enhances its sensitivity as a spectrophotometric reagent. Its sensitivity

as measured by ε_{max}, 1 and ε_{max}, 2 is close to that in chloroform, the other solvent which has been used extensively as a solvent with dithizone [7,10]. Both solvents have higher dielectric constants and dipole moments than carbon tetrachloride which may be partially responsible for increasing the molar absorptivities of dithizone.

3.1. Spectral characteristics of dithizone metal complexes in dichloromethane

It is known that dithizone reacts with metal ions to give highly coloured neutral chelates according to Eq. (1).

$$n\mathrm{H_2Dz_{org.}} + \mathrm{M_{aq}^{n+}} \overset{K_{ext}}{=} \mathrm{M(HDz)_{n_{org.}}} + n\mathrm{H_{aq.}^{+}} \qquad (1)$$

which can be extracted into organic solvents. The spectral data of several metal dithizonate complexes in dichloromethane are also given in Table 1 together with the corresponding values in carbon tetrachloride [8,10]. These spectral data indicate that the λ_{max} values of Cd(II), Co(II), Cu(II), Pb(II), Zn(II) were slightly shifted to lower wavelengths whereas their ε_{max}, 1 values increased by ca. 2 to 24%.

Although λ_{max}, values of mercury(II), Bi(III), Ag(I) and In(III) have been slightly shifted towards longer wavelengths nevertheless, their ε_{max} values have also increased by ca. 3–46%. So, in addition to being a safer alternative solvent to carbon tetrachloride, dichloromethane was found to enhance the sensitivity of dithizone towards most metal ions.

3.2. Extraction equilibria of metal dithizonate complexes in dichloromethane

Table 1 gives the extraction constants and the $pH_{1/2}$ values for metal dithizonates in dichloromethane as well as in carbon tetrachloride for comparison and the following conclusions may be drawn from those data.

1. The much higher $pH_{1/2}$ value of dithizone in dichloromethane (10.35) than the corresponding value (8.88) in carbon tetrachloride suggests that dithizone has a higher partition coefficient in the former solvent.
2. The K_{ext} values of metal dithizonate complexes in dichloromethane are generally lower than the corresponding values in carbon tetrachloride. On the other hand, the $pH_{1/2}$ values of metal dithizonate complexes in dichloromethane are higher than the corresponding $pH_{1/2}$ values in carbon tetrachloride. The $pH_{1/2}$ values of metal-ligand complexes may be considered indicators of the bonding strength of dithizone towards a particular metal in a particular two phase system. These relatively lower values of K_{ext} and $pH_{1/2}$ in CH_2Cl_2 than the corresponding values in CCl_4 may be attributed to the lower dipole moment and lower polarity of the latter solvent (CCl_4) [22].
3. Dichloromethane was found to be a better solvent than carbon tetrachloride or chloroform in the separation of cadmium(II) from zinc(II) as shown in Fig. 1. This solvent effect in enhancing the separation of Cd(II) from Zn(II) dithizonate complexes may be also attributed to the relatively higher polarity of dithochloromethane as well as its higher dipole moments. It is known that both Zn(II) and

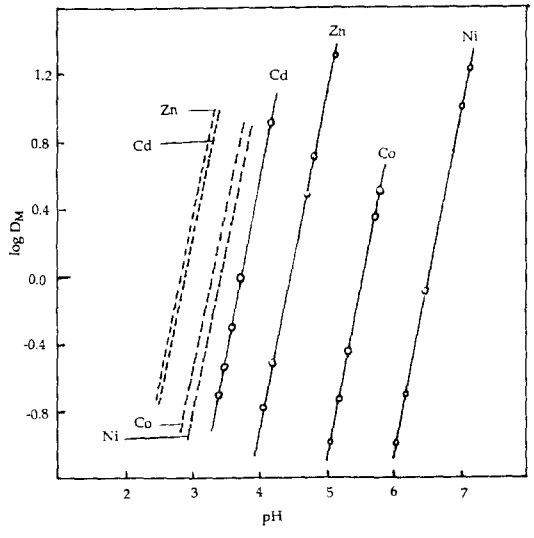

Fig. 1. log D_M (distribution coefficient), where M is Cd or Zn, Co or Ni vs. pH. Calculated from K_{ext} based on the assumption that 1.0×10^{-4} M dithizone is used as the extractant in CH_2Cl_2 (——) or CCl_4 (— - - —). Aq. phase: 0.5 M $NaClO_4$,–0.2 M sodium acetate.

Cd(II) have comparable electronic configuration viz., [Ar] $3d^{10}$ and [Kr] $3d^{10}$ respectively, through their different effective ionic radii viz., 74 pm and 95 pm [23] respectively seem to play a role in enhancing the selectivity of reaction with dithizone in dichloromethane. Similar results of improving the separation of Cd(II) from Zn(II) were reported by modifying the structure of dithizone by introducing certain substituents in the phenyl nuclei of dithizone, thus increasing the selectivity of the dithizone analogue towards one of the two metals [24–26].

4. Dichloromethane was also found to be a better solvent than carbon tetrachloride or chloroform for the separation of Co(II) from Ni(II) as shown in Fig. 1.
5. The $pH_{1/2}$ values (Table 1) also indicate that dichloromethane is a better solvent for the separation of Pb(II) from Ni(II) or Co(II). On the other hand, dichloromethane seems to be inferior to carbon tetrachloride for the separation of Cu(II) from Bi(III) or Zn(II) from Pb(II).

Cyclodextrin enhanced fluorimetric determination of malonaldehyde by the thiobarbituric acid method

Sofia Erazo Castrejón, Anatoly K. Yatsimirsky *

Facultad de Química, Universidad Nacional Autónoma de México, 04510 México D.F., México

Received 15 July 1996; received in revised form 14 October 1996; accepted 18 October 1996

Abstract

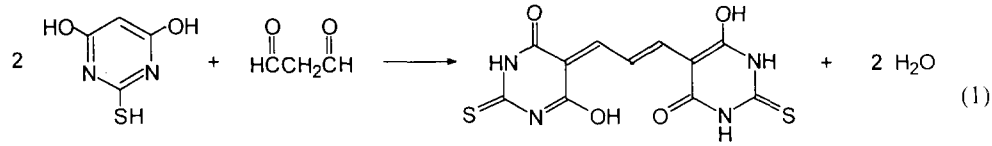
The enhancement effects of α-, β-, γ- and hydroxypropyl-β-cyclodextrins on the fluorescence of a 2:1 thiobarbituric acid/malonaldehyde adduct in acid aqueous solutions have been studied. The best characteristics as a fluorescence enhancement agent showed hydroxypropyl-β-cyclodextrin which bound the adduct sufficiently tightly ($K = 180$ l mol^{-1}) and caused a five-fold increase in its fluorescence. A kinetic-fluorimetric method of determination of malonaldehyde in the range 0.1–10 μM at room temperature with hydroxypropyl-β-cyclodextrin as the enhancement agent is proposed and applied for the analysis of raw and cooked meat samples. © 1997 Elsevier Science B.V.

Keywords: Cyclodextrin; Malonaldehyde; Thiobarbituric acid

1. Introduction

The thiobarbituric acid (TBA) method is the most widely used test for measuring the extent of oxidative deterioration of lipids [1–10]. In this method TBA reacts at 60–95°C with malonaldehyde (MA), a degradation product of lipid hydroperoxides, to give a red fluorescent 1:2 MA/TBA adduct (TMT), reaction Eq. 1, [11] which usually is quantified spectrophotometrically at 525-532 nm [2–11].

Although TMT possesses a very high, ca. 1.6×10^5 l mol^{-1} cm^{-1}, molar absorptivity [8], the method is considered not sufficiently sensitive [9]. To achieve a higher sensitivity a solid phase extraction method [9], different variants of extraction-fluorimetric [4,12–16], and, recently, a kinetic-fluorimetric [17] TBA methods of determination of MA have been proposed. The extraction fluorimetry allows one to determine as low as 0.1 μM MA and the kinetic–fluorimetric method even 15 nM (1.1 ng ml^{-1}), although the reasons of this enhanced sensitivity are not clear.



(1)

TBA MA TMT

PII S0039-9140(96)02141-8

Actually, the limit of detection of 0.1 μM is very close to that of the spectrophotometric procedure and therefore a simple fluorimetric determination of MA does not give any considerable improvement. However, a fluorimetric method frequently can be further improved by use of cyclodextrin (CD) solutions as reaction media due to the complexation-induced fluorescence enhancement effect [18,19]. A hydrophobic character of TMT, manifested in its extractability into organic solvents [4,8,14,15], is indicative of its ability to form the inclusion complexes. Therefore, it seems logical to test CDs as fluorescence enhancement agents for MA determination.

This paper reports a study of CD effects on the TMT fluorescence in aqueous acid medium. The expected enhancement effects have been observed and used for the development of a kinetic–fluorimetric method, which possesses the sensitivity of conventional fluorimetric or spectrophotometric determination with prolonged heating, but operates at room temperature. A method of MA determination avoiding the heating is desirable because it makes possible determination of free MA, unbound to proteins, amino acids and other sample components [1,5]. The bound forms of MA are thought to be destroyed by heating and, therefore, the conventional TBA methods measure total MA of a sample. Evidently, a combination of low and high temperature methods can be used when determination of both free and bound MA is necessary.

2. Experimental

2.1. Materials

TBA, malonaldehyde bis(diethyl acetal), α-, β-, and γ-cyclodextrins (Aldrich), butylated hydroxytoluene (Sigma), hydroxypropyl-β-cyclodextrin (HP-β-CD) (Amaizo), and 70% perchloric acid (Mallinkrodt) were used as obtained without further purification. All solutions were prepared in purified (Milli-Q Reagent Water System) water.

2.2. Instrumentation

Fluorescence measurements were made on a FluoroMax SPEX spectrofluorometer and absorption spectra were recorded on a Hewlett Packard 8452A diode array spectrophotometer. Both instruments were equipped with thermostated cell holders and magnetic stirrers.

2.3. Procedures

Fluorescence intensity was measured at 548–553 nm, depending on reaction conditions, with the excitation wavelength 520 nm. Absorption was measured at 532 nm. All fluorescence intensities and absorbances were corrected for the respective background signals by use of appropriate blanks.

A stock solution was prepared weekly by dissolving 22.0 mg malonaldehyde bis(diethyl acetal) in 100 ml of water. Working solutions of MA were made daily by diluting the stock solution with 0.1 M $HClO_4$ and subsequent heating in a boiling water bath for 5 min to ensure the complete hydrolysis of the acetal [6]. A 0.03 M standard solution of TBA was prepared by dissolving a weighed amount of solid TBA in water.

2.4. Cyclodextrin effects on TMT fluorescence

0.1 μM TMT solution was prepared by heating the mixture of 0.1 μM MA and 0.015 M TBA in 0.05 M $HClO_4$ in a boiling water bath for 15 min and subsequent cooling with cold tap water. Then a weighed amount of the solid CD was dissolved in a portion of TMT solution to obtain the highest concentration of a given CD and the intermediate concentrations were obtained by mixing this and initial TMT solutions at different proportions.

2.5. Analytical procedures

The basic procedure of the sample (raw beef and smoked pork) treatment was the same as in [9]. Ground meat (10 g) was homogenized with 40 ml of 0.1 M $HClO_4$ for 1 min. Butylated hydroxytoluene (20 mg) was added before the homogenization to prevent the autoxidation of the blend during homogenization. The blend was centrifuged (Damon/IEC HT Division) at 10 000 × *g* for 5 min, the supernatant was filtered through Whatman paper No. 5 into a 50 ml volumetric flask and the volume was adjusted to 50 ml with 0.1 M perchloric acid.

These extracts were analyzed by the conventional TBA spectrophotometric method, following in general the procedure described in [5], and by the new fluorimetric procedure proposed in this paper.

2.5.1. Spectrophotometric method

To 2.0 ml of the extract 2.0 ml of 0.03 M TBA were added and the mixture was incubated for 15 min at 94°C in a water bath. Then the mixture was cooled by tap water and its absorbance at 532 nm was measured. The calibration graph was constructed using the absorbances of the mixtures of 2.0 ml of 0.1–10 μM MA working solutions in 0.1 M perchloric acid with 2.0 ml of 0.03 M TBA treated as described above for the sample solution.

2.5.2. Fluorimetric method

A solution containing 0.03 M TBA and 0.07 M HP-β-CD was prepared by dissolving a weighed amount of HP-β-CD in TBA solution. To 1 ml of this solution, placed in a stirred fluorimetric cell, 1 ml of the working MA or sample solution, containing 0.1 M $HClO_4$, was added and the fluorescence recording started. Construction of the calibration graph is described in the text.

3. Results and discussion

3.1. Cyclodextrin effects on the fluorescence of TMT

Reported emission maxima for TMT vary from 547 to 553 nm [16], probably, due to some differences in reaction media. The excitation maximum should coincide with the absorption maximum (532 nm), but some authors [14,15,17] use shorter excitation wavelengths, between 515 and 525 nm, in order to minimize the effect of Rayleigh scattering, which strongly disturbs the emission spectra when the excitation wavelength lies near the emission maximum. We found that with the excitation wavelength 520 nm Rayleigh scattering does not disturb the region of the emission maximum and the fluorescence intensity is high enough to detect 0.1 μM TMT, which is a typical sensitivity of the fluorescence determinations.

Fig. 1 Fig. 2 Fig. 3 Fig. 4 show the effects of different cyclodextrins on the fluorescence of TMT in aqueous acid solution. The acid medium was used because reaction Eq. 1 is known to be acid-catalyzed and all variants of the TBA method employ acid solutions with pH values in the range 1–3 [4]. Evidently, all cyclodextrins cause a fluorescence enhancement. With α-cyclodextrin, Fig. 1, the effect is very modest, ca. 50% at the highest cyclodextrin concentration, and the fluorescence intensity versus cyclodextrin concentration plot does not show any tendency to saturation. On the contrary, it deviates from linearity in a way, which implies the involvement of a quadratic term in α-cyclodextrin concentration. The best fit of the results gives Eq. (2)

$$I(\text{cps}) = 1160 + 3160[\alpha\text{-CD}] + 35100[\alpha\text{-CD}]^2 \quad (2)$$

where I is the fluorescence intensity.

These observations indicate that the binding constant of TMT to α-cyclodextrin is very small and, probably, the inclusion complex has 2:1 α-CD/TMT stoichiometry.

Other cyclodextrins show higher enhancement effects and typical for the formation of 1:1 inclusion complexes hyperbolic plots [20], which fitted well to the theoretical Eq. (3)

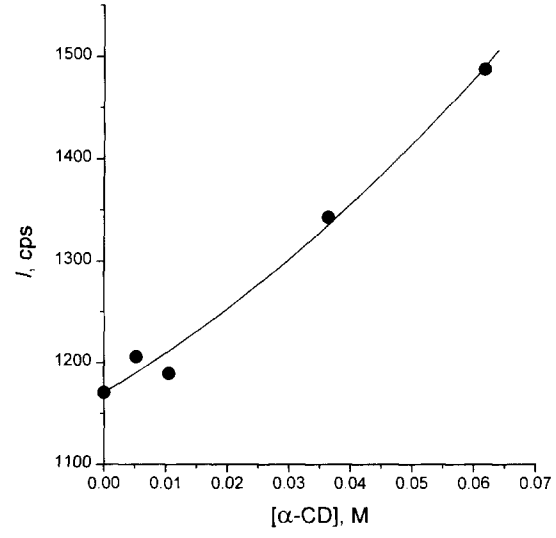

Fig. 1. The fluorescence intensity (counts s^{-1}, cps) of 0.1 μM TMT in 0.05 M $HClO_4$ at 553 nm (excitation wavelength 520 nm) versus α-CD concentration. The curve is the fitting profile calculated from Eq. (2).

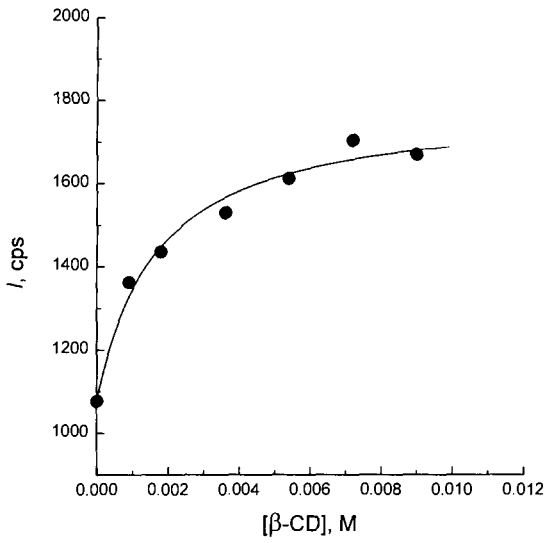

Fig. 2. The fluorescence intensity (counts s^{-1}, cps) of 0.1 μM TMT in 0.05 M $HClO_4$ at 544 nm (excitation wavelength 520 nm) versus β-CD concentration. The curve is the theoretical profile calculated from Eq. (3) with parameters given in Table 1.

$$I(\text{cps}) = \frac{I_0 + I_C K[\text{CD}]}{1 + K[\text{CD}]} \quad (3)$$

where I_0 and I_C are the fluorescence intensities of free and complexed TMT and K is the binding constant. The parameters of Eq. (3) for β-, γ- and HP-β-CD are given in Table 1.

Additions of these cyclodextrins induced both fluorescence enhancements and shifts in the emission wavelength maximum of TMT from 553 nm in water to 544 nm in the presence of β-CD and 548 nm in the presence of γ- and HP-β-CDs. Such blue cyclodextrin-induced shifts are typically observed for different analytes [19]. Also typical is a weaker binding of TMT to HP-β-CD than to unsubstituted β-CD [19]. The general trend in the binding constants, α-CD < γ-CD < HP-β-CD < β-CD, can be interpreted in such a way that the cavities of α-CD and γ-CD are, respectively, too small and too big for the complementary inclusion of TMT, which is a requisite for the tight binding. At the same time, the fluorescence enhancement factor, evaluated as the ratio I_C/I_0, Table 1, increases in the order β-CD < HP-β-CD < γ-CD, indicating the cavity volume and not the tightness of the binding to be the dominant factor. This observation is in agreement with a general conclusion regarding the mechanism of CD-induced fluorescence enhancement, which is attributed to the protection of the bound analyte from the quenching by water molecules [19].

The highest value of the ratio I_C/I_0 was found for γ-CD, but the use of this CD is impractical due to the very small binding constant of TMT and, consequently, the necessity to apply very high concentrations of this expensive CD. The highest binding constant is observed for β-CD, but the enhancement factor for this CD is less than 2. An optimum between the binding ability and the enhancement factor is reached with HP-β-CD. The standard calibration curve of the fluorescence intensity versus TMT concentration in the presence of 0.035 M HP-β-CD obeys the equation (obtained using seven different analyte concentrations and blank, each measured three times)

$$I(\text{cps}) = (120 \pm 10) + (37 \pm 2)[\text{TMT}] \quad (4)$$

where [TMT] is in nM. The limit of detection, calculated by 3 × (S.D. in the intercept)/(slope), equals 0.8 nM and the application range is between 1.5 and 50 nM.

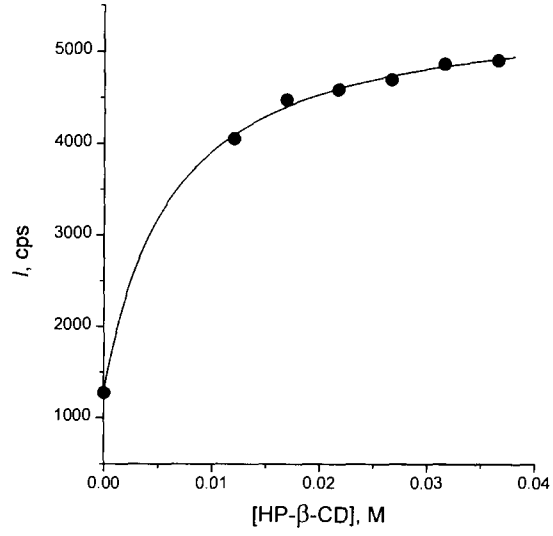

Fig. 3. The fluorescence intensity (counts s^{-1}, cps) of 0.1 μM TMT in 0.05 M $HClO_4$ at 548 nm (excitation wavelength 520 nm) versus HP-β-CD concentration. The curve is the theoretical profile calculated from Eq. (3) with parameters given in Table 1.

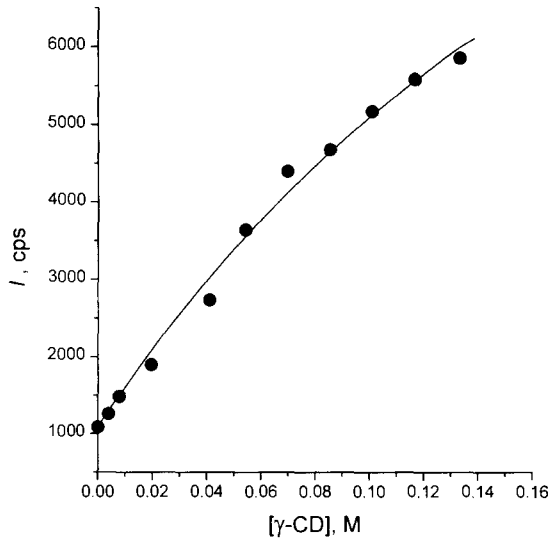

Fig. 4. The fluorescence intensity (counts s^{-1}, cps) of 0.1 μM TMT in 0.05 M $HClO_4$ at 548 nm (excitation wavelength 520 nm) versus γ-CD concentration. The curve is the theoretical profile calculated from Eq. (3) with parameters given in Table 1.

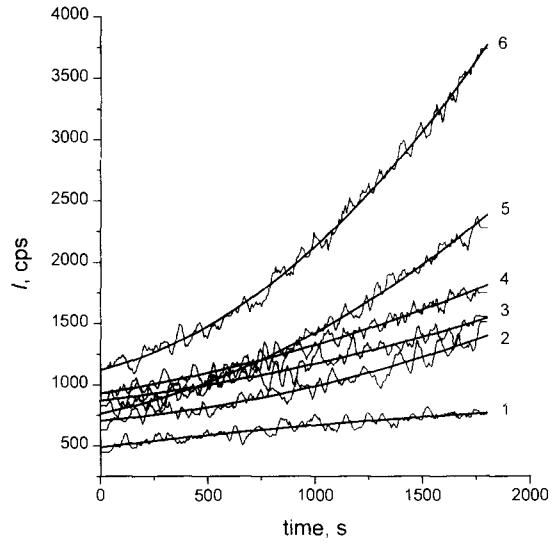

Fig. 5. The fluorescence intensity at 548 nm (excitation wavelength 520 nm) versus time profiles for the reaction of MA with 0.015 M TBA in the presence of 0.035 M HP-β-CD in 0.05 M $HClO_4$ at 25°C. Curves 1–6 correspond to MA concentrations 0; 0.08; 0.15; 0.3; 0.6 and 1.0 μM. Solid thick lines are the fitting profiles calculated with Eq. (5).

Such high sensitivity allows one to detect MA at a nM level, but it also can be useful for the development of a method with 'normal' sensitivity, i.e., in the range 0.1–10 μM, which would not need a prolonged heating for the conversion of MA into TMT. Reaction Eq. 1 is slow and the heating, usually at 60–95°C, is necessary to make the reaction time reasonably short, usually 10–60 min. The HP-β-CD enhanced fluorimetric method allows one, however, to detect 0.1 μM MA when only 1% of the aldehyde is converted into TMT. One can expect that such a low conversion can be achieved during 60 min or less even at room temperature and this prompted us to investigate such a possibility.

Table 1
Parameters of Eq. (3) for different cyclodextrins at 25°C in 0.05 M $HClO_4$

Cyclodextrin	I_0, cps	I_C, cps	K, $l \cdot mol^{-1}$	I_C/I_0
β-CD	1080 ± 30	1800 ± 40	600 ± 100	1.7
HP-β-CD	1100 ± 30	5500 ± 200	180 ± 30	5.0
γ-CD	1080 ± 30	16 400 ± 3000	3.5 ± 1.0	15.2

3.2. Kinetic-fluorimetric HP-β-CD enhanced determination of MA

In preliminary experiments we investigated the stability of TBA solutions in the presence of HP-β-CD in acid media. Unexpectedly, a slow formation of an unidentified yellow product was observed. Fortunately, this color did not interfere with TMT fluorescence under conditions employed.

Fig. 5 shows some typical fluorescence versus time profiles obtained in the presence of 0.035 M HP-β-CD at room temperature. In accordance with data of Espinosa-Mansilla et al. [17] the plots are curved downward. Such curvature may indicate a chain mechanism, autocatalysis or a mechanism which involves several consecutive steps, the colored TMT product being formed in the last of them. A detailed mechanistic study of reaction Eq. 1, which will be published elsewhere,

Table 2
Determination of MA in raw beef and smoked pork by the proposed kinetic–fluorimetric method at room temperature and by conventional spectrophotometry

Sample	Method	Equation of calibration graph	MA added, (mg kg^{-1})[a]	MA found,[b] (mg kg^{-1})[a]	Recovery, %
Raw beef	Kinetic –fluorimetric	Eq. (6)	0	0.15 ± 0.03	
			1.05	1.47 ± 0.07	126
			2.1	2.81 ± 0.07	125
		Eq. (7)	0	0.10 ± 0.01	
			1.05	1.10 ± 0.02	96
			2.1	2.45 ± 0.06	93
	Spectrophotometric		0	0.14 ± 0.01	
			1.05	0.85 ± 0.01	67
			2.1	1.48 ± 0.01	64
Smoked pork	Kinetic –fluorimetric	Eq. (6)	0	0.035 ± 0.002	
			1.14	0.98 ± 0.01	83
			2.3	1.97 ± 0.08	84
		Eq. (7)	0	0.041 ± 0.004	
			1.14	0.85 ± 0.01	71
			2.3	1.58 ± 0.07	67
	Spectrophotometric		0	0.084 ± 0.004	
			1.14	0.92 ± 0.01	73
			2.3	1.80 ± 0.02	75

[b] Errors are the standard deviations from three measurements.

shows the last option to be correct. In any case, the curvature does not allow one to use the slopes of kinetic curves for the construction of the calibration graph. We used therefore the fixed time method in the following modification: the kinetic curves (I at 548 nm versus time (t) profiles) were fitted to a quadratic Eq. (5) and the values of ΔI at $t = 15$ min (ΔI_{15}) and $t = 30$ min (ΔI_{30}) were calculated as the differences between the respective calculated values of I and a_0 and used for the construction of calibration graphs represented by Eq. (6) and Eq. (7).

$$I = a_0 + a_1 t + a_2 t^2 \quad (5)$$

$$\Delta I_{15} = (150 \pm 20) + (0.65 \pm 0.04)[\mathrm{TMT}] \quad (6)$$

$$\Delta I_{30} = (320 \pm 50) + (2.2 \pm 0.1)[\mathrm{TMT}] \quad (7)$$

where [TMT] is in nM. The calibration graphs were obtained using 11 different MA concentrations and blank, each measured twice. The limits of detection, calculated by $3 \times$ (S.D. in the intercept)/(slope), equal to 90 and 70 nM for the calibration graphs Eq. (6) and Eq. (7), respectively, and the application range is between 0.1 and 10 μM for both graphs.

The fluorimetric determination of MA is known to be more selective than the spectrophotometric [17]. We tested as interferences glyoxal, 2-furfuraldehyde, 5-hydroxymethyl-2-furfuraldehyde, fructose and glucose taken at 100:1 molar ratio to MA and did not observe any interference in determination of 1 μM MA in accordance with data of Espinosa-Mansilla et al. for the selectivity of the kinetic-fluorimetric method without enhancement reagents [17].

The method was applied for the determination of MA in raw beef and smoked pork. Both samples were analyzed also by the conventional spec-trophotometric TBA method. The results are collected in Table 2.

In the case of raw beef both methods give close results, while the level of MA in smoked pork detected by the new method is considerably lower than that determined by spectrophotometry with heating. This difference cannot be attributed to the difference in recovery and, most probably, reflects the difference in concentrations of free and total (free + bound) MA of the sample, Section I. The TBA method usually gives low, 60–80%, recovery for meat samples [9]. The new method shows the same level of recovery for smoked pork, but higher levels for raw beef. The results obtained with 15 min interval, Eq. (6), differ considerably from those with 30 min interval, Eq. (7), for raw meat, but are reasonably close for smoked pork. Taking into account an obvious overestimation of MA with Eq. (6), one can consider the results with 30 min interval more confident.

In general, the results of this study shows HP-β-CD to be the best fluorescence enhancement reagent in agreement with conclusion of Frankewich et al. [19], and by using this cyclodextrin the sensitivity of MA determination can be improved to an extent that allows one to determine as low as 0.1 μM MA at room temperature.

Kinetic determination of organic vapor mixtures with single piezoelectric quartz crystal sensor using artificial neural networks

Wan-Li Xing, Xi-Wen He *

Department of Chemistry, Nankai University, Tianjin 300071, People's Republic of China

Received 19 July 1996; received in revised form 17 October 1996; accepted 17 October 1996

Abstract

A single piezoelectric quartz crystal coated with one kind of crown ether was applied to the simultaneous determination of binary acid and amine vapor mixtures. From the adsorption and desorption curves of analytes, which were somewhat different in shape, frequency shifts from ten time windows were taken as inputs for artificial neural networks (ANN). Prediction results were satisfactory for ANN in both sample sets. The average relative errors, for formic acid and acrylic acid were 5%, for *n*-butylamine and aniline, they were 3% with ANN respectively. The effects of number of neurons in the hidden layer of ANN on the performance of the network are also discussed. © 1997 Elsevier Science B.V.

Keywords: Artificial neural networks (ANN); Hidden layer; Organic vapors; Piezoelectric quartz crystal

1. Introduction

Recently the piezoelectric crystal sensor has received much attention as a fast, convenient and sensitive analytical tool. Based on the linear relationship between the sensor frequency shift and the total mass change of the adsorptive coating, many sensitive analytical techniques have been developed for both vapors and liquids [1–3]. For multi-component analysis in gaseous phases, the use of piezoelectric crystal array has been proposed. Carey et al. [4] used a piezoelectric crystal array modified by different coating films to detect two and three component organic vapor mixtures. Chang et al. [5] identified odorants with a piezoelectric crystal sensor array through artificial neural network pattern recognition. Barko et al. [6] used an array of four piezoelectric crystal sensors each coated with a GC stationary phases to identify organic vapors, such as benzene, *n*-pentane, acetone, et al. using pattern recognition. Our laboratory has also detected some organic vapor mixtures with an array of nine piezoelectric crystal sensor coated with different crown ether derivatives [7]. The interaction between crown ethers and organic species, which leads to different response patterns of the analytes, is affected not only by the size of the ring, the type and

* Corresponding author.

PII S0039-9140(96)02142-X

basicity of the hetero atom (O, N, S), and the property of the substituent, but also by the molar mass, polarity, and steric hindrance of analytes [8]. In the process of measurement, we discovered that the adsorption and desorption model for some analytes had some differences. So in this paper, we only used one single piezoelectric crystal sensor coated with one kind of crown ether to detect organic vapor mixtures. Two groups of analytes each contained two components were detected with ANN. The frequency shifts from ten time windows were taken as inputs for ANN. This single crystal method makes the detection device more convenient and practical. We have also tested this method successfully to simultaneously determine the concentration of sulfuric dioxide and the relative humidity [9].

Artificial neural networks (ANN) are a form of artificial intelligence that mathematically simulate biological nervous system. Thay have been employed in chemistry since 1960 [10], for instance using data from a metal-oxide-semiconductor field-effect-transistors (MOSFETS) sensor array to determinate of individual components in a gas mixture, such as hydrogen, ammonia, et al. [11]. The approach is selected because of its adaptability to almost any mathematical function [12]. In this paper we deal with the signals from ten time windows of a single piezoelectric crystal sensor in two group of two-component mixtures. Our goal is not only to identify the gas mixtures, but also to determine independently and with sufficient accuracy the concentrations of the individual components, which is a somewhat more difficult problem than the identification of a gas mixture. It was proved by our experiment that our ANN model provided adequate prediction.

2. Experimental

2.1. Apparatus and reagent

The apparatus shown in Fig. 1 consisted of an AT-cut, 9 MHz piezoelectric quartz crystal, 12.5 mm in diameter, having two coated silver electrodes, 6.00 mm in diameter, was obtained commercially (Peking). The lead wires soldered to electrodes were connected to a TTL oscillator made in our laboratory. The frequency change was monitored by an N3165 frequency counter and the power was supplied by a PL2002A d.c. voltage regulator. The ANN data analysis program was written in Turbo C language by ourselves. All data analysis were treated by an PC-DX486 computer.

Analytes of formic acid, acrylic acid, *n*-butylamine and aniline were all of analytical-reagent grade. The coating material, crown ethers, were synthesized by Polymer Chemistry Institute in our school. Their molecular structure is showed in Fig. 2. The first one, *N*, *N'*-bis(4-methoxyl-phehyl)-1,10-diaza-18-crown-6, was used to detect the first sample set consisting of formic acid and acrylic acid. The second one, dibenzo-18-crown-6, was used to detect the second sample set consisting of *n*-butylamine and aniline. Coating solutions were prepared by dissolving about 100 mg of the substrate in 50 ml of chloroform or

methanol. The obtained concentrations of the solutions were about 2 mg ml^{-1}. Both sides of the crystals were coated with crown ethers via the dropping method using a microsyringe. The thin film of the coating was formed by solvent evaporation. The mass of the coating caused a frequency shift of about 5 kHz.

art2.2. Measurement procedure

The piezoelectric quartz was mounted in an 1.4 l flask which was thermostated at 30 ± 0.5°C. The stable oscillation frequency f_0 was recorded. Then we decreased the pressure in detection cell with an vacuum pump until it arrived about 5 mm Hg and the stable frequency f_1 was recorded. At this pressure, analytes evaporate completely in a very short time. After injecting a certain amount of mixture of analytes using a microsyringe, i.e., formic acid and acrylic acid or *n*-butylamine and aniline, the initial reaction time was recorded. After the injection, 5 min, the air was introduced in and the pressure in the detection cell became normal. The system was equilibrated for another 5 min, then the detection cell was purged with dried and purified air at 3 l min^{-1} till the frequency of the sensor was restored to its fundamental value. From the initial reaction time, the frequency values ($f(t)$) at every 10 s were injection of the samples and 15 min after purging the detection cell. In order to avoid too many input neurons leading much longer training time of ANN, in each sample set, every pure component with four concentrations covering the range of calibration set were detected under the same experiment conditions as other samples in the calibration set. Among the 150 $f(t)$, the average change rates of frequency shift of the four concentrations for every component at every time point, $\Delta f(t)_{\text{sample}(i)} = f(t)_{\text{sample}(i)} - f(t-1)_{\text{sample}(i)}$, were calculated. Then the differences of $\Delta f(t)_{\text{sample}(i)}$ between the two components of every sample set at the same time point were calculated. Among these differences, ten of the largest ones were selected.

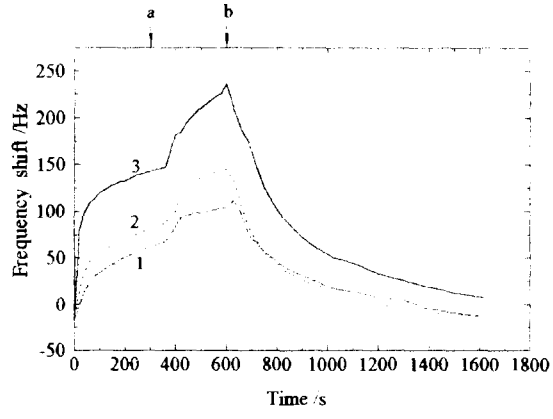

Fig. 5. Frequency shift patterns for *n*-butylamine and aniline: (1) *n*-butylamine (0.5 mg l^{-1}); (2) aniline (0.714 mg l^{-1}); and (3) sum of *n*-butylamine (0.5 mg l^{-1}) and aniline (0.714 mg l^{-1}). (a) The air was introduced in and the pressure in the detection cell became normal. (b) The dectection cell was purged with dried and purified air.

Table 1
Calibration sample concentrations

Sample No.	Set 1, mg l^{-1}		Set 2, mg l^{-1}	
	Formic acid	Acrylic acid	*n*-Butylamine	Aniline
1	0.87	0	0	0.71
2	0	1.60	0	1.43
3	0	3.20	0.50	0
4	2.61	0	1.00	0
5	0.87	1.60	0.50	0.71
6	2.61	3.20	1.00	1.43
7	1.74	4.00	0.75	1.79
8	3.48	2.40	1.25	1.07

The frequency shifts at these ten time points, which could reflect the characteristics of the components' adsorption and desorption process were taken as inputs for ANN. More inputs were tested, but they did not improve the prediction results obviously. Each sample was measured in triplicate in order to obtain an estimation of the precision of the sensor response.

2.3. Network design

Fig. 3 shows a generalized two-layer back-propagation network used in our experiment that has ten inputs (frequency shifts from ten time windows) in the input layer, an arbitrary number of artificial neurons in the hidden layer and two artificial neurons in the output layer (organic vapors). Each of the inputs is multiplied by an associated weight. The output signal y_i is further processed by sigmoid activation function F, so the neural output o_i is given by

$$o_i = 1/[1 + \exp(-y_i)] \tag{1}$$

and

$$y_i = \sum_{i=1}^{n} w_i x_i \tag{2}$$

The learning rules specify the initial set of weights and determine how these weights should change to improve the network performance. In all our parametric studies, we have used the BP algorithm and the delta learning rule, where the difference δ_i between target value t_i and actual neuronal output o_i is propagated back through the network to the input. The weights of the processing elements are thus iteratively changed until the output errors are be acceptable. A correction of Δ_i is made to the weights where

$$\Delta_i(m+1) = \eta\delta_i x_i + \alpha\Delta_i(m) \tag{3}$$

$$W_i(m+1) = W_i(m) + \Delta_i(m+1) \tag{4}$$

So the weights are adjusted by one term that is propagational to the error with a constant of the proportionality, called the learning rate. The second term is used to improve the stability of the learning process and is called the momentum term. The performance of each network and learning rule was determined by an error function, E, usually defined as the total squared error [10], from

$$E = \frac{1}{2}\sum_j \sum_k (t_{jk} - o_{jk})^2 \tag{5}$$

where j is the number of sensor response samples in the training and test set and k is the number of outputs in the output layer. After each iteration of the back-propagation process, the network error should gradually fall and converge to an asymptotic value.

In the our experiment, learning rate in the network training was set as 0.1, the momentum coefficient, 0.6. The number of neurons in the hidden layer was set as 6. The order of presentation of the training set samples was randomized at

the beginning of each epoch to speed convergence. In order to avoid overtraining, a point when a network training should be stopped is determined by cross-validation method [13].

3. Results and discussion

It can be seen in Fig. 4 and Fig. 5 when the crystal under 5 mm Hg pressure, its frequency was higher than its fundamental frequency, this is because of the stress on the surface of crystal decreased, after injection of analytes, they evaporated and were adsorbed by the coating material on the surface of the crystal, leading to the decreasing of the frequency, and the rate of decreasing became slow gradually with time. After the pressure became normal, the sensor's frequency decreased further and became stable gradually. While purged with air, the analytes were desorpted from the coating material on the surface of crystal, the frequency of the sensor rose progressively to its fundamental value. The rate of increasing also became slow gradually with time.

As showed by the figures, the outlines of the adsorption and desorption curves for the analytes were similar. But there were some differences in detail because of the difference of interaction between the analytes and the coating material, crown ethers. For example, the desorption rate for formic acid was faster than that of acrylic acid. The interaction between the analytes and the crown ethers was explained in detail elsewhere [7].

In Fig. 4 and Fig. 5, the frequency shift patterns for the two groups of analytes were plotted to show the degree of similarity, which indicate that there are some differences between the components, but they are not very obvious. The frequency shifts at different time are basically proportional to the concentrations of the analytes but not strictly.

3.1. Sample analysis

In each group, eight mixtures of analytes of various concentrations were prepared as a calibration set according to factorial-design, as showed in Table 1, four other mixtures of analytes were prepared as a test set which were not contained in the calibration set and measured under the same experimental conditions.

The predicted concentration results are given in Table 2 and Table 3. For the first sample set of formic acid and acrylic acid, the average relative error was 5%. For the second sample set of *n*-butylamine and aniline, the average relative error was 3%. The great prediction capacity for ANN is due to its advantageous ability to treat nonlinear problem, since while analyzing vapor mixtures, several components simultaneously interacted with the coating, crown ether, which may lead to complex relationship between the responses of the sensor and the concentrations of the vapors.

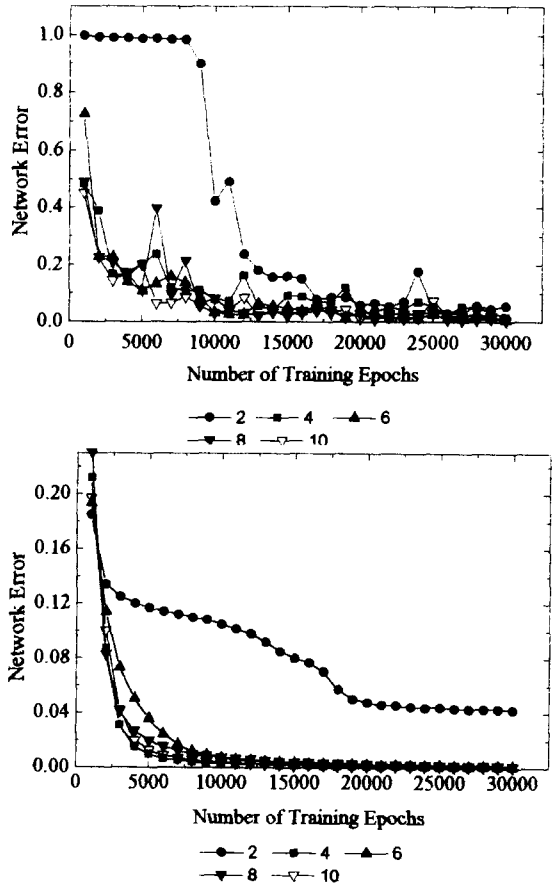

Fig. 6. (a) Effects of the number of neurons in hidden layer on the performance of neural networks in the first sample set. (b) Effects of the number of neurons in hidden layer on the performance of neural networks in the second sample set.

3.2. Network architecture and training

3.2.1. Number of neurons in the hidden layer

During the training phase for neural network analysis, we performed extensive experimentation to define appropriate network parameters. Although the selection of neurons in the hidden layers in a BP network was empirical, it is recognized that this choice can have a significant effect on network performance. A large number of hidden neurons can provide more predicting power, but the network will require more computation time and may also suffer in ability to generalize for an unknown data set [14]. In our experiment we tested different number of neurons in the hidden layer (from two to ten) for learning rate as 0.1 and momentum term as 0.6. Fig. 6(a, b) illustrates the relation between the network error and the number of training epochs for different number of neurons in the hidden layer. We can see that the performance of the network stabilized after inclusion of an adequate number of hidden units (more than four). The network with too few neurons in the hidden layer, e.g., in this experiment, two, can not converge effectively. This phenomena can also be found in our another work [7].

4. Conclusion

In this paper, we only used a single piezoelectric quartz crystal sensor to detect organic vapor mixtures using kinetic method. Compared with a piezoelectric quartz crystal sensor array, this detection system is more convenient and practical, although the sensor array method has its own advantages. This single crystal method can be extended to other analytes and detection systems

as long as there are some differences in the kinetic process. It is hopeful to become an practical method for multicomponent analysis. For quantitative analysis of the individual concentration in the vapor mixtures, it is important to keep the sensitivity of the coating material unchanged with time so as to ensure the precision of the frequency shifts. Crown ethers can satisfy this criterion because of its small volatility, long life-stan and reversible interaction with the analytes. In the data analysis of our study, the BP ANN model provided satisfactory prediction.

An automatic back titration method for microchemical analysis

Aimin Tan *, Cailin Xiao

Department of Chemistry, Central South University of Technology, Changsha 410083, People's Republic of China

Received 9 September 1996; received in revised form 24 October 1996; accepted 25 October 1996

Abstract

An automatic back titration method for microchemical analysis is introduced, which is based on conventional volumetric analysis's principle and the use of flow injection analysis apparatus for the automation and microminiaturization of the process. The sample and a known, but excess amount of a calibrated reagent solution are injected and propelled into a titration cell, where their reaction takes place. The excess of the reagent is then titrated with a titrant containing an indicator and the end point is monitored photometrically. Since homogeneous mixing in the titration cell is obtained magnetically in the whole process, there is a linear relationship between the analyte's concentration and the volume of the titrant consumed. Nickel in the range of 10–70 g l^{-1} is determined by the above method, in which 30 μl of sample and 500 μl of EDTA are injected and the excess of EDTA is titrated with a standard zinc salt solution containing xylenol orange which could be blocked by nickel ion in a direct titration. This method is characteristic of low sample and reagent consumption, high sampling rate as high as 45 samples h^{-1}, negligible effect of sample's viscosity, small carry-over effect (lower than 0.14%), and very good precision, whose relative standard deviations are as small as 0.24%. © 1997 Elsevier Science B.V.

1. Introduction

In recent years, much attention is attracted to flow injection titration for its advantages over conventional automatic titrator, including high sampling rate, low reagent and sample consumption, simplicity in instrumentation, versatility in solution handling, and rich in information [1]. However, flow injection titration's precision and accuracy is not so satisfactory as its advantages since its readout is not directly related to analyte's concentration, but to the logarithm of the concentration. Several new methods have therefore been proposed to increase the precision by making the readout linearly related to the analyte's concentration and maintaining most of its advantages.

A majority of these methods are based on varying the flow rate ratio between titrant and sample stream to obtain the equivalence point. Martinez Calatayud et al. [2] proposed a flow method for the titration of weak acids or weak bases using linear titration plots. The method involves continuous titrations based on mixing of titrant, propelled at a constant flow rate, and titrant, propelled at a manually varied flow rate, and pH measurements in a flow cell. The depen-

* Corresponding author.

PII S0039-9140(96)02158-3

dence of the response of this potentiometric detector on the flow-rate requires calibration at each flow rate used. Extensive work has been developed by Valcarcel and co-workers discussing in depth the use of programmable flow rate gradients [3–6] and their application to acid–base [7], complexometric and redox titrations [8,9], as well as to calculating acidity [10] and kinetics constants [11]. All the titration procedure based on a single gradient need a previous calibration of the system, although this step can be avoided by using two successive and diametrically opposite gradients as in the automatic titration system proposed by Hernandez Corboda et al. [12].

Ruzicka et al. [13] present a simple and rapid continuous flow injection system equipped with a mixing chamber, which is actually a combination of automated titration and automated dilution. The balance can be tipped towards either end to meet the special requirements of a particular analysis. When the analyte concentration varies over a wide dynamic range, the dilution function should be emphasized so that the analysis time can be shortened. On the other hand, when analyte varies over a narrow concentration range, the titration function is emphasized to differentiate between samples better. In addition, they introduced two application cases with the readout is logarithmic in the first and linear in the second, respectively.

Fumio Sagara et al. [14] proposed a micro flow spectrophotometric titration method which is the same as conventional titration in principle, but different in apparatus. For example, fused-silica capillary tubes in gas chromatography is employed as microburettes. The solution in a microbeaker, as small as 500 μl, was circulated through the micro-flow cell of a spectrophotometer to determine the indicator endpoint. This method's main advantage is that the reagent and sample's consumption is reduced to as small as μl.

In addition, the linear pH-buffering single-point titration using potentiometric detection [15–17] allows for linear system response, too, though it is limited to diluted samples.

The above developments in flow titration methodologies imply a continued interest in this field. However, in all these methods, back titration is very difficult to be automated, and no example is yet reported, even though back titration procedures are widely used in conventional titrimetric analysis while a suitable indicator is not available or where the reaction between an anlyte and a titrant occurs too slowly. In addition, since titrimetric analysis methods are usually employed for the determination of concentrated components, which requires high precision, most of the above methods based on the adjustment of flow rate are thus not suitable because their precision, r.s.d. is as high as 2%. Furthermore, the fluctuation of sample's viscosity has large influence on the determinations; and the concentrated analytes are usually difficult to be titrated directly without predilutions.

Recently, we proposed an automatic micro-titration method [18] which is based on the injection of a very small volume of sample and homogeneous mixing in a titration cell of the injected sample with a titrant solution propelled at a constant flow rate by a peristaltic pump. The mixture in the titration cell is monitored by photometry for endpoint. On the basis of the above method, automatic back titration method for microchemical analysis is developed, in which both a sample and an excess of standard reagent solution are injected and the excess is then titrated with a titrant. Since the sample volume, albeit small as 30 μl, could be maintained unchanged for a long period, the reduction of sample and reagent consumption is achieved but without any loss of precision. In addition, the method's precision is further increased with the titrant propelled by a stepper motor driven syringe piston pump in place of a conventional peristaltic pump. Concentrated samples can be titrated directly without predilutions, while the influence of sample's viscosity on the determinations is negligible. Moreover, since the titration cell is drained, it eliminates the long washing out time accompanied with the mixing chamber titration system. Finally, the above method is employed for the determination of nickel, in which an excess of EDTA is injected to react with nickel and the excess is then titrated with zinc salt solution containing xylenol orange (XO) as the indicator, which could be blocked by nickel ion in a direct titration. End point is determined while a sharp increase of absorbance at the

wavelength of 560 nm occurs owing to the formation of the red zinc-XO complex.

R: 0.1000 mol l^{-1} Na_2-EDTA + 1.5 mol l^{-1} hexamine buffer at pH 5.5

T: 0.005000 mol l^{-1} zinc + 0.002% (w/v) xylenol orange + 1.0 mol l^{-1} hexamine buffer at pH 5.5.

Nickel sulphate solution containing 80.00 g l^{-1} of nickel and 1.0 mol l^{-1} H_2SO_4.

All the reagents except otherwise stated are of analytical grade.

3. Apparatus

The micro-titration system depicted in Fig. 1 were constructed from the following components: a 16-port rotary valve (Zhaofa Automatic Analysis Research Institute, Shenyang, China), two self-designed variable-speed, linear flow piston pumps, each equipped with two disposable plastic syringes of 10 ml (diameter 17 mm); a self-constructed titration cell; a photometer based on LED and phototransistor; a magnetic stirrer

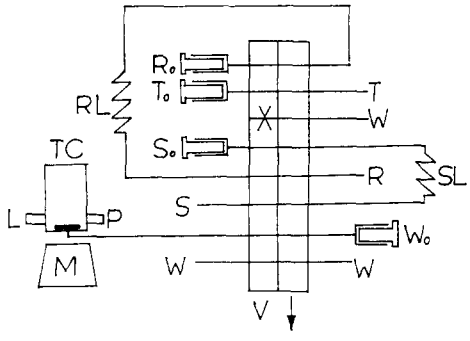

Fig. 1. The system configuration. Ro, So, To and Wo are the syringes for the calibrated reagent solution (R), sample (S), titrant (T), and the drainage of the titration cell (TC), respectively. *V* is the valve. *W* is the waste. *M* is the magnetic stirrer. SL is a 30 µl sample loop. RL is a 500 µl reagent loop. L and P are the LED and the phototransistor, respectively.

(Model GSP-80-04, Taixian Radio Factory, Jiangsu, China), and an intel 8031 based single-chip microcomputer system for the control of pump, valve, and stirrer, data acquisition and processing. The valve is driven by a stepper motor (Model 45BF3/3A, Shanghai Instrument Motor Factory, China) through two gears with a diameter ratio of 1:4.5. Through the control of the microcomputer, the valve can be turned to either load or inject position. The piston pumps, also driven by stepper motors, can be controlled to a precision of 2 µl. Since syringes need to be refilled, the pump's movements should be in accordance with the valve's position. The piston's forward movement requires the valve in inject position, while backward movement needs the valve in load position. Each determination always begins with the piston backward movement for filling the syringes, and ends with the piston's forward movement to deliver reagent. The titration cell, made of glass, has a volume about 12 ml. In its outside, near the bottom are mounted a green LED, whose emission maximum is at 560 nm, and a phototransistor, which, opposite to each other, are 18 mm apart. The titration cell together with the photometric components are put in a light-tight box to prevent the influence of ambient lights. For further details about the photometric detector, readers are referred to Ref. [19] and [20].

There are two distinct steps in the procedure, sampling and titration. During the first step, the valve turns to the load position, the syringes move backward, the titrant taken into the titrant syringe directly, while the sample flowing through the sample loop first and then to the sample syringe. The calibrated reagent solution is also loaded into the reagent loop. At the same time, the titration cell is drained by another syringe, which should be operated a little bit longer than the titrant syringes to secure the complete drainage of the titration cell. The blank signal for the following absorbance measurements is taken when the titration cell becomes empty. After sampling step, the valve is turned to inject position, followed by the forward movement of the syringes. The titrant delivered by syringe propels the loaded sample and the reagent solution into the titration cell one after the other. After the reagent

solution loaded in the reagent loop is propelled into the cell, stop the titrant's forward movement for a while until the reaction goes well to completion. Then restart the titrant pump to titrate the excess of the reagent and the endpoint is continuously monitored. Once a sharp increase in absorbance is detected, stop the addition of titrant, and read the volume of titrant delivered. Since homogeneous mixing of the solution in the titration cell is obtained by a magnetic stirrer, the principle is similar to that in conventional back titration methods, and the unknown concentration of a sample could be calculated similarly.

4. Results and discussion

4.1. Calibration curve and result calculation

As homogeneous mixing is employed in the titration, the principle of this method is quite similar to the conventional titration, except for that the sample's volume in this method is much smaller. The analyte's concentration in an unknown (C_X) can be calculated from the following equation,

$$C_X = (C_R V_R - C_T V_T)/V_0 \quad (1)$$

where C_R is the concentration of the calibrated reagent solution, i.e., the concentration of EDTA; C_T is the concentration of the titrant, zinc; V_R, V_0, and V_T are the volumes of reagent loop, sample loop, and titrant consumed, respectively. Since C_R and C_T are known, the unknown sample's concentration can be readily calculated if the volumes are determined accurately. Considering the difficulty in accurately determining the small volumes of sample and reagent loops, seven standard nickel solutions with increasing content of nickel from 10 to 70 g l^{-1} with 10 g l^{-1} interval are employed to calibrate these unknown volumes and other uncertainties altogether,obtaining the following regression equation,

$$C_X\ (\mathrm{g\ l^{-1}}) = 98.07 - 9.731 V_T\ (\mathrm{ml}) \quad (2)$$

whose regression coefficient is 0.9999. The linearity error, i.e., the relative difference between the known concentration and that calculated by the regression equation, in the whole range is below 0.21%. The relative standard deviation for delivering a known volume is 0.033%, which is much better than the linearity because of the small variations in the inner diameter of the syringe.

Since both the sample loop's volume and the reagent loop's volume, albeit small, can be maintained constant over a very long period, and the precision for delivering titrant by computer controlled piston pump does not fluctuate so easily as in peristaltic pump, frequent calibration is thus unnecessary.

5. The carry-over effect

As the titration cell and the tube connecting the cell to the valve is drained, the carry-over effect in this method depends mainly on the volume of the residual solution after drainage (V_r), its concentration (C_r), and the concentration of the next sample (C_x). The reagent's concentration in residual solution may be expressed as

$$C_r = T_e C_R V_R / V_s \quad (3)$$

where T_e is the titration error; V_s is the total volume of the mixture in the titration cell at endpoint. Therefore, the relative error (RE) caused by carry-over effect is as following,

$$\mathrm{RE} = (V_r T_e C_R V_R / V_S)/(V_0 C_X) \quad (4)$$

where V_0 is the volume of sample injected.

To determine the residual solution's volume approximately, a sample containing 100 g l^{-1} of cobalt is injected and diluted to 10 ml, the residual solution after drainage is then washed with distilled water and the cobalt content in the resulting solution is determined by spectrophotometry with nitroso *R* salt [21], from which the volume of the residual solution may be determined. The residual solution's volume, as the results of 11 measurements done this way determines, ranges from 0.01 to a maximum of 0.1 ml.

For the most unfavourable situation, V_S and C_X takes the minimum of 3.4 ml and 0.17 mol l^{-1}, respectively, the resulting relative error being as low as $\pm 0.14\%$ if the titration error is $\pm 0.5\%$.

To demonstrate by experiments: two samples with 10 and 70 g l^{-1} of nickel are titrated alternatively, no appreciable carry-over effect is found, since the titration error is practically smaller than 0.5%, and the residual solution's volume may be smaller than 0.1 ml, also.

6. The influence of sample's viscosity

In conventional FIA titration method, increased sample viscosity increases the pressure drop with the system and reduce the dispersion and mixing. The pressure drop increase is so predictable that it has been used by Betteridge et al. for the measurement of viscosity [22]. However, the influence of sample's viscosity in this method is greatly reduced because the length of the tube connecting the valve and the titration cell, i.e., the passage a sample transported, is as short as 10 cm, and homogeneous mixing is employed in the titration process. Even though the loaded samples with different viscosities might have increasing trailing, the analyte may be flushed to the titration cell completely by the reagent in the reagent loop as large as 500 μl. To demonstrate, when several samples containing 30 g l^{-1} of nickel but with increasing amounts of glycerin were determined, no appreciable viscosity effect is found even for the glycerin's content as high as 50% (V/V).

7. Sampling rate

The time for a typical analysis includes the time for draining the titration cell, the time for the analyte to react with the calibrated reagent solution, and the time to deliver the required volume of titrant, which depends on both the sample's concentration and the flow rates. The time for the sampling period should be kept constant, and large enough for draining the largest volume possible, since one may not know the titrant's volume consumed by the previous sample. During the titration, titrant is delivered quickly at first, and at a lower rate during the detection of end point. This is accomplished by comparing the measured absorbance with a set absorbance value (lower than the absorbance value corresponding to the equivalence point). Once the measured absorbance is larger than the set value, it is indicated that the equivalence point is approaching, slow down the titrant's delivering rate. The slower the titrant is delivered, the better the precision would be. Because the flow rates could be easily varied, the time for one determination varies, too. Here, to make a compromise between precision and sampling rate, 30 and 60 s are assigned for sampling and titration steps, respectively, whose sampling rate is 45 samples h^{-1}.

8. Sample analysis

Although the complex of nickel with EDTA is very stable, concentrated nickel can't be determined by direct titration since it will block most of the metal indicators (the nickel-indicator complex is more stable than the nickel-EDTA complex). In addition, sample dilution is necessary to reduce the influence of nickel ion's colour and NiY's colour on the endpoint determination in conventional titrimetric analysis. While this method is employed for the determination of nickel in the range of 10–70 g l^{-1}, the blocking to indicator is overcome by back titration; and the color's interference on endpoint detection is eliminated by dilution and the selection of a suitable wavelength far away from their absorption maxima. Several concentrated nickel sulphate solution samples from a metallurgical plant were determined by this method, whose results together with those obtained by manually performed back titration method with EDTA [17] are listed in Table 1. The results indicate that both the accuracy and precision in this method are quite good.

9. Conclusion

Automatic back titration method for microchemical analysis is achieved by injecting two accurately known small volumes of sample and a calibrated reagent solution, and the reagent consumption is thus, reduced. The excess of the

Table 1
The results of sample analysis (g l^{-1})

Sample No.	Manual titration	This method					Average	RSD
1	70.36	70.29	70.13	70.37	70.39	70.25	70.29	0.15%
2	45.09	45.03	44.91	45.10	45.11	44.97	45.02	0.19%

4	13.48	13.52	13.47	13.49	13.54	13.55	13.51	0.24%

reagent after reaction with the analyte is then titrated by a titrant and the endpoint is determined photometrically. Although it is used for the complexometric determination of nickel, the method, in principle, could be employed for the determination of a wide variety of analytes by using different reagents and adjusting the volumes of two loops and the concentration of reagent solutions. Furthermore, if the small variations in the inner diameter of the titrant syringe could be adequately calibrated, high precision as good as 0.1%, or even higher, might be obtained. More related research work and its application to displacement titrations are in progress at our laboratory.

Abstract

A novel amperometric biosensor for the determination of lactate was constructed by first immobilizing lactate oxidase and an osmium redox polymer ($[Os(bpy)_2(PVP)_{10}Cl]Cl$; abbreviated Os-polymer) on the surface of a glassy carbon electrode, followed by coating with a sol-gel film derived from methyltriethoxysilane (MTEOS). The electrooxidation current of this electrode was found to be diffusion controlled. In the presence of lactate, a clear electrocatalytic oxidation wave was observed, and lactate could be determined amperometrically at 400 mV versus Ag/AgCl. The concentration range of linear response, slope of linear response and detection limit were 0.1–9 mM, 1.02 μA mM^{-1}, and 0.05 mM, respectively. Although L-ascorbate was electrooxidized at this potential, uric acid, paracetamol and glucose were found not to interfere. © 1997 Elsevier Science B.V.

Keywords: Amperometric biosensor; Lactate determination; Osmium polymer; Sol-gel

1. Introduction

Enzyme-based, amperometric biosensors have attracted much interest for clinical, environmental, agricultural, and biotechnological applications. An important area of biosensor research is the immobilization of enzymes at transducer surfaces. Conventional methods of enzyme immobilization include covalent binding, physical adsorption, encapsulation in polymers, or cross-linking to a suitable supporting matrix. Generally, supporting matrices are constructed of conductive and nonconductive polymers [1–3], conductive organic salts [4], and carbon-based composite materials [5–8], or layer of enzymes adsorbed onto electrode surfaces [9]. Recent research has demonstrated that silicate glasses obtained by the sol-gel method can provide such a supporting matrix and that biomolecules can be immobilized by this method [10–17]. These bioceramic materials have been further applied to produce silica-based photometric and FI detectors [18–22]. More recently, low temperature processing conditions, chemical inertness, negligible swelling effects, tunable

porosity, thermal stability and the high purity of sol-gel-derived glasses make them ideal for many sensor applications [23,24]. The formation of sol-gel based sensors has been reviewed by Lev et al. [25]. Although most applications to date have been based on spectroscopic techniques, a few papers have emerged recently on the use of electroanalytical procedures. For instance, Narang et al. [26] have described a series of prototype tetraethylorthosilicate(TEOS)-derived sol-gel thin films for immobilization of glucose oxidase. Audebert et al. [27] have demonstrated the activity of glucose oxidase doped within a sol-gel-derived matrix(tetramethylorthosilicate; TMOS) using hydroxymethylferrocene as mediator. Glezer and Lev [28], however, prepared platinum electrodes with glucose oxidase entrapped within a vanadium pentaoxide gel and demonstrated the possibility of detection of glucose by cyclic voltammetry. Pankratov and Lev [29] have demonstrated the use of silica/carbon-based glucose sensor containing tetrathiafulvalene as mediator. In our previous study [30], we demonstrated the construction of a sol-gel based amperometric glucose biosensor incoporating an osmium redox polymer as mediator.

The rapid, accurate and selective assay of lactate is necessary in clinical and industrial food laboratories. Dempsey et al. [31] prepared a L-lactate biosensor immobilizing lactate oxidase in an *o*-phenylenediamine film. Mizutani et al. [32] prepared an amperometric enzyme electrode for lactate by immobilizing lactate oxidase in a polyion complex membrane. Spohn et al. [33] investigated the influence of different additives on the performance of a bienzyme carbon paste electrode for detection of lactate. Murr et al. [34] constructed an amperometric lactate biosensor by confining lactate oxidase and hydroxymethyl-ferrocene as mediator in a carbon paste electrode. Heller et al. [35] also demonstrated the use of a poly(1-vinylimidazole)-based lactate sensor containing $Os(4,4'\text{-dimethylbpy})_2Cl$ as a mediator. Zhang et al. [36] prepared an amperometric tetrathiafulvalene mediated reduced NADH sensor co-immobilizing lactate oxidase and lactate dehydrogenase on an Eastman-AQ-TTF-modified electrode. These methods result, however, in shorter linear response ranges than the method described in this paper.

This paper describes the feasibility of a sol-gel based amperometric L-lactate sensor based on lactate oxidase and an osmium redox polymer as mediator for the determination of L-lactate. We have investigated the electrochemical behaviour of this electrode and shown that L-lactate can be determined amperometrically with good analytical characteristics.

2. Experimental

2.1. Materials

The source of all chemicals used for experiments are given in parenthesis: methyltriethoxysilane (MTEOS, Aldrich), lactate oxidase (EC number, not assigned;from Pediococcus sp., 34 unit mg^{-1}, Sigma), L-lactic acid (Fluka), Glucose (Sigma), Uric acid (Aldrich), Paracetamol (BDH), L-ascorbic acid (Aldrich), Na_2HPO_4 and NaH_2PO_4 (BDH). All aqueous solutions were prepared in deionized water (Easypure RF, Branstead water purification system). The Os-polymer, $[Os(bpy)_2(PVP)_{10}Cl]Cl$, used as an electron transfer mediator, was prepared as described elsewhere [37].

2.2. Instrumentation

Cyclic voltammetry experiments and steady-state measurements were carried out using a BAS (W. Lafayette, USA) CV-100W voltammetric analyzer interfaced to an IBM-PC compatible computer. pH Measurements were performed using an RE 357 Microprocessor pH meter (EDT Instruments, UK).

2.3. Preparation of sol-gel derived electrode

The silica sol was prepared by mixing 4.5 ml of MTEOS, 1.6 ml of deionized water and 0.03 ml of 0.05 M HCl (which was used to catalyze the reaction) in a glass vial. After 3 h of mixing, a clear sol-gel solution resulted. The resulting molar ratio of MTEOS to water was 1:4. To prepare the

modified electrode, 3 μl of 1% Os polymer (in methanol) was coated on the surface of a glassy carbon electrode and dried at room temperature to evaporate off methanol, and then a 3 μl aliquot of LOD solution (680 units ml^{-1}; prepared in phosphate buffer, pH 6.8) was coated onto the surface of the modified electrode and allowed to air dry in a covered beaker. After 24 h a sol-gel layer was spin coated onto the surface.

2.4. Procedures

All measurements were carried out in a three-electrode system using a platinum wire and Ag/AgCl (sat'd KCl) as the auxiliary and reference electrode, respectively. All steady state measurement were performed at 400 mV versus Ag/AgCl in 0.1 M phosphate buffer, pH 6.8. Argon gas was passed through the cell to prohibit the competition of oxygen with the osmium redox centre [38]. The solution was stirred at 1000 rpm using a magnetic stirrer.

3. Results and discussion

3.1. Electrochemical behaviour of sol-gel derived electrode

Fig. 1 shows the typical voltammetric behaviour of a sol-gel based electrode containing LOD and Os-polymer as mediator in 0.1 M phosphate buffer, pH 6.8, at different scan rates. In the absence of lactate, the enzyme gives no response and only the Os-polymer electrochemistry is observed. Under the experimental conditions used in this study and over the range of potential scanned (− 100–550 mV) and range of potential scan rate ($v = 2$–200 mV s^{-1}), the dependence of peak current on the scan rate was investigated in order to identify the type of current. The current function ($i_p/v^{1/2}$) had a constant value at different scan rates. This means that the catalytic electrooxidation current of the sol-gel derived electrode is diffusion controlled current [39].

3.2. Bioelectrocatalytic oxidation of lactate

In the presence of L-lactate, a clear electrocatalytic oxidation wave was observed (Fig. 2). This means that lactate oxidase is reduced by the lactate penetrating the sol-gel film, electrons are transferred from the LOD-$FADH_2$ to the Os^{3+} site, Os^{3+} sites are reduced to Os^{2+}, followed by re-oxidation of this reduced form. The redox centre of LOD, i.e., FAD, is reduced by L-lactate as follows:

$$\text{LOD} - \text{FAD} + \text{L} - \text{lactate} + 2\text{H}^{+} \rightarrow \text{LOD} - \text{FADH}_2 + \text{pyruvate} \quad (1)$$

The Os^{3+} sites then oxidize the reduced LOD-$FADH_2$, regenerating LOD-FAD:

$$\text{LOD} - \text{FADH}_2 + 2\text{Os}^{3+} \rightarrow \text{LOD} - \text{FAD} + \text{Os}^{2+} + 2\text{H}^{+} \quad (2)$$

This is followed by the oxidation of reduced form of the mediator on the electrode surface:

$$2\text{Os}^{2+} \rightarrow 2\text{Os}^{3+} + 2\text{e} \quad (3)$$

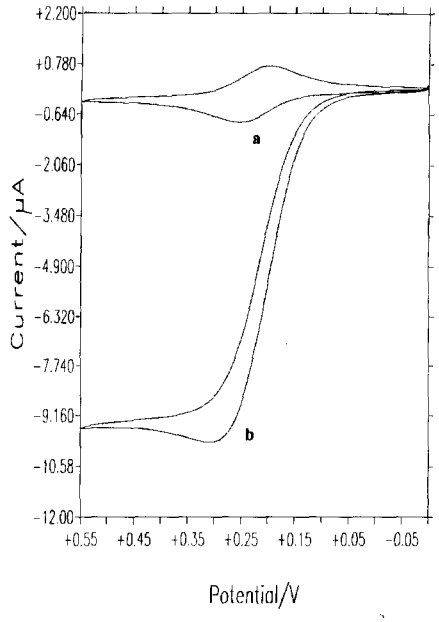

Fig. 2. Cyclic voltammograms of a sol-gel based lactate biosensor in 0.1 M phosphate buffer solution, pH 6.8: scan rate 2 mV s^{-1}, 1000 rpm, Ar; (a) no analyte, (b) 10 mM lactate.

The elimination of a reduction peak means that the reduced state of sol-gel film is maintained. Fig. 3 shows the potential dependence of the L-lactate electrocatalytic oxidation current at steady-state condition under argon. The L-lactate electrocatalytic oxidation current reached a plateau at 350 mV versus Ag/AgCl. In order to obtain constant and high electrocatalytic oxidation currents, the electrode potential was maintained at 400 mV versus Ag/AgCl for amperometric measurements.

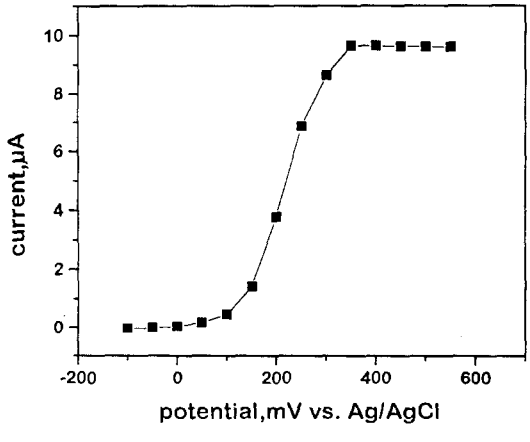

Fig. 3. Potential dependence of the steady-state current for the lactate electrode: 100 rpm, Ar, 10 mM lactate.

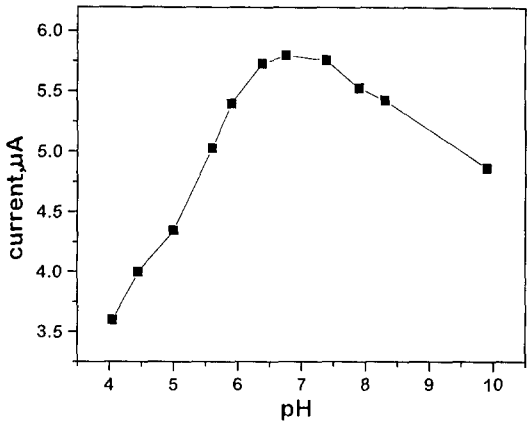

Fig. 4. Dependence of pH on electrocatalytic oxidation currents for a sol-gel based lactate electrode: 1000 rpm, Ar, 5 mM lactate.

3.3. pH studies

Fig. 4 shows the pH dependence of the catalytic current for the sol-gel based L-lactate electrode attained at a concentration of 5 mM lactate in 0.1 M phosphate buffer stirred at 1000 rpm under argon. The curves exhibit a plateau from pH 6.3 to 7.4. We selected a pH 6.8 for all further experiments in consideration of analytical sensitivity.

3.4. Steady-state current measurements

Fig. 5 shows the typical steady state current-time response of a sol-gel derived L-lactate biosensor. The electrode response time was about 10 s until steady state values were obtained. The fast response is attributed to the thin active film and short penetration depth of this electrode. The electrode response was found to be linear within the concentration range 0.1–9 mM with a correlation coefficient, $r = 0.9985$. The detection limit and slope of linear response were 0.05 mM and 1.02 μA mM^{-1} with 5.3% RSD, respectively. The

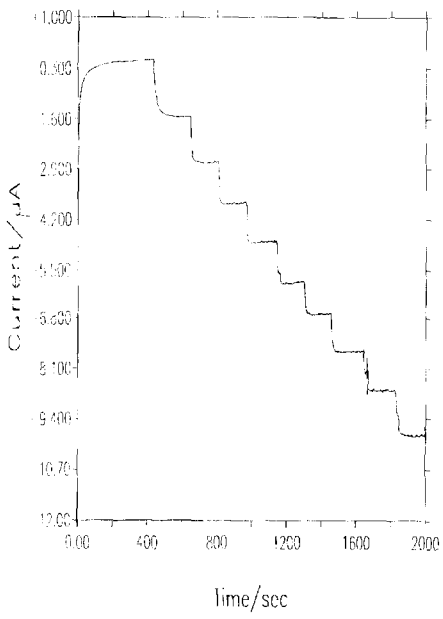

Fig. 5. Amperometric responses of a sol-gel based lactate biosensor on addition of lactate in 0.1 M phosphate buffer (pH 6.8): $E_{appl} = 400$ mV versus Ag/AgCl; 1000 rpm, Ar.

detection limit was calculated based on twice the value of the background currents. The short-term stability was shown to be within ± 5% RSD over a 1 week period.

3.5. Interferences studies

Interference effects were investigated by testing the response of the sol-gel derived electrode to L-ascorbic acid, paracetamol (4-acetamidophenol), uric acid, and glucose. As shown in Table 1 the presence of L-ascorbic acid greatly affects the response of the electrode, but uric acid, paracetamol and glucose did not interfere to any great extent. The use of an alternative mediator with a lower redox potential, a change in the composition of the sol-gel, or some form of prior separation, remains to be investigated to counteract this interference problem.

4. Conclusions

In this work we have demonstrated the feasibility of a novel sol-gel based amperometric L-lactate biosensor using an osmium redox polymer as mediator. Our results demonstrate that the electrocataytic oxidation current of a sol-gel film coated LOD/Os-polymer/glassy carbon electrode were diffusion controlled current. This electrode can be used as an amperometric lactate biosensor that provides a linear response and detection limit to lactate within the concentration range between 0.1 and 9 mM, and 0.05 mM, respectively. L-ascorbate was electrooxidized at this potential, but uric acid, paracetamol and glucose were found not to interfere. In previous studies [31–35], other authors obtained a smaller linear range than the sol-gel system described in this paper. This may be due to diffusional constraints caused by a lower permeability in the sol-gel layer described in this paper. The use of sol-gel immobilization may be useful for situations in which there are high lactate concentrations, e.g., in critical care monitoring. It may also prove to be a more robust method of immobilization compared with polymer-modified electrodes.

Table 1
Response of the sol-gel-based amperometric sensor to interferents

Interferents	5 mM lactate (μA)	Interferent + 5 mM lactate (μA)	% Diff.
1 mM acetaminophen	5.820	5.820	0
1 mM uric acid	5.813	5.813	0
0.1 mM ascorbic acid	5.823	5.963	2.4
1 mM ascorbic acid	5.823	7.395	23.7
1 mM glucose	5.820	5.821	0

Received 31 July 1996; received in revised form 4 November 1996; accepted 5 November 1996

Abstract

A flotation spectrophotometric method for the determination of germanium with isochromatic dye ion-pairs is described. The molar ratio of germanium to rhodamine 6G to tetrabromofluorescein is 1:5:5. The apparent molar absorptivity is 5.8×10^5 l mol^{-1} cm^{-1} at 531 nm. Beer's law is obeyed over the concentration range of 5.0×10^{-8}–1.25×10^{-6} mol l^{-1}. The proposed method is sensitive and accuracy and can be applied satisfactorily to the determination of germanium in vegetables. © 1997 Elsevier Science B.V.

Keywords: Flotation-spectrophotometric; Germanium; Isochromatic dye

1. Introduction

Phenylfluorone [1–8] and its replacement [9–16] are commonly used as sensitive spectrophotometric reagents for determining germanium and their molar absorptivities do not in general exceed 1.8×10^5. High sensitivity characterizes methods based on the formation of sparingly water-soluble compounds of molybdogermanic acid with xanthene dye (e.g., Rhodamine B, Rhodamine 6G) [17,18]. These compounds can be dissolved in enthanol or acetone after flotation with toluene or butyl acetate [18,19]. Some other methods for the extractive-spectrophotometric and flotation-spectrophotometric determination of germanium are described in the literature [20–22], but the sensitivities of these methods are lower than this paper's.

In this paper, the flotation-spectrophotometric determination of germanium with isochromatic dye ion-pairs is studied. The isochromatric dye was formed by R6G($C_{26}H_{27}ClN_2O_3$) with TBF($C_{20}H_6Br_4Na_2O_5$) at acetate buffer (pH 5.5). TBF is similar in colour to R6G and they associated with the molar ratio TBF: R6G = 1:1 at pH 5.5. During the determination process, R6G formed a ternary complex with germanoalizarincomplexone first. The molar ratio of germanium to alizarincomplexone (AC) to R6G was 1:3:5 [23], and its absorptivity was 2.9×10^5. Then de-

PII S0039-9140(96)02167-4

composed the ternary complex with NaOH, added TBF to the aqueous solution, the isochromatric dye ion-pairs of TBF with R6G was floated with toluene again, added acetate to dissolve the flotation. Owing to the isochromatic effect of ion-pairs, the sensitivity for the determination of germanium was enhanced and the molar absorptivity is achieved 5.8×10^5 at 531 nm. The proposed method has been applied to the determination of germanium in vegetables with good precision and accuracy.

2. Experiment

2.1. Apparatus

The absorbance was measured with a Model UV-265 spectrophotometer (Shimadzu Corporation, Kyoto, Japan). The pH measurements were made with a Model pHS-3C pH meter (Shanghai Leici Instrument Factory).

2.2. Reagents

All solutions were prepared with analytical reagent and deionized water. Standard solution, containing 1.00 mg ml^{-1} germanium, was prepared by dissolving 0.1000 g of Ge powder in 5.0 ml of 1 mol l^{-1} NaOH, acidified the solution with hydrochloric acid, and diluted to the mark in a 100 ml volumetric flask with water.

Acetate buffer solution, pH 5.5, was prepared by mixing 1 mol l^{-1} acetic acid and 1 mol l^{-1} sodium acetate solution. The pH was ultimately adjusted using a pH meter.

Tetrabromofluorescein (TBF) solution, 1.0×10^{-2} mol l^{-1}, was prepared by dissolving 1.7298 g of TBF in 500 ml of water.

Rhodamine 6G (R6G) solution, 1.0×10^{-3} mol l^{-1}, was prepared by dissolving 0.2935 of R6G in 500 ml of water.

Alizarine complexone (AC) solution, 0.0015 mol l^{-1}, was prepared by dissolving 0.1445 g of the reagent in 50 ml of water containing 0.5 ml of concentrated ammonia. Added 0.5 ml of glacial acetic acid, and diluted with water to exactly 250 ml.

2.3. Procedure for the determination of Ge

The solution containing not more than 1.5 μg of Ge, 3.0 ml of 1.0×10^{-4} mol l^{-1} AC solution, 5.0 ml of 1.0×10^{-4} mol l^{-1} R6G and 1 ml of pH 5.5 acetate buffer were added to a 30 ml separating funnel. The solution was shaken for about 30 min in a mechanical shaker with 5 ml toluene. Discarded the aqueous phase. Washed the flotation three times with 10 ml of 0.1 mol l^{-1} NaCl. Added 0.1 mol l^{-1} NaOH to the flotation, the ternary complex (the molar ratio Ge:AC:R6G = 1:3:5) [23] was then decomposed. Acidified the solution with 0.05 mol l^{-1} H_2SO_4. Added successively 3.0 ml of 1.0×10^{-4} mol l^{-1} TBF, 2.0 ml of pH 5.5 acetate buffer. Shook the solution for 3 min. The flotation of TBF with R6G was adhered on the wall of the separating funnel, discarded the solution, washed the flotation three times with 10 ml of 0.1 mol l^{-1} NaCl and the flotation was dissolved in 10 ml of acetone. The absorbance was measured at 531 nm in a 1.0 cm cell against reagent blank.

3. Results and discussion

3.1. Spectral characteristics

The absorption spectra of 1.0×10^{-5} mol l^{-1} TBF solution, of 1.0×10^{-5} mol l^{-1} R6G solution and of the 1.0×10^{-5} mol l^{-1} acetone solution of the isochromatic dye ion-pairs of TBF with R6G (the molar ratio of TBF to R6G was 1:1) are shown in Fig. 1.

All results showed that TBF and R6G were similar in colour in acetone and the sensitivity was enhanced by the use of isochromatic ion-pairs of TBF with R6G at 531 nm.

3.2. Select of organic solvents

The ion associate of germanoalizarincomplexone acid with R6G is insoluble in water. It cannot be extracted into polar or non-polar organic solvents, but it can be floated [23].

The isochromatic dye ion-pairs of TBF with R6G was floated with toluene at pH 5.5 acetate

buffer. Consequently, toluene was chosen as the optimum flotation agent.

3.3. Effect of pH

It was reported in literature [24] that the optimum pH range of the ternary complex was from 5 to 6. The range of pH was controlled in 3–11 with the acetate buffer and NaOH. A study of the complexation of TBF with R6G at different pH values showed that the isochromatic dye ion-pairs had a higher absorbance at the pH 5.5 (see Fig. 2). Consequently, a pH of 5.5 acetate buffer was chosen as the optimum for this work.

3.4. Effect of developer concentration

Fig. 3 shows the effect of TBF concentration. 2.5–4.0 ml of 1.0×10^{-4} mol l^{-1} TBF solution gave a maximum and constant absorbance with 5.0×10^{-7} mol l^{-1} of Ge, so that 3.0 ml of 1.0×10^{-4} mol l^{-1} TBF was used in the determinations. AC and R6G concentration were not less than 60 and 100 times of Ge concentration.

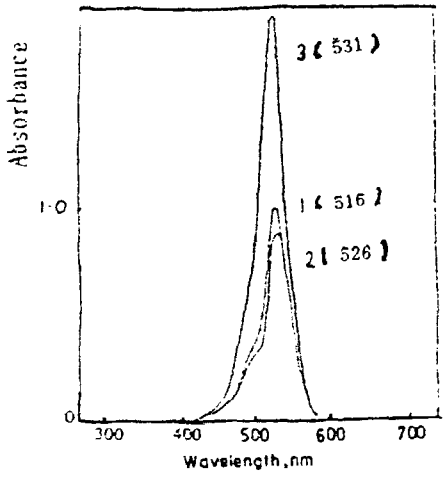

Fig. 1. Absorption spectra of TBF, R6G and TBF·R6G. (1) 1.0×10^{-5} mol l^{-1} TBF solution measured against water, (2) 1.0×10^{-5} mol l^{-1} R6G solution measured against water, (3) 1.0×10^{-5} mol l^{-1} TBF:R6G acetone solution against reagent blank.

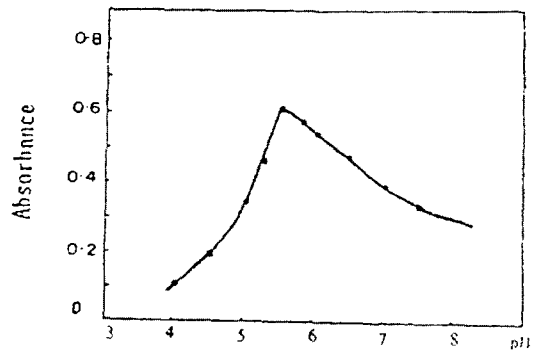

Fig. 2. Effect of pH on the isochromatic dye ion-pairs of TBF with R6G. R6G: 3.0×10^{-5} mol l^{-1}, TBF: 5.0×10^{-5} mol l^{-1}. Absorbance measured at 531 nm against corresponding reagent blank.

3.5. Composition of the ion-pairs

The composition of the complex were investigated by the continuous variations and equilibrium shifting methods. Both the molar ratio of TBF to R6G and R6G to AC were found to be 1:1.

3.6. Stability of the ion-pairs TBF·R6G and AC·R6G

Ksp was regarded as an association capacity of the complex [24]. It was found that Ksp of TBF·R6G and AC·R6G were 5.9×10^{-12} and 1.88×10^{-11}, respectively. The results showed

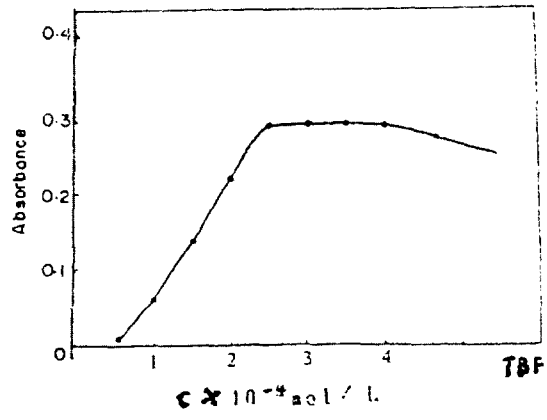

Fig. 3. Effect of reagent concentration. Germanium: 5.0×10^{-7} mol l^{-1}.

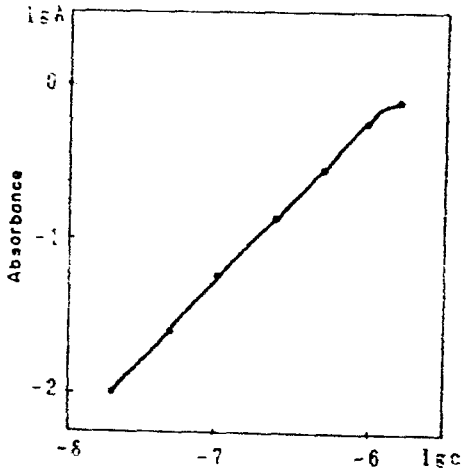

Fig. 4. Analytical curves of germanium.

that TBF associated extremely R6G of the ternary complex.

3.7. Analytical curves and sensitivity of the method

According to the recommended procedure outlined above, analytical curves were prepared by taking the appropriate amount of the standard germanium solution. During the flotation process, the TBF of adsorption on the precipitate was washed with 0.1 mol l^{-1} NaCl. Thus, good linearity was obtained at concentration of germanium between 5.0×10^{-8}–1.25×10^{-6} mol l^{-1} (Fig. 4). From this straight line the apparent molar absorptivity coefficient was 5.8×10^5 l mol^{-1} cm^{-1} at 531 nm.

3.8. Determination of germanium in samples

The contents of Ge in vegetables were determined. Washed thoroughly the vegetables with water, then with distilled water. Powered the vegetables after 24 h in oven at temperature 50°C. Samples (0.5000 g) were placed in pressure vessels, added 4 ml of HNO_3. The vessels were then sealed and kept at 120°C for 3 h. After cooling the vessels were opened. Ultimately the solution transferred into a 25 ml calibrated flask, diluted to the mark with deionized water. Then extractive separation of Ge, added sufficient concentrated hydrochloric acid to the sample solution to give a final acid concentration of at least 9.0 mol l^{-1}. Shook the acidic solution for 2 min in a separating funnel with two portions of CCl_4, and washed the combined organic extracts with 9.0 mol l^{-1} HCl. Stripped the Ge by shaking the CCl_4 solution with 10.0 ml of water followed by 5.0 ml of water containing 1 drop of 1 mol l^{-1} NaOH (shaking for 1 min) and determined by the proposed method. The results are given in Table 1.

3.9. Effect of diverse ions

The literature [24] had investigated the effects of 0.16 mol l^{-1} SO_4^{2-}, F^-, Cl^-, CH_3COO^-, Br^-, I^-, ClO_4^-, NO_3^- on the flotation under the optimum pH. SO_4^{2-}, F^- did not interfere in the absorbance of the complex. Cl^-, Br^-, NO_3^- decreased strongly the flotation, and I^-, ClO_4^- interfered seriously in the flotation. The diverse ions were not obtained in the following work.

Table 1
Determination of Ge in samples

Sample	By AAS method μg g^{-1} dry weight	By the present method μg g^{-1} dry weight	S.D.%	Number of determinations
Cabbage	0.2922	0.2915	4.2	5
Chives	0.2842	0.2850	4.4	5

Received 17 July 1996; received in revised form 5 November 1996; accepted 13 November 1996

Abstract

GC/MS and GC/MS/MS in a quadrupole ion trap were used to analyze for anthraquinone, alkyl anthraquinones, benz[a]anthracene-7,12-dione and 9-fluoranone in a sediment obtained from an aluminum smelter settling pond contaminated with polycyclic aromatic hydrocarbons. By standard GC/MS analysis many of these target compounds were either undetectable or their confirmation uncertain because of matrix interferences. Detection and identification were greatly improved by using GC/MS/MS. GC/MS/MS analyses were performed by selecting the molecular ion (M) of a target compound and fragmenting it via collision induced dissociation (CID) to yield product ions corresponding to loss of CO for unsubstituted compounds or CO plus CH_3 for alkylated compounds. The CID conditions were optimized using anthraquinone and 2-methylanthraquinone standards by varying the CID excitation energy and RF storage levels to yield optimum amounts of fragment ions. CID experiments were performed using both resonant and non-resonant wave forms. Although both excitation techniques gave comparable results for the removal of matrix interferences, non-resonant excitation provided more characteristic spectra for the alkylated anthraquinones. Monitoring of secondary fragmentation products, such as M-2CO, provided greater discrimination from matrix interferences than the use of primary fragmentation products, such as M-CO. © 1997 Elsevier Science B.V.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) constitute a class of environmental contaminants that are produced in large amounts through incomplete combustion processes, pyrolysis, and via dispersion of petroleum products [1]. Because many PAHs are potent mutagens or carcinogens [2] numerous analytical techniques have been developed for determining their concentrations in environmental samples. However, toxicity of PAH contaminants is not exclusively dependent on the parent compounds. Air particulates contaminated with PAHs have been found to be more carcino-

* Corresponding author. Fax: + 1 604 8222847.

PII S0039-9140(96)02172-8

genic than can be accounted for by their PAH content alone [3]. This increased toxicity is potentially attributable to PAH oxidation products such as polyaromatic quinones [4,5]. For example, quinones of the non-mutagenic PAH pyrene, as well as some polyaromatic ketones (PAKs) of benzofluorenes and 7H-benz[d,e]anthracene have been found to be mutagenic [5,6].

Because the toxicological and environmental effects of a PAH can be significantly altered following a chemical transformation, such as oxidation, a full accounting of the impact of PAHs should also include their transformation products. However, since PAHs are often associated with complex matrixes, such as soils or sediments, the detection and quantification of trace level transformation products is often a difficult task, usually requiring extensive fractionation by liquid chromatography [7]. This in turn will generally lead to loss of analyte. In order to be able to routinely screen for trace level PAH transformation products together with their precursors, new methods which do not require extensive sample manipulation need to be developed. Such methods could involve simple extractions with minimal solvent workup followed by a rapid chromatographic step to remove highly polar impurities if gas chromatography is to be used.

Capillary GC/MS is usually the analytical technique of choice when analyzing complex mixtures of PAHs, as it combines efficient chromatographic separation with mass spectral information. Selectivity and sensitivity can be achieved by software extraction of the molecular or fragment ion chromatograms for a particular analyte, as long as coeluting matrix compounds do not interfere at the specific m/z values of the analyte. However, when analyzing for trace level substances, such as the transformation products of PAHs, their molecular or characteristic fragment ions are often obscured throughout the ion chromatogram by abundant matrix ions. Standards will generally not be available for many transformation products thus, a confirmatory spectrum has to be obtained, a difficult task when other coeluting interferences are present. To differentiate analytes obscured by coeluting interferences a GC tandem mass spectrometry method (GC/MS/MS) is required. In the first step molecular ions of the appropriate m/z value can be preselected, eliminating interfering ions with m/z values different from the analyte. The preselected molecular ions can then be fragmented via CID leading to characteristic fragments. If coeluting interferences of the same preselected m/z are also present they will likely lead to different fragment ions. Consequently, identification and quantitation of the target analyte can be performed using its characteristic CID product ions.

Although GC/MS/MS can be performed using multi sector [8,9] or triple quadrupole instruments, [10,11] the use of an ion trap affords better sensitivity since it eliminates losses of ions during transfer between different analyzers [12]. The recent availability of reliable commercial GC Ion Trap MS (GC/ITMS) systems has enabled GC/MS/MS experiments to be readily performed at pg–fg levels [13,14].

Besides improved sensitivity other advantages of an ion trap include the possibility of performing analyses in the field because of the compact nature of the instrument and significantly lower instrument cost when compared with other mass spectrometer systems [15].

The present work demonstrates a relatively simple yet powerful technique for the analysis of trace level PAH oxidation products in a complex matrix by performing GC/MS/MS in an ion trap. The ion trap used in this study has two modes of CID excitation, resonant excitation (RCID) and non-resonant excitation (NRCID). Resonant excitation involves the application of a high frequency RF potential to the end-caps, corresponding to the oscillation frequency of the selected ion. Non resonant excitation uses a low frequency dipole square wave which causes simultaneous excitation of all ions in the trap. The amount of energy imparted onto the excited ion will depend upon the amplitude of the CID waveform, its duration, the RF storage level and the nature and pressure of the collision gas. In our work the He mobile phase from the GC served as the collision gas. The CID amplitude and the RF storage level were the two parameters optimized to yield the maximum amount of the required fragment ions.

It is important to note CID in an ion trap leads to the formation of products via the lowest energy dissociation pathways, [16] resulting in non-standard MS/MS spectra, as compared with the higher energy CID MS/MS spectra obtained in triple quadrupole or multi sector instruments. Thus, the MS/MS spectra from ion trap experiments will not necessarily be identical to published reference electron ionization (EI) mass spectra, and the extent of fragmentation will depend upon the CID conditions. Nevertheless, all major fragments present in EI spectra should be observed under varying CID conditions.

Anthraquinone (AQ) and 2-methylanthraquinone (2-MeAQ) were selected as the target compounds for optimization of the CID method. These compounds can arise from the oxidation of anthracene, [17] and 2-methylanthracene respectively, substances that are present in high concentration in the contaminated sediment extract investigated here [18]. AQ yields two major fragment ions, m/z 180 and 152, corresponding to two successive losses of CO. In addition 2-MeAQ shows loss of a methyl radical.

By using the optimized resonant and non-resonant CID conditions established for AQ, and 2-MeAQ an extract from a contaminated sediment obtained from an aluminum smelter settling pond was analyzed for AQ, methyl AQs, C_2-AQs (dimethyl or ethyl) and C_3-AQs.

This work is part of an extensive investigation into the environmental effects of the large scale generation of PAHs in an aluminum smelter on the west coast of Canada and their disposal into the environment.

2. Experimental

2.1. Reagents

Anthraquinone, 2-methylanthraquinone, 9-fluoranone, and benz[a]anthracene-7,12-dione were obtained from Aldrich (Milwaukee, WI, USA). The internal standard D_{10}-anthracene was obtained from CIL (Woburn, MA, USA). All solvents used were of HPLC grade (Fisher Scientific, Nepean, ON, Canada).

2.2. Instrumentation

All experiments were performed on a Saturn 4D GC/MS/MS system (Varian, Walnut Creek, CA, USA) equipped with a Wave-Board for the generation of user-defined wave forms applied to the ion-trap electrodes. The software used for general operation of the instrument was the Saturn version 5.2. The 'Toolkit' version 1.0 software was used for performing sequential MS/MS experiments during the optimization procedure.

2.3. Analytical procedures

2.3.1. Sample preparation and quantitation

The contaminated sediment was obtained from a settling pond at the Alcan aluminum smelter in Kitimat, British Columbia, Canada, as described elsewhere [18]. The sediment was freeze dried and a 5 g sample was spiked with 4.5 μg of D_{10}-anthracene and extracted for 15 min with 40 ml of dichloromethane and acetone (5:1) using an Accelerated Solvent Extraction System (Dionex, Sunnyvale, CA, USA) operated at 125°C and 2000 psi. A 1 ml aliquot, containing 10 mg of crude extract, was placed on a column containing 5 g of silica and flushed with acetone to collect all the non polar (aliphatics, PAHs) and semi polar compounds (heteroaromatics). This acetone extract was used to perform all the analyses discussed in this paper.

Although partial fractionation of the aliphatic, PAHs and heteroaromatics can be performed using a gradient elution starting with hexane, no fractionation was attempted in this work in order to determine the viability of performing analyses on a single complex extract. The amounts of anthracene, anthraquinone, 2-methylanthracene and 2-methylanthraquinone in the sediment extract were determined by using the D_{10}-anthracene internal standard and appropriate relative response factors obtained by analyzing a mixture containing these four compounds together with D_{10}-anthracene under non-resonant CID conditions. Calibration curves were obtained for AQ, anthracene and D_{10}-anthracene to determine the dynamic range of the method. A series of control samples of uncontaminated sediment (as deter-

mined by prior analysis) spiked with 20 μg of anthracene or AQ were also extracted to determine the extraction efficiency of AQ and to monitor for any oxidation of anthracene to AQ during the extraction or cleanup processes.

2.3.2. Gas chromatography

Samples were introduced via splitless injection of 1–2 μl of solution, at an injector temperature of 290°C, onto a DB5 capillary column (J&W, Folsom, CA, USA), 30 m × 0.25 mm I.D., 0.25 μm film thickness. The end of the column was inserted directly into the ion trap via a transfer line. The latter was held at 280°C and the ion trap temperature at 250°C. The GC column was held at 90°C for 0.1 min followed by a 6°C min^{-1} ramp to 280°C, holding at 280°C for 1 min and then ramping to 300°C at 20°C min^{-1} and holding for 20 min. Helium carrier gas (99.996% purity, Linde, ON, Canada) coupled to a carrier gas purifier (Supelco, ON, Canada) was adjusted to give a linear velocity of 32 cm s^{-1}, corresponding to a flow of approximately 1 ml min^{-1} into the ion trap.

2.3.3. Ion trap

Details on the operation of the trapping and scan functions for the Saturn ion trap have been described elsewhere [13,14]. All experi-

ments were performed under automatic gain control (AGC) with a target value of 30 000 for GC/MS and 10 000 for GC/MS/MS. The filament emission current was 40 μAmps and the multiplier voltage was set to give a gain of 10^5. The RF was ramped to produce a scan rate of 5600 amu s^{-1} over a mass range of 100–300 m/z. The MS/MS parameters used are indicated in Fig. 1. For all these experiments the storage RF (SRF) was maintained to store ions above m/z 80.

For the AQ and 2-MeAQ CID experiment the optimum excitation voltage yielding maximum production of fragment ions was determined by a series of multistep experiments in which the CID voltage (resonant or non-resonant) was increased in ten sequential steps. With a scan rate of 0.2 s per step a ten step experiment took 2 s allowing five experiments to be performed during the 10 s wide chromatographic band containing 50 ng of compound. The data obtained for each ion of interest were normalized as a percent of the total ion current (TIC).

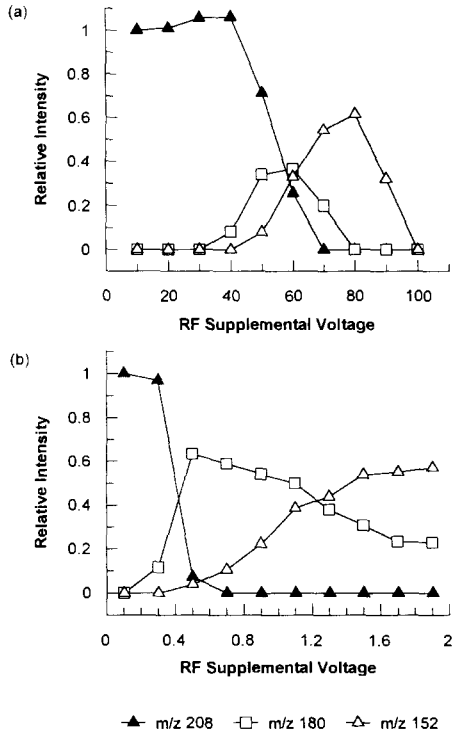

Fig. 2. Decomposition curves for anthraquinone molecular ion using (a) non-resonant excitation: parent mass = m/z 208, CID time 20 ms, CID energy 10–100 volts; and (b) resonant excitation: parent mass = m/z 208, CID time 20 ms, CID energy 0.1–1.9 volts.

3. Results and discussion

3.1. Optimization of CID conditions

The resonant and non-resonant decomposition curves for the molecular ions of AQ and 2-MeAQ are shown as a function of CID voltage in Fig. 2 and Fig. 3, respectively. From these curves CID voltages were selected to provide maximum information concerning characteristic fragmentation of these compounds. Under non-resonant excitation the CID voltage selected for both AQ and 2-Me AQ was 60 volts. At this voltage approximately 25% of the molecular ion signal remained and for AQ the M-CO (m/z 180) and M-2CO (m/z 152) fragment ions were present in approximately equal proportions. For 2-MeAQ the M-CH_3 (m/z 207), M-CH_3,CO (m/z 179) and M-CH_3,2CO (m/z 151) ions were present in significantly lower amounts than the M-CO (m/z 194) and M-2CO (m/z 166) ions. For resonant excitation the CID voltages chosen were 1.1 volts for AQ and 1.5 volts for 2-MeAQ. The latter voltage was the smallest value that yielded detectable amounts of the m/z 151 fragment.

For all experiments the CID excitation period was kept at 20 msec; variations from 10–40 ms did not significantly affect the fragmentation behavior of AQ and 2-MeAQ.

Although standards are available for AQ and 2-MeAQ allowing their identification in unknown samples via both mass spectral data and retention times, other alkylated AQs isomers for which standards were not available (i.e., 1-MeAQ and C_2-AQs) can only be identified by their mass spectral patterns. Consequently, it is necessary to obtain a good characteristic spectrum with enough fragmentation data to identify the compound.

3.2. Qualitative analysis of contaminated sediment

From the GC/MS analysis of the sediment extract, a portion (t_R = 18–20 min) of the total ion chromatogram and the mass chromatograms for

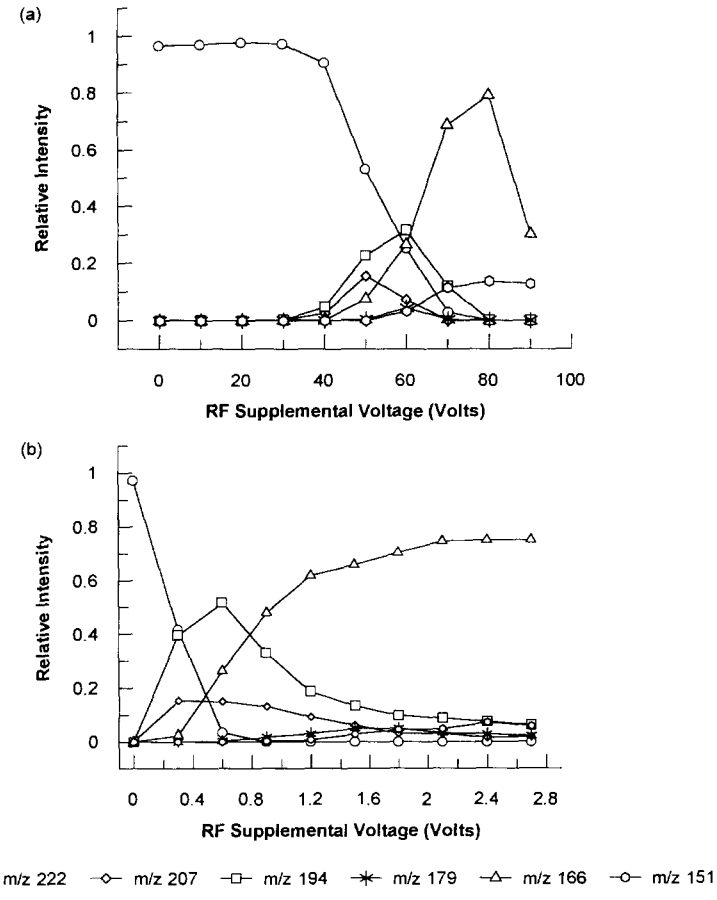

Fig. 3. Decomposition curves for 2-methylanthraquinone molecular ion using (a) non-resonant excitation: parent mass = m/z 222, CID time 20 ms, CID energy 0–90 volts; and (b) resonant excitation: parent mass = m/z 222, CID time 20 ms, CID energy 0–2.7 volts.

m/z = 208, 180 and 152 are displayed in Fig. 4a. The various signals observed in the chromatogram, during this retention period, originate from intact molecular ions and/or fragment ions of different compounds present in the sediment extract. The mass spectrum at the retention time of AQ (19.4 min) is reproduced in Fig. 4b. Although ions characteristic for AQ (208, 180, 152) are observable, the spectrum is dominated by a coeluting interference with m/z 204. By employing GC/MS/MS in non-resonant (Fig. 5a) or resonant (Fig. 6a) modes the m/z 180 and 152 mass chromatograms are 'cleaned up' significantly resulting in clear confirmatory spectra (Fig. 5b and Fig. 6b) for AQ.

The real advantage of the MS/MS technique is demonstrated in the search for MeAQs (MW = 222) and C_2-AQs (MW = 236) in the sediment extract. As indicated previously for 2-MeAQ, MeAQs yield in addition to the molecular ion (m/z 222) fragments at m/z 207, 194, 179, 166 and 151. The TIC and mass chromatograms corresponding to these masses in GC/MS, GC/MS/MS non-resonant and resonant modes are shown in Fig. 7a-c, respectively. The corresponding mass spectra extracted at positions 1 (t_R = 20.9 min) and 2 (t_R = 21.6 min) are reproduced in Fig. 8a-c. Position 2 corresponds to 2-methyl AQ as confirmed by the retention time of the standard. Because AQ appears to be the only dominant MW

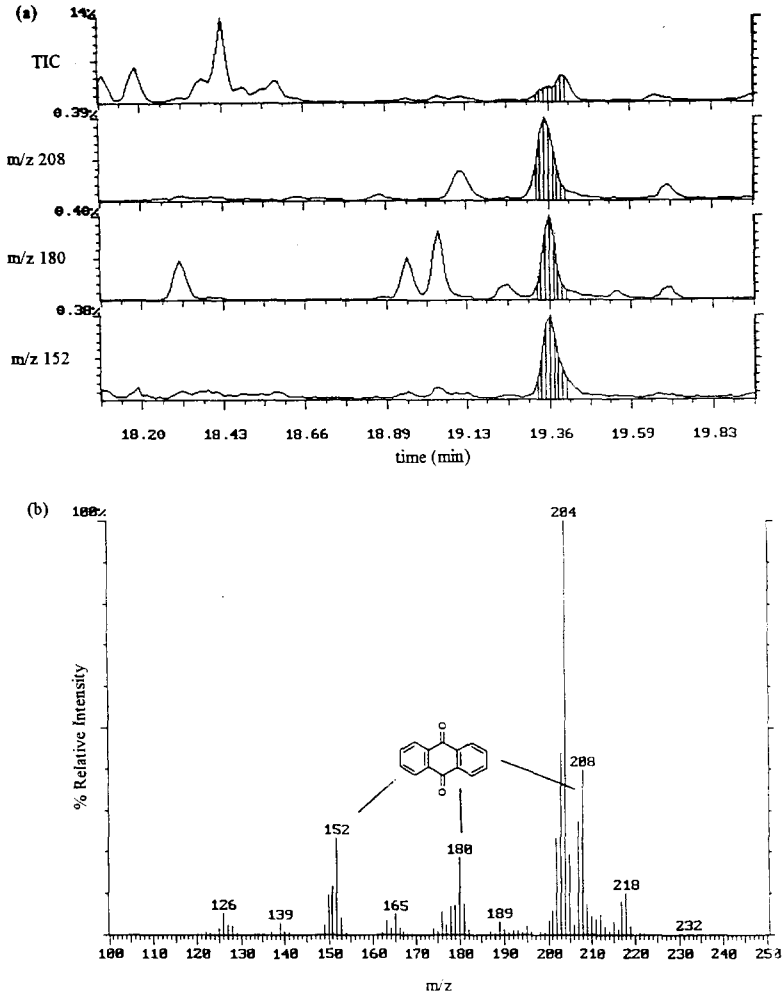

Fig. 4. GC/MS analysis of sediment extract. (a) TIC and m/z 208, 180, 152 ion chromatograms, (b) background subtracted mass spectrum at $t_R = 19.4$ min in (a).

208 quinone detected in the sediment extract, it is unlikely that the m/z (208 + 14) and m/z (208 + 28) alkyl isomers are not AQ in nature. The standard library reference spectra of 1,4-anthraquinone (NIST # 48 970), another possible anthraquinone isomer, displays an intense M-82 ion due to loss of COC_2H_2CO which is not observed in any of the spectra obtained in this work. The retention time of 9,10-phenanthrenequinone, another structural isomer of AQ, was found to be over 3 min longer than that of AQ.

Given that only two possible monomethyl isomers of AQ exist, the chromatographic signals at position 1 must correspond to 1-methyl AQ. The unavailability of a standard for this compound makes full mass spectral data necessary for structural confirmation.

Furthermore, when comparing Fig. 8b1 and 8b2 it is noticed that ions m/z 207 and 179 are absent in the former. This difference is most likely due to an interaction between the carbonyl oxy-gen and the methyl protons, similar to the ortho effect described by Schwartz [19], leading to the formation of the ion at m/z 177 (compound 1, Fig. 8b). This ion is not observed in the 2-MeAQ mass spectrum.

A number of small ions at m/z 202, 210 and 211 are also observed in the mass spectra shown in Fig.

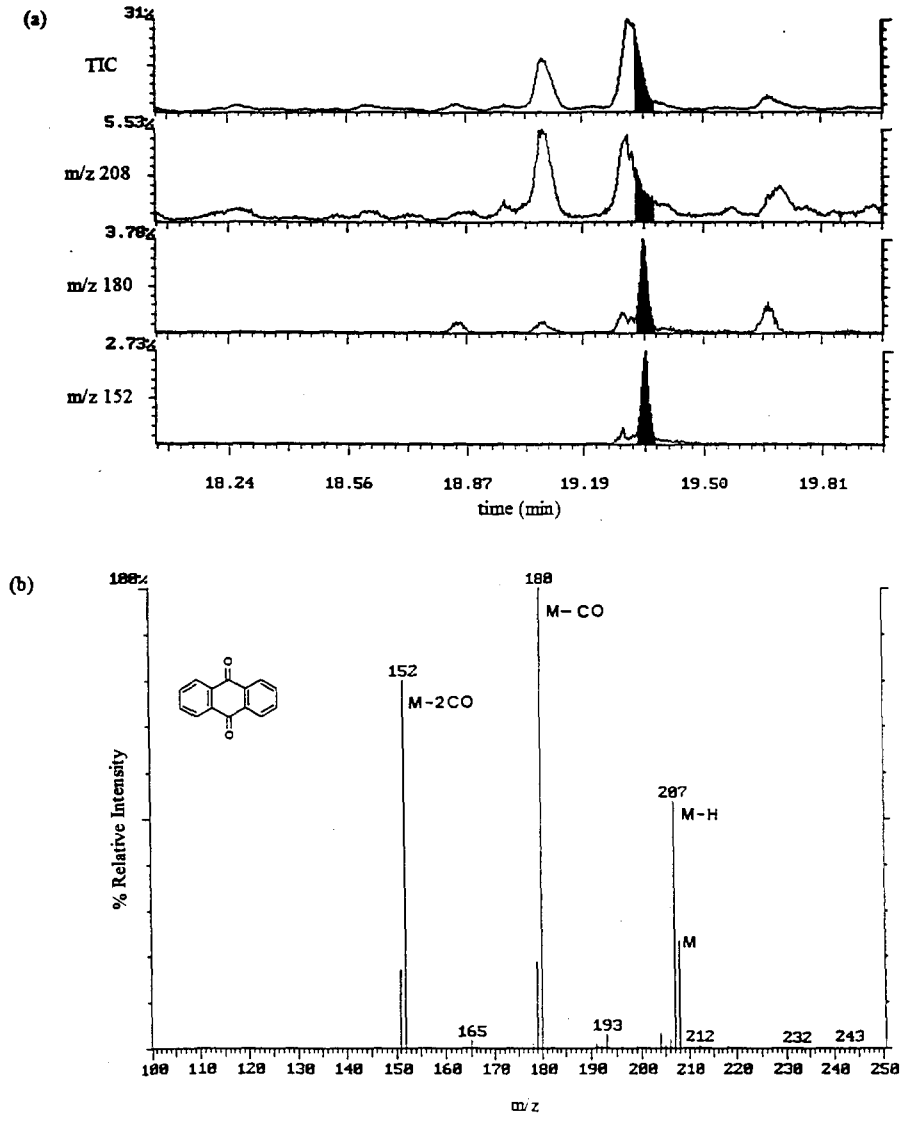

Fig. 5. Non-resonant GC/MS/MS analysis of sediment extract. (a) TIC and m/z 208, 180, 152 ion chromatograms, (b) background subtracted mass spectrum at t_R = 19.4 min in (a).

8b1. As these ions do not correspond to any logical losses from m/z 222, they are most likely due to co-eluting interferences. For example, the m/z 202 ion probably corresponds to pyrene (MW 202), since large amounts of this substance, present in concentrations two orders of magnitude higher than C1-AQ, are found to coelute in this region (t_R = 20.86 min). One has to recognize that during the CID process, (step 7, Fig. 1), eluants from the GC column are constantly entering the trap and can interact with the ions which have been isolated. Given that the ionization potential of anthraquinone and its fragmentation products is greater than that of pyrene [20] the m/z 202 pyrene ions may be formed via charge transfer reactions with the stored m/z 222 ions. Similarly, the m/z 210 and 211 ions could arise from ion molecule reactions between matrix molecules and stored ions.

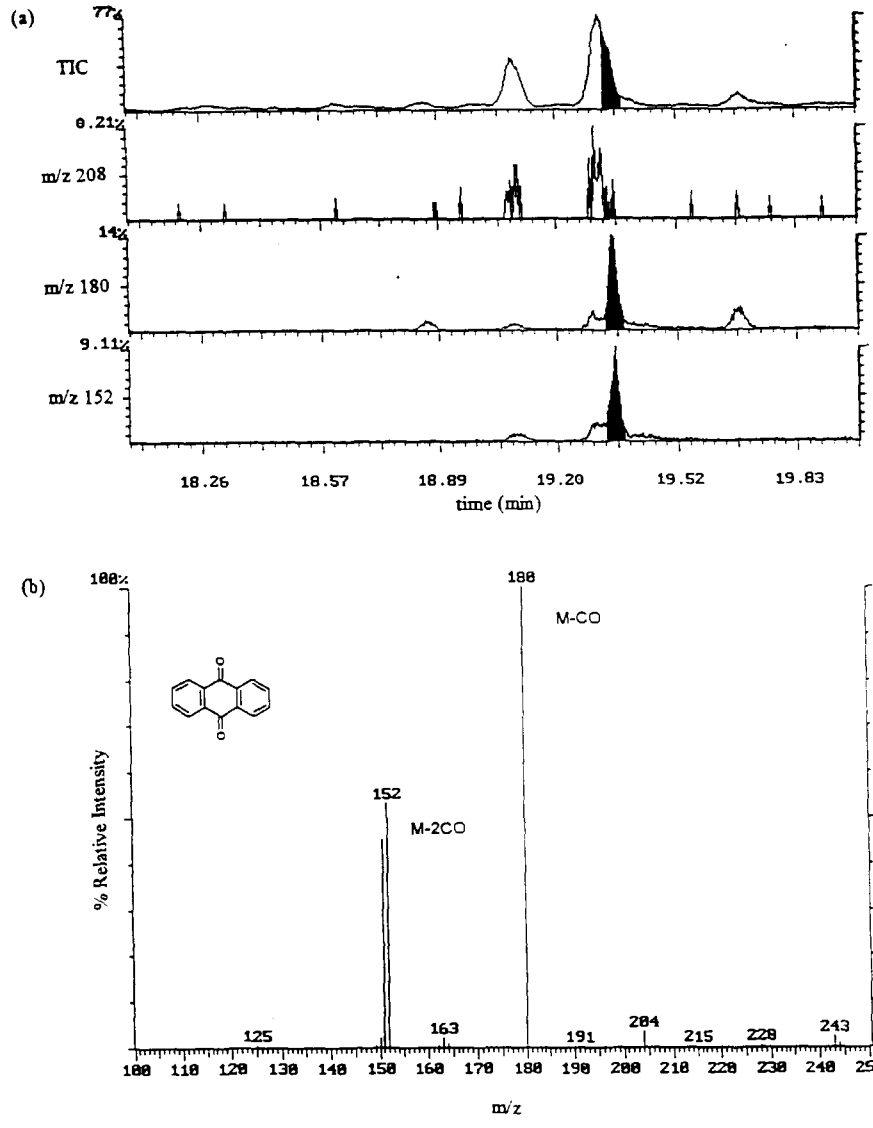

Fig. 6. Resonant GC/MS/MS analysis of sediment extract. (a) TIC and m/z 208, 180, 152 ion chromatograms, (b) background subtracted mass spectrum at $t_R = 19.4$ min in (a).

Although the isolation of m/z 222 for the CID experiments was performed with a 1 amu window, these data demonstrate that the presence of relatively large amounts of co-eluting substances can generate small spectral interferences.

Comparison of the mass chromatograms (Fig. 7b and c) and mass spectra (Fig. 8b and c), reveals that the non-resonant experiment does in general provide slightly cleaner chromatograms and more intense characteristic fragment ions. In addition, in the resonant mode at certain energies loss of H is also observed (m/z 165, Fig. 8c), regardless of position of the methyl substituent, thus, complicating the mass search. Consequently, for the C_2-AQs only data obtained in non-resonant mode were considered. C_2-AQ signals were not detectable by GC/MS analysis.

The non-resonant GC/MS/MS search for C_2-AQ (dimethyl or mono ethyl) used m/z 236 as a precursor

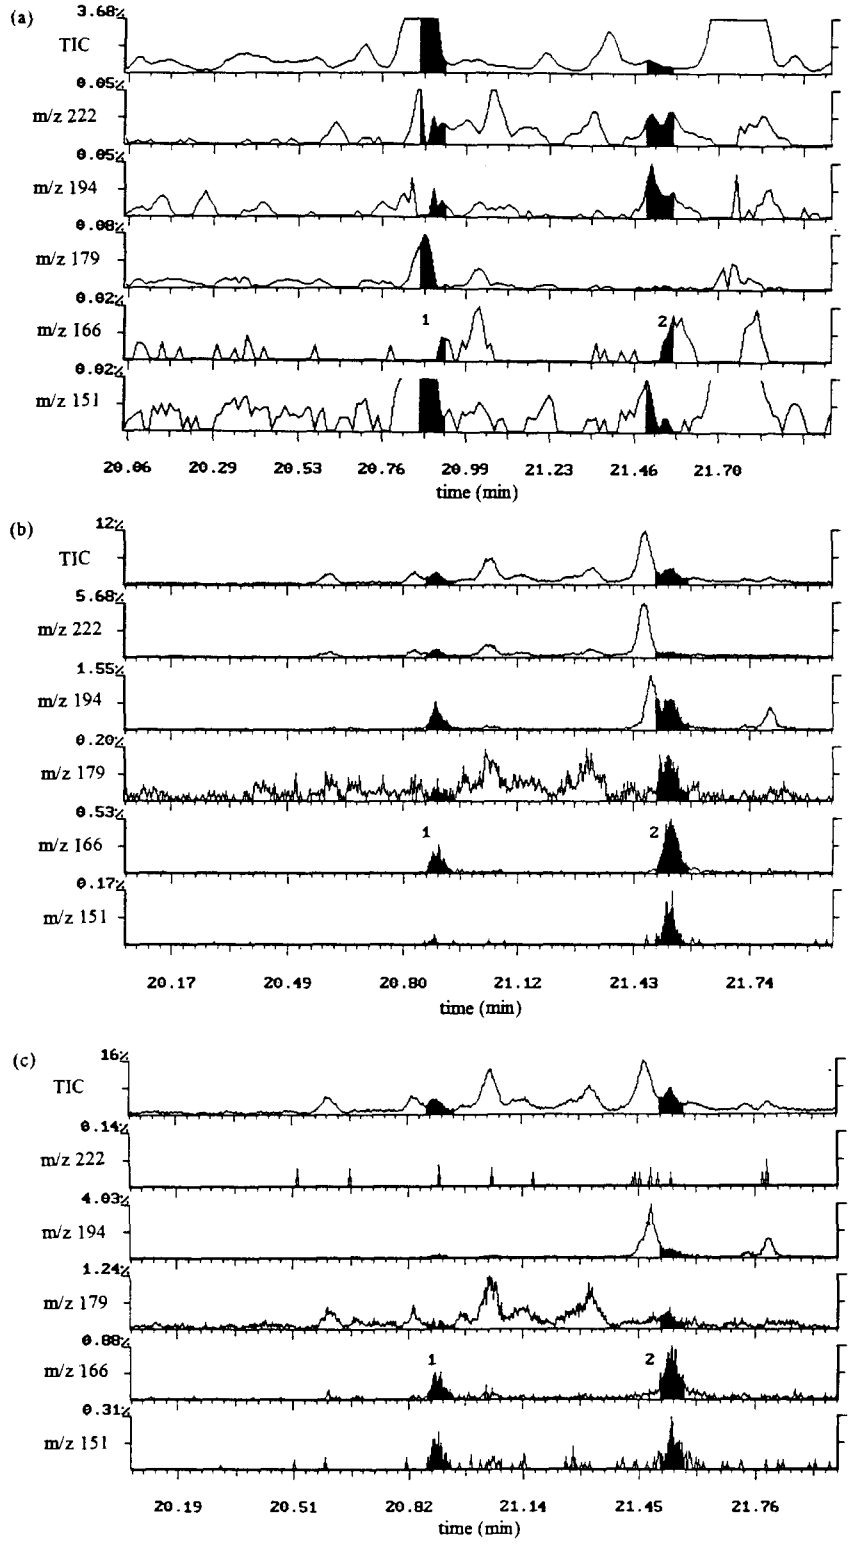

Fig. 7. TIC and m/z 222, 194, 179, 166, 151 ion chromatograms for sediment extract in (a) GC/MS, (b) non-resonant GC/MS/MS, (c) resonant GC/MS/MS modes.

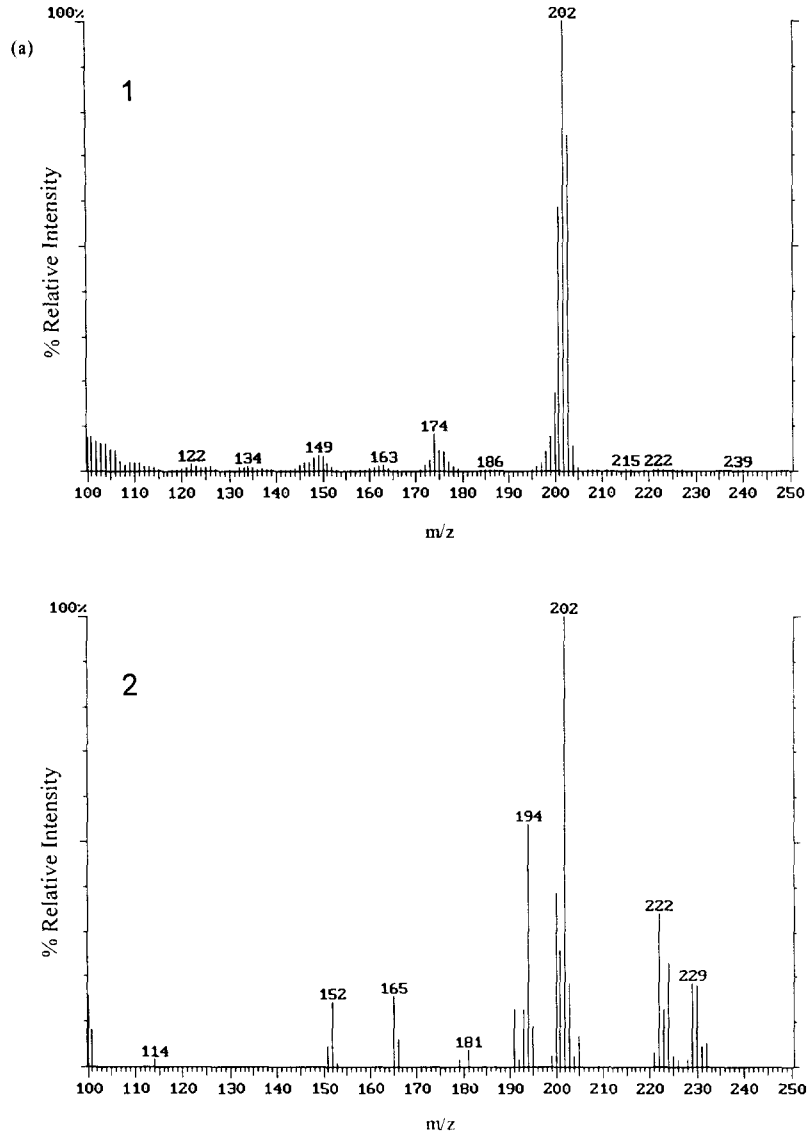

Fig. 8.

ion. Fragments at m/z 221 (M-CH_3), 208 (M-CO), 207 (M-C_2H_5 or M-HCO), 193 (M-CO, CH_3), 180 (M-2CO) and 165 (M-2CO, CH_3) could be expected. The corresponding ion chromatograms are shown in Fig. 9. Mass spectra extracted at positions 1 ($t_R = 23.1$ min) and 2 ($t_R = 23.6$ min) are shown in Fig. 10. The spectra confirm the presence of C_2-AQ in the sediment extract. Ions of m/z 207 at position 1 could be due to loss of C_2H_5 from the parent ion and/or loss of CO + H because of the close proximity of the carbonyl oxygen(s) and an alkyl group; the latter also applies to the m/z 179 in the spectra from positions 1 and 2. In consideration of the ion at m/z 165 in the spectra of the MeAQs in Fig. 8c (1 and 2) a dimethyl substitution is more likely than an ethyl substituent.

The three experiments outlined above, searching for presence of anthraquinone and its C_1 and C_2 alkylated analogues in the sediment extract, were carried out first individually to determine the

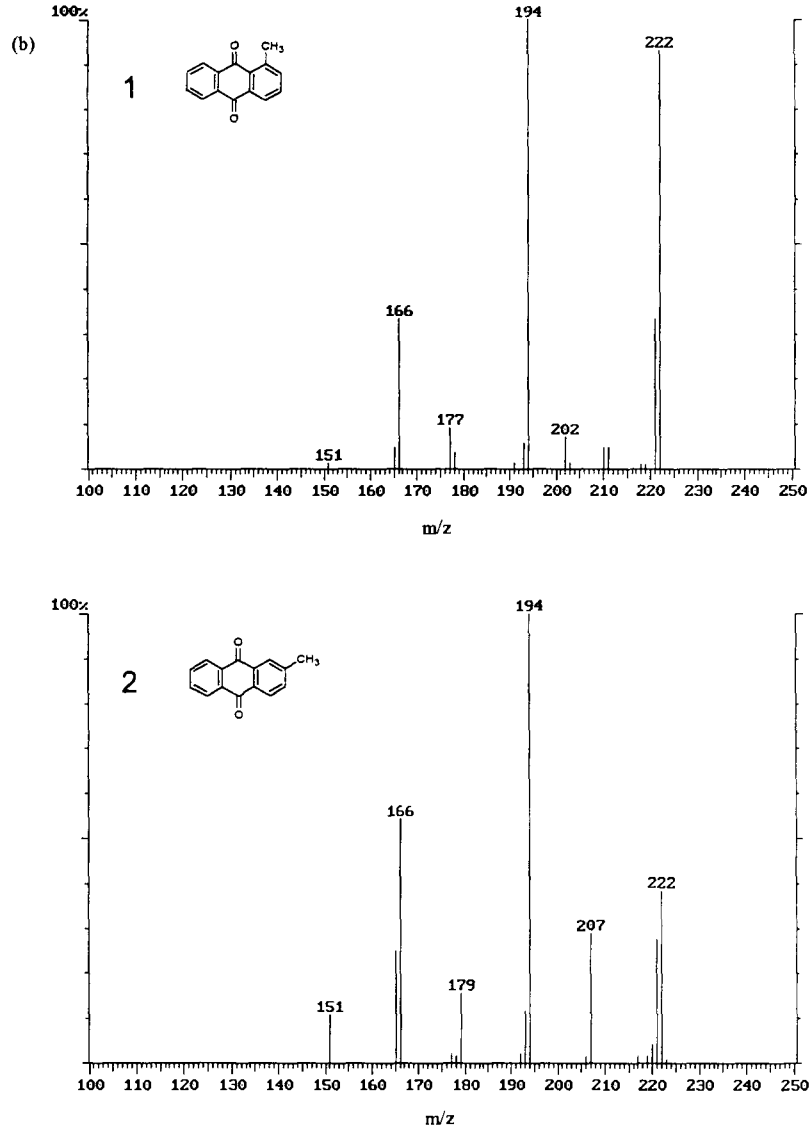

Fig. 8.

appropriate elution windows, followed by a single combined experiment in which the three time windows were defined for the three different CID precursor masses (m/z 208, 222, 236). As expected, there was no detectable difference in the results obtained. The ability to perform multiple CID experiments during a single GC run, either for method development or for analytical purposes, is advantageous especially if only small amounts of sample are available or if a large number of samples has to be analyzed.

3.3. Quantitation

Although a large number of fragment ions is desirable for compound identification, for quantification of the compounds discussed here it is important to remove as many coeluting interferences as possible, thus, GC/MS/MS would be the method of choice particularly if strong ion chromatograms are available from secondary fragmentation products such as the m/z 152 (M-2CO) ion of AQ, the m/z 151 (M-2CO, CH_3) and m/z 166

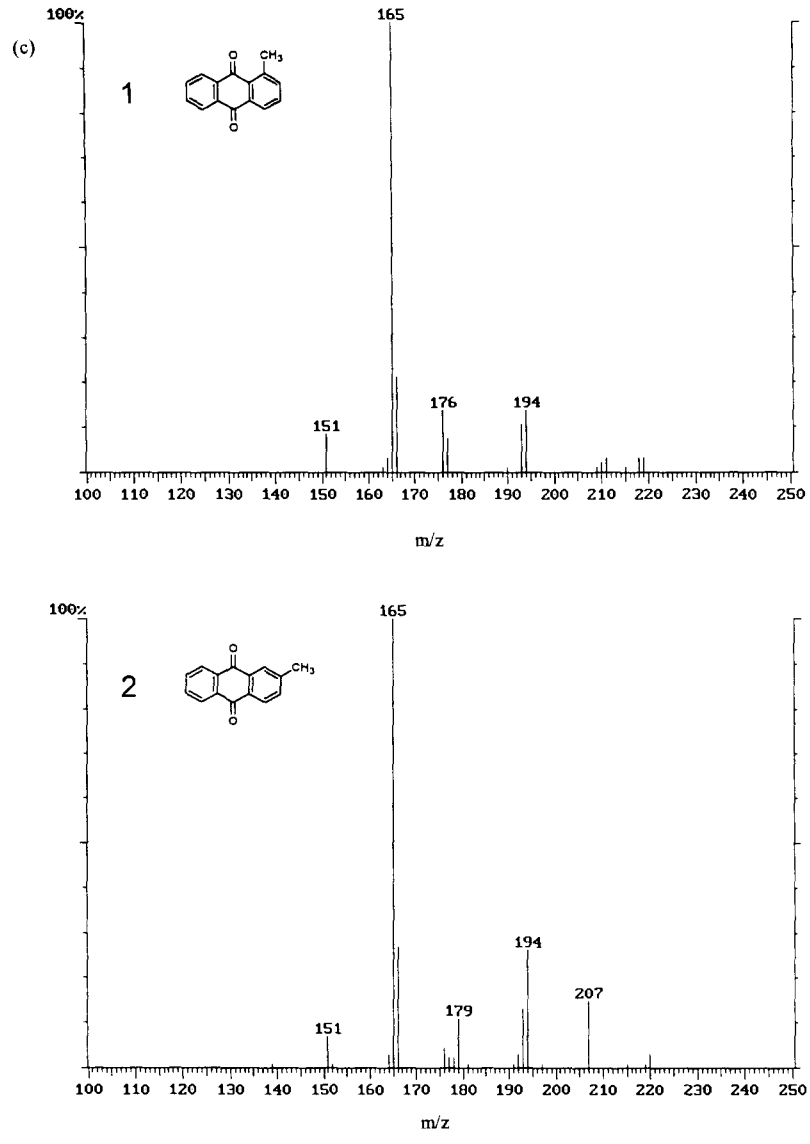

Fig. 8. Background subtracted mass spectra extracted at position 1 and 2 in Fig. 7. (a) GC/MS, (b) non-resonant GC/MS/MS, (c) resonant GC/MS/MS conditions.

(M-2CO) ions of MeAQs and the m/z 180 (M-2CO) and m/z 165 (M-2CO, CH_3) ions of C_2-MeAQs. As clearly demonstrated by the ion chromatograms in Fig. 7 and Fig. 9 these fragments provide the best selectivity over matrix interferences. Consequently, for quantitation purposes the CID conditions should be optimized to yield maximum amounts of these ions. For example, in the case of AQ and 2-MeAQ a non-resonant CID energy of 80 volts (see Fig. 2 and Fig. 3) provides the maximum yield of secondary fragments.

Calibration curves for AQ, obtained using the m/z 152, were linear ($r = 0.99$) over a range of 1 pg to 10 000 pg for both resonant and non-resonant CID analyses. The lowest detectable amount of AQ by GC/MS/MS was approximately 0.5–1.5 pg using the m/z 152 ion for quantitation.

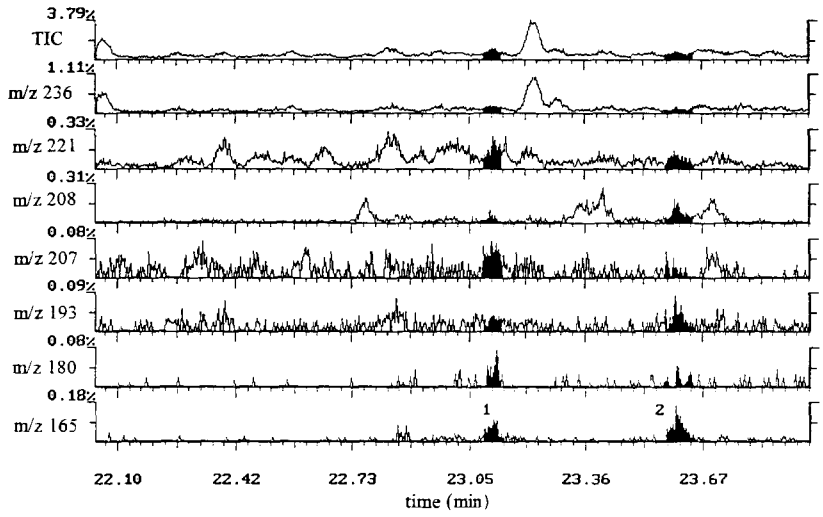

Fig. 9. TIC and m/z 236, 221, 208, 207, 193, 180, 165 ion chromatograms for sediment extract in non-resonant GC/MS/MS mode.

The extraction efficiency of AQ determined using a spiked uncontaminated sediment was approximately (70–130%). This is significantly higher than the recovery of anthracene and D_{10}-anthracene (50–70%). This large difference can be explained by the fact that acetone was employed in the extraction process, thus facilitating the extraction of the more polar components. Furthermore, from the sediment spiked with an thracene it was found that approximately 6% of the anthracene in a spiked sample was converted to AQ. Injections of pure anthracene revealed that oxidation to AQ did not occur in the injector. Consequently, this observed oxidation must have taken place during the extraction or cleanup procedures.

These results indicate the importance of monitoring for transformation products as part of an analytical protocol to determine if low extraction efficiencies are due to merely adherence to the matrix or due to actual loss of analyte through chemical transformation. The importance of the transformation of PAHs during extraction was recently indicated by Soheila et al. [21] who identified the presence of bianthracene as a polymerization product of anthracene.

The concentrations of anthracene, 2-methylanthracene, AQ and 2-MeAQ in the freeze dried sediment were determined using the internal standard anthracene-D_{10} m/z 188 molecular ion chromatogram and the M-2CO ion chromatograms for the quinones, together with the appropriate relative response factors. For the anthraquinone and 2-methylanthraquinone, a correction factor corresponding to 6% of the non oxidized compound, (anthracene or 2-methylanthracene), was employed to account for potential oxidation during the sample preparation. The results obtained from non-resonant analysis indicate concentrations in dry sediment of: 400–600 $\mu g\ g^{-1}$ anthracene, 40–60 $\mu g\ g^{-1}$ 2-methylanthracene, 6–24 $\mu g\ g^{-1}$ anthraquinone and 1–7 $\mu g\ g^{-1}$ 2-methylanthraquinone. For the other quinones analyzed, for which standards were not available, concentration values were estimated by using the response factor of 2-MeAQ. The values obtained were: 0.9–1.8 $\mu g\ g^{-1}$ 1-methylanthraquinone and 1.0–1.9 $\mu g\ g^{-1}$ for the sum of the two C_2-AQs (positions 1 plus 2 in Fig. 9).

4. Analysis of other PAH oxidation products

GC/MS and NRCID GC/MS/MS analyses were also performed for 9-fluoranone (MW 180) and benz[a]anthracene-7,12-dione (MW 258) for which standards were available to obtain retention times and develop optimum CID conditions. The former, being a monoketone, only offers one major fragment for identification (m/z 152, M-CO) while the latter

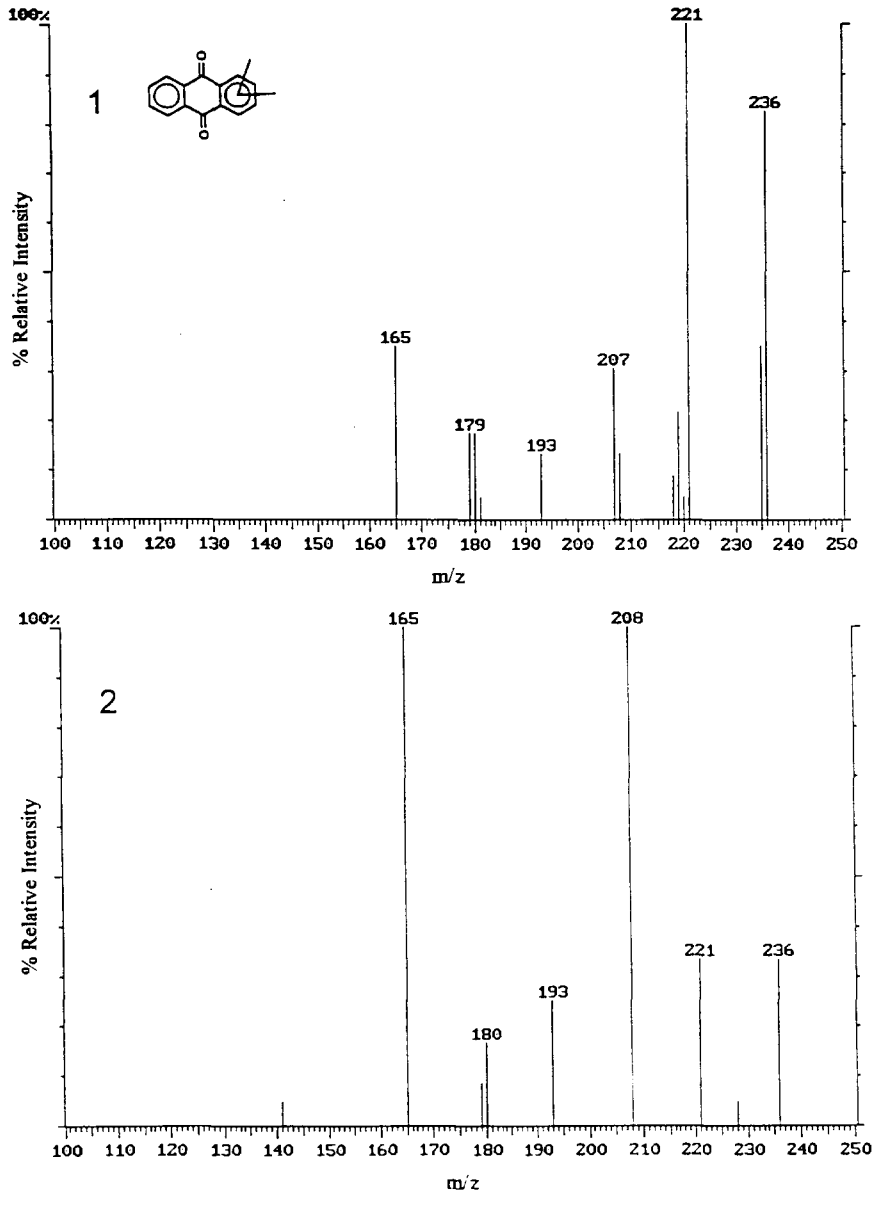

Fig. 10. Background subtracted mass spectra extracted at position 1 and 2 in Fig. 9.

offers two fragments (m/z 230, M-CO and m/z 202, M-2CO). Using the two standards the optimum NRCID fragmentation conditions to yield maximum amounts of m/z 152 for 9-fluoranone and m/z 202 for benz[a]anthracene-7,12-dione were 90 and 60 volts, respectively. Using these NRCID conditions, during the appropriate retention time windows, these two compounds were targeted in the sediment extract. The 9-fluoranone m/z 152 ion chromatogram and the benz[a]anthracene-7,12-dione m/z 202 ion chromatogram obtained for both GC/MS and GC/MS/MS analysis are shown in Fig. 11. The latter compound was only detectable by GC/MS/MS. Furthermore, comparison of the data reveals that the M-2CO ion chromatogram of benz[a]anthracene-7,12-dione does not contain any

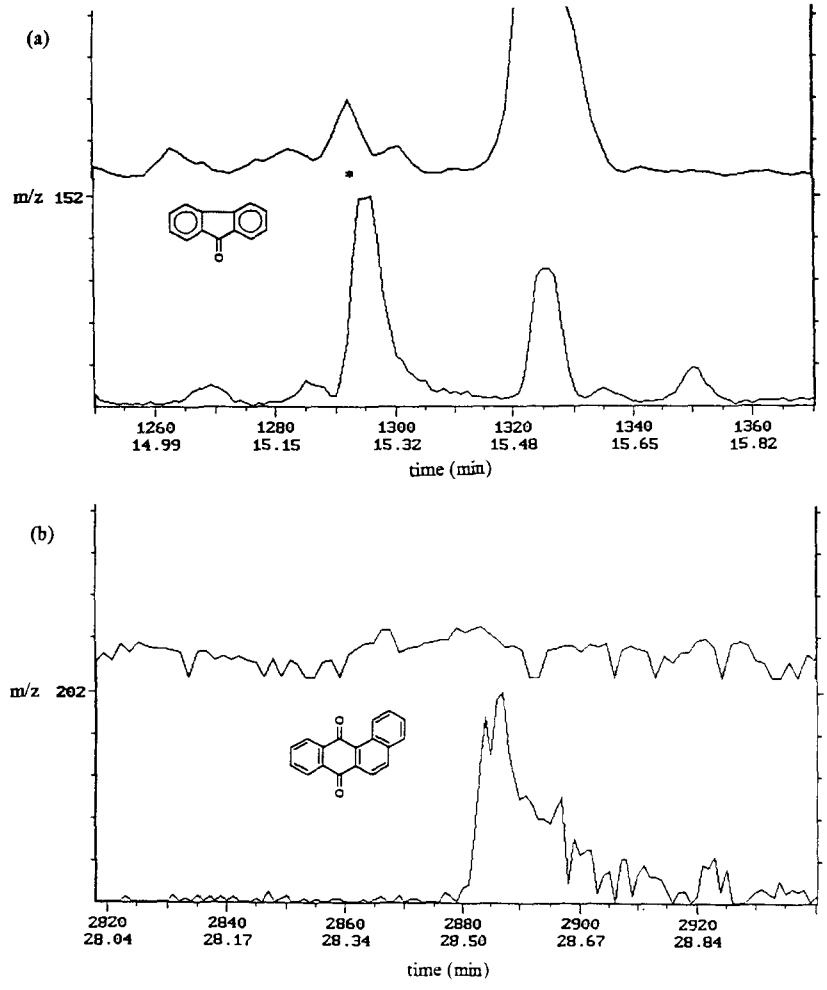

Fig. 11. GC/MS (top trace) and NRCID GC/MS/MS (bottom trace) ion chromatograms for (a) 9-fluoranone (m/z 152) and (b) benz[a]anthracene-7,12-dione (m/z 202) in sediment extract.

other eluting compounds while the M-CO ion chromatogram of 9-fluoranone contains several other eluting substances. Although the GC/MS/MS analysis results in a strong enhancement of the 9-fluoranone ($t_R = 15.3$ min) signal it does not completely eliminate other compounds from the chromatogram. These results further demonstrate the greater specificity obtained by monitoring secondary fragmentation products. From these analyses the concentrations in dry sediment of 9-fluoranone and benz[a]anthracene-7,12-dione were estimated to be 20–40 and 10–20 μg g^{-1}, respectively.

5. Conclusion

The data obtained in this study demonstrate the usefulness of ion trap GC/MS/MS experiments for detecting and quantifying trace amounts of polyaromatic quinones which would ordinarily be obscured by matrix interferences when using standard GC/MS techniques. Improvements are especially notable when secondary fragmentation products, such as M-2CO, are monitored. Non-resonant CID is preferred when characteristic spectra are required for confirmation, it provides intense fragment ions together with molecular ion information.

The development of techniques able to analyze for trace level transformation products of contaminants in complex matrixes, such as the one outlined in this work, are important tools in monitoring the recovery of contaminated ecosystems.

Acknowledgements

The authors thank Varian Canada for providing the MS/MS capabilities to the Saturn GC/MS system. We acknowledge financial support from the Department of Indian Affairs and Northern Development (DIAND) and the National Science and Engineering Research Council (NSERC) of Canada. We would also like to thank Dionex Canada Ltd. for providing access to the ASE system and C. Simpson for collecting the settling pond sediment.

Abstract

A new matrix modifier composed of calcium and chromium[VI] was proposed for the determination of tributyltin (TBT) in toluene extract from sea water containing sediment by graphite furnace atomic absorption spectrometry (GFAAS). Fourteen inorganic and organic compounds (barium, calcium, chromium[VI], lanthanum, magnesium, nickel, palladium, strontium, calcium–chromium[VI], calcium–strontium, nickel isocaprylate, 5%-, 10%-aqueous solution of ascorbic acid and toluene-saturated solution of ascorbic acid) as a matrix modifier were comparatively studied and a matrix modifier composed from 5 μg of calcium and 1 μg of chromium[VI] was found to give the best performance. The interference effects of co-existing elements in sea water containing sediment (aluminium, iron, magnesium, sodium and strontium) were studied. TBT in eight toluene extracts was determined by GFAAS with the proposed matrix modifier. The relative standard deviation was 3.0% for 63 ng ml^{-1} of TBT ($n = 11$). The recoveries were 88–104%. The characteristic mass was 7 pg. The linearity range was 0–250 ng mg^{-1}. © 1997 Elsevier Science B.V.

Keywords: Matrix modifier; Sea water; Toluene

1. Introduction

In recent 30 years, organotin compounds are widely used in industry and agriculture resulting in increasing influences on environment. Tributyltin (TBT) used as antifouling agents in paint formulation is released into sea-water, more or less degraded, adsorbed on floating particles and accumulated in marine sediments. This released TBT even in trace amounts could seriously impair marine organisms and becomes one of the most important pollutants in marine environment.

The objective environmental concentrations of organotin compounds are 8 ng l^{-1} for France and United Kingdom, 4 ng l^{-1} for Japan and USA.

Graphite furnace atomic absorption spectrometry (GFAAS) is a favourable method for the determination of TBT at very low concentration. But the tendency of tin to form volatile compounds during the drying and ashing steps, and

its interaction with the carbon of the graphite tube wall causes erratic results easily. Moreover the organotin compounds have different behaviours in the furnace from the inorganotin compounds. These problems could be resolved by use of a suitable matrix modifier. Up to now, several inorganic and organic compounds have been proposed for this purpose. For example, palladium was used by Kashin et al. [1]; 4-methylpentane-2-one solution of palladium was selected by Dadfarnia et al. [2]; 0.1% ammonium dichromate was chosen by Parks et al. [3]; 0.4% potassium dichromate–0.2% ammonium dihydrogenophosphate in 2% nitric acid was proposed by Pinel et al. [4]; 0.01% picric acid was reported by Astruc et al. [5].

The investigation for the adsorption character of TBT on marine sediment is necessary for understanding the contamination behaviour of TBT in marine environment. So we study the determination of TBT in toluene extract from sea water containing sediment by GFAAS. Several inorganic and organic compounds were compared as a matrix modifier. From the results obtained a new mixed matrix modifier composed of calcium and chromium[VI] was selected.

2. Experimental

2.1. Apparatus

A Perkin–Elmer Model 5000 Atomic absorption spectrometer equipped with a Model HGA 500 graphite furnace, a Data Station 10 and a PR 100 printer was used. An L233 type hollow cathod lamp made by Hamamatsu TV and a Perkin–Elmer pyrolytic tube were used. An eppendorf micropipette was used for injecting sample solution into graphite furnace.

Instrumental parameters and operating conditions were optimized by means of experiments, and shown in Table 1.

2.2. Reagents

All chemicals used were of analytical grade, and distilled, deionized water was used throughout.

A stock standard solution of TBT (1000 mg l^{-1}) was prepared by dissolving 122.2 mg tributyltin chloride and diluting to 100 ml with methanol. The working standard solutions were prepared by successive dilution of the stock stan-

dard solution to following concentrations (0, 50, 100, 150, 250 ng ml^{-1}) with toluene.

A 1 g l^{-1} solution of chromium[VI] was prepared by dissolving potassium dichromate in 0.2% nitric acid. A 1 g l^{-1} solution of calcium was prepared by dissolving calcium nitrate in 0.2% nitric acid. A mixed matrix modifier composed from 5 μg of calcium and 1 μg of chromium[VI] was prepared by the above-mentioned solutions of chromium[VI] and calcium.

1 g l^{-1} solutions of aluminium, barium, iron, lanthanium, magnesium, nickel, palladium, sodium and strontium were prepared by dissolving their nitrate or chloride salts in 0.2% nitric acid. A 1 g l^{-1} solution of nickel isocaprylate was prepared by dissolving nickel isocaprylate in toluene. 5%- and 10%-aqueous solutions of ascorbic acid were prepared by dissolving ascorbic acid in water. A toluene-saturated solution of ascorbic acid was prepared by dissolving ascorbic acid in toluene as much as possible.

These solutions were used as a matrix modifier for the comparative study of their performances or used as an interferent for the study of their interference effects.

2.3. Procedure

A certain amount of TBT methanol solution was added into 50 ml sea water containing 0.5 g sediment. This solution was oscillated 12 h at 200 rpm and centrifuged 20 min at 3000 rpm. The 20 ml supernatant liquid was transferred into a separatory funnel.

Toluene, 2 ml, were added, shaken vigorously for 2 min and allowed to stand for phase separation. After draining off the aqueous phase, the toluene phase was washed with 10 ml water three times in order to remove the remaining interferent such as sodium chloride and transferred into test tube.

A 5 μl aliquot of the sample solution in test tube at first and then a 10 μl solution of the mixed matrix modifier were injected into the graphite furnace consecutively, and the peak height was measured.

3. Results and discussion

3.1. Effects of heating rate mode in atomization step

The heating rate mode in atomization step influences appreciably on the analytical sensitivity of TBT.

The model HGA 500 graphite furnace has two heating rate modes: temperature-controlled maximum heating (ramp time = 0 s) and conventional voltage-controlled heating (ramp time ≥ 1 s).

The former without any matrix modifier can produce 23% of the absorption signal which is obtained with a calcium–chromium[VI] matrix modifier. But the latter can not produce any absorption signal even with a calcium–chromium[VI] matrix modifier. So the former was used.

3.2. Effect of ashing- and atomization-temperature

The effects of atomization temperatures were studied from 2500–1600°C. The results showed this temperature range to give the same effects. Under the condition of using a matrix modifier composed of calcium and chromium[VI], ashing temperature could be increased up to 1300°C. At 1350 and 1400°C, the absorbances obtained decreased about 13 and 40% of that at 1300°C, respectively. From the above results, 2200 and 1200°C were selected as atomization- and ashing-temperature, respectively.

3.3. Comparative study of the performances of 14 matrix modifiers

The authors have reported that the analytical sensitivity for TBT can be significantly improved by the addition of di(methylcyano) palladium [$PbCl_2(CH_3CN)_2$] [6]. But the compound was not available now, so an inorganic palladium compound was tried to replace it. The ordinary matrix modifiers such as lanthanum, magnesium, nickel, strontium and calcium salts were studied also.

Moreover, the analytical sensitivity of tin could be improved not only by a reducing agent such as ascorbic acid [7–10], but also by an oxidizing agent such as potassium dichromate [3].

Table 2
Relative enhancement ratios for the analytical sensitivity of TBT using 14 compounds as matrix modifier (relative to palladium)

Matrix modifier		Pd	Ba	Ca	Cr[VI]	La	Mg	Ni	Sr	Ca–Cr[VI]	Ca–Sr	$Ni(C_8H_{14}O_2)_2$	Ascorbic acid		
Concentration (mg ml^{-1})		1	1	1	1	1	1	1	1	0.5–0.1	0.5–0.5	1	0.5% aqueous	10% aqueous	Toluene-saturated
Enhancement ratio		1.0	0.8	1.0	1.3	0.1	0.4	0.4	1.1	1.7	1.6	0.7	0.7	0.8	0.5

Accordingly, the 14 inorganic and organic compounds (barium, calcium, chromium[VI], lanthanium, nickel, palladium, strontium, calcium–chromium[VI], calcium–strontium, nickel isocaprylate, 5%- and 10%-aqueous solution of ascorbic acid and toluene-saturated solution) were taken as a matrix modifier to study their performances for increasing the analytical sensitivity of TBT.

The results shown in Table 2, indicate the two mixed matrix modifiers (calcium–chromium[VI] and calcium–strontium) to give the higher sensitivities among 14 compounds. The precision of calcium–chromium[VI] (RSD = 1.0% for 100 ng ml^{-1} standard solution of TBT) is higher than that of calcium–strontium (RSD = 1.6% for the same TBT solution). So a mixed matrix modifier composed of calcium and chromium[VI] was selected.

3.4. Optimal composition of a calcium–chromium[VI] matrix modifier

The optimal amounts of each component of a calcium–chromium[VI] matrix modifier were studied.

The concentrations beyond 0.2 mg ml^{-1} of chromium[VI] cause blank value to increase, and the concentration range from 0.05–1 mg ml^{-1} of calcium gives the same sensitivity. So a mixture composed from 0.5 mg ml^{-1} of calcium and 0.1 mg ml^{-1} of chromium[VI] was chosen as a matrix modifier.

3.5. Interferences of coexisting elements

Calcium, magnesium, potassium, sodium, aluminium, iron and strontium contained in sea water and sediment may interfere on the determination of TBT. Though these elements could not be extracted in toluene phase, but the

Table 3

7	115	90	85	94
8	128	90	88	98

[a] Value of sample number 4 is means of 11 determinations. All the other values are means of three determinations.

trace amount might be mixed in toluene phase. So, the interference effects from the above elements except for calcium and potassium (because calcium and potassium were contained in a matrix modifier used) were studied with a matrix modifier composed of calcium and chromium[VI].

It is seen from Table 3 that sodium shows the severest interference effect among these coexisting elements. For example, under the coexistances of 5 and 10 ng of sodium the recoveries of TBT were 94 and 76%, respectively. This showed that the larger amounts of sodium than 5 ng cause the interference effect. So, the toluene phase should be washed with water three times to remove its remaining interferents, especially sodium [3].

3.6. Determination of TBT in toluene extract from sea water containing different sediments

The investigation of the adsorption character of TBT on sediment was carried out by using different sorts of marine sediments. A certain amount of TBT was added into sea water containing different sediments and the remaining TBT in sea water was measured by the proposed method after extracting with toluene. The results are shown in Table 4.

The relative standard deviation was 3.0% for 63 ng ml^{-1} of TBT ($n = 11$, 62, 69, 62, 63, 62, 64, 61, 64, 61, 63, 67). A characteristic mass was 7 pg. The linear range of the calibration curve was 0–250 ng ml^{-1} and its correlation coefficient was 0.999. The recoveries were 88–104%.

The above data demonstrate that the proposed method has good accuracy, precision and sensitivity.

Flow injection analysis of sulphite by gas-phase molecular absorption UV/VIS spectrophotometry

A. Safavi *, B. Haghighi

Department of Chemistry, College of Sciences, Shiraz University, Shiraz 71454, Iran

Received 23 July 1996; received in revised form 6 November 1996; accepted 15 November 1996

Abstract

A flow injection gas-phase molecular absorption spectrophotometric method is described for the determination of sulphite in aqueous solution. The sulphite solution, 200 μl, is introduced into a stream of distilled water. The carrier stream containing a sulphite zone is reacted, in the first mixing coil, with a stream of sulphuric acid (1 M). The evolved sulphur dioxide is purged to the segments of nitrogen flow through the second mixing coil. The gaseous phase is separated from the liquid stream by the use of a purpose built gas-liquid separator and then is swept into a purpose built flow-through cell. The absorbance of the gaseous phase is measured at 200 nm using a UV/VIS spectrophotometer. Up to 440 μg of sulphite is determined. The limit of detection is 0.8 μg and the R.D.S. for the determination of 70 and 220 μg of sulphite are 1.02 and 0.76%, respectively. Up to 40 samples h^{-1} can be analyzed. The effect of several anions and cations on the determination of sulphite was studied and the results showed that the method is relatively free from interferences. The proposed method was applied to the determination of sulphite in a synthetic sample, water sample and lemon juice. © 1997 Elsevier Science B.V.

Keywords: FIA; GPMAS; Lemon juice; Sulphite

1. Introduction

Sulphite and sulphur dioxide are widely used as preservatives in the food and pharmaceutical industries because of their ability to prevent oxidation, bacterial growth and inhibit discolouration in order to improve the appearance of dried fruit [1]. Strict control over their concentrations in industrial products is mandatory because of their toxicity. Sulphur dioxide is also a major pollutant that has been causing environmental concern over recent decades. It has been identified as one of the main causes of increasing acidification of the environment through the generation of acid rain. Sulphur dioxide is released into the atmosphere primarily from the combustion of coal and petroleum, the smelting of sulphur-containing ores, production of sulphuric acid and the paper manufacturing industry. Its adverse effects on living organisms are well known [2].

Both sulphite and sulphur dioxide have been determined by a variety of analytical methods [3]. These include titrimetry [4], ion chromatography [5], coulometry [6], conductimetry [7], polarogra-

phy [8], flame photometry [9], chemiluminescence [10], UV/VIS spectrophotometry [11], molecular-emission cavity analysis [12], kinetic analysis [13] and FIA [14].

The determination of anions and cations in solution by conversion of the determinant into a volatile molecular species followed by their molecular absorbance measurements in the gas phase has been thoroughly investigated in the past two decades. The gaseous product is carried by a stream of air or nitrogen to a flow-through absorption cell which is positioned in the light path of the spectrometer in the space normally occupied by the flame of an atomic absorption spectrometer. A narrow band of radiation from a hollow cathode or deuterium lamp corresponding to an absorption maximum of the evolved compound is passed through the cell and the absorbance signal of the compound is measured. The technique is known as gas-phase molecular absorption spectrometry (GPMAS). The GPMAS technique is sensitive, reproducible and a versatile non-flame molecular absorption method [15].

The GPMAS technique has been introduced by Syty [16,17], who utilized the characteristics UV absorption bands of sulphur dioxide for its determination in solution. In Cresser's laboratory [18,19], GPMAS was developed during a search for a rapid and reliable method for the determination of ammonium–nitrogen in digests of soil and plant samples using the Kjeldahl method. Their methods were manual and involved considerable manipulation. Later, Cresser et al. described a method for the determination of sulphite [15] by automated GPMAS with a similar procedure. However, the manifold is complex and the system needs the use of an atomic absorption spectrometer (AAS).

The introduction of diode-array detection systems in UV/VIS spectrophotometers allowed new developments in GPMAS by Sanz et al. for single [20,21] and multicomponent simultaneous determinations [22,23]. Cabredo Pinillos et al. [24] described a continuous method for the simultaneous determination of sulphide and sulphite by the use of GPMAS with diode-array detection.

The purpose of this study was to investigate the possibilities for developing a modification of the above method for simple, precise and fast determination of small amounts (μg) of sulphite with low reagents consumption, when small volumes of samples are available. The method utilizes a UV/VIS spectrophotometer instead of an AAS which has been used before [15] with a purpose built gas liquid separator and a simple flow injection manifold. The absorbance of the generated gas (SO_2) is measured at 200 nm as it is swept into a purpose built flow-through cell positioned in the space of the cell compartment of a UV/VIS spectrophotometer. Up to 440 μg of sulphite can be determined precisely with a sampling rate of 40 samples h^{-1}.

2. Experimental

2.1. Apparatus

A Philips PU8275 UV/VIS spectrophotometer interfaced to an IBM compatible computer (AUVA, 386 SX) via an RS-232C port was used for monitoring and collecting absorbance data at 1 s intervals.

The flow injection system consisted of a Desaga PLG-peristaltic pump with Desaga silicon tubing E, Rheodyne Teflon rotary valve type 50, Supelco Teflon tubing (0.5 mm i.d.) and couplings, a purpose built gas-liquid separator and a purpose built flow-thorough cell.

The gas-liquid separator (Fig. 1) was made of two coaxial glass tubes in which the outer glass tube is sealed around an inner glass tube. The separator chamber had about 2.3 ml inner volume with one inlet and two outlets. Placement of the inner glass tube in the separator chamber provides a large flat area, on which, the incoming gas–solution mixture from the mixing coil is dispersed and efficiently separated. Also, the inner glass tube provides a channel for circulating water so the temperature of the chamber could be easily controlled. More details and dimension of the separator chamber are shown in Fig. 1. The flow-through cell of the standard U-type design was made of a cylindrical block of polyethylene (50 mm length, 30 mm o.d. and 5 mm i.d.) with quartz windows.

A program written by the authors collected and saved data in the Excel format for further processing.

2.2. Reagents

Analytical reagent grade chemicals from Merck and deionized, triple distilled water were used. A stock solution of sulphite (2500 μg ml^{-1}) was prepared daily by dissolving 0.3935 g of anhydrous Na_2SO_3 in 100 ml of 0.02 M sodium hydroxide solution. Working solutions were prepared by the least number of dilution steps, immediately before use. A stock solution of sulphuric acid (2 M) was prepared by diluting 28.0 ml of concentrated H_2SO_4 (98% and 1.84 g ml^{-1}) to 250 ml. Working sulphuric acid solutions were prepared by appropriate dilution. Solutions of a range of interferent cations and anions were prepared from analytical reagent grade salts.

2.3. Manifold and procedure

The flow injection manifold is shown in Fig. 2. The streams of sulphuric acid (1 M) and triple distilled water were delivered by the pump at flow

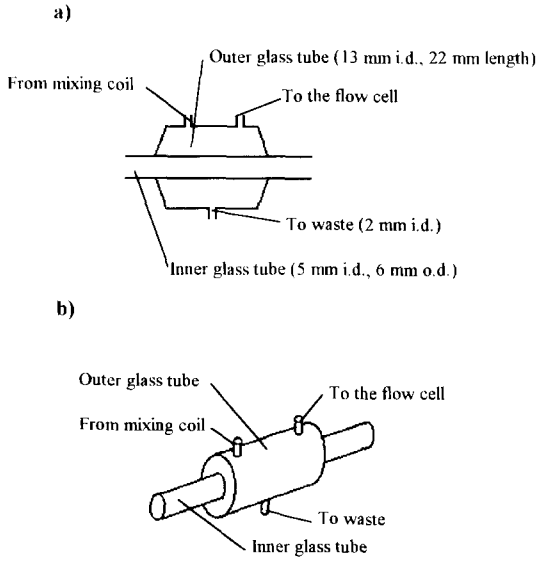

Fig. 1. Cross section view (a) and schematic diagram (b) of the purpose built gas-liquid separator.

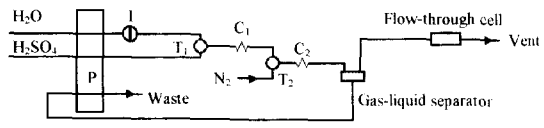

Fig. 2. The manifold design for the generation and measurement of sulphur dioxide; P, pump; I, injection port; C_1 and C_2, mixing coils; T_1 an T_2, 3-way connector.

rates of 1.9 ml min^{-1}. 200 μl Sulphite solution (100 μg ml^{-1}) was injected at I, via the six port rotary valve into a stream of triple distilled water and was mixed with a sulphuric acid stream at the first three-way connector (T_1). The reaction between the sulphuric acid and sulphite was completed in mixing coil C_1 (length 50 cm). Nitrogen gas at a flow rate of 17.0 ml min^{-1} was introduced to the stream containing the product of the reaction between sulphite and sulphuric acid at the second three-way connector (T_2). The evolved sulphur dioxide (SO_2) diffused into the nitrogen gas segments through the second mixing coil C_2 (length 30 cm). In the gas-liquid separator, the gas phase containing SO_2 was separated from the liquid phase and was passed through the flow cell. The molecular absorbance of the gaseous phase was recorded at 200 nm and at 1 s intervals. The temperature of the separator's stream of water was 25°C in all the experiments. All the optimization processes were performed on the determination of 200 μl of 100 μg ml^{-1} of sulphite.

3. Results and discussion

The spectrum of the SO_2 gas evolved in the process was obtained by a UV/VIS spectrophotometer which showed similar results to those cited in the literature [15]. The experimental variables influencing the performance of the proposed manifold were studied and optimized as discussed below.

3.1. Effect of N_2 flow rate

The influence of N_2 flow which carried the evolved SO_2 to the separator chamber and then to the flow cell was investigated. The results showed

that the absorbance increases with increasing N_2 flow rate from 6.2 to 17.0 ml min^{-1}, while further increase in N_2 flow rates up to 52.1 ml min^{-1} caused the signal to decrease (Fig. 3). Thus, a N_2 flow rate of 17.0 ml min^{-1} was selected for further studies. The effect of an auxiliary nitrogen flow for carrying SO_2 from the separator to the flow cell was also studied but no improvement in sensitivity was observed.

3.2. Effect of carrier solution flow rate

The effect of flow rates of carrier solutions was studied for flow rates of 0.4 up to 4.5 ml min^{-1}. Increasing the flow rates caused the peak width to decrease. The peak heights increased for carriers flow rates up to 1.9 ml min^{-1}, further increase in carriers flow rates did not affect the absorption signal intensities (Fig. 3). A flow rate of 1.9 ml min^{-1} was selected for further studies.

3.3. Effect of length of mixing coils C_1 and C_2

The effect of length of mixing coil C_1 on peak height was investigated. The results obtained indicate an increase in peak heights when the length of mixing coil C_1 was varied from 10 to 50 cm. Use of mixing coils longer than 50 and up to 450 cm did not increase the peak heights so the length of mixing coil C_1 was selected as 50 cm for further studies.

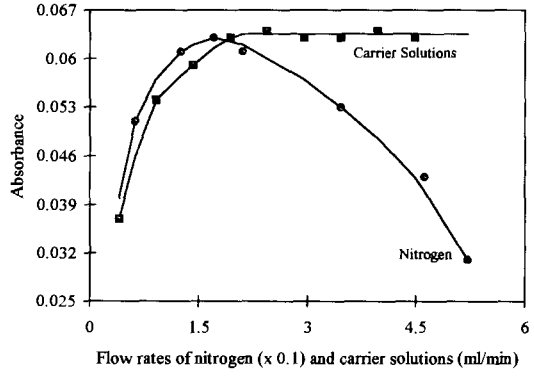

Fig. 3. Effect of N_2 and carrier solutions flow rates on the absorption signal intensities. Conditions: N_2 flow, 15.8 ml min^{-1} (for optimization of flow rates of carrier solutions); carrier solutions flow rates, 1.4 ml min^{-1} (for optimization of N_2 flow); mixing coil C_1, 96 cm; mixing coil C_2, 130 cm; sample volume, 200 μl, concentration of sulphite, 100 μg ml^{-1}; concentration of H_2SO_4, 2 M; λ_{max}, 200 nm; temperature, 25°C.

Studies on the effect of length of mixing coil C_2 on the peak height showed a small increase in peak heights with increasing length of mixing coil C_2 from 10 to 30 cm, while longer mixing coils up to 150 cm resulted in a slight decrease in peak heights. Therefore, the optimized length of mixing coil C_2 was selected as 30 cm.

Increasing the length of mixing coil C_1 had no significant effect on peak widths, while increasing the length of mixing coil C_2 increased the peak widths.

3.4. Effect of sample volume

It was found that by increasing the sample volume from 60 to 200 μl, with constant concentration of sulphite (100 μg ml^{-1}), the peak height was increased (absorbance changed from 0.027 to 0.064). However, further increase in sample volume up to 400 μl caused a slight decrease in absorption signal intensities (absorbance changed from 0.064 to 0.059). Also, the peak width was increased with increasing sample volume. A volume of 200 μl was therefore, chosen for further studies.

3.5. Effect of concentration of H_2SO_4

Increasing the concentration of H_2SO_4 from 0.2 to 2 M showed no significant improvement in absorption signal intensities. Also, the blank signal was not affected with increasing concentration of H_2SO_4. So, a concentration of 1 M H_2SO_4 was chosen for further studies.

3.6. Effect of temperature

The effect of temperature on the rate of evolution of SO_2 was investigated by placing the mixing coils C_1 and C_2 in a water bath and at the same time circulating water at the same temperature in the inner glass tube of the gas-liquid separator. The results showed that 40°C gives the highest signal (Table 1). However, 25°C was chosen for further studies as it is close to ambient temperature, making experimental manipulation easier.

Table 1
Effect of temperature on the absorption signal intensity

Temperature (°C)	Absorption signal intensity
24	0.064
29	0.071
5	0.074
40	0.080
45	0.078
50	0.075
60	0.071

Conditions: N_2 flow, 17.0 ml min^{-1}; carrier solutions flow rates, 1.9 ml min^{-1}; mixing coil C_1, 50 cm; mixing coil C_2, 30 cm; sample volume, 200 μl; concentration of sulphite, 100 μg ml^{-1} of sulphite; concentration of H_2SO_4, 1 M; λ_{max}, 200 nm.

3.7. Analytical performance of the manifold

The analytical performance achieved by the proposed manifold, including calibration equations and linear dynamic ranges are listed in Table 2. The presented calibration equations are obtained with similar operational parameters (optimum condition). As is obvious, three linear dynamic ranges are achieved. The theoretical detection limit calculated on the basis of three times the S.D. of the measurements of the blank signal [25],was obtained as 0.8 μg. Typical calibration traces are shown in Fig. 4. As can be seen, up to 40 samples h^{-1} can be analyzed.

Table 2
Analytical performance of the proposed manifold.

Linear dynamic range (μg)	Calibration equation	Correlation coefficient
≤120	$A = -1.744 \times 10^{-3} + 3.8345 \times 10^{-3} C$	0.9994
120–240	$A = 0.1546 + 2.6875 \times 10^{-3} C$	0.9995
240–440	$A = 0.3443 + 1.9722 \times 10^{-3} C$	0.9981

A, Absorbance; C, amount of sulphite in μg.

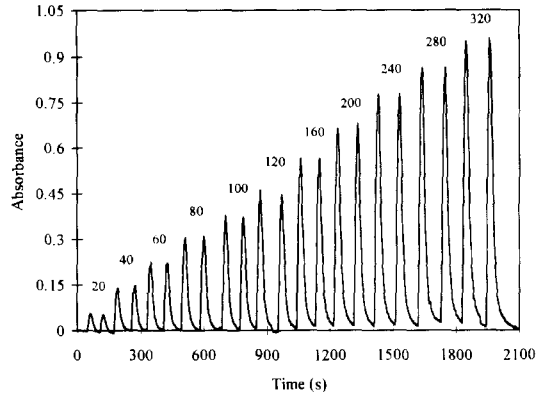

Fig. 4. Typical calibration trace for a series of standard sulphite solutions. Numbers above peaks denote amount of sulphite in μg.

3.8. Interferences

The effect of various anions and cations on the evolved SO_2 was studied. A range of solutions was prepared containing 50 μg ml^{-1} of sulphite and 3200 μg ml^{-1} of possible interfering anions (as K or Na salts). The solutions containing the sulphite sample plus the potential interferent anion (3200 μg ml^{-1}) were analyzed by the proposed method. The response was compared with those obtained from an uncontaminated sulphite solution. The results obtained are summarized in Table 3.

As expected, sulphide caused an enhancement effect on sulphite signal. This effect is due to the evolution of hydrogen sulphide which absorbs at 198 nm. An absorbance value of 0.016 was obtained when 25 μg ml^{-1} of sulphide were analyzed alone.

The interference effects of various cations (as SO_4^{2-} or NO_3^- salts) were investigated by a procedure similar to that used for anions. As it is shown in Table 3, the cations Na^+, K^+, Cr^{3+} and Mg^{2+} at a concentration of 1600 μg ml^{-1} had no effect on the determination of sulphite (50 μg ml^{-1}). The ions Mn^{2+}, Cu^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+} and Cd^{2+} formed a precipitate after mixing with sulphite solution.

Preparation of similar solutions in EDTA (0.001 M of di sodium salt of EDTA) is effective in removing the interference effect of cations and

anions. The addition of EDTA solution at a concentration of 0.001 M resulted in the dissolution of the above mentioned precipitates. Also the depressive interference effect of Cl^- and Br^- on sulphite is restored by the addition of EDTA (0.001 M) solution. However, Mn^{2+} and S^{2-} were the most severe interferents of the cations and anions investigated.

The results showed that introduction of EDTA in concentration ranges of 1×10^{-6} to 1×10^{-2} M into the sulphite solution not only stabilized the sulphite solution [15] and prevent the interference of some interferent cations and anions, but also, increases the sensitivity of the sulphite determination about two fold.

4. Application

To examine the reliability of the method certain amounts of standard sulphite solutions were added to a synthetic and water sample and analyzed according to the proposed method. The method was also applied to the determination of sulphite in lemon juice. Results obtained including recovery and precision are summarized in Table 4. It can be seen from the results that the method can be satisfactorily employed for the determination of sulphite.

5. Conclusion

By the use of a UV/VIS spectrophotometer for measuring the absorbance, a purpose built gas-liquid separator and a purpose built flow-through

cell, the determination of sulphite and dissolved sulphur dioxide is possible by the proposed flow injection gas-phase molecular absorption method. The proposed system is attractive because of its efficiency and simplicity. Interferences in the proposed method are few and are readily overcome by the addition of EDTA solution. Addition of EDTA solution to the sample solution also causes the sensitivity and selectivity of the proposed method to increase. Time saving, low reagent consumption, need of small sample volume, good precision, large dynamic range and high sample throughput (40 samples h^{-1}) are important features of the proposed system.

Determination of trace amounts of some metals in samples with high salt content by atomic absorption spectrometry after cobalt-diethyldithiocarbamate coprecipitation

Latif Elçi *, Uğur Şahin, Sibel Öztaş

Erciyes University, Art and Sciences Faculty, Chemistry Department, 38039 Kayseri, Turkey

Received 7 August 1996; received in revised form 18 November 1996; accepted 19 November 1996

Abstract

A method for determination of trace amounts of Cu, Fe, Pb, Mn, Zn, Cd, Ni, Bi and Cr in aqueous solutions by flame atomic absorption spectrometry after coprecipitation by using a combination of sodium diethyldithiocarbamate as a chelating agent and cobalt as a carrier element was introduced. Different factors including amounts of reagents, pH of sample solution, standing time, sample volume for the precipitation and matrix effects were examined. Under selected conditions, the relative standard deviation of the combined method of sample treatment, coprecipitation and determination with flame AAS ($n = 9$) is generally about 3.5–6.9%; the limits of detection (3 s, $n = 20$) for the analytes were found to be between 4 and 64 μg l^{-1}. The procedure was applied to the analysis of sea water and dialysis concentrate samples with quantitative recovery, ≥95%. © 1997 Elsevier Science B.V.

Keywords: Co-DDTC; Coprecipitation; Dialysis concentrate; Sea water

1. Introduction

Many techniques have been proposed to preconcentrate trace metals from matrices that adversely influence atomic absorption spectrometric detection. Separation methods used for this purpose include solvent extraction [1,2], ion exchange supports [3,4], chelating resins [5,6], sorbent extraction [7–9] and coprecipitation [10,11]. The combination of coprecipitation and filtration offer a simple and rapid preconcentration technique mainly in water analysis. Among coprecipitation precipitates, metal chelates are the most attractive gathering precipitate because of the excellent multi-elements trace recovery and sufficient separation factors especially for alkali and alkaline earth elements. Various procedures involving the use of metal-chelating precipitates are well documentated in the literatures [12,13]. Many metal ions, such as Co, Cu, Fe, Pb, Mn, Zn, Cd, Ni, Bi and Cr, form stable chelates with sodium diethyldithiocarbamate (NaDDTC). These chelates have been used for the extraction of some metal ions from aqueous solutions to an organic phase [12–14]. Co-DDTC is a considerably stable chelate [12]. Furthermore it is insoluble in water.

PII S0039-9140(96)02186-8

We conclude from the data given above that the employment of Co-DDTC in the study of the coprecipitation of trace metal ions in aqueous solutions as a collector of intent.

The purpose of the present work was to study the conditions of coprecipitation of Cu, Fe, Pb, Mn, Zn, Cd, Ni, Bi and Cr at trace level in aqueous solutions including high salinity by aid of Co-DDTC chelate.

2. Experimental

2.1. Instrument

A Hitachi atomic absorption spectrometer (Model Z-8000) with an air/acetylene flame and a Zeeman background corrector was used throughout the determination of the metal ions in model solutions and samples. The analysing solutions as 100 μl were introduced into the nebulizer of flame AAS with an injection method [15]. The operating conditions suggested in the instrument data processor were followed for the determination of metals.

2.2. Chemicals

Analytical reagent grade pure chemicals were used throughout the experiments. Doubly de-ionized water was redistilled in a quartz apparatus. Stock solutions of 1000 μg ml^{-1} in 1 M HNO_3 for each element of interest were used for the preparation of standard and model solutions. A solution of NaDDTC (5%, m/v) was prepared by dissolving of solid NaDDTC (Merck) in the water. The solution should be filtered through a membrane filter with 0.45 μm pore size and then kept at 4°C for longer storage. A solution of cobalt (500 μg ml^{-1}) as a carrier element was prepared by dissolving of proper amount as nitrate salt in the water.

The buffer used were phosphoric acid/dihydrogenphosphate for pH 2, ammonium acetate/acetic acid for pH 4–6, ammonium hydroxide/ammonium chloride for pH 8 to 10. pH 1 was obtained with nitric acid.

The membrane filter used was made of cellulose nitrate (0.45 μm pore size, 47 mm diameter and Whatman Cat. No: 7184 004).

3. Procedures

3.1. Model working

In the experiments for the recovery of examined metal ions, 100 ml portion of an aqueous solution containing an appropriate amount of them, 5 μg for Cu, Ni, Fe, Mn, Bi, Cr and Pb, and 1 μg for Cd and Zn was placed in a glass vial. The pH and acid concentration of the solutions were adjusted with a appropriate buffer solution and concentrated nitric acid, respectively. Cobalt as a carrier element, 600 μg, was added to this solution. Then, the required volume of 5% NaDDTC solution for 200 mg NaDDTC was poured into the glass vial. After 10 min, the solution containing precipitate loaded with the analytes was filtered through a membrane filter made of cellulose nitrate by aid of vacuum. The precipitate was washed with the blank solution without cobalt. The precipitate together with the membrane were dissolved with 1–2 ml of conc. HNO_3 and the solution was evaporated almost to dryness. The residue was diluted up to 2 or 5 ml with 1 M HNO_3 solution. The analytes in the solution were determined with the injection method by flame AAS.

3.2. Analysis of sea water

Sea water sample, collected from the Mersin bay on east of the mediterranean sea, was immediately filtered through a 0.45 μm cellulose nitrate membrane, acidified to pH 3 with hydrochloric acid, and stored in precleaned polyethylene bottles. The procedure was applied to the sample within 15 days. Since the storage period was so short, it was considered that there was no apparent loss of the analytes. For the analysis, the sample containing 400 ml of acidified seawater were firstly neutralized and then pH of which was buffered to 6. Cobalt, 600 μg, and 200 mg NaDDTC were successively added to the buffered sample. Subsequent treatments were the same as

to those described in the model working. The volume of the final solution was 2 ml.

3.3. Analysis of dialysis concentrate

A 150 ml portion of a dialysis concentrate used for the hemodialysis of patients suffering from renal function deficiency, without pretreatments, was transferred into a 250 ml beaker. It was buffered to pH 6. After 600 μg cobalt and 200 mg NaDDTC were added, the concentration and determination steps were carried out as described above. The volume of the final analysing solution was 2 ml.

4. Results and discussion

4.1. Amount of coprecipitation reagents

The reason why cobalt as the carrier metal was used is that cobalt is a suitable matrix for the determination of elements of interest by AAS. This reason was tested with a preliminary experiment. The solution containing fixed amount of examined elements and preparing with increasing concentrations of cobalt was analysed by flame AAS without any pretreatment. As a result, no significant interference had been observed up to 350 μg ml^{-1} Co. The concentration of cobalt found is considerably higher than the concentration of cobalt, max. 300 μg ml^{-1}, in the final solution obtained after the coprecipitation. The another reason is that the compound NaDDTC forms a more stable chelate with cobalt than that of examined elements such as Cu, Ni, Bi, Pb, Zn, Fe, Cr ve Mn [12].

After the findings above, the influence of amount of cobalt as a carrier element and amount of NaDDTC as a chelating agent on the coprecipitation of metals of interest was examined. The influence of cobalt was investigated with the multielement test solutions containing different amounts of Co, ranging from 0 to 1250 μg (Table 1). Although high recovery yields would be expected with a high amount of cobalt, there was difficulty associated the filtration of test solutions including 1250 μg of cobalt. The results indicate that quantitative recoveries for Cu, Pb, Fe, Mn, Zn, Cd and Ni in aqueous solutions were easily obtained with the ranging of 500–1000 μg cobalt. In the same range of cobalt, the recoveries for Bi and Cr were found between 40 and 60%.

The experiments were also repeated without cobalt. In this case, the recovery yields were found to be as less than 60%. However, the repeatability of recovery values was considerably poor($s/\bar{x} \geq$ 25%). As the concentration of trace elements is at the μg ml^{-1} level or even lower, they can not form completely their own independent solid phases. Also, NaDDTC can not precipitate in water [12]. Probably, the low recoveries are due to these two reasons. Therefore, for the precipitation of the trace elements from aqueous solution, a solid phase must be formed.

In this procedure, NaDDTC performs two functions. Firstly, it forms the solid phase with cobalt. Secondly, it reacts with the trace element ions to form the chelates in aqueous solution. Therefore, the effect of NaDDTC amount on the coprecipitation was examined with the fixed amount of cobalt, 600 μg, in the model solution. The amount of NaDDTC was increased from 12.5 to 250 mg. To obtain quantitative recovery, the optimal amount of NaDDTC was found to be 200 mg for the examined metal ions. Consequently, 600 μg of cobalt and 200 mg of NaDDTC were used in subsequent studies. Also, it can be expected that the recoveries obtained with the experiments repeated without both cobalt and NaDDTC will be smaller than 20%.

Table 1
Effect of cobalt amount on coprecipitation of analytes ($n = 3$)

Co amount (mg)	Recovery, %						
	Cu	Fe	Pb	Mn	Zn	Cd	Ni

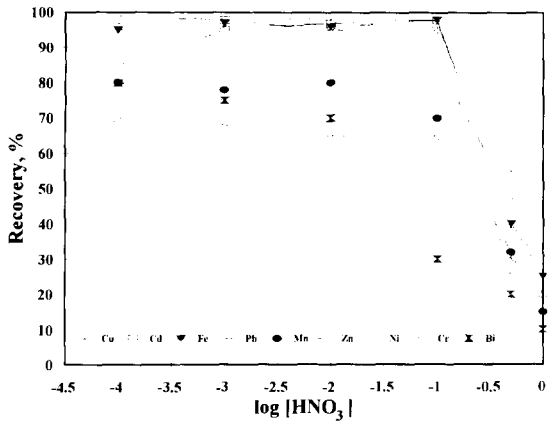

Fig. 1. Effect of HNO_3 concentration on coprecipitation of Cu, Cd, Fe, Pb, Mn, Zn, Ni, Cr and Bi.

4.2. Effect of acid concentration and pH on coprecipitation

Firstly, the effect of sample solution acidity on the coprecipitation of examined metal ions with Co-NaDDTC complex was investigated by use of HNO_3. As shown in Fig. 1, copper, lead and iron in range of 10^{-4}–10^{-1} M, zinc in a range of 10^{-4}–10^{-2} M and, cadmium and nickel in a range of 10^{-3}–10^{-1} M HNO_3 were quantitatively coprecipitated. The recoveries of Mn, Cr and Bi in a range of 10^{-4}–10^{-1} M HNO_3 were lower than 80%. However, the recoveries for the examined metals considerably decrease after 10^{-1} M HNO_3. This fact is probably connected with the stability of NaDDTC in acidic solution. It is well known that NaDDTC decomposes easily in acidic solution [12,16].

The coprecipitation of the metal ions was also studied with buffer solutions. As seen from Fig. 2, Cu, Fe, Pb in a range of pH = 1.0–10.0 and Ni, Zn and Cd in a range of pH = 1.0–8.0 were coprecipitated quantitatively. In contrast to HNO_3, buffer solutions in a range of pH = 4–8 are also suitable for the quantitatative recovery of Mn(II). The recoveries for Cr and Bi were lower than 80%. Due to the number of recovered elements, the model solution buffered to pH = 6 were used in subsequent experiments.

4.3. Standing time for coprecipitation

The standing time for precipitate formation was also optimized as it is an other important factor which influences the quality of coprecipitation. After 5 min, the quantitative recoveries for the all elements were obtained. Consequently, 5 min at least for the completion of coprecipitation were stood in all experiments. This period consists of the formation of preprecipitate and the adsorption of traces on the precipitate.

4.4. Sample volume

In the analysis of a real sample using preconcentration procedures, the sample volume is one of important parameters used to obtain a high concentration factor. Therefore, the recoveries of Cu, Fe, Pb, Mn, Zn, Cd and Ni from different sample volumes were tested in concentration range of 2–50 μg l^{-1} as depending on the elements. The results showed that the recoveries, except for Mn (up to 250 ml), were quantitative up to 450 ml. Due to two of the final solution volumes, the highest concentration factor was found to be 225.

4.5. Effect of matrix ions on coprecipitation

The effect of major components, such as Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, CH_3COO^-, Dextrose in

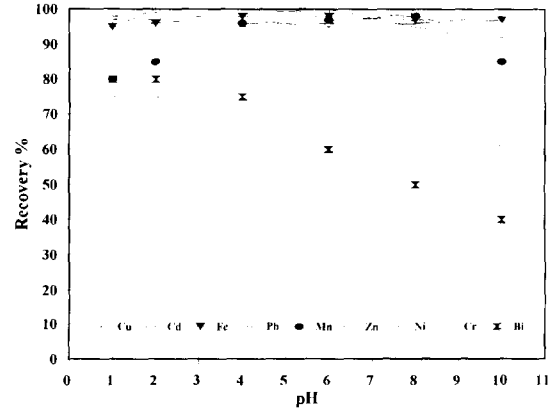

Fig. 2. Effect of pH on coprecipitation of Cu, Cd, Fe, Pb, Mn, Zn, Ni, Cr and Bi.

Table 2
Maximum tolerance limits for matrix ions on coprecipitation of analytes ($n = 3$, sample Vol. 100 ml)

n.d. Not determined.

sea water and dialysis concentrate, on the coprecipitation were studied systematically. Various amounts of matrix ions were added to a solution containing fixed amounts of analytes and the present procedure was followed. The results were listed in Table 2. The tolerance limit is defined as the ion concentration causing a relative error smaller than ± 5% related to the coprecipitation and determination of examined elements. As seen from Table 2, the low recoveries for the matrix ions are helpful in the determinations of interest trace heavy metals. The tolerance limits are higher than the concentrations of Na^+, K^+, Ca^{2+} and Mg^{2+} in sea water [17], and of Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, CH_3COO^- and dextrose in dialysis concentrate [18,19]. The these results are desired in view of applications to these samples.

4.6. Analytical performance

The analytical performance of the proposed procedure was illustrated by the results from flame atomic absorption spectrometric measurements. The relative standard deviations, ($s/\bar{x}$, $n = 7$), in the case of 20–100 μg l^{-1} of examined metal ions for 100.0 ml of sample volumes were found to be as ≤7%. The recoveries obtained with model solutions in redistilled water and in the presence of an interferent up to a certain concentration were higher than 95%, thus confirming the accuracy of the procedure. Also, the correctness of present method was confirmed by the recoveries of spikes from the real samples including various salts at high concentration levels. For the sea water and dialysis concentrate analysis, the efficiency of recovery of metal spikes from a sea water sample and a dialysis concentrate was investigated. As seen from Table 3, the analytical errors for the all analytes in both two samples were always lower than 5%. Thus, the accuracy of the procedure and its independence from matrix effects were confirmed for high salinity solution. The detection limits ($s = 3$, $n = 20$) for Cu, Fe, Pb, Mn, Cd, Ni and Zn from the blank solution were found to be as 16, 54, 64, 15, 4, 18 and 20 μg l^{-1}, respectively [20].

4.7. Application of the method

In this work, the recommended procedure as described under experimental was applied to some samples with high salinity such as a sea water and a commercial dialysis concentrate. The results which are shown in Table 4 and Table 5 have been calculated on the assumption of 100% recovery of the analytes. The concentration factors for sea water and dialysis concentrate were 225 and 75, respectively. For the analysis, the relative standard deviation of the procedure varies in range of 3.5–6.9% ($n = 9$).

5. Conclusion

The coprecipitation procedure with Co-DDTC examined in this paper provides a very simple, fairly rapidly, precise, accurate and reliable technique for the preconcentration of some trace metal ions from aqueous solutions of high salinity. The recoveries obtained with model solutions in redistilled water and in the presence of the most common matrix elements including the alkaline and alkaline earth metals were always higher than 95% (Fig. 1 and Table 3), thus, confirming the accuracy of the procedure and its independence from matrix effects.

Future work will be focused on application to other sample types containing high salinity, such as urine and spring water.

Received 10 September 1996; received in revised form 18 November 1996; accepted 19 November 1996

Abstract

Normal phase liquid chromatography combined with particle beam mass spectrometry has been applied to the analysis of fluconazole, an anti-fungal agent, [2-(2,4-difluorophenyl)-1,3-bis(1H-1,2,4-triazol-1-yl)-propan-2-ol] and a related intermediate, UK-51060 [2-(2,4-difluorophenyl)-1-(1H-1,2,4-triazol-1-yl)-ethan-2-one]. Electron ionisation and chemical ionisation have been investigated in combination with quadrupole ion trap and magnetic sector mass spectrometers and the spectra obtained compared with those for direct probe analyis. A novel method for the introduction of the chemical ionisation reagent gas via the interface is described for particle beam-magnetic sector mass spectrometry. Multi-stage scan routines have been implemented on the ion trap for the selective storage of analyte species and removal of solvent ions. Detection limits for both spectrometers have been determined and are discussed in terms of interface geometry and analyte transport characteristics. Normal phase HPLC on silica provided a good separation of the intermediate from the later eluting fluconaole peak. © 1997 Elsevier Science B.V.

Keywords: Chemical ionisation; Fluconazole; High performance liquid chromatography; Ion trap; Mass spectrometry; Normal phase; Particle beam

1. Introduction

Fluconazole is a difluorophenyl bis-triazole compound, used in the treatment of superficial and deep-seated fungal infections caused by Candida and *Cryptococcus neoformans* [1,2]. Other applications include the treatment of fungal meningitus and endophthalmitus [3,4]. In-vivo and in-vitro fluconazole levels have been determined by HPLC with UV detection [5] and GC with nitrogen–phosphorus [6] and electron-capture [7] detection. The mass spectrometry of fluconazole and related compounds has also been investigated [8].

Of the currently available interfaces for LC-MS, only the particle beam (PB) device produces classical electron ionisation (EI) and chemical ionisation (CI) spectra for HPLC analytes, being a sample/solvent enrichment technique independent of the ionisation mechanism [9]. The EI and CI

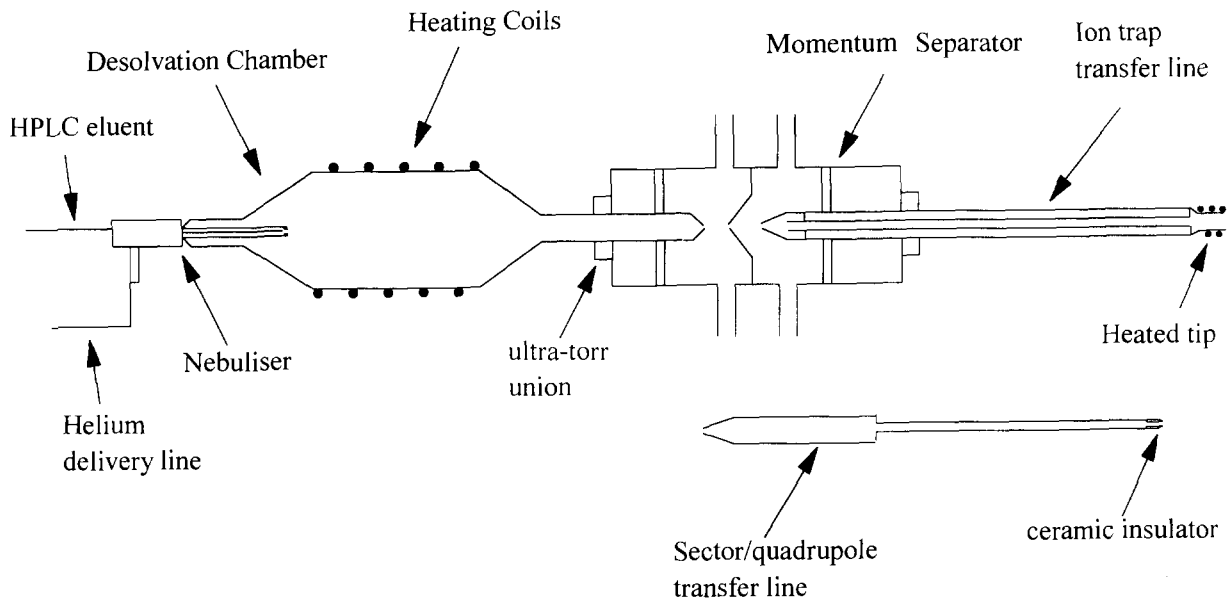

Fig. 1. Particle beam schematic.

spectra obtained contain useful structural information, as a result of fragmentation processes not observed using other interfacing techniques, and EI spectra can be compared with library spectra to confirm the presence of a target compound. These, and other, features have led to the successful use of the particle beam device for a wide variety of analyses, including many biomedical applications [9].

The separation of fluconazole and related compounds by reverse phase HPLC-PB-CI/MS has been reported [10] as part of an evaluation of on-line HPLC-NMR-MS. The determination of the triazole-containing compound [9-(4-methoxyphenylthiocarbamoyl)-6-(2-chlorophenyl) -1-methyl-4,7,8,10-tetrahydro-pyrido [4′,3′-4,5] thieno [3,2-f]—1,2,4-triazolo [4,3-a]-1,4-diazepine, a strong synthetic platelet activating factor antagonist, by reverse phase HPLC-PB-MS has also been discussed [11,12]. However, the use of normal-phase HPLC conditions for HPLC-PB-MS analyses of compounds of biomedical interest has not been extensively reported although the higher volatility of the mobile phase makes such separations well suited to the particle-beam interface [9].

We have recently reported a particle beam interface design that can be coupled to various beam and trapping mass spectrometers, yielding good mass spectral data for a number of different analytes [13]. In this paper we report the normal phase liquid-chromatographic separation of the anti-fungal drug fluconazole (1) and a reaction intermediate (2) combined with particle beam-mass spectrometric detection. This analysis has been used to compare various aspects of magnetic sector and ion trap HPLC-PB-MS instruments, using both EI and CI ionisation techniques.

2. Experimental

Fig. 1 shows a schematic of the two-stage particle beam interface, fabricated to our design (ASH

instruments, Macclesfield, UK). Details of the design and construction of the device are given elsewhere [13]. The modular construction allowed various operational parameters to be optimised without disturbing vacuum conditions, and facilitated easy replacement or repair of components. The operational principle was similar to other PB interfaces [9].

The nebuliser was constructed using two concentric tubes of fused-silica (40 μm i.d.) and glass (approx. 250 μm i.d.), and the glass desolvation chamber was fitted with a resistively heated coil to aid vaporisation (approx. temperature 40°C). The momentum separator and transfer line were constructed from aluminium and stainless steel and coupled to two 18 m^3/h rotary pumps (Edwards high vacuum, Sussex, UK). A cold trap (Edwards) was fitted between the first vacuum chamber and the rotary pump. Nozzle-skimmer and skimmer–skimmer distances, adjustable from 0 to greater than 20 mm, were fixed using 'ultra-torr' unions (Cajon, OH, USA) at either end of the momentum separator body. Balanced gas flow was ensured by the use of two opposed pumping ports per chamber.

The ion trap spectrometer (Finnigan MAT ITMS, San Jose, CA, USA) was operated at 180°C and calibrated with perfluorotributylamine. The manifold pressure with the interface in position and both solvent and nebuliser helium gas flowing was 1.5×10^{-5} torr (uncorrected). Helium bath gas was added through the vacuum manifold fine metering valve (Meggitt Avionics, Portsmouth, UK) to give an operating pressure of 1.0×10^{-4} torr. The ion trap transfer line consisted of two concentric stainless steel tubes (3/8″ and 1/8″ i.d.). Connections for a heater and a thermocouple were passed between the tubes up to the transfer line tip. In operation, the heater was maintained at a temperature of approx. 240°C. The interface was introduced into the ITMS manifold via the probe lock and the tip placed approximately 0.5–1.0 mm from the face of the Roulon inlet to the trap. This was found to give best spectral quality with minimal space charging effects, and good sensitivity.

The magnetic sector spectrometer (VG 7070E-HF, VG Micromass, Altrincham, UK) was operated at a source pressure of 2.3×10^{-6} torr (uncorrected), as indicated by the source housing ion gauge, under particle beam operation. The source temperature was 300°C. Connection of the interface to the mass spectrometer was made via the probe lock, using a 3/8″ o.d. stainless steel transfer line (Fig. 1). This transfer line was not heated: rapid particle vaporisation was achieved by impact with the hot ion source. An insulating tip of machinable ceramic (Macor, Corning Glass) was fitted to the probe end to insulate the interface from the accelerating voltage of the ion source, which was operated at 4 kV.

Ammonia-CI spectra of 1 and 2 using probe introduction were obtained on a Kratos 1S double focusing magnetic sector spectrometer (Kratos Analytical, Manchester, UK). The instrument was tuned with PFK in the EI mode and then operated under ammonia CI conditions with a source housing pressure of 4×10^{-5} torr. The source temperature and accelerating potential were 120°C and 8 kV, respectively.

Normal phase HPLC separations were carried out on either a 2.1 mm × 250 mm × 5 μm silica column (Techsphere, HPLC technology, Manchester, UK) or a 4.6 mm × 250 mm × 5 μm silica column (Hypersil, Shandon, Runcorn, UK). The mobile phase, 60:40 hexane: 2% diethylamine in methanol, was delivered at a flow rate of 0.3 ml min^{-1} using a Milton Roy Constametric 300 pump (LDC Analytical, Staffordshire, UK). Injections were made using a Rheodyne 7125 injection valve (Cotati, CA, USA) fitted with a 20 μl loop. All solvents used were HPLC or AR grade and analytes were used as received without further purification.

3. Results and discussion

The EI spectra of 1 and 2, obtained on the magnetic sector and ion trap spectrometers using the same particle beam interface, are shown in Fig. 2. The spectra from magnetic sector and ion

trap instruments are similar and in both cases are good matches to spectra from the probe-EI analysis of these compounds [8], with little interference from solvent or other instrumental artifacts. Fragment ion structures are assigned tentatively in Scheme 1 based on accurate mass and linked-scan tandem mass spectrometric data [8]. The origin of the species at m/z 200 (18%) in the PB-ion trap spectrum of 1 is not assigned. Fig. 3 shows the selected ion chromatograms obtained for 1 (m/z 224) and 2 (m/z 141) using the 2.1 mm i.d. normal phase silica column-ion trap mass spectrometer combination, and illustrates the HPLC separation obtained in combination with the particle beam interface. A similar chromatographic separation

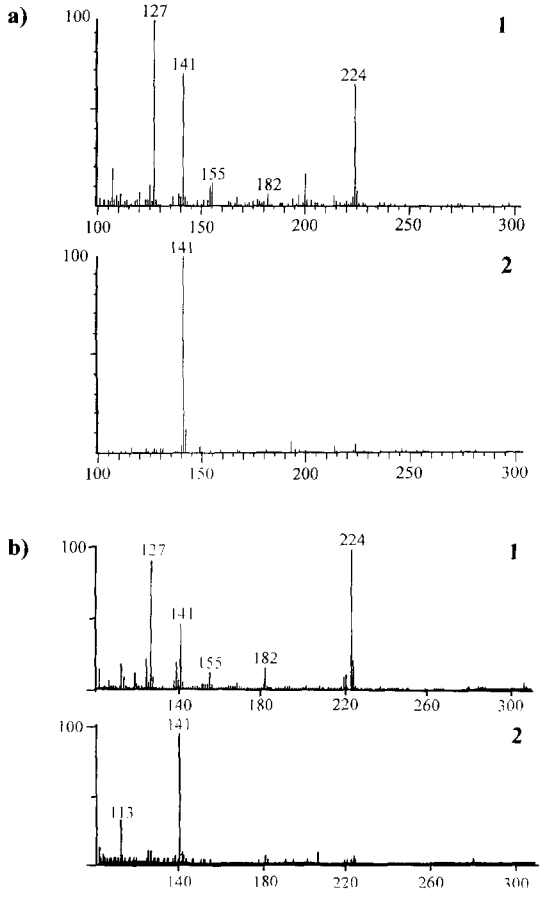

Fig. 2. EI spectra of 1 and 2 obtained from HPLC-PB-MS analysis: (a) ion trap; (b) magnetic sector.

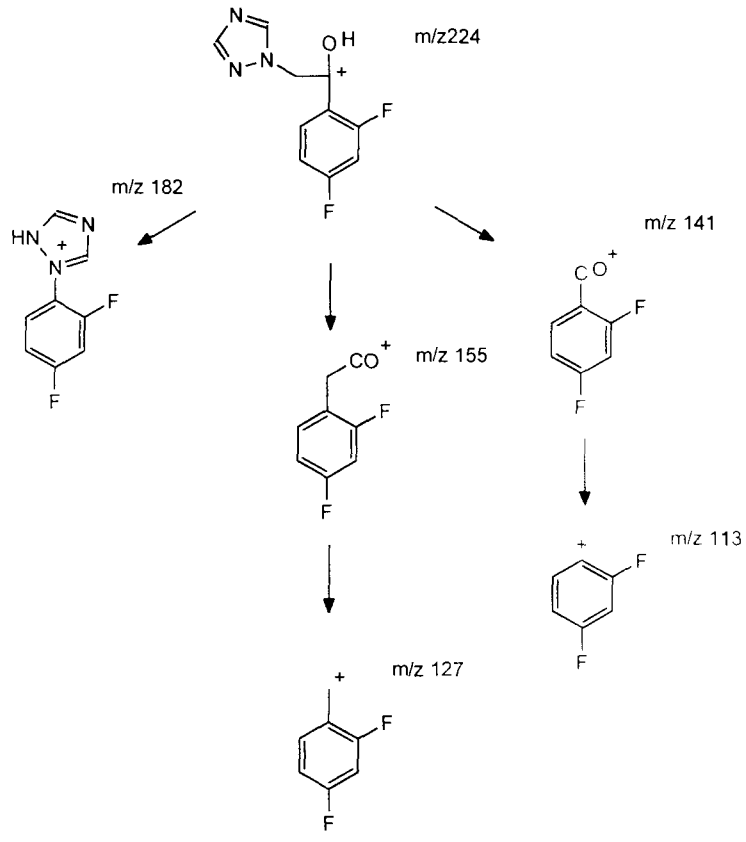
of the analytes was achieved on the particle beam-magnetic sector spectrometer. Some peak tailing was observed in the chromatograms obtained from both spectrometers, a common feature of PB-MS systems [9], arising from sample hold-up in the momentum separator/transfer line and slow particle volatilisation off the source walls/heated probe tip.

In order to obtain good quality EI spectra on the PB-ion trap instrument, it was necessary to construct a scan routine consisting of several ion accumulation steps [13]. Each individual step consisted of an ionisation pulse (500 μs), with the operating conditions of the trap set to retain all ions with masses greater than a 20 amu low mass cut-off, followed by an increase in the RF voltage to give a 100 amu low mass cut-off. The low mass cut-off was then reset to 20 amu for the next ionisation pulse. These operating conditions corresponded to ion trap q_z values of 0.055 (20 amu) and 0.275 (100 amu) where the q_z parameter, derived from the Mathieu equation, is defined as:

$$q_z = \frac{-4eV}{mr^2\Omega_0^2}$$

for an ion of mass m and single charge e, held in a quadrupole ion trap of radius r_0, operating with an RF voltage of V and an RF drive frequency $\Omega/2\pi$. Ions having stable trajectories within the trap will possess q_z values of between 0 and 0.906, depending on the value of V, at any given time.

This ionisation method was found to improve the sensitivity for LC-PB-ion trap MS analysis [13]. The advantages of this complex routine were three-fold. Firstly, ions formed at low $q_{z(\text{ionise})}$ have low initial kinetic energy, and are therefore stored more efficiently in the trap volume than ions created at higher $q_{z(\text{ionise})}$ values [14]. Secondly, ionisation at low $q_{z(\text{ionise})}$ increases the initial trap ionisation volume [15] and lowers the electron energy [16], two factors which improve ion intensity. Finally, increasing q_z to a higher value after ionisation raised the low mass cut-off to a level high enough to ensure that all mobile phase derived ions were ejected from the trap before the next ionisation step. This prevented a high population of low mass solvent ions accumulating in the trap volume and causing space charg-



Scheme 1. EI fragmentation pathways for 1 and 2.

ing and solvent-CI effects, both of which lead to a deterioration in spectral quality.

Fig. 4 illustrates how the signal intensity for the m/z 224 ion of 1 changes as $q_{z(\text{ionise})}$ increases (Fig. 4a), and as ionisation pulse length increases at a constant total ionisation time (Fig. 4b). These show that the best ionisation conditions were $q_{z(\text{ionise})} = 0.06$ (low mass cut-off = 20 amu) and pulse width = 500 μs. The spectra obtained with a high $q_{z(\text{ionise})}$ or a single long ionisation pulse length (4 ms) compare poorly to the spectra in Fig. 2(b), with large noise peaks evident due to decreased S/N levels. In addition, ions derived from solvent CI processes (m/z 307, $(M + H)^+$ of 1) were observed for low $q_{z(\text{ionise})}$, long pulse length ionisation, due to the large population of solvent ions present. The importance of low $q_{z(\text{ionise})}$ conditions has been noted by other investigators [17].

Fig. 5 shows the UV and selected ion chromatograms obtained from HPLC-PB-magnetic sector MS analysis of a sample prepared containing 95% 1 and 5% 2 (4.6 mm i.d. silica column). The fluconazole peak exhibits some tailing in comparison with the UV trace, but the advantage of the normal phase separation used in these experiments, compared with the reverse phase analysis normally employed for pharmaceutical products, is that 2 elutes before the main product 1, avoiding the elution of a minor peak on the tail of a major one and thus allowing clear identification and quantitation of both compounds.

Sensitivity on the HPLC-PB-magnetic sector instrument was fairly typical for PB-MS analysis

[9], with injections of 18 ng of 1 (m/z 224) and 60 ng of 2 (m/z 141) in the full scan mode yielding single ion chromatographic peaks of S/N 3:1 (2.1 mm i.d. silica column). The HPLC-PB-ion trap instrument showed poorer sensitivity for these analytes, injections of 5 μg of 1 and 2 yielding peaks of S/N 18:1 (m/z 224) and 16:1 (m/z 141), respectively. This can probably be attributed to analyte hold-up in the narrow ion trap transfer line and to sample decomposition [9], which was particularly severe at high probe tip temperatures (approx. 300°C). Detection limits in the low nanogram range have been reported for this PB-ion trap configuration on a number of other analytes [13].

Ammonia CI was carried out on compounds 1 and 2 using the double-focusing spectrometer. The major ions observed are tabulated in Table 1, together with the results for direct probe introduction of 1 and 2 into a CI source, and those for HPLC-PB-solvent-CI ion trap MS of the same compounds (see below). All the spectra obtained on magnetic sector instruments show prominent $[M+H]^+$ ions for both 1 and 2. However, the results for PB-sector analysis demonstrate a large degree of fragmentation when compared with the probe data, with the base peak for 1 at m/z 222. This species was of very low intensity in the probe-CI spectrum, but similarly intense under

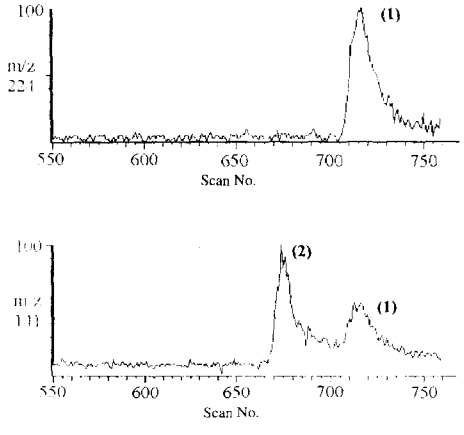


Fig. 3. Selected ion chromatograms for the separation of 1 and 2 obtained from HPLC-PB-ion trap MS analysis (250 ng μl^{-1} 1 and 2).

ammonia-CI conditions for a commercial PB-quadrupole MS system using reverse phase HPLC [10]. This suggests that under high pressure ammonia-CI conditions, some particles of analyte striking the hot source walls may undergo thermal degradation and the thermal fragments formed then react with reagent ions in the CI plasma. Anomalous ions due to thermal degradation in HPLC-PB-MS spectra have been reported in the literature, using both EI and CI techniques [9]. Full scan sensitivity for PB-magnetic sector CI was lower than that observed under EI operation, with injections of 120 ng 1 and 150 ng 2 yielding single ion chromatographic peaks of S/N 7:1 (m/z 307) and 2:1 (m/z 224) respectively.

The lower sensitivity under ammonia CI conditions, compared with EI, for the double focusing spectrometer may be due to the source geometry: CI gas at relatively high pressure was entering the source exactly opposite the particle beam entrance and was possibly affecting the efficiency of particle transmission into the source. Previous work on GC-CI/MS using a high resolution spectrometer [18] has shown that analyte peak area and sensitivity can be markedly improved by introducing the reagent gas co-axially to the eluent flow. Although this exact configuration could not be implemented on the PB-MS instrumentation during these experiments, it was possible to introduce the ammonia into the particle beam via an inlet between skimmers 1 and 2, which eliminated any detrimental turbulence in the source.

To characterise this new 'inter-skimmer' CI inlet technique, a comparison was made between the use of the normal source CI gas inlet and the 'inter-skimmer' CI approach. Post-column injections of 500 ng fluconazole were made under CI ionisation conditions using both inlet configurations at a variety of source housing pressures, set by adjusting the ammonia flow to the source or momentum separator. The resulting signal peak areas were recorded, using TIC and selected ion data. The results are illustrated in graphical form in Fig. 6. During the initial rise in source pressure, both sets of data show an increase in the intensity of CI-derived $[M+H]^+$ species, with a corresponding drop in EI-derived fragment ion strength. This trend continues at higher pressures

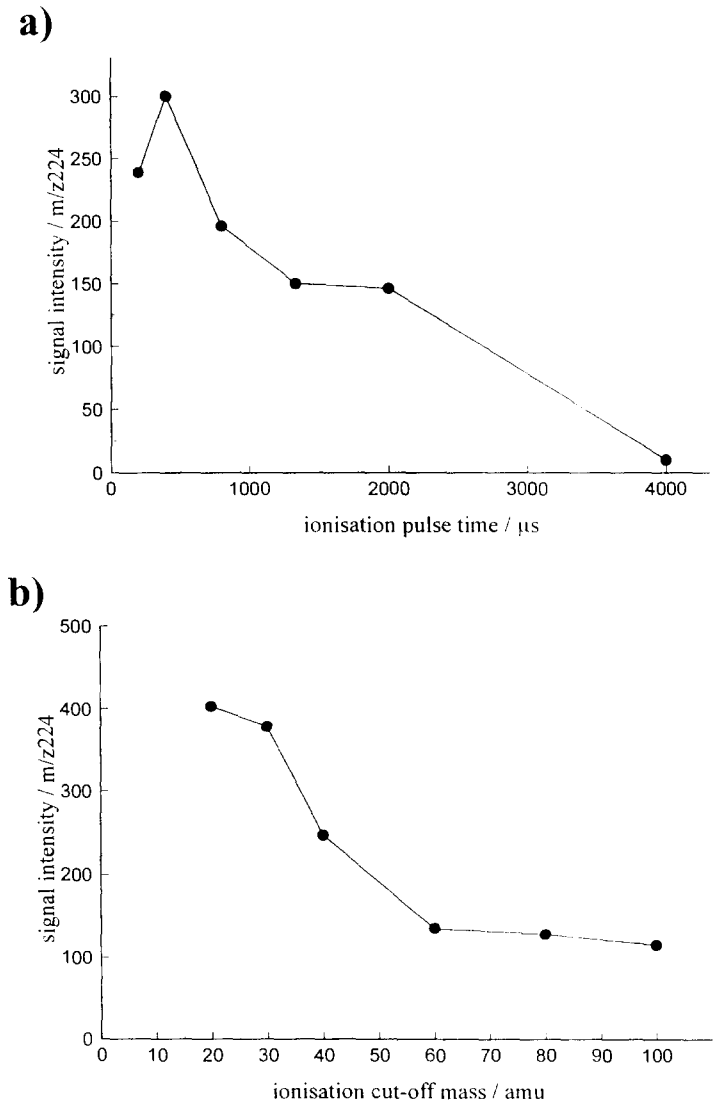

Fig. 4. Variation of m/z 224 peak area for fluconazole injections monitored by PB-ion trap MS with: (a) ionisation pulse length; (b) q_z (ionise) value.

using the inter-skimmer inlet technique (Fig. 6a), with only a small drop in the total ion current (TIC). However, using the standard source CI inlet (Fig. 6b) the intensity of both CI and EI ions decreases above a certain reagent gas pressure, with the TIC dropping significantly.

The inter-skimmer approach can therefore give measurable improvements in sensitivity for PB-CI/MS analysis. A CI inlet arrangement co-axial with the transfer line exit, rather than the second skimmer as in this approach, should not affect particle transmission in either the source or the momentum separator and therefore sensitivity in CI mode might be further enhanced by this approach.

In contrast to conventional 'beam' type instruments, ion trap chemical ionisation routines utilise low (10^{-5}–10^{-6} torr) pressures of reagent gas for

long (up to 100 ms) reaction times [19]. This presents few problems for inlet systems such as heated probes or gas chromatographs that impose little or no vacuum restrictions. However, for LC-MS inlets such as the particle beam, that transmit significant quantities of vapourised solvent into the analyser, ionising and storing a population of CI reagent ions can prove difficult, due to space charge limitations and reagent-solvent reactions, both of which will quickly deplete the number of stored reagent ions. This was found to be the case during experiments on a PB-ion trap system utilising a three stage momentum separator with inter-skimmer helium flushing to reduce solvent levels to an absolute minimum [20]. With the much simpler two-stage design used in this work the results were similar. A large ion count could be obtained easily for the RF/DC

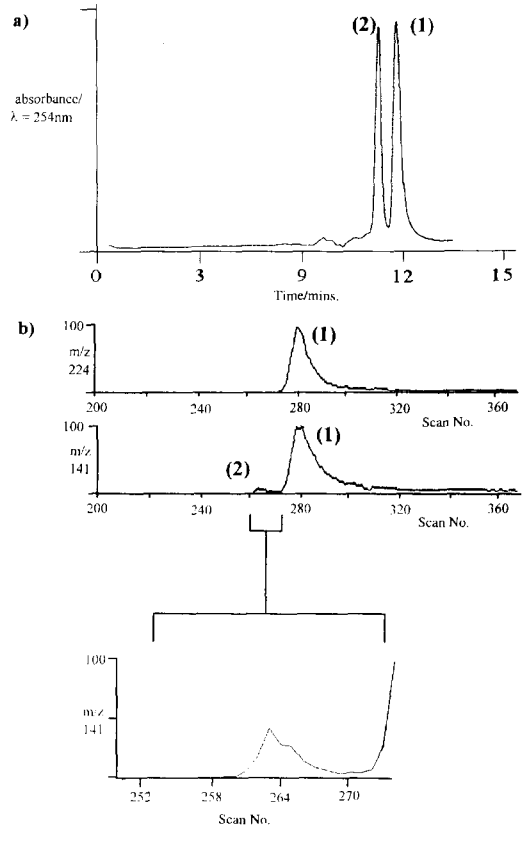

Fig. 5. (a) UV and (b) PB-MS chromatograms for the separation of a mixture containing 95% 1 and 5% 2.

Table 1
Major ions obtained from CI-MS analysis of 1 and 2, using different CI reagents and sample introduction methods

isolated NH_4^+ reagent ion from ammonia with the interface in place, but without solvent or sample introduction. However, with methanol/hexane/DEA solvent flows as low as 0.1 ml min^{-1}, the count was reduced to under 5% of its initial reading, with significant amounts of $[CH_3OH_2]^+$ ions derived from methanol solvent molecules being formed. Whilst the application of a notched broadband axial ejection signal [21] during ionisation might eliminate the space charge problem, the solvent-reagent ion reactions would still occur, particularly with less selective CI species such as CH_5^+. Consequently, standard CI ion trap routines seem not to be applicable to PB introduction.

However, chemical ionisation in the ion trap can be carried by using the solvent vapor itself as a source of reagent ions. Table 1 tabulates the solvent-CI spectra of 1 and 2, obtained on the HPLC-PB-ion trap instrument using the RF/DC isolated $[CH_3OH_2]^+$ reagent ion, derived from residual methanol mobile phase [19], as the proton donor. The spectra show strong $[M+H]^+$ ions with little fragmentation compared with the PB/MS CI data obtained with the sector instrument using the ammonium reagent ion, although an ion is observed at m/z 238, $[M\text{-}C_2N_3H_3]^+$, in

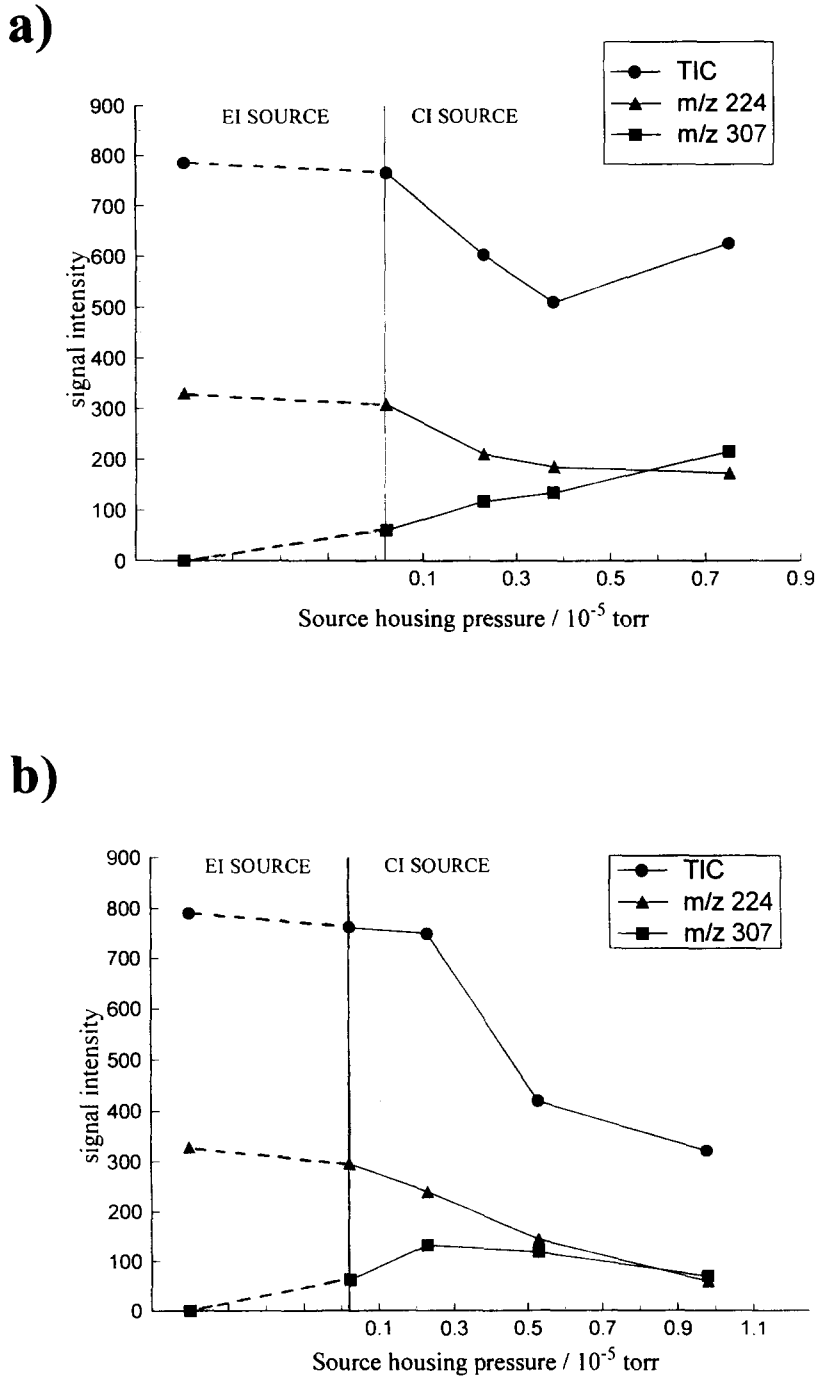

Fig. 6. Variation of fluconazole signal intensity (m/z 307, 224 and TIC) with CI source pressure using (a) PB inter-skimmer CI inlet (b) source CI inlet.

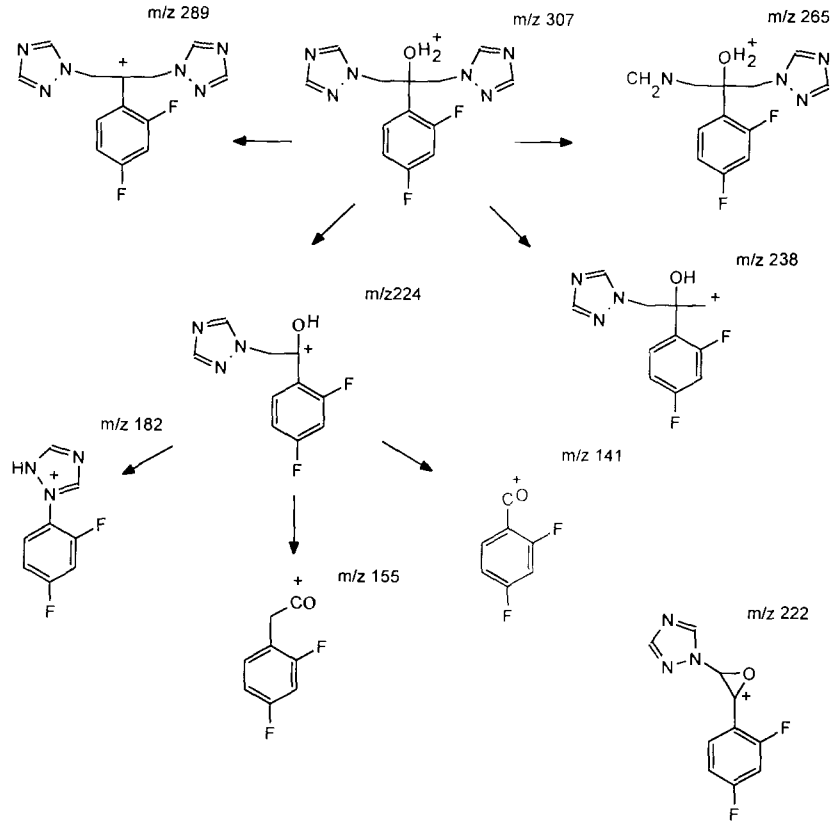

Scheme 2. CI fragmentation pathways for 1.

the methanol CI spectrum of 1, which is not observed in the ammonium CI spectrum. Scheme 2 shows the tentative assignment of ions observed in sector and ion trap CI spectra (those common to EI acquisition are show in Scheme 1) [8]. The absence of extensive fragmentation in the ion trap spectra is suprising, since methanol has a lower proton affinity than ammonia (761 and 854 kJ mol^{-1}, respectively [22]) and the methanol-CI reaction is therefore more exothermic. This suggests that competing processes other than proton transfer were occurring in the high temperature (300°C), high pressure magnetic sector CI source, but not in the ion trap where a single reactant ion can be isolated prior to analyte ionisation, and these processes can have a significant effect on the CI spectra obtained.

4. Conclusions

Normal phase HPLC separation of difluorophenyl triazoles has been monitored by magnetic sector and ion trap mass spectrometers using a two-stage particle beam interface fitted with an appropriate transfer line. EI and CI spectra were both obtained for these triazoles on both instruments. The sensitivity of the technique was system-dependent due to differences in particle transmission/volatilisation. Good EI spectral quality on the ion trap was achieved using a modified scan routine to minimise solvent ion interactions and maximise analyte ion populations. Introduction of CI reagent into the momentum separator for analysis in the double focusing spectrometer gave results comparable to those

obtained using introduction of reagent directly into the source volume.

Equilibrium and kinetic properties of a fast iminodiacetate based chelating ion exchanger and its incorporation in a FIA-ICP-AES system

Payman Hashemi *, Åke Olin

Department of Analytical Chemistry, Uppsala University, P.O. Box 531, S-751 21 Uppsala, Sweden

Received 6 September 1996; received in revised form 22 November 1996; accepted 23 November 1996

Abstract

The equilibrium and kinetic properties of an iminodiacetate (IDA) based chelating ion exchanger with a crosslinked agarose, Novarose™, as support has been investigated. The second and third acidity constants and some complexation constants of the ligand were determined for adsorbents with metal binding capacities of 140, 55 and 18 μmol ml^{-1}, respectively. The adsorbent of medium capacity showed fast adsorption and desorption of Cu(II), Cd(II), Ni(II) and Ca(II) both in the batch and column mode. It was found to be about 50 times faster than Chelex-100 (50–100 mesh) in accumulation of these metal ions in the batch mode. Studies of the adsorbent in a flow system, using a 5 mm × 6 mm i.d. column, indicated quantitative accumulation of Cu(II), Cd(II), and Ni(II) at volumetric flow rates up to 110 ml min^{-1}. Linear calibration curves with $r > 0.999$ and signal enhancement factors up to 1300 were obtained. Preconcentration by a FIA system connected to an ICP-AES instrument will make simultaneous measurement of ultratrace concentrations of a number of metal ions possible within reasonable cycle times due to the high flow rates which can be used with the adsorbent. Trace amounts of cadmium and copper in tap water were determined successfully at 60 ml min^{-1}. However, copper and nickel in tap water are strongly complexed and do not accumulate quantitatively even at low flow rates. Hence a sample pretreatment is needed. Copper was completely adsorbed after UV-treatment of the sample. © 1997 Elsevier Science B.V.

1. Introduction

Chelating ion-exchangers have been widely used for preconcentration in trace metal determinations by atomic spectrometry [1–5]. A separation from interfering alkali and alkaline earth metals can be achieved concurrently. More recently elimination of anions, such as chloride and sulphate, has become an important aspect of the ion-exchange preconcentration-separation procedure as these ions are precursors to some of the disturbing species in determinations by inductively coupled plasma mass spectrometry [6,7]. The most commonly used ligand in chelating ion-exchangers is

* Corresponding author.

PII S0039-9140(96)02189-3

no doubt the iminodiacetate group. It is attached by a $-CH_2-$ link to a styrene- divinylbenzene polymer in the much used adsorbent Chelex-100.

The preconcentration is usually performed in a flow system containing the adsorbent in a column [8,9]. Conditioning and washing of the column, loading of the sample, elution of the enriched sample and transport to the spectrometer are often carried out in a manifold under computer control [10–13]. The dimensions of the column holding the adsorbent are typically 2–3 mm i.d. × 50 mm corresponding to a volume of about 0.15–0.35 ml. A representative pumping speed is 5 ml min^{-1}. The calculated residence time of the sample in the column is then around 0.7–1.7 s for a void volume of 40%. Under these conditions most metal ions are quantitatively retained on Chelex-100 (100–200 mesh). However, an increase in the flow rate or in the particle size to 50–100 mesh, in order to diminish the backpressure, soon leads to losses [10].

The rate of removal of zinc, cadmium, lead and copper ions from solution by Chelex-100 has been studied in bulk experiments [14]. The observed first-order rate constants, corresponding to half-lives of about 1 min, did not differ by more than 10%, which indicates that mass transfer, rather than the rate of complexation, was the main resistance in the accumulation process. The recoveries obtained for a large number of metal ions, accumulated on a 0.1 ml column of Chelex-100 (50–100 mesh) and a flow rate of 9.5 ml min^{-1}, were around 55% with moderate variation [9]. This again suggests that mass transfer rather than the rate of a chemical reaction limits the quantitative accumulation of the metal ions. Related observations have been made by others [11].

Preconcentration ratios of the order of 100–1000 are required for trace and ultra-trace determinations of metals by inductively coupled plasma atomic emission spectrometry in tap water, ultra-pure waters, such as reactor waters in the nuclear power industry, etc. In order to diminish analysis time at high preconcentration ratios, much higher flow rates are needed than normally used with Chelex-100 and other adsorbents. Crosslinked agarose is a hydrophilic support with moderate resistance to flow. Covalent bonding of chelating ligands to this material has been studied in connection with the preparation of adsorbents for immobilised metal ion affinity chromatography (IMAC) [15]. As the iminodiacetate group appears to have fast kinetics both with respect to bonding and release of a metal ion, this group was selected in preference to others which may show stronger bonding but, at the same time, slower kinetics. We report here on the properties of a commercially available IMAC adsorbent based on a highly crosslinked agarose gel with attached iminoacetate groups, in particular with respect to the preconcentration of trace metals at high flow rates.

2. Experimental

2.1. Chemicals

The chelating ion-exchanger was obtained from Scand Inovata AB, Stockholm, Sweden. The support is a highly crosslinked agarose with the trade name of Novarose™. The adsorbent can be obtained with different metal binding capacities and exclusion limits. The ion-exchangers studied had an exclusion limit of about 200 000 and the bead size ranged between 30 and 60 μm. The ion-exchanger will be written IDA-Novarose in the following.

Standard solutions of hydrochloric acid and sodium hydroxide were prepared from ampoules (P.H. Tamm, Uppsala, Sweden) and further diluted when needed. Test solutions of metal ions were made by appropriate dilution of AAS standards (Referensmaterial AB, Sweden). Synthetic tap water samples were prepared by 200 times dilution of a stock solution containing 1 M Ca and respectively, 20, 2, 12, 12, 4 and 50 mg l^{-1} Al, Fe, Ba, Zn, Mn, and Sr. The chemicals used were of analytical grade (Merck) and all solutions made up with Milli-Q filtered distilled water.

2.2. Apparatus and analysis

The metal ion binding capacity and preconcentration measurements at flow rates below 8 ml min^{-1} were carried out with the TraceCon com-

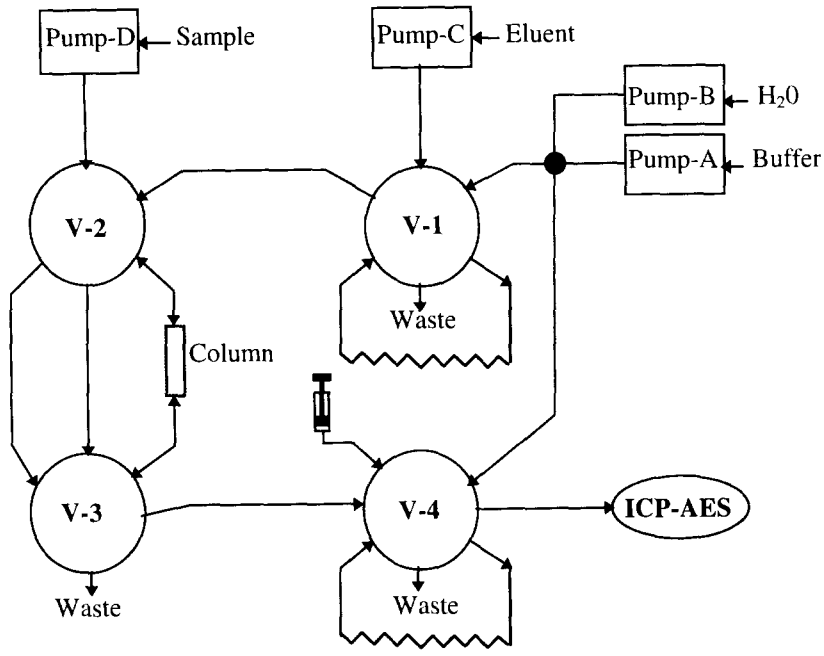

Fig. 1. Block diagram of the FIA-ICP-AES system with four pumps, four switching valves (V-1–V-4), acid and external standard loops and the IDA-Novarose column.

puter controlled flow analysis equipment (Knapp Logistics, Graz, Austria). At higher flow rates a variable reciprocating pump was used (Model-QD, Fluid Metering, NY).

Metal ion concentrations were determined by FAAS (Perkin-Elmer 2380) or by ICP-AES (Spectroflame, Spectro, Kleve, Germany). The instrumental settings of the manufacturers were followed. AC-R3A integrator (Shimadzu, Japan) was used for integration of the signals measured by FAAS.

GFAAS, with platform technique, was used for direct measurements of concentrations in tap water. Copper concentrations were measured by a Perkin Elmer 5000 instrument with deuterium background correction. A Zeeman GFAAS, Perkin Elmer 4100 ZL, was used for cadmium (multiple injection) and nickel (preconcentration by freeze-drying). The analysis made by MeAna-Konsult, Uppsala, Sweden.

The flow injection system shown in Fig. 1 was comprised of a Pharmacia FPLC manifold, four MV-7 seven port rotating valves (V-1 to V-4), two P-500 displacement pumps (Pump-A and Pump-B), one P-1 peristaltic pump (Pump-C) all from Pharmacia, and a reciprocating pump (Pump-D). The fittings and tubings were mostly from Tefzel material (Upchurch Scientific, WA). The FIA system, including the reciprocating pump and the integrator, were controlled from a Pharmacia LCC-500 LC controller.

The columns for holding the adsorbent were either of fixed length, 8 mm i.d. × 14 mm, (Inovata AB, Stockholm) or of variable length, 6 mm i.d. × 5 mm (min), (Omnifit).

The pH measurements were made with a Radiometer PHM 84 (Radiometer, Copenhagen, Denmark). For the potentiometric measurements a double junction (0.1 M $NaNO_3$) Ag/AgCl reference electrode and a pHG201 glass electrode (Radiometer) were used. The electrode was calibrated in the usual way on the concentration scale by adding strong acid to the ionic medium. In all other experiments a combined glass electrode was used and calibrated against certified pH buffers (Merck).

A home-build UV irradiation apparatus, equipped with a TQ 718 high pressure mercury lamp (Heraeus), was used for photo-digestion of the samples [16].

2.3. Water content and volume stability of IDA-Novarose

The IDA-Novarose columns were packed by gravity settling while a slight underpressure was applied at the outlet. Packed adsorbent, 1 ml, is the unit used for the amount of IDA-Novarose taken in an experiment. Accordingly, the analytical results are expressed per ml of packed adsorbent.

The pore volume of the adsorbent was estimated as follows. IDA-Novarose packed in a column was flushed with nitrogen gas until water was no longer expelled (5 min). The adsorbent was then extruded, weighed and dried to constant weight at 80°C. The pore volume was 0.60 ± 0.02 ml ml^{-1} packed adsorbent.

The volume change of IDA-Novarose with pH was studied by observing the change in column height when solutions of different pH were passed through the adsorbent. No volume change was observed between the extremes 1 M hydrochloric acid and 0.2 M potassium hydroxide.

2.4. Acid dissociation constants

A known volume of about 0.5 ml of IDA-Novarose in a column was converted to the fully protonated form by treatment with 5 ml of 1 M hydrochloric acid. The adsorbent was then washed with water until the effluent was neutral. This treatment changes IDA-Novarose to the zwitterion form. It was then extruded into 45 ml of 0.1 M sodium nitrate as ionic medium. The titrations were performed in an N_2 atmosphere by stepwise addition of sodium hydroxide to a pH of about 9. Back titrations with hydrochloric acid were also performed to obtain information on the reversibility of the acid–base equilibria. After each addition of titrant the emf was followed until a constant reading was observed (< 0.2 mV 10 min^{-1}), which generally took less than 15 min.

The degree of deprotonation, α, of the adsorbent was calculated from

$$\alpha = \{(V_O + V_{OH})[H^+] - [OH^-]) + V_{OH}C_{OH}\}/Qw - \alpha_{blank}$$

Here V_O is the initial solution volume and V_{OH} the added volume of base of concentration C_{OH}. Q is the concentration of IDA groups as determined from the inflection point on the titration curve and w the volume of IDA-Novarose. The proton concentration, $[H^+]$, was calculated from the glass electrode potential calibrated on the concentration scale. The expression for α neglects the amount of protons in the pore volume, which is difficult to find in an exact way but can be estimated to be negligible over most of the studied pH range. The underivatised Novarose showed a small acid–base capacity which was corrected for by α_{blank}.

2.5. Capacity determinations

The static metal ion binding capacity was determined in the column mode as described previously [5].

The dynamic capacity is defined here as the amount of metal ion captured by the adsorbent until the metal ion concentration in the column effluent has increased to 1% of the in-going solution. It was determined for an 8 mm i.d. × 14 mm column by continuously pumping a solution of the test ion through the column and directing the effluent into the nebulizer of the FAAS instrument. Since the loading flow rates used were higher than the normal aspiration rate of the FAAS instrument, a simple flow splitter was used after the column to yield a constant aspiration rate of 5 ml min^{-1}.

2.6. Sorption isotherms

A known volume of about 1 or 2 ml of the adsorbent was converted to the zwitterion form in a column and extruded into a 200 ml portion of 5 μM Ni^{2+} or Cd^{2+} in water or 0.1 M sodium nitrate. The initial pH of the solution was adjusted to about 6.7 by 1 M ammonium acetate. The magnetic stirrer used for mixing hanged in a

thin, freely rotatable Teflon string in order to avoid grinding of the adsorbent. The pH of the solution was changed by additions of 1 M acetic or hydrochloric acid and measured by a combined glass electrode. The solution was sampled 15 min after a change in pH had been made. A 3 ml portion was withdrawn by a pipette equipped with a 25 μm filter at the tip and further filtered through a 0.45 μm membrane filter into a test tube. Duplicates were collected at each pH and analysed by ICP-AES.

2.7. Adsorption and desorption kinetics

The kinetic measurements of the adsorption and desorption of the metal ions were performed in the batch mode. The experimental conditions were selected so that pseudo first order reaction conditions could be assumed [17]. A 200 ml portion of 5 μM Cd^{2+}, Ni^{2+}, Cu^{2+} and Ca^{2+} in 10 mM acetate buffer, pH 4.7, was prepared in a beaker and continuously sampled by a peristaltic pump. The sample was transported through a filter to the ICP-AES instrument at a constant flow rate of 2 ml min^{-1}. When the base lines had stabilised, 1.0 ml of IDA-Novarose or 1.6 ml of Chelex-100 (50–100 mesh) was quickly added to the rapidly stirred solution. The adsorption of the metals was followed by recording the emission signal every other second.

The metal loaded adsorbent and the virtually metal free solution after the adsorption measurement were then used to the study of the desorption profiles. The filter was cleaned from resin particles, the pump restarted, concentrated hydrochloric acid added to a final concentration of 1 M and the increase in metal ion concentrations determined by ICP-AES.

2.8. The FIA-ICP-AES procedure

The flow injection system is presented in Fig. 1. The column was first conditioned by 6 ml of a 0.1 M acetate buffer, pH 5.5, delivered by pump-A at a flow rate of 4 ml min^{-1}. The sample was then enriched, usually at a flow rate of 60 ml min^{-1} (unless otherwise stated), washed by 4 ml of the buffer and eluted by 1 ml of acid in the direction opposite to the enrichment flow. The acid was loaded in a 1 ml loop by pump-C and carried to the column by the flow from pump-A. A flow of Milli-Q water at 4 ml min^{-1} from pump-B bypassed the column and was aspirated into the plasma during sampling. The cycle time is 3 min plus the sample enrichment time (up to 10 min). The transient signals were recorded during the washing and elution steps by the ICP-AES computer software. The area and height of the elution peaks were evaluated using a home made program. The sample loop connected to valve-4 was used for introduction of an external standard as a check of the sensitivity of the instruments. The FIA system can also be connected to a FAAS instrument as was done here in the preliminary experiments.

For tap water analysis, the system was used also in an off-line mode. The eluted analytes were collected in about 6 ml and determined by ICP-AES, against matched standards.

2.9. Photo-digestion of tap water

Portions of tap water, 50 ml, were weighed into 12 quartz tubes and 50 μl 30% hydrogen peroxide were added. Six portions were acidified by 50 μl (0.012 M) and the others by 420 μl (0.1 M) of hydrochloric acid. The tubes were UV-irradiated with a mercury lamp, operated at 500 W, for 3 h. After the photo-digestion, the evaporated water (normally < 1 ml) was compensated by Milli-Q water.

3. Results and discussion

3.1. Acidity constants

Iminodiacetic acid is a three-protonic acid and the different forms of IDA-Novarose can be represented by $R\text{-}NH^{+}(CH_2COOH)_2$, $R\text{-}NH^{+}(CH_2COO^{-})(CH_2COOH)$ (zwitterion form), $R\text{-}NH^{+}(CH_2COO^{-})_2$ and $R\text{-}N(CH_2COO^{-})_2$. In equations further simplification to $R\text{-}H_3^{+}$ ... R_2^{-} will be made. The potentiometric titrations started from the zwitterion form, which appears to be the only form of IDA based ion exchangers which can

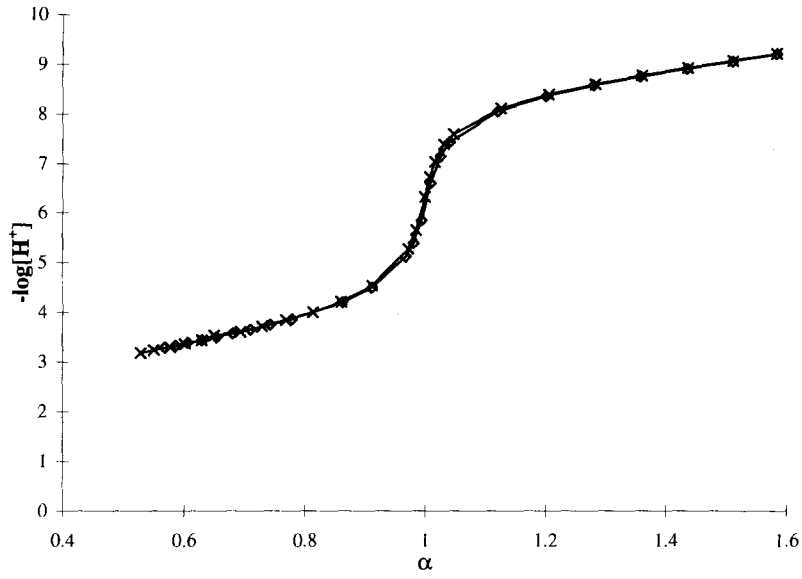

Fig. 2. Titration curve of the high capacity IDA-Novarose, showing the dependence of the degree of deprotonation (α) on $-\log[H^+]$. ×, forward and ◇, reverse titration. Adsorbent volume, 0.43 ml; temperature, 23(±1)°C; forward titrant, 10 mM NaOH; backward titrant, 10 mM HCl.

be obtained with a well-defined stoichiometry [18]. The titration curve exhibits a reasonably sharp equivalence point for the titration of the first proton in the zwitterion. It was used to calculate the number of IDA groups and the degree of deprotonation, α, of the zwitterion as exemplified in Fig. 2. The fair agreement between the forward and reverse titrations indicates that the acid–base equilibria are reversible and the attainment of equilibrium appears to be markedly faster than for Chelex-100 [19,20].

The equilibria and apparent acidity constants can be written

$$R-NH^+(CH_2COO^-)(CH_2COOH) = R-NH^+(CH_2COO^-)_2 + H^+(aq) \quad \text{(I)}$$

$$K_1 = \frac{\overline{\{R-H^-\}}[H^+]}{\overline{\{R-H_2\}}} = \frac{\alpha}{1-\alpha}[H^+] \quad (1)$$

and

$$R-NH^+(CH_2COO^-)_2 = R-N(CH_2COO^-)_2 + H^+(aq) \quad \text{(II)}$$

$$K_2 = \frac{\overline{\{R^{2-}\}}[H^+]}{\overline{\{R-H^-\}}} = \frac{\alpha-1}{2-\alpha}[H^+] \quad (2)$$

Square and curled brackets denote concentration and activity, respectively, and the bar is used for quantities in the ion-exchanger phase. While the apparent acidity constants are readily calculated from the experimental data, they are of somewhat limited usefulness because they depend on the degree of deprotonation and the ionic composition of the solution phase.

A number of approaches has been used to calculate the acidity constants in the resin phase [19,21,22]. The intrinsic acidity constants are defined by:

$$K_{1i} = \frac{\overline{\{R-H^-\}\{H^+\}}}{\overline{\{R-H_2\}}} \text{ and } K_{2i} = \frac{\overline{\{R^{2-}\}\{H^+\}}}{\overline{\{R-H^-\}}} \quad (3)$$

The method proposed by Pesavento et al. [19] has been used to estimate K_{1i} and K_{2i}. The relationship between K_n and K_{ni} is

$$K_{ni} = K_n \frac{\bar{\gamma}_H \bar{\gamma}_{RH_{n-1}}}{\bar{\gamma}_{RH_n}} \frac{\overline{\{H^+\}}}{\{H^+\}} \cong K_n \gamma_H \frac{\overline{\{Na^+\}}}{\{Na^+\}} \cong K_n \frac{\overline{\{Na^+\}}}{[Na^+]} \quad (4)$$

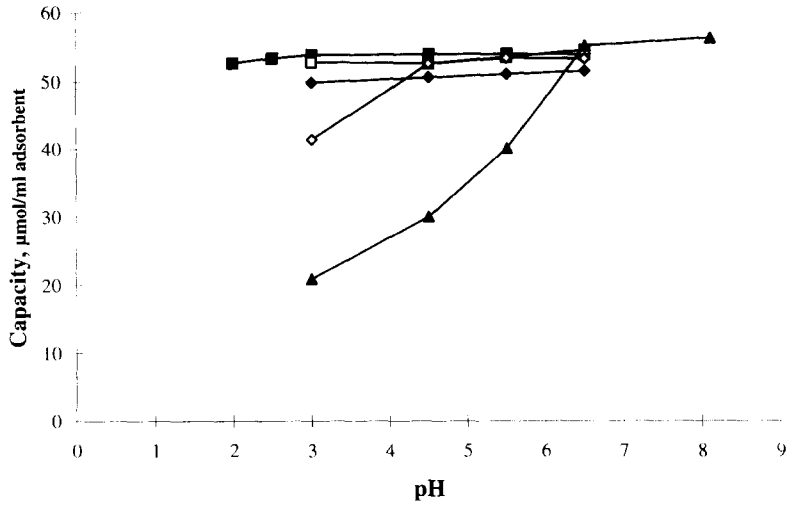

Fig. 3. Capacity of the medium capacity IDA-Novarose at different pH for Cu^{2+} (■), Ni^{2+} (□), Pb^{2+} (◆), Cd^{2+} (◇), and Ca^{2+} (▲). Adsorbent volume, 0.5 ml; buffer concentration, 0.01 M for Ca^{2+} and 0.1 M for the other ions.

The ratio of the activity coefficients (γ) in the resin phase is assumed to be 1. This assumption together with the Donnan equilibrium $\overline{\{H^+\}}/\{H^+\} = \overline{\{Na^+\}}/\{Na^+\}$ leads to the second step in Eq. (4). The last step assumes that the activity coefficients of H^+ and Na^+ cancel in the solution phase. The sodium ion concentration in the resin phase was calculated as suggested by Pesavento et al. [19] and $\bar{\gamma}_{Na}$ was taken from tabulated data of the mean activity coefficient of sodium nitrate [23].

Three IDA-Novarose preparations with the capacities 18, 55 and 140 μmol H^+ ml^{-1}, respectively, were studied. The titrations were stopped at about pH 9 since titrations on underivatised Novarose showed a substantial increase in the consumption of added base by the agarose support above this pH. The measurements covered a range in α from 0.5 to 1.9. The value of pK_{2i} obtained was 8.65 ± 0.1 and there was little or no variation of this value with the degree of deprotonation or with the capacity of the adsorbent. The result for pK_{1i}, on the other hand, showed a significant trend with α and increased from 2.95 to 3.20 when α increased from 0.5 to 0.9. Part of this trend may be caused by experimental errors since the trend became more pronounced with decreasing capacity of the ion-exchanger and for α values above 0.9. The value of pK_{1i} extrapolated to $\alpha = 0$ is 2.6.

The pK_{1i} value is similar to the result obtained for Chelex-100 [19,22], whereas pK_{2i} is lower by 0.5 units [21]. The attachment of the iminodiacetate group to the support is quite different in Chelex-100 and in IDA-Novarose. In the latter adsorbent the group is held by an alkyl chain containing hydroxyl groups. It may therefore be appropriate to compare the intrinsic acidity constants with the corresponding constants of *N*(2-hydroxyethyl)iminodiacetic acid. The reported values are $pK_1 = 2.2$ and $pK_2 = 8.73$ ($I = 0.1$ M) [24], of which the latter is quite similar to the results obtained for IDA-Novarose.

3.2. Sorption isoterms

The sorption of Cu^{2+}, Ni^{2+}, Cd^{2+}, Pb^{2+} and Ca^{2+} by the adsorbent of medium capacity was measured in the column mode. The result at different pH is shown in Fig. 3. The maximum capacity was about 55 μmol ml^{-1} adsorbent for all of the ions tested. The final capacity for Ca^{2+} was only reached at a pH higher than 6.5. After washing the column with 3, 10 and 20 ml of a 0.1 M acetate buffer, pH 5.5, the calcium remaining on the column decreased to 5.9, 0.3 and 0.2 μmol

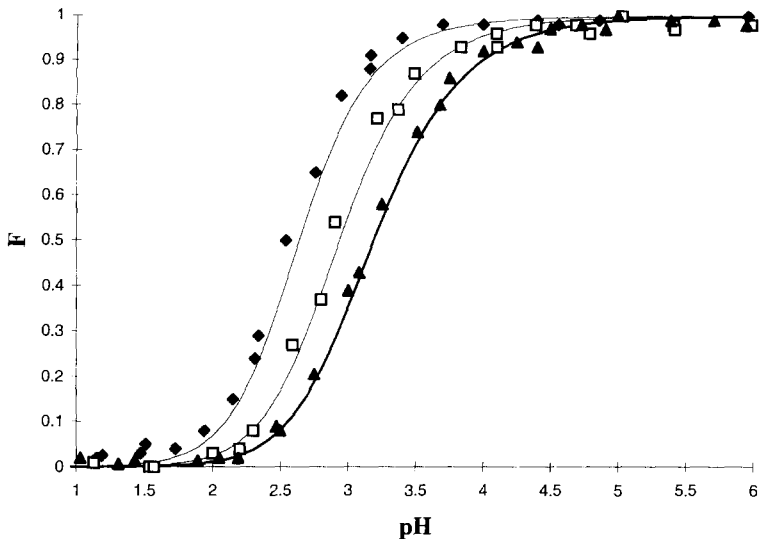

Fig. 4. Adsorption of nickel on high (◆), medium (□) and low (▲) capacity IDA-Novarose as a function of pH. The curves depict the calculated sorption isotherms from Eq. (7).

ml^{-1}, respectively. The other metal ions were not eluted by this treatment. This behaviour indicates that calcium can be removed from the enriched sample by washing the column with a buffer solution after enrichment but before the elution. The high capacity ion-exchanger (140 μmol ml^{-1}) also exhibited the same capacities for Cu^{2+}, Ni^{2+} and Cd^{2+}, whereas the capacity for Pb^{2+} was about 120 μmol ml^{-1}.

Sorption isotherms were studied more closely only for nickel and cadmium and at two ionic strengths, $I = 0.1$ and 0. Two sets of isotherms are presented in Figs. 4 and 5, which demonstrate the influence of the capacity of the sorbent. It has been shown that the iminodiacetate group binds nickel as a tridentate ligand in Chelex-100 [25] and the interpretation of the sorption isotherms was started on this hypothesis. The equilibrium reaction would then be

$$M^{2+} + \overline{R-H_2} = \overline{R-M} + 2H^+ \qquad \text{(III)}$$

with

$$\beta_1 = \frac{\overline{[R-M][H^+]^2}}{\overline{[R-H_2]}[M^{2+}]} \qquad (5)$$

The fraction sorbed, F, is

$$F = \frac{v\overline{[R-M]}}{V[M^{2+}] + v\overline{[R-M]}} \qquad (6)$$

in which v is the volume of the sorbent and V the volume of the surrounding solution. In the pH range studied, $R-H_2$ and $R-H^-$ predominate in the resin phase since the loading of the resin was small compared with its total capacity. Introduction of the total capacity, R_t, and the apparent acidity constant from Eq. (1) into Eq. (6) yields

$$F = \frac{1}{1 + \dfrac{V[H^+](K_1 + [H^+])}{\beta_1 v R_t}} = \frac{1}{1 + \varphi[H^+](K_1 + [H^+])} \qquad (7)$$

in which φ is a constant. The value of φ, of course, depends on the experimental conditions chosen and was determined by curve fitting. Curves, $F = f([H^+], K_1, \varphi)$, were calculated with K_1-values extracted from the acid–base titrations. Very good fits could be achieved between the experimental data and the calculated curves. However, the β_1-values obtained from the φ-values showed a more or less definite trend towards smaller values with decreasing total capacity.

It has been suggested that the following reaction

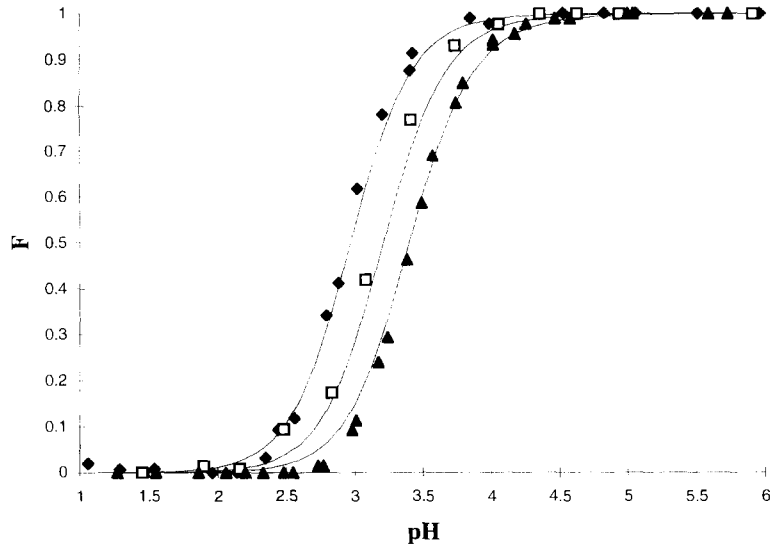

Fig. 5. Adsorption of cadmium on high (◆), medium (□) and low (▲) capacity IDA-Novarose as a function of pH. The curves depict the calculated sorption isotherms from Eq. (7).

$$M^{2+} + 2\overline{R-H_2} = \overline{M(RH)_2} + 2H^+ \qquad \text{(IV)}$$

plays a major part in the sorption in addition to reaction(III). Inclusion of this reaction, which can be envisaged also as an ion exchange reaction rather than as complexation by two bidentate ligands, removed some of the trend in the β_1-values. On the whole, however, no convincing evidence of the presence of the species $\overline{M(RH)_2}$ was found.

One reason for the trend in the value of the equilibrium constant might be that β_1 does not have a definite value in the resin phase but covers a range of values instead [26]. Some positions in the sorbent could allow further complexation to take place by adjacent carboxylate groups, which should lead to a stronger binding of the metal ion. If such a distribution of positions is present, it can be anticipated that the positions will be occupied in descending order of strength. In the sorption experiments, the relative loading of the sorbent increased with decreasing total capacity and hence, according to the hypothesis, the β_1-value would decrease with R_t as observed.

It is also known that the agarose matrix contains some sulphate and carboxylate groups and that additional carboxylate groups may be introduced by the crosslinking procedure [27]. These groups will probably contribute to the total capacity, which is measured at a pH of about 5 and a relatively high metal ion concentration, but they may contribute little in most of the pH range covered by the sorption isotherm measurements. The blank titrations on Novarose showed a base consumption corresponding to about 5 μmol ml^{-1} at pH 5 indicating that groups other than iminodiacetate could contribute to the capacity. As a consequence, the chelating capacity would be overrated. By subtracting 7.5 μmol ml^{-1} from the total capacities good agreement between experimental and calculated results were obtained for a constant value of β_1 as shown in Fig. 4 and Fig. 5. The results are summarised in Table 1. Since

the applied correction is small for the sorbent with the highest capacity, the reported data are close to the values obtained for this sorbent without the correction. The value of β_1 for nickel is quite close to the value obtained for *N*(2-hydoxyethyl)iminodiacetic acid, whereas the constant for cadmium is about five times larger. It has been observed that the isotherms on Chelex-100 follow the same pattern. The sorption takes place at a lower pH than expected from the stability constants determined in homogeneous solution, particularly for weak complexes [19]. To account for the higher than expected sorption to Chelex-100, reaction(IV) was introduced into the sorption model. Although convincing evidence for this reaction could not be found here from the sorption isotherms of nickel and cadmium, it is likely that ion exchange mechanisms play a major role in the sorption of more weakly complexing ions.

3.3. Kinetic measurements

3.3.1. Batch experiments

The kinetics of the metal ion adsorption and desorption were studied in the batch mode for Chelex-100 and medium capacity IDA-Novarose. Different volumes of the adsorbents were taken in order to make the dry weight of each adsorbent equal to 0.2 g. This choice leads to an about five-fold larger exchange capacity in the experiments with Chelex-100, which is offset by a smaller surface area due to a larger particle size. Otherwise the experimental conditions were the same for the two adsorbents. Results from the adsorption experiments are shown in Fig. 6. The great difference in the rate of accumulation of the metal ions on the two adsorbents is evident from the graph. The enrichment is quantitative except for Ca^{2+} on IDA-Novarose. As the equilibrium concentration is expected to be inversely proportional to the square of the capacity, the sequestering of Ca^{2+} is more efficient, and even quantitative, by Chelex-100. There is little variation between the adsorption curves belonging to the same adsorbent, indicating that mass transfer is rate limiting. Conditional first order rate constant were calculated for the four metal ions studied and the average and standard deviation of the adsorption half-times were 10.7 ± 2.9 s for IDA-Novarose and 525 ± 30 s for Chelex-100. Thus the new adsorbent is about 50 times faster than Chelex-100, which appears too large to be attributed solely to the difference in particle size.

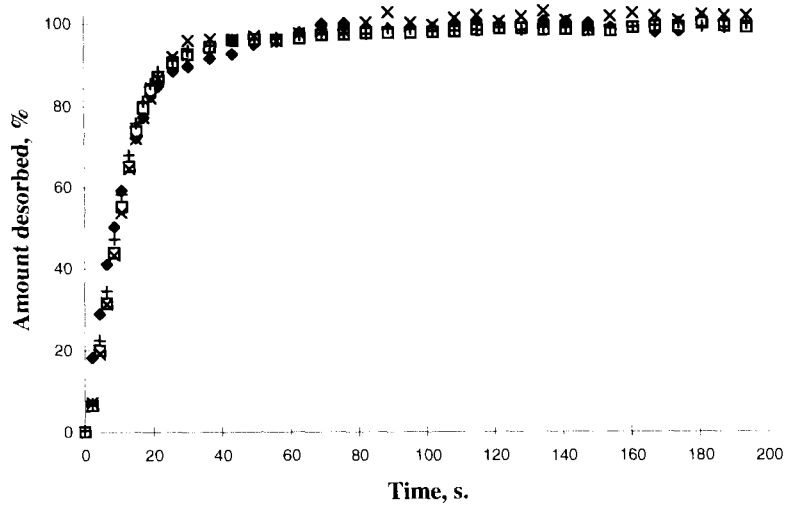

Fig. 7. Desorption of Ca^{2+} (◆), Cd^{2+} (□), Cu^{2+} (+) and Ni^{2+} (×) from medium capacity IDA-Novarose in the batch mode as a function of time. Many experimental points have been omitted for clarity.

Differences in the hydrophobicities and the anchoring of the chelating group to the support most likely play a role here. Schulze and Elsholz [14] determined the adsorption half-times of 15 sorbents and found substantial differences between them. The ratio between the half-times of Chelex-100 and the fastest adsorbent was about four. Due to the variation in the nature of the exchanging group in this study, it is difficult to discern the influence of the matrix but, in general, sorbents based on a hydrophilic support appear to be faster than those based on an organic polymer matrix.

The desorption profiles in 1 M hydrochloric acid are shown in Fig. 7 and Fig. 8. The curves for IDA-Novarose are similar and the average desorption half-time is 7.0 ± 0.8 s. The desorption and adsorption rates are thus rather equal and again point to the mass transfer characteristics of the experimental system as rate limiting. For Chelex- 100, the half-time for Cu^{2+} was similar to the result obtained for IDA-Novarose, whereas the values for Ca^{2+} and Ni^{2+} were 2–3 times larger. The slow desorption of Cd^{2+} is due to the composition of the eluent and may be explained as follows. At a high chloride concentration a large fraction of the cadmium is present as the anionic complexes $CdCl_3^-$ and $CdCl_4^{2-}$. Concurrently the high concentration of acid protonates the iminodiacetate group which becomes positively charged. The adsorbent will hence become a 'strong' anion exchanger leading to a delayed desorption determined by the rate of exchange of the complexes by the chloride ion. Evidence for this hypothesis was obtained by a change of the eluent to 1 M perchloric acid. In this medium no anionic complexes are formed and the behaviour of Cd^{2+} was normal. Lowering the concentration of the hydrochloric acid eluent to 0.25 M also substantially increased the desorption rate. We can thus conclude that the desorption from the two adsorbents proceeds at similar rates, at least for low loadings. The normal desorption process can, however, be affected by the charge rendered to the sorbents at low pH. Such complications would be less pronounced for low capacity sorbents as observed here.

3.3.2. Column experiments

The efficiency of the IDA-Novarose adsorbent for accumulation of metal ions at high flow rates was studied in the column mode. A 500 μg l^{-1} mixture of Cu^{2+}, Cd^{2+}, Ni^{2+}, and Sr^{2+} (as an alternative to Ca^{2+} with less risk of contamination) in 10 mM acetate buffer, pH 5.5, was passed through the 8 mm i.d. × 14 mm column at flow

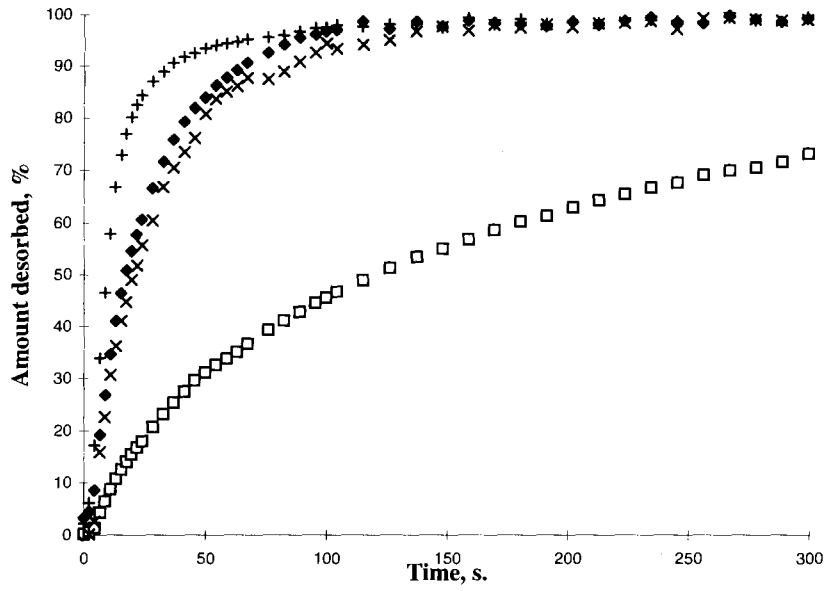

Fig. 8. Desorption of Ca^{2+} (◆), Cd^{2+} (□), Cu^{2+} (+) and Ni^{2+} (×) from Chelex-100 in the batch mode as a function of time. Many experimental points have been omitted for clarity.

rates between 10 and 100 ml min^{-1}. Analysis of the column effluent by ICP-AES indicated that greater than 99% of Cu^{2+}, Cd^{2+} or Ni^{2+}, was taken up by the column at all flow rates studied. In the case of Sr^{2+}, however, a breakthrough occurred after 40–50 ml of test solution. The high flow rates slightly compressed the adsorbent and decreased the bed volume. It is, hence, recommended to pack the column under pressure to avoid this problem or add more adsorbent to the column after compression. The exchange properties of the column were unaffected by the volume change.

The effect of the loading flow rate on the adsorption of Cu^{2+} has been studied for Chelex-100 by Liu and Ingle, Jr [10]. A 3 mm i.d. × 50 mm column, packed with the 100–200 mesh resin, adsorbed the metal ion quantitatively at flow rates up to 15 ml min^{-1}, the highest flow rate studied. For smaller particle sizes the packing collapsed because of the high back pressure. Other investigations generally report flow rates below 10 ml min^{-1} or unacceptable losses of analyte at high flow rates for IDA-based as well as some other chelating sorbents [9,28,29].

The influence of the flow rate was further investigated by a measurement of the dynamic capacity of the adsorbent for Cu^{2+}, Cd^{2+} and Ni^{2+} at input concentrations of 0.16 and 0.48 μM and the flow rates of 10 and 50 ml min^{-1}. The dynamic capacity, expressed in percent of the static capacity, was found to be dependent both on the sample flow rate and the concentration as exemplified in Fig. 9. The dynamic capacities decreased with increasing flow rate and increased with sample concentration. The capacities at 10 ml min^{-1} were 80–95% and at 50 ml min^{-1} 50–80% of the static capacity. These values are considerably better than for the previously studied polyethyleneimine-Novarose adsorbent [5]. The dynamic capacities of Cu^{2+}, Cd^{2+} and Ni^{2+} were 35, 10 and 2%, respectively, at a concentration of 1 g l^{-1} and a flow rate of only 5 ml min^{-1}.

3.4. The FIA-FAAS and FIA-ICP systems

The performance of IDA-Novarose in the FIA-FAAS and FIA-ICP configurations was very similar. Therefore, mainly the results from the experiments with ICP-AES detection will be re-

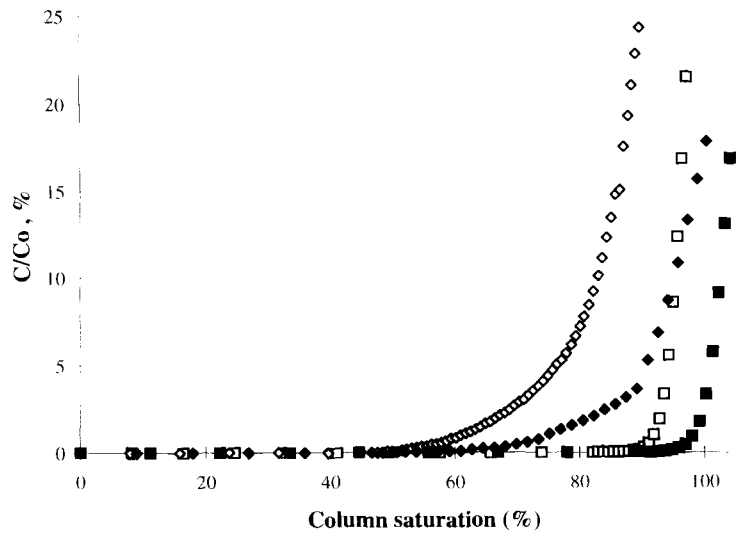

Fig. 9. Break through curves for cadmium at different sample concentrations and flow rates. □, 0.16 μM, 10 ml min^{-1}; ◇, 0.16 μM, 50 ml min^{-1}; ■, 0.48 μM, 10 ml min^{-1}; ◆, 0.48 μM, 50 ml min^{-1}.

ported. The increased backpressure caused by the tubing and valves of the FIA manifold necessitated a decrease in the column length to achieve high flow rates. The shortest column packing that could be realised in the adjustable holder was 5 mm (0.14 ml). The small packing was tested by passing 500 ng of Cd^{2+} at pH 5.5 through the column at flow rates between 10 and 110 ml min^{-1}. The absorbance signals of the eluates did not vary indicating complete accumulation of the test ion. This finding was corroborated by diminishing the active length of the 8 mm i.d. × 14 mm column packing to 3.5 mm. This was accomplished by replacing 10.5 mm of the IDA-Novarose packing by underivatised Novarose and repeating the test, which again indicated complete uptake. Hence, the 6 mm i.d. column with 5 mm packings was used in the following experiments.

The effect of the volume and concentration of the hydrochloric acid eluent on the transient analyte signal was investigated in the ranges 0.10–1.5 ml and 0.12–2 M, respectively. The area and height of the signal reached constant values for concentrations and volumes larger than 0.5 M and 500 μl, respectively, and 1 ml of 1 M HCl was used henceforth. The effect of the elution flow rate on the emission signals was studied at 2 and 4 ml min^{-1}. The signal height at the lower flow rate was greater by a few percent but the peaks tailed excessively. Thus, the higher flow rate, 4 ml min^{-1}, was used.

The elution profiles of Cu^{2+}, Cd^{2+} and Ni^{2+} obtained from 260 ng of each metal ion are presented in Fig. 10. Yttrium was added to the eluent and used to indicate the dispersion of the eluent plug. A comparison of the profiles demonstrates the similarity of the desorption kinetics. Cadmium, however, seems to desorb at lower concentrations of acid than the others, which probably reflects the lower binding strength of this element. The peak width of Y^{3+}, which estimates the final volume of the acid plug, was calculated to be about 2.5 ml, whereas the widths of the eluted peaks were about 1 ml.

Work at low concentrations increases the risk of contamination. Hence, the purity of the acetate buffer and Milli-Q water was tested by passing 600 ml portions through the column. No significant contamination problems were encountered for Cd^{2+} and Ni^{2+}. For Cu^{2+}, however, varying degrees of contaminations, up to 60 ng l^{-1}, were observed. The source of the contamination could not be identified but it was not due to a copper impurity in the acetate buffer. The effect of sam-

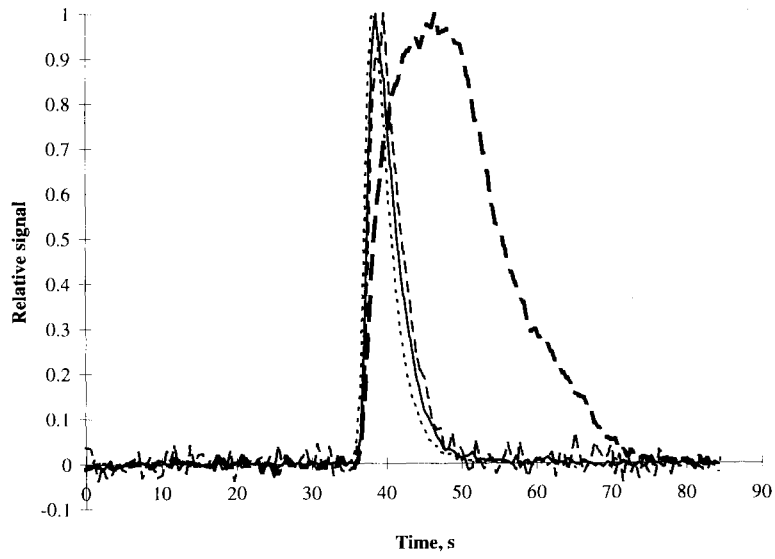

Fig. 10. Comparison of the elution profiles of Cd^{2+} (dotted line), Cu^{2+} (solid line), and Ni^{2+} (dashed line) in the FIA-ICP-AES system. Y^{+3} (thick dashed line) signal indicates the distribution of the 1 ml eluent plug. The first 35 s of the graph show the signals during the washing step.

ple volume and concentration on the recovery was investigated in the concentration range 50–500 ng l^{-1} for Cd^{2+}, 150–1500 ng l^{-1} for Cu^{2+}, and 300 to 3000 ng l^{-1} for Ni^{2+}. The volumes and concentrations were chosen so that constant amounts of the test ions were collected. No significant change was observed in the emission signals of Cd^{2+} and Ni^{2+} from the eluate. In the case of Cu^{2+}, however, a slight increase in the peak area with the volume of the sample was observed. The amount collected was 85 ng. This trend probably originates from the contamination problems met for this element and was not observed at the higher concentrations used with FAAS detection.

The linearity of the calibration curves for Cd^{2+}, Cu^{2+} and Ni^{2+} were studied in somewhat different concentration ranges depending on their relative sensitivities. Appropriate volumes of a standard solution were passed through the column and the peak area used to establish the calibration curves, which were linear ($r > 0.999$) in the studied loading ranges, respectively, 15–120, 45–350 and 90–700 ng. The detection limits, calculated as three times the standard deviation of the estimated noise contribution from the baseline, were for Cd^{2+}, Cu^{2+} and Ni^{2+}, respectively, 4, 7 and 22 ng (peak height) and 2, 5 and 10 ng (peak area).

Considering 10 min as a reasonable enrichment time, and 60 ml min^{-1} as an appropriate and practical sample flow rate, the peak area detection limits in ng can be transformed to the corresponding concentrations limits of 3, 8 and 16 ng l^{-1}. The signal enhancement for a 600 ml sample is estimated to about 1300. This estimate is based on a comparison of the peak height from an enriched sample of Cd^{2+} with the signal obtained by continuous aspiration of a 1 ppm solution of the element. Since the elution peak is present in a volume of about 1 ml, the preconcentration factor is numerically about equal to the enriched volume. The relative standard deviation of the peak area for four replicates was 1.8, 2.4 and 1.3% for Cd^{2+} (50 ng), Cu^{2+} (150 ng) and Ni^{2+} (300 ng), respectively.

The possible interference from calcium, a major matrix element in water samples, on the FAAS and ICP determinations was evaluated. Calcium can be removed from the column by washing with 0.1 M ammonium acetate. This treatment does not affect the test ions but will displace other

loosely held ions such as Mg^{2+} and Mn^{2+}. In FAAS, elimination of accumulated calcium by washing was unnecessary as the absorbance signal was unaffected at the concentration present in the effluent from the column. Enrichment of cadmium from solutions containing 5 mM calcium chloride, pH 5.5, yielded complete recovery, which shows that calcium does not disturb the adsorption.

3.5. Analysis of tap water

Cadmium and nickel are present in natural waters at ng l^{-1} levels and cannot be directly measured by ICP-AES and the copper concentration is close to the detection limit of the technique. Thus, preconcentration and determination of these elements in tap water was selected as an application. In the initial enrichment experiments on tap water and ICP detection, the column was washed with 2 ml of buffer solution before elution. The base line of the cadmium and nickel signals, were then found to be disturbed by the effluent from the washing step right up to the start of the analyte peaks. It is likely that the disturbance is caused by changes in the plasma from the relatively high concentrations of alkaline and alkaline earth metals present in the effluent. The same effect was observed for synthetic tap water as well as for samples containing Ca^{2+} as the only matrix element. Therefore, the effect of different washing volumes on the calcium and magnesium signals was studied. It was found that 4 ml of the 0.1 M acetate buffer sufficed to remove the majority of Ca^{2+} and Mg^{2+} from the column. Using this volume, the disturbed part of the cadmium and nickel base lines were well separated from the analyte peak. Experiments with blanks, containing only the tap water matrix, indicated that the remaining part of Ca^{2+} in the elution step does not change the background signal.

In order to study the effect of the tap water matrix on the recovery of the analytes, tap water was spiked with 0.5, 1.5 and 3.0 μg l^{-1} of Cd^{2+}, Cu^{2+} and Ni^{2+}, respectively, after acetate buffering to pH 5.5. Different volumes of the solutions were enriched on the column. Linear relationships ($r > 0.999$) were obtained between peak area and sample volume. The recovery of added Cd^{2+} was not significantly different from 100%, whereas the recovery of Ni^{2+} was about 90% and greater than 100% for Cu^{2+}. It can therefore be concluded that the first results for copper were due to an erroneous calibration curve caused by losses of copper in the solutions of pH 5.5 and low analyte and acetate concentrations. The results for nickel could be explained by the fact that, in presence of calcium and magnesium at relatively high concentrations, the adsorbent is mostly in the Ca^{2+}, Mg^{2+}, rather than H^+ or NH_4^+, form. This might affect the kinetics of the chelation of nickel. Experiments on the effect of the enrichment flow rate were in agreement with this hypothesis. A 2 μg l^{-1} Ni^{2+} sample, containing 10 mM Ca^{2+}, was loaded at flow rates of 60, 30 and 15 ml min^{-1}, and the recoveries obtained were 75, 92 and 101%, respectively.

For the determination of copper in tap water the column was enriched with 100 ml increments of the sample buffered at pH 5.0. The water sample contained 4.8 μg Cu l^{-1} as determined by GFAAS. The eluates were collected in the off-line mode in order to increase the accuracy, and analysed by ICP-AES. While a recovery of 99% was obtained for standard solutions of the same concentration run in parallel, only about 60% of copper was recovered from the tap water sample and the rest, 40%, was found in the column effluent. Loading flow rates of 60, 30 and 12 ml min^{-1} for a natural and a synthetic tap water resulted in quantitative uptake for the synthetic sample, while recoveries of 68, 72 and 78%, respectively, were obtained for the natural tap water. The effluent concentrations were in agreement with the recovery figures. The results for the synthetic sample clearly indicate that the matrix effects from inorganic constituents are negligible. Hence, the reason for the loss of copper is probably complexation with humic substances or other organic ligands present in the tap water. This was tested by a measurement of the recovery of a photo-digested tap water. The column was enriched with two tap water samples UV-irradiated at pH 2.3 and 1.2, respectively. No significant amounts of copper was found in the column

effluents indicating quantitative adsorption of the analyte from both samples (< 5% loss).

For nickel, it was necessary to enrich more than 400 ml of tap water to get reasonable signals in the FIA-ICP-AES system. The sample was buffered at pH 5.5 and enriched at flow rate of 60 ml min^{-1}. Enrichment of a 0.45 μg Ni l^{-1} tap water resulted in an uptake of only 0.22 μg l^{-1}. The effluent concentration was measured to be about 0.2 μg l^{-1} in agreement with the previous figure. Hence, the recovery of nickel at this flow rate is about 50%. This is less than obtained for spiked, synthetic tap water samples (see above). Thus, complexation of nickel with humic substances is indicated. Digestion experiments were not performed for this element due to the large sample volumes required.

For determination of the cadmium concentration, the column was enriched with 400 ml increments of a tap water at pH 5.5, 6.5 (adjusted) and 7.7 (natural). A mean value of 36 ± 6 ng l^{-1} ($n = 2 \times 3$) was obtained for the cadmium concentration. No trend in the result with pH could be discerned with the present precision, which, however, is not as good as could be expected from the estimated detection limit. Analysis by GFAAS, using multiple injections, resulted in the concentration 36 ± 4 ng l^{-1} in agreement with the result obtained from the preconcentration by IDA-Novarose. Analysis of the column effluent, resulted in cadmium concentrations below the detection limit (< 2 ng l^{-1}).

4. Conclusions

This work has demonstrated the rapid exchange of metal ions on IDA-Novarose. In particular, the adsorption appears to proceed much faster than on Chelex-100, the most common adsorbent with iminodiacetate groups. The new adsorbent can tolerate relatively high pressures with no change in adsorption properties. Metal ions, at least in an uncomplexed form, can be quantitatively sequestered at high volumetric flow rates on a small column. Large preconcentration factors can then be reached within a moderate accumulation time.

The large preconcentration factor, 500–1000, needed in ultra trace analysis with ICP-AES detection, will create an unbalance between the preconcentration and quantitation times even at high sample flow rates. Automated preconcentration off-line could then be considered. In case a preconcentration factor of 50–100 is needed, a more balanced situation is at hand, and the high flow rate permissible with IDA-Novarose will considerably increase the sample throughput.

Analysis of tap water indicates the capability of the adsorbent to quantitatively adsorb cadmium at high flow rates. Effects of humic substances and other matrix components on the kinetics of the adsorption of copper and nickel lead to incomplete recoveries even at low flow rates.

Sorptive behavior of Zn(II) on a lake sediment by sequential extraction-radiotracer technique

Ryoko Fujiyoshi *, Tomoo Gomei, Sadashi Sawamura

Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

Received 9 July 1996; received in revised form 2 December 1996; accepted 3 December 1996

Abstract

A sequential extraction-radiotracer technique was applied to a sediment core sample collected from Lake Biwa (Japan) in order to evaluate relative importance of the fractionated solid components to sorb Zn(II) ions. The core was previously divided into three parts from the surface of the sediment: upper (0–6 cm), middle (6–12 cm) and bottom (12–18 cm). The solid residue after each chemical treatment was collected to perform a sorption experiment by using ^{65}Zn as a tracer. A difference in the amount of Zn(II) sorption was observed among original samples without any chemical treatments at each depth. The amounts were very small (10^{-5}–10^{-4} mol Zn(II) 100 g^{-1} of dry sample) in all fractions of the sediment. Electrochemical measurements of cadmium and copper ion sorption supported the results from the radiometric sorption experiment. The effects of several potential factors on zinc sorption were investigated. Ion exchange of zinc with protons on the mineral surfaces was a significant cause of the zinc sorption.

Keywords: Extraction-radiotracer; Fractionated solid; Lake sediment

1. Introduction

Factors controlling fates of pollutants like heavy metals and radionuclides in the aquatic environment have been extensively studied. They are found to be very complex, partly because there are several forms of pollutants themselves depending on in situ conditions as well as those of solid phases with which the pollutants interact [1,2].

In the previous papers [3,4], the authors investigated a sequential extraction-radiotracer technique to elucidate mineral phases of several natural samples with which pertinent pollutants would be taken up. Good results were obtained in those cases; the Zn(II) sorption was relevant to the amount and the properties of some solid components of the samples remaining after certain chemical treatments.

The technique is further applied to an oxic lake sediment collected from Lake Biwa (Siga Prefecture, Japan) to find possible scavengers and the sorbed amount of Zn(II) in the aquatic environment.

2. Experimental

2.1. Reagents and materials

The core sediment used in this study was supplied by the courtesy of Dr Masuzawa of Nagoya University (Japan). It was collected at a point south west of Chikubu Island in Lake Biwa (Siga Prefecture, Japan) on November 21 1985. The sample was cut into three portions from the top of the sediment; upper (0–6 cm), middle (6–12 cm) and bottom (12–18 cm). After drying at room temperature, those subsamples were then ground to homogeneous powders.

Zinc-65 was purchased from Japan Radioisotope Association in the form of chloride in 0.5 M hydrochloric acid(stock solution). The nominal sp. act. was 105 GBq gZn^{-1}, with a radionuclidic purity of 99.00% and a radiochemical purity of 99.00%. The $^{65}Zn(II)$ tracer solution (925 $kBqcm^{-3}$) was prepared from the stock solution by diluting with a standard zinc nitrate solution (1000 $mgZn\ dm^{-3}$) to avoid the Zn(II)-chloro complexation in the solution. Almost all zinc ions in the solution is to be in the form of nitrates which have lower complexing capacities with Zn(II) than chloride ions. The specific activity of this working solution was 2.36 GBq g^{-1} of zinc.

2.2. Instruments

GM counting system (Aloka Type 203B); X-ray diffractometer (Mac Science MXP); centrifuge (Kokusan Partner); ion analyzer (Orion EA940); pH meter (Horiba D-12); spectrophotometer (Hitachi 3000); mechanical shaker (Yamato Model SA-31); thermal analyzer (Shimazu DTA-50 and Shimazu TG-50).

2.3. Procedure

The sequential extraction of the lake sediment. A dried and ground original sample (F0) was treated sequentially with the following chemical reagents: (i) 1 M NaCl (F1); (ii) 25% CH_3COOH (F2); (iii) 0.04 M $NH_2OH \cdot HCl$ in 25% CH_3COOH (pH 2) (F3); (iv) 30% H_2O_2 (pH 2) (F4); and (v) 7 M HNO_3 (F5). In the previous works [3,4], 1 M CH_3COONH_4 was used in the first step treatment (i) to obtain ion exchangeable components. However, the treatment with ammonium acetate was not suitable for dissolving ion exchangeable components of this sediment with low zero point of charge (ZPC). Instead, 1 M sodium chloride solution was used for the purpose. Both carbonate and oxide phases contained in a sediment had been dissolved simultaneously into an acid/reductant mixed solution in the previous works [3,4]. The present sample was thus, treated first with (ii) 25% CH_3COOH and then with (iii) 0.04 M $NH_2OH \cdot HCl$ in 25% CH_3COOH. It is therefore to be six fractions (F0, F1, F2, F3, F4 and F5) of the sediment including the original sample without any chemical treatment (F0).

The sorption experiments were carried out as follows; a dried sample (F0–F5) was weighed and transferred to a centrifuge tube (10 cm^3). The total volume of the suspension was adjusted to 10 cm^3 with distilled water. A small amount of the $^{65}Zn(II)$ tracer solution (10–80 μl) was added to the suspension, which was shaken mechanically for 40 min. The suspension was then centrifuged (3000 rpm, 30 min). An aliquot (1 cm^3) of the supernatant solution was pipetted into an aluminum container, and dried completely for γ-counting.

The ^{65}Zn activity was measured using a GM counter. The specific activity of the $^{65}Zn(II)$ tracer solution used in this study was found to be 2.36 GBq gZn^{-1}, and the efficiency of the counting was 0.327% in total. Several standards of known activity were used to evaluate values obtained under the same counting conditions.

The cation exchange capacity (CEC) of each sample was measured electrochemically with an ammonia electrode (Orion 95-10); all the cation sites of a sample in an aqueous suspension were previously substituted with ammonium ions (1 M NH_4Cl). After centrifugation of the suspension, the residue was washed repeatedly with distilled water and then treated with 0.1 N NaCl solution. The amount of NH_4^+ ions released from the solid phase by the exchange with Na^+ ions was determined electrochemically.

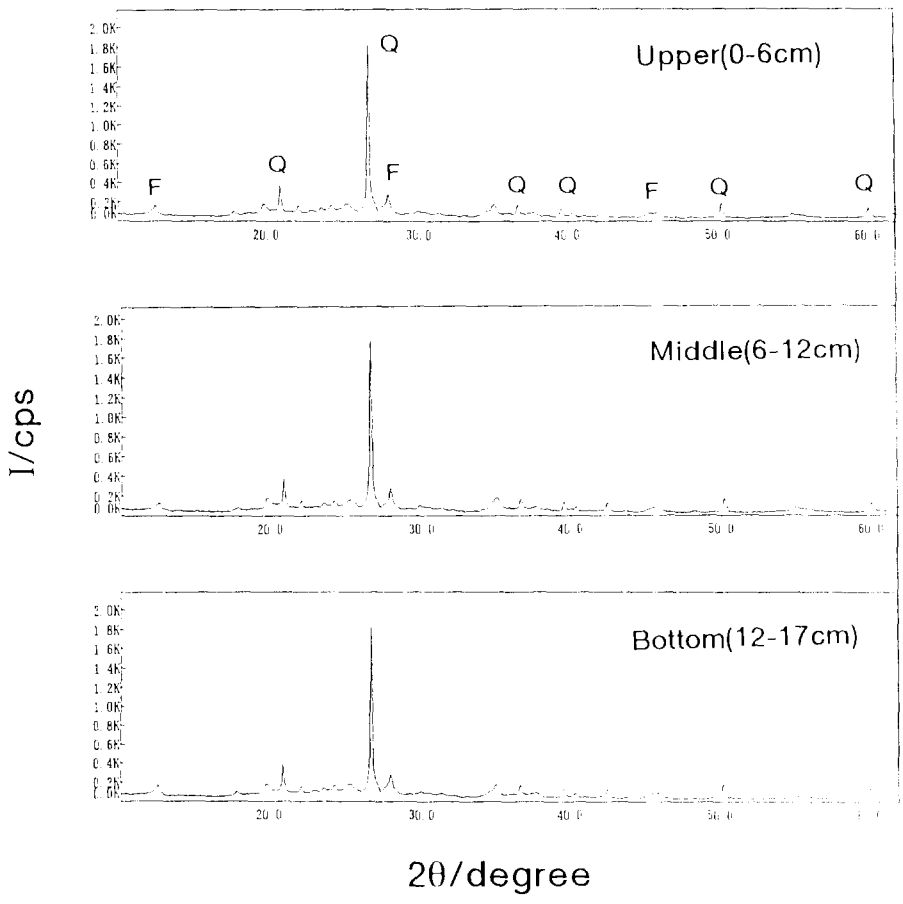

Fig. 1. X-ray diffraction patterns of the untreated fractions (F0) of the core sediment sample. Q: quartz, F: feldspar.

pH Effect was also investigated on Cd(II) and Cu(II) sorption by using ion selective electrodes of both ions (Orion 94-48 cadmium electrode and Orion 94-29 cupric electrode). It was actually evaluated from the emf measurement of a liquid phase before and after the sorption equilibrium in each system.

The mineral phases of the sediment samples after the various chemical treatments were identified by powder X-ray diffraction analysis [5].

The surface area of the sediment samples were measured spectrophotometrically by using methylene blue as a coloring agent [6].

Thermal analyses of the untreated samples were carried out by DTA and TG in which the initial heating rate was 10°C min^{-1}, and the temperature of the furnace was then kept constant at 450°C for 2 h. Weight loss of each sample after the combustion was calculated.

3. Results and discussion

The Lake Biwa is the largest lake in Japan, and many studies have been done on this lake ecologically and hydrodynamically so far [7]. However, information on the chemistry of bottom sediments of the lake seems to be rather scant.

Fig. 1 shows the X-ray diffraction patterns of untreated fractions (F0) of the three portions (upper, middle and bottom) of the core sample. There appear quartz and feldspars in all samples, and no apparent differences exist in the pattern among them. Similar patterns were observed in all

Table 1
Weight loss (%) of individual fractions of the sediment samples upon each chemical treatment

Chemical treatment	Upper (0–6 cm)	Middle (6–12 cm)	Bottom (12–17 cm)
Electrolyte	2.4	2.5	0.7
Weak acid	2.7	2.0	3.2
Reductant	1.3	1.8	1.8
Oxidant	5.2	4.9	5.1
Strong acid	4.2	3.7	2.4
Residue	84.2	85.1	86.8

All values are on a dry sediment weight bases. Possible errors of those values are estimated to be less than ± 5%.

other fractions of the sediment. It is considerable that major mineral components of the sediment may be stable enough not to be leached appreciably by any chemical treatments other than conc. HNO_3. Results on the weight loss of the sample upon each treatment supports this assumption (Table 1). It should be noted that there exist some clay minerals and also hydrous ferric oxides in the sediment sample [7]. Those minerals may play a role to sorb Zn(II) ions, however, as shown later, the sorbed amount was very small as a whole.

Sorption experiments were then carried out radiometrically on 15 fractionated samples by using ^{65}Zn as a tracer. Fig. 2 shows the sorption isotherm on three portions of the untreated sediments; upper (F0), middle (F0) and bottom (F0). The good linearity of the isotherms leads to calculate the sorbed amount of ^{65}Zn at maximum (A_m).

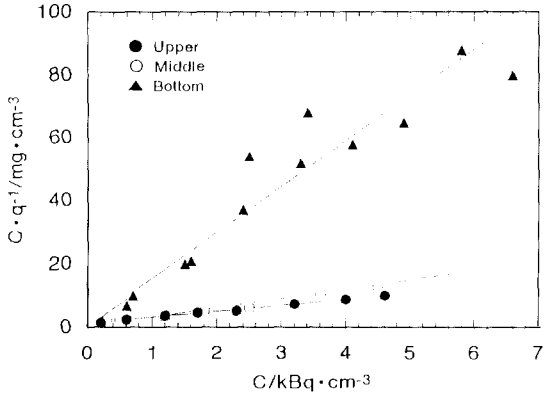

Fig. 2. Sorption isotherms on untreated fractions (F0) of the sediment sample. C and q denote the $^{65}Zn(II)$ activities in the aqueous and solid phases, respectively. ●: upper, ○: middle, ▲: bottom.

As shown in Table 2, the value is found to be highest at the surface (upper) and extremely low in the deepest portion (bottom) of the core sediment.

In order to elucidate possible reasons for such differences in the sorption, the surface area of each sample was measured colorimetrically. No clear relationship exists between the surface area and the A_m value of those samples (Table 2). The result suggests that the surface area is not a predominant factor controlling the Zn(II) sorption under the present experimental condition.

Fig. 3 shows the CEC of each fractionated sample of the sediment. The values are higher in all fractions of the upper portion than those in other portions of the sediment. As shown in Table 2, the CEC values on F0 samples are more than 30 times higher than the sorbed amount of ^{65}Zn at maximum (A_m). As described in the experimental section, the CEC was obtained electrochemically by using an ammonia electrode, in which the electrode potential caused by the ion exchange between Na^+ and NH_4^+ in the solution was measured. It is thus possible that the sites for Zn(II) ions to be sorbed may not be just the same as those for NH_4^+ ions, since there are differences in charge and also in ionic radius between them.

The CEC is obviously affected by surface states of solid phases, and it is closely related to the pH value at zero point of charge (pH_{ZPC}) of the solids. The apparent pH_{ZPC} of the untreated fractions (F0) of the sediment is estimated by pH change of the solid suspension before and after the sorption equilibrium [d(pH)]. Fig. 4 shows that the pH value at which d(pH) is to be zero on the curve may be approximated to be the pH_{ZPC}

Table 2
Comparative lists of data on surface area, sorbed amount of ^{65}Zn at maximum (A_m), CEC, pH_{ZPC} and ignition loss at 450°C of three portions (upper, middle and bottom) of the untreated sediment sample (F0)

	Upper (0–6) cm^{-1}	Middle (6–12) cm^{-1}	Bottom (12–17) cm^{-1}
Surface area ($m^2\ g^{-1}$)	15 ± 3	15 ± 3	10 ± 3
A_m (10^{-4} mol 100 g^{-1})	3.43 ± 0.07	2.21 ± 0.04	0.51 ± 0.01
CEC (meq 100 g^{-1})	9.59 ± 0.36	6.98 ± 0.49	6.73 ± 0.92
pH_{ZPC}	6.6 ± 0.1	6.3 ± 0.1	6.2 ± 0.1
Ignition loss at 450°C (%)	6.60 ± 0.01	6.29 ± 0.01	6.13 ± 0.01

of each F0 sample. As shown in Table 2, the resulting value is highest at the upper portion and the lowest at the deepest one of the sediment, which is consistent with the result obtained in the radio-metric ^{65}Zn sorption experiment. It is therefore possible that the Zn(II) sorption is related to the proton exchange on the sediment surfaces, i.e., the more negative solid surfaces provide more sites for cation sorption in the aqueous phase.

In order to evaluate the above results on other ions than Zn(II), the electrochemical approach was carried out by using ion selective electrodes of cadmium and copper. Fig. 5 shows the results of both cadmium (II) and copper (II) sorption on three portions of the nontreated sediment samples (F0) at pH_{ZPC}. The sorbed amount of Cu(II) is consistently larger than that of Cd(II) at any depth of the sediment samples. Such a difference in sorptive ability between two metal ions can be explained by considering their hydrated radii and coordination properties of aqua-complexes. The values are in the same order of magnitude as those of the sorbed amount of ^{65}Zn at maximum obtained from the tracer experiment (Table 2).

Those results suggest that the sorption of the divalent metal ions like Zn(II), Cu(II) and Cd(II) occur rather selectively through the ion exchange with protons on mineral surfaces of this lake sediment. A mineral which provides a surface with proton exchangeable sites thus, enables those metal ions to be sorbed to a great extent. This may also be true in the organic matter which will provide protons from carboxylic and phenolic groups. The organic contents of the non-treated sediments may be estimated from their ignition loss at 450°C. As shown in Table 2, the value is highest at the upper portion and the lowest at the bottom of the core.

The crucial role of protons is well known in biosorption. Shiewer and Volesky [8] observed biosorption of Cd^{2+}, Cu^{2+} and Zn^{2+} on a non-

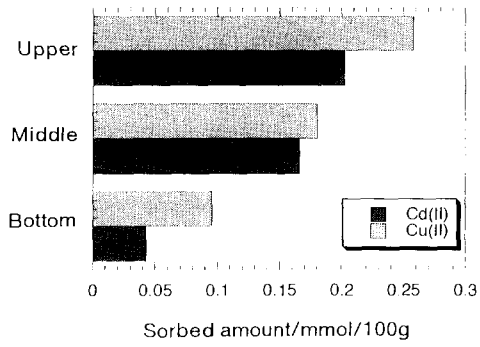

Fig. 5. Sorption of Cd(II) and Cu(II) on three portions of the untreated sediment sample (F0) at pH_{ZPC}.

living biomass of the marine alga (Sargassum fluitans). They modeled the sorption using a modified multicomponent Langmuir equation to describe metal ion-proton exchanges.

It is apparent that there are several factors controlling sorption behavior of the divalent metal ions on various sediments; chemical forms of metal ions, surface states of minerals especially on number of proton exchangeable sites, and probably the existence of organic matter as complexing agents with metals as well as usual in situ temperature, pressure and redox conditions. Chemical forms of metal ions are also dependent on pH value of the aqueous phase.

Sorption processes in natural environment are therefore intrinsically heterogeneous in nature. Weber et al. [9] reviewed sorption phenomena in subsurface systems in order to elucidate the behavior, transport and ultimate fate of contaminants. And then they introduced the distributed reactivity model which was derived on the basis of different distributions of sorption reactions and mechanisms for different solute–solid combinations [10]. They showed experimental evidence to conclude the model to be valid.

The sequential extraction-radiotracer technique should help to evaluate sorption capacities of individual components of a sediment, if they could be leached sequentially by suitable chemical treatments. The present authors previously reported the results on this technique applying to a scale sample collected from a water still and also a marine sediment [3,4]. The sorbed amount of Zn(II) was found to be clearly correlated with the kind and amount of mineral phases contained in the solid sample.

From the results obtained in a series of experiments, it is concluded that the Zn(II) sorption is significantly controlled by the proton concentration of both aqueous and solid phases. A solid phase containing much amount of acidic minerals (or organic matter with carboxylic groups) tends to release protons into the aqueous phase to result in its suspension with low pH. The amount of Zn(II) sorbed is to be very small in such a case. The sequential extraction-radiotracer technique is thus, useful to evaluate the capacity of each component of the sediment to scavenge toxic heavy metals, when its pH_{ZPC} is relatively high ($pH > 8$). Anyway, a sediment with low pH_{ZPC} has only a small capacity for scavenging as a whole.

Further experimental study should be continued to elucidate the reversibility of the sorption and also competitive sorption among metal ions with various ionic radius and complexing abilities.

Received 16 July 1996; received in revised form 25 November 1996; accepted 2 December 1996

Abstract

A method for immobilization of 5-formyl-3-arylazosalicylic acid derivatives on the surface of silica gel is described. The new silica gel phases were synthesized by a very simple and rapid route which can be defined as a one-step reaction. The phases were proved to show an excellent improvement in the iron (III) extraction and the determined mmol g^{-1} values are in the range of 1.24–1.32. The metal-uptake properties of eleven metal ions were also evaluated at different pH values and shaking times. The process of selective extraction of iron (III), in presence of an interfering ion, by these phases was also studied by both column and batch equilibrium techniques in order to identify the possible type of interference of each metal ion in this process. Three divalent metal ions (Mg, Ca and Mn) exhibited a minimum interference in iron (III) extraction. A group of six divalent metal ions (Co, Ni, Cu, Zn, Cd and Pb) were found to be interfering in the selective extraction of iron (III) via the arylazo-moiety of the silica phase, while Cr(III) was found to show a specific interference type based on the affinity of Cr(III) for binding to the chelation centers of the salicylic acid moiety of the silica phase. © 1997 Elsevier Science B.V.

1. Introduction

Immobilization of chelating compounds on the surface of silica gel has received special interest in recent years because of the wide range of applicability of these phases in metal-ion uptake and pre-concentration [1–10], separation of transition and non-transition metal ions [11–15], solvent clean-up from undesired metal ions and selective extraction of metal ions from different solvent systems [16]. The selectivity incorporated and encountered in such phases is mainly attributed to the presence of donor atoms capable of metal-complex formation with certain metal ions [5,17]. The most commonly used donor atoms in metal complexes are oxygen, nitrogen and sulfur, which are bound to the metal ion in a certain fashion for forcing selective extraction of metal ions. A method for selective extraction of alkali-metal ions by silica-immobilized crown ether derivatives was reported [18]. Silica gel modified with γ-aminopropyltriethoxysilane was shown to be a

PII S0039-9140(96)02194-7

selective phase for preconcentration of gold (III), Platinum (IV) and palladium (II) [19]. Oxygen- and nitrogen-donor-containing macro-cyclic compounds immobilized on silica gel surface showed high selectivity for copper (II) in presence of cobalt (II), nickel (II), zinc (II) and cadmium (II) [20]. Palladium (II) was selectively extracted from other interfering metal ions by the use of silica-immobilized thioaniline derivatives [21].

Recently, we have reported the method of immobilization of two isomeric formylsalicylic acid derivatives on the surface of silica gel modified with aminosylating agent through the Schiff base formation between the aldehydic and the amino groups. The phases were found to be highly selective for iron (III) extraction from a mixture of different interfering metal ions [22]. The selectivity of iron (III) through chelation with the two oxygen atoms furnished by the hydroxyl and the carboxyl groups [23].

In this paper, 5-formylsalicylic acid is derivatized to the corresponding arylazo derivatives via diazotization reaction with aniline, 2-aminophenol, 2-aminothiophenol and 2-aminobenzoic acid. This was done in an attempt to explore the phenomenon of selective extraction of iron (III) by silica-immobilized salicylic acid derivatives, increase the possibility of metal-ion uptake, especially iron (III), by the presence of additional chelating functional groups and study the influence of such additional chelating centers on the selective extraction process.

2. Experimental

2.1. Apparatus

Infrared spectra of 5-formylsalicylic acid arylazo-derivatives were recorded on a Perkin-Elmer 1430 ratio-recording spectrophotometer. Atomic absorption measurements of the different metal ions were carried out by using a Perkin-Elmer 2380 atomic absorption spectrophotometer operated at the specific wavelength of absorption of each metal ion. The pH values of the various buffer solutions were measured by using a Schott Geräte pH-meter calibrated against two standard buffer solutions of pH 4.0 and 9.2. Elemental analyses of the various 5-formyl-3-arylazosalicylic acid derivatives and modified phases were done at the microanalysis center at Cairo University.

2.2. Reagents and materials

5-Formylsalicylic acid was prepared according to previously reported method [24]. Aniline, 2-aminophenol, 2-aminothiophenol and 2-aminobenzoic acid were purchased from BDH Chemicals, Poole, England and used as received. 3-Aminopropyltriethoxysilane was purchased from Aldrich Chemical Company, USA. The silica gel used in this study is of TLC grade with 70–230 mesh size and 60 Å pore diameter, purchased from Woelm Pharma, Eschwege, Germany. Organic solvents were purified and dried according to conventional methods.

5-Formyl-3-arylazosalicylic acid derivatives of aniline, 2-aminophenol, 2-aminothiophenol and 2-aminobenzoic acid were synthesized by diazotization of the corresponding arylamine below 5°C with conc. HCl and sodium nitrite, followed by coupling with an alkaline solution of 5-formylsalicylic acid [25]. The separated azo-derivatives were filtered off, washed with water, air dried and recrystallized from methanol.

Silica-gel-bound arylazoderivatives were prepared by mixing 5.0 g of dry amino-modified silica gel with 10 mmol of the azo-derivative, already dissolved in 300 ml of hot dry toluene, and the reaction mixture was refluxed for 2 h. After completion of the reaction, detected by the colour stability of the silica gel, the product was filtered off, washed with toluene, alcohol and diethylether and dried under vacuum at 80°C for 6 h.

2.3. Surface coverage and metal capacity of modified silica

The surface coverage (mmol g^{-1}) of silica gel with arylazo-derivatives was determined on the basis of percent carbon of the modified silica phases. The metal capacity values (mmol g^{-1}) of the newly synthesized phases for the different metal ions in various buffer solutions (pH 1.0, 2.0,

3.8, 5.0 and 10.0) and in 1.0 M sodium acetate were determined in triplicate by the batch equilibrium technique. Of the dry phase, 30 mg was added to a mixture of 1.0 ml of 0.1 M metal ion and 9.0 ml of the selected buffer solution and automatically shaken for 30 min. After equilibration, the mixture was filtered, washed with 80 ml double-distilled deionized water and the unbound metal ions were subjected to complexometric titration using the proper indicator and/or atomic absorption analysis.

The effect of shaking time on the amount of extracted metal ion (mmol g^{-1}) was also studied by the batch equilibrium technique. Of the dry phase, 30 mg were added to 1.0 ml of 0.1 M metal ion and 9.0 ml of the buffer solution which showed the maximum metal capacity value in the previous section and the mixture was automatically shaken for the selected time and the metal capacity value (mmol g^{-1}) was determined as above.

2.4. Selective extraction of iron (III)

Selective extraction of iron (III) in presence of an interfering metal ion was evaluated by using both column and batch equilibrium technique. In the column technique, a column identical to that previously reported [1] was established and packed with 30 mg of the required phase in slurry of 5 ml double-distilled deionized water. A mixture containing 0.1 M iron (III) and the interfering metal ion, 1.0 ml each, was mixed with 15 ml of 1.0 M sodium acetate and drawn through the column with a flow rate of approximately 0.5 ml min^{-1}. The column was then flushed with double-distilled deionized water and the eluents were collected and diluted with double-distilled deionized water to a total volume of 100 ml in a volumetric flask. The mixture was subjected to further dilution to meet the requirements of the linear dynamic range of the calibration curves set up by the atomic absorption analysis for each metal ion.

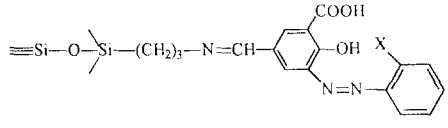
The batch equilibrium technique study of the selective extraction of iron (III) in presence of an interfering metal ion was accomplished by mixing 30 mg of the phase with 1.0 ml each of 0.1 M iron (III) and the interfering metal ion and 15 ml of 1.0 M sodium acetate in a 50 ml measuring flask. The mixture was automatically shaken for 30 min, filtered, washed with double-distilled deionized water and the total volume of the metal ion mixture was completed to 100 ml in a measuring flask and subjected to further dilution as above for the atomic absorption analysis.

3. Results and discussion

The structure of the arylazo-compounds was confirmed on the basis of IR analysis which showed the presence of the symmetric stretching vibration mode of the azo group in the range 1430–1491 cm^{-1}. The band correspond to the asymmetrical N=N stretching mode, near 1600 cm^{-1}, was not detected as it merged with strong C=C ring vibration [26]. The structure of silica-immobilized 5-formyl-3-arylazosalicylic acid derivatives is shown below in Scheme 1.

The IR studies of the modified silica gel Phases I–IV showed the evidence for the formation of a new band corresponding to the coupling between the 5-formyl group and the amino group of modified silica with 3-aminotriethoxysilane. The product of this coupling is the C=N Schiff base bond formation which is identified in the IR spectra of I-IV at $\nu_{C=N}$ 1525–1580 cm^{-1}. The other characteristic functional groups such as $\nu_{C=O}$ at 1600–1700 cm^{-1} and ν_{OH} at 3600 cm^{-1} were confirmed from the IR spectra of Phases I–IV.

It is important to declare here that the immobilization of arylazo-compounds on the surface of silica was accomplished in only one simple and fast reaction rather than the multi-step reactions reported by others [27–29]. The double bond nature of the Schiff-base-characteristic bond,



Phase I, X = H Phase III, X = SH

Phase II, X = OH Phase IV, X = COOH

Scheme 1.

C=N, is known to be strong enough and the hydrolysis of Phases I–IV by the studied buffer solutions was found to be insignificant based on the distinguished colour formation of filtrate solution of these phases with iron (III), a property that can be used for a wide range of pH application of these phases. Moreover, the surface coverage determined on the basis of percent carbon by elemental analysis was found to be in the range of 0.75–0.82 mmol g^{-1}, which is superior to the reported low values of silica gel surface coverage by azo-compounds [27,28].

3.1. Metal capacity study

The metal capacity values (mmol g^{-1}) determined for the twelve tested metal ions, namely Mg (II), Ca (II), Cr (III), Mn (II), Fe (III), Co (II), Ni (II), Cu (II), Zn (II), Cd (II), Hg (II) and Pb (II), by the newly modified silica gel Phases I–IV are compiled in Table 1. The values were determined in different buffer solutions to decide the optimum pH value for each metal ion extraction and evaluate the effect of the pH value on the metal capacity.

Several conclusions can be drawn from the data given in Table 1. The most important is the exceptionally high iron (III) metal capacity values demonstrated by the four phases. These values are 1.24, 1.32, 1.30 and 1.28 for Phases I, II, III and IV, respectively. Such high mmol g^{-1} values of iron extraction compared with our previously reported data [22] can only be interpreted on the basis of the additional chelating functional groups present in Phases I–IV from the arylazo-moiety. These chelating groups acted together with the salicylic acid moiety to enhance the metal capacity value of iron (III) and this trend suggests the participation of all chelating functional groups in iron (III) extraction by Phases I–IV, as shown in Scheme 1. The effect of pH variation on the process of iron (III) extraction is evident in Table 1, and can be summarized by the gradual increase of the mmol/g values with increasing the pH of the iron (III) solution to a maximum value in 1.0 M sodium acetate, which is determined to have a pH of 5.6 and known to be the highest pH-limit for iron (III) extraction in presence of a buffer solution. However, the mmol/g values determined in buffer solutions of pH 5.6 and 5.0 revealed no or minimal contribution of the iron (III) hydroxide.

The metal capacity values of the other metal ions listed in Table 1 can be classified into three categories. The first includes Mg(II), Ca (II) and Zn (II) ions, which were found to show little affinity for extraction by Phases I–IV in acidic buffer solutions. The metal capacity values for these metal ions ranged from 0.00–0.10 mmol g^{-1} which are very low compared with other metal ions. The use of basic buffer solutions, especially pH 10, was found to improve the metal capacity values of these three metal ions to the range of 0.10–0.30 mmol g^{-1}. The order of metal ion extraction is Mg (II) < Ca (II) < Zn (II).

The second category of metal ions involves Cr (III), Cu (II), Cd (II) and Hg (II) and shows maximum metal capacity values in 0.1 M sodium acetate solution (pH 5.8–6.2). The 0.40–0.52 mmol g^{-1} values of Cu (II), giving the following order of increasing metal capacity, Cd (II) < Cr (III) ≈ Hg (II) < Cu (II). The third category consists of Mn (II), Co (II), Ni (II) and Pb (II) ions. This group of metal ions showed an intermediate behavior between the first and second category. Mn (II) < Ni (II) ≈ Pb (II) < Co (II). A comparison between the metal capacity values of some of the tested metal ions by Phases I-IV and those previously reported [22] indicates a close similarity in the mmol g^{-1} range of Co (II), Ni (II), Cu (II) and Pb (II) by the two phase types, while the corresponding value of Cd (II) was improved by the new phases.

The effect of shaking time on the percent extraction of metal ions was studied because it is important to identify the discrimination order in the behavior of the newly synthesized Phases I–IV towards the metal ion extraction. Three representative metal ions from the previously classified categories, Fe (III), Cu (II) and Pb (II), were selected and tested at different shaking times. The results of this study are shown in Figs. 1–3 and designate the rapid interaction of Phases I–IV with metal ions, judging from the percent extraction of metal ions. As shown in Fig. 1 Fig. 2 Fig. 3, only 2 min shaking time was sufficient to force

at least 70% of the total capacity determined in case of Fe (III) and Cu (II), while this shaking time affects 60% extraction of Pb (II). In addition, 20 min shaking time showed 98–99% of Fe (III) extraction, 90–95% of Cu (II) and 79–100% of Pb (II) extraction. It is clear from the data given that the metal ion—silica phase binding process is very fast, but no discrimination order can be

outlined from the effect of shaking time on the value of mmol g^{-1} and percent extraction of these metal ions.

3.2. Selectivity study

The determined values of metal capacity (mmol g^{-1}) of the various metal ions by Phases I–IV demonstrate that iron (III) is the most extractable metal ion amongst all tested metal ions, or, in other words, Phases I–IV can be successfully used for selective extraction of iron (III). In this study we preferred to evaluate the approach of selective extraction of iron (III) in presence of only one interfering species rather than a mixture of different interfering metal ions as we reported before [22], in an attempt to investigate the individual behavior of iron (III) in presence of only one interfering metal ion.

It is well known that the column technique is widely applicable in trace metal preconcentration from large-volume sample solution, in addition to the possibility of further separation of adsorbed or chemically bonded metal ions on the packing material surface [30]. This property is taken as an advantage over the batch equilibrium technique. However, the advantage of using the latter is the simplicity of operation and time saving compared with the column technique.

In the selectivity study, both column and batch equilibrium techniques were employed for the comparison. The experimental conditions such as dilution, washing and time of equilibration between the metal ion solution and the phases were almost identical. The results of this experiment are presented in Table 2. Values in Table 2 are expressed in mmol g^{-1} for simple and direct comparison with the values given in Table 1. Three different trends can be summarized from the mmol g^{-1} values of iron (III) in presence of an interfering metal ion. The first trend is the less- or non-interfering group of elements which includes Mg (II), Ca (II) and Mn(II), classified on the basis of the high metal capacity values of iron (III) which closely approaches the mmol g^{-1} value determined for iron (III) separately (Table 1), and the very low mmol g^{-1} values of the other three interfering metal ions. Therefore, Phases I–IV can be successfully used for selective extraction and separation of iron (III) in presence of Mg (II), Ca (II) and Mn (II). The second trend is demonstrated by the general behavior of Co (II), Ni (II), Cu (II), Zn (II), Cd (II) and Pb (II) metal ions. Although the metal capacity values of iron (III) given in Table 2 are high and considered in good agreement with those shown in Table 1, a strong evidence for the interference of this group of metals in the selective extraction of iron (III) comes from the similar good agreement of mmol g^{-1} values compiled in Table 1 and 2 for each metal ion, except Cu (II) which showed lower mmol g^{-1} values in Table 2. The number of accessible functional groups available for chelation and complex formation with the metal ion must be considered to account for this type of interference through selective extraction of iron (III), mainly by complex formation via the salicylic acid moiety, leaving the other chelating functional groups derived from the arylazo-moiety free for participation in the extraction of the interfering metal ion, thus, enforcing such type of interference denoted in Table 2 as arylazo chelation centers interference. This behavior of binding more than one metal ion is common and well known in the mixed metal complex formation by binucleating ligands [26,31–35].

The third trend in this study clearly shows another type of interference based on the selective extraction of iron (III) in presence of Cr (III). The metal capacity values of Cr (III) shown in Table 2 are consistent with those in Table 1, but those of Fe (III) given in Table 2 are dramatically lowered compared with those found in Table 1. The reason for this is attributed to the strong competition between iron (III) and Cr (III) ions for complex formation with the same chelating centers, namely the salicylic acid active chelating groups. This type of interference can be correlated to the similarity of the charge on both metal ions and the strong affinity of both cations to the same chelation sites.

Finally, the column and batch equilibrium data listed in Table 2 refer to the consistency between both techniques in evaluating metal uptake properties, metal ion extraction and interference processes, but the column technique is superior if further chromatographic separation between such metal ions is needed.

4. Conclusion

The studied silica-gel-bound 5-formyl-3-arylazosalicylic acid phases show very important and interesting results. The guide for designing new selective silica gel phases for metal ion extraction must be well defined on the basis of the number of interference types described in this study. The presence of an excessive number of chelating centers may enhance the chance of increasing the metal capacity of one or more metal ions, but undoubtedly will assist the possibility of strong interference by other metal ions, which diminishes the possibility of using such phases for selective extraction of a certain metal ion in presence of interfering metal ion(s). Therefore, it is important to design the new selective silica gel phases on the basis of the least number of chelating centers and selectively direct these centers to bind only the desired metal ion. Elimination of other factors which may cause any sort of interference is also recommended.

Synergistic enhancement of the horseradish peroxidase-catalyzed oxidation of luminol by 4-substituted phenylboronic acids

Larry J. Kricka *, Xiaoying Ji

Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia, PA 19104, USA

Received 11 June 1996; received in revised form 2 December 1996; accepted 3 December 1996

Abstract

Combinations of 4-substituted phenylboronic acids [phenyl, iodo, bromo, and trans-4-(3-propenoic acid) substituents] have been discovered to have synergistic effects in the horseradish peroxidase (HRP) catalyzed chemiluminescent oxidation of luminol. Three types of effect have been observed: 1. synergistic reduction in the background light emission of a luminol-peroxide assay reagent to a value lower than the background obtained with either enhancer individually; 2. increase in signal to background ratio (S/B) in the presence of HRP to a value higher than the S/B obtained with either enhancer individually (synergy) or to a value higher than the combined S/B obtained with each enhancer (synergistic enhancement); and 3. for some combinations of enhancers, an increase in signal in the presence of HRP to a value higher than the signal obtained with either enhancer individually (synergy), or to a value higher than the combined signal obtained with each enhancer (synergistic enhancement). The magnitude of the effect was moderate but the synergistic decreases in background and increases in signal produced increases in S/B up to four-fold. Examples of synergistic pairs of enhancers included 4-biphenyl and 4-bromophenylboronic acid; 4-biphenyl and 4-iodophenylboronic acid; and trans-4-(3-propenoic acid) and 4-iodophenylboronic acid. Generally, synergy was obtained at several concentrations of all of the combinations of enhancers tested, and at different time points in the reaction due to the different light emission kinetics of the enhanced reactions. The mechanism of this synergistic effect has not been elucidated but may involve the enhancers acting at different points in the complex chemiluminescent peroxidase catalyzed oxidation reaction. © 1997 Elsevier Science B.V.

Keywords: Aryl boronic acids; Chemiluminescence; Horseradish peroxidase; Luminol

1. Introduction

The discovery that firefly luciferin enhanced light emission from the chemiluminescent horseradish peroxidase (HRP) catalyzed oxidation of luminol [1,2] led to a search for other molecules that would act as enhancers in this reaction. Subsequently, potent 4-substituted phenols [3,4], substituted naphthols [4], aromatic amines [5], phenylboronic acids [6,7], and a series of aromatic molecules (e.g., 4-hydroxyacetanilide) [8] have been identified as enhancers. In an effort to further improve the enhancement effect (increased

PII S0039-9140(96)02195-9

signal, decreased background) we have investigated the enhancement properties of combinations of enhancers and we describe here our results with combinations of 4-substituted phenyl boronic acids.

2. Experimental

2.1. Materials

Luminol (Aldrich, Milwaukee, WI) was purified as the sodium salt by recrystallization from sodium hydroxide as described previously [9]. Light emission was measured using either an Amerlite analyzer (Amerlite Diagnostics PLC, Amersham, UK), or ML-3000 microtiter plate luminometer (Dynatech Laboratories, Chantilly, VA). Horseradish peroxidase (HRP, type VI-A) and phenylboronic acid were purchased from Sigma (St Louis, MO). 1,1′-Biphenyl-4-yl boronic acid, hydrogen peroxide (30% w/v), and 3-aminophenylboronic acid were purchased from Aldrich. 4-Bromophenylboronic acid was purchased from Lancaster Synthesis (Windham, NH). 4-Iodophenylboronic acid and trans-4-(3-propenoic acid) phenylboronic acid were synthesized by Cookson Chemicals (Southampton, UK).

2.2. Experimental protocol

Matrix experiments were designed in which a range of concentrations of each enhancer were tested. The matrix experiments investigated combinations of 1,1′-biphenyl-4-yl boronic acid, 4-iodophenylboronic acid, 4-bromophenylboronic acid, and trans-4-(3-propenoic acid) phenylboronic acid. The enhancers were tested in: (i) a luminol-peroxide reaction to determine if combinations of the enhancers reduced the assay background; and (ii) a luminol-peroxide-HRP (type VI-A) reaction to determine if combinations of the enhancers increased the signal due to HRP. The signal to background ratio (S/B) was calculated to determine if combinations of the enhancers produced an improvement in the S/B for detection of HRP. For each combination of enhancers, a range of concentrations either side of the optimum concentration for each enhancer was tested.

2.3. Screening procedure

Two 11×4 matrix experiments were devised involving enhancer combinations as follows: enhancer 1 (0, 0.005, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 10, 20 mmol l^{-1}) and enhancer 2 (0, 0.01, 0.1, 1 mmol l^{-1}) or enhancer 1 (0, 0.01, 0.1, 1 mmol l^{-1}) and enhancer 2 (0, 0.005, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 10, 20 mmol l^{-1}). Stock solutions of enhancer 1 (20 mmol l^{-1}) and enhancer 2 (20 mmol l^{-1}) were prepared in DMSO, and then diluted in Tris buffer (0.1 mol l^{-1}, pH 8.6). The luminol—hydrogen peroxide reagent was prepared as follows: sodium luminol (12.5 mg) was dissolved in 50 ml of Tris buffer (0.1 mol l^{-1}, pH 8.6), and 15.5 μl of hydrogen peroxide (30% w/v) was mixed with 0.5 ml of Tris buffer (0.1 mol l^{-1}, pH 8.6). These two solutions were combined and diluted 1:10 in Tris buffer (0.1 mol l^{-1}, pH 8.6). Enhancer 1, 10 μL, 10 μl of enhancer 2, 10 μl of Tris buffer, and 100 μl of luminol-peroxide were mixed in a microwell and the light emission was measured using an Amerlite analyzer. The experiment was repeated, except that a sample of HRP (10 μl, 1:10 000 dilution of a 1 mg ml^{-1} stock solution in Tris buffer, pH 8.6) replaced the Tris buffer added to the microwell.

3. Results

3.1. Types of synergy and synergistic enhancement

Several analytically desirable effects may occur as a result of mixing together two enhancers. A. Assay reagent background may be reduced to a value lower than the background obtained with either enhancer individually. Low background light emission from a luminol-peroxide assay reagent is desirable because this is a major factor limiting the detection limit for HRP in this type of chemiluminescent assay. B. Signal in the presence of HRP may be increased to a value higher than the signal obtained with either enhancer individu-

ally (synergy). Alternatively, the light emission signal in the presence of HRP may be increased to a value higher than the combined signal obtained with either enhancer individually (synergistic enhancement). High signals in the presence of peroxidase are desirable because the measurement of high light levels is simple and convenient (e.g., wide range of light emission detectors can be used—photographic film, silicon photodiodes). C. S/B in the presence of HRP may be increased to a value higher than the S/B obtained with either enhancer individually (synergy). Alternatively, the S/B in the presence of HRP may be increased to a value higher than the combined S/B obtained with either enhancer individually (synergistic enhancement). An increase in the S/B can be achieved from an increase in the signal, a decrease in the background, or from combinations of these effects. For example, an increased S/B can be obtained from a combination of enhancers that lower the signal in the presence of HRP, but produce a major reduction in the assay background. Increased S/B in the presence of peroxidase is desirable because this improves assay sensitivity and hence the ability to discriminate between incremental amounts of peroxidase or a peroxidase label.

3.2. Matrix experiment

Table 1 illustrates data from two separate experiments for synergy and synergistic enhancement with a pair of enhancers (1,1'-biphenyl-4-yl boronic acid + 4-iodophenylboronic acid). Background light emission for the enhancer combination was lower than obtained with either enhancer individually, indicating synergy. The signal and S/B was higher than with either enhancer individually or the sum of values thus, indicating synergy and synergistic enhancement.

All combinations of enhancers produced a concentration dependent decrease in the assay background (synergy). The concentration dependence of the background reduction is illustrated for the combination of the 4-bromophenylboronic acid and 1,1'-biphenyl-4-yl boronic acid in Fig. 1. Generally, background light emission was reduced as the concentrations of the added 1,1'-biphenyl-4-yl boronic acid was increased. However, at high enhancer concentration (>0.1 mmol l^{-1} final concentration) the signal was reduced and thus, optimal signal is obtained at lower enhancer concentration (Fig. 1). The net effect of decreased background and increases signal was an improvement of the S/B by up to 4-fold (Fig. 1, 0.154 mmol l^{-1} 4-bromophenylboronic acid).

Combinations of enhancers that produced a synergistic enhancement in light emission and a synergistic enhancement in S/B in the presence of peroxidase included 1,1'-biphenyl-4-yl boronic acid in combination with trans-4-(3-propenoic acid) phenylboronic acid or 4-bromophenylboronic acid or 4-iodophenylboronic acid, and 4-iodophenylboronic acid combined with trans-4-

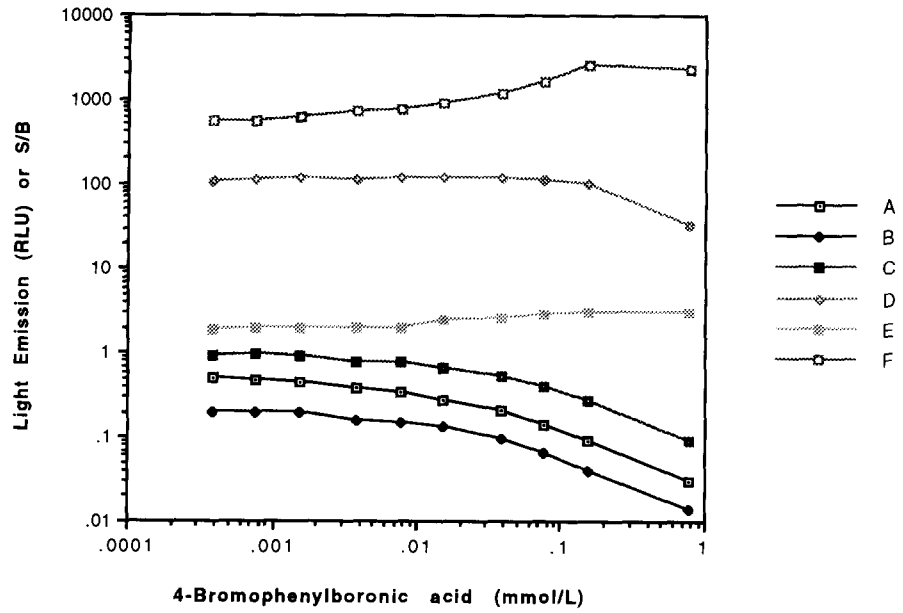

Fig. 1. Effect of 1,1′-biphenyl-4-yl boronic acid on luminol—peroxide—4-bromophenylboronic acid reaction background (A), signal (HRP 25 fmol) (C), and signal/background ratio (E) in absence of 1,1′-biphenyl-4-yl boronic acid; background (B), signal (HRP 25 fmol) (D), and signal/background ratio (F) in presence of 1,1′-biphenyl-4-yl boronic acid (76.9 μmol l^{-1}); light emission was measured immediately after initiation of the reaction using a Amerlite analyzer.

(3-propenoic acid) phenylboronic acid. Generally, synergy was obtained at several concentrations of all of the combinations of enhancers tested. An example of the effect of combining 1,1′-biphenyl-4-yl boronic acid and 4-iodophenylboronic acid is shown in Fig. 2. Successive addition of 1,1′-biphenyl-4-yl boronic acid reduced the background, increased the signal, and produced a significant improvement in S/B. Above 0.03 mmol l^{-1} of 1,1′-biphenyl-4-yl boronic acid (Fig. 2) there was no further improvement in S/B and at concentrations of 1,1′-biphenyl-4-yl boronic acid greater than 0.2 mmol l^{-1} a decline in S/B was observed.

The kinetics of the light emission from enhanced chemiluminescent reactions using different boronates show some differences. For example, the light emission kinetics with 4-bromophenylboronic acid rises slowly and then decays slowly. In contrast, 1,1′-biphenyl-4-yl boronic acid shows a more rapid rise and fall in light emission. Consequently in experiments that combine two enhancers, the presence of synergy or synergistic enhancement can vary over the time course of the reaction. This is illustrated in Fig. 3 that shows data from twelve replicate 1,1′-biphenyl-4-yl boronic acid and 4-iodophenylboronic acid synergy experiments performed in a microplate. The kinetics of 1,1′-biphenyl-4-yl boronic acid reaction are rapid compared with 4-iodophenylboronic acid, and thus the time taken to initiate the reactions in the wells and serial measurement significantly effects the observed synergy in the light emission signal. Panel A show the data for wells 1–12 immediately after initiation of the reaction ($t = 0$). Panel B in Fig. 3 shows light emission data 5 min after initiation of the reactions. The signal from the wells containing peroxidase and the mixture of enhancers varies at both time points (0, 5 min). This reflects the kinetics of the reaction and the time taken to measure light emission from each well in the plate. However, a synergistic enhancement of the light emission was observed for each of the replicate experiments. This temporal variability restricts its analytical utility because it would require very tight control of initiation and light measurement.

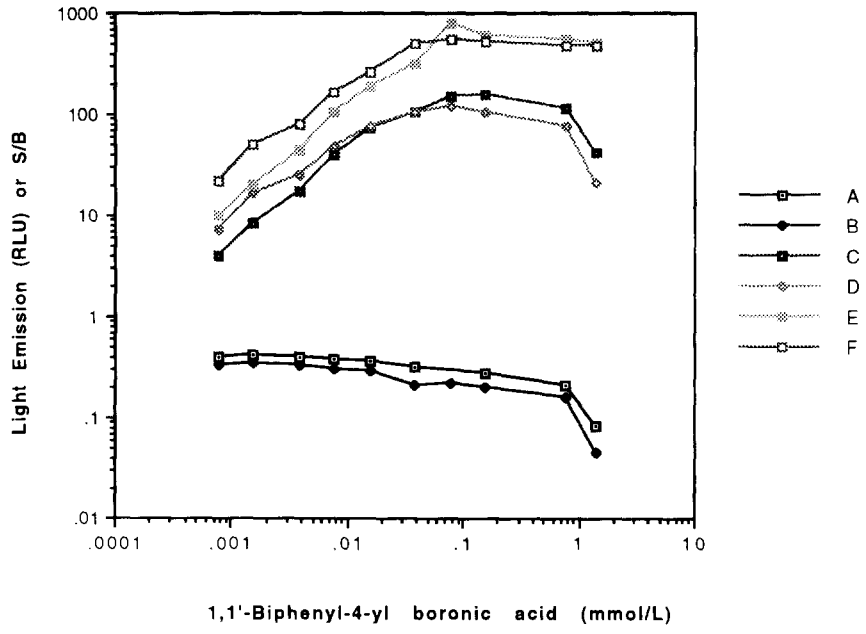

Fig. 2. Effect of 4-iodophenylboronic acid on luminol—peroxide—1,1′-biphenyl-4-yl boronic acid reaction background (A), signal (HRP 25 fmol) (C), and signal/background ratio (E) in absence of 4-iodophenylboronic acid; background (B), signal (HRP 25 fmol) (D), and signal/background ratio (F) in presence of 4-iodophenylboronic acid (76.9 μmol l^{-1}); light emission was measured immediately after initiation of the reaction using a Amerlite analyzer.

4. Discussion

The synergistic enhancement effect was unexpected and is complex. It is dependent on the particular pair of enhancers and on their relative concentrations and time of measurement of the light emission. Background reduction was the most important component of the synergy effect. The effect on signal is seen at enhancer combinations that are suboptimal and it is possible to obtain higher signals using one of the enhancers at its optimal concentration. However, in the presence of a second enhancer the background reduction exceeds any diminution in signal and a net improvement in S/B is obtained.

Some studies of the mechanism of boronate enhancement of the HRP catalyzed chemiluminescent oxidation of luminol have been undertaken (e.g., determination of rate constants for reactions with HRP compounds I and II) [10], but the precise mechanism remains unknown. Likewise, the mechanism of the background reduction by enhancers is not fully understood. Complexion of metal ions that catalyze the chemiluminescent decomposition of luminol is one possible mode of background reduction. The antioxidant properties of the enhancers (boronates are potent antioxidants) [11] may also be a contributing factor. In a previous study, we found some correlation between the electronic properties of the 4-substituent Hammett constant (σ_p^+) on the boronic acid and the enhancer properties of the molecule (e.g., σ_p^+ value for a 4-substituted aryl boronic acid ≥ -0.31 conferred enhancer properties) [12]. In this study we noted that the combination of an enhancer with a positive Hammett constant and an enhancer with a negative Hammett constant produced a synergistic effect (e.g., σ_p^+ Ph $= -0.18$, Br $= +0.15$, I $= +0.14$). We are currently studying other enhancers in an effort to clarify the mechanism and to identify superior combinations for analysis of peroxidase and peroxidase labels.

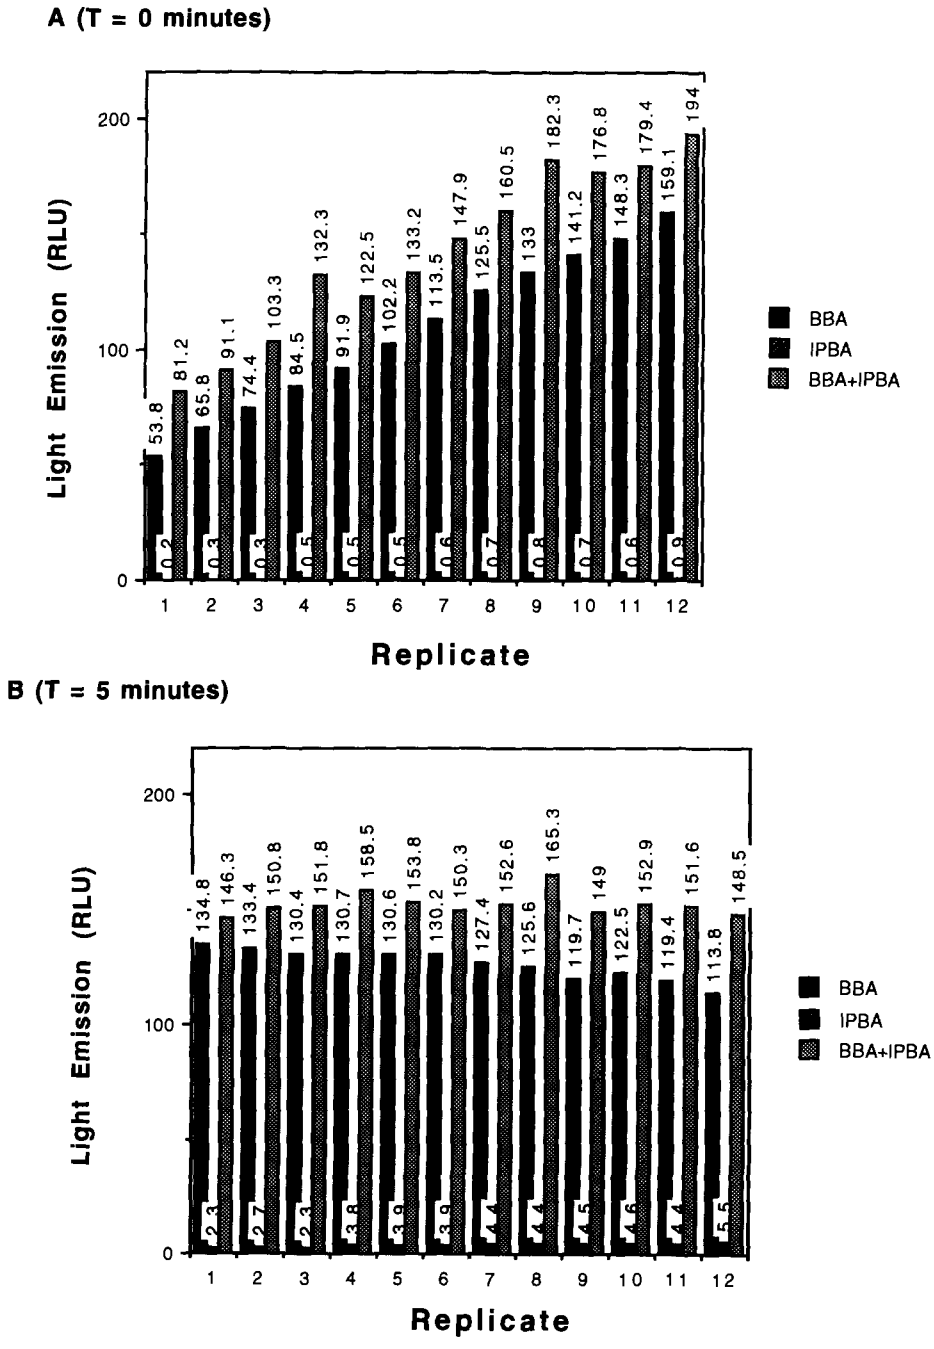

Fig. 3. Light emission from twelve replicate assays for peroxidase using 4-iodophenylboronic acid (IPBA 76.9 μmol l^{-1}), 1,1′-biphenyl-4-yl boronic acid (BBA 76.9 μmol l^{-1}) and a combination of these two enhancers. Light emission was measured immediately after initiation (Panel A) and 5 min after initiation (Panel B) using a ML-3000 microtiter plate luminometer.

Determination of aluminium in tree samples by cathodic adsorptive stripping voltammetry

Jadwiga Opydo

Institute of Chemistry, Poznań University of Technology, 60-965 Poznań, Poland

Received 20 May 1996; received in revised form 26 November 1996; accepted 3 December 1996

Abstract

This paper presents a method of determination of aluminium in tree samples (wood, leaves, roots) based on the cathodic adsorptive stripping voltammetry. Al(III) complexed with alizarin S was determined by ASV method using a hanging mercury drop electrode. Optimal conditions were found to be: accumulation time 30–90 s, accumulation potential −0.70 V versus SCE, supporting electrolyte 0.1 M ammonia–ammonium chloride buffer at pH 8.2 and concentration of alizarin 1×10^{-5} M. The response of the system, a linear current-concentration relationship was observed up to 8×10^{-6} M. The developed method has been tested by analysing international reference materials (BCR 62 Olive leaves and BCR 101 spruce needles). © 1997 Elsevier Science B.V.

Keywords: Adsorptive stripping voltammetry; Aluminium; Alizarin S; Tree samples

1. Introduction

The increasing process of soil acidification in recent years has caused the release of Al(III) ions in natural environment. This is the so-called exchangeable aluminium, which when taken up through plant roots may induce a number of phenomena unfavourable to the development and growth of plants [1,2]. This 'aluminium danger' in recent years has been conducive to intense studies on the development of new, rapid and reliable methods for monitoring aluminium in the environment.

Especially useful in this respect seems to be adsorptive stripping voltammetry. This method consists in producing an aluminium complex compound with organic ligands. This complex is accumulated adsorptively at a chosen potential on the cathode. Then, peaks of aluminium complexes, the currents of which are directly proportional to Al concentration, are registered. Solochrome Violet SR [3–6], calmagit [7–10], cupferron [11] and alizarin S (1,2-dihydroxy- anthraquinone-3-sulphonic acid) [12,13] are most frequently used for aluminium complexation. Out of all these complex compounds the most suitable seems to alizarin S. Its complex with aluminium is obtainable for several s at a room temperature, without heating. Alizarin S in BES buffer (*N,N'*-bis-2-hydroxyethyl-2-amino-ethane sulphonic acid) was used to determine Al in seawater [12,13]. However, the application of BES solution as a supporting electrolyte causes production of the aliz./Al peak at the potential of −1.25 V versus

PII S0039-9140(96)02198-4

Ag/AgCl, which causes interference by high concentrations of zinc (> 50 nM) [12]. The employment of this method for the analysis of samples containing not more than 50–100 nM Al was caused by the necessity to perform additional analytical operations, i.e., Zn(II) masking by the use of EDTA. This method, therefore, does not permit to determine Al in trees, where Zn concentration is on the level of 1–20 μM [1,14,15].

The objectives of the present work were: (i) to establish optimal conditions for aluminium determination by the method of cathodic adsorptive stripping voltammetry in differential pulse technique using alizarin S as a complexing factor and 0.1 M ammonia–ammonium chloride buffer as a supporting electrolyte; and (ii) to develop a method for aluminium determination in tree samples.

2. Experimental

2.1. Apparatus

Cathodic stripping voltammograms were obtained with a PA-4 polarographic analyzer, Laboratorni Pristroje (Czech republic). The electrochemical measurements were performed in a 3-electrode system: hanging mercury drop electrode (HMDE), produced by Laboratorni Pristroje, saturated calomel electrode (SCE) produced by Radiometer and Pt wire electrode. The differential pulse amplitude was 50 mV and the scan-rate was 10 mV s^{-1}.

Microwave digestion system were: low-pressure vessels type P/N 323000, CEM (USA); home microwave oven Sharp, 850 W (Japan).

2.2. Reagents

Nitric acid 'Suprapur' and alizarin S (Merck). Hydrogen peroxide, ammonia, ammonium chloride, analytical grade, were produced by POCh (Poland). Certified reference materials: BCR No. 62 Olive leaves and BCR No. 101 Spruce needles (Belgium).

Standard solutions of Al, Cd, Pb, Cu, Ni, Co and Zn containing 1 g l^{-1} were prepared from ampoules (Merck). Solutions with concentrations below 10^{-3} M were prepared just before use. Water was doubly distilled in a quartz still.

2.3. Procedure

Tree samples were taken from several oak trees *Quercus robur* L., on each investigated area. Wood samples were taken with a Pressler's bore at a height of 1.3 m above the ground. Roots samples were collected from the main and lateral roots. Leaves samples were at the end of the vegetation season—in September 1994.

0.1–0.2 g biological samples were placed in low pressure vessels and a mixture of nitric acid and hydrogen peroxide (1 ml each) was added. The vessels were put into a microwave chamber to perform mineralization: 2 min with 225 W, 3 min with 425 W, 5 min with 595 W and 5 min with 850 W. Intervals of 5 min were made after each cycle.

After mineralization in low pressure vessels the solution was transferred into a conical quartz cup and the excess of nitric acid was evaporated. The residue was dilluted in 0.1 M ammonia–ammonium chloride buffer pH 8.2 (in the amount providing the aluminium content to be within the range $1–5 \times 10^{-6}$ M) and 1×10^{-5} M alizarin S was added.

20 ml of the solution was transferred into a measuring vessel. After deaeration of the solution with purified nitrogen the aliz./Al complex was adsorptively accumulated for 30–90 s (depending on the amount of aluminium) at the potential of −0.7 V by stirring the solution. The stirrer was stopped and after 15 s voltammetric cathodic curves over the potential range −0.7– −1.2 V were registered, at a scan rate of 10 mV s^{-1}, with a pulse amplitude of 50 mV. The cycle was repeated three times. The content of aluminium was evaluated by the method of standard additions.

3. Results and discussion

3.1. Response characteristics

Alizarin adsorbed on a drop electrode forms a cathodic peak at the potential of −0.63 V and

two anodic peaks at the potentials of −0.63 and −0.55 V. A repeated cycle on the same mercury drop affects an increase in the peak height due to alizarin adsorption on the electrode and causes the appearance of one more cathode peak at the potential of −0.51 V. These voltammograms are consistent with the previous ones obtained in BES buffer at pH 7.1 [12]. They indicate a reversible reduction of free alizarin ligands on a mercury drop.

Introduction of Al(III) into the system causes the occurrence of cathode peak at the potential of −0.87 V, being the result of adsorptive reduction of the aliz./Al complex. Fig. 1 shows cyclic voltammograms for 0.1 M ammonia–ammonium chloride buffer at pH 8.2 containing 1×10^{-5} M alizarin S and 4×10^{-6} M Al(III). This reduction step is irreversible; no peaks are observed upon scanning in the positive direction. A repeated measuring cycle (dashed line) causes a very strong decrease in the reduction peak due to diffusion of the dye and the aluminium away from the electrode.

The process of adsorptive accumulation of aluminium depends on many parameters. One of them is the accumulation time. Being too long it causes competitive saturation of the electrode surface with free ligand and decreases the effectiveness of Al determination. This relationship for alizarin in ammonia–ammonium chloride buffer at pH 8.2 is presented in Fig. 2. It is linear within quite a wide range 15–180 s. According to it, the optimal time of adsorptive accumulation at alizarin concentration 1×10^{-5} M is within the range of 30–90 s.

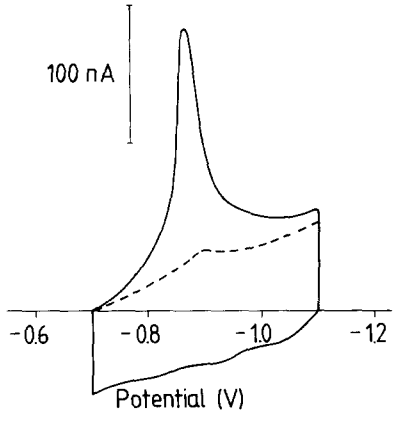

Fig. 1. Cyclic voltammograms for 1×10^{-5} M Alizarin S with 4×10^{-6} M Al(III) in unstirred 0.1 M NH_3-NH_4Cl buffer at pH 8.2. Conditions: scan rate, 100 mV s^{-1}; adsorption potential −0.7 V; adsorption time, 30 s. Solid line: scan on the new mercury drop. Dashed line: repetitive scan on the same drop.

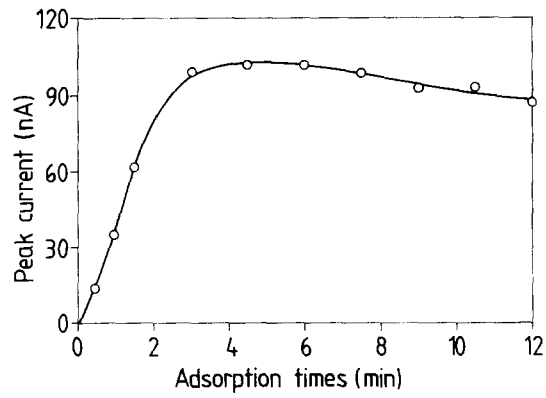

Fig. 2. Dependence of the differential-pulse peak height for the Aliz./Al complex on adsorption time. Al(III) concentration, 1.5×10^{-6} M. Supporting electrolyte, 0.1 M NH_3-NH_4Cl buffer at pH 8.2. Alizarin concentration, 1×10^{-5} M. Adsorption potential, −0.7 V; scan rate, 10 mV s^{-1}; pulse amplitude, 50 mV.

Another, not less important parameter is the adsorptive potential (Fig. 3). A decrease of the Al peak height is observed when performing accumulation in the range of free ligand adsorption (to the potential of −0.65 V); also under these conditions the peak of the aliz./Al complex is masked by free ligand adsorption.

The influence of electrolyte pH and alizarin concentration is illustrated in Fig. 4 and 5. Fig. 4 presents the dependence of Al peak height on pH of 0.1 M ammonia–ammonium chloride buffer, whereas Fig. 5 shows the dependence of Al peak on the concentration of alizarin obtained in 0.1 M ammonia–ammonium chloride buffer at pH 8.2.

The best analytical signal is obtained by complexing aluminium at pH 8.0 and 8.2 in the presence of 1×10^{-5} M alizarin. Changes in the solution pH and a reduction in alizarin concentra-

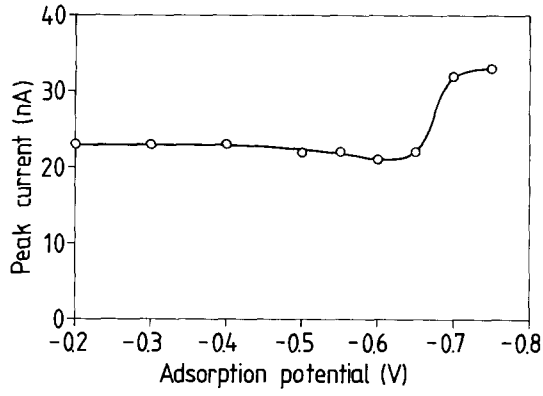

Fig. 3. Dependence of the differential-pulse peak height for the Aliz./Al complex on adsorption potential. Al(III) concentration, 1.5×10^{-6} M. Supporting electrolyte, 0.1 M NH_3-NH_4Cl buffer at pH 8.2. Alizarin concentration, 1×10^{-5} M. Adsorption time, 30 s; scan rate, 10 mV s^{-1}; pulse amplitude, 50 mV.

tion decrease the effectiveness of complexating, whereas an increase in alizarin concentration, likewise a long accumulation time, has a similar effect—it suppresses the Al peak.

On the basis of Figs. 1–5 the optimal conditions for aluminium determination are as follows:

- solution pH 8.2;
- alizarin concentration – 10 μM;

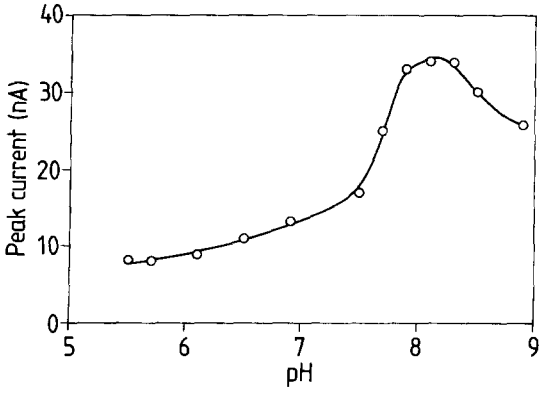

Fig. 4. Dependence of the differential-pulse peak height for the Aliz./Al complex on pH of the solution. Al(III) concentration, 1.5×10^{-6} M. Alizarin concentration, 1×10^{-5} M. Supporting electrolyte, 0.1 M NH_3-NH_4Cl buffer. Adsorption potential, – 0.7 V; adsorption time, 30 s; scan rate, 10 mV s^{-1}; pulse amplitude, 50 mV.

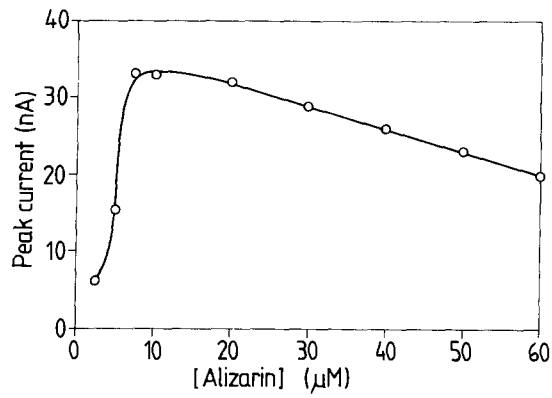

Fig. 5. Dependence of the differential-pulse peak height for the Aliz./Al complex on Alizarin concentration. Al(III) concentration, 1.5×10^{-6} M. Supporting electrolyte, 0.1 M NH_3-NH_4Cl buffer at pH 8.2. Other conditions as for Fig. 4.

- accumulation potential – 0.70 V;
- accumulation time 30–90 s.

Under the above conditions the dependence of the aliz./Al peak height on Al concentration is linear within the concentration range of $1–8 \times 10^{-6}$ M (Fig. 6). This range is incomparable with possibil-

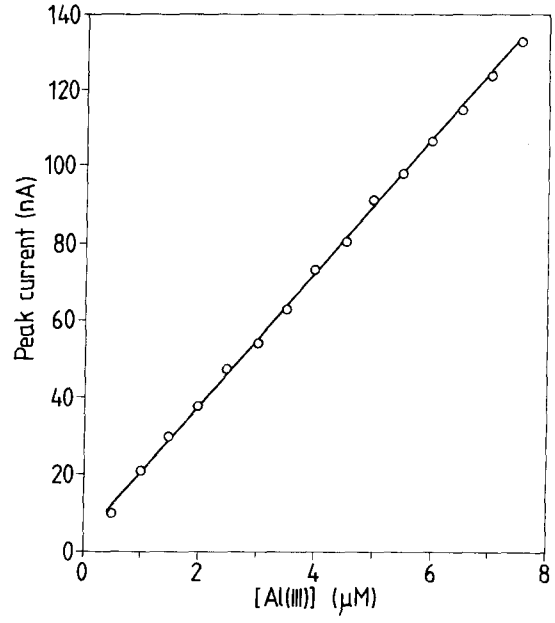

Fig. 6. Dependence of the differential-pulse peak height for the Aliz./Al complex on Al(III) concentration. Alizarin concentration, 1×10^{-5} M. Supporting electrolyte, 0.1 M NH_3-NH_4Cl buffer at pH 8.2. Other conditions as for Fig. 4.

ities of the methods developed in [12], where the limit of detectability is 1 nM. This however, is a sufficient (and even a more suitable) range for analysing biological materials, if 0.1–1.0 g samples are used (e.g., 5×10^{-6} M Al in 1 g sample 25 ml $^{-1}$ corresponds to 3.4 μg g^{-1} Al).

The limit of detectability can be reduced to 2.5×10^{-8} M. For that purpose the accumulation time should be extended to 3 min at a simultaneous decrease of alizarin concentration to 2.5×10^{-6} M. A linear dependence under these conditions was obtained for the range 2.5×10^{-8}–3.5×10^{-7} M Al(III).

3.2. Interferences

The influence of Zn(II), Cd(II), Pb(II), Cu(II), Ni(II), Co(III) and Fe(III) on the height of aliz./Al peak was examined.

As shown by the experiments, 1 μM of Zn, Cd, Pb, Cu and Ni or 25 μM Co and Fe have no effect on determination of 1.5 μM Al. An increase in the contents of Zn, Cd, Pb, Cu or Ni to 25 μM, causes a decrease in the height of Al peak, in some cases by 30%, but, however, it enables Al determination by the method of standard additions. Besides that, it should be emphasized that the contents on these ions on the level 25 μM l^{-1} correspond to 100–1000 μg g^{-1} in samples and, for instance, in biological materials they are very rare.

The influence of surfactants was tested on the example of sodium dodecylsulphate and Triton X-100. The both, one and another surfactants present in the amount of 1×10^{-4}% cause a very strong deformation and suppression of Al peak, making impossible its determination. Their influence can be completely eliminated by a thorough mineralization of samples.

3.3. Analytical applications

According to the procedure described in point 2.3. an analysis was carried out on samples collected from oaks *Quercus robur* L., growing under conditions of different pH of soils. Fig. 7 gives an example of aluminium determination in the wood of oaks by the method of standard additions. The

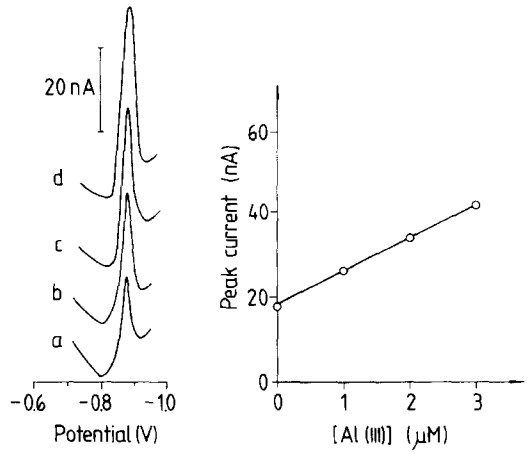

Fig. 7. Voltammograms and calibration curve from the determination of Al(III) in a sample in wood by the method of standard addition. Curve (a) is of the sample. Curves (b)–(d) result from the further addition of 1×10^{-6} M Al(III). Conditions as for Fig. 4.

standard addition plot was linear. The Al(III) content evaluated from it is 4.7×10^{-6} M.

Results of the oak analysis are presented in Table 1. The first studied oak stand is located in the region of the Głogów-Lubin copper basin, characterized by a very acid soil. This soil contains significant amounts of exchangeable aluminium. The second oak stand is located in Krakowsko-Częstochowska Upland, characterized by neutral soil and by the same lack of aluminium. The third oak stand belongs to the experimental forest of the Institute of Dendrology in Kórnik. The level of exchangeable aluminium content in soils is reflected in different Al absorption by trees. As seen from Table 1, the precision of the proposed method is satisfactory (the relative standard deviation ranged within 3.4–10.1%).

The accuracy of the developed method has been tested by analysing certified reference materials: BCR 62 Olive leaves and BCR 101 Spruce needles. The results are given in Table 2. They are satisfactory.

The developed method was used in estimation of the effect of industrial pollutions on the oak stand decline on the Krotoszyn Plateau (West-Central part of Poland) [16].

A novel potassium ion membrane sensor based on rifamycin neutral ionophore

Saad S.M. Hassan *, Wagiha H. Mahmoud, Abdel Hameed M. Othman

Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt

Received 22 July 1996; received in revised form 6 November 1996; accepted 3 December 1996

Abstract

A novel potentiometric membrane sensor for potassium ion based on the use of rifamycin as a neutral ionophore is described. The sensing membrane is formulated with 2 wt.% rifamycin-SV, 69 wt.% dibutylsebacate plasticizer and 29 wt.% PVC. Linear and stable potential response with near-Nernstian slope of 56.7 ± 0.2 mV decade^{-1} are obtained over the concentration range 1×10^{-1}–3×10^{-5} M K^+. The detection limit is 0.3 μg ml^{-1} K^+, the response time is 10–30 s and the working pH range is 4–11. Responses of the sensor toward alkali and alkaline earth metal ions are in the order $K^+ > Rb^+ > Cs^+ > Na^+ > NH_4^+ > Ba^{2+} > Mg^{2+} > Ca^{2+} > Sr^{2+} > Li^+$. The selectivity coefficient data reveal negligible interference from transition metal ions. Direct potentiometric determination of K^+ in the presence of 10–50-fold excess of alkali and alkaline earth metals gives results with an average recovery of 99.1%, and a mean standard deviation of 1.2%. The data agree fairly well with those obtained by flame photometry.

Keywords: Dibutylsebacate plasticizer; Potassium PVC membrane sensor; Rifamycin neutral ionophore

1. Introduction

Potentiometric sensors for potassium ion are steadily replacing flame photometry and other assay techniques for monitoring potassium in various matrices and have been widely used in various analytical applications [1]. These sensors incorporate valinomycin [2–6], crown ethers [7–10] and nonactin [11] neutral ionophores as active membrane components. Nature and characteristics of various types of potassium ion membrane sensors have been reviewed [12]. Although valinomycin is, by far, the most successful ionophore for potassium ion, it is a very expensive reagent with potentiometric selectivity in the order: $Rb^+ > Cs^+ > K^+ \gg Na^+$. Crown ethers and nonactin based sensors respond to the alkali metals in the order: $Rb^+ > K^+ > Cs^+ > Na^+$ and $Cs^+ > Rb^+ > K^+ > Na^+$, respectively. It is evident from most of the published reports dealing with these ionophores that Rb^+ and Cs^+ are seriously interfere in the determination of K^+.

In the work reported here, attempts were made to use some derivatives of rifamycins as novel neutral carriers for K^+ ion, in PVC matrix membrane sensors. Rifamycins are a class of antibi-

PII S0039-9140(96)02199-6

otics known to stimulate the release of K^+ ion remarkably from isolated living mitachondria and from red blood cells [13]. This is attributed to the interaction of these compounds with the biological membrane causing a change in their permeability to K^+ ion. We have found that rifamycin-SV, a commercially available cheap antibiotic, has an excellent electrochemical response for potassium ion and a sensor based on it displays a potentiometric selectivity in the order $K^+ > Rb^+ > Cs^+ > Na^+ > Li^+$. Performance characteristics of rifamycin-SV based sensor including linear response range, calibration slope, lower detection limit, selectivity order, nature of solvent mediator, effect of pH and analytical application have been investigated.

2. Experimental

2.1. Reagents

Chemicals of analytical–reagent grade were used unless stated otherwise. Doubly distilled deionized water was used throughout. Rifamycin-SV, 3-formyl rifamycin, rifampicin, poly(vinyl chloride) powder (PVC), potassium tetra-*p*-chlorophenylborate (KT-pClPB) and tetrahydrofuran (THF) were obtained from Fluka. Dibutylsebacate (DBS), 2-nitrophenyloctylether (NPOE), dioctylphthalate (DOP) and dinonylphthalate (DNP) were purchased from Aldrich. Alkali, alkaline earth and transition metal salts in the form of chloride or nitrate were obtained from B.D.H. Standard solutions were freshly prepared with deionized doubly distilled water. Pharmaceutical preparations containing K^+ were obtained for local pharmaceutical companies.

2.2. Apparatus

Measurements of potassium were made at 25 ± 1°C with an Orion Ionalyzer (model 920 digital pH/mV meter) using rifamycin-SV PVC membrane sensor in conjunction with an Orion single junction Ag–AgCl reference electrode (Model 90-02). An Orion combination pH electrode (model 91-02) was used for pH adjustment. All spectrophotometric measurements were made on a Perkin Elmer Lambda 15 uv/vis spectrophotometer using 10 mm cuvettes. Flame photometry were made on Corning Clinical Flame photometer 410 C.

2.3. Potassium rifamycin PVC membrane sensors

The polymeric membranes were prepared by mixing 10 mg of rifamycin-SV, 190 mg PVC and 360 mg of DBS with 3 ml THF. The resulting homogeneous syrup was poured into a 50 mm diameter ground glass casting ring and the solvent was allowed to evaporate off slowly at room temperature over a period of 48 h. A semi transparent flexible membrane with a thickness of 0.25 mm was obtained. A disc (8 mm diameter) was cut using a cork borer and pasting using THF [14–17], to an interchangeable PVC tip which was clipped on to the end of the electrode glass body. A solution of potassium chloride 1×10^{-2} M was used as an internal reference solution and Ag–AgCl wire (1 mm diameter) was used as an internal reference electrode. The sensor was preconditioned after preparations by soaking for at least 24 h in 1×10^{-2} M potassium chloride solution and stored in the same solution when not in use. The sensor was washed with doubly deionized water and blotted with tissue-paper between measurements.

Sensor calibration was carried out by measuring the potential of 1×10^{-6}–1×10^{-2} MKCl solutions starting from the low to the high concentrations. The potentials were plotted as a function of potassium ion concentrations. The lower

Detection limit, (M)	8.5×10^{-6}
Working range, (pH)	4–11
Response time for 10^{-3} M, (s)	10 ± 2
Recovery time for 10^{-3} M, (s)	40 ± 2

[a] Mean of five measurements.

detection limit was taken at the point of intersection of the extrapolated linear segments of the potassium calibration curve. Repeatability was measured by immersing the sensor alternatively into 10^{-2} and 10^{-3} M KCl solutions at 25°C. Sensor life span was examined by repeated monitoring of the slope of potassium calibration curve periodically. Selectivity coefficients of the sensor were determined using the separate solution method [1,18] and calculated from the rearranged Nicolsky equation:

$$\text{Log } K^{\text{pot}}_{\text{K,M}} = [E_{\text{K}} - E_{\text{M}}/S] + [1 + Z_{\text{K}}/Z_{\text{M}}] \text{ Log } \text{K}^{+}$$

Where E_{K} is the potential measured in 10^{-2} M KCl solution, E_{M} is the potential measured in a 10^{-2} M solution of the chloride of the interfering cation, Z_{K} and Z_{M} are the charges of the potassium and interfering ion, respectively, and S is the slope of the electrode calibration plot.

2.4. Determination of potassium in pharmaceutical products

The contents of potassium syrup solutions and the contents of ten tablets containing potassium salt were mixed well. An accurate weight equivalent to one tablet and a 5.0 ml aliquot of the syrup solution were transferred to 1 l volumetric flask, and completed to the mark with doubly distilled deionized water. A 3.0 ml aliquot of the solution was diluted to 25 ml and rifamycin-SV PVC (DBS) membrane sensor in conjunction with an Ag–AgCl reference electrode was immersed in the solution. The potential was measured before and after addition of 1.0 ml of 10^{-1} M KCl solution. The original concentration of K^{+} in the test solution was measured using the standard addition equation [1,18].

3. Results and discussion

3.1. Rifamycin neutral ionophore

Plasticized poly(vinyl chloride) membranes doped with three different derivatives of rifamycin, namely, rifamycin-SV, 3-formyl rifamycin and rifampicin (Fig. 1) were prepared and electrochemically evaluated as prospective sensors for potassium ion according to IUPAC standards [18]. Table 1 shows that rifamycin-SV based sensor displays the best performance char-

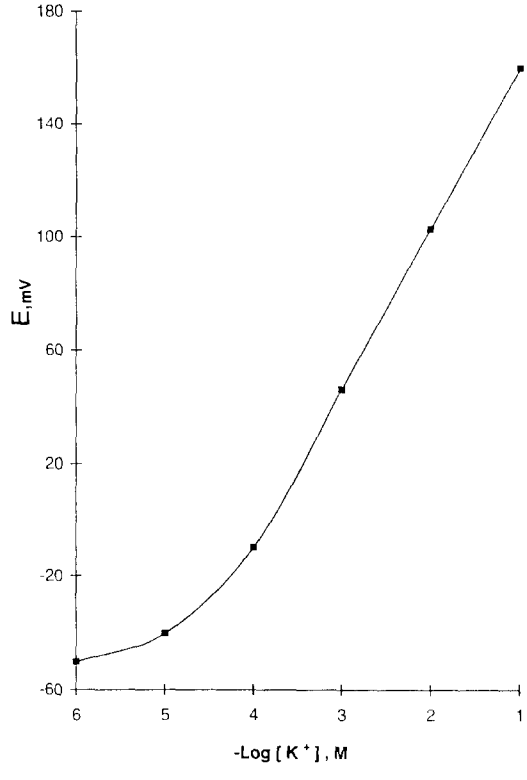

Fig. 2. Calibration curve for potassium PVC membrane sensor based on rifamycin-SV ionophore and dibutylsebacate (DBS) plasticizer.

Table 2
Effect of rifamycin ionophores on the response to K^+ using dibutylsebacate (DBS) as a solvent mediator

Ionophore	Slope, mV decade^{-1}	Linear range, M	Lower limit of detection, M
Rifamycin-SV	56.7 ± 0.2	1×10^{-1}–3×10^{-5}	8×10^{-6}
3-Formyl rifamycin	51.3 ± 0.3	1×10^{-1}–1×10^{-4}	3×10^{-5}
Rifampicin	42.2 ± 0.3	1×10^{-1}–1×10^{-4}	5×10^{-5}

acteristics for potassium ions compared with the other two derivatives. Optimization of membrane composition led to the composition of 28, 2 and 70 wt.%, poly(vinyl chloride), rifamycin-SV, and solvent mediator, respectively.

Typical calibration graph and response characteristics of potassium ion sensor based on rifamycin-SV ionophore and dibutylsebacate solvent mediator are reported in Fig. 2 and Table 2, respectively. At 25°C, the sensor displays a linear response for potassium ions over the concentration range 1×10^{-1}–3×10^{-5} M with a detection limit of 8.5×10^{-6} M and a calibration slope of 56.7 ± 0.2 mV decade^{-1} ($n > 6$). Repeated calibrations of the sensor over a period of 3 weeks with potassium chloride solutions show potential and slope stabilities within ±1 and 0.8 mV decade^{-1}, respectively. The extended linearity of the calibration plots without Donnan failure up to 10^{-1} M K^+ in solutions of KCl, KBr, KI, KNO_3 and KSCN indicates complete co-ion exclusion under the present conditions.

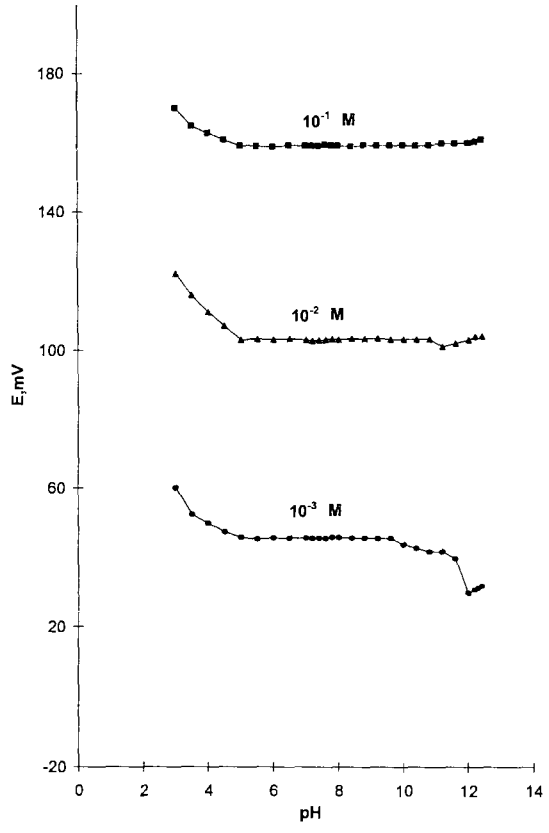

Fig. 3. Effect of pH on the response of rifamycin-SV PVC (DBS) membrane sensor for different potassium ion concentrations.

The response time (t_{95}) of rifamycin-SV potassium ion sensor was tested by measuring the time required to achieve a 95% steady potential for 10^{-4} and 10^{-3} M KCl solutions when their concentrations were rapidly increased by one decade. Fairly short response times of 10 s for $[K^+] > 10^{-3}$ M and 30 s for $[K^+] < 10^{-4}$ M, were obtained. Reasonably stable behaviour of the sensor was maintained during at least 6 weeks, then a drop of the sensitivity as a function of time was observed. This response decay could be attributed to leaching of the ionophore from the membrane.

The pH dependence of rifamycin-SV potassium sensor was examined using 10^{-1}, 10^{-2} and 10^{-3} M KCl solutions. Stable response over the pH range 4–11 was obtained (Fig. 3). Adjustment of pH was performed using dilute lithium hydroxide and hydrochloric acid. Below pH 5, the sensor response increases with the increase of the analyte acidity. At such high acidities the membrane may extract H^+ ion in addition to K^+ ions as rifamycin is also known to extract H^+ [13].

Table 3
Effect of solvent mediators on the response to K^+ using rifamycin-SV ionophore

Solvent mediators	Dielectric constant, ϵ	Slope, mV decade^{-1}	Linear range, M	Lower limit of detection, M
Dibutylsebacate (DBS)	4	56.7 ± 0.2	1×10^{-1} – 3×10^{-5}	8×10^{-6}
Dioctylphthalate (DOP)	7	44.6 ± 0.5	1×10^{-1} – 1×10^{-3}	1×10^{-5}
Dinonylphthalate (DNP)	9	38.3 ± 0.3	1×10^{-1} – 1×10^{-3}	5×10^{-5}
2-Nitrophenyl octylether (NPOE)	24	14.7 ± 0.4	1×10^{-1} – 1×10^{-2}	7×10^{-3}

3.2. Effect of solvent mediators

Potentiometric response of sensors based on neutral ionophores is greatly influenced by the polarity of the membrane medium, which is in turn defined by the dielectric constants of the major membrane components. Potassium PVC matrix membrane incorporating rifamycin-SV with four different plasticizers having dielectric constants over the range 4–24, namely dibutylsebacate (DBS), dioctylphthalate (DOP), dinonylphthalate (DNP) and 2-nitrophenyloctylether (NPOE) were prepared, tested and the results are shown in Table 3. Performance characteristics of membranes plasticized with DBS showed high sensitivity, reasonable selectivity, wide linear response range and near Nernstian slope. With DOP and DNP plasticizers, however, narrower linear response range (1×10^{-1}–1×10^{-3} M) and non-Nernstian slope (35 ± 1 mV decade^{-1}) were obtained. Poor response was detected with membranes plasticized with NPOE.

These data indicate that non polar ester type solvent mediators give a potassium ion sensor with more favourable potentiometric characteristics than polar solvents of the ether type with high

dielectric constants. This is in good agreement with previous reports showing that the response characteristics and selectivities of monovalent cations are favoured by low dielectric constant solvents [5,19].

3.3. Selectivity of rifamycin membrane

The potentiometric selectivity coefficients K^{pot}_{KM} of potassium rifamycin-SV sensor were evaluated using the separate solution method [1,18] with 10^{-2} M concentration level of alkali, alkaline earth and transition metal ions. The results obtained (Table 4) show that the selectivity of the sensor with regard to alkali metal ions is in the order: $K^+ > Rb^+ > Cs^+ > Na^+ \gg Li^+$. Although the hydrophobicity and free energy of transfer (ΔG_t) data parameters of these metal cations are in the sequence: $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$ [20,21], selective complexation of K^+ with rifamycin-SV displaces Cs^+ and Rb^+ in respect of the above order of hydrophilicity and strict $\Delta G_t/K^{pot}_{K,M}$ correlation is no longer valid. Accordingly, the selective response of rifamycin-SV membrane towards K^+ could be mainly explained in term of interaction between rifamycin-SV and K^+ ions and a preferred extraction of K^+ ion into the plasticized membrane phase. Measurements of the electronic absorption spectra of rifamycin-SV in the presence of K^+, Rb^+, Cs^+ and Na^+ ions show absorption maxima at 536, 526, 524 and 515 nm, respectively.

As shown in Fig. 4, K^+ ions induce the greatest shift of the maximum absorption in the visible spectrum of rifamycin-SV and also induce the greatest change of the molar absorptivities when compared with the other alkali metal ions. This observation confirms the preferential complexation of K^+ ions over other metal cations with rifamycin-SV ionophore and supports a neutral carrier ion exchange mechanism. The electrostatic interactions between the ionic charge of K^+ ions and the dipoles of rifamycin-SV ionophore are primarily responsible for the fast and stable complex. The electrostatic interaction between potassium rifamycin-SV complex and the surrounding membrane solvent is a further contribution to the stability of rifamycin-SV complex in the membrane.

The influence of quaternary ammonium chlorides on K^+ based rifamycin-SV sensor was tested by soaking the membrane sensor for different time intervals (20–40 min) in 0.1 mM tetramethyl ammonium chloride (TMACl) before sensor calibration in KCl solutions. In contrast to K^+ based valinomycin sensor [22], the potentimetric response of the present sensor is less disturbed by quaternary ammonium salts. Potassium rifamycin-SV sensor pre-soaked in lipophilic TMA^+ cation exhibits near-Nernstian slope towards K^+ (40–45 mV decade^{-1}) depending on pre-soaking time without a significant variation in the lower detection limit. A membrane sensor pre-soaked in 10^{-2} M TMA^+ for 20 min exhibits a linear calibration slope of 32 mV decade^{-1} over

[b] High and low selectivity coefficient values reported in the literature.

the concentration range 10^{-3}–10^{-1} M with a lower limit of detection of 5×10^{-4} M TMA^+.

The cation response order of potassium rifamycin-SV sensor for alkaline earth ions is $Ba^{2+} > Mg^{2+} > Ca^{2+} > Sr^{2+}$. The response for Ba^{2+} is < 37 mV decade^{-1}, whereas response for other divalent cations are considerably less. The responses of the transition metal ions are poor with response order of $Zn^{2+} > Fe^{2+} > Co^{2+} = Ni^{2+} > Cu^{2+}$. The rejection of divalent and trivalent ions is favoured more in DBS than in NPOE plasticized membranes. Interferences caused by high concentrations (> 1000-fold excess) of Al^{3+}, Fe^{2+}, Fe^{3+}, and Zn^{2+} ions are completely circumvented by potentiometric measurements at pH 10, at which these metal ions are precipitated as hydroxides and–or converted into non interfering anionic species such as $[Al(OH)_4]^-$ and $[Zn(OH)_3]^-$.

An effort was also made to improve the response characteristics of rifamycin-SV sensor, by incorporating potassium tetra-*p*-chloro-phenylborate (KT*p*ClPB) in the sensor cocktail to act as anion excluder, to improve the selectivity for potassium, to reduce the membrane resistance and to reduce the activation barrier of the membrane–solution interface [23]. No improvement of the sensor selectivity for K^+ over other alkali metal cations was noticed. On the contrary, the response of the sensor for Rb^+ and Cs^+ cations was improved over K^+ ions; probably due to the stronger interaction of Rb^+ and Cs^+ with KT*p*-ClPB. Interaction of alkali metal ions with tetraphenylborate is known to increase with the increase of the ionic diameter of the alkali metals, that is in line with the ΔG_t sequence [24].

3.4. Analytical applications

Utility, sensitivity and selectivity of rifamycin-SV sensor were verified by determining 10 μg ml^{-1} of K^+ in synthetic mixtures containing 10–50-fold molar excess of different alkali (except Na^+) and alkaline earth metal cations using the standard addition (spiking) technique. Results with an average recovery of 99.1% and a mean standard deviation of 1.2% were obtained. The sensor was also used for the determination of potassium ions in some pharmaceutical products. The average recovery was 99.8% of the nominal and the mean standard deviation was 0.6% (Table 5). These results were compared with data obtained using flame photometry (average recovery 98.7%, mean standard deviation 1.3%). The *F*-test reveals that no significant difference between the means and variances of the two sets of results. The good agreement between potentiometric and spectrometric data demonstrates the applicability of the sensor for routine analysis of real samples containing potassium without a prior separation.

4. Conclusions

The most interesting features of rifamycin-SV based potassium ion sensor compared with those incorporating valinomycin, crown ethers and nonactin are: (a) better potentiometric selectivity for K^+ ion over Rb^+, Cs^+ and NH_4^+ ions; (b) fast and stable potentiometric response; (c) weak potential disturbant in presence of quaternary ammonium cations and (d) commercial availability of rifamycin-SV ionophore at a considerably cheap price. These characteristics (Table 6) make the use of the proposed sensor useful and convenient substituent for all other K^+ sensors except in cases when the Na^+-K^+ ratio is significantly high as in blood serum (Na^+-K^+ ratio >35).

Abstract

A cold dissolution procedure for the determination of uranium in various geological materials like rocks, minerals, soils etc., has been described. Samples are allowed to react with HF and HNO_3 at room temperature overnight. Boric acid is added to complex excess fluoride ions. From the clear solution thus obtained, uranium is determined directly in laser fluorimeter after the addition of fluorescence enhancing reagents. The results of few standard reference materials analysed by the present method agree with the certified values. This methodology does not require platinum or teflon ware, exhaust system and time consuming solvent extraction step. Hazardous acid vapours are not left in air, so there is no air pollution. Chemicals consumption is minimal. Therefore the method is economical. The method can be employed for high sample throughput which is the prerequisite for exploration geochemists. © 1997 Elsevier Science B.V.

Keywords: Geological materials; Laser fluorimetry; Uranium

1. Introduction

Exploration geochemists generate large number of samples for the delineation of anomalous zones, favourable for uranium. Therefore a rapid and economical feedback of the data is always desired. Among the various dissolution procedures for the determination of total uranium, in various matrices, dissolution [1,2] with HF and HNO_3 mixture in platinum dishes followed by Na_2O_2 fusion of residue, if any left, is practiced mostly. But this methodology requires platinum or teflon ware and exhaust system, for sample opening. So big batch analysis cannot be carried out rapidly and economically. The determination of different constituents of solid samples after aquaregia and HF attack at room temperature is well established [3–5]. Fluorescence of aqueous uranyl solution is quite weak, therefore intense excitation source in the presence of various fluorescence enhancing reagents [6–12] is used for very low level detection. Chloride ions in aquaregia quenches [13] uranium fluoresence even with intense excitation source and various known fluorescence enhancers. Also chloride ions leads to extraction [14] of Fe(III) in ethyl acetate which is a quenching agent in the fluorimetric determination of uranium. Therefore HCl (Aqua regia) is

* Corresponding author.

PII S0039-9140(96)02201-1

mostly avoided in the uranium determination by fluorimetry which is the most sensitive method for uranium.

In the present method samples of rock, mineral, soil and stream sediments are allowed to react with HF-HNO_3 at room temperature overnight in wide mouth screw cap polythene bottles and excess fluoride ions are complexed by the addition of H_3BO_3. From the clear solution uranium is determined [8] by laser excited fluorimetry after the addition of fluorescence enhancing reagents. To test the accuracy and precision of the present method standard reference materials (SRMS) and inhouse standards were analysed. The results obtained are in agreement with the certified and recommended values.

2. Experimental

Instrumentation: Scintrex UA-3. Uranium analyser (Scintrex, Canada). N_2-Laser pulse rate 16 times s^{-1}. Pulse duration 3–4 nanoseconds. Excitation wavelength 337.1 nm. Measurement wavelength 516 nm.

Reagents: all the reagents used are of analytical grade.

Fluoresence enhancing buffer mixture: $NH_4H_2PO_4$ (500 g) and H_3PO_4 (50 ml) made up to 2 l volume.

Plastic ware: 125 ml capacity wide mouth screw cap polythene bottles.

2.1. Procedure

Of each of the powdered (− 200 mesh) samples, 0.1 g, were weighed into polythene bottles. Reagent blank was also run simultaneously. Conc. HNO_3, 5 ml, and 5 ml of 40% HF were added. The bottles were tightly capped and allowed to stand at room temperature overnight. The demineralised water, 50 ml, and 15 ml of saturated boric acid added to the bottles and shaken for a few minutes with cap fixed tightly. The contents of the bottles were carefully transferred to 100 ml volumetric flasks quantitatively, diluted to volume with demineralised water and shaken thoroughly to get clear solution. An aliquot of 1 ml was transferred to a 10 ml volumetric flask, 4 ml of buffer mixture was added and made up to volume. Fluorescence readings were obtained using UA-3 Uranium Analyser. Using pure uranium standards calibration graphs were prepared for 0–2 and 2–20 ppb U. For higher Uranium content in sample, suitable dilution is made before drawing an aliquot of 1 ml for fluorescence measurement.

3. Results and discussion

Boric acid is added to neutralise fluoride ions which attack glass. Fluoborate does not interfere in uranium determination. Most of the elements that decrease the intensity of uranium fluorescence are taken care of by the dilution technique followed and total uranium is quantitatively determined in a variety of geological materials. Dolostone [15] and syenite [16] samples are associated with pitchblende and betafite, pyrochlore and monazite minerals respectively, which are the source for uranium. In these minerals [17] uranium is also present in tetra valency state. In the present method uranium tetrafluoride (UF_4) has not precipitated and lost but oxidised to hexavalency state and kept in solution. This is confirmed from the data presented in Table 1. Samples containing 50% of uranium in tetra valency state [18] have been analysed by the present method. The results obtained for total uranium compare favourably with the conventional method of dissolution [1,2] and estimation [9,14] demonstrating efficacy of the proposed method of dissolution for the determination of uranium. A variety of international standards (SRMS) rocks and minerals were analysed by the present method and the values obtained are in good agreement with the certified values [19] (Table 2).

Although Dolostone samples contain very high calcium, i.e., around 30% CaO [15] and Calcium precipitates as CaF_2, the uranium concentration obtained from the supernatant solution agreed very well with the inhouse standard values (Table 3). Luminescence of aqueous uranyl solution is quite weak and enhanced fluorescence yields have been achieved by using intense excitation source

2	0.076	0.080	0.037	0.035
3	0.049	0.051	0.025	0.025

[a] Each value is an average of three determinations.

in the presence of various fluorescence enhancing reagents [6–12]. Fluran [9,10] sodium pyrophosphate, sodium dihydrogen phosphate [11] and sodium polysilicate [12] are reported fluorescence enhancing reagents. These are strongly pH dependent and at pH lower than seven their effect is greatly reduced. Tolerance for inorganic quenchers (Fe, Mn, Cu, Co) is also less. Orthophosphoric acid [6,7] has been extensively used as an enhancer of Uranyl fluorescence both as direct additive to U VI solutions and as a stripping agent for Uranylnitrate from ethyl acetate extractive phase. A mixture of orthophosphoric acid and ammonium dihydrogen phosphate [8] has a fairly high tolerance for inorganic quenching ions and for Ca, Mg, Nb, Ta, Ti, Al etc. Uranium in solid sample solution of 10% acidity prepared by the present cold dissolution is directly determined using this reagent [8]. It is not highly pH sensitive and has high tolerance for inorganic quenchers, while determining nanogram ml^{-1} of uranium.

The precision expressed as coefficient of variation is within $\pm$ 10%. This work is most suitable for Geochemical exploration of uranium where anomalous values are important, so a variation of 10% at these low values (Table 3) will be sufficient. The accuracy of the method is also within $\pm$ 10% at low concentration of uranium (Table 2).

4. Conclusion

The present cold dissolution technique and Laser fluorimetric method of uranium determination is highly useful for exploration Geochemists where speed, economy and high sample throughput are the prerequisite. The present method does not require costly platinum or teflon ware for sample dissolution, acid and other reagents used are minimal. Therefore it is highly economical. Since no defluoridisation step is involved by evaporation, air pollution is not there and there is no solvent extractive stage for removal of interferents and hence the method is eco-friendly also. Another advantage of this method of dissolution is the limited attention required at the dissolution stage, which decreases the likelihood of errors. The use of plastic ware, the avoidance of heating and after dilution with demineralised water, direct determination of uranium in laser fluorimeter renders the method adoptable for big batch analysis in geochemical exploration work in field conditions.

Fluorometric fiber optic drop sensor for atmospheric hydrogen sulfide

Arnaldo A. Cardoso [1], Hanghui Liu, Purnendu K. Dasgupta *

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409–1061, USA

Received 4 November 1996; received in revised form 4 December 1996; accepted 4 December 1996

Abstract

A fluorometric technique based on a liquid drop excited from its interior by an optical fiber is described for the measurement of low concentrations of atmospheric hydrogen sulfide (H_2S). A drop of alkaline fluorescein mercuric acetate (FMA) solution is suspended in a flowing air sample stream and serves as a renewable sensor. An optical fiber contained within the conduit that forms the drop, brings in the excitation beam; the fluorescence emission is measured by an inexpensive photodiode positioned close to the drop. As H_2S in the sample is collected by the alkaline drop, it reacts rapidly with FMA resulting in a significant decrease in fluorescence intensity, proportional to the concentration of H_2S sampled. The chemistry of this uniquely selective reaction has been well established for many years; the present technique permits a simple fast inexpensive near real-time measurement with very little reagent consumption. Even without prolonged sampling/preconcentration steps, limits of detection (LODs) in the double digit ppbv range is readily attainable. © 1997 Elsevier Science B.V.

1. Introduction

Sulfur gases and their reaction products have taken on a new significance in recent years due to their involvement in the formation of atmospheric aerosols, acid precipitation, planetary radiative equilibrium and a number of other issues, including the biogeochemical cycling of sulfur in the marine environment [1]. Sulfur dioxide is the only sulfur compound that is emitted with the sulfur in the +4 oxidation state. Most of the emitted sulfur compounds contain sulfur in the −2 oxidation state, these include dimethyl sulfide, carbonyl sulfide and H_2S. The natural emission of H_2S into the atmosphere was once believed to be the dominant sulfur emission [2]. But over the years, the importance of this contribution has been continuously revised downward and is now believed to be relatively small [3]. Except in remote regions, anthropogenic, mostly petroleum related, sources dominate H_2S emissions. Regardless of the decreased perceived importance of H_2S

PII S0039-9140(96)02202-3

in the global sulfur cycle, it has long been known that at a local level even low levels of H_2S contributes to material corrosion, paint damage and troubles for the electronics industry [4]. In addition, of the sulfur gases mentioned above, H_2S is by far the most toxic. Here in West Texas, known for its oilfields, dead pigeons around oil storage tanks are a common sight; accidental human fatalities also occur.

The measurement of atmospheric H_2S has therefore received considerable attention and a number of analytical methods have been developed over the years [5–9]. In the following discussion, we confine ourselves to simple, field deployable, affordable methods. Most of these methods require a collection/preconcentration step (typically using a $Cd(OH)_2$ suspension to make CdS) before actual analysis is carried out [6–9]. Atmospheric oxidants can interfere in the collection step, the collected CdS photodecomposes and the physical design of the absorber can cause varied results, leading to conflicting, questionable and erroneous conclusions [10,11]. Post-sampling reactions can also occur with glass collection vessels [12].

In recent years, we have become enamored with the potential of liquid drops and films as analytical devices, notably as gas sensors. Such a sensor has a truly renewable collection surface like a wetted denuder [13,14] but requires much less collection liquid and can be produced in a compact form more conveniently and reproducibly. In the first drop based gas sampling system, an 18 μl static drop of diluted H_2SO_4 suspended in a sample stream was used to collect ppbv levels of NH_3 [15]. The drop contents were then withdrawn into a microscale elctroosmotically pumped sequential injection system for detection. Instead of withdrawing the drop for analysis elsewhere, in many cases it is possible to use a reagent in the drop that can result in a property change that can be followed in real-time, thus a selective reproducible sensor results. In this vein, a drop/film of Griess-Saltzman reagent suspended on a wire support forms the basis for sensing NO_2 at ppbv level using simple light emitting diode (LED) based interrogation of the drop/film [16]. Hydroperoxides were selectively detected using in-situ electrochemical sensing in a drop [17]. A gaseous chlorine sensor was developed with a continuously growing and falling drop of tetramethylbenzidine solution suspended in a sample stream and photometry with an LED based system [18].

It has occurred to us that a drop system is also particularly suitable for exciting fluorescence by placing a light source, such as an optical fiber terminus within the drop, because of the small optical path length, there is little attenuation of the excitation beam and efficient excitation of the liquid can take place. Further, such a scheme eliminates interfacial scattering of the excitation beam at the air/container wall interface. In this work, we demonstrate a near real-time fluorometric detection method for H_2S using a drop sampler. The H_2S is collected by a drop of alkaline fluorescein mercuric acetate (FMA) solution. This well known sensitive reaction, selective for sulfhydryl groups, results in a quenching of the native FMA fluorescence [7,8,19].

2. Experimental

2.1. Chemicals

All chemicals were reagent grade quality and used without further purification. Deionized water was used throughout. The FMA stock solution (20 μM) was prepared in 0.1 M NaOH. An FMA solution of 6.0 μM, diluted from the stock solution with 0.1 M NaOH, was used to form the drop sampler for gaseous H_2S.

2.2. Measurement system

The measurement system arrangement is shown in Fig. 1 (a) with the cross section view from the top shown in Fig. 1 (b). Silica optical fiber *F* (1000 μm core, fused silica, Ensign-Bickford Optics, Avon, CT) is positioned inside Teflon tube *T* (3.8 mm i.d., 4.8 mm o.d. and 27.0 mm in length) to carry the excitation beam. The axis of optical fiber F is 1 mm away from the axis of tube *T* and the end of the fiber is ~2 mm above the tip of tube *T*. A Teflon tube *C* (0.3 mm i.d. and 0.6 mm o.d.) is also inserted into tube *T* to deliver the

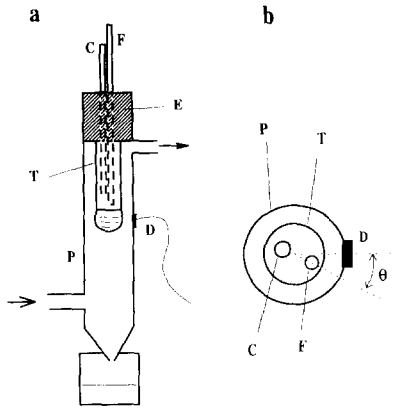

Fig. 1. Schematic diagram of the drop based sampling/detection chamber. *C*, Teflon tube for the delivery of FMA solution; *F*, silica optical fiber; *T*, Teflon tube for drop formation; *E*, fitting (the gas outlet arm is an integral part of this), *P*, opaque PVC tube; *D* photodiode. The drawing is not to scale.

FMA reagent. Tube *T* is fixed in a fitting *E* that is screwed into an opaque PVC tube *P* (12 mm i.d., 17 mm o.d. and 110 mm in length) through which the sample gas is aspirated. The FMA solution is allowed to flow by gravity through tube *C* to form a drop on the tip of tube *T*. A solenoid valve (SV in Fig. 2) is incorporated in the liquid inlet line. The FMA solution flow is stopped when the valve is shut off. The maximum drop volume of a drop for such an arrangement is about 60 μl, after that, the drop falls. The fall of a drop is readily discernible from the optical signal. Using the instant of drop detachment as a marker, keeping the solenoid valve on for a given period of time past this instant allows one to form a drop of desired size (up to the maximum) reproducibly. The beam from a 25 W Tungsten lamp source (Lamp source type 01 coupled to grating AMC1-03, PTR Optics, Waltham, MA) is coupled to optical fiber *F*, with the grating wavelength set at 495 nm. A small silicon photodiode *D* equipped with an interference filter centered at 530 nm (T5-STK-530, Intor, Socorro, NM, TO-5 package) is put into a hole on the wall of tube *P* (approximately on the same side as fiber optic *F*; vide infra) to detect the fluorescence emission from the drop. The center of the photodiode is in the same horizontal plane as the center of the drop. A home-built current detector, based on a low noise switched integrator [20] is used to convert the photocurrent detected to a voltage signal.

Schematic diagram of the experimental arrangement. *A* and *B*, sequential columns for air purification; FC 1–3, mass flow controllers; *G*, pressure gauge and regulator; *T*, thermostated enclosure; *P*, permeation chamber; *V*, three-way Teflon solenoid valve; *L*, light source; *S*, FMA solution; SV, liquid on/off valve; *M*, drop based sampling/detection chamber; *Q*, signal processor and readout; *C*, air aspiration pump.

2.3. Gas generation and sampling

The arrangement for H_2S standard gas generation and sampling system is illustrated in Fig. 2. All gas flows are regulated by mass flow controllers FC1-3 (Model FC280, Tylan General, Torrance, CA). Air purified by sequential columns *A* (activated carbon) and *B* (silica gel/soda lime) is metered by flow controller FC1 through a permeation chamber *P* housed in a thermostated enclosure *T* maintained at 30°C. A permeation wafer device (VICI Metronics, Santa Clara, CA) emitting H_2S at ~ 100 ng min^{-1} is placed inside the permeation chamber. The H_2S gas stream from the chamber is diluted by pure air metered by FC2. Any excess flow of the standard gas, metered by FC3, is aspirated to waste, while the desired amount (FC1 + FC2 − FC3) flows through the sampling chamber. By activating three-way valve V, pure air, controlled by FC2, can be sampled instead of the analyte. Soda lime trap tubes are placed in all vent lines to avoid contamination of the laboratory atmosphere with the noxious gas.

Unless otherwise stated, the experiment procedures are as follows: (a) form a drop of ~ μl in volume and begin recording the fluorescence signal synchronous with the solenoid valve being shut off; (b) sample H_2S of desired concentration for 2 min at a flow rate of 0.16 l min^{-1}; (c)

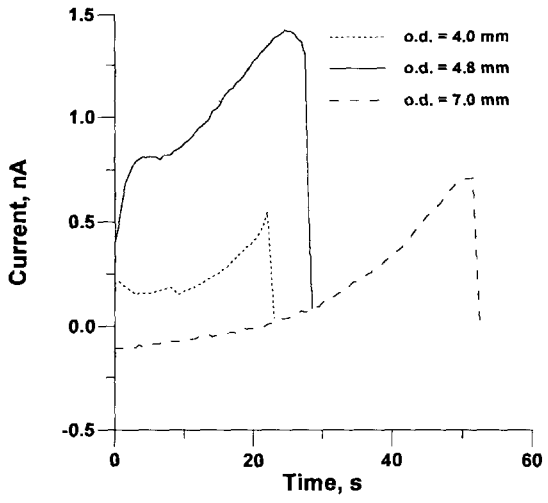

Fig. 3. Fluorescence signal in during the lifetime of a single drop for various diameters of Teflon tube T; liquid flow rate is held constant.

activate three-way valve V to flush the measurement chamber with pure air for 10 s; (d) cease all gas flow; and (e) reestablish liquid flow, form a new drop and begin a new cycle. A complete cycle takes ~ 5 min.

3. Results and discussion

3.1. Effect of drop size

As noted in the Section 2, the drop size can be varied by the timing of the solenoid valve. The maximum attainable drop size, on the other hand, can be changed by varying the diameter of the drop tube T. Experiments were conducted with different outer diameters of T with a drop continuously forming and falling while the fluorescence signal was monitored, the optical fiber being coaxial with tube T. The results are shown in Fig. 3. In each case, the fluorescence signal increases as the drop grows and reaches a maximum shortly before drop detachment occurs. The results do not show an unidirectional change with an increase in drop diameter, rather, the observed fluorescence intensity is substantially higher for the 4.8 mm tube. In these experiments, the observed fluorescence signal is a complex function of many factors. Some of the light launched from the fiber undergoes internal reflection at the drop/air interface; McMillan et al. have made an excellent and detailed analysis as to how such multiple internal reflections can occur in a drop [21]. In the present case, it is intuitive that the number of internal reflections should also be dependent on the convexity of the drop bottom, decreasing with increasing tube diameter. However, there is a substantially larger amount of liquid (and thence a substantially larger number of molecules) to be excited as the tube diameter increases. On the other hand, the detector position and photosensitive area remains fixed regardless of drop size, keeping its field of view fixed. Finally, the drop also behaves like a lens and its focus changes as a function of size; past a certain size, it may actually block the vision of the detector towards the most luminescent region.

Clearly, it is impossible to assess the contribution of each individual factor from the results in Fig. 3. The data however, allowed us to choose the intermediate tube diameter of 4.8 mm as the optimum in our specific experimental setup for further work. We also elected to choose a drop volume of 50 μl for further work, just short of the maximum drop volume (at which point the drop may be more subject to premature detachment due to shock/vibration).

3.2. Position of the optical fiber and the detector

Fig. 4 (a) shows the detector photocurrent as a function of the depth of protrusion of the fiber beyond the mouth of tube T, with negative values indicating that the fiber is inside tube T. Maximum photocurrent is observed with the fiber ca. 2 mm inside tube T. This is likely a function of the numerical aperture of the fiber and the consequent angular dispersion of the light as it enters the liquid as well as the drop size. Experiments also showed that maximum photocurrent is produced with the fiber slightly off the coaxial position within the tube T, the highest photocurrent being observed with the fiber axis in a position ~ 1 mm off the tube axis in the direction close to the detector. Light launched from an off-axis fiber and perpendicularly incident on the interior of the

drop surface encounters an area with greater curvature relative to when the fiber is concentric with tube T. We believe therefore that the off axis position of the fiber likely increases the extent of internal reflections, thus resulting in signal enhancement.

The emitted photon flux around the drop becomes anisotropic when the fiber is no longer coaxial with the tube. The position of the detector now becomes a variable. Referring to Fig. 1 (b), we can define its relative position by considering the angle θ between the center of the photodiode D, the axis of tube T and the axis of fiber F on an horizontal plane. With the detector D fixed on the wall of tube P, the above relative position can be changed by rotating tube P with respect to tube T (and vice-versa). For $\theta = 0°$ (F is in the closest possible position to D), the photocurrent was observed to be 1.18 nA, this increased to a maximum of 1.40 nA at $\theta = 30°$ and decreased to a minimum of 750 pA at $\theta = 180°$. Overall, relative to the coaxial position, the 1 mm off-axis position of the fiber and the 30° viewing angle of the detector led to a significant enhancement of the observed photocurrent. In addition, the amount of scattered excitation light registered by the detector (as measured by the signal when a NaOH solution was substituted for alkaline fluorescein) is also minimum at an observation angle of 30°.

Thus, with the optimum positioning of fiber F vertically, radially and relative to detector D, Fig. 4 (b) shows the photocurrent from a growing and falling drop (three sequential drop traces are shown) of (a) a NaOH blank solution and (b) a solution of 6 μM FMA in 0.1 M NaOH. Clearly, if we consider the ratio of the signal in case b versus the signal in case a as the index of the signal to noise ratio (the noise is assumed to be linearly related to the blank), this is maximized shortly before the drop grows to its maximum size. The choice of a static drop size of ~ 50 μl is thus further justified.

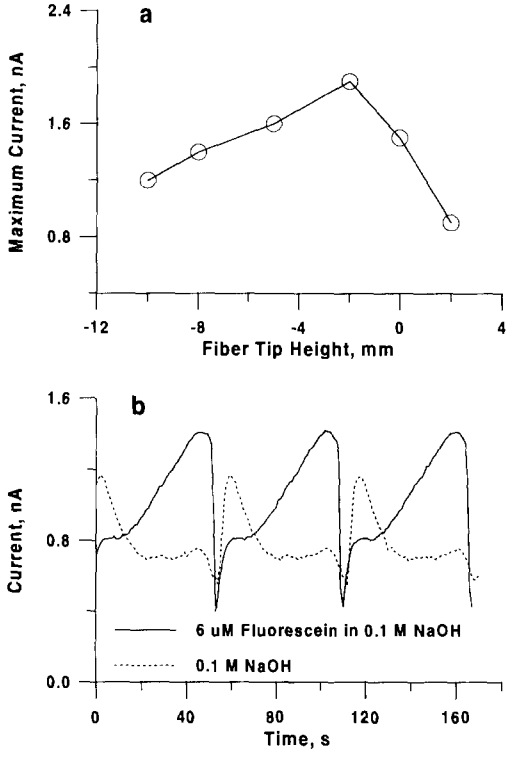

Fig. 4. (a) Fluorescence signal as a function of vertical position of the terminus of fiber F, zero connotes a position flush with the terminus of tube T and negative values indicate a position inside the tube. (b) Signals from an alkaline drop containing a fluorescent analyte and a drop containing only NaOH with optimized positions of the fiber and the detector, three successive drops are shown in each case.

3.3. Reduction of stray light with fiber in drop

Two experimental situations were compared. In the first, conventional setup, the excitation fiber was introduced through an aperture in the wall of the tube P in the same horizontal plane as the photodiode and the center of the drop. The fiber terminus was located 2 mm away from the drop boundary. The point of the fiber terminus, the drop and the photodetector formed a 90° angle in the same horizontal plane. In the second experiment, the optimized position of the fiber (1 mm off-axis, 2 mm inside the tube) and the detector (at an angle of 30°). Only a drop of water was used in the tube so that the signal registered by the photo detector is essentially due to stray/refracted light. The mean current due to stray light was 225% greater in the first vs. the second case, testifying to the advantage of the design.

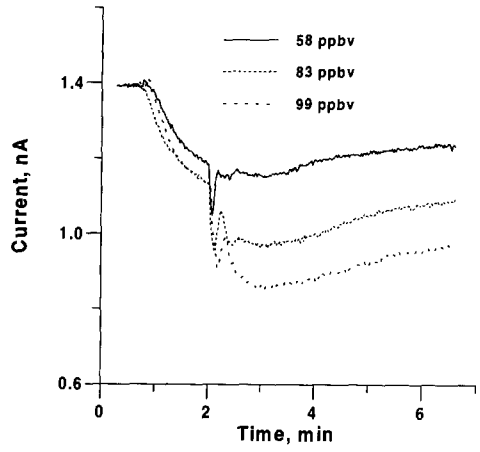

Fig. 5. Temporal profiles of the fluorescence signal for three different H_2S concentrations.

3.4. Response characteristics

A typical trace of the detector photocurrent as a function of time is shown in Fig. 5 for several different H_2S concentrations. A careful study of the traces will reveal that the length of this quiescent period is dependent on the H_2S concentration sampled, decreasing with increasing H_2S concentration. This can occur either because the reaction has an induction period that is dependent on the concentration of HS^- at the droplet surface (dependent in turn on the concentration of H_2S sampled) or more likely, the quiescent period reflects the time necessary for a finite concentration of the quenching species generated at the surface to travel to the region that is effectively probed by the exciting radiation. From first principles this period is likely to be related to the logarithm of the concentration sampled, this was not explored in the present study.

At a time of 2 min, the gas sampling is stopped and pure air flow is turned on for 10 s. This flow switching results in a perturbation in the status of dynamic mixing of the drop, apparently enhancing it momentarily and bringing in more of the quencher species in the most effectively probed region of the drop. (It should be noted that the mixing in the drop is not simply due to diffusion, the frictional drag of the gas moving past the liquid generates a circulatory motion on the surface that is very readily visible [15].) All gas flow is then ceased. The current initially increases after the cessation of all flow and decreases again to a minimum and then increases slowly to a stable plateau. The analytical signal ΔS can be taken to be the difference between the photocurrent at the beginning of the experiment and that at the minimum occurring between 2.3 and 3.5 min, leading to a linear relationship within the H_2S concentration range of 0–100 ppb H_2S:

$$\Delta S = 7.04(\pm 0.22) \times 10^{-3}[H_2S, \text{ppb}] - 0.1520 \pm 0.0154, \quad r^2 = 0.9991 \quad (1)$$

Alternatively, ΔS can also be taken to be the difference between the initial photocurrent and that at some point after cessation of sampling, e.g., when the difference between $t = 0$ and 4 min are considered, we obtain the following linear relationship:

$$\Delta S = 6.65(\pm 0.37) \times 10^{-3}[H_2S, \text{ppb}] - 0.1778 \pm 0.0254, \quad r^2 = 0.9967 \quad (2)$$

The lowest concentration tested was 28 ppbv H_2S, at this concentration, a detectable signal was observed. The relative standard deviation ranged from less than 2% to 12% in the 28–100 ppbv concentration range.

3.5. Effect of gas flow rate

If the collection of the gas by the drop is diffusion limited, the analytical signal ΔS should be related to the flow rate Q through a relationship of the type:

$$\Delta S = Q(1 - ae^{-b/Q})/c \quad (3)$$

where a, b and c are constants [17]. Fig. 6 (a) shows the experimental data for the flow rate range of 60–350 ml min^{-1}; a good fit ($a = 4.115$, $b = 1284$, $c = 1165$, $r^2 = 0.9969$) is obviously obtained.

3.6. Effect of water vapor and other gases

Relative humidity (RH) of the sample indirectly affects the measurements in that a low sample RH leads to greater evaporation of the droplet.

At this droplet size, as the droplet evaporates and there is greater concentration of FMA within the smaller droplet (probably the surface concentration is greater), the observed photocurrent increases. Fig. 6 (b) shows the situation when pure dry air is sampled at 0.16 l min^{-1}. Beyond a period of 5 min, the increase in photocurrent is sufficient to cause too great an analytical error if not compensated for. Of course, this is the worst case situation, a more humid sample will cause far less evaporation. In any case, this compensation can be provided by a second fluorescent dye incorporated into the drop which is inert to H_2S and fluoresces at a wavelength different from that for FMA when excited by the same incident beam. This fluorescence intensity can be read by a second, symmetrically placed photodiode, equipped with a suitable interference filter.

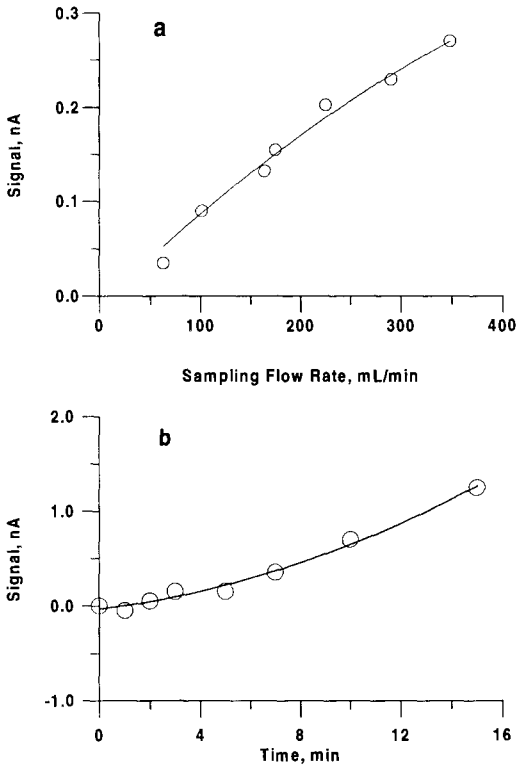

Fig. 6. (a) Analytical signal as a function of sampling flow rate. The sample gas concentration is 49 ppbv; (b) Signal observed for pure air as a function of sampling time.

As may be expected, the chemistry used in the present case responds to other gases bearing –SH groups such as CH_3SH. However, prolonged collection is not a feature of the present technique and oxidants such as NO_2 which was found to be a significant interference in early deployment of this chemistry [8] did not interfere. We found no interference in the determination of 49 ppb H_2S by 180 ppb NO_2.

In summary, the present application shows that a fluorescence based drop sensor can be configured simply and provide impressive limits of detection even with a photodiode detector. Initial experiments show that appropriately filtered blue LED sources can work as well or better in this application relative to the lamp/grating combination used in this work, thus further simplifying deployment.

Investigation of conductometric humidity sensors

Jurgis Barkauskas

Department of General and Inorganic Chemistry, Vilnius University, LT-2734 Vilnius, Lithuania

Received 24 January 1995; received in revised form 31 March 1995; accepted 9 December 1996

Abstract

Sensors for determining humidity in air have been described and investigated. Sensing film of the devices was prepared from polyvinylalcohol and graphitized carbon black disperse phase. The composition, thermal treatment and design of sensing films were investigated and optimized. An optimized humidity sensor has better metrological parameters as compared with its prototype (response time ~45 s, detection limit 0.17%, slope 6.25 ± 0.05 Ω/R.H., standard deviation of measurement 0.15%, standard deviation of analytical signal in the graduation equation 8.29Ω). Such construction of sensors have prospects in analytical practice. © 1997 Elsevier Science B.V.

Keywords: Air; Conductometric humidity sensors; Graphitized carbon; Polyvinylalcohol

1. Introduction

Looking through the evolution in field of humidity sensors during the last years devices based on varying of resistance stand out. Majority of this kind are thin hydrophile polymer films sometimes including a disperse phase of first-class conductor [1–3]. The conductivity of thin film changes owing to the swelling process of hydrophile polymer layer [4]. First-class conductor dispersed in the polymer matrix improves metrological parameters of the sensor. There the resistance of thin film is significantly lower and the use of more simple and reliable measuring equipment is possible [5]. These sensors are used for measuring humidity in gaseous, liquid and solid phases [6,7].

Except named positive features these sensors are not lack of shortcomings limiting their application. The most distinct are: relatively long response time, hysteresis and high level of uncertainty. Notwithstanding, only a few sources directly dealing with metrological improvement problem its possible to discover [8,9]. Getting clear that further development of polymer-film sensors with first-class conductor will advance only after elimination of enumerated shortcomings this work is an attempt to make a step in this direction.

2. Experimental

Resistance of thin polymer film was measured using constant current ohmmeter (model V7-38, running voltage 1.0 V) and registered with recorder N 307. Thin polymer film (thickness of 30 μm) was formed by means of spin-coating

PII S0039-9140(96)02203-5

(device model OPn-8). The constant temperature in the system was maintained using thermostat MLW-UH. The air stream saturated up to fixed humidity was transported to the sensor by means of microcompressor (model AEN-3). Artificial aging of the sensors was carried out in device SKVS-4.5.4, 54/ZI-1. This device consists from an insulated camera with controlled level of relative humidity (R.H.) and temperature inside. Sensors were kept at the R.H. 100% and temperature 50°C in this camera for 10 h.

The chemicals used were analytical grade. Polyvinylalcohol, 10%, (PVA) (type PVS; av. mol. mass 60 000) solution was prepared after swelling and dissolving at 60°C. Graphitized carbon black (CB) for conducting disperse phase was synthesized according to Brauer [10] from gaseous carbon monoxide at 600 C using Fe as catalyst and purified by means of permanent hot extraction with HCl. The grain size of CB synthesized under above mentioned conditions is ~ 15 nm [10]. Dispersion of CB in PVA was observed using light microscope (Leitz-Wetzlar, type 307-107.002). There the conglomerates of inhomogeneity reaches 1.0–2.0 μm.

Connection between the sensor's design and metrological parameters was examined. For that purpose sensors of different structure were prepared (Fig. 1A, B). Both kind consisted from two electrodes and thin sensing film. The sensors were designed on the glass plate. Two electrodes were made from Al foil. In one of these modifications electrodes were coated with transition layer of high-concentrated CB dispersion in PVA, treated at 300°C (Fig. 1B). Etched glass (glass treated with 10% Na_2SiO_3 solution up to 300°C for 6 h; Fig. 1B) and heated PVA (at 300 C) sublayers were used to improve adhesion between polymer film and substrate. The morphology of etched glass was observed by means of light microscope. Surface roughness of etched samples reaches 0.5 mm, dimensions of chaotically scattered crystallites varies within 0.5–5.0 μm. Thin films heated at 300°C show gradual discoloration, embrittlement and reduction of water absorbency. There the polymer exists in cross-linked state incapable for swelling [11]. Thin films of PVA formed from aqueous solutions well when placed in contact with humid air. The state of polymer there is thermoplastic and swelling process is reversible. Humidity sensing CB/PVA film was prepared by means of spin-coating at 1000 turns min^{-1}. In the process of calibration, the stream of air was saturated up to indicated value of relative humidity (R.H.) by means of blowing it through bubblers (stream velocity 25 cm min^{-1}). The bubblers were filled with solutions of salts and in common with measurement cell were placed into thermostat at 20 C. Salts for solutions used and R.H. reached (pointed out in blackets) were as follows [12]: K_2SO_4 (99); $(NH_4)_2SO_4$ (81); NH_4NO_3 (67); $NaHSO_4 \cdot H_2O$ (52); $CaCl_2 \cdot 6H_2O$ (33); $LiCl \cdot H_2O$ (15); H_2SO_4 (0). Measurements were repeated five times.

3. Results and discussion

Parameters most often used for metrological description of humidity sensors are as follows [13]: response time (τ), detection limit (ΔX_{lim}), slope ± confidence limits ($b \pm \epsilon_b$), standard deviation of measurement (σ_X), standard deviation of analytical signal in graduation equation (σ_Y). The slope was linear in all cases inside investigated R.H. interval (Table 1). Named parameters are sensitive to the composition and design of humidity sensor and could be used for the optimization.

The contact quality between polymer film and substrate directly acts on the analytical signal. In the case of poor contact the sensor gradually becomes degraded at that time increasing the uncertainty of results (Table 1). Sublayers positively affect on the quality of sensor. This fact is evident comparing metrological parameters of the sensors after artificial aging: the one without sublayer degrades. There we can draw and conclusion that the sensors including sublayers are more stable in time.

Heating of PVA reduces the hydrophobity and swelling capacity of the film due to forming of cross-linked structure [11]:

Statistics and other results accompanying the heating of sensing film at various temperatures are presented in Table 1. These data show strict correlation between heating temperature and standard deviation of analytical signal. This could be explained taking into account interaction between CB grains and PVA matrix. At lower temperatures the chemical interaction is weak and CB grains are not fixed in the polymer matrix very steady. Working with humidity-sensing films prepared under these conditions we observe standard deviation of analytical signal reaching significant values. One of the possible explanation of this phenomena could be that during multiple process of swelling and contraction of the polymer matrix CB grains are affected by the irreversible process of spatial orientation. This could occur where bonds between PVA molecules and CB grains are weak. The conjecture is affirmed by the fact that standard deviation of humidity-sensing film prepared at higher temperatures reduces to insignificant values. Taking into account that under higher temperatures –OH groups from PVA chain reacts with surface of CB grains (see reaction above), these grains being fixed more steadily in the polymer matrix. Under these conditions we could expect that the irreversible process of grains spatial orientation has no place. The swelling capacity of humidity-sensing films, treated at higher temperatures, is reduced as well as their sensitivity. Detection limit being the function of slope reaches minimum values after heating at 100°C.

The amount of conducting CB phase in polymer matrix affects the metrological parameters of humidity sensors too (Table 1). In the case of less amounts CB grains are insulated by PVA matrix and resistance of the film is high. The standard deviation of analytical signal there is significant apparently due to lower reliability of equipment as well as to high values of resistance and less amounts of microcontacts between CB grains. In the case of greater amount when carbon grains prevails over polymer in the bulk of sensing film

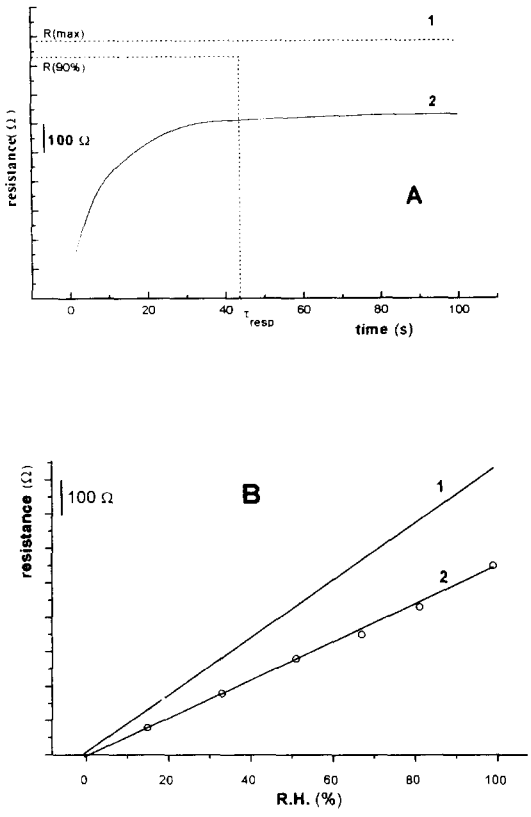

Fig. 2. Response transients (A) and calibration curves (b) of two-layer humidity sensor (1) and heated (at 100°C) sensing film (2).

the sensitivity to humidity falls abruptly. Mass, 57–59, percent amount of CB in PVA matrix is an optimum for humidity sensing films.

Design of this humidity sensor has some joints we could distinguish as 'weak points' in the circuit of resistance measurement. Those are (see Fig. 1A):

- Construction allows direct interaction between electrodes, e.g., by reaching a dew point. Electrode material should be insulated using an inert coating. Chemical inactive CB coating is used for improvement the sensor's quality.
- CB grains in PVA bulk are scattered and insulated by the polymer. During the swelling process positions of CB grains changes in three-dimensional coordinates. Limiting this process in two-dimensional coordinates the sensitivity should be improved. To solve this problem is possible using composite sensing film with separated CB and PVA layers.
- Quality of adhesion between sensing film and substrate affects on the sensor's metrological parameters (Table 1). For better adhesion the sublayer of etched glass is used.

Taking into account these notes above design of humidity sensor has been changed (Fig. 1B). New one included composite two-layer humidity sensing film. Additionally a sublayer of etched glass and inert transition layer on the electrodes were formed. Metrological parameters of the sensor are given in Table 1. Response transient and calibration curve of this sensor are presented comparing with analogous data of other sensor in Fig. 2. It's evident, that precision and sensitivity are increased using two layer humidity sensors. Thus, the conclusion about correction direction in sensor's design optimization could be done.

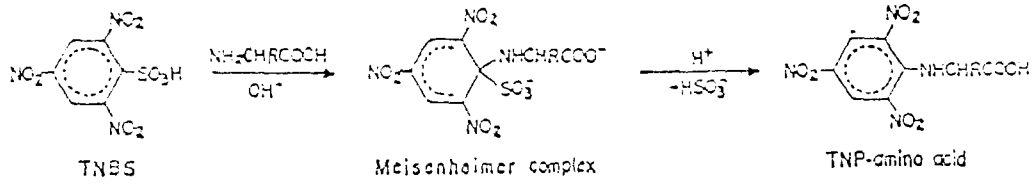
Abstract

Some kinetic aspects of the reaction of glutamic acid (GLU) and Trinitrobenzenesulfonic acid (TNBS) were studied spectrophotometrically (420 nm), under pseudo-first order reaction conditions. The effect of GLU, TNBS, SO_3^{2-} and H^+ had been investigated. Working curves for the initial rates IR versus [GLU] are linear in the range 7.5–30.0 mM. The regression equation is $IR = (8 \pm 8)E - 6 + (39 \pm 0.5) \cdot [GLU]$ and the correlation coefficient $r = 0.9998$. The limit of quantitation is 1.5 μM GLU and the relative standard deviation of the method 1.2%. The kinetics of the interfering TNBS hydrolysis reaction in alkaline range of pH, as well as the effect of sulfite concentration on the main reaction, are also presented. The analytical application of the reaction for the kinetic spectrophotometric assay of GLU and other aminoacids, as well as TNBS, is presented and the relevant advantages and disadvantages of the method are discussed. © 1997 Elsevier Science B.V.

Keywords: Glutamic acid; Kinetic study; Kinetic determination; Trinitrobenzenesulfonic acid

1. Introduction

K. Satake and his group [1,2] applied the reaction of Trinitrobenzenesulfonic acid (TNBS) with α- and β-aminoacids (AM), amines and proteins for their assay in different samples. The same investigator found that this reaction belongs to the category of the bimolecular reactions of aromatic nucleophilic substitution and takes place according to the following general scheme [3]:



TNBS — Meisenheimer complex — TNP-amino acid

* Corresponding author.

PII S0039-9140(96)02205-9

Freedman and Radda [4] studied the rate of the reaction of TNBS and -SH, while Goldfard [5] the effect of SO_3^{2-} on the formation of its complex with the TNP-Am, at 420 nm.

R. Fields [6] made a detailed study of the reaction at 420 nm and observed the various factors affecting the value of the second order reaction rate constant k. Many investigators made use of this reaction: (i) for the spectrophotometric determination of aminoacids, amines, peptides, proteins and their mixtures [7–10]; (ii) for the measurement of the activity of enzymes [11]; (iii) for the inhibition of the activity of enzymes [12]; and (iv) for the construction and analytical applications of an ion selective electrode responding to trinitrobenzenesulfonic acid [13,14].

The use of a buffer of pH higher than 8.5 is necessary, because the reaction goes on the unprotonated aminogroup. All investigators who have so far used this reaction have observed, that at pH values over 10.0 the determination of the $-NH_2$ is problematic, because of side reactions mainly initiated by the hydrolysis of TNBS, itself.

In the present work we have studied the reaction of glutamic acid (GLU) and TNBS and its interfering hydrolysis of TNBS to picric acid.

2. Theoretical considerations

The reactions of TNBS with GLU as well as its alkaline hydrolysis to picric acid, are bimolecular (second order) aromatic nucleophilic substitutions. Both are taking place in two consecutive steps, the first of which is slow and reaction rate determining:

$$T + G \xrightarrow{k_1} MC1 \rightarrow P_1 \quad (1)$$

$$T + C \xrightarrow{k_2} MC2 \rightarrow P_2 \quad (2)$$

where T, G, C, MC, P_1 and P_2 stand for TNBS, GLU, OH^-, Meisenheimer complex, TNP-GLU and picric acid, respectively.

Under the conditions where T is in excess ($[T] \gg [G]$ and $[T] \gg [C]$) we have pseudo-first order reactions and the following equations are valid:

$$\frac{d[P_1]}{dt} = k_1[T][G] \quad (3)$$

$$\frac{d[P_2]}{dt} = k_2[T][C] \quad (4)$$

The absorbancies (A) of the reacting mixture are additive:

$$A_t = A_{p_1} + A_{p_2} = \epsilon_1 b P_1 + \epsilon_2 b P_2 \quad (5)$$

By differentiating Eq. (5) we receive:

$$\frac{dA_t}{dt} = \epsilon_1 b\left(\frac{dP_1}{dt}\right) + \epsilon_2 b\left(\frac{dP_2}{dt}\right) \quad (6)$$

and substituting Eq. (3) and Eq. (4) to Eq. (6) we finally receive:

$$\frac{dA_t}{dt} = \epsilon_1 b k_1[T][G] + \epsilon_2 b k_2[T][C]$$

or

$$\frac{dA_t}{dt} = k_{ob_1}[G] + k_{ob_2}[C] \quad (7)$$

where $k_{ob_1} = \epsilon_1 b k_1[T]$ and $k_{ob_2} = \epsilon_2 b k_2[T]$.In the above equations, [G] is the concentration of the unprotonated aminoacid, which can be determined from the dissociation constant k_2 of the aminoacid and the known $[H^+]$ using Eq. (8):

$$[G] = C_G \frac{k_2}{k_2 + [H^+]} = b C_G \quad (8)$$

where C_G is the analytical concentration of glutamic acid and the factor β represents the fraction of the unprotonated aminoacid.

The second order reaction rate constant k was calculated by dividing the observed rate constants, by the fraction of aminoacid with unprotonated aminogroup.

3. Materials and methods

3.1. Apparatus

Kinetic measurements for the reaction of GLU with TNBS were done with a filter spectrophotometer (Metrohm Model 662 Photometer) equipped with fiber optic for the transmission of the light and a 1 cm immersed-type optical cell.

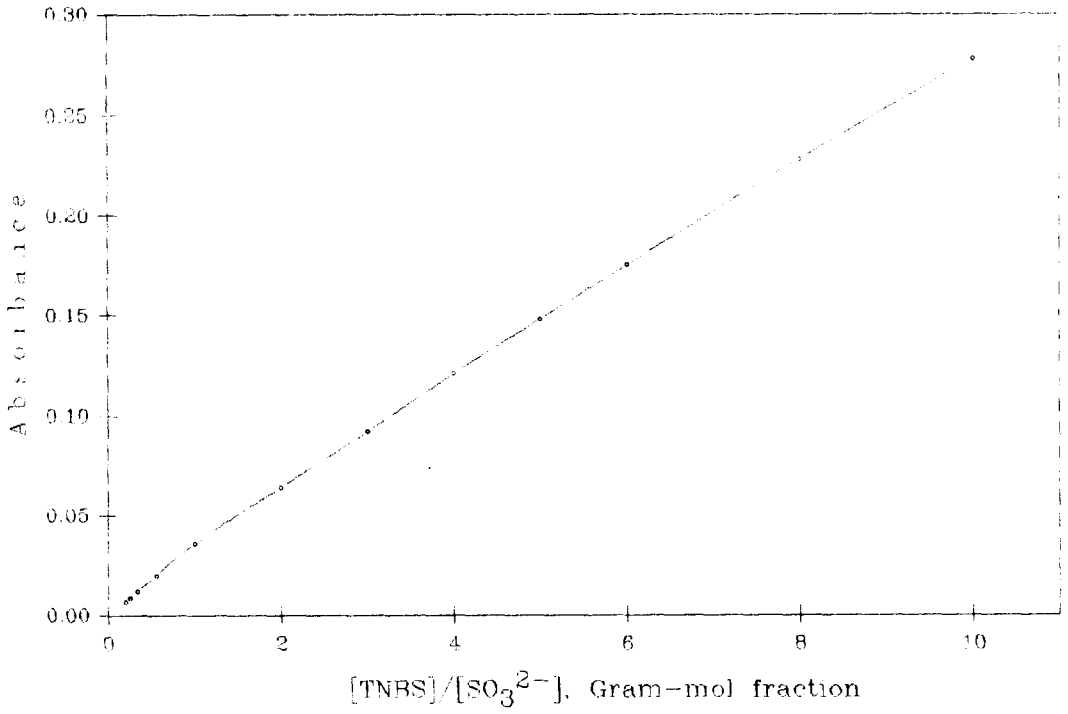


Fig. 1. Absorbance versus [TNBS]/[SO_3^{2-}] Gram-mol, fraction at pH 9.5 and $t = 25.0 \pm 0.1$°C, [SO_3^{2-}] = 1.0 mM.

The reaction cell was thermostatted at 25.0 ± 0.1°C. The measurements were carried out under stirring conditions with a mechanical stirrer (Radiometer TTA 80).

Spectra of the reagents and the products were taken with a double beam spectrophotometer (Perkin–Elmer Model Lambda 15).

A pH/pIon meter (Radiometer PHM 83) was used for pH measurements. Data acquisition was performed by an IBM data acquisition and control adaptor (Mendelson Electronics) and an IBM-compatible PC. Data collection and acquisition software was written in Microsoft Quick-BASIC. The program allows the collection of 2500 points, the plotting of the reaction curve $A_t = f(t)$, the determination of k_{ob} applying the infinite time method and the measurements of the slope $\delta A/\delta t$ in any point of the reaction curve.

4. Reagents

All the solutions were prepared in distilled water from p.a. grade reagents.

Buffers: the buffers used were 0.025 M $Na_2B_4O_7 \cdot 10H_2O$–0.1 M HCl for pH 8.5–9.0 and 0.025 M $Na_2B_4O_7 \cdot 10H_2O$–0.1 M NaOH for pH 9.5–11.0.

Na_2SO_3: a stock solution 0.4 M was prepared and stored at 4°C for 3 days.

GLU, TNBS and Picric Acid: aqueous stock solutions 0.004 M were prepared and stored at 4°C. For TNBS, fresh working solutions were prepared every 2 days.

4.1. Procedure

Borate buffer, 15.0 ml, 0.040 ml of sulfite stock 0.4 M solution and 0.100 ml of aminoacid work-

[TNBS] = 6.0×10^{-4} M, [GLU] = 1.2×10^{-5}, $t = 25 \pm 0.1$°C.

ing solution were pipetted in the reaction cell. The mixture was equilibrated at 25 ± 0.1°C, the wavelength set at 420 nm (except otherwise stated) and the transmittance adjusted to 100%. Then 0.100 ml of the TNBS working solution was rapidly injected in the reaction cell and the measuring system activated. The total measuring time and the interval between points were set accordingly. The reaction curve was plotted and the observed reaction constant k_{ob} and the initial reaction rate $(\delta A/\delta t)$ were calculated using the software.

For the study of hydrolysis of TNBS the same procedure was followed, except that GLU was omitted from the reaction cell. The observed reaction rate constant k_{ob} or other parameters were determined using the same software.

The reaction curve received by this procedure is the composite curve for both reactions leading to products P_1 and P_2 with k_{ob_1} and k_{ob_2}, respectively. The rate constant k_{ob} of the main reaction between TNBS, GLU and SO_3^{2-} may be calculated by the following equation:

$$k_{ob} = k_{ob_1} + k_{ob_2}$$

5. Results and discussion

5.1. Effect of sulfite concentration

By the addition of TNBS in a buffered solution of SO_2^{2-} a red product was formed very rapidly. Its absorption spectrum shows λ_{max} at 350 nm and absorptivities depending on the pH (Fig. 4, point A). This red product, already cited by previous investigators as a complex compound [5,6], is a meisenheimer like product of TNBS with SO_3^{2-}. An effort to determine its coordination number at pH 9.5, gave the results of Fig. 1. The almost linear dependence of its absorbance on the $[TNBS]/[SO_3^{2-}]$ ratio for a wide range of sulfite concentrations higher than 0.1 mM, denotes rather the formation of an equilibrium product. A small change of the slope in the range above 1 of $[TNBS]/[SO_3^{2-}]$ might mean the formation of a complex in a 1:1 ratio followed by the formation of a second equilibrium product with almost the same absorptivity.

The study of the effect of $[SO_3^{2-}]$ on the reaction rate constant of the main reaction between

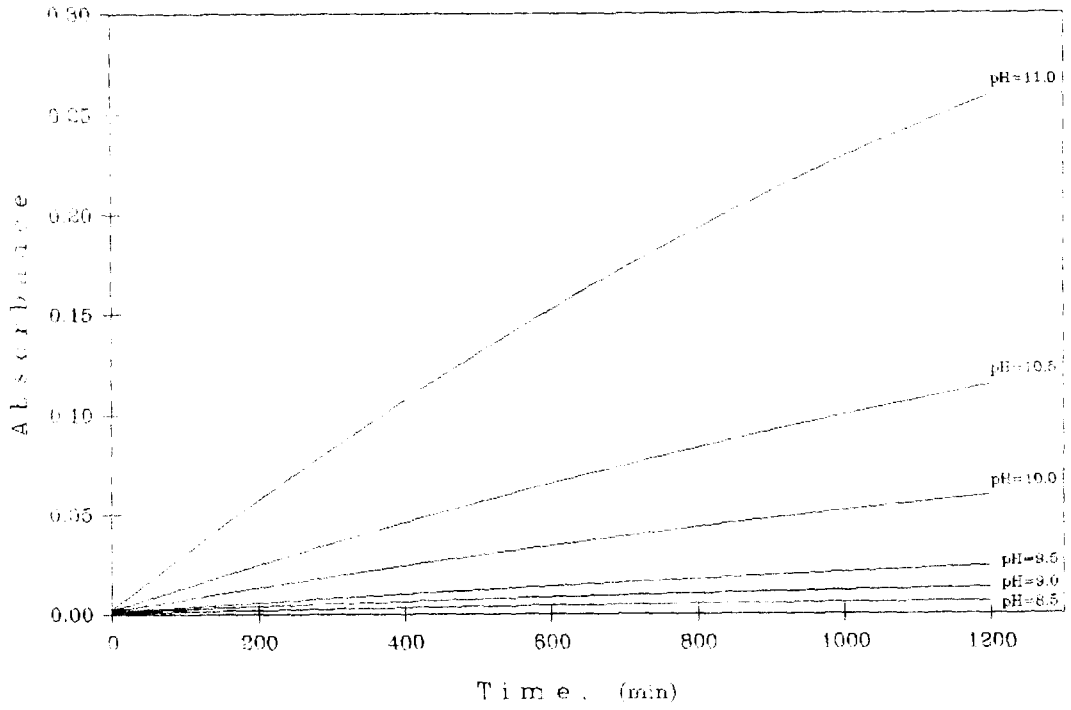

Fig. 2. Reaction curves, $A = f(t)$ for the reaction of hydrolysis of TNBS at different pHs. $\lambda = 420$ nm, $[SO_3^{2-}] = 1.0$ mM, [TNBS] = 0.73 mM, $t = 25.0 \pm 0.1$°C.

TNBS, GLU and SO_3^{2-}, shows that $[SO_3^{2-}]$ in the range 1.0–4.0 mM gives constant values for k_{ob}, k_{ob_1}, k_{ob_2} and initial rates $(\delta A/\delta t)_{in}$, as shown in Table 1.

5.2. Effect of TNBS hydrolysis to picric acid

The spectrum of picric acid shows maximum absorption at 360 nm and therefore contributes very little to the total absorption of the reaction mixture at 420 nm.

Fig. 2 shows the reaction curves (absorbance versus time) of the hydrolysis of TNBS at different pH values. The second order rate constant k_2 for the hydrolysis reaction of TNBS to picric acid at pH 9.5 was found to be $k_2 = 0.15$ s^{-1} M^{-1} (Fig. 3, Curve A), while $k_1 = 3.00$ s^{-1} M^{-1}. Therefore its interference with the main reaction seems to be significant only at pH values over 10.0, while at lower values it is negligible (Fig. 3). The big difference of molar absorptivities values between TNBS and picric acid at $\lambda = 420$ nm ($\epsilon_{TNBS} = 600$ cm^{-1} M^{-1} and $\epsilon_{p.ac.} = 7500$ cm^{-1} M^{-1}) and the increased contribution of the hydrolysis reaction at higher pHs might give a good explanation for the behaviour of the system, under these conditions.

5.3. The effect of pH

The pH of the reacting mixture TNBS-GLU-SO_3^{2-} affects the concentration of species participating in the reaction. It determines:

- The concentration of the unprotonated amino group ($K_2 = 3.39 \cdot 10^{-10}$ at pH 9.5).
- The addition of SO_3^{2-} on TNBS. TNBS is an electrophilic reagent and the degree of this substitution by SO_3^{2-} increases with pH ($K_{HSO_3^-} = 1.02 \cdot 10^{-7}$).
- The formation of the final coloured P_1, as shown in the proposed schemes of the reactions.
- The rate of hydrolysis of TNBS to picric acid at pH values higher than 10.0.

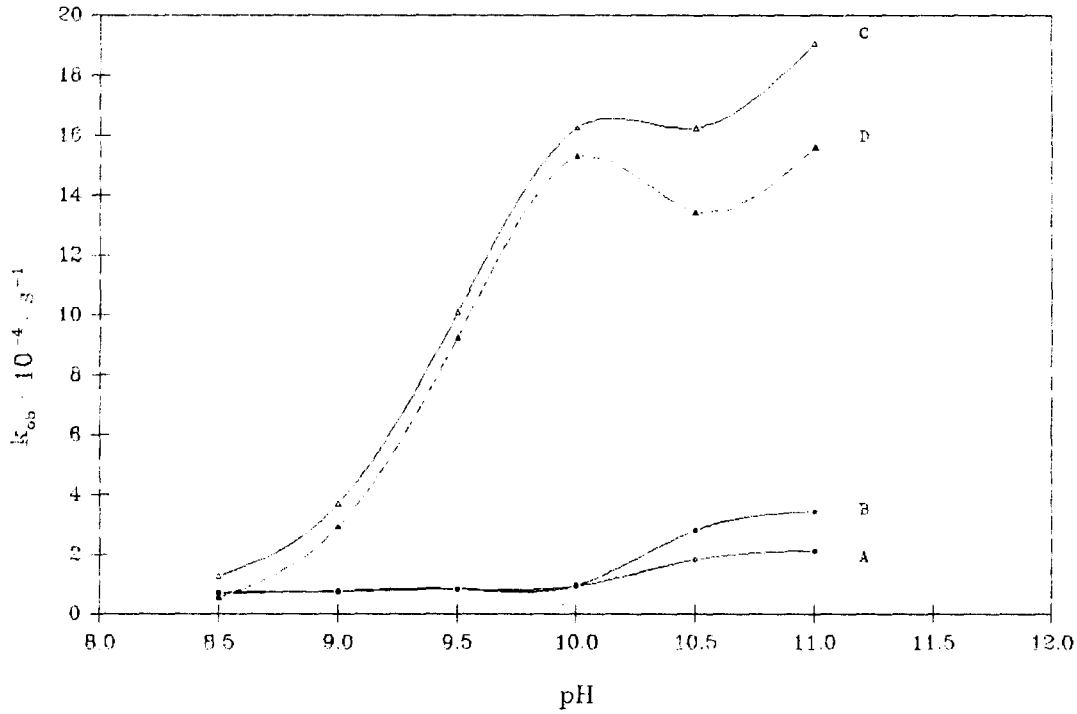

Fig. 3. Dependence of k_{ob}, k_{ob1}, k_{ob2} and k'_{ob} on the pH value at $t = 25.0 \pm 0.1$°C. Curve A: k'_{ob} for TNBS (0.6 mM) hydrolysis in the absence of SO_3^{2-}. Curve B: k_{ob2} for TNBS (0.6 mM) hydrolysis in the presence of SO_3^{2-} (1.0 mM). Curve C: experimental k_{ob}. [TNBS] = 0.6 mM, [GLU] = 0.01 mM, $[SO_3^{2-}] = 1.0$ mM. Curve D: k_{ob1} calculated after correction of k_{ob} ($k_{ob1} = k_{ob} - k_{ob2}$).

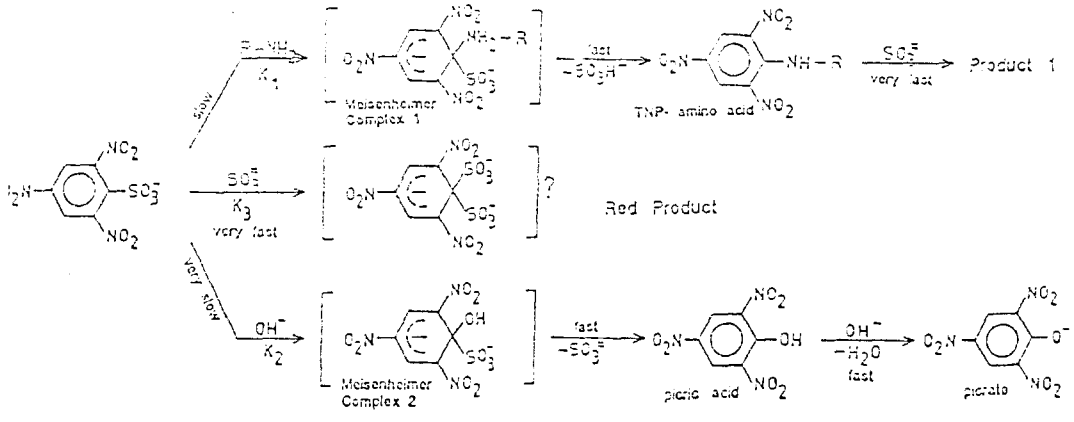
The reaction curves $A = f(t)$ for the reaction of GLU with TNBS at different pHs and $\lambda = 420$ nm, are shown in Fig. 4 (after point B). The reaction curves at $\lambda = 500$ nm show the same profiles. Our experimental results show that pH values in the range 9.5–10.0 ensure maximum value for the second order rate constant k_1, keeping the interference of the side reactions at negligible level. From our experimental results we are proposing the following sequences for the main and side reactions:



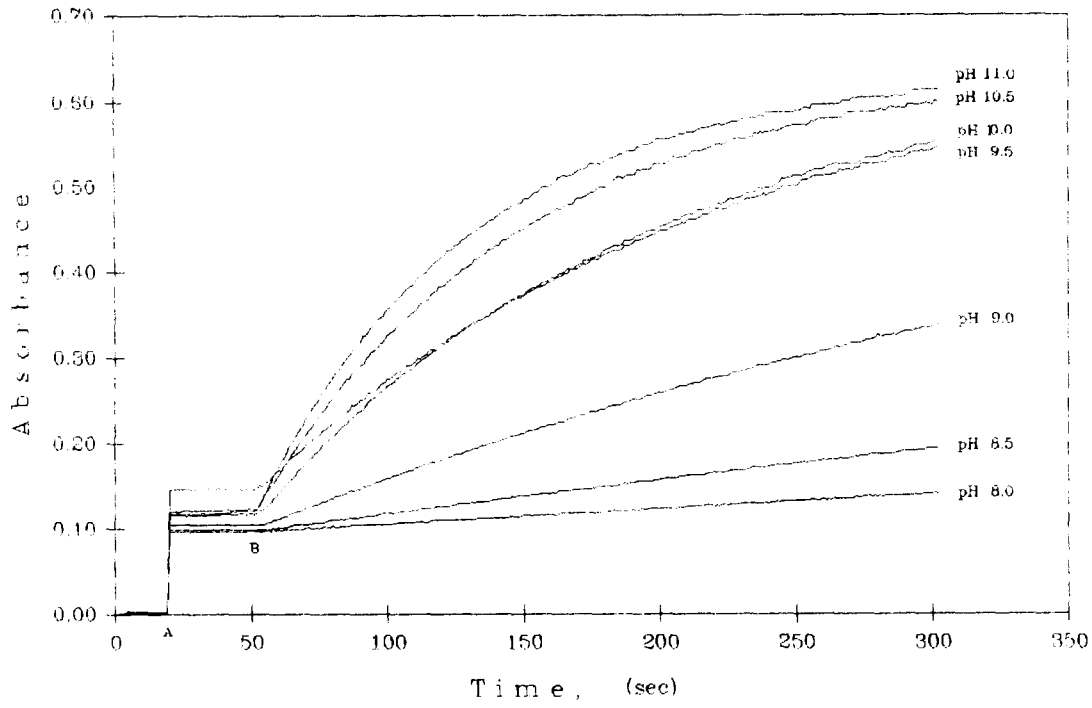


Fig. 4. Reaction curves, $A = f(t)$ for the main reaction between TNBS (4 mM) and GLU (0.066 mM) in the presence of SO_3^{2-} (1.0 mM), at different pH values. $\lambda = 25.0 \pm 0.1$°C. Point A: addition of TNBS in the reaction cell with the buffered sulfite solution. Point B: addition of GLU in the reaction cell with the buffered sulfite solution and TNBS.

5.4. Kinetic determination of GLU and TNBS

The effect of [GLU] or [TNBS] on the reaction rate was studied under pseudo-first order conditions and constant pH, $[SO_3^{2-}]$ and temperature. The results are presented in Table 2. The applicability of this procedure for the development of a reaction rate method for the determination of GLU, other aminoacids or TNBS in aqueous solutions, seems to have very good prospectives.

For [GLU] and [TNBS], in the range of 7.5–30 μM the working curves $(\delta A/\delta t)_{in} = f$[GLU] and $(\delta A/\delta t)_{in} = f$[TNBS] are linear, as shown in Fig. 5. The regression equations of the curves are:

$$(\delta A/\delta t)_{in} = (8 \pm 8)E-6 + (39 \pm 0.5)[\text{GLU}] \quad (9)$$

and

$$(\delta A/\delta t)_{in} = (7 \pm 6)E-6 + (36.7 \pm 0.4)[\text{TNBS}] \quad (10)$$

at pH = 9.5, $[SO_3^{2-}] = 1.0$ mM and $t = 25 \pm 0.1$°C. The correlation coefficient for both curves is $r = 0.9998$. Concentration of GLU and TNBS in Eq. (9) and Eq. (10) are applied in molar concentrations, M.

The accuracy of the method for both determinations is better than 1.5%. The limits of detection are 1.5 μM GLU and 1.2 μM TNBS. The method can be applied for the kinetic assay of many other amino acids in aqueous solutions, in combination with chromatographic separation. The kinetic method is more accurate, precise, sensitive, fast and therefore advantageous compared to the stoichiometric methods, because the initial rate is measured during the first 30–100 s after the injection of TNBS, where interference due to hydrolysis of TNBS is almost negligible. It can be also applied for the study of hydrolysis of various proteins and total of free aminoacids in mixtures. The method is not selective and cannot

differentiate the different aminoacids. It can be applied to samples which contain only one aminoacid. Since the reaction rate is almost the same for all aminoacids with one aminogroup [13] it can be applied for determination of total aminogroups of aminoacids.

Specific extraction behavior of amide derivative of calix[4]arene for silver (I) and gold (III) ions from highly acidic chloride media

Keisuke Ohto *, Hiroshi Yamaga, Emi Murakami, Katsutoshi Inoue

Department of Applied Chemistry, Faculty of Science and Engineering, Saga University, Honjo, Saga 840, Japan

Received 24 September 1996; received in revised form 3 January 1997; accepted 6 January 1997

Abstract

25,26,27,28-tetrakis(*N*,*N*-diethylaminocarbonylmethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene, a macrocyclic extraction reagent, and *p*-(1,1,3,3-tetra-methylbutyl)phenoxymethyl-*N*,*N*-diethylamide, an acyclic extraction reagent corresponding to the former one, were synthesized to investigate their extraction behavior for silver(I), gold(III), palladium(II), and platinum(IV) from highly acidic solution into chloroform. In the extraction of silver and gold from hydrochloric acid solution, a completely different extraction behavior was observed between these two types of the reagents. The extraction behavior was examined in detail for silver and was found to be dependent on whether silver ion was extracted as a cationic species or a anionic species complexed with chloride ion. This was supported by proton nuclear magnetic resonance study of the calix[4]arene derivative. As a result, the extraction of silver ion with calix[4]arene derivative was very peculiar which was attributable to the fitting between cyclic size of calix[4]arene and ionic radius of silver. © 1997 Elsevier Science B.V.

Keywords: Calixarene amide derivative; Chemical shift; Competition; Highly acidic chloride media; Silver ion; Solvent extraction

1. Introduction

Calixarenes and their derivatives have been attracting much attention as novel types of interesting host compounds [1–4]. Their recognition and discrimination ability for metal ions are one of the remarkable features as a specific receptor [5,6].

In the previous work, we synthesized 25,26,27,28-tetrakis(acetomethoxy)-5,11,17,23-tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene as a carbonyl compound to investigate the extraction behavior for silver (I) and palladium (II) from the highly acidic solution into chloroform. In nitrate media, the ketonic tetramer was found to selectively extract silver ion over palladium ion in the highly acidic region [7,8], suggesting, therefore, that carbonyl compounds are capable of extracting some metal ions from highly acidic solution.

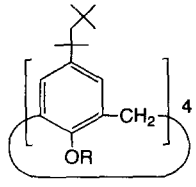
Among carbonyl compounds, amide compounds have high dipole moment and tautomerize at high concentration of mineral acid [9–12]. Many authors have reported about the extraction of some metal ions with the amide compounds including diamide compound [10–29]. Recently, amides have been attracting much attention as good extractants for the recovery of actinides, in particular, which can alternate with tributylphosphate, a typical conventional extractant for actinides. The amide type derivatives of calixarenes have been also reported in relation to solvent extraction of some metal ions [30–33], though no paper have been reported on those from highly acidic solution.

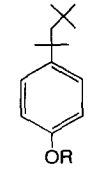
In the present work, an amide type derivative of calix[4]arene have been synthesized to investigate the solvent extraction of some precious metal ions from acidic solution and compared with the extraction behavior of the corresponding monomeric amide.

2. Experimental

2.1. Reagent

The chemical structures of the extractants employed in the present work are shown in Fig. 1. Synthesis of carboxylate derivative of calix[4]arene ($\mathbf{2_4}$) was described in the previous paper [34]. The syntheses of the amide derivatives were carried out according to the similar manners with those of calixarene derivatives with *t*-butyl groups as alkyl radicals [35–37].





$\mathbf{1_4}$: R = CH_2CONEt_2 $\mathbf{1_1}$: R = CH_2CONEt_2

$\mathbf{2_4}$: R = CH_2COOH

Fig. 1. Chemical structures of the extractants.

25,26,27,28-tetrakis(*n*,*n*-diethylaminocarbonylmethoxy)-5,11,17,23- tetrakis(1,1,3,3-tetramethylbutyl)calix[4]arene (cone conformation) ($\mathbf{1_4}$)

Under a nitrogen stream, to 300 cm^3 of dry toluene were added carboxylate derivative $\mathbf{2_4}$ (15.67 g, 14.2 mmol) and thionylchloride (160 g, 1.34 mol). The solution was refluxed for 20 h. After cooling, the solvent was removed in vacuo. The residue was dissolved into 150 cm^3 of dry toluene and to the solution was carefully added diethylamine (16.5 g, 226 mmol) in 50 cm^3 of dry toluene in an ice bath. The mixture was stirred at 0°C for 2 h and at room temperature for 48 h. The solvent was removed in vacuo and to the residue was added 500 cm^3 of chloroform. The organic layer was washed three times with 1 $moldm^{-3}$ hydrochloric acid and with distilled water. After drying over anhydrous magnesium sulfate, filtration, and evaporation, to the residue was added acetone and distilled water to reprecipitate three times the desired compound. It was filtered to get white powder; 13.1 g (81%), m.p. 148°C, TLC(SiO_2, chloroform:methanol = 5:1 (v/v), $R_f = 0.91$); IR(KBr) $\nu_{C=O}$ 1664 cm^{-1}, $\nu_{C\text{-}N}$ 1434 cm^{-1}; ^{1}H-NMR (270MHz, $CDCl_3$, TMS, 27°C) δ 0.69 (36H,s,$C(CH_3)_3$), 1.09 (48H,m,$C(CH_3)_2 + (CH_2CH_3)_2$), 1.53 (8H,s,CCH_2C), 3.17 (4H,d,$ArCH_2Ar$(exo), J = 13.18 Hz), 3.31 (16H,m,$(CH_2CH_3)_2$), 5.00 (8H,s,OCH_2CO), 5.29 (4H,d,$ArCH_2Ar$(endo), J = 13.19 Hz), 6.74 (8H,s,ArH).

p-(1,1,3,3-tetramethylbutyl)

phenoxymethyl-*N*,*N*-diethylamide ($\mathbf{1_1}$)

N,*N*-Diethylchloroacetoamide was synthesized from chloroacetyl chloride and *N*,*N*-diethyl amine in toluene according to the paper reported by Cope and Ciganek [38].

Under a nitrogen stream, to 600 cm^3 of dry acetone were added sodium iodide (5.25 g, 35 mmol) *N*,*N*-diethylchloroacetoamide (10.47 g, 70 mmol), *p*-(1,1,3,3-tetramethylbutyl)phenol (10.32 g, 50 mmol), and potassium carbonate (13.82 g, 100 mmol) to reflux for 8 days. After cooling, the solvent was removed in vacuo. To the residue was added 400 cm^3 of chloroform to extract the desired compound. The organic layer was washed twice with 1 mol dm^{-3} hydrochloric acid and

three times with distilled water. After drying over anhydrous magnesium sulfate, filtration, and evaporation, to the residue was distilled in vacuo as pale yellow liquid; 12.35 g (77%), TLC(SiO_2, chloroform, $R_f = 0.73$); IR(neat) $\nu_{C=O}$ 1651 cm^{-1}, ν_{C-N} 1436 cm^{-1}; 1H-NMR (270 MHz, $CDCl_3$, TMS, 20°C) δ 0.70 (9H,s,$C(CH_3)_3$), 1.16(6H,m,$(CH_2CH_3)_2$), 1.33(6H,s,$C(CH_3)_2$), 1.69 (2H,s,CCH_2C), 3.39 (4H,s,$(CH_2CH_3)_2$)), 4.64 (2H,s,OCH_2CO), 6.86 (2H,d,O-ArH), 7.27 (2H,d,C-ArH).

2.2. Distribution equilibria

An organic solution was prepared by diluting each extractant into an analytical grade of chloroform to a desired concentration. An aqueous solution was prepared by dissolving metal salts to a desired concentration into aqueous hydrochloric acid or nitric acid solution. Chloroauric acid was employed as a gold salt. Equal volumes (10 cm^3) of both phases were mixed and vigorously shaken at 30°C for more than 48 h, which was sufficient enough to attain equilibrium in a preliminary experiment. After phase separation, the concentration of proton in the aqueous phase was determined by neutralization titration with sodium hydroxide aqueous solution using phenolphthalein as an indicator or by using a pH meter (Beckman, ϕ-45). Concentrations of metal ions were measured by atomic absorption spectrometer (Seiko Instruments, SAS-7500) and inductively coupled plasma atomic emission spectrophotometer (Shimadzu, ICPS-2000). The amount of extracted metal ions were calculated from the differences of the metal concentrations in the aqueous phase between before and after the extraction.

2.3. Proton nuclear magnetic resonance study

An organic sample solution was prepared by dissolving 1_4 into an analytical grade of deuterium chloroform to a desired concentration. An aqueous solution was prepared by dissolving silver nitrate or sodium nitrate into an analytical grade of deuterium oxide or distilled water. The initial concentration of sodium and silver were appropriately adjusted. Both phases were mixed and vigorously shaken at 30°C for more than 48 h. After phase separation, the peaks of $\mathbf{1_4}$ in the organic phase were measured by proton nuclear magnetic resonance spectrometer (Jeol, JNM-GX270).

3. Results and discussion

3.1. Distribution equilibria in the extraction from nitrate media

The effects of the concentration of nitric acid on percentage extraction of gold(III), silver(I), palladium(II) and platinum(IV) with $\mathbf{1_4}$ and $\mathbf{1_1}$ are shown in Fig. 2a and b, respectively. With $\mathbf{1_4}$, gold was quantitatively extracted over the whole concentration region of nitric acid except for at 10 mol dm^{-3} where the extraction decreased to 80%. The percentage extraction of silver was about 80% over the whole concentration region, though it reached about 100% at 10 $moldm^{-3}$. Palladium was extracted to the extent of only about 15% in the concentration region less than 4 $moldm^{-3}$ while it abruptly increased up to 100% in the region greater than 4 $moldm^{-3}$. The extraction of platinum was not observed in the concentration region greater than 0.1 $moldm^{-3}$. On the other hand, in the extraction with $\mathbf{1_1}$, the plots of the % extraction for gold appear to lie on a convex curve having a maximum of 68% at 1 $moldm^{-3}$, while the plots for silver appear to lie on concave curve having a minimum of 21% at 0.5 $moldm^{-3}$. Palladium was hardly extracted over the whole region. The extraction of platinum with $\mathbf{1_1}$ was similar to that with $\mathbf{1_4}$. As described above, the percentage extractions of all kinds of metal ions examined with $\mathbf{1_1}$ was much lower than those with $\mathbf{1_4}$, except for platinum. The higher extraction ability of $\mathbf{1_4}$ may be considered to be attributable to the following factors: size matching between the ring size of calix[4]arene and the ionic diameters of metal ions, aggregation of functional groups based on cone conformation.

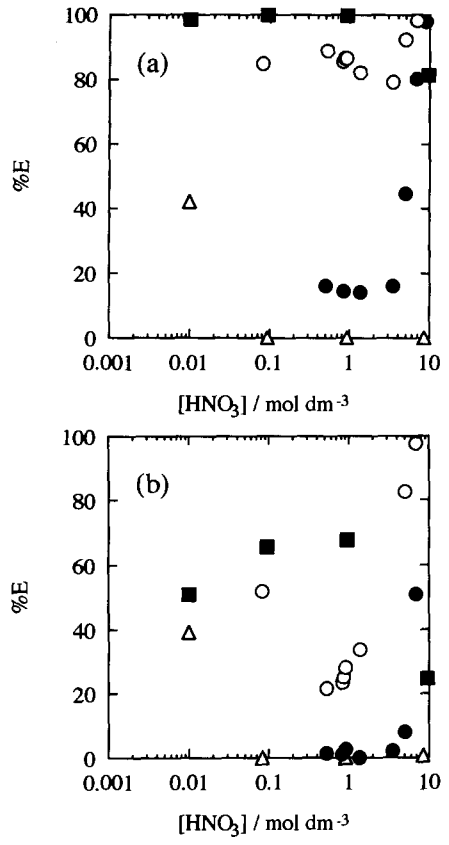


Fig. 2. Effect of the concentration of nitric acid on percent extraction. (a) $\mathbf{1}_4$; (b) $\mathbf{1}_1$; ■, gold; ○, silver; ●, palladium; △, platinum, $[\mathbf{1}_4] = 3.3 \times 10^{-3}$ moldm^{-3}, $[\mathbf{1}_1] = 1.33 \times 10^{-2}$ moldm^{-3}, $[Au^{3+}] = [Ag^{+}] = [Pd^{2+}] = [Pt^{4+}] = 1.0 \times 10^{-4}$ moldm^{-3}.

3.2. Distribution equilibrium in chloride media

The effects of hydrochloric acid concentration on percentage extraction of precious metals with $\mathbf{1}_4$ and $\mathbf{1}_1$ are shown in Fig. 3a and b, respectively. In the extraction of silver, since great majority was precipitated in the hydrochloric acid concentration region less than 3 moldm^{-3}, lithium chloride was added so as to maintain the total chloride concentration constant at 3 moldm^{-3} in the region of hydrochloric acid less than 3 moldm^{-3} to prevent the formation of the precipitate. In nitrate media, although the large difference in the extraction ability was observed between monomeric and tetrameric extractants, the order of selectivity for precious metals was the same between these two regents. In chloride media, however, the drastic change in the extraction of gold and silver ions was observed between $\mathbf{1}_4$ and $\mathbf{1}_1$. The tetrameric $\mathbf{1}_4$ can quantitatively extract gold, while the monomeric $\mathbf{1}_1$ scarcely extract gold over the whole concentration region of hydrochloric acid except for 10 moldm^{-3}, where gold was quantitatively extracted. Concerned with silver, although the percentage extraction with the tetramer is constant in the hydrogen ion concentration region less than 3 moldm^{-3} since total chloride ion concentration is maintained constant at 3 moldm^{-3}, it decreases with the increase of chloride concentration in the region greater than 3 moldm^{-3}, attributable to the suppression of ex-

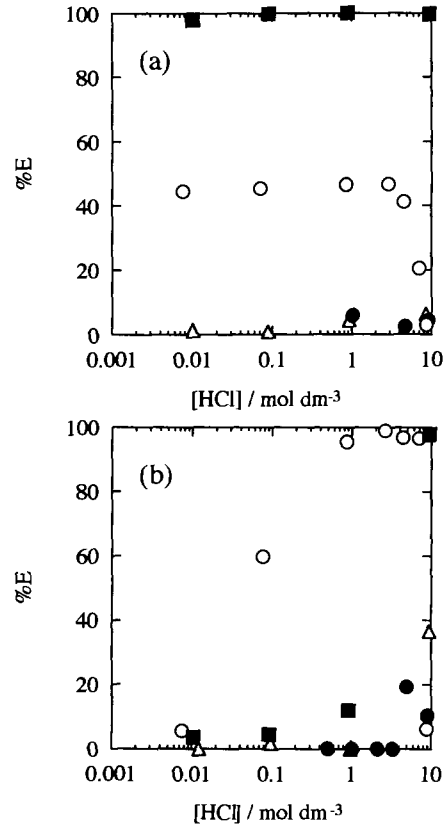

Fig. 3. Effect of the concentration of hydrochloric acid on percent extraction. (a) $\mathbf{1}_4$; (b) $\mathbf{1}_1$; ■, gold; ○, silver; ●, palladium; △, platinum; $[\mathbf{1}_4] = 3.3 \times 10^{-3}$ moldm^{-3}; $[\mathbf{1}_1] = 1.33 \times 10^{-2}$ moldm^{-3}; $[Au^{3+}] = [Ag^{+}] = [Pd^{2+}] = [Pt^{4+}] = 1.0 \times 10^{-4}$ moldm^{-3}.

traction due to the complexation of silver ion with chloride anions. Contrarily, the % extraction of silver with the monomeric analog increases with the increase of proton concentration, and attains to 100% extraction in the concentration region greater than 1 moldm^{-3}, though it abruptly and drastically decreases to nearly 0% at 10 moldm^{-3}. This extraction behavior is similar to the extraction of anionic metal complexes with protonated extractant such as high-molecular-weight amines, suggesting that the monomeric analog extracts silver as anionic species.

In order to clarify the extremely different extraction behavior between these two extractants, further experiment was carried out for silver ion in particular. The effect of the concentration of proton on percentage extraction of silver ion with $\mathbf{1}_4$ and $\mathbf{1}_1$ was compared in Fig. 4a and b, respectively. As described above, since the precipitate was formed in the concentration region of hydrochloric acid below 3 moldm^{-3}, lithium chloride was added so as to keep the chloride concentrations constant at 5 and 3 moldm^{-3} in the experiment of Fig. 4a and b, respectively. In the chloride concentration region above 5 or 3 moldm^{-3}, hydrochloric acid was added to increase proton and chloride concentration as in the previous case. The decrease of the added amount of chloride ion from 5 to 3 moldm^{-3} increases the percentage extraction of silver ion with $\mathbf{1}_4$, while only slightly decreased with $\mathbf{1}_1$, indicating the opposite extraction behavior between $\mathbf{1}_4$ and $\mathbf{1}_1$. As mentioned earlier, the difference in the extraction behavior is attributable to the difference in the species of silver extracted with each extractant. That is, since the calix[4]arene derivative $\mathbf{1}_4$ is suggested to extract silver ion as cationic species, the extraction is suppressed by the complexation of silver ion with chloride ion to form anionic species with the increase of chloride concentration. On the other hand, since the monomeric derivative $\mathbf{1}_1$ is considered to extract metals as anionic species, the percent extraction increases with the increase of chloride concentration in low acidic region, and it also increases with the increase of the concentration of the protonated extractant in highly acidic region. This result shows that the difference of the silver species

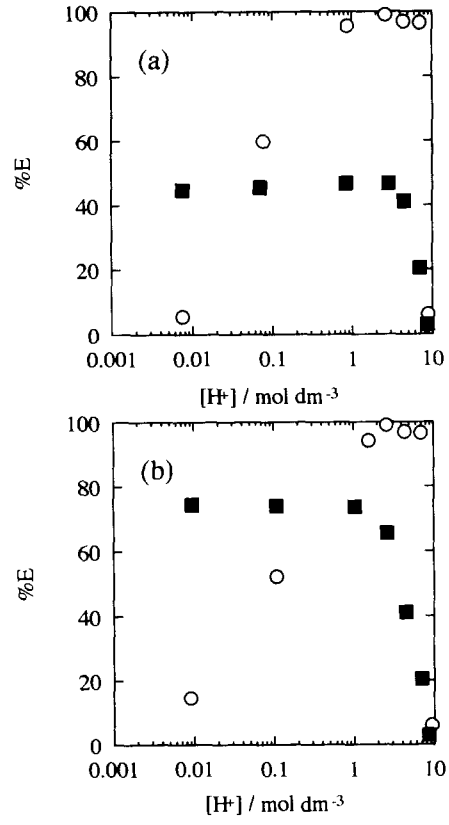

Fig. 4. Effect of the concentration of proton on percent extraction of silver ion with $\mathbf{1}_4$ and $\mathbf{1}_1$. (a) 5 moldm^{-3} of chloride ion and (b) 3 moldm^{-3} of chloride ion in the low hydrochloric acid concentration ■, $\mathbf{1}_4$; ○, $\mathbf{1}_1$; $[\mathbf{2}_4] = 3.3 \times 10^{-3}$ moldm^{-3}; $[\mathbf{2}_1] = 1.33 \times 10^{-2}$ moldm^{-3}; $[Ag^+] = 1.0 \times 10^{-4}$ moldm^{-3}.

extracted depends on whether the structure of the extractant is cyclic or acyclic and on the fitting between cyclic size and ionic radius in the case of cyclic compound.

The extraction of gold (III) ion with the amide extractants $\mathbf{1}_4$ and $\mathbf{1}_1$ shown in Fig. 3a and b seems to exhibit more significant difference of the metal species extracted. That is, the calix[4]arene derivative $\mathbf{1}_4$ and the monomeric derivative $\mathbf{1}_1$ are considered to extract gold as cationic and anionic species, respectively, similarly to the extraction of silver. However, different from the extraction of silver, the extraction of gold with the calix[4]arene derivative $\mathbf{1}_4$ is hardly suppressed by the complexation of gold ion with chloride ion due to the

strong affinity of gold ion with $\mathbf{1}_4$. The extraction of gold with the monomeric derivative $\mathbf{1}_1$ is very poor in the region of hydrochloric acid concentration less than 1 moldm^{-3}, while quantitatively extraction was observed at 10 moldm^{-3}. Thus, gold was suggested to be easily extracted as cationic species and to be scarcely extracted as anionic species less than 1 moldm^{-3} with $\mathbf{1}_4$ not with $\mathbf{1}_1$, and was extracted as anionic species at 10 moldm^{-3} with $\mathbf{1}_1$.

3.3. Dependency of the extraction of silver ion on the extractant concentration

The effect of the extractant concentration on the extraction of silver ion was examined for the purpose of clarifying the stoichiometry of the extracted complex as shown in Fig. 5. The plots for $\mathbf{1}_4$ appear to lie on a straight line with the slope of 1, while those for $\mathbf{1}_1$ appear to lie on a straight line with the slope of 2, suggesting the numbers of the molecules of the reagent species which takes part in the extraction of the silver ion to be 1 and 2 for $\mathbf{1}_4$ and $\mathbf{1}_1$, respectively.

3.4. Proton nuclear magnetic resonance study for the complex of 1_4 and silver ion

As the amide $\mathbf{1}_4$ effectively extracted silver ion as well as the tetrameric ketonic derivative [7,8],

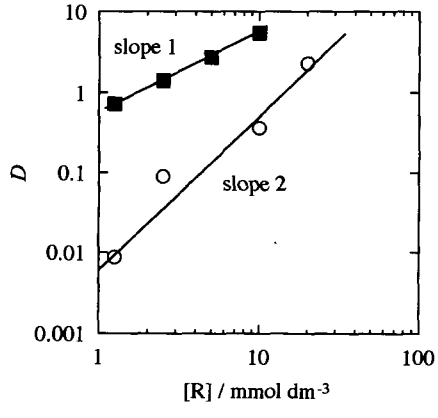

Fig. 5. Effect of the extractant concentration on percent extraction of silver ion with $\mathbf{1}_4$ and $\mathbf{1}_1$. ■, $\mathbf{1}_4$; ○, $\mathbf{1}_1$; [HCl] = 1 moldm^{-3}; [Ag$^+$] = 1.0×10^{-4} moldm^{-3}.

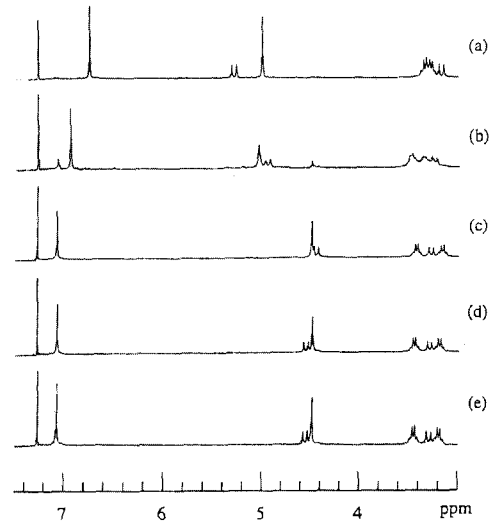

Fig. 6. Partial proton nuclear resonance spectra of $\mathbf{1}_4$. [$\mathbf{1}_4$] = 2.0×10^{-3} moldm^{-3}; $D_2O/CDCl_3$ = (1 cm^3/1.6 cm^3); (a) original, contacting with; (b) 5 moldm^{-3} hydrochloric acid solution; (c) 0.4 moldm^{-3} sodium ion in 1 moldm^{-3} hydrochloric acid solution; (d) 0.16 moldm^{-3} silver ion in 5 moldm^{-3} nitric acid solution; (e) 0.08 moldm^{-3} silver ion in deuterium oxide.

the participation of carbonyl groups in the extraction reaction should be taken into consideration. However, the extraction behavior of the monomeric derivative suggested the participation of the protonated form of the extractant in the extraction reaction in highly acidic region. In order to clarify the participation of the carbonyl groups and the protonation of the $\mathbf{1}_4$, the proton nuclear magnetic resonance study was also conducted. The partial proton nuclear magnetic resonance spectra of $\mathbf{1}_4$ was shown in Fig. 6. The chemical shifts for the peaks of $\mathbf{1}_4$ was observed in the sample prepared by only contacting with hydrochloric acid solution, suggesting the protonation of $\mathbf{1}_4$, since, as is well-known, amide compounds are protonated at carbonyl oxygens in highly acidic region. The addition of silver ion caused further chemical shifts of $\mathbf{1}_4$ through the extraction. The addition of sodium ion also caused similar shifts. However, the shifted peaks of ketonic derivative which extracted silver ion

appeared at approximately the same position as those which extracted sodium ion, whereas the position of the shifted peaks of amide derivative which coordinated silver ion was partially different from that which coordinated sodium ion. Therefore, it can be considered that the coordination of silver and sodium ions takes place at same sites with the ketonic derivative, while it takes place at slightly different sites with the amide $\mathbf{1}_4$. Since the peaks assigned to aryl proton were hardly shifted, the difference between the ketonic and amide extractants was considered to be attributable to that of the participation of carbonyl groups of amide compound and ketonic compounds to the coordination to metal ions; but, further detailed investigation should be conducted on this respect.

3.5. Extraction mechanism of silver

According to the above-mentioned experimental results, the extraction reactions of silver (I) were inferred to be expressed as follows; For $\mathbf{1}_4$,

$$H_4R^{4+}4Cl^- + AgCl_3^{2-} = RAg^+Cl^- + 6Cl^- + 4H^+ \quad (1)$$

,and for $\mathbf{1}_1$

$$2(HR^+Cl^-) + AgCl_3^{2-} = (HR)_2^+AgCl_3^{2-} + 2Cl^-. \quad (2)$$

where $H_4R^{4+}4Cl^-$ and HR^+Cl^- denote the protonated $\mathbf{1}_4$ and $\mathbf{1}_1$, respectively. Since the protonation of the extractant 1_4 was supported by the proton nuclear magnetic resonance study as described above, the extraction of silver ion with calixarene derivative is suppressed not only with the increase of the proton concentration but also with that of the chloride concentration.

The proposal structures of the complexes of silver ions formed with the extractants $\mathbf{1}_4$ and $\mathbf{1}_1$ are shown in Fig. 7a and b. The ionic diameter of silver (I) is about 1.94Å which fits for the ring size of calix[4]arene. However, the diameters of the chloride complexes of silver are much greater than that of the cationic species and no longer fits for the size of the calix[4]arene. Thus, the remarkably great difference of the specific extraction behavior between monomeric and tetrameric derivatives was suggested to be attributable to the fact that calix[4]arene derivative can extract silver ion only as a cationic species.

Abstract

Lipophilic acyclic dibenzopolyether diamides, 12 kinds, have been designed to prepare solvent polymeric membrane ion-selective electrodes (ISEs) for Pb^{2+}. The ionophores include 1,5-bis[2-(*N*,*N*-dialkylcarbamoylmethoxy)phenoxy]-3-oxapentanes **1**–**4**, 1,5-bis[2-(*N*,*N*-dialkylcarbamoylpentadecyloxy)phenoxy]-3-oxapentanes **5**–**8**, and 1,2-bis[2-(2′-*N*,*N*-dialkylcarbamoylpentadecyloxy)phenoxy]ethanes **9**–**12**. Linear response concentration range of the ISE based on **9** is $3 \times 10^{-2} - 1 \times 10^{-6}$ M of Pb^{2+} (average slope = 28.5 mV decade^{-1}). Potentiometric selectivities of the ISEs based on **1**–**12** for Pb^{2+} over other heavy metal cations, alkali metal cations, and alkaline earth metal cations have been assessed. These ISEs exhibit remarkably high selectivities for Pb^{2+} relative to heavy metal cations, such as Cu^{2+}, Fe^{2+}, and Ni^{2+}, the selectivity coefficients ($K^{Pot}_{Pb,Cu}$) being $5 \times 10^{-5} - 6 \times 10^{-5}$ for **1**–**4** and ca. 6×10^{-4} for **9**. For the Pb^{2+} selectivities over alkali metal cations, such as Na^+ and K^+, **9** which has an ethylene glycol spacer and a *N*,*N*-diethyl group is superior to other dibenzopolyether diamide ionophores **1**–**8** and **10**–**12**. © 1997 Elsevier Science B.V.

Keywords: Acyclic dibenzopolyether diamides; Electrode; Lead-selective ionophore; Poly(vinyl chloride) membrane

1. Introduction

Much effort has been placed on the development of ion-selective electrodes (ISEs) for various metal cations. However, relatively a little attention has been paid to development of Pb^{2+}-selective electrodes [1]. Several solid-state Pb^{2+}-ISEs based on PbS/Ag_2S have been reported [2–8]. However, the presence of some heavy metal cations, such as Cu^{2+} and Fe^{2+}, greatly interfered with the measurement of Pb^{2+} by the solid-state ISEs.

Some polymeric membrane ISEs based on neutral carriers for Pb^{2+} have been developed. Acyclic [9,10] and cyclic [11] oxamides which show selectivities for PbX^+ (X^-: OH^-, Cl^-,

* Corresponding author.

PII S0039-9140(97)00021-0

and NO_3^-) and Pb^{2+} have been examined. Malinowska et al. reported polymeric membrane ISEs based on thioamide functionalized calix[4]arenes for which the selectivity coefficients for Pb^{2+} relative to Cu^{2+} ($K^{Pot}_{Pb,Cu}$) were $10^{-3}-10^{-4}$ [12]. Polymeric membrane ISEs based on polyalkoxylates [13] and liquid ion-exchangers [14] for Pb^{2+} have been reported. Also a Pb^{2+} selective field effect transistor (FET) was developed [15].

Recently acyclic dibenzopolyether dicarboxylic acids, such as 1,5-bis[2-(2′-carboxyheptyloxy)phenoxy]-3-oxapentane, have been prepared as selective extractants for Pb^{2+} [16,17]. These extractants exhibited excellent selectivities for Pb^{2+} over Cu^{2+}. Condensation polymerization of the acyclic dibenzopolyether dicarboxylic acids provided effective chelating resins for Pb^{2+} separation [17,18]. In our short communication, we reported the synthesis of lipophilic *N,N*-dipentylamide derivatives of the dibenzopolyether dicarboxylic acids, such as 1,5-bis[2-(*N,N*-dipentylcarbamoylmethoxy)phenoxy]-3-oxapentane, and briefly described that a polymeric membrane ISE based on the ionophore showed remarkably high Pb^{2+}/Cu^{2+} selectivity [19].

In this study, we have made solvent polymeric membrane ISEs by using 12 kinds of *N,N*-dialkylamide derivatives of the dibenzopolyether dicarboxylic acids **1**–**12** (Fig. 1) as Pb^{2+}-selective neutral carriers. Potentiometric selectivities of the ISEs for Pb^{2+} over other heavy metal cations, alkali metal cations, and alkaline earth metal cations have been assessed. The effect of the length of ethylene glycol spacer which connects two benzene-ring in the ionophores and that of the length of alkyl group in the amide end-group upon the potentiometric selectivities will be discussed.

2. Experimental

2.1. Chemicals

Poly(vinyl chloride) (PVC) with an average polymerization degree of 1100 was purchased from Wako Pure Chemical Industries (Osaka, Japan). *o*-Nitrophenyl octyl ether (NPOE) and potassium tetrakis(*p*-chlorophenyl)borate (KTpClPB) were obtained from Dojindo Laboratories (Kumamoto, Japan). Metal nitrates including $Pb(NO_3)_2$ and tetrahydrofuran (THF) were reagent-grade chemicals. Deionized water was prepared by passing distilled water through an Organo G-10 cartridge.

Acyclic dibenzopolyether diamides with diethylene glycol spacers **4** and **8** are known compounds [19]. Other compounds **1**–**3**, **5**–**7**, and

Fig. 1. Structures of dibenzopolyether diamides.

9–12 were prepared by adaptation of the reported compounds and their analytical data were provided elsewhere [20].

2.2. Preparation of PVC membranes

PVC (50 mg), NPOE (100 mg), the dibenzopolyether diamide (5.0 mg), and KTpClPB (1.0 mg) were dissolved in 1.5 ml of THF. An aliquot of the THF solution was poured onto a porous polytetrafluoroethylene (PTFE) membrane attached to a PVC tube and the solvent was allowed to evaporate for 15–20 min. Addition of the THF solution and evaporation were repeated eight or nine times. The resulting PVC tube with the coated PTFE membrane was fixed on a Denki Kagaku Keiki (DKK, Tokyo, Japan) number 7900 electrode body. An internal filling solution of 1 mM $PbCl_2$ was added to the electrode. The electrode was conditioned by soaking in a 1 mM Pb $(NO_3)_2$ solution for 12 h before use.

2.3. Measurements

Potentiometric measurements with a membrane electrode were carried out at 24–25°C with a voltage meter (DKK PHL-40 pH meter), a double junction Ag-AgCl reference electrode (DKK number 4083), and a magnetic stirrer to agitate the sample solution. The electrode cell was Ag-AgCl/1 mM $PbCl_2$/PVC membrane/sample solution/0.1 M $MgCl_2$/3 M KCl/Ag-AgCl. Single ion activities were obtained as described in our previous paper [21]. The selectivity coefficient ($K^{Pot}_{Pb,M}$) for Pb^{2+} over other metal cations were determined by the Fixed interference method [22]. The constant background concentration was made by the addition of 0.01–0.1 M of interfering metal nitrates.

3. Results and discussion

Acyclic dibenzopolyether diamides **1–12** were incorporated into solvent polymeric membranes in which PVC was the polymer and NPOE was the membrane solvent. For the ISEs prepared from these membranes, potentiometric selectivities for Pb^{2+} relative to other heavy metal cations, alkali metal cations, and alkaline earth metal cations were determined by the Fixed interference method [22].

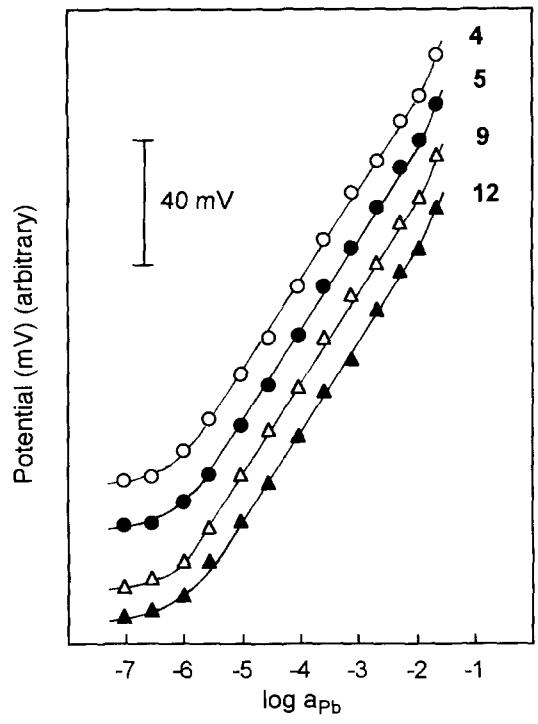

Fig. 2. Potential responses of ISEs based on **4**, **5**, **9** and **12** to the change of Pb^{2+} activity. $Pb(NO_3)_2$ solution was used.

3.1. Response of ISEs based on dibenzopolyether diamides

Typical responses of ISEs based on **4**, **5**, **9** and 12 to the change of Pb^{2+} activity are shown in Fig. 2. Nernstian responses or near Nernstian responses (average slope = 28.5 mV decade^{-1}) were observed for all of those ISEs in the ranges of $3 \times 10^{-2} - 1 \times 10^{-6}$ M for **9** and $3 \times 10^{-2} - 3 \times 10^{-6}$ M for **4**, **5** and **12**. It is found that dibenzopolyether diamides which have diethylene glycol spacers and ethylene glycol spacers provide good responses for Pb^{2+}. Other dibenzopolyether diamides **1–3**, **6–8**, **10** and **11**, gave similar good responses.

3.2. Potentiometric selectivities of dibenzopolyether diamides with diethylene glycol spacers

Selectivity coefficients expressed as $\log K^{Pot}_{Pb,M}$ for ISEs based on **1–4** are presented in Fig. 3. Compounds **1–4** are *N,N*-dialkylamide derivatives of 1,5-bis[2-(carboxymethoxy)phenoxy]-3-oxapentane. It was reported that the dibenzopolyether dicarboxylic acid exhibited a good selectivity for Pb^{2+} relative to Cu^{2+} in solvent extraction (ca. 100-fold selectivity in the extraction constant K_{ex}) [16]. The $\log K^{Pot}_{Pb,Cu}$ values of ISEs based on **1–4** are more negative than -4, which means the dibenzopolyether diamides have remarkably high selectivities for Pb^{2+} over Cu^{2+}.

Similarly the ISEs based on **1–4** exhibit quite high selectivities for Pb^{2+} relative to some divalent heavy metal cations, the $\log K^{Pot}_{Pb,M}$ values being -3.9– -4.7 for $M = Fe^{2+}$ and -3.6– -3.9 for $M = Ni^{2+}$. However, the selectivities for Pb^{2+} over alkali metal cations, such as Na^+ and K^+, for the ISEs are not good. The $\log K^{Pot}_{Pb,M}$ values are 0–0.1 when $M = Na^+$ and -0.7– -0.6 when $M = K^+$.

Compounds **1–4** are homologs which have ethyl, propyl, butyl, and pentyl groups, respectively, as *N,N*-dialky groups in the amide end-group. The selectivities for Pb^{2+} are not much dependent on the length of the alkyl group for most of interfering cations. However, lengthening the alkyl group from ethyl to pentyl provides

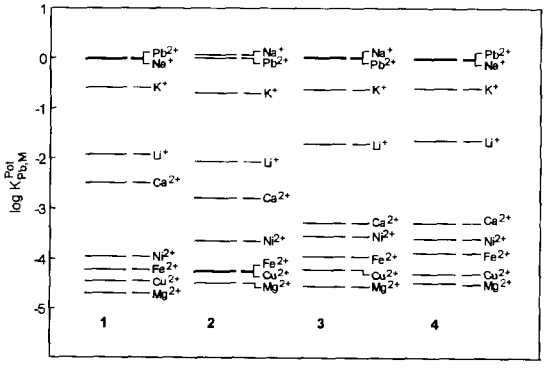

Fig. 3. Potentiometric selectivities expressed as $\log K^{Pot}_{Pb,M}$ of ISEs based on **1–4** for Pb^{2+} over other metal cations.

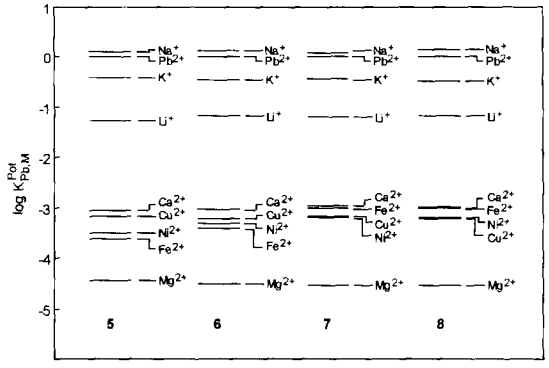

Fig. 4. Potentiometric selectivities expressed as $\log K^{Pot}_{Pb,M}$ of ISEs based on **5–8** for Pb^{2+} over other metal cations.

some increase in the Pb^{2+}/Ca^{2+} selectivity (0.8 unit in the $\log K^{Pot}_{Pb,Ca}$); whereas the same lengthening lowers the Pb^{2+}/Fe^{2+} selectivity (0.8 unit in the $\log K^{Pot}_{Pb,Fe}$).

Compounds **5–8** are tetradecyl-attached derivatives of **1–4** at the β-position of carbonyl group. The $\log K^{Pot}_{Pb,M}$ values of ISEs based on **5–8** are summarized in Fig. 4. Compared with **1–4**, the $\log K^{Pot}_{Pb,Cu}$ values for **5–8** are more positive by 1.0–1.1 unit. It appears that attachment of the long alkyl group reduces the Pb^{2+}/Cu^{2+} selectivity. This tendency is also observed for the Pb^{2+}/Fe^{2+} selectivity. The $\log K^{Pot}_{Pb,Fe}$ values for **5–8** are more positive than those for **1–4** by 0.9–1.1 unit. The Pb^{2+} selectivities over Na^+ and K^+ for **5–8** are about the same as those for **1–4**.

3.3. Potentiometric selectivities of dibenzopolyether diamides with ethylene glycol spacers

Compounds **9–12** possess ethylene glycol spacers which connect two benzene-ring instead of diethylene glycol spacers in **5–8**. The $\log K^{Pot}_{Pb,M}$ values of ISEs based on **9–12** are summarized in Fig. 5.

Compared with **5** which has a diethylene glycol spacer and a *N,N*-diethyl group, the $\log K^{Pot}_{Pb,M}$ values for **9** are more negative by 0.5 unit when $M = Li^+$, 1.3 unit when $M = Na^+$, and 0.8 unit when $M = K^+$. It is anticipated that the introduction of ethylene glycol spacer enhances the selectivities for Pb^{2+} relative to the alkali metal

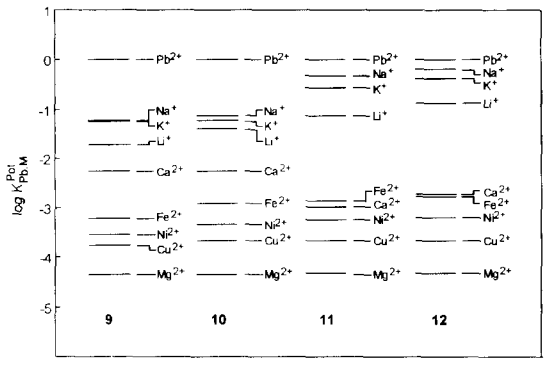

Fig. 5. Potentiometric selectivities expressed as log $K^{Pot}_{Pb,M}$ of ISEs based on **9**–**12** for Pb^{2+} over other metal cations.

cations. Lengthening the alkyl group in the amide end-group from ethyl to pentyl reduces the selectivities for Pb^{2+} relative to alkali metal cations by 0.9, 1.1, and 0.9 units in the values of log $K^{Pot}_{Pb,Li}$, log $K^{Pot}_{Pb,Na}$ and log $K^{Pot}_{Pb,K}$, respectively.

Also the introduction of ethylene glycol spacer provides an increase in the Pb^{2+}/Cu^{2+} selectivities by 0.4–0.6 unit in the log $K^{Pot}_{Pb,Cu}$ value. It is proposed that ethylene glycol spacers are good for the Pb^{2+} complexation compared with diethylene glycol spacers.

Taking into account the high selectivities for Pb^{2+} over alkali metal cations, such as Na^+ and K^+, as well as over heavy metal cations, compound **9**, which has an ethylene glycol spacer and a *N*,*N*-diethyl group, seems excellent as a Pb^{2+}-selective neutral carrier for polymeric membrane ISE. The log $K^{Pot}_{Pb,Cu}$ value for **9** is -3.8 which is somewhat worse than those for **1**–**4**; whereas the selectivity is still much superior to those for solid-state ISEs [3,5]. The ISE based on **9** show almost constant response (slope and selectivity) over 3 months with measurement every 2 or 3 days.

Short communication

On the feasibility of using molecularly imprinted poly (Hema) as a sensor component

K. Sreenivasan

Biomedical Technology Wing, Sree Chitra Tirunal Institute for Medical Sciences and Technology, Poojapura, Trivandrum 695 012, India

Received 8 September 1995; received in revised form 28 November 1996; accepted 6 December 1996

Keywords: Feasibility; Molecularly imprinted poly (Hema); Sensor component

1. Introduction

The recent years have witnessed a considerable growth in the usage of sensors for the detection of clinically and industrially relevant molecules. To achieve specificity, sensors normally employ molecules of biological origin like enzymes. The poor stability together with the high cost are perhaps the major drawbacks of the sensors containing biomolecules.

The systems based on stable chemicals, though look attractive, may not be specific which is indeed the most crucial factor of a sensor. The technique of molecular imprinting has emerged as a powerful method to impart specificity in common synthetic polymers [1–3]. During the last few years several molecularly imprinted polymers have been synthesised for a variety applications. The high degree of selectivity and specified functionality of this class of polymers have been demonstrated in several studies [4–7]. In spite of all these studies, however, the studies related to the use of molecularly imprinted polymers as sensor component have leastly been reported [8].

Normally molecularly imprinted polymers (MIPs) are synthesised either by thermal initiators or by photo polymerisation [9]. In both cases extra components are added as polymerisation aids. These additives may interfere with the rearrangement of monomers around the print molecules subsequently affecting the density of recognition sites. We have recently synthesised MIPs using—radiation method [10,11]. The radiation process appears to be more effective and simpler than the other methods.

The report discusses our preliminary results on the feasibility of using MIP as a sensing element. Radiation polymerised poly (2 hydroxy ethyl methacrylate) molecularly imprinted for the recognition of salicylic acid, is used in this study as a sensing component for sensing salicylic acid in urine.

PII S0039-9140(96)02204-7

2. Experimental

2-hydroxy ethyl methacrylate (HEMA) and ethylene glycol dimethacrylate (EDMA), obtained from Sigma Chemicals, St. Louis, USA were used after removing the stabiliser by vacuum distillation. All other chemicals (chromatographic grade or analytical grade) were obtained from EMerck, Bombay, India.

3. Synthesis of MIP

2 g HEMA, 300 mg salicylic acid and 1 g EDMA were dissolved in 10 ml methanol. The solution was placed in a polyethylene container, purged with nitrogen, sealed and subjected to γ-irradiation from a Co^{60} source (Panoramic batch irradiator, BARC, Bombay) to a total dose of 0.5 Mrad at a rate 0.25 Mrad/h. The polymer in the form of a film having a thickness of 0.1 mm was taken out and washed extensively used water followed by methanol for removing salicylic acid and unpolymerised monomer if any. The complete removal of salicylic acid was ensured prior to the use of the polymer for further studies. HEMA was also polymerised under the similar conditions without adding the print molecules (salicylic acid) to serve as control. Phthalic acid was used as a molecule of comparable shape and structure of salicylic acid to check the specificity of the MIP towards salicylic acid.

4. Instrumental

A Waters Assoc. High performance liquid chromatographic system consisting of a model 6000A solvent delivery pump model U6K injector and a model 486 tunable absorbance detector was used for the chromatographic studies. A μ-Bondapak C_{18} column in conjunction with methanol:water (90:10 v/v) was used as mobile phase at a flow rate of 1 ml min^{-1} for the chromatographic estimation of salicylic acid and phthalic acid. The column effluents were monitored at 236 and 254 nm for the estimation of salicylic acid and phthalic acid, respectively. The chromatograms were obtained on an omini scribe strip chart recorder (Houston Instruments, TX, USA).

5. Method

Standard solutions of salicylic acid in urine were prepared by dissolving appropriate amount of salicylic acid in freshly collected human urine. The solutions were filtered using 0.45 μm filters. Solutions of phthalic acid were also prepared in a similar fashion.

About 40 mg MIP was placed in 5 ml solution for 30 min at room temperature (26 ± 0.1°C). Calibration plot was constructed between the concentration and peak height of salicylic acid. The urine solutions were subjected to chromatographic analysis before and after placing the MIP. The amount of salicylic acid in the solutions were estimated using the peak height on the calibration plot. The difference in concentration of salicylic acid before and after placing MIP is taken as the amount of salicylic acid adsorbed by the polymer. Poly (HEMA) prepared under similar experimental conditions without print molecule was used as control. The extent of uptake of phthalic acid was also monitored by the chromatographic procedure as mentioned earlier.

6. Results and discussion

Table 1 summarises the extent of uptake of salicylic acid by MIP and control polymer. The amount of salicylic acid adsorbed by the control polymer is negligibly small. It may be reasonable to presume that salicylic acid molecules might

Table 1

14	2.6
18	3.5
20	3.7

Table 2
Extent of uptake of phthalic acid by MIP and control polymer

Amount adsorbed by MIP (μg)	Amount adsorbed by control (μg)
0.92	1.06
1.40	1.38
1.81	1.90

have trapped in the porous structure of the control polymer comparatively the higher uptake of salicylic acid by the MIP clearly point out the creation of recognition sites in the polymer. The sites favour the selective interaction of salicylic acid leading to the increased adsorption.

It is mandatory that a sensing element should have high degree of selectivity. In this study we used phthalic acid as a molecule of comparable features of salicylic acid. The uptake of phthalic acid by MIP and control polymer is summarised in Table 2. It can be seen that there is not considerable variation in the extent of adsorption of this molecule by MIP and control poly (HEMA). Indeed a small quantity of phthalic acid is adsorbed by MIP which is comparable with the amount of phthalic acid adsorbed by the control polymer forcing to conclude that the component is simply trapped in the polymer matrix. By comparing the extent of adsorption of salicylic acid and phthalic acid by MIP and control poly (HEMA), we could conclude that MIP does not have any specific affinity towards phthalic acid and this data further suggest that imprinted poly (HEMA) has a specific, recognising ability.

It is found that the equilibrium swelling of MIP and control poly (HEMA) in methanol are very less ($< 0.8\%$) by reflecting the extensive cross linking leading to the formation of rigid matrices. Moreover, nearly identical swelling of both MIP and control polymer (Equilibrium swelling of MIP—0.76%) point out that both these polymers have a nearly identical morphology.

Concentration dependent functionality is one of the prime factor of any sensing device. The uptake of salicylic acid vary as a function of concentration. This aspect is highlighted in Fig. 1. The extent of adsorption of salicylic acid is linear up to 300 μg ml^{-1} which is indeed higher than the normal concentration of drugs in a biological matrix like urine. The linearity up to this concentration, in fact, indicates that the MIP based system could be used as a sensing element.

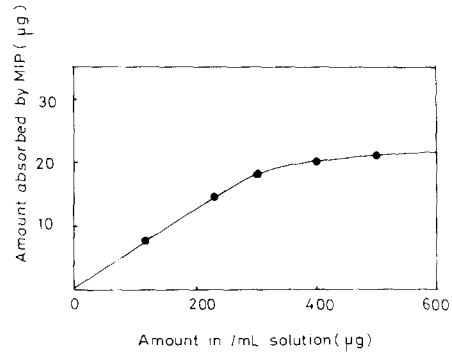

Fig. 1. A graphical representation of the extent of uptake of salicylic acid by MIP as a function of concentration.

The absorbed salicylic acid can completely be removed from the MIP by simply extracting with methanol reflecting the feasibility of reusing the MIP in a continuous manner.

The poor stability is the major drawback of any sensing element containing a biomolecule which is one of the additional advantage of MIP.

An ideal sensor should have high degree of selectivity together with the ability to visualise the event of binding of the molecule to be detected in the form of a visual colour change. This eventuality may be possible by incorporating additional reagents in the MIP which would be addressed in our forthcoming publications.

The results presented here are highly preliminary. Our aim is just to demonstrate the feasibility of employing MIPs in sensor construction. Further extensive studies are needed to optimise these synthetic systems to employ routinely in sensors.

Received 20 June 1996; received in revised form 19 August 1996; accepted 20 August 1996

Abstract

A simple and very sensitive kinetic fluorimetric method is reported for the determination of trace amount of thiocyanate. The proposed method is based on the inhibition effect of thiocyanate on oxidation of rhodamine 6G by potassium bromate in sulfuric acid solution. The detection limit for thiocyanate is 1.63×10^{-6} mmol/l. The linear range of the determination is 4.82×10^{-6}–4.13×10^{-5} mmol/l. This method has been used to determine trace thiocyanate in urine and saliva of smokers and non-smokers. The results obtained are satisfactory. © 1997 Elsevier Science B.V.

Keywords: Body fluids; Inhibition; Kinetic fluorimetric method; Rhodamine 6G; Thiocyanate

1. Introduction

Thiocyanate is present in the human body as a metabolic degradation product of sulphur-containing compounds in tobacco. It is a detoxication product of cyanide and its content is higher in the body fluids of smokers. For this reason the concentration of thiocyanate has been considered to be a good indicator for distinguishing between smokers and non-smokers [1–3].

Thiocyanate is also administered as a drug in the treatment of thyroid conditions. In addition, the higher concentration of thiocyanate in the human body will lead to vertigo or unconciousness. Therefore, an accurate and reliable method for the determiantion of thiocyanate in biological sample is of medical interest.

Several methods for the determination of thiocyanate have been published. The spectrophotometric method is mainly based on the formation of the red iron(III)-thiocyanate complex [4,5]. It can meet the requirment of sensitivity for the determination of thiocyanate in body fluids, but does not possess sufficient selectivity. Flow injection method [2] is rapid and simple, but its sensitivity is lower. It can't meet other applications which require high sensitivity. The other methods such as linear sweep polarography [6], ion-selective electrodes [7,8], pulse-polarography [9] and gas chromatography [10,11] were also used for the determination of thiocyanate. Unfortunately, most of these methods are laborious to perform and involve use of hamful reagents. Also, some of those need more expensive instruments so that they can not easily be popularized.

PII S0039-9140(96)02080-2

So far there is only one report on the determination of thiocyanate by catalytic fluorimetric photometry [12]. It is based on the catalytic effect of thiocyanate on oxidation of As(III) by Ce(IV). However, the compound of As(III) is toxic and therefore unfavourable for environmental reasons. Furthermore, the sensitivity of this method has been unsatisfactory.

In this work, a detailed study of the appropriate conditions for the inhibition effect of thiocyanate on the oxidation of rhodamine 6G by potassium bromate and of the best reagent concentration have been conducted. On the basis of this, a new way for the determination of trace thiocyanate with high sensitivity and selectivity was proposed. The method is simple, rapid and reliable. Its detection limit is 1.63×10^{-6} mmol/l, which is lower than that of any other method reported in the literature. This method has been applied for the determination of thiocyanate in urine and saliva of smokers and non-smokers. The result is satisfactory.

2. Experimental

2.1. Reagents and instruments

2.1.1. Thiocyanate solution

The solution was prepared from the potassium thiocyanate and standardized with standard silver nitrate solution by Volhard method [13]. The standardized concentration of thiocyanate is 1.0×10^{2} mmol l^{-1}. Working standards were prepared by suitable dilution.

Rhodamine 6G solution: 0.1 mmol l^{-1};

Potassium bromate solution: 1.0×10^{2} mmol l^{-1};

Sulfuric acid solution: 5.0×10^{2} mmol l^{-1};

Sodium acetate: 2.00×10^{3} mmol l^{-1};

RF-5000 (Japan) fluorophotometer;

Model 930 (Shang hai, China) fluorophotometer;

Model 501 super constant temperature meter.

All of the reagents used in the experiment were analytical grade or guaranteed reagent. Redistilled water was used to prepare solutions.

2.2. Procedure

Add proper amount of standard thiocyanate solution, 3.00 ml of 5.0×10^{2} mmol l^{-1} sulfuric acid and 0.30 ml of 0.1 mmol l^{-1} rhodamine 6G to a 25 ml measuring flask, then dilute the solution with water to 20 ml. Then add 0.70 ml of 1.0×10^{2} mmol l^{-1} potassium bromate into the flask, dilute up to the mark before shaking. After heating the sample in a thermostatted water bath (30 ± 0.2°C) for 9 min, add 1.00 ml of 2.0×10^{3} mmol l^{-1} sodium acetate to stop the reaction. Its fluorescence value I_F and blank value I_{F0} (I_{F0} is recorded when no thiocyanate is present) were determined at an excitation wavelength of 348.4 nm and emission wavelength of 548.4 nm. Then values of $\Delta I_F = I_F - I_{F0}$ was calculated.

3. Results and discussion

Rhodamine 6G is a triphenylmenthane dye. It emits very strong yellow-green fluorescent light. When oxidized by a strong oxidizer—potassium bromate, its molecular structure is destroyed and the fluorescence disappears. When trace amounts of thiocyanate are present, this oxidation reaction is inhibited (Fig. 1, 3–3′), as shown in Fig. 1. On the basis of this, a new kinetic fluorimetric method for the determination of trace thiocyanate has been proposed and the experimental conditions have been studied.

3.1. Choice of the best experimental conditions(with thiocyanate concentration being 2.07×10^{-5} mmol l^{-1} under all conditions).

3.1.1. Choice of medium and influence of its concentration level

The following media have been tried in the proposed experiments: sulfuric acid, phosphoric acid, hydrochloric acid. It was found that the sensitivity of reaction is very low in the medium of phosphoric acid. In hydrochloric acid, the reaction is interfered seriously because of the exit of a large amount of Cl^{-}. Only in sulfuric acid, the inhibition effect of thiocyanate is striking. The sensitivity is high and the reproducibility is good.

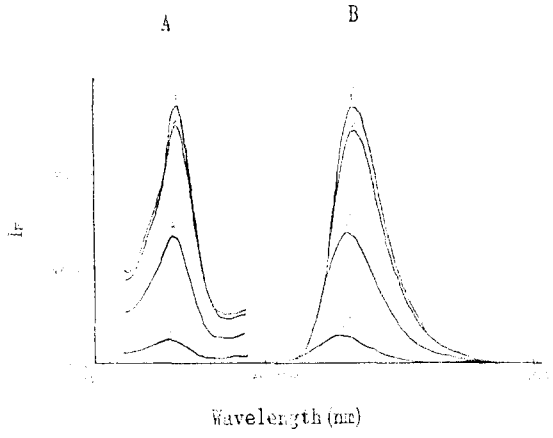

Fig. 1. Excitation (A) and emission (B) spectra of Rhodamine 6G in the presence of diferent reagents: $[SCN^-] = 3.44 \times 10^-$ 5 mM; 60 mM H_2SO_4; 1.2×10^{-3} mM Rh6G; 2.8 mM $KBrO_3$; Temperature: 30°C; Time: 9 min. 1-1′: Rh6G, H_2SO_4. 2-2′: Rh6G, $KBrO_3$. 3-3′: Rh6G, $KBrO_3$, H_2SO_4, SCN^-. 4-4′: Rh6G, $KBrO_3$, H_2SO_4. (1-1′,2-2′,3-3′,4-4′ pairs of curves were obtained through scanning different reaction systems, which were listed above).

Therefore, sulfuric acid was selected as the reaction medium.

The influence of the concentration level of 5.0×10^2 mmol l^{-1} sulfuric acid has been investigated. The results were shown in Fig. 2. It can be seen from this figure that ΔI_F value increases with

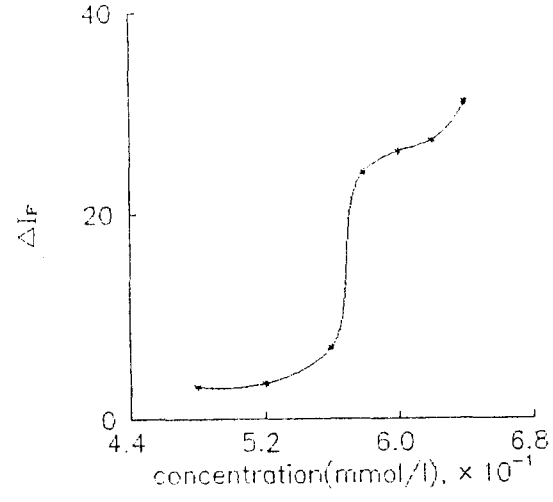

Fig. 2. Influence of sulfuric acid concentration upon I_F: 1.2×10^{-3} mM Rh6G; 2.8 mM $KBrO_3$; Temperature: 30°C; Time: 9 min.

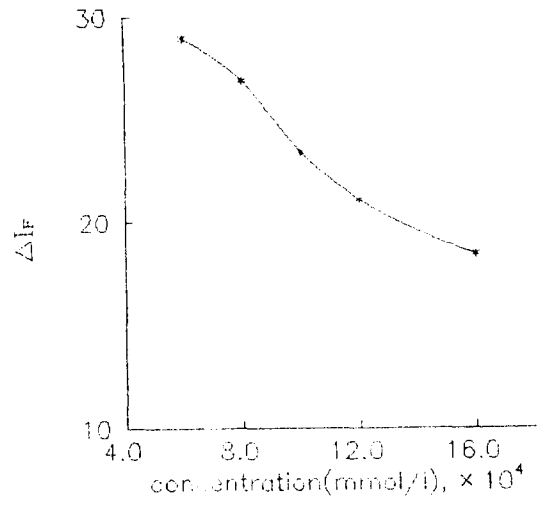

Fig. 3. Influence of Rh6G concentration upon I_F: 60 mM H_2SO_4; 2.8 mM $KBrO_3$; Temperature: 30°C; Time: 9 min.

increasing concentration of sulfuric acid. When the concentration is in the ranges of 48–56 mmol l^{-1} and 58–62 mmol l^{-1}, ΔI_F value changes slowly. But in the latter range, the sensitivity is higher. So 3.00 ml of 5.0×10^2 mmol l^{-1} sulfuric acid is chosen.

3.1.2. Influence of rhodamine 6G concentration level

Fig. 3 shows the influence of rhodamine 6G concentration upon I_F value. It is apparent that ΔI_F value decreases with increasing concentration of rhodamine 6G. On the contrary, the lower rhodamine 6G concentration is, the higher the test sensitivity is. However, the reproducibility is not good when the concentration of rhodamine 6G is low. So 0.30 ml of rhodamine 6G was used in this work.

3.1.3. Influence of concentration level of potassium bromate

The influence of potassium bromate upon I_F has been studied. The results obtained are shown in Fig. 4. Obviously, ΔI_F value increases with increasing concentration of potassium bromate. But a large amount of potassium bromate will result in bad reproducibility. So 0.70 ml of potassium bromate is best choice.

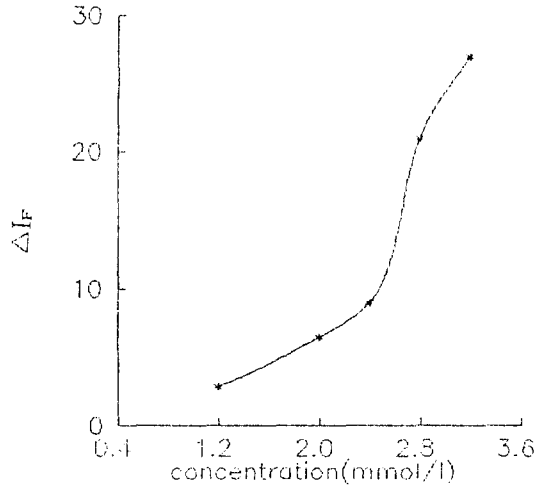

Fig. 4. Influence of potassium bromate concentration upon I_F: 60 mM H_2SO_4; 1.2×10^{-3} mM Rh6G; Temperature: 30°C; Time: 9 min.

3.1.4. Influence of reaction temperature

The effect of reaction temperature was studied in the range 20–35°. Fig. 5 shows that the reaction rate increases with increasing temperature up to 30°C. When the temperature is higher than 30°C, ΔI_F value diminishes. Thus, 30°C was used in this study.

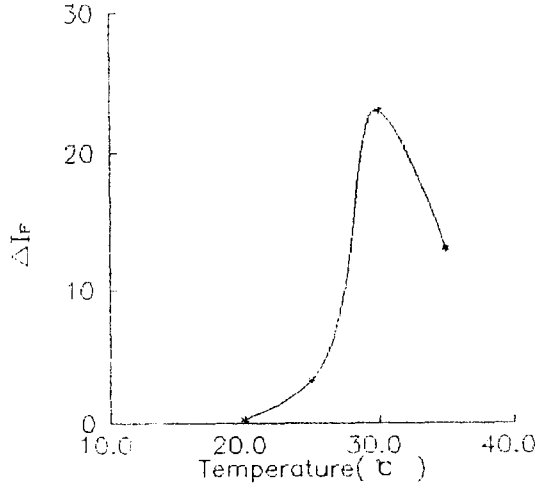

Fig. 5. Influence of temperature upon I_F: 60 mM H_2SO_4; 1.2×10^{-3} mM Rh6G; 2.8 mM $KBrO_3$; Time: 9 min.

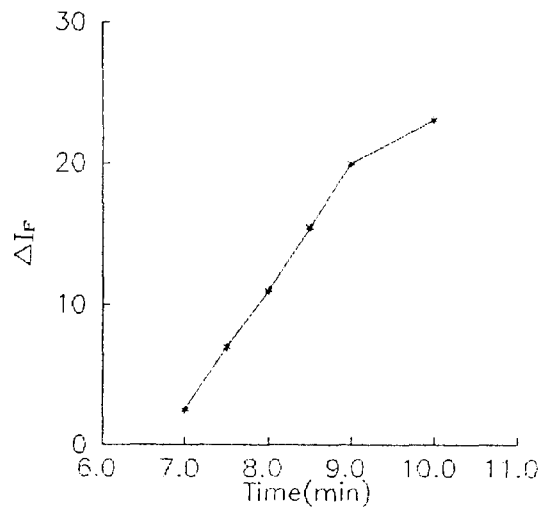

Fig. 6. ΔI_F-Reaction time curve of the system: 60 mM H_2SO_4; 1.2×10^{-3} mM Rh6G; 2.8 mM $KBrO_3$; Temperature: 30°C.

3.1.5. Influence of reaction time

The influence of reaction time upon fluorescence intensity was shown in Fig. 6. It can be seen that ΔI_F–t curve is linear in the range of 7–9 min. Thus, 9 min is taken as the reaction time.

3.1.6. The end of reaction

Considering the fact that the experiment was conducted by a fixed-time method, we have to find out an efficient way to end the reaction. In this study, the effect of PH on the reaction rate is notable. So 1.0 ml sodium acetate were added to end the reaction efficiently.

3.2. Relation between thiocyanate and I_F

According to the experimental method described above, values of I_F were determined and the calibration curve was drawn (Fig. 7). It can be seen that within the range of 4.82×10^{-6}–4.13×10^{-5} mmol l^{-1}, a linear relation was found between ΔI_F value and thiocyanate concentration. The linear equation obtained by a least-square analysis is found to be $\Delta I_F = 0.3967 + 1.065 \times 10^6$ C (mmol l^{-1}), with correlation coefficient $r = 0.9992$.

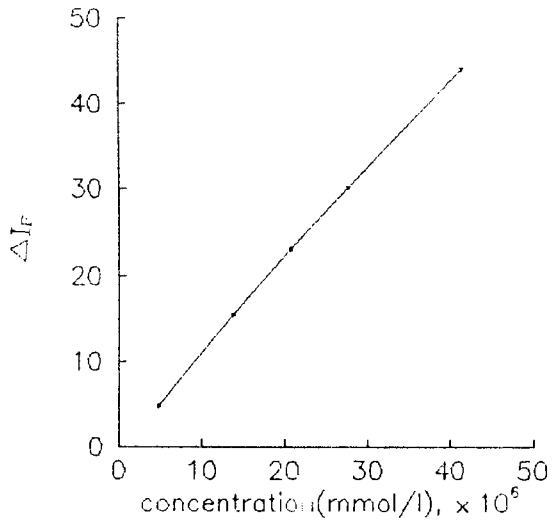

Fig. 7. Alibration graph.

3.3. Interference of coexistence ions

Under the chosen experimental conditions, an interference experiment was conducted on more than 30 common ions. When the permitted relative deviation from the I_F value is ±5%, the interference is listed in Table 1.

3.4. Sensitivity and accuracy of the method

Parallel experiments, 11, were made on the following test solutions. The results are as follows:

I_F values of the reagent blank: standard deviation S.D. = 0.58; detection limit: 1.63×10^{-6} mmol l^{-1}.

The measured I_F values for 6.89×10^{-6} mmol l^{-1} thiocyanate solution: standard deviation S.D. = 0.56; coefficient of variation: 0.89%.

The measured I_F value for 2.07×10^{-5} mmol l^{-1} thiocyanate solution: standard deviation S.D. = 1.13; coefficient of variation: 1.41%.

3.5. Sample analysis

The proposed method can be used successfully to determine thiocyanate in urine and saliva of smokers and non-smokers. The sensitivity of this system makes it possible to reduce the preparation procedures of samples. Samples only need centrifugate to be free from suspended matter. Then the samples were diluted and to be analysed directly. The results obtained have been compared with those of Ali A. Ensafi et al. [14] from catalytic photometric method.

3.5.1. Determination of trace thiocyanate in urine

Urine samples, 10, (five for smokers and five for non-smokers after getting up in the morning) were

[a] Catalytic photometric method [14].

collected, contrifugated for 5 min with the rate of 2000 r min^{-1}. Then the sample was diluted about 7000-fold and analysed using the procedures described before. At the same time, a blank test was conducted. Thus, obtained thiocyanate content in the urine sample and the result of addition recovery test are shown in Table 2. It is evident that the agreement between the results obtained from the two methods is reasonably good.

Determination of trace thiocyanate in saliva. The procedure of sample collection, centrifugation, dilution and determination is the same as described above. The result is also included in Table 2.

Densen et al. [1] reported that the thiocyanate levels in urine is 0.3 mmol l^{-1} for non-smokers and 0.6 mmol l^{-1} for smokers, and those in saliva were 0.9 mmol l^{-1} and 3.1 mmol l^{-1}, respectively.

Therfore, our results are in excellent agreement with those given by Densen et al. [1]

Equilibrium studies of organotin(IV) complexes with vitamin B_6

M.M. Shoukry *, E.M. Khairy, M.M.A. Mohamed

Department of Chemistry, Faculty of Science, Cairo University, Giza, Cairo, Egypt

Received 10 April 1996; received in revised form 23 September 1996; accepted 24 September 1996

Abstract

The complex-formation equilibria of dimethyltin(IV), trimethyltin(IV) and tributyltin(IV) with pyridoxamine were investigated in dioxane-water mixtures and at different temperatures using a potentiometric technique. The stepwise formation constants of the complexes formed in solution were calculated using the non-linear least-square program MINIQUAD-75. The effect of dioxane as a solvent on the protonation constants of pyridoxamine and the formation constants of organotin(IV) complexes was discussed. The thermodynamic parameters $\Delta H°$ and $\Delta S°$ calculated from the temperature dependence of the equilibrium constants were investigated. The concentration distribution of the various complex species was evaluated as a function of pH. © 1997 Elsevier Science B.V.

Keywords: Organotin(IV); Stability constants; Vitamin B_6

1. Introduction

Vitamin B_6 pyridoxol, pyridoxal and pyridoxamine and their phosphorylated derivatives form many complexes with metal ions [1,2]. Pyridoxamine, in particular, forms quite stable complexes in solution [3] and may act as a monodentate or bidentate ligand utilizing the *m*-oxy and amino-moiety of the *p*-aminomethyl group. Their complex formation equilibria may act as models mirroring the effects of exogenenous ligands in biological processes involving vitamin B_6.

In the context of studies on the antitumour properties of complexes involving organotin(IV) moieties with fragments of biological systems, the effect of organotin(IV) compounds with pyridoxamine against L 1210 leukemia has been investigated [4–6].

We considered that a systematic study of the coordination chemistry of organotin(IV) complexes with the pharmacologically active pyridoxamine might provide further information on their antitumour and cytotoxic activity. In conjunction with our research project directed to study the solution chemistry [7–10] of diorganotin(IV) and triorganotin(IV) complexes with amino acids and related compounds, the present paper aims to characterize the reaction of pyridoxamine with trimethyl-, dimethyl- and tributyltin(IV) chlorides. The effect of temperature and solvent on the

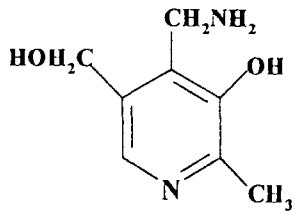
complex formation equilibria were also investigated.



Pyridoxamine

2. Experimental

2.1. Materials and reagents

Pyridoxamine dihydrochloride [$Pm(HCl)_2$] provided by (Fluka AG) was used as supplied. Trimethyltin(IV) chloride [TMT], dimethyltin(IV) chloride [DMT] and tributyltin(IV)chloride [TBT] were from Merck Chem. Sodium hydroxide stock solutions were prepared by diluting the content of BDH concentrated volumetric solution vials. These solution were systematically checked by titration against potassium hydrogen phthalate. TBT solutions were prepared in dioxane. The other solutions were in deionized water.

2.2. Procedure and measuring techniques

The potentiometric titrations were performed using a Metrohm 686 titroprocessor equipped with a 665 dosimat (Switzerland-Herisaue). The titroprocessor and electrode were calibrated with standard buffer solutions, prepared according to NBS specifications [11]. The titrations were carried out in a purified nitrogen atmosphere using a titration vessel described previously [12]. The temperature was maintained constant by a Colora Ultrathermostat.

The following mixtures (A–C) were prepared and titrated potentiometrically with standardized NaOH solution (~ 0.1 M).

(A) 40 ml of a solution containing [$Pm(HCl)_2$] (2.5×10^{-3} M) and $NaNO_3$ (0.1 M).

(B) 40 ml of a solution containing [$Pm(HCl)_2$] (2.5×10^{-3} M), DMT (1.25×10^{-3} M) and $NaNO_3$ (0.1 M).

(C) 40 ml of a solution containing [$Pm(HCl)_2$] (2.5×10^{-3} M), TMT or TBT (2.5×10^{-3} M), and $NaNO_3$ (0.1 M).

All mixtures were titrated in different percentage (v/v) dioxane-water solutions (25.0, 37.5, 50.0, 62.5 and 75.0) and at different temperatures (15.0, 20.0, 25.0, 30.0 and 35.0°C).

The equilibrium constants were evaluated from titration data, defined by Eq. (1) and Eq. (2).

$$l(M) + p(L) + q(H) \rightleftharpoons (M)_l(L)_p(H)_q \quad (1)$$

$$\beta_{pqr} = \frac{[(M)_l(L)_p(H)_q]}{[M]^l[L]^p[H]^q} \quad (2)$$

where M, L and H represent organotin(IV), pyridoxamine and proton respectively. The calculations were performed using the computer program [13] MINIQUAD-75 by means of an IBM-4366

computer. The stoichiometries and stability constants of the complexes formed were determined by trying various possible composition models. The model selected gave the best statistical fit and was chemically consistent with the titration data without giving any systematic drifts in the magnitudes of various residuals, as described elsewhere [13]. The fitted model was tested by comparing the experimental titration data points and the theoretical curve (simulated) calculated from the values of acid dissociation constant of the ligand and formation constants of the corresponding complexes. Fig. 1 shows a comparison between the experimental data points of the titration of dimethyltin(IV)-pyridoxamine system, taken as a typical example, and the theoretical curve. Table 1 and Table 2 list the formation constants together with their standard deviations and the sum of square of residuals as was obtained from the program MINIQUAD-75. Concentration distribution diagrams were obtained using the program Species [14].

3. Results and discussion

3.1. Protonation equilibria

The acid dissociation constants of pyridoxamine were determined under the same experimental conditions of ionic strength and temperature which are used for the study of organotin(IV) complex equilibria. A maximum number of three protons can be released from pyridoxamine in the fully protonated form (H_3L^{2+}) on titration with strong base in the pH range (3.2–11.0). The titration data indicates the presence solely of simple HL, H_2L^+ and H_3L^{2+} complexes, where HL represents pyridoxamine in the neutral form. The overall protonation constants ($\log \beta_{011}$, $\log \beta_{012}$ and $\log \beta_{013}$) of pyridoxamine were calculated. The values obtained (Table 1) are in good agreement with the literature data [3], after considering changes in experimental conditions. The stepwise protonation constants in aqueous solution at 25°C can be represented by: $\log K_1^H = 10.61$, $\log K_2^H = 8.24$ and $\log K_3^H = 3.35$. These values correspond to the phenolic (OH), ammonium (NH_3^+) and protonated pyridine groups, respectively.

3.2. Complex formation equilibria

The potentiometric equilibrium titration curves of pyridoxamine in the presence and absence of trimethyltin(IV), taken as a representative example, are given in Fig. 2. The complex titration curve starts at pH ~ 3.10 and is significantly lower than the ligand curve. This may be conceived as a visual indication of complex formation through a release of hydrogen ions. The results of triorganotin(IV) complexes show the formation of the 1:1 (organotin:ligand) complex and the corresponding protonated complex species. On the other hand, the results in the diorganotin(IV) system show the formation of 1:1 and 1:2 complexes and of the protonated species of the 1:1 complex. The formation constants of the butyltin(IV) complexes, Table 1, were found to be lower than those of the methyl analogues. This may be due to steric crowding between the bulky butyl group and pyridoxamine. The formation constant of the 1:1 complex with DMT is higher than with TMT. This is explained on the premise that pyridoxamine binds to DMT and TMT as bidentate- and monodentate ligands, respectively. The coordination geometry around tin in $(CH_3)_3Sn(IV)$ in aqueous solution is believed to be trigonal bipyramidal in which the three methyl groups are situated in the equatorial plane. Complex formationwould then involve pyridoxamine binding in the apical site. The same behaviour was reported for $(CH_3)_3Sn(IV)$-pyridine complex [15]. Dimethyltin(IV), on the other hand, is able to form octahedral complex with the two methyl groups are probably colinear and placed vertically following the rules of group theory. A similar structure was reported for $(CH_3)_2Sn(IV)$-Br_2(pyridine)$_2$ complex [16]. Further studies are needed to support the structural elucidation of the coordination geometry of the organotin(IV) complexes, e.g., ^1H-^{119} Sn and/or ^{13}C-^{119} Sn nmr measurements. However such studies are not yet available and will be considered in the future.

The acid dissociation constants of the protonated complexes are given by relation Eq. (3)

$$pK^{(H)}_{M(L)(H)} = \log K^{M}_{M(L)(H)} - \log K^{M}_{M(L)} \quad (3)$$

[c] Sum of square of residuals.

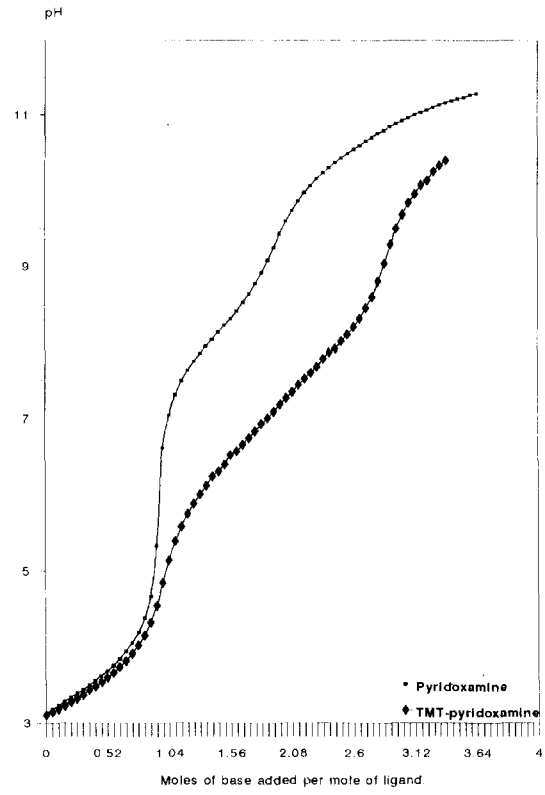

Fig. 2. Potentiometric titration curves of TMT-pyridoxamine sysytem.

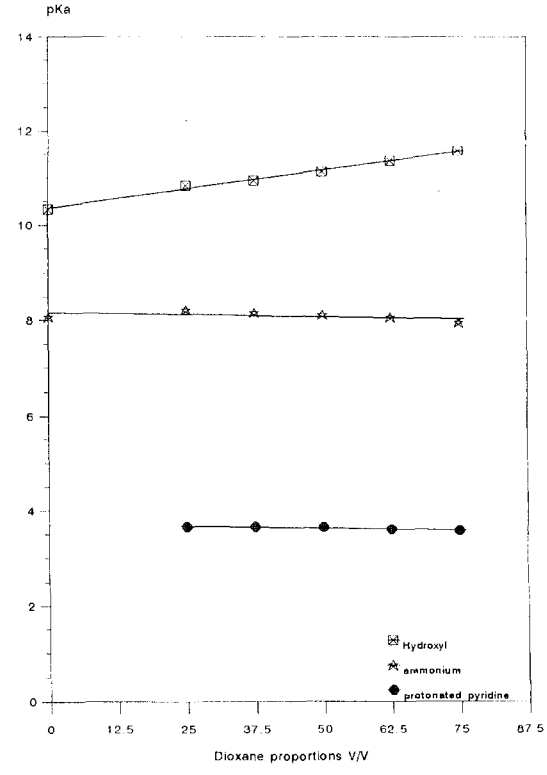

Fig. 3. Effect of dioxane proportions on pK_a of pyridoxamine.

The pK^H values are 7.57, 7.23 and 5.75 for trimethyltin(IV), tributyltin(IV) and dimethyltin(IV) complexes. The pK^H values of triorganotin(IV) complexes are in close agreement with the log K_2^H of the (NH_3^+) of the free pyridoxamine ligand. This indicates that the phenolic OH group is involved in complex formation through proton ionization, leaving the NH_2 group noncoordinated. The pK^H of the dimethyltin(IV) complex may be compared with that of pyridine after considering the increase in basicity as a result of proton ionization from pyridoxamine. This re-

veals that both -OH and NH_2 groups of pyridoxamine are involved in complex formation.

The values obtained for the thermodynamic parameters $\Delta H°$, $\Delta S°$ associated with the protonation of pyridoxamine and complex formation with the organotin(IV) species were calculated in the usual way from the temperature dependence of the data shown in Table 1. The values thus, obtained are reported in Table 3. These data can be employed to extrapolate the equilibrium constants to other temperatures. The main conclusions from the thermodynamic data can be summarized as follows:

(a) The protonation reaction of pyridoxamine associated with L^-, which corresponds to $\log K_1^H$, is more exothermic than those of $\log K_2^H$ and $\log K_3^H$. This may be explained on the basis of different coulombic forces between the proton and the pyridoxamine species (L^-, HL and H_2L^+).

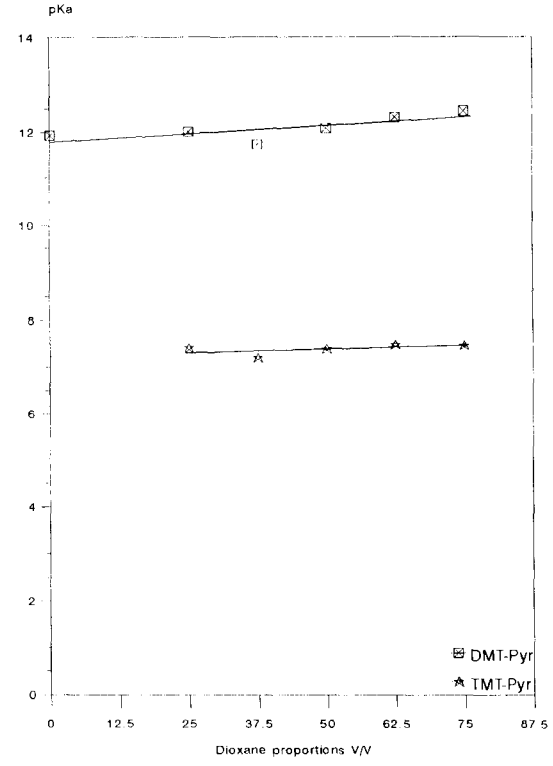

Fig. 4. Effect of dioxane proportions on the formation constants of the pyridoxamine complexes with dimethyltin(IV).

(b) The formation of the protonated 1:1 complex of pyridoxamine with TMT is more exothermic than with TBT. This means than the methyltin complex is more favoured than its butyltin homologue which suffers steric crowding between the bulky butyl group and pyridoxamine.

(c) The complex-formation of pyridoxamine with DMT is exothermic for the 1:1 complex and endothermic for the 1:2 complex. This may be explained statistically based on the presumption that more coordination sites are available for binding pyridoxamine in 1:1 than in 1:2 complexes.

3.3. Effect of solvent

It is well established that the 'effective' or 'equivalent solution' dielectric constants in proteins [17,18] or active site cavities of enzymes [19] are smaller compared with that in bulk water. Estimates for the dielectric constants in such locations range from ≈ 30 to 70 [17–19]. Hence by using aqueous solutions containing ≈ 10–50% dioxane [20], one may expect to simulate to some degree the situation in active site cavities [21], hence to extrapolate the data to physiological conditions. The variation of the pK^H values of pyridoxamine as a function of solvent composition is shown in Fig. 3. These values increase almost linearly with increasing the concentration of the organic solvent. However, the increase in the pK^H value of the -OH group is more significant. This may be correlated with the ability of a solvent of relatively low dielectric constant to increase the electrostatic forces between the ions in ($-O^- - H^+$) and to facilitate the formation of molecular species [22]. The variation of the formation constants of the pyridoxamine complexes with dimethyltin(IV) and trimethyltin(IV) as a function of solvent composition is exhibited in Fig. 4. The formation constant increases with increasing the dioxane content of the solvent. This behaviour can be explained by the variation of the protonation ability of the hydroxyl group of pyridoxamine, one of the binding sites in the complexes, as the organic solvent content increases.

Estimation of equilibrium concentrations of organotin(IV) ions and their pyridoxamine com-

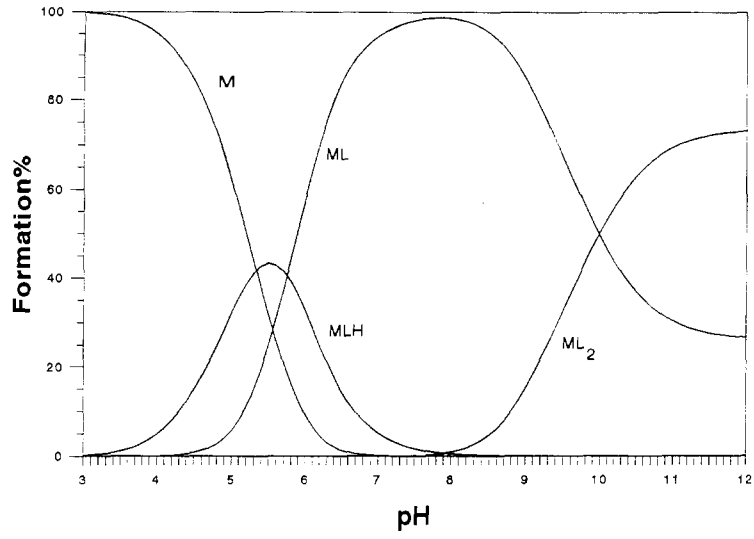

Fig. 5. Concentration of distribution of various species as a function of pH in the DMT-pyridoxamine system, where M = DMT; L = pyridoxamine; [L] = 2[DMT] = 0.0025 M.

plexes as a function of pH provides a useful picture of the organotin binding with pyridoxamine. The speciation diagrams obtained for di- and trimethyltin(IV) complexes are given in Fig. 5 and Fig. 6. The protonated complex with trimethyltin(IV) starts to form at pH = 4 and reaches a maximum concentration of 34.2% at pH = 7.30. The deprotonated complex concentration increases with increasing pH, predominating with a maximum concentration of 99% at pH = 10.00. For the diorganotin(IV) complexes, the concentration of the 1:1 complex species increases with increasing pH, attaining a maximum of 97.77% at pH = 8.20. Further increase in pH is accompanied by a decrease in the 1:1 complex concentration and increase in the 1:2 complex concentration

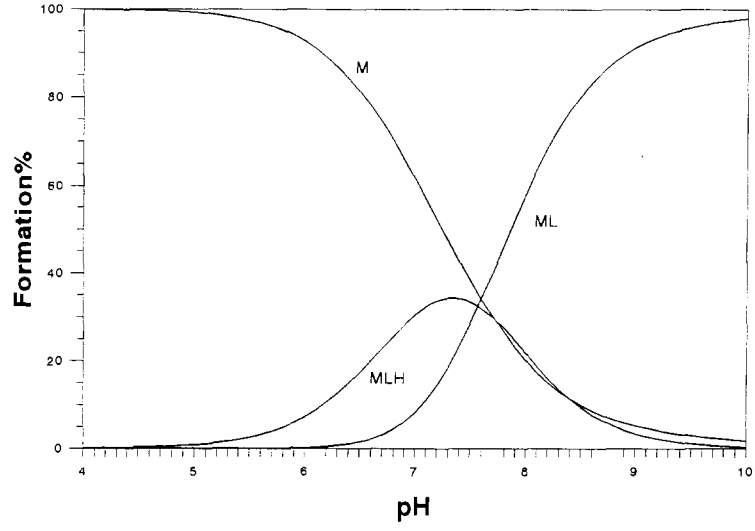

Fig. 6. Concentration distribution of various species as a function of pH in the TMT-pyridoxamine system, where M = TMT; L = pyridoxamine; [L] = [TMT] = 0.0025 M.

attaining a maximum of 73.20% at pH = 12.00. This reveals that in the physiological pH range, i.e., at pH 7.4, the (1:1) DMT-pyridoxamine complex is the predominant species and may have a chance to interact with DNA. This may provide some explanation for the reactivity of DMT-pyridoxamine complex against leukemia.

Received 10 May 1996; received in revised form 22 October 1996; accepted 25 October 1996

Abstract

The procedure of hafnium determination in workplace air has been elaborated, which allows its determination at the level starting from 0.125 mg m^{-3}, which for a 400 l sample corresponds to the requirement for maximal allowable concentration. The method is based on excitation of the mineralized filter containing the analyte in inductively coupled plasma. © 1997 Elsevier Science B.V.

Keywords: Air analysis; Atomic emission spectrometry; Hafnium; Inductively coupled plasma

1. Introduction

Hafnium is used in production of highly resistant materials, as anticorrosive layers, explosives, special glasses and in ceramic industry. The dust containing hafnium is toxic through respiratory and alimentary tracks. The value of $LD_{50} = 76$ mg kg^{-1} has been evaluated for mice. Hafnium bound to transferrin was after 4 days detected in blood plasma in 95% [1]. The hafnium tetrachloride (for rats $LD_{50} = 2000$ mg kg^{-1}) results in renal degeneration and small intestine inflammation. In Poland the threshold limit value (TLV) for total hafnium in air has been proposed as 0.5 mg m^{-3} [2]. This corresponds to the value in other countries (Australia, Belgium, Danemark, France, Germany, UK, Switzerland, USA). In UK the short term exposure limit (STEL) equals 1.5 mg m^{-3}.

In the literature there are mainly spectrophotometric procedures for routine determination small amounts of hafnium [3], however other techniques have also been used [4]. Various materials have been analyzed using X-ray fluorescence and neutron activation analysis [5]. The atomic absorption spectrometry with flame atomization in nitrous oxide-acetylene flame has poor limit of detection and suffers interferences [6]. Atomic absorption spectrometry has been also proposed by OSHA [7] for hafnium determination at the workplace. In optimal conditions the limit of detection equals 2.0 μg ml^{-1} and the characteristic concentration 15 μg ml^{-1}.

PII S0039-9140(96)02152-2

The inductively coupled plasma optical emission spectrometry has been sugested for determination of hafnium in workplace air [8,9]. The limit of detection has been indicated at the level of a few ng ml^{-1}. It can be also used for hafnium determination in complex matrices [10], however in the case of complex matrices either the matrix should be separated or its effect compensated by matrix matched calibration solutions [11,12]. For determination of hafnium in geological samples also inductively coupled plasma mass spectrometry has been applied and the detection limit was found to be 20 ng g^{-1} [13].

In this paper the procedure was elaborated which makes possible determination of hafnium collected on filters from the workplace air.

2. Experimental

2.1. Instrumentation

The ICP-AES spectrometer Jobin-Yvon 70 Plus with a peristaltic pump (Instruments S.A.) was used for recording the emission spectra. Air aspirator with a constant air flow 20 l min^{-1} according to Polish Standard [14] was used for suction of air through the nitrocellulose membrane filters, Synpor 3, diameter 50 mm and porosity 0.6–0.8 μm.

2.2. Reagents

Hafnium metal (99.95%) purchased from Merck was used for preparation of stock solutions by dissolution of 1 g of metal in 40% hydrofluoric acid, and dilution up to 1 l with 5% hydrofluoric acid in a polypropylene flask. The working solution – 50 mg l^{-1} was prepared by appropriate dilution of the stock solution with 5% hydrofluoric acid.

Hydrofluoric acid – 40 and 5%, nitric acid – 65% and perchloric acid – 62% all of analytical grade were also purchased from Merck.

2.3. Procedure of determination

The samples should be taken according to Polish Standards [14] by aspiration of 400 l of air at the rate 20 l min^{-1}, through the membrane filter. The filters are mineralized in teflon crucibles using 3 ml of concentrated nitric acid. After evaporation till dryness, in the next step 3 ml of concentrated nitric acid and five drops of concentrated perchloric acid were used and again evaporated. In subsequent steps 3 ml of concentrated nitric acid + 5 ml of hydrofluoric acid and 1 ml of concentrated nitric acid + 5 ml hydrofluoric acid, respectively, were used. Finally the residue was dissolved in 3–5 ml of 5% hydrofluoric acid. In a 50 ml measuring flask the same acid should be added till the mark. The analyte line is measured at the wavelength 282.022 nm, with single point background correction. The experimental parameters of the ICP excitation are generally based on the manufacturers recommendations and are given in Table 1. The blank is obtained by using the pure filter of the same type mineralized as filters with sample dust.

The concentrations are read from the calibration graph, prepared with standards containing 1.0, 2.5,...10.0 ml of working hafnium solution, diluted with 5% hydrofluoric acid up to 50 ml.

3. Results and discussion

For determination of hafnium a few emission lines can be used. These are Hf II 282.022 nm, Hf II 277.336 nm, Hf II 264.141 nm and Hf II 232.247 nm. The 277.336 nm line is interfered in the case of the presence of iron and a number of

Concentration of hafnium in solution = 5 μg/ml.
[a] In conditions of sampling air.

other concomitants. The measurements based on the line 264.141 nm, suggested by NIOSH [8], exhibit poor precision. The largest tolerance as well as best precision was found in the case of line 282.022 nm and this line was used in the elaborated analytical procedure. This line provided a sufficient limit of detection and lack of interference. The analytical signals were investigated in the presence of common concomitants and the maximum tolerable concentration was evaluated based on the limiting error of ± 5% (Table 2).

The figures of merit of the ICP-OES measurements were evaluated at the concentration level 4 mg l^{-1}, corresponding to the threshold limit value for 400 l air sample. Each of the five samples was measured nine times, and the relative standard deviation was in the range from 0.3 to 1.8%.

The calibration function is rectilinear with the equation C(mg l^{-1}) = −0.02254 + 0.000913 I (relative intensity readings). The calibration function was based on six model solutions, the first one not containing hafnium. For any calibration point the relative standard deviation was larger than 1.5%.

As there are no standard aerosol (dust) samples available containing the known content of hafnium, the recovery test was based on filters with known amount of added hafnium in the form of standard solution. Such procedure was assumed to give less uncertainty than using reference material with recommended Hf values but with a completely different matrices. The amount of hafnium on the filters was 0.100, 0.200 and 0.400 mg, which corresponds to 0.25, 0.50 and 1.00 mg m^{-3} of hafnium in air, which is below and above TLV (0.50 mg m^{-3}). The relative standard deviation was for all samples below 2%, and the recovery was in the range from 98 to 102%. The concentration of hafnium in the air (X) is calculated on the basis of the calibration function, relating the concentrations of hafnium (mg l^{-1}) in the sample (c), the concentration in the blank (c_0), the volume (l) of solution of the sample (v_1) and the volume (m^3) of the sampled air (v):

$$X = (c - c_0)v_1/v$$

4. Conclusions

The method of hafnium determination in the range from 50 to 500 μg has been developed using the inductively coupled plasma-optical emission spectrometry technique. This range, for a 400 l air

sample, corresponds to concentration of hafnium in air from 0.125 to 1.25 mg m^{-3}. This makes possible to use this procedure for determination of hafnium below and above the threshold limit value at the workplace (TLV = 0.5 mg m^{-3}). The hafnium containing dust is collected at the filter, dissolved and hafnium is excited in the ICP-OES technique. Accompanying elements which may potentially be present in the sampled air do not interfere.

Determination of butyl- and phenyltin compounds in sediments by GC-FPD after $NaBEt_4$ ethylation

C. Carlier-Pinasseau, G. Lespes *, M. Astruc

Laboratoire de Chimie Analytique, CURS, Université de Pau et des Pays de l'Adour, Avenue de l'Université, 64000 Pau, France

Received 16 July 1996; received in revised form 16 October 1996; accepted 29 October 1996

Abstract

A reliable and rapid speciation method for the simultaneous determination of butyl- and phenyltin species in sediment samples has been developed. Two extraction procedures are compared: methanolic hydrochloric acid (at four different concentrations) and ethanoic acid leaching. Derivatization is carried out by the one-step ethylation/extraction procedure using the sodium tetraethylborate reagent directly in aqueous phase in the presence of an isooctane layer. Analysis is performed by capillary gas chromatography hyphenated to flame photometric detection (GC-FPD). Detection limits range from 0.5 to 1.5 ng(Sn) g^{-1}(dry weight). Analysis of environmental samples and certified reference materials demonstrate the accuracy of the analytical method. © 1997 Elsevier Science B.V.

Keywords: Butyltin; GC-FPD; $NaBEt_4$ ethylation; Phenyltin; Sediment

1. Introduction

Organotin compounds have been extensively used as biocides. Contamination of marine and fresh water environments by the highly toxic tributyltin (TBT) is primarily due to its use in antifouling paints on vessels [1]. The ecotoxicological impact of TBT has been demonstrated [1,2]. Triphenyltin (TPhT) compounds are used as agricultural fungicides in crop protection [3]. But TPhT was found to be a non selective pesticide, detrimental to fresh water fauna [4]. Moreover TPhT has been shown to have a high bioaccumulation potential [3]. In the aquatic environment, triorganotin compounds have low aqueous solubility and low mobility. They are easily adsorbed by particulate matter in the water, which, upon settling to the bottom, can be incorporated into the sediment [5]. Considerable concentrations of these compounds and their metabolites were detected in sediments of Swiss Lakes [6].

The recognition of organotin toxicity at low concentration levels has stimulated the development of accurate and sensitive analytical methods for organotin determinations. Many efficient analytical procedures combine chromatographic separation and various detection techniques such as atomic absorption spec-

trometry (AAS) [7–10], mass spectrometry (MS) [4], atomic emission spectrometry (AES) [4,11] or flame photometric detection (FPD) [12–14]. Despite recent improvements in instrumentation, several limitations remain present especially in the sample preparation steps. Prior to gas chromatography (GC) organotin compounds need to be liberated from the sediment before being derivatized into forms suitable for chromatography. Extraction of organotin compounds after acid leaching from the matrix followed by hydridization using $NaBH_4$ or alkylation with Grignard reagent are the most common approaches. Alternatives to acid leaching are the use of super critical fluid [11,15] or soxhlet [4] extractions.

A new organotin derivatization procedure directly applied to aqueous extracts using sodium tetraethylborate ($NaBEt_4$) has been recently proposed. Ethylation and extraction of compounds are performed in a single operating flask [8,16–18]. It allows simultaneous speciation of butyl- and phenyltin and is much more simple and rapid than procedures using Grignard reaction.

The method of speciation associating this derivatization with GC-FPD was proved to be very performant in analysis of complex matrices [18]. This is due to the simplicity of the whole process and the specificity of the detector. Nevertheless, to our knowledge, it has never been used in the analysis of natural samples such as sediment. Moreover, it allowed the determination of several organotin species including the phenyltin compounds which are critical to determine.

In this paper, such a method has been developed for the simultaneous determination of butyl- and phenyltins. First, the optimal conditions for the extraction of these species have been evaluated on the BCR Certified Reference Material CRM 462 spiked with TPhT. Different approaches of organotin leaching from the material have been tested. Second, from the row extract, the in-situ derivatization with $NaBEt_4$ reagent and direct analysis using capillary gas chromatography and flame photometric detection (GC-FPD) were performed. The optimized method was applied to the analysis of the Canadian Reference Material PACS-1 and of fresh water sediment samples.

2. Experimental

All organotin concentrations reported in this paper are expressed as the mass of tin per sample mass or solution volume unit.

2.1. Apparatus

A Varian 3300 Gas Chromatograph (GC) was used for this study. It was fitted with a split/splitless injector, a J&W Scientific capillary column coated with polydimethylsiloxane (inner diameter 250 μm, length 30 m, film thickness 0.25 μm) and a Flame Photometric Detector (FPD). The detector was operated with a 610 nm optical filter (from MTO Optique Instrumentale) and an air/hydrogen flame. Nitrogen was used as carrier gas.

2.2. Reagents and standards

Tripropyltinchloride (TPT, 98%), monobutyltintrichloride (MBT, 95%), dibutyltindichloride (DBT, 97%), tributyltinchloride (TBT, 96%), monophenyltintrichloride (MPhT, 98%), diphenyltindichloride (DPhT, 96%) and triphenyltinchloride (TPhT, 95%) were purchased from Aldrich. Tetrabutyltin (TeBT, 98%) was obtained from Fluka. Stock organotin solutions (1000 mg l^{-1} as Sn) were prepared in methanol. Stored at +4°C in the dark, they are stable for several months [19]. Working standards were obtained by dilution in methanol weekly for 10 mg l^{-1} and daily for 100 μg l^{-1} and stored in the dark at +4°C.

Methanol and sodium ethanoate were purchased from Prolabo, nitric acid, hydrochloric acid, and ethanoic acid obtained from Merck, and isooctane from Fluka. The deionized water used was 18 MΩ (Millipore System).

Ethanoate buffer (pH 4.8, 0.2 mol l^{-1}) was prepared by dissolving 16.4 g of sodium ethanoate in 1 l of deionized water followed by pH adjustment with ethanoic acid. Sodium tetraethylborate ($NaBEt_4$) was obtained from Strem Chemical. Working solution was made up daily by dissolving 0.02 g $NaBEt_4$ in 1 ml of deionized water and stored in the dark at +4°C.

Glassware was rinsed in deionized water, decontaminated overnight in 10% (v/v) nitric acid solution and then rinsed again.

2.3. Samples

2.3.1. BCR certified reference material 462

It is certified to contain [20]:

70 ± 14 ng(cation) g^{-1}(dry weight) i.e., 29 ± 6 ng(Sn) g^{-1} for TBT

128 ± 16 ng(cation) g^{-1}(dry weight) i.e., 65 ± 8 ng(Sn) g^{-1} for DBT

It was found free of TPhT, so we spiked it before analysis with TPhT at the concentration of 50 ng(Sn) g^{-1}(dry weight). CRM 462 contains also MBT and MPhT but the concentrations of these species are not certified.

2.3.2. PACS-1 reference material

The PACS-1 reference sediment is a dry sample prepared by the National Research Council of Canada. It is certified for its DBT and TBT contents (Table 5).

2.3.3. Environmental sediments

Two different samples from Leman Lake (Swiss) were given by Dr Becker Van Slooten from Polytechnic Federal School of Lausanne. They were collected on different sites of Port d'Ouchy at different dates.

2.4. Extraction and analytical procedure

A scheme of the different procedures tested is shown on Fig. 1.

2.4.1. Extraction

Two extraction methods were tested on the spiked CRM 462 sample;

2.4.1.1. Methanolic/hydrochloric acid digestion. The action of HCl as leaching agent was tested at four different concentrations: from 0.1 to 3 mol l^{-1} in methanol using the following procedure:

1 g of sediment sample was introduced in a capped 50 ml polycarbonate tube with 0.5 ml of a 100 ng(Sn) ml^{-1} TPT methanolic solution as internal standard and 2.5 ml of methanol. Tubes were shaken at 420 rpm for 2 h to humidify the material. This rehumidification step was carried out only 1 h for wet samples. 12.5 ml of HCl at the appropriate concentration in methanol was then added and the mixture was treated ultrasonically for 1 h. The suspension was centrifuged at 3000 rpm for 15 min. The supernatant was then withdrawn.

2.4.1.2. Ethanoic acid digestion. Dry sediment sample, 1 g, was introduced in a capped 50 ml polycarbonate tube with 0.5 ml of a 100 ng(Sn) ml^{-1} TPT methanolic solution as internal standard and 20 ml of glacial ethanoic acid. Tubes were shaken at 420 rpm for 4 h. The suspension was centrifuged at 3000 rpm for 15 min. The supernatant was then withdrawn.

2.4.2. Derivatization and analysis

Extracts, 1–3 ml, were directly introduced in the derivatization reactor without any further

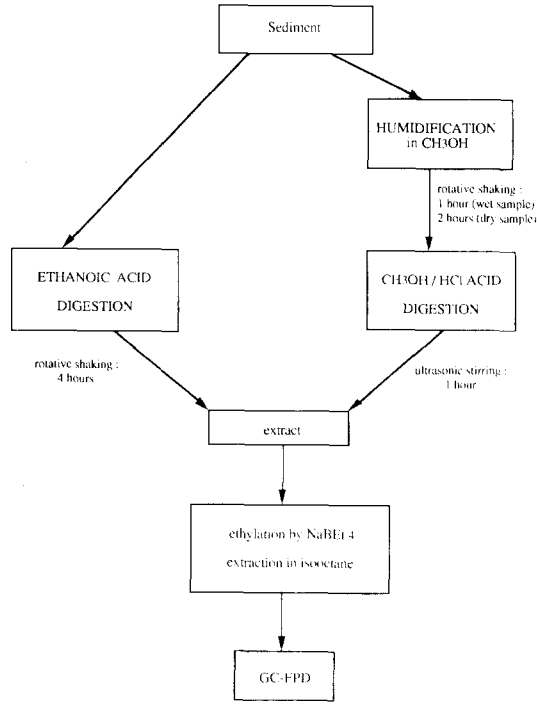

Fig. 1. Schematic representation of different sample preparation procedures used for isolation of organotin compounds from sediments.

Table 1
Analytical conditions for determination of organotin compounds by GC-FPD

Injector parameters			
	Sample amount		From 2 to 5 μl
	Injection temperature		290°C
	Relay	Initial relay	+1 (splitless)
		Relay time	1 min
		Final relay	−1 (split)
GC parameters			
	Carrier gras	Nitrogen	
		Flow rate	0.7 cm^3 min^{-1}
	Oven program	Initial temperature	70°C for 1 min
		1st heat up rate	30°C min^{-1}
		Intermediate temperature	190°C for 10 min
		2nd heat up rate	15°C min^{-1}
		Final temperature	270°C for 5 min
FPD parameters			
	Detection temperature		290°C
	Flame	Air/hydrogen	
		Hydrogen flow rate	185 cm^3 min^{-1}
		Air flow rate	250 cm^3 min^{-1}
	Make up	Nitrogen	
		Flow rate	30 cm^3 min^{-1}

treatment. Organotin compounds were ethylated in 100 ml of ethanoate buffer (pH = 4.8) with 0.1 ml of $NaBEt_4$ solution in the presence of 0.4 ml of isooctane. The mixture was shaken at 420 rpm for 30 min. Isooctane extracts, 2–5 μl, were directly injected into the GC-FPD. Analytical parameters were optimized and precisely described elsewhere [18]. Chromatographic conditions are summarized in Table 1.

The determination of organotin concentrations in samples were made on seven sediment extracts: two by standard additions and five else using TPT as internal standard (five replicates for each extract). This procedure allows a maximum reliability and accuracy without to be too time-consuming.

3. Results and discussion

3.1. Optimization of extraction and analytical performances

To our knowledge, acid leaching of sediments directly followed by $NaBEt_4$ derivatization for the determination of phenyltin compounds, as described in this paper, has not been previously reported in the literature. So, its influence on the analytical procedure has to be evaluated due to the possible disturbances on the derivatization step or on the GC-FPD signal.

Moreover, a such process appeared very simple. The number of sample handling steps was reduced, the clean-up step being found not necessary. We did not note any problem of column contamination or background interferences as indicated by Kuballa et al. [21] and Martin-Landa et al. [22].

Methanolic/HCl treatment is one of the most common way used to break the bonding between species and sediments. It has been especially employed in butyltin determination but does not seem to be applied to phenyltin extraction. Extraction experiments have been previously carried out with different HCl concentrations in methanol depending on their authors [22–24] and ranging between 0.48 and 6.7 mol l^{-1}. So, it was necessary to compare methanolic/HCl extractions at four different concentrations.

In most published works, organotin compounds are further complexed by ligands such as tropolone [10,14,22,24] to improve their extraction yields into an organic solvent before Grignard derivatization. Such procedures are more time and man-power consuming; losses and degradation may occur. So, we chose not to use any complexing agent.

Ethanoic acid digestion was developed by Desauziers et al. to analyse butyltin compounds in sediments [25], but it seems to have only been applied to leach butyltin compounds [9,25,26]. Therefore the efficiency of this extraction procedure as regards phenyltin species had also to be studied in this work.

3.1.1. Study of extraction

Recoveries of butyl- and phenyltin species presented in Table 2 are calculated by comparison with the certified reference butyltin values (DBT: 65 ± 8 ng(Sn) g^{-1} and TBT: 29 ± 6 ng(Sn) g^{-1}) or to the spiking TPhT concentration (50 ng(Sn) g^{-1}) TPhT.

3.1.1.1. Methanolic/hydrochloric acid digestion. Disturbances of the GC-FPD signal such as discontinuity of the baseline were observed when HCl concentration was used over 2 mol l^{-1}. More generally, random peaks could then appear. Baseline decreased or increased in the beginning of the chromatogram as showed in Fig. 2, whatever the HCl concentration was. These observations proved that a matrix effect could occurred according to the nature of the extraction solution.

Quantitative recoveries of DBT and TBT were obtained when using 0.1–2 mol l^{-1} methanolic HCl solutions while quantitative recovery of TPhT is obtained only for 0.1 mol l^{-1} HCl.

Simultaneously MBT and MPhT peak heights were maximum with 1 mol l^{-1} hydrochloric solution (Fig. 2), before disappearing when too concentrated HCl was used, probably due to inorganic tin occurrence.

In order to improve the knowledge of the behaviour of the organotin species during hydrochloric acid digestion, stability studies were carried out. First, in methanolic standard solutions containing either one of the six butyl- or phenyltin compounds, addition of HCl at different concentrations was made. Significant degradations were observed over 0.1 mol l^{-1} acid concentration. This phenomenon appeared all the more the organotin was substituted, the TBT and the TPhT being particularly subject to decompositions. The phenylated species were always less stable than the butylated ones. Second, according to these results, the trisubstituted standard solutions were submitted to the same conditions of extraction (data in brackets in Table 2). These experiments confirmed that the use of 0.1 molar HCl avoided any degradation and seemed convenient for extraction.

Moreover, it seems from Table 2 data that butyltin compounds are more stable in sediment matrix, especially TBT. This is in agreement with previous constatations [27]. It is well known that TBT half life times range from months to years in sediments instead of days to weeks for the water column [28].

At the difference of butyltins, phenyltin compounds had the same degradation behaviour either in sediment extracts or in standard solutions, indicating probably a difference in bonding sites. At HCl concentrations higher than 0.1 mol l^{-1}, TPhT was transformed directly into monophenyl-

Table 2
Recoveries of organotins after analysis of the spiked certified reference material 462 using different extraction procedures and, in brackets, recoveries from standard solutions of TBT and TPhT submitted to the same conditions

Extraction method	DBT% [a]	TBT% [a]	TPhT% [a]
HCl/methanol 0.1 mol l^{-1}	98	108 (100%)	92 (100%)
HCl/methanol 1 mol l^{-1}	109	91 (77%)	64 (60%)
HCl/methanol 2 mol l^{-1}	90	96 (71%)	64 (57%)

Ethanoic acid	6	6	6	12	7	9

[a] The compound was never detected.

and inorganic tin: the HCl/methanol extraction can not be successfully applied to leach phenyltin compounds from sediments except at very low (≤ 0.1 molar) HCl concentration.

3.1.1.2. Ethanoic acid digestion. Quantitative recoveries are obtained by ethanoic acid extraction. The possible decomposition of butyl- and phenyltin compounds during the extraction step was also checked by incubation of TBT and TPhT in ethanoic acid using leaching extraction conditions (Table 2). Analysis of the incubated standard solutions leads to a quantitative recovery of TBT and TPhT. These results agree with those reported in the literature for butyltin determination [9,25,26] but are new for TPhT.

Moreover, no disturbance of the GC-FPD signal was observed. Extraction and derivatization by $NaBEt_4$ are all the more compatible with this extraction procedure as the $NaBEt_4$ reaction needs an ethanoate/ethanoic acid buffer. So ethanoic acid leaching is preferred to analyse sediments. Butyl- and phenyltin compounds are determined simultaneously and quantitatively, without any noticeable degradation.

3.1.2. Performances of the analytical procedure

3.1.2.1. Reproducibility. Reproducibility was studied by evaluation of the relative standard deviation for the analysis of seven different extracts. Results obtained with different extraction procedures and for each compound are reported in Table 3. The reproducibility using methanolic HCl extraction is low except at very low HCl concentration. Ethanoic acid leaching is performant and results reproducible.

3.1.2.2. Detection limits. Detection limits (DL) reported in Table 4 were determined according to IUPAC recommendations with $k = 3$. They are calculated from the slope of calibration curves of all compounds and base line noise.

DL are slightly higher with the ethanoic acid method than with the 0.1 mol l^{-1} HCl/methanol one. However for phenyltin species, DL are generally lower than most of those reported in literature when organotin determinations are performed by GC-FPD following Grignard derivatization and HCl leaching or super critical fluid extraction (from 2.2 to 5.8 ng(Sn) g^{-1}(dry weight) [13,15]). As regards butyltin species, detection limits are close to those given for analysis performed by GC-FPD after Grignard derivatization (from 0.2 to 1.8 ng(Sn) g^{-1}(dry weight) [13–15]) and lower than those reported after $NaBEt_4$ ethylation: 25, 36 and 61 ng(Sn) g^{-1}(dry weight) for respectively TBT, DBT and MBT [7] using 2.2 molar HCl for the extraction and 0.44 ng(Sn) g^{-1}(dry weight) for TBT [8] using 0.5 molar HCl. Such differences may be due to the extraction procedure. From this study we retained the ethanoic acid extraction procedure for further studies.

3.2. Applications

The ethanoic acid leaching procedure was further validated by the analysis of three different environmental samples.

3.2.1. PACS-1 reference material

Mean concentrations obtained from five determinations are given in Table 5. Concentrations obtained are in agreement with the certified ones.

Table 4
Relative detection limits expressed in ng(Sn) g^{-1} (dry weight)

Extraction method	MBT	DBT	TBT	MPhT	DPhT	PhT
HCl/methanol 0.1 mol l^{-1}	0.5	0.7	0.7	1.1	0.9	1
HCl/methanol 1 mol l^{-1}	0.6	0.7	1	2.7	[a]	1.4
HCl/methanol 2 mol l^{-1}	0.6	0.7	0.9	[a]	[a]	1
HCl/methanol 3 mol l^{-1}	0.9	1.1	0.9	[a]	[a]	[a]
Ethanoic acid	1.2	1.2	0.8	1.8	0.8	1.5

[a] The compound was never detected.

Concentrations found ± S.D. ($n = 5$)	1174 ± 86	1044 ± 67

S.D., standard deviation.

According to the standard deviation values, the analytical method appears accurate.

3.2.2. *Sediments from Port D'Ouchy, Leman Lake, Switzerland*

Two different freshwater sediment samples were analysed and results obtained are reported in Table 6. They are compared with those determined by Dr Becker Van Slooten using a Grignard derivatization/GC-FPD procedure [29]. Results obtained by the two different analytical techniques are in very good agreement. Organotin concentrations in Port d'Ouchy sediments are quite high. This marina has a housing capacity of 603 places for pleasure boats staying all year round [6]. Every fourth boat is repainted annually. Becker Van Slooten and Tarradellas tentatively estimated the total number of boats protected by an organotin-containing antifouling paint to about 30% for the marinas of Leman Lake [6] and attributed the high sediment organotin pollution to boat paint leaching and the high stability of organotins in sediments.

4. Conclusion

After study of the operating conditions and comparison of two extraction methods, both butyl- and phenyltin species were determined in sediments.

Results show that ethanoic acid leaching is a convenient method to release simultaneously and

quantitatively butyl- and phenyltin compounds. Nevertheless, quantitative recoveries can also be reached with HCl/methanol solubilization if the HCl concentration is about 0.1 mol l^{-1} in methanol. Higher HCl concentrations lead to degradation of organotin compounds particularly of phenyltin ones.

The ethanoic acid extraction procedure is preferred because of its performances. Simple and rapid, it can be easily applied to a routine method. It is directly compatible with the one-step aqueous ethylation-extraction/capillary gas chromatography-flame photometric detection method. It allows an accurate simultaneous determination of butyl- and phenyltin compounds from fresh water and sea water sediments with detection limits in the ng(Sn) g^{-1} range.

Utility of diphenylamine and *N*-bromosuccinimide for colorimetric determination of certain phenothiazine drugs

Abd El-Maaboud Ismail Mohamed

Department of Analytical Pharmaceutical Chemistry, Faculty of Pharmacy, Assiut University, Assiut, Egypt

Received 20 May 1996; received in revised form 27 August 1996; accepted 29 October 1996

Abstract

A sensitive colorimetric method for the quantitative estimation of 11 phenothiazine drugs was developed. The method was based on the interaction of phenothiazine compounds with diphenylamine in presence of *N*-bromosuccinimide and sulfuric acid. Most of studied phenothiazines yielded bluish green products with two absorption maxima, one in the range of 392–396 nm with higher molar absorptivity and the other in the range of 770–780 nm with lower molar absorptivity. Phenothiazine base, mepazine HCl and pericyazine yielded blue products with only one maximum at 655, 775 and 778 nm, respectively. The color was stable for at least 1 h. The reproducibility and recovery of the method were excellent. The method was applied successfully to the determination of some commercially available phenothiazines in different dosage forms. Results were comparable to those obtained by official and reported methods. © 1997 Elsevier Science B.V.

Keywords: Pharmaceuticals; Phenothiazines; Spectrophotometry

1. Introduction

Numerous methods used to assay phenothiazine drugs in bulk as well as in pharmaceutical preparations and biological fluids. Among these methods are titrimetric [1–5], chromatographic [6–14], electro-chemical [15–20], ultraviolet and visible spectrophotometric [21–34] and fluorimetric methods [35–38]. Many of these procedures suffer interference from excipients, coloring and flavoring agents, degradation and/or oxidation products of phenothiazine drugs. Thus, increasing selectivity and avoiding interferences was a main objective in this study.

The interaction between phenothiazine drugs and some selected amine compounds in presence of certain oxidants were investigated previously in our laboratory and some successful methods were developed [26–29]. The applicability of this reaction for developing more sensitive, selective and time saving procedures has been investigated. As a result of this investigation, a rapid, sensitive and reproducible colorimetric method for determination of 11 phenothiazine drugs has been developed.

[a] Measured at 392–396 nm.
[b] Measured at 770–780 nm.
[c] Correlation coefficient.
[d] Measured at 655 nm.

butaperazine maleate and oxomemazine tartrate were obtained as gifts from various manufacturers and were used as working standards without further treatment. Promazine sulfoxide was prepared by a reported procedure [39]. All solvents used throughout this work were analytical grade.

(c) *N*-Bromosuccinimide (NBS) solution: into 50 ml volumetric flask, add 250 mg NBS. Add about 40 ml of water and shake well. After complete dissolution dilute solution to volume with water. Mix well and use for 24 h.

(d) Diphenylamine solution: 1% w/v diphenylamine solution in methanol or ethanol.

(e) 2 M sulfuric acid solution.

(f) Dosage forms: various commercial preparations purchased from local sources and listed in Table 6.

2.2. Preparation of standards

Dissolve an accurately weighed amount of each phenothiazine drug as free base or its salt in methanol and dilute quantitatively with the same solvent to obtain the appropriate dilution for each drug (Table 1).

2.3. Preparation of samples

2.3.1. Tablets

Weigh 20 tablets and finely powder. Transfer accurately weighed amount of powder equivalent to 25 mg of studied drug to 100 ml volumetric flask and dilute to about 80 ml with methanol. Shake the mixture well for about 10 min, dilute to the mark with the same solvent and filter. Discard first portion of filtrate. Use clear solution obtained as stock solution. Dilute stock solution quantitatively with methanol to obtain the suitable working sample solution for studied drug (Table 1).

2.3.2. Liquid preparations (Syrups, Vials and Drops)

Dilute an accurately measured volume of each preparation equivalent to 25 mg of the declared drug quantitatively to obtain the suitable working sample dilution for studied drug (Table 1).

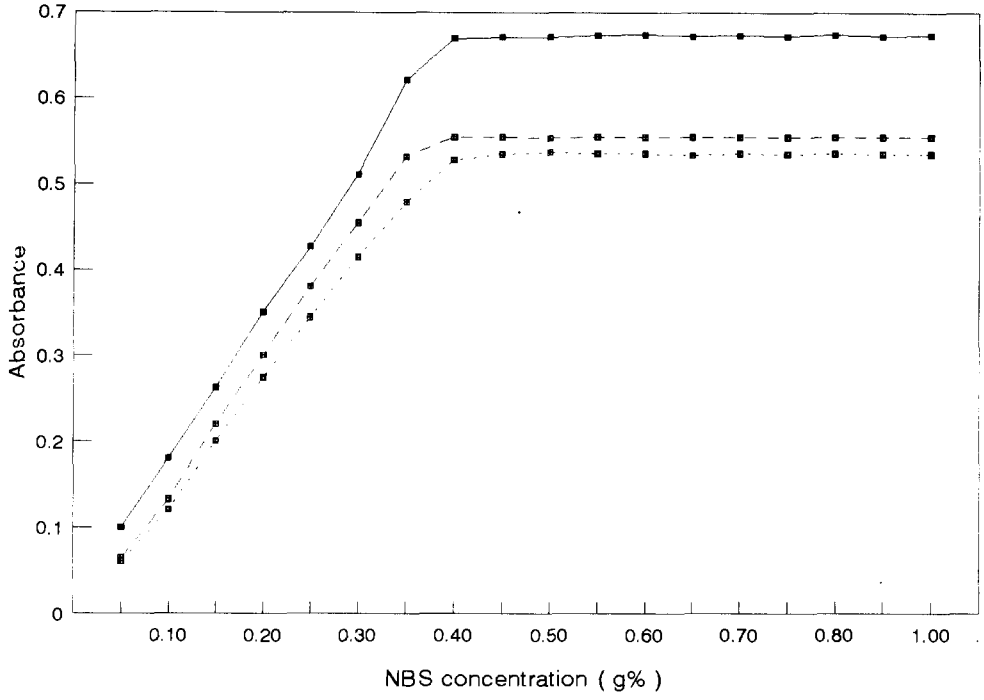

Fig. 2. Effect of NBS concentration on the absorbtion intensity of reaction products of 8 μg phenothiazine base, 10 μg promazine HCl and 4 μg methotrimeprazine maleate ml^{-1}.

2.3.3. Suppositories

Weigh and molten five suppositories. Transfer an accurately weighed amount of suppositories equivalent to 25 mg of chlorpromazine HCl or 10 mg of thiethylperazine to 50 ml volumetric flask. Add about 40 ml of methanol and warm to about 45°C. Shake well for about 10 min keeping the solution warm. Cool, dilute to the mark, shake and filter. Discard the first portion of the filtrate. Use the obtained filtrate as final sample dilution in the case of thiethylperazine or dilute quantitatively with methanol to obtain a working sample solution of chlorpromazine HCl containing 200 μg ml^{-1}.

2.3.4. Recovery study

Add an accurately weighed amount of declared drug for each preparation to 100 ml volumetric flask, containing accurately weighed quantity of the powdered tablets or moltened suppositories or accurately measured volume of liquid preparations. Either dissolve contents of flask in methanol and treat as described for tablets and suppositories or dilute quantitatively with methanol to obtain required concentration as described for liquid preparations.

2.4. Determination

To 1 ml of either standard or sample phenothiazine solution in 10 ml volumetric flask, add 1 ml diphenylamine solution followed by 1 ml NBS solution and 0.5 ml of sulfuric. Mix well and then dilute the solution to volume with methanol. Measure absorbance at either 392–396 or 770–780 nm through about 15 min against a blank treated similarly (measure phenothiazine base, mepazine HCl and pericyazine at 655, 775 and 778 nm, respectively).

3. Results and discussion

3.1. Absorption characteristics

The absorption spectra for the highly colored products of most phenothiazine drugs from reaction with diphenylamine and NBS reagents exhibit two maxima with different absorption intensities (Table 1 and Fig. 1). One absorption maximum is in the range of 392–396 nm, and the other in the 770–780 nm range. Each of phenothiazine base, mepazine HCl and pericyazine have one maximum at 655, 775 and 778 nm, respectively. The shorter wavelength peaks show higher

[a] All measurements are taken at the range of 770–780 nm.
[b] Average of five determinations.
[c] Concentrations in the final measured solutions.

absorption intensity compared with that of longer ones. Measurements were conducted at both wavelengths throughout this work. The ratio between absorptivities of the two maxima calculated at different concentration levels was found to be constant with small coefficients of variation. This ratio may be useful for identification of some drugs such as promazine HCl, chlorpromazine HCl and thioridazine HCl which have characteristic values (Table 1).

Beer's law was obeyed for all phenothiazines studied at the corresponding maxima. Table 2, shows typical linear regression correlations for the studied drugs with relative standard deviation of slope less than 2% in all cases.

3.2. Effect of diphenylamine concentration

Several solutions of diphenylamine in the concentration range from 0.2 to 2.0% w/v were prepared and tested with the studied drugs. Highest color intensities were obtained by using diphenylamine solution in concentrations ranging from 0.6 to 1.4% w/v. Therefore, 1 ml of 1% w/v diphenylamine solution was used throughout this work.

3.3. Effect of NBS concentration

Fig. 2 illustrates the effect of NBS on the absorption intensity of the colored products for phenothiazine base, promazine HCl and methotrimeprazine maleate. It is quite clear from the results that color formation could be maximized by using from 0.4 to 1.0% w/v NBS solutions. Therefore, 1 ml of 1% w/v NBS solution was used throughout this work.

3.4. Effect of acid concentration

Sulfuric acid solutions ranging from 0.2 to 5 M were prepared and tested with the studied phenothiazines. It was found that, maximum color intensity was obtained by using sulfuric acid concentrations more than 1 M. In this study, 0.5 ml of 2 M sulfuric acid solution was used throughout all of the work.

Violet	—	—	0.54	565
Orange	—	—	0.66	402

[a] Eluting system is ammonium acetate-water-methanol (3+20+100, w/v/v).
[b] Maxima of eluted spots.
[c] Major spots.

3.5. Effect of dilution by different solvents

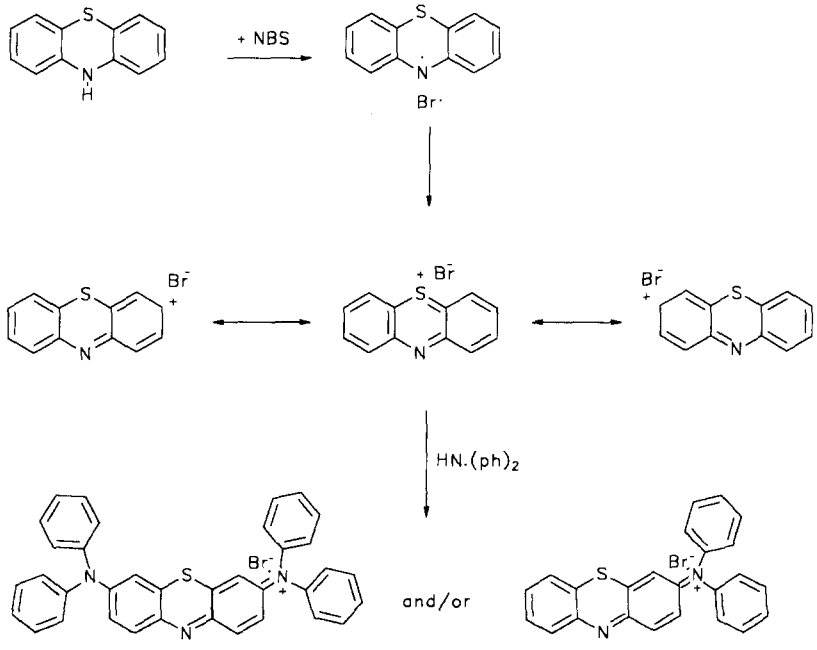
Dilution of the colored products by different solvents showed that, there was no effect or slight effect on the position of absorption maxima in case of alcohols, but absorption intensities were influenced. Table 3, indicates that methanol is the suitable diluting solvent because it gave the highest and most stable absorption intensity.

3.6. Effect of time

The reaction time was determined by following the color development at ambient temperature (25 ± 2°C). It was found that, color intensity was maximum just after addition of sulfuric acid and remained stable for further 15 min and then decreased gradually. On the other hand, colored products were stable for at least 1 h when diluted with methanol immediately and this may reflect the stabilizing effect of the solvent. In this study, the reaction mixtures were diluted with methanol rapidly after addition of sulfuric acid and absorption measured through 15 min after dilution with solvent.

3.7. Effect of the sequence of addition

Table 4, indicates the different possibilities studied in this work. It is clear from the results that the only sequence of addition to be followed is drug, amine, NBS and finally the acid.



Scheme 1. Suggested sequence of reaction of phenothiazine with diphenylamine and *N*-bromosuccinimide reagents to form methylene blue-like dyes.

3.8. Specificity of the reaction

To assess the selectivity of the method to phenothiazines in presence of some oxidation products, the concentrations of promazine HCl and alimemazine tartrate were determined in several standard solutions containing promazine sulfoxide and oxomemazine tartrate (Alimemazine-5,5-dioxide), respectively. Excellent recoveries (99.4–100.5) of the intact drugs in these mixtures confirms that the assay is specific for unchanged drugs in presence of their oxidation products (Table 5).

The C-2 substituted phenothiazines with Hammett σ-values larger than 0.23 for the C-2 substituents, e.g., trifluoperazine HCl (0.54) and butaperazine maleate (0.48), gave no colored products under the studied reaction conditions.

3.9. Analysis of pharmaceuticals

The proposed method was applied for the determination of promazine HCl, promethazine HCl, chlorpromazine HCl, thioridazine HCl, thiethylperazine and methotrimeprazine as the drug entity in various pharmaceutical formulations. Recovery experiments were carried out for each drug in its respective pharmaceutical formulations. The results were compared with those obtained by applying the official or reported methods. As shown in Table 6, the results are in good agreement with those of official methods, and the recovery experiments indicate the absence of interferences from frequently encountered excipients, additives or coloring matter. It is better to use a larger volume of NBS solution (1.5 ml of 0.5% w/v solution) especially in the case of liquid preparations to overcome any interference due to the presence of antioxidants or any methanol soluble materials having strong reducing properties.

Application of Job's method of continuous variation [40] showed that all studied drugs reacted with diphenylamine in the molar ratio of 1:2 except promethazine HCl (2:3) and phenothiazine base (1:1). All other reagents and experimental conditions were kept constant.

Although the determined molar ratio for most phenothiazines was 1:2, the reaction was expected to be more complex, because at least three different spots were obtained when the reaction mixture was spotted on the thin layer chromatographic plates (Precoated silica gel, E. Merck, 0.25 mm with fluorescent indicators) as shown in Table 7.

Scheme 1 shows a suggestion for the possible pathway as predicted from literature reports [26–29,41,42] and from findings obtained in this work.

4. Conclusion

The method is simple, rapid and selective for analysis of intact phenothiazines without interference from the common oxidation and degradation products. Therefore, this method can be used as a measure for the rate of oxidation or degradation of phenothiazines (stability indicating assay). In addition, the use of diphenylamine in this work provides a higher sensitivity and better reproducibility compared with other similar previously used reagents. The method can be successfully used for the routine analysis of phenothiazine drugs in pure forms and in different pharmaceutical formulations.

Received 24 July 1996; received in revised form 31 October 1996; accepted 4 November 1996

Abstract

In electrothermal atomic absorption spectroscopy (ETAAS) effective stabilization of analytes can be achieved by an initial in situ electrodeposition of 0.2 μg of Pd. This amount of Pd is on average a factor of 50 lower than that typically used for conventional chemical modification. The surface features of this modifier have been characterized by scanning electron microscopy (SEM) measurements on sectioned pyrolytic graphite furnaces and contrasted with those for modifier produced from thermally reduced Pd salts. Electrodeposition produces a uniform array of Pd domains stretching approximately 2 mm from the centrally positioned Pt/Ir anode (which doubles as the autosampler sample delivery tube). In contrast, thermally reduced Pd salts produce a modifier which concentrates in domains near the drying edge of the modifier solution. Anodic stripping voltammetry (ASV) established that Pb electrodeposited onto Pd-modified pyrolytic graphite affixes to the Pd rather than the graphite. ASV measurements using a basal plane pyrolytic graphite working electrode also established that (i) the stripping potentials for monolayer and multilayer Pb are shifted anodically by 0.16 and 0.18 V, respectively by binding to Pd rather than graphite and (ii) deposition of Pb from dilute acidic medium (1% HNO_3) leads only to monolayer Pb, in contrast to deposition from acetate buffer (pH 4.0–4.4) which produces predominantly multilayer Pb. © 1997 Elsevier Science B.V.

Keywords: Electrodeposition; Palladium modifier; Stripping potential; Thermal stabilization

1. Introduction

Many analytical protocols in electrothermal atomic absorption spectroscopy (ETAAS) require stabilization of the analyte prior to, or within, the atomization phase. Often the objectives are to minimize the premature loss of volatile molecular analyte species, to improve separation of analyte and matrix components during the ashing phase and/or to increase the atomization temperature. The necessary stabilization can be achieved by

PII S0039-9140(96)02155-8

encapsulation of the analyte within a much larger mass of less volatile thermally produced matrix, e.g., MgO, or by alloying the analyte with a large mass of thermally produced metal, such as Ni or Pd [1]. Palladium is also used to preconcentrate hydrides of As, Sb, Se, Bi and Sn as compounds of low volatility prior to atomization from the pyrolytic graphite furnace [2].

A common problem with the use of chemical modifiers is the large mass required relative to the mass of analyte and therefore the associated risk of contamination. For example, the masses of Ni and Pd used are typically in the range 10–50 and 1–20 μg, respectively [1]. Recently we have reported the use of electrodeposited Pd as a modifier [3]. This modifier is significantly more effective than thermally reduced Pd at stabilizing the volatile analytes Pb, Cd, Cu [3] and H_2Se [4] to higher temperatures. Typically a mass of only 0.2 μg is required, being produced in situ in the pyrolytic graphite coated furnace. For example, our ETAAS results for stabilization of Pb by thermally generated (3.0 μg) and eletrodeposited (0.25 μg) Pd confirm more efficient stabilization by the latter: based on the ashing loss curves, stabilization of Pb by 500 K using electrodeposited Pd contrasts with only 150 K for thermally produced modifier [3]. The contribution of modifier contaminants with more negative reduction potentials is diminished by programming the autosampler to remove spent electrolyte after modifier deposition. The modifier blank can be further reduced by an acid wash. The modifier can be used for analysis of analytes by conventional methods, or by their electrodeposition onto the Pd. In the electrodeposition protocol the analyte can be quantitatively separated in 60 s deposition from such troublesome matrices as 0.5 M NaCl; the background absorption by NaCl is reduced by more than 99.5% [3].

In this paper we make a comparison of electrochemically and thermally produced Pd modifiers on the basis of their scanning electron micrographs. Modifiers produced from different electrolytes (HNO_3, HCl) are compared. Evidence is presented from differential pulse ASV that electrodeposited analytes affix to the Pd domains rather than to the much larger area of uncoated pyrolytic graphite. From ASV measurements on a basal plane pyrolytic graphite cathode it is established that the relative amounts of (the more highly stabilized) monolayer and bulk Pb deposited onto Pd (or graphite) depend on sample pH. The additional stabilization of Pb by deposition onto Pd rather than graphite is approximately $\Delta G = -31$ kJ mol^{-1}.

2. Experimental

2.1. Instrumentation

Scanning electron micrographs were taken with a Jeol JXA-840 scanning microanalyzer operating with an accelerating voltage of 30 kV and capable of 12–50 000 × magnification.

A GBC GF-3000 graphite furnace system, incorporated into a GBC 932 atomic absorption spectrometer was used to clean and condition miniature graphite furnace sections used for depositions. The standard graphite furnace tube (GBC Part No. G 19310121) was modified for this purpose by removing the internal central partitions so as to accommodate the furnace sections for cleaning and for thermal reduction of Pd.

ASV measurements were effected with a PAR 384B polarographic analyzer. Solution volumes of 6 ml were held in a perspex cell of 10 ml capacity designed for use with the PAR 303A stirrer and were stirred with a magnetic follower at 700 rpm. The working electrode (3 mm × 4 mm) was fabricated from a thin section of basal plane pyrolytic graphite mounted at the flanged base of a perspex tube (6 mm o.d.) by sealing in Araldite; electrical contact was via a drop of Hg on the reverse side. The auxiliary electrode was a 2 mm dia disk of high density graphite; the Ag,AgCl/Cl^- (3 M) reference electrode was separated from the test solution by a Vycor tip.

2.2. Reagents

Sodium acetate, HNO_3 and HCl were Aristar (BDH) quality. Acetic acid (BDH Analar) was further purified by isopiestic distillation. Stock solutions of Pd and Pb (100 mg l^{-1}) were pre-

pared by dissolving $PdCl_2$ (Aldrich 99.99%) and $Pb(NO_3)_2$ (BDH) in dilute Aristar HNO_3 or HCl. All dilutions were in Milli-Q water.

2.3. Procedure

For scanning electron microscopy (SEM) studies, electrodeposition was onto the concave surface of sections (9 × 3 mm) prepared by grinding pyrolytically coated miniature GBC GF-1000 furnaces (Ringsdorff Werke RWO/PyC) lengthwise to approximately half the original size. The sections were cleaned by heating twice inside a modified GF-3000 tube at 2500°C for 5 s with the internal Ar flow. The electrodepositions, at 5 V uncontrolled potential, were effected from 10 μl aliquots in the half furnaces, using a purpose-built stand in which the position of the Pt/Ir anode was controlled by an attached Agla micrometer. The anode-cathode separation was set at 0.7 mm, similar to that achieved in ETAAS experiments [3]. Following deposition of Pd (60 s, 20–30 mA) from 100 mg l^{-1} solution in 1% HNO_3 or 0.5% HCl, the furnace section was washed thoroughly in 0.1% Aristar HNO_3, then Milli-Q water and dried at 100°C. Lead was deposited over the Pd layer from 100–300 mg l^{-1} Pb in 1% HNO_3 or 0.03 M acetate buffer. Conditions were identical to those for Pd except the deposits were washed initially with Milli-Q water under applied voltage and then immersed in Milli-Q water prior to drying. For thermally produced modifier, 10 μl aliquots of 1000 mg l^{-1} Pd solution in 5% HCl were dried in half furnaces, followed by conditioning at 1200°C for 20 s.

ASV measurements were performed in a class 100 clean room. The electrode surface was initially cleaned by abrasion on an acid-soaked quantitative filter paper then by anodic polarization at 0.70 V for several minutes in stirred 1% HNO_3. Solution concentrations were: Pb, 120–225 μg l^{-1} in 0.03 M acetate buffer, pH 4.4, or in 0.1% HNO_3; Pd 5.0 mg l^{-1} in 0.05% HNO_3. Instrumental parameters were: N_2 flush 10 min, deposition time 60–1500 s, deposition potential −0.70 V (Pb) or 0.20 V (Pd), final potential 0.60 V, mode DPSV, modulation 25 mV, stripping speed 10 mV s^{-1}.

3. Results and discussion

3.1. Scanning electron microscopy

Surface distribution of thermally produced modifiers on pyrolytic graphite coated furnaces has been a subject of several SEM studies [5–7]. There is a general consensus that Pd or Ir modifier is concentrated towards the edges of the deposited solution. This is either ascribed to uneven distribution of the modifier during the drying step [5] or to its migration towards the edges during pyrolysis [6]. However, our experiments at 250 × magnification (not shown) confirm that the uneven distribution of Pd modifier stems from the drying process and is substantially maintained during pyrolysis up to 1200°C. In contrast, electrodeposited modifier is more uniformly and densely distributed. This difference in distribution is consistent with the observation that trapping of H_2Se injected through the furnace orifice following external generation is more efficient by Pd electrodeposited from 1% HNO_3 [4]. Modifier (Pd) electrodeposited from HCl contrasts with that from HNO_3. Evolution of Cl_2 at the anode leads to the dissolution of Pd [8] from the cathode area opposite the Pt/Ir probe.

Fig. 1(a)–(d) shows the scanning electron micrographs (2500 × magnification) and corresponding X-ray dot maps for Pd electrodeposited from 0.5% HCl and from 1% HNO_3. From HCl medium a more uniform, higher density of domains was achieved. At 2500 × magnification the Pd domains electrodeposited from HNO_3 medium appeared to fluoresce. Fluorescence (cathodoluminescence) is characteristic of non-conducting or semiconductor materials [9]. This suggests that under the conditions of vacuum and electron bombardment in the spectrometer the linkage between the Pd domains and the graphite substrate has a low electrical conductivity. As seen in Fig. 1(b), Pd deposits from HNO_3 indeed appear not to adhere as well to the pyrolytic graphite surface as those from HCl medium.

An additional feature associated with Pd deposited from HCl was a 'glazed' appearance. This feature is consistent with adsorption of Cl^- on the surface of the Pd domains (despite a 30 min

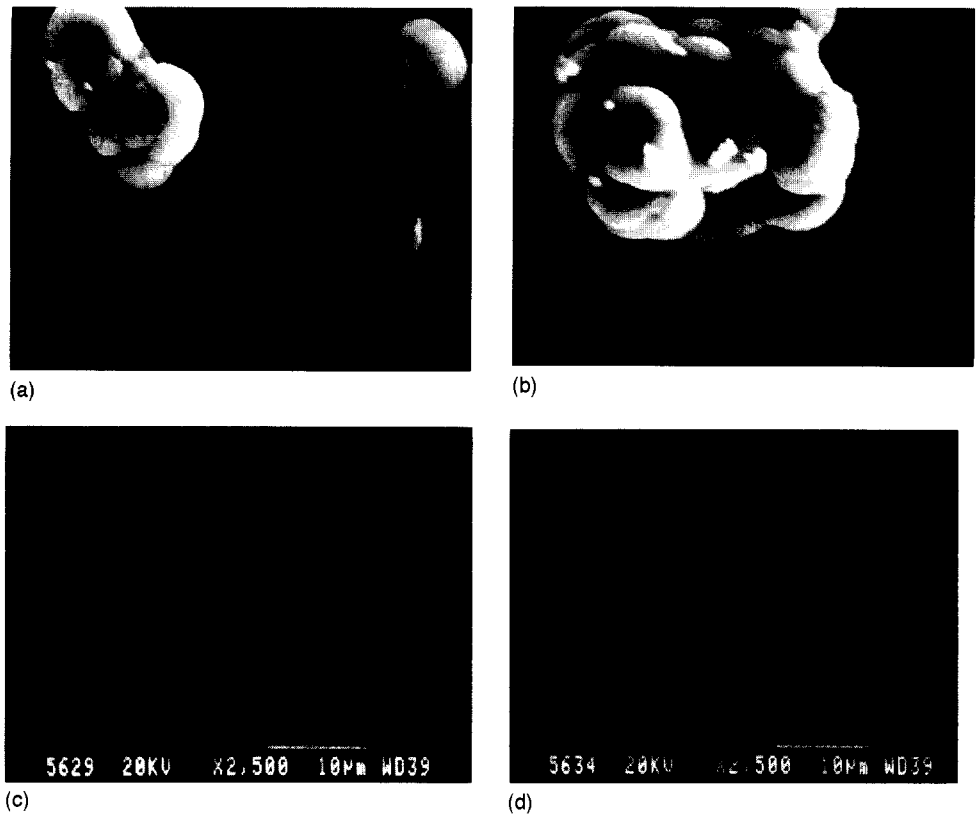

Fig. 1. Scanning electron micrographs at 2500 × magnification of 1 μg Pd electrodeposited from (a) 0.5% HCl and (b) 1% HNO_3 with corresponding X-ray dot maps measured at Pd $L\alpha_1$ 2.838 keV line (c) and (d), respectively.

wash in 0.1% HNO_3). An intense Cl fluorescence, its source physically coincident with Pd fluorescence, was observed in the SEM.

Although the mass of Pd used was well in excess of that required for a monolayer coverage (but of the same order as the amount required for the production of electrodeposited modifier), the Pd deposited from 0.5% HCl (Fig. 1(a) and (c)) is concentrated in a series of domains representing less than 20% of the surface area. Fig. 2 documents that, when viewed at the same magnification, thermally produced modifier provides a more uniform coverage (but less dense) relative to the same quantity of Pd electrodeposited from HCl. The scattered domains which arise from thermal evaporation and reduction of Pd salts (as documented previously [7]) indicate that sites with discrete activity are a feature of the adsorption and nucleation processes.

The formation of highly concentrated domains of Pd by electrodeposition on graphite surfaces, as observed for metal deposition on a glassy carbon electrode, indicates the presence of electroactive sites [10]. It may be expected that Pd electrodeposition is directed preferentially towards the most active sites. However, recent observations for thermally generated Ir modifier have confirmed that its distribution is non-reproducible even when carried out under the same conditions and that thermal pretreament results in modifier redistribution dictated by the surface features (rather than active sites) of the graphite tube [5].

Our observations confirm that surface morphology of the pyrolytic graphite coating plays a

significant role in determining the deposition pattern. The grade of graphite used displays a range of raised features and it is on these that preferential deposition takes place.

In ETAAS the amount of analyte determined is typically much smaller than the quantity of Pd modifier used. However, the low sensitivity of the XRF technique necessitates the use of unrealistically high amounts of analyte to obtain usable results. Despite using three orders of magnitude higher amount of Pb for SEM investigations (relative to the ASV work), detection still proved difficult. In order to highlight X-ray dot maps, these are presented in Fig. 3 and Fig. 4 as negative images. It appears from overlaps of X-ray dot maps for Pd and Pb that, for both HNO_3 and acetate buffer, these elements favour the same regions of the pyrolytic graphite surface. It should be noted that the dot maps are not exactly coincident, however, coincidence of the deposits is indicated by the displacement of the Pb ashing loss curve in the presence of electrodeposited Pd [3], and from the ASV results presented below. It was observed that the intensity of fluorescent radiation for Pd was noticeably weaker when Pb was deposited over the Pd layer (Fig. 3(b) and Fig. 4(b) compared with Fig. 1(c)).

3.2. Anodic stripping voltammetry

3.2.1. Deposition of Pb on graphite

Fig. 5 shows the differential pulse stripping voltammograms as a function of deposition time for Pb deposited at −0.80 V from a 120 μg l^{-1} solution in 0.03 M acetate buffer, pH 4.0. Broad stripping peaks are observed at $E_p = -0.45$, −0.06 and 0.21 V versus Ag,AgCl/Cl^- (3 M). The more cathodic peak at potential $E_p = -0.45$ V, is ascribed to the stripping of Pb from multilayer (bulk) deposits. For reference, the E° for Pb^{2+}/Pb is −0.32 V and $E_{1/2}$ for Pb^{2+}/(Pb/Hg) is −0.31 V, both relative to Ag,AgCl/Cl^- (3 M) [11]. The most anodic peak is ascribed to the stripping of monolayer Pb (designated Type I Pb). This indicates an underpotential of 0.66 V. The peak at −0.06 V may arise from Pb deposits at surface sites different from those at which the more stable monolayer is formed [12]. Szabo [13] has noted the energetic heterogeneity of substrate surfaces and thus the existence of multiple energy states for monolayers. Alternatively, the peak at −0.06 V may arise from stripping of the Pb layer next to that in direct contact with the graphite substrate. The atomic environment in this layer will be unique and the atoms will be partially stabilized by interaction with the electrode material.

Fig. 6 shows a plot of peak height versus deposition time for the three stripping peaks. The peak height for monolayer stripping increases systematically with deposition time, but much less rapidly than that for multilayer Pb. The peak at $E_p = -0.06$ V is almost invariant with deposition time. This is consistent with it representing monolayer deposition at sites for which the activation

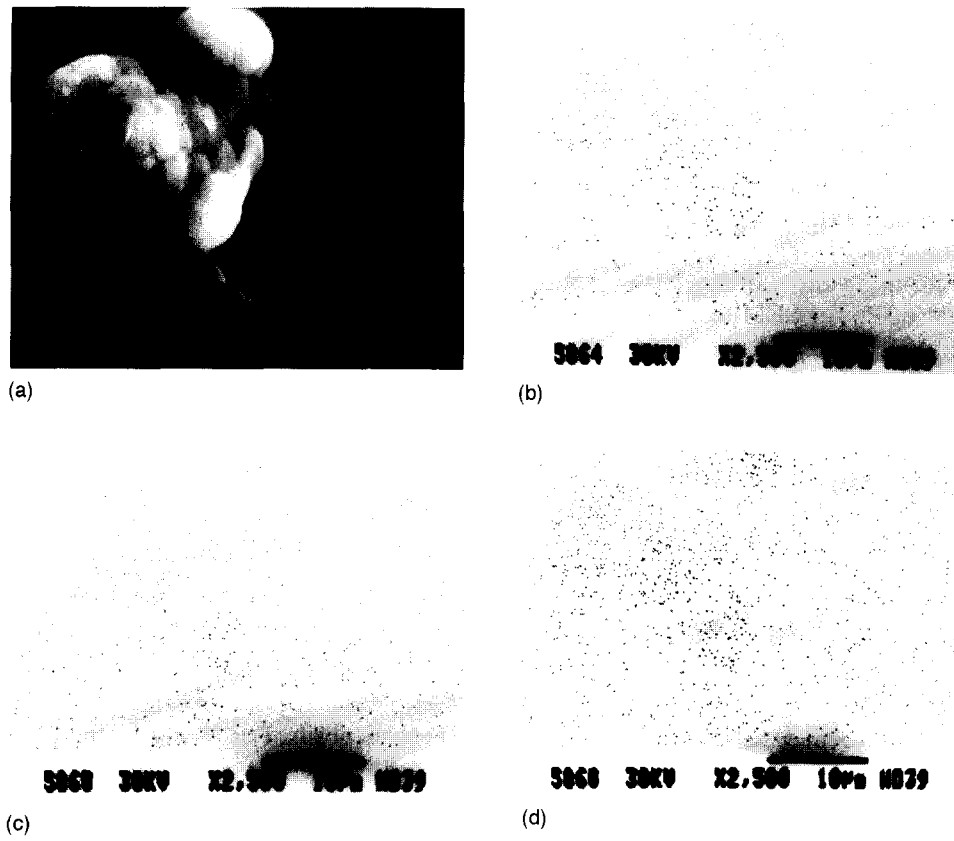

Fig. 3. Scanning electron micrographs at 2500 × magnification of 3 μg Pb electrodeposited from 1% HNO_3 over 1 μg Pd electrodeposited from 0.5% HCl (a) and corresponding X-ray dot maps measured at Pd $L\alpha_1$ 2.838 keV line (b) and Pb $M\alpha_1$ 2.346 keV line (c). X-ray dot map (d) is a composite of (b) and (c). Negative images are used for (b), (c) and (d).

energy for deposition is low and the number of sites is unaffected by the impact which cumulative deposition or gas evolution has on the surface properties. (This is designated Type II Pb.) It is not consistent with a unique second layer of Pb deposited over the expanding monolayer coverage. Both of the monolayer peaks are of significant magnitude after zero deposition time (70–90 s scan from −0.70 V in unstirred solution).

The unique stability of the monolayer Pb deposits is illustrated by the effect of a 20 s rinse of the electrode in 0.5% HNO_3 following a 360 s deposition at −0.80 V. Fig. 7, curve A indicates that all of the multilayer Pb (from 360 s deposition) is dissolved by the acid treatment. From the relative peak heights at 0.21 V and −0.06 V it is inferred that, compared with Fig. 5, a partial dissolution of the less stable Type II monolayer also occurs. Fig. 7, curves B and C show the stripping voltammograms following 60 s and 500 s depositions of Pb from a 0.1% HNO_3 solution, respectively. Only the more stable monolayer, Type I, accumulates; the monolayer Pb is more resistant to oxidative dissolution in the presence of O_2 [14], consistent with its more positive stripping potential. The E_p value for Type I Pb indicates a stabilization of $\Delta G° = -127$ kJ mol^{-1} $(= -zF\Delta E)$ relative to multilayer Pb. The resistance of the graphite-Pb monolayer to acid dissolution is consistent with the negative value of E for $Pb(C) + 2H^+ = Pb^{2+} + C + H_2$.

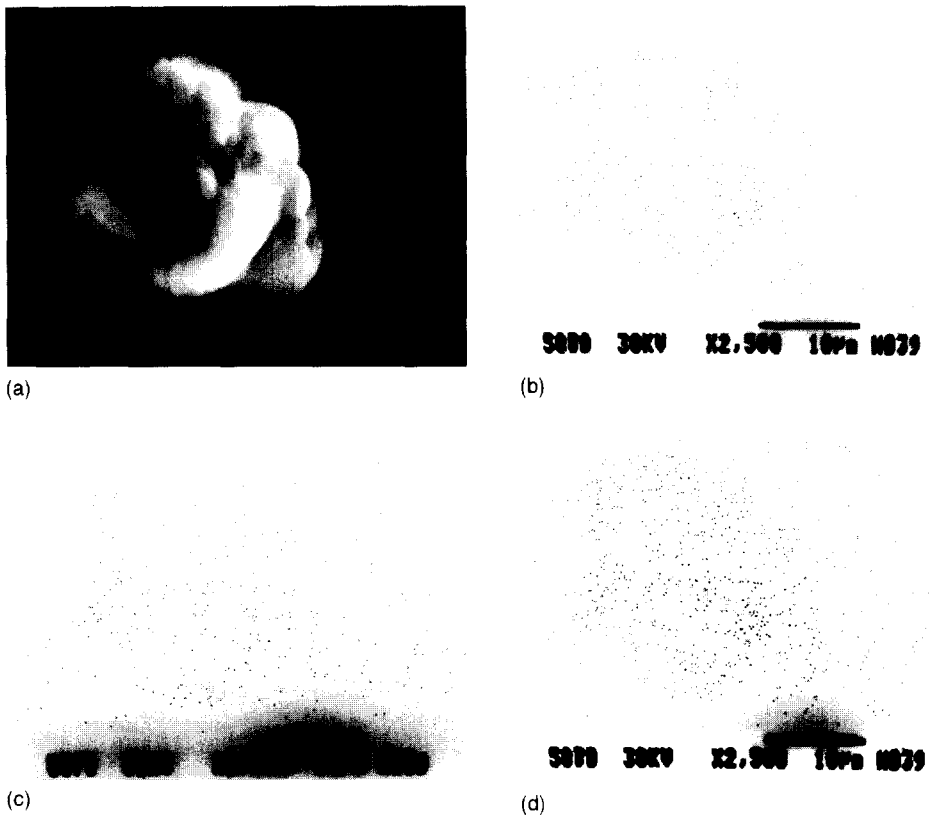

Fig. 4. Scanning electron micrographs at 2500 × magnification of 1 μg Pb electrodeposited from 0.03 M acetate buffer over 1 μg Pd electrodeposited from 0.5% HCl (a) and corresponding X-ray dot maps measured at Pd $L\alpha_1$ 2.838 keV line (b) and Pb $M\alpha_1$ 2.346 keV line (c). X-ray dot map (d) is a composite of (b) and (c). Negative images are used for (b), (c) and (d).

3.2.2. Deposition of Pd on graphite

Deposition of Pd onto pyrolytic graphite was effected at 0.20 V from a solution containing 5.0 mg l^{-1} Pd in 0.05% (0.08 M) HNO_3. The stripping voltammogram taken from −0.70 V, immediately following 100 s deposition showed a double peak with maxima at −0.18 V and approximately 0.00 V (Fig. 8, curve A). Because $E^{\circ}_{Pd^{2+}/Pd} = 0.95$ V (versus NHE) these peaks must involve a species other than (or in addition to) $Pd_{(s)}$. Possible assignments include the oxidation processes:

$$Pd_2H = 2Pd + H^+ + e^- \quad (1)$$

and

$$Pd(H_2) = Pd + 2H^+ + 2e^- \quad (2)$$

In contrast, stripping following a 60 s electrolysis at −0.70 V in acetate buffer gave a single peak at −0.16 V (Fig. 8, curve B). For the reduction process Eq. (1), the standard reduction potential $E^{\circ} = 0.048 - 0.059$ pH versus NHE [15], giving $E = -0.21$ V versus Ag,AgCl/Cl^- (3 M) at $[H^+] = 0.08$ M. For the reduction process Eq. (2), $E^{\circ} = 0.00$ V versus NHE, giving $E = -0.26$ V versus Ag,AgCl/Cl^- (3 M) at $[H^+] = 0.08$ M. These values are for bulk Pd; different values could be expected for small Pd domains on a graphite substrate [16]. As indicated below, the position of the peak(s) is very sensitive to the deposition of analyte (Pb) onto Pd.

3.2.3. Deposition of Pb on Pd

The electrode was precoated with Pd by 600 s deposition from 5.0 mg l^{-1} solution at 0.20 V. Deposition of Pb from 0.03 M acetate buffer (pH 4.4) onto electrodeposited Pd on pyrolytic graphite gave a stripping voltammogram with peaks at -0.27, -0.17 to 0.09 and 0.37 V (Fig. 9, curves A–E) for 0–1500 s depositions. The former was assigned to multilayer Pb and the latter to monolayer Pb on Pd. The shift in stripping potential for multilayer Pb (relative to E_p on graphite) was unexpected; it may be a consequence of the low mass of analyte involved, hence the proximity of all Pb atoms to the electrode (Pd) surface. The difference between E_p for monolayer Pb deposited on graphite and for monolayer deposition on Pd, $\Delta E_p = 0.16$ V, corresponds to a stabilization (on Pd) of $\Delta G° = -31$ kJ mol^{-1} ($= -zF\Delta E_p$). This is the energy difference for the processes

$$Pb(C) = Pb^{2+}_{(aq)} + 2e^- \quad (3)$$

and

$$Pb(Pd) = Pb^{2+}_{(aq)} + 2e^- \quad (4)$$

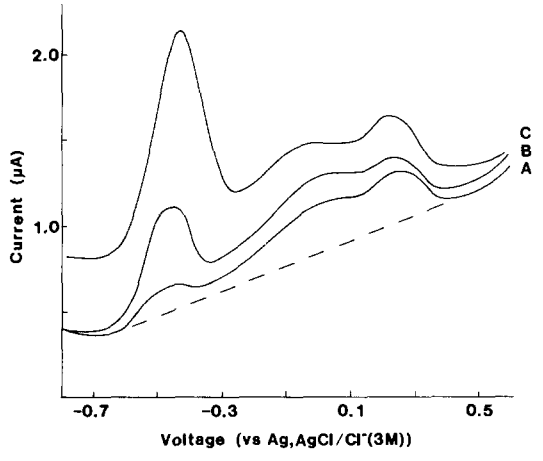

Fig. 5. Differential pulse stripping voltammograms for Pb deposited on pyrolytic graphite from acetate buffer (0.03 M, pH 4.0). Conditions: 120 μg l^{-1} Pb, conditioning potential 0.70 V, deposition potential -0.80 V. Voltammograms shown for (A) 60, (B) 180 and (C) 600 s deposition from stirred solutions.

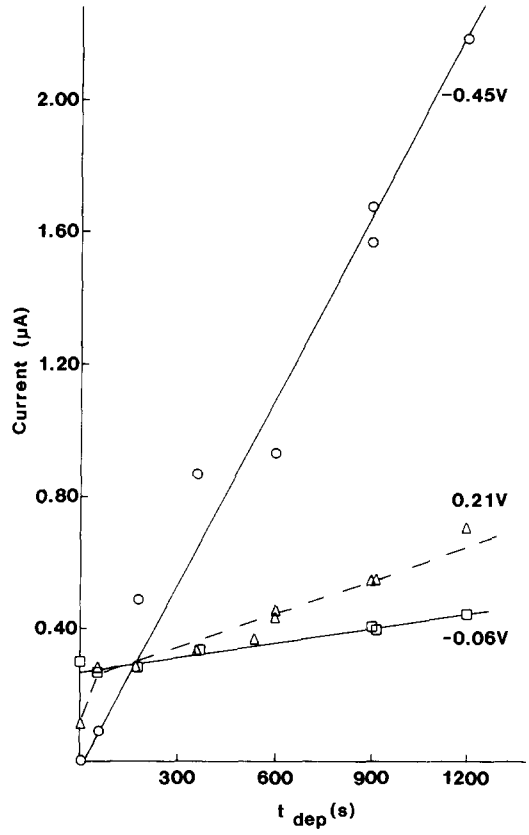

Fig. 6. Plot of differential pulse stripping peak height versus deposition time for bulk Pb ($E_p = -0.45$ V) and monolayer Pb bound to graphite, type I ($E_p = 0.21$ V) and type II ($E_p = -0.06$ V). Deposition conditions as for Fig. 3.

Yan and Ni [17] determined the activation energies for release (first order kinetics) of Pb from graphite and palladium surfaces (301 and 418–518 kJ mol^{-1}, respectively). They inferred that these energy terms are a measure of the analyte-surface interaction energy. If this is so, then the difference in stability of the two surface states of the analyte is c. -(100–200) kJ mol^{-1}. However these terms are kinetic parameters (activation energies) rather than thermodynamic parameters. Further, there is no guarantee that the process leading to the observed activation energy involves monolayer, as distinct from polylayer atomic species. For comparison, the stabilization of monolayer Pb on Pd relative to bulk Pb on Pd is calculated as $\Delta G° = -124$ kJ mol^{-1} from the shift in stripping potentials.

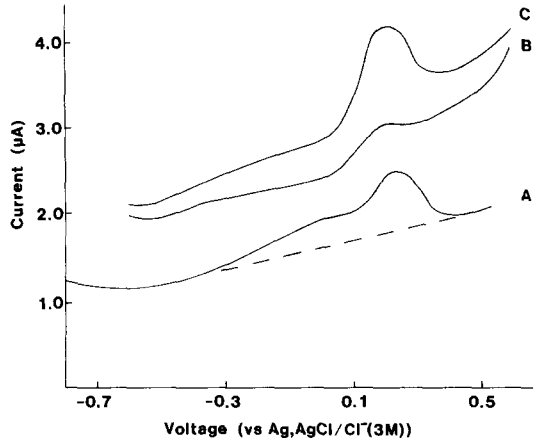

Fig. 7. Differential pulse stripping voltammograms for Pb deposited on graphite in acid (HNO_3) solution. Curve A, 200 s conditioning at 0.70 V, 360 s deposition from acetate buffer (0.03 M, pH 4.0) at −0.80 V, followed by 20 s in 0.5% HNO_3 before stripping. Curves B and C for deposition (60 and 500 s, respectively) and stripping in 0.1% HNO_3 (curve C at 1/3 sensitivity).

The position of the central stripping peak was very sensitive to plating time (mass of Pb deposited), Fig. 9, curves A–E. It shifted from −0.17 V for 0 s deposition to 0.09 V for deposition times greater than 1000 s, an effect which parallels that of Pb 'adatoms' on Pd catalysts; Mallat et al. [16] report the oxidation of H_2 from

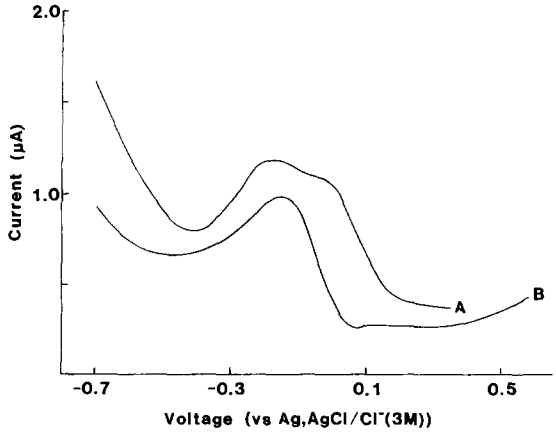

Fig. 8. Differential pulse stripping voltammograms for Pd deposited on pyrolytic graphite. Curve A: 100 s deposition from 5.0 mg l^{-1} Pd (0.05% HNO_3) at 0.20 V. Curve B: 60 s electrolysis at −0.70 V of Pd-coated pyrolytic graphite electrode (curve A) in 0.03 M acetate buffer (pH 4.4).

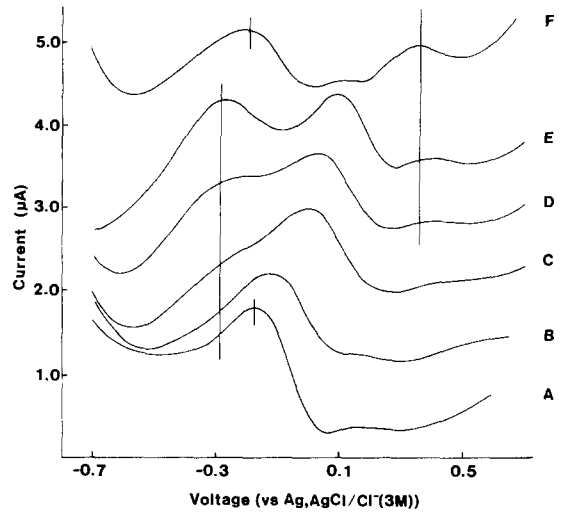

Fig. 9. Differential pulse stripping voltammograms for depositions from 225 μg l^{-1} Pb in 0.03 M acetate buffer (pH 4.4) onto pyrolytic graphite precoated with electrodeposited Pd. Curve A, blank (Pd only), B 60 s, C 240 s, D 480 s, E 1500 s deposition at −0.70 V. Curve F for 480 s deposition followed by 20 s in 1% HNO_3 before stripping.

β-Pd shifts from 0.15 V (versus NHE) for clean Pd to 0.30 V after Pb poisoning. In contrast, the stripping current was independent of plating time but was larger for scans in 0.5% HNO_3 than in acetate buffer. The stripping current increased with mass of deposited Pd. A 15 s wash with 1% HNO_3 following a 480 s deposition from pH 4.4 acetate buffer shifted this peak from 0.02 V back to −0.19 V (curve F). This wash also caused the loss of the −0.27 V peak. There was also an apparent three-fold increase in the monolayer peak at 0.37 V, presumably arising from the reactions:

$$2Pb + O_2 + 4H^+ = 2Pb^{2+} + H_2O \quad (5)$$

and

$$Pb^{2+} + Pd(H_2) = Pb/Pd + 2H^+ \quad (6)$$

Thus, analogous to deposition on graphite, only the Pb monolayer resists dissolution in dilute acid.

Deposition of Pb onto Pd from 1% (or 3%) HNO_3 gave monolayer Pb only (Fig. 10, curve A). The stripping current was proportional to $(t_{dep})^n$, where n is less than 1.0. The stripping voltammogram also showed the $Pd(H_2)$ oxidation peak

at −0.01 V. An interesting feature of this voltammogram is a ten-fold enhancement of the monolayer peak relative to that produced from acetate buffer for the same deposition time (Fig. 10, curve B). From this it may be inferred that in acetate buffer the rate (activation energy) for deposition of Pb onto Pb is greater (smaller) than that for deposition onto Pd. In the application of the electrodeposition—ETAAS technique it was found advantageous to effect 1% HNO_3 redeposition of Pb initially deposited from more weakly acidic acetate buffer solutions. This minimized losses during the subsequent rinsing stage (used to dilute matrix components such as NaCl). This can now be understood in terms of the dissolution of bulk Pb and its redeposition in more stable monolayer forms which resist dissolution during rinsing with air-saturated Milli-Q water.

A potential problem with quantitative deposition of analytes from dilute solutions is the competitive reaction from dissolved O_2, or other oxidants generated at the anode [14,18,19]. An advantage arising from monolayer deposition onto a Pd modifier is the substantial increase in stability of the Pb(s) phase. This will contribute to the success of the electrodeposition—ETAAS method.

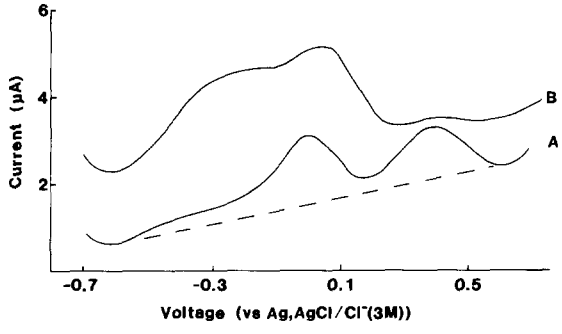

Fig. 10. Differential pulse stripping voltammograms for 225 μg l^{-1} Pb deposited on pyrolytic graphite coated with electrodeposited Pd. Curve A, 480 s deposition from and stripping into 1% HNO_3. Curve B, 480 s deposition from acetate buffer (pH 4.4).

3.2.4. Effect of analyte stabilization on appearance temperatures

Using a simplified approach it is possible to estimate the effect on the ETAAS appearance temperature of Pb (T_{app}) arising from its stabilization as a monolayer on Pd. From the relationship $\Delta(\Delta G^\circ) \cong -zF(\Delta E_p)$ applied to the redox reactions Eq. (7) and Eq. (8) the relative stability (Gibbs free energy) of the monolayers Pb(C) and Pb(Pd) can be estimated.

$$Pb^{2+} + 2e + C_{(s)} = Pb(C) \quad (7)$$

$$Pb^{2+} + 2e + Pd_{(s)} = Pb(Pd) \quad (8)$$

Using the relationship $\Delta(\Delta G^\circ) = -R\Delta(T \ln K_p)$ applied to reactions Eq. (9) and Eq. (10)

$$Pb(C) = Pb_{(g)} + C_{(s)} \quad (9)$$

$$Pb(Pd) = Pb_{(g)} + Pd_{(s)} \quad (10)$$

$\Delta(\Delta G^\circ)$ can be used to estimate:

(i) the ratio of partial pressures of Pb above the two monolayers at a given temperature, or

(ii) the shift in appearance temperature (T_{app}) corresponding to a specific vapour pressure of Pb,

$$\Delta(\Delta G^\circ) = -R\Delta(T_{app}) \ln P_{app}$$

However, some approximations are necessary. It is assumed that $\Delta(\Delta G^\circ)$ is not affected significantly by a change in temperature. If it is assumed that T_{app} corresponds to a mass of analyte similar to the characteristic mass (8 pg for Pb [3]) and that the effective volume occupied by the gaseous analyte at T_{app} is ca. 100 μl then at (say) 1000°C the ideal gas equation gives $P_{app} = 4 \times 10^{-8}$ atm. An ideal gas assumption is reasonable considering the high temperature involved. From the observed shift in stripping potentials (0.16 V) the calculated value for $\Delta(T_{app})$ is approximately 220 K, a value in reasonable agreement with the displacement of ashing loss curves by 250 K reported previously by Matousek and Powell [3]. Such calculations do not take cognisance of the kinetic factors involved in the atom release processes, nor the fact that the system may not be at equilibrium around the appearance temperature. However, they serve to indicate the insight to be gained about surface stabilization of analytes from measurement of their stripping potentials.

Abstract

A reversed phase ion-paired chromatographic method that can be used to determine trace amounts of iron (II,III), nickel (II) and copper (II) was developed and applied to the determination of iron (II) and iron (III) levels in natural water. The separation of these metal ions as their 4,7-diphenyl-1,10-phenanthroline (bathophenanthroline) chelates on an Inertsil ODS column was investigated by using acetonitrile-water (80/20, v/v) containing 0.06 M perchloric acid as mobile phase and diode array spectrophotometric detection at 250–650 nm. Chromatographic parameters such as composition of mobile phase and concentration of perchloric acid in mobile phase were optimized. The calibration graphs of iron (II), nickel (II) and copper (II) ions were linear ($r > 0.991$) in the concentration range 0–0.5, 0–2.0 and 0–4.0 μg ml^{-1}, respectively. The detection limit of iron (II), nickel (II) and copper (II) were 2.67, 5.42 and 18.2 ng ml^{-1} with relative standard deviation ($n = 5$) of 3.11, 5.81 and 7.16% at a concentration level of 10 ng ml^{-1} for iron (II) and nickel (II) and 25 ng ml^{-1} for copper (II), respectively. The proposed method was applied to the determination of iron(II) and iron(III) in tap water and sea water samples without any interference from other common metal ions. © 1997 Elsevier Science B.V.

Keywords: Determination of iron (II,III); 4,7-diphenyl-1,10-phenanthroline; Ion-paired chromatography; Nickel (II) and copper (II)

1. Introduction

The simultaneous determination of metal ions as their chelates with organic reagents by high performance liquid chromatography (HPLC) has received increasing attention and has been used for inorganic analysis in recent years [1–4]. In particular, reversed-phase (RP) HPLC seems to offer excellent potential for the determination of many metals owing to its high efficiency and simplicity of operation [5]. Several reviews on this subject have appeared in the literature [6,7]. Many organic chelating agents such as dithiocarbamates [8], 8-hydroxy-quinoline [9], chlorophyll [10,11] and other highly sensitive azo dyes including PAR [12], PAN [13] and 1,10-phenanthroline [14,15] have been used for complexation prior to separa-

PII S0039-9140(96)02156-X

tion by HPLC. These reagents form either neutral or ionic chelates with a large number of metal ions, and the chelates in the eluate can be detected spectrophotometrically. Most recently, 1,10-phenanthroline also has been used for the determination of serum iron in human blood by high performance capillary electrophoresis (HPCE) after precipitation of serum proteins and reducing iron (III) to iron (II) with hydroxyl amine [16]. With this method, a single drop (10 μl) of serum would be sufficient to determine the serum iron concentration.

Some derivatives of 1,10-phenanthroline also have been developed for chelating reagents but most of them were only a little superior to the parent reagent. However, 4,7-diphenyl-1,10-phenanthroline (bathophenanthroline: Bphen) is an exception. Bathophenanthroline reacts with iron(II) and other metal ions very similarly to 1,10-phenanthroline. Both methods are of similar selectivity, but the bathophenanthroline method is twice as sensitive. The molar absorptivity of iron (II) bathophenanthroline at 534 nm varies between 2.24–2.56 ($\times 10^4$) depending upon the solvents used [17]. Colorimetric [18], spectrophotometric [19] and flow injection [20] methods using this reagent have been reported but their selectivity is still poor due to the interference from several metal ions such as Cu^{II}, Ni^{II}, Co^{II} and Zn^{II} which also form chelates with bathophenanthroline. So far, there has been still few reports regarding the use of bathophenanthroline as a pre-column reagents for the determination of metal ions by HPLC. If its chelates can be separated and detected spectrophotometrically by means of HPLC, the reagent could give a highly sensitive and selective HPLC method for simultaneous determination of some metal ions.

The aim of the present study is to develop a simple, selective and sensitive method for the determination of iron (II,III), nickel (II) and copper (II) using spectrophotometric detection with batho-phenanthroline as a pre-column reagent. The separation, identification and quantitation of different metals can be performed in one procedure by taking advantages of HPLC. The method was then applied to the direct determination of iron (II) and iron (III) at ppb level in tap water and sea water to demonstrate its applicability.

2. Experimental

2.1. Apparatus and reagents

A home-built HPLC system was used for the separation and determination of iron (II), nickel (II) and copper (II) as their bathophenanthroline chelates. Samples were injected into a Reodyne 7125 (100 μl loop) injector and passed through a filter and a guard column before passing to an Inertsil ODS AI525 column (5 μm, 4.6 × 250 mm from GL Sciences). The guard column of 4.0 mm was packed with 5 μm Inertsil ODS (GL Sciences). The pump (Jasco PU-980 intelligent pump together with LC-980-2 Ternary gradient unit and DG-980-50 3-line degasser) was adjusted so that the flow rate was 1.0 ml min^{-1}. The diode array spectrophotometer (Jasco Multi-340 multichannel) used as a detector was interfaced with a personal computer (NEC PC-980 VM) for the purpose of peak analysis and was operated between 250–650 nm. The mobile phase was prepared by volume and consisted of acetonitrile-water (80/20 v/v) and 0.06 M $HClO_4$ and was ultrasonically mixed for several minutes before use. The typical UV-Vis spectra were recorded by a Jasco V-550 UV/VIS spectrophotometer.

Bathophenanthroline was obtained from Aldrich and was used without further purification. Acetonitrile (special grade) and distilled water (HPLC grade) were purchased from Katayama Chemical Industries. Perchloric acid for counter ion and sodium acetate for buffer solution were obtained from Junsei and Wako, respectively. Stock solutions of iron(II), iron (III), nickel (II) and copper (II) were prepared from their corresponding salts which were purchased from the following sources: $FeSO_4$ $(NH_4)SO_4.6H_2O$ and $CuCl_2.2H_2O$ were from Wako Pure Chemical Industries, $NiSO_4.6H_2O$ from Showa and $Fe_2(SO_4)_3(NH_4)_2SO_4.12H_2O$ from Kokusan Chemical Works. All chemicals were analytical grade.

2.2. Preparation of metal chelates

Solid chelates of iron (II), nickel (II) and copper (II) bathophenanthroline were prepared as their perchlorate salts. The chelates were obtained by a modification of the procedure described by either Schilt and Taylor [21] or K. Miyoshi et al. [22]. The procedure, in general, consisted of dissolving corresponding metal salts and bathophenanthroline at a mole ratio 1:3 for iron(II) and nickel(II) and 1:2 for copper(II) in hot water (about 80°C) containing 50% of ethanol, followed by adding sodium perchlorate. The resulting crystals were washed with water and recrystallized from hot water and dried in vacuo. The crystalline complexes were then identified by elemental analysis and absorption spectroscopy.

2.2.1. Results of elemental analysis

$Fe(C_{24}H_{16}N_2)_3(ClO_4)_2$. Calculated: C = 69.06; H = 3.86; N = 6.71%. Found: C = 69.03, H = 3.66, N = 6.81%.$Ni(C_{24}H_{16}N_2)_3(ClO_4)_2.1/2H_2O$. Calculated: C = 68.35; H = 3.87; N = 6.70%. Found: C = 68.03, H = 3.83, N = 6.55%.$Cu(C_{24}H_{16}N_2)_2(ClO_4)_2$. Calculated: C = 62.17; H = 3.48; N = 6.04%. Found: C = 62.24, H = 3.50, N = 6.29%.

2.3. Analytical procedure

The HPLC of metal bathophenanthroline chelates was studied by using their aqueous solutions and the chelates were made up according to the following procedure. The required quantity of stock solution (100 mg ml^{-1}) of each metal ion was taken volumetrically into 25 ml calibrated flasks. After diluting the solution to about 10 ml with mobile phase, 2 ml of 5% sodium acetate and a sufficient amount (ca. 5 ml) of 0.002 M bathophenanthroline were added to the diluted solution. The solution was then heated to boiling for 15 min, cooled to room temperature and finally diluted to the mark with the mobile phase. The samples of tap water and sea water were filtered through 0.45 μm filter before treated as described above.

3. Results and discussion

3.1. Absorption spectra and pre-column derivatization conditions

The ultraviolet absorption spectra of free ligand and its metal chelates in chloroform are shown in Fig. 1. Both free ligand and its metal chelates give strong absorption in the ultraviolet region between 250–350 nm due to the conjugated structure of bathophenanthroline i.e., intra-ligand $\pi-\pi^*$ absorption. However the absorption maxima of the metal chelates are shifted towards longer wavelength compared with that of free ligand, proving the existence of coordination of ligand to metal ions. In addition, the absorption maximum of iron (II)-bathophenanthroline chelate is also observed in the visible region and corresponds to metal–to–ligand charge transfer ($d-\pi^*$) absorption. This strong visible absorption at 534 nm is the basis of the application of the ligand to colorimetric determination of iron [23]. The absorption maxima and molar absorptivity of ligand and metal chelates are summarized in Table 1. It is obvious from the table that all metal

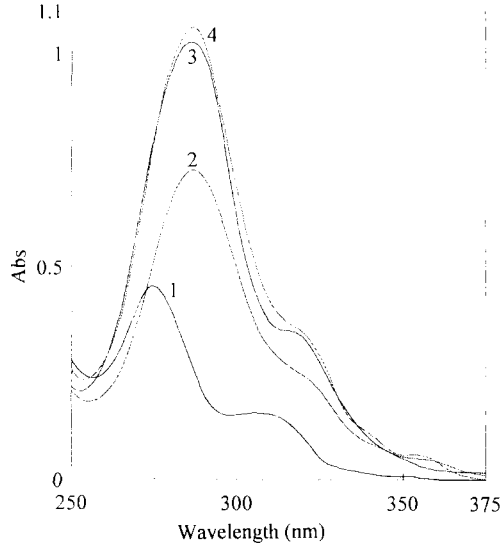

Fig. 1. Absorption spectra of metal bathophenanthroline chelates in ultraviolet region. (1) bathophenanthroline; (2) $Cu(Bphen)_2(ClO)_2$; (3) $Fe(Bphen)_3(ClO)_2$; and (4) $Ni(Bphen)_3(ClO)_2$.

Table 1
Absorption maxima (λ_{max}) and molar absorptivity (ϵ) of metal-bathophenanthroline chelates[a]

Compounds	λ_{max} (nm)	ϵ (cm^{-1} mol^{-1} l)
Bathophenanthroline(Bphen)	277	4.62×10^4
Tris(Bphen)Fe(ClO_4)$_2$	289	1.31×10^5
	534	2.26×10^4
Tris(Bphen)Ni(ClO_4)$_2$	290	1.35×10^5
Bis(Bphen)Cu(ClO_4)$_2$	289	9.28×10^4

[a] Dissolved in chloroform.

chelates have a maximum of detection sensitivity at about 290 nm. Therefore, a detection wavelength of 290 nm was selected for analytical purpose in the present study.

Bathophenanthroline reacts readily either with metal ions such as iron (II), nickel (II) and ruthenium (II) ions to form an octahedral chelate or with metal ions such as copper (II) ions to give a tetrahedral chelate over the wide range of pH 2–9 in acetate or tartrate buffer [17]. These differences in structure as well as their coordination numbers are considered to be the basis of chromatographic separation with a reversed phase column. We found by experiments that the concentration of bathophenanthroline in solution should be kept higher than 4.8×10^{-4} M for a solution containing 0.5, 2.0 and 4.0 μg ml^{-1} of iron (II), nickel (II) and copper (II) ions, respectively. Otherwise two peaks of nickel chelates which are assumed to be Ni(Bphen)$_2^{2+}$ and Ni(Bphen)$_3^{2+}$ will appear.

3.2. Separation of metal chelates

The separation of metal chelates Cu(Bphen)$_2^{2+}$, Fe(Bphen)$_3^{2+}$ and Ni(Bphen)$_3^{2+}$ on an Inertsil ODS column was studied using a combination of mobile phases such as water, methanol and acetonitrile. A good separation was achieved when the mobile phase consisted of acetonitrile–water (80/20 v/v) and 0.06 M perchloric acid was applied. All three peaks of metal chelates are resolved and well-separated from a peak due to the ligand, HBphen$^+$. The typical three dimensional chromatogram of metal chelates obtained by means of this composition of mobile phase is

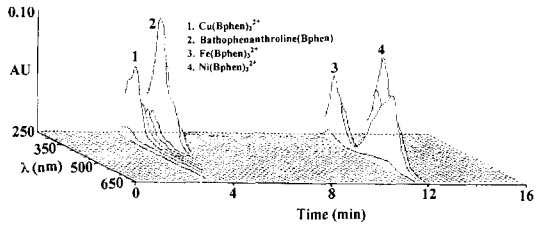

Fig. 2. Typical three dimensional chromatogram of metal bathophenanthroline chelates. Mobile phase, acetonitrile–water (80/20 v/v) containing 0.06 M $HClO_4$; column, Inertsil ODS; flow rate, 1.0 ml min^{-1}; and detection, 250–650 nm.

shown in Fig. 2. The retention time of all these species are 3.4, 4.7, 12.8 and 14.9 min for Cu(Bphen)$_2^{2+}$, HBphen$^+$, Fe(Bphen)$_3^{2+}$ and Ni(Bphen)$_3^{2+}$, respectively. The resolution (R_s) of Cu(Bphen)$_2^{2+}$, Fe(Bphen)$_3^{2+}$ and Ni(Bphen)$_3^{2+}$ from the ligand HBphen$^+$ calculated from the observed retention time (t_R) and measurements of peak widths (w_b) are 1.44, 12.46 and 13.60, respectively. The R_s values are quite sufficient for accurate quantification ($R_s > 1$) [24].

The retention behavior of metal chelates with acetonitrile based solvents was investigated as a function of the concentration of organic component and the plots of their capacity factor (log k′) against the composition of mobile phase are presented in Fig. 3. The retention time of all species were found to increase with the water content of the mobile phase. This tendency is consistent with

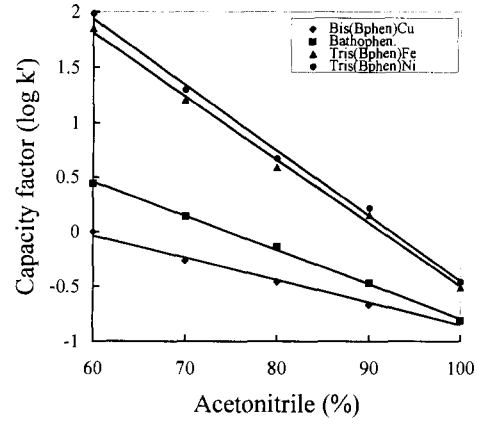

Fig. 3. Effect of acetonitrile concentration (%v) in mobile phase on capacity factor (log k′) of metal bathophenanthroline chelates

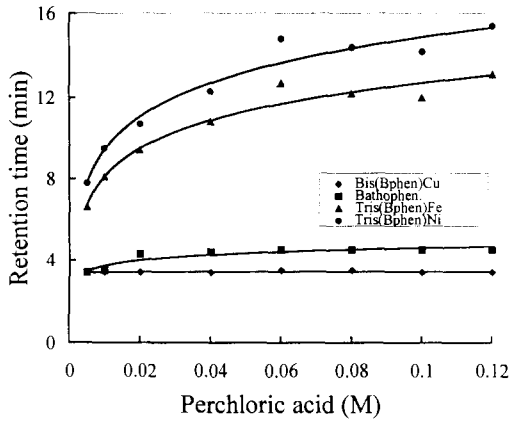

Fig. 4. Effect of perchloric acid concentration (M) in mobile phase on retention time of metal bathophenanthroline chelates.

what would be expected from the solvophobic theory. The optimum composition of mobile phase was reached at approximately 20% of water content. The resolution continued to increase at the higher concentration of water in acetonitrile but the metal chelates, except $Cu(Bphen)_2^{2+}$, gradually became insoluble and the retention time became too long for the purpose of practical analysis.

3.3. Effect of perchlorate concentration on retention time

From the previous work [25] on separation of iron (II) complexes of 1,10-phenanthroline and its derivatives, it was found that perchlorate ion was the most suitable counter ion for the separation compared with other counter ions such as alkylsulfonate and phosphate ion. The reason why perchlorate ion becomes the most suitable counter ion also has been discussed. On the basis of that results, perchlorate ion was selected as a counter ion for the separation of metal-bathophenanthroline chelates.

The relationship between perchlorate concentration and retention time of the chelates was studied by varying perchloric acid concentration in the mobile phase from 0.05 to 0.12 M. Fig. 4 shows that the retention time of metal chelates increases slightly with the perchlorate concentration up to 0.05 M and then becomes almost steady at the concentration greater than 0.05 M. This behavior indicates that a perchlorate concentration of about 0.05 M in the mobile phase was sufficient enough for the formation of ion-pair association so that further addition of perchlorate ion has no longer effect on retention time of the chelates. Even though the retention time is not influenced significantly, the use of perchloric acid concentration above 0.08 M was not suggested because it would decrease pH of the mobile phase. Probably column packing material could be damaged if the column is operated below the recommended pH of reverse-phase column operation (between 2–11). Moreover, protonation of the free ligand may occur at a lower pH of the mobile phase which can cause the metal chelates to dissociate due to the restoration of equilibrium conditions with the free ligands [26].

The effect of pH on the separation of metal chelates was not studied in the present work. Replacing perchloric acid in mobile phase (pH ca. 2) by lithium perchlorate (pH ca. 7) gave no significant effect on retention time, but the peak of $Cu(Bphen)_2^{2+}$ became broader and more tailing. This is probably due to the conversion of colorless $Cu(Bphen)_2^{2+}$ chelate to another species (yellow) as the mobile phase became neutral or alkaline [19]. For this reason and for its large solubility in the mobile phase compared with lithium perchlorate, perchloric acid was selected as a counter ion for further study.

3.4. Calibration graphs and interferences

In order to know the performance of the present method, a calibration graph for each metal ion was constructed according to the analytical procedure described in experimental section. The calibration graphs of peak area versus metal ion concentration were linear in the concentration ranges 0.05–0.5, 0.25–2.0 and 0.25–4.0 μg ml^{-1} for iron (II), nickel (II) and copper (II) ions, respectively. The correlation coefficients for all metal ions are above 0.991 ($n = 3$). The repeatability was examined with five injections at a concentration level of 10 ng ml^{-1} for iron (II) and nickel (II) ions and at a concentration level of 25 ng

Table 2
Analytical performance of the proposed method

Metal ion	Regression equation[a]	r	Detection limit (ng ml^{-1})[b]	RSD (%)[c]
Fe (290 nm)	$y = 2.94x + 0.03$	0.995	2.67	3.11
Fe (534 nm)	$y = 2.62x + 0.04$	0.992	5.15	7.37
Ni	$y = 1.94x + 0.08$	0.993	5.42	5.81
Cu	$y = 0.47x + 0.01$	0.998	18.20	7.16

[a] Where y is the peak area and x is the concentration (in μg ml^{-1}).
[b] Defined as the analyte concentration giving a signal equal to three times the standard deviation.
[c] Measured at 10 ng ml^{-1} for iron (II) and nickel (II) and at 25 ng ml^{-1} for copper (II) ($n = 5$).

ml^{-1} for copper(II) ion. The relative standard deviation of all metal ions was found to be below 7.5%. The detail analytical performance of the present method including regression equation, correlation coefficients (r), detection limit (for S/N = 3) and relative standard deviation (RSD) are listed in Table 2. Since $Fe(Bphen)_3^{2+}$ also gave an absorption maximum in the visible region at 534 nm, a calibration graph for iron(II) ion at this detection wavelength was also constructed for the purpose of comparison.

Because the analytical method developed is to be applied to the determination of iron (II) and iron (III) in natural water, possible interferences from other metal ions such as Ni^{II}, Co^{II}, Zn^{II}, Cu^{II}, Al^{III}, Sn^{II}, Mo^{IV} and Pb^{II} [4] which commonly exist in natural water should be aware. Among those metal ions, nickel (II) and copper (II) are reported to interfere strongly with the determination of iron (II) as bathophenanthroline chelate by spectrophotometry, while cobalt (II) and zinc (II) interfere slightly [17]. Fortunately, nickel (II) and copper (II) are well-separated from iron (II) under this analytical condition, and thus investigation was focused on cobalt (II) and zinc (II) ions. Aluminium (III), even though no interference is reported, was also investigated because this ion is most likely to be encountered in natural water in relatively high concentration.

Solutions of cobalt (II), zinc (II) and aluminium (III) (100 μg ml^{-1}) were prepared by dissolving their corresponding salts in distilled water. The concentration of each metal ion examined was adjusted 20 times higher than that of iron (II) so that it was also high enough compared with usual concentration encountered in real samples. The solution of bathophenanthroline chelate with cobalt (II), zinc (II) or aluminium (III) was prepared by the procedure described in experimental section and then injected into the HPLC system. No peaks other than those of iron (II) chelate and excess ligand were detected for cobalt (II), zinc (II) or aluminium (III) solution, suggesting that these chelates are probably decomposed during the separation process in the column because cobalt (II), zinc (II) chelates of bathophenanthroline are considered as labile chelate [15]. It was confirmed that the coexistence of cobalt (II), zinc (II) or aluminium (III) ions does not interfere with the present ion-paired chromatographic (IPC) determination of iron (II), nickel (II) and copper (II) in natural water.

3.5. Determination of iron (II) and iron (III)

The developed method was applied to the determination of iron (II) and iron (III) in tap water in Yokohama and sea water obtained from environmental chemistry laboratory, Keio University. Copper (II) and nickel (II) were not determined because their content in natural water is normally below the detection limit [2]. Iron (III) is also able to form chelate with bathophenanthroline but the stability of the chelate is very low compared with that of iron (II) chelate [17]. Preliminary investigation by injecting iron (III) chelate into the HPLC system showed that the chelate was eluted around 8 min before iron (II) chelate but the peak was very broad and tailing. Therefore, it is not possible to determine iron (III) and iron (II) simultaneously. Here, iron (II) and total iron were determined separately by reducing iron (III) to

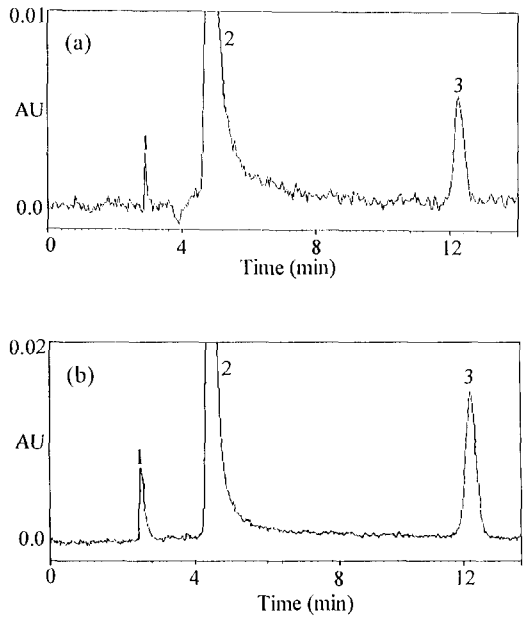

Fig. 5. Typical chromatograms for the determination of iron(II) in tap water sample (a) and total iron in sea water sample (b). Conditions as in Fig. 2 (1) solvent; (2) bathophenanthroline; and (3) $Fe(Bphen)_3^{2+}$.

iron (II) with hydroxyl amine hydrochloride for the total iron determination. Iron (III) content was then calculated by substracting iron (II) from the total iron content (iron (II) plus iron (III) ions).

Since bathophenanthroline is a very sensitive reagent toward iron (II), an extra-care should be taken against iron (II) contaminant from outside sources. Every determination should be corrected subsequently by blank solution especially for the determination of total iron because it is difficult to find a reducing agent free from iron (II). Total iron should be corrected with the blank solution also containing the reducing agent, and one fails to do so will have the result higher than it should be. Fig. 5 shows the typical chromatogram of iron (II) determination in tap water (a) and total iron determination in sea water (b). The results of the determination and their relative standard deviations are listed in Table 3, together with the analytical results obtained by spectrophotometry. It is clear that both sets of results (IPC and spectrophotometry) are comparable. A little higher results of spectrophotometry in sea water are attributed to the complexity of sea water matrix which slightly increases the measured absorbance. As a result, calculated concentrations of iron (II) and iron (III) in sea water are higher than they should be. In conclusion, it has been demonstrated that the developed IPC method is a simple and practical technique for the determination of iron (II) and iron (III) in tap water and sea water. The method may also be applied to the simultaneous determination of iron (II), nickel (II) and copper (II) in other samples containing these metal ions in the higher levels than those of limit detection.

Micellar enhanced cyanide ion determination in samples from synthetic organic processes

John O. Egekeze *, Thomas M. Dowling, Nelu Grinberg, Holly J. Perpall, Gary R. Bicker

Merck Research Laboratories, R80Y-115, P.O. Box 2000, Rahway, NJ 07065-0914, USA

Received 20 August 1996; received in revised form 21 October 1996; accepted 25 October 1996

Abstract

A method was developed for the recovery and determination of cyanide ion in organic sample matrices. To facilitate the solubilization of cyanide ions, cetyltrimethylammonium bromide (CTAB) was added at concentrations above the critical micelle concentration. Sample cyanation reaction products consisted of solvent mixtures of a hydroxynitrile in DMF-toluene or DMF-isopropylacetate (IPAC). Spectrophotometric determination of cyanide ion at 578 nm by the pyridine-barbituric acid method was automated by flow injection analysis. Recovery of cyanide ion from spiked samples was 93.2% in DMF-IPAC solvent matrix and 93.9% in DMF-toluene. Low alkali concentration was observed to favor solubilization of cyanide ion in the micellar solution. © 1997 Elsevier Science B.V.

Keywords: Cyanide determination; Micellar solution; Organic samples

1. Introduction

Cyanation is a commonly used synthetic organic reaction in the pharmaceutical and specialty chemical industries [1–4]. When this reaction is run on a pilot plant or factory scale, a product mixture generally results that is high in cyanide ion concentration. If the nitrile produced is an intermediate in the synthesis of a bulk drug candidate, the concentration of cyanide ion must be considerably reduced before the intermediate can be used in the next synthetic step. The high toxicity of cyanide ion at low doses and the environmental problem posed by cyanide waste disposal make accurate determination of this ion in organic sample matrices an important task. Published methods for cyanide ion determination have addressed cyanide (free/bound or HCN) assays in aqueous samples. A popular procedure in these methods involved distillation of the acidified sample solution to transfer evolved HCN into an aqueous sodium hydroxide solution where it was converted to cyanide ion. The cyanide ion produced has been determined by spectrophotometry [5–10], potentiometry [11], amperometry [12,13], fluorescence spectroscopy [14], and ion chromatography [15].

When the cyanide ion is present in a liquid organic sample, acidification and distillation to

PII S0039-9140(96)02160-1

evolve HCN leads to increased pressure in the distillation system due to production of a large volume of organic vapor. The distillation method is therefore unsafe for the analyst because of the likelihood for liquid boil over or explosion. Cyanide ion in an organic sample matrix can be made available for determination by the use of amphiphilic molecules (surfactants) each of which consists of a hydrophobic tail joined to a hydrophilic head. Surfactants are classified as anionic, cationic, or zwitterionic, depending upon the nature of the polar head [16]. When dissolved in water at concentrations equal to or above the critical micelle concentration (cmc), surfactants tend to form spherical aggregates called micelles or organized molecular assemblies. Micelles exhibit several properties which facilitate analytical measurements. These include their ability to solubilize and concentrate analytes, alter acidity and polarity of solutes, and modify reaction rates and chemical equilibria [17–19]. The most important of these properties is the ability of micelles to solubilize within their microscopic local environment compounds which are insoluble or sparingly soluble in water. Ionic micelles also provide charged structures where attractive or repulsive interactions with ionic solutes may take place. The use of an aqueous micellar medium to improve the spectrophotometric determination of cyanide ion with the organic disulfide 5,5′-dithiobis(2-nitrobenzoic acid), usually referred to as (DTNB), was reported by Hinze [20]. The problem with the use of DTNB is that the compound is sensitive to both cyanide and sulfite ions and is not ideal for a sample that contains both ions as is the case in this study.

This paper reports the use of aqueous micellar solutions of the cationic surfactant cetyltrimethylammonium bromide (CTAB) to facilitate the recovery of cyanide ion from a cyanation reaction product mixture. The samples used in the study were liquid hydroxynitrile concentrates from cyanation reactions between sodium cyanide and an organic sulfite. One group of nitrile samples was prepared in a solvent mixture consisting of 5% dimethylformamide (DMF) in isopropylacetate (IPAC), and the other group was prepared in a solvent mixture consisting of 12% DMF in toluene. Cyanide in these organic liquids is postulated to be in the form of HCN retained by dipole–dipole interactions with DMF [21]. The assay technique is based on the fact that the micellar solution of CTAB solubilizes the organic and inorganic components of the sample thereby facilitating cyanide ion determination. Cyanide ion was detected spectrophotometrically at 578 nm by the pyridine-barbituric acid method [18]. The effects of surfactant and alkali concentrations on cyanide ion recovery from these samples are discussed.

2. Experimental

2.1. Instrumentation

The instrumentation consisted of two Spectra Physics (San Jose, CA, USA) HPLC pumps, a Hewlett Packard (San Fernando, CA, USA) model HP1050 autosampler with 10 μl sample loop, a knitted teflon reaction coil (AURA Industries, Staten Island, New York, USA) 15 m × 0.5 mm internal diameter and total internal volume of 3 ml, and a model 759A variable wavelength UV/VIS absorbance detector with tungsten lamp (Applied Biosystems, Foster City, CA, USA). The data analysis was performed using a PE Nelson (Cupertino, CA, USA) Access*Chrom software.

2.2. Reagents for color development

All reagents were analytical grade chemicals purchased from Aldrich Chemical, Milwaukee, WI, USA.

Phosphate buffer (0.100 M) was prepared by dissolving 13.8 g of dibasic sodium phosphate monohydrate (MW = 138.0) in about 900 ml of deionized water and adjusting the pH of the resulting solution to 7.0 with sodium hydroxide. The final volume was brought to 1 l with deionized water.

Chloramine-T solution (0.044 M) was prepared by dissolving 10.0 g of chloramine-T (*N*-chloro-4-methylbenzene sulfonamide sodium salt, MW = 227.67) in about 500 ml of the previously prepared phosphate buffer and diluting to a final

volume of 1 l with the buffer. The prepared solution was filtered with 0.45 micron filter paper and stored in the refrigerator. The solution was allowed to warm up to room temperature before use.

Barbituric acid-pyridine solution (0.375 M) was prepared by dissolving 48.0 g of barbituric acid (MW = 128.09) in 240 ml of pyridine with constant stirring. Concentrated hydrochloric acid was added in four 12 ml portions while continuously stirring the solution. Each portion of hydrochloric acid was added in 5 min intervals. After adding all of the hydrochloric acid and allowing the solution to cool to room temperature, the final volume was brought to 1 l with deionized water. Stirring was continued until complete dissolution of solutes. The resulting solution was filtered with 0.45 μm filter paper and stored in the refrigerator when not in use. The solution was allowed to warm to room temperature before use.

2.3. Reagents for standard preparation

Sodium hydroxide solution (0.05 M) was prepared by dissolving 4.0 g of sodium hydroxide pellets in deionized water and bringing the final volume to 2 l with deionized water. Alkaline surfactant solution (0.001 M CTAB in 0.05 M NaOH) was prepared by dissolving 0.365 g of CTAB (MW = 364.46) in about 500 ml of 0.05 M NaOH. The final volume of the prepared solution was brought to 1 l with 0.05 M NaOH. The solution was filtered with 0.45 μm filter paper. For the preparation of a 0.002 M CTAB solution in 0.05 M NaOH, dissolve 0.730 g of CTAB l^{-1} of solution. A 200 μg ml^{-1} (ppm) cyanide stock solution was prepared by dissolving 0.07538 g of sodium cyanide in 100 ml of 0.05 M NaOH and bringing the final volume to 200 ml with 0.05 M NaOH. The solution was mixed thoroughly and stored at room temperature.

Cyanide standard solutions (0.25, 0.50, 1.00, 3.00, 4.00 and 5.00 ppm) were prepared by pipeting 0.125, 0.25, 0.50, 1.50, 2.00 and 2.50 ml, respectively, of the 200 ppm cyanide stock solution into a 100 ml volumetric flask. The final volume of each standard was brought to 100 ml with the appropriate alkaline micellar solution.

2.4. Sample preparation and handling

A 0.5 ml sample was diluted to volume in a 100 ml volumetric flask with the appropriate alkaline micellar solution. Reaction samples in DMF-IPAC or aqueous solvent matrices were diluted with 0.001 M alkaline CTAB. Reaction samples in DMF-toluene solvent matrix were diluted with 0.002 M alkaline CTAB. The volume of the sample diluted or the total volume of prepared solution could be adjusted to accommodate samples that are low or high in cyanide content. For accuracy, organic liquid samples were dispensed using volumetric pipets. The resulting solution was mixed thoroughly by vigorous stirring only after diluting to the final volume because foaming occurs when surfactant solutions are mixed.

2.5. Determination of cyanide

A schematic diagram of the flow-injection system is shown in Fig. 1. The sample was injected into a buffered chloramine-T stream R2 which then merged with a pyridine solution of barbituric acid R1 in a reaction coil C to provide mixing and reaction. Cyanide ion in the sample was oxidized by chloramine-T (Fig. 2) to form cyanogen chloride (CNCl), a compound which contains the CN^+ cation. Reaction between this cation and pyridine led to the formation of the *N*-cyanopyridinium ion which hydrolyzed to a conjugated dialdehyde, glutaconic aldehyde. Further reaction between the conjugated dialdehyde and the reactive tautomer of barbituric acid led to the formation of a reddish blue (purple) dye which was detected at 578 nm [22–24]. The flow injection response was processed by a PE Nelson data acquisition system.

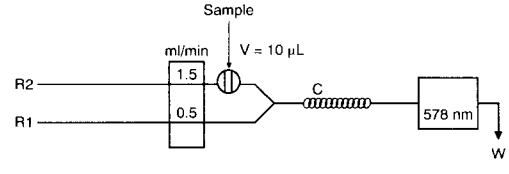

Fig. 1. FIA manifold for the determination of cyanide ion. R1 = pyridine-barbituric acid solution; R2 = chloramine-T solution in phosphate buffer.

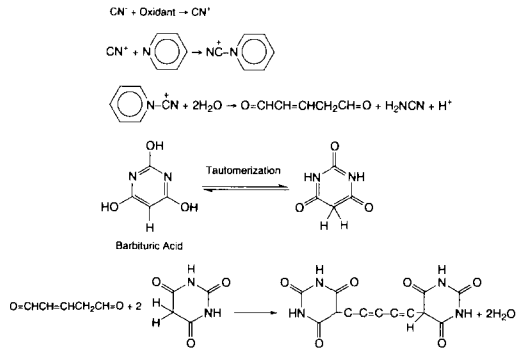

Fig. 2. Reaction sequence for color formation in the pyridine-barbituric acid method for cyanide analysis.

The average response factor (Rs) for a number (n) of cyanide standards, and the concentration (Cs) of cyanide ion in the sample are calculated according to Eq. (1) and Eq. (2), respectively.

$$Rs = \Sigma(\text{peak height of standard}/\text{concentration of standard})/n \quad (1)$$

$$Cs = (\text{Sample Peak Height} \times \text{Dilution Factor})/(\text{Response factor}) \quad (2)$$

Samples were diluted such that responses were within the linear range of the calibration graph. The FIA system was rinsed daily before shut down by pumping pyridine through the barbituric acid delivery tube and water through the chloramine-T delivery tube for a period of at least 30 min to prevent blockage by salts.

3. Results and discussion

3.1. NaOH as sample diluent

A basic solution with pH above 11.2 is required to completely ionize inorganic cyanide (pK_a of HCN = 9.2). Since samples analyzed in this study were cyanide-containing organic liquids, the mixture that resulted when samples were diluted with aqueous sodium hydroxide consisted of an organic layer and an aqueous layer. Cyanide ion is present in both layers even after prolonged mixing but higher levels of cyanide ion were detected in the aqueous layer as the concentration of the NaOH diluent decreased (Table 1). This observation was attributed to increased partitioning of cyanide ion from the organic layer into water as NaOH concentration decreased. The existence of two cyanide-containing layers makes aqueous sodium hydroxide an inappropriate diluent for organic liquid samples. There is therefore the need for a procedure that will incorporate an alkaline medium and also provide adequate solubilization of the organic and inorganic components of the sample.

3.2. Alkaline surfactant as sample diluent

Accurate cyanide ion determination in an organic liquid sample will only be possible if there is complete solubilization of the sample. A solution to the problem of solubilizing organic liquid samples was found by taking advantage of the role of surfactants as emulsifying agents. An alkaline solution of the cationic surfactant CTAB (0.001 M CTAB in 0.05 M NaOH) was observed to provide optimum solubilization of the reaction samples in the DMF-IPAC solvent mixture. A more concentrated surfactant solution (0.002 M CTAB in 0.05 M NaOH) was required to solubilize the reaction samples in the DMF-toluene solvent mixture. Higher CTAB concentration was required to solubilize the DMF-toluene solvent mixture (Table 2) as compared with the more polar DMF-IPAC solvent mixture. The degree of solubilization of the organic liquid sample by the surfactant was

Table 1
Effects of NaOH concentration on the amount of cyanide ion detected in samples

Nitrile sample matrix	Concentration of NaOH (M)	Cyanide ion detected (μg ml^{-1}) (Mean ± %RSD, $n = 3$)
DMF-toluene	0.05	182.0 ± 1.7
	0.1	125.0 ± 1.1
	0.5	49.0 ± 2.1
DMF-IPAC	0.05	122.0 ± 1.6
	0.1	104.0 ± 2.0
	0.5	81.9 ± 1.0

Table 2
Effects of surfactant concentration on cyanide ion detected in reaction samples

Sample matrix	Sample diluent	Cyanide concentration ($\mu g\ ml^{-1}$) (Mean ± RSD, $n = 3$)
DMF-toluene	0.05 M NaOH	14.3+2.6
	0.0005 M CTAB in 0.05 M NaOH	48.0+2.5
	0.001 M CTAB in 0.05 M NaOH	50.7+2.8
	0.002 M CTAB in 0.05 M NaOH	57.0+3.6
	0.003 M CTAB in 0.05 M NaOH	54.1+3.0
DMF-IPAC	0.05 M NaOH	132.1 ± 2.8
	0.0005 M CTAB in 0.05 M NaOH	137.0+2.0
	0.001 M CTAB in 0.05 M NaOH	155.0+3.2
	0.002 M CTAB in 0.05 M NaOH	149.4+3.1

determined by the concentration of cyanide ion detected in the surfactant-sample mixture.

The reported cmc of CTAB is 9.2×10^{-4} M in water [25] and 3.4×10^{-4} M in 0.05 M NaOH [26]. Micelle formation and solubilization of solutes were therefore expected at the alkaline CTAB concentrations of the two diluents used in this study. The organic constituents of the sample are preferentially solubilized by the hydrophobic chain of the cationic CTAB micelles resulting in a homogeneous mixture. Cyanide ion is electrostatically attracted to the micelles, thereby increasing the chance of reaction with solubilized chloramine-T and barbituric acid. The effects of the alkaline surfactant concentration on recovery of cyanide ion from organic samples are illustrated in Table 2. A general observation from this table is that the alkaline micellar diluents facilitated the detection of cyanide ion in organic liquid samples because of their ability to solubilize the sample as compared with aqueous NaOH.

3.3. Characteristics of the method

The dilution ratio of sample to alkaline micellar solution during sample preparation made the resulting solution aqueous in nature. The reagent volume ratio of 1:3 barbituric acid to chloramine-T provided excess barbituric acid required to assure complete reaction with cyanide ion and maximum absorbance for the reaction product. The pH of the mixed solution in the reaction coil was 5.8, a value within the pH range (5.4–6.0) reported in the literature for this reaction [27]. The use of flow injection analysis to automate the detection reaction provided a fast, precise and sensitive method for cyanide ion determination. On-line mixing of samples with reagents reduced analysis time and operator contact with the noxious pyridine reagent.

A typical flow injection response obtained for a series of cyanide standards in 0.002 M alkaline CTAB ranging in concentration from 0.25 to 5.00 ppm is shown in Fig. 3. Similar response was obtained for cyanide ion in 0.001 M alkaline CTAB but the linear range was from 0.25 to 10.0 ppm. Peak height (Y,mv) versus cyanide concentration (X, $\mu g\ ml^{-1}$) for cyanide ion in alkaline 0.002 M CTAB were related by the regression equation $Y = 18.8\ [CN^-] - 0.5$ with a correlation coefficient of 0.99878. In the 0.001 M alkaline CTAB solution, the regression equation was

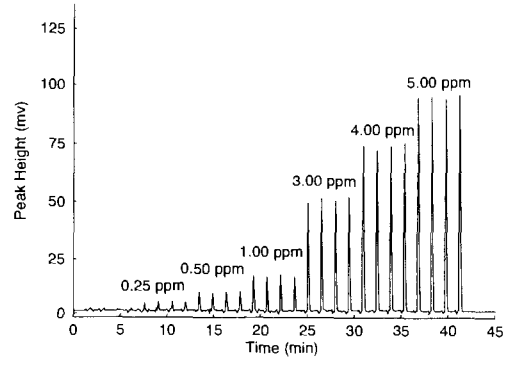

Fig. 3. FIA response for cyanide ion standards in alkaline 0.002 M CTAB.

Table 3
Recovery of added cyanide ion from reaction samples

Sample matrix	Cyanide concentration (μg ml^{-1})			
	Initial	Added	Found	Recovery (%)
DMF-IPAC				
1	105.0	198	184.5	93.3
2	79.5	74.8	68.8	92.0
3	119.1	100	91.5	91.5
4	489.0	76.6	73.7	96.2
Mean recovery ± %RSD				93.2 ± 2.3
DMF-toluene				
1	31.2	69.3	64.6	93.3
2	31.2	68.9	67.0	97.2
3	31.2	68.9	64.4	93.5
4	31.2	68.9	62.8	91.2
Mean recovery ± %RSD				93.8 + 2.6

$Y = 67.8\ [CN^-] - 8.6$ with a correlation coefficient of 0.99901. The detection limit for cyanide ion in both micellar solutions calculated as three times S/N was 0.10 ppm. The precision of injection for a 1.0 ppm cyanide standard solution was 2.1% ($n = 6$) in 0.002 M alkaline CTAB and 1.8% ($n = 6$) in 0.001 M alkaline CTAB. The FIA system performed 40 injections h^{-1}.

3.4. Recovery of cyanide ion from reaction samples

Reaction samples in DMF-IPAC or DMF-toluene solvent mixture were analyzed to determine the initial cyanide content, and then spiked with known amounts of cyanide ion. A 10 ml volume of spiked sample in DMF-toluene was diluted to 500 ml with the 0.002 M alkaline micellar CTAB solution and mixed by stirring before cyanide assay. For the spiked reaction sample in DMF-IPAC, 10 ml of the solution was diluted to 500 ml with alkaline 0.001 M CTAB and mixed by stirring before assay. Average recovery of added cyanide ion was 93.8 ± 2.6% RSD for nitrile in DMF-toluene and 93.2 ± 2.3% RSD in DMF/IPAC (Table 3). These results show that quantitative recovery of cyanide ion impurity from organic samples can be achieved by the use of alkaline micellar solutions as sample diluents.

4. Conclusions

A simple method based on the use of an alkaline micellar CTAB solution to improve solubilization and detection of cyanide ion in organic samples was developed. Automation of the method by flow injection analysis provided high sample throughput and reduced contact with noxious pyridine reagent used in the detection reaction. Recovery of cyanide ion spiked into pilot plant reaction samples was greater than 90%.

Spectrophotometric methods for the determination of omeprazole in bulk form and pharmaceutical formulations

Chilukuri S.P. Sastry *, Petla Yerrayya Naidu, S.S.N. Murty

Foods and Drugs Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530 003, India

Received 23 July 1996; received in revised form 24 October 1996; accepted 25 October 1996

Abstract

Four simple and sensitive methods for the assay of omeprazole (OMZ) were developed. These methods are based on the formation of colored species by treating OMZ with 3-methyl-2-benzothiazolinone hydrazone (MBTH) following oxidation with ferric chloride (method A) or *m*-aminophenol following oxidation with chloramine-*T* (CAT) (method B) or Folin–Ciocalteau reagent (F–C) (method D), or by oxidizing OMZ with excess *N*-bromosuccinimide (NBS) and determining the consumed NBS with a decrease in color intensity of Celestine blue (CB) (method C). All variables have been optimized. Regression analysis of Beer's plots showed good correlation in the concentration range of 1.0–10, 2.0–32, 0.4–2.4 and 0.8–10 μg ml^{-1} for methods A, B, C and D, respectively. No interference was observed for formulation additives and the validity of each method was tested by analysing capsules containing OMZ. Recoveries were 98.7–100.1%. © 1997 Elsevier Science B.V.

Keywords: Spectrophotometric; Omeprazole; Bulk form

1. Introduction

Omeprazole [5-methoxy-2-(4-methoxy-3, 5-dimethyl pyridin-2-yl-methyl sulphinyl)-1H-benzimidazole), a substituted benzimidazole compound and prototype anti-secretary agent, is the first of the 'proton pump inhibitors' widely used for the treatment of symptomatic gastro-oesophagal reflux. It is officially listed in the British Pharmacopoeia (B.P.) [1]. Two UV [2,3], one differential pulse polarographic [4], and three HPLC [5–7] procedures have been reported for its determination. In view of the fact that there is no visible spectrophotometric method for the determination of OMZ, sensitive and accurate visible spectrophotometric methods were viewed as essential to avoid interference due to UV absorbing compounds in the determination of OMZ in bulk samples or pharmaceutical dosage forms. This paper describes four visible spectrophotometric methods for the determination of OMZ utilizing its unique structural features.

Sawicki et al. developed a visible spectrophotometric procedure for determining phenols and amines by condensation with 3-methyl 2-benzothiazolinone hydrazone (MBTH) in the presence of an oxidant to form an intensely colored oxidized product [8,9]. Sastry et al. reported a visible spec-

* Corresponding author.

trophotometric method for the determination of indomethacin with *m*-aminophenol and chloramine-*T* [10]. Sastry et al. also developed a visible spectrophotometric procedure for the determination of a few drugs with *N*-bromosuccinimide and celestine blue (CB) [1-amino-carbonyl-7-diethyl amino-3, 4-dihydroxyphenoxazine-5-ium chloride; C.I. No. 51050] [11]. The Folin–Ciocalteau reagent was preferred by a number of workers for visible spectrophotometric determination of drugs exhibiting reducing reactivity [12].

We have applied these sensitive visible spectrophotometric procedures in the determination of OMZ in bulk samples and pharmaceutical formulations. Method A describes the determination of OMZ with MBTH following oxidation with ferric chloride (Fe III). Method B describes the determination of OMZ with *m*-amino phenol (*m*-AP) following oxidation with chloramine-*T* (CAT). Method C involves the addition of excess NBS of known concentration in the presence of 0.25 M HCl and unreacted NBS is determined by measurement of the decrease in absorbance of celestine blue. Method D describes the determination of OMZ with Folin–Ciocalteau reagent in the presence of sodium carbonate (Na_2CO_3).

2. Experimental

2.1. Apparatus

A systronics model 106 spectrophotometer with 1 cm matched glass cells and a Milton Roy spectronic 1201 spectrophotometer with 1 cm matched quartz cells were used for absorbance measurements in the visible and ultraviolet regions, respectively. An Elico-digital model LI-120 pH meter was used for pH measurements.

2.2. Materials and reagents

All reagents were analytical grade and all solutions were prepared with double-distilled water. Freshly prepared solutions were always used.

Aqueous solutions of 8.56×10^{-3} M MBTH (Aldrich) and 2.96×10^{-2} M iron (III) chloride hexahydrate (Wilson Laboratories) were prepared for method A. Aqueous solutions of 9.17×10^{-3} M *m*-aminophenol (BDH) in 0.025 M HCl, 0.03 M CAT (Loba-Chemic) and 0.05 M potassium acid phthalate (E. merck) were prepared for method B. Aqueous solutions of 100 μg ml^{-1} NBS (Loba), 100 μg ml^{-1} Celestine blue (E. Gurr) and 5 M hydrochloric acid (BDH) were prepared for method C. Aqueous solutions of 10% sodium carbonate (BDH), and commercially available 2*N* Folin–Ciocalteau (Loba-Chemic), reagent were used for method D.

2.3. Preparation of standard drug solutions

For method A: 10 mg of B.P. grade OMZ was dissolved and diluted to 200 ml with glacial acetic acid (50 μg ml^{-1}).

For methods B, C and D: 100 mg of B.P. grade OMZ was dissolved in 10 ml of 0.1 M NaOH solution and diluted with distilled water, to prepare working solutions of 200, 10, 50 μg ml^{-1} for methods B, C and D, respectively.

2.4. Procedures

2.4.1. Method A

To 20 ml graduated test tubes containing list volumes (0.4–4.0 ml) of 50 μg ml^{-1} OMZ solution was added 2.0 ml of MBTH solution and allowed to react for 2 min at room temperature. After that, 1.5 ml of iron (III) chloride solution was added, allowed to react for 5 min, and diluted to 20 ml with distilled water. Absorbances were measured during the next 20 min at 660 nm against a reagent blank prepared in a similar manner omitting the drug. The drug concentration was determined with a standard plot prepared under identical conditions.

2.4.2. Method B

To 25 ml graduated test tubes containing list volumes (0.25–4.0 ml) of 200 μg ml^{-1} OMZ solution was added 15 ml of 0.05 M potassium hydrogen phthalate solution, 3 ml each of CAT and *m*-AP solution and diluted to 25 ml with distilled water. The pH of the resulting solution was between 4.0 and 5.0. Absorbance was mea-

sured at 420 nm within 10 min against a reagent blank prepared in a similar manner. The omeprazole concentration was determined with a standard plot prepared with known solutions prepared under identical conditions.

2.4.3. Method C

To 25 ml graduated test tubes containing list volumes (1.0–6.0 ml) of 10 μg ml^{-1} OMZ solution was added 1.25 ml of 5 M HCl and 2.5 ml of 100 μg ml^{-1} NBS and the volume increased to 15 ml with distilled water. After 10 min, 10 ml of 100 μg ml CB was added and mixed thoroughly. After 5 min the absorbance was measured at 540 nm against distilled water. Blank was prepared similarly omitting the drug and its absorbance was measured against distilled water. The decrease in absorbance corresponding to consumed NBS and, in turn, to drug concentration, was obtained by subtracting the absorbance of the blank solution from that of the test solution. The calibration graph was drawn by plotting the decrease in the absorbance of the dye (CB) against the amount of drug. The drug concentration was determined with the above standard plot.

2.4.4. Method D

To 25 ml graduated test tubes containing list volumes (0.4–5.0 ml) of 50 μg ml^{-1} OMZ solution was added 2.0 ml of F–C reagent and 9.0 ml of Na_2CO_3 solution and allowed to react for 10 min at laboratory temperature. The solution was diluted to 25 ml with distilled water and the absorbance of each solution measured at 770 nm against reagent blank prepared simultaneously within the stability period (5 min–4 h). The drug content was determined with a standard plot.

2.5. Analysis of pharmaceutical formulations

Capsules, 20, were emptied and blended. Samples, 10 mg, for method A or 100 mg samples for methods B, C and D were massed and solutions prepared as described for the standard solutions and filtered if insoluble materials was present prior to analysis as described for pure samples.

2.6. Results and discussion

The optimum conditions for the development of methods A, B, C and D were established by varying parameters one at a time [13] and observing the effect produced on the absorbance of the colored species.

In order to establish experimental conditions for the determination of OMZ using method A, the applicability of MBTH in conjunction with various oxidizing agents such as Fe(III), Ce (IV), Cr (VI), IO_4^-, CAT, and $S_2O_8^{2-}$ were examined and Fe(III) was found to be the best. The effect of reagent concentrations [MBTH and Fe(III)], temperature, time, and order of addition of reagents with respect to maximum absorbance and stability were studied in preliminary experiments. For color development solutions of list volumes (1.5–2.5 ml) of MBTH, list volumes (1.0–2.0 ml) of Fe(III) and an ambient temperature of (28 ± 5°C) were found to be optimal. Reversing the order of addition, i.e., drug, plus iron (III) plus MBTH, resulted in considerable loss of sensitivity. Maximum color intensity was attained within 5 min after the addition of iron (III). The colored product was found to be stable up to 20 min after the attainment of maximum intensity at 660 nm.

Optimum conditions for method B were established after a thorough systematic study of parameters such as coupler–oxidant combination, acid strength (pH), reagent concentration, and order of addition of reagents. Of the various combinations of *o*-, *m*-, *p*- or *P*-*N*-methyl amino phenols, phenols (phenol, catechol, resorcinol, pyrogallol and phloroglucinol), and oxidizing agents [CAT, OCl^-, IO_4^-, IO_3^-, Cr (VI), Fe(III), $S_2O_8^{2-}$, and H_2O_2], examined for the development of color under acidic or alkaline conditions at laboratory temperature (28 ± 5°C), *m*-amino phenol-CAT was found to be superior. A volume of 15.0 ml of potassium hydrogen phthalate solution was found to be necessary to maintain the pH of the solution between 4.0 and 5.0. For color development, solutions of 2.5–3.5 ml of CAT and 2.5–3.5 ml of *m*-amino phenol were found optimal. Maximum color intensity was attained within 3 min after the addition of *m*-amino phenol solution. The colored product was found to be stable

Table 1
Optical and regression characteristics, precision and accuracy of the proposed methods

[b]Six replicate samples, (concentration of 7.5, 16.0, 1.2 or 6.0 μg ml^{-1} of pure drug for methods A, B, C and D, respectively).

for 10 min after the attainment of maximum intensity at 420 nm.

In method C, the effect of reagent concentration (acidity, NBS and CB), reaction period in each step were studied by means of controlled experiments varying one parameter at a time. Studies of the variation of acid concentration indicated that a constant absorbance was obtained with 0.15–0.35 M HCl, 0.1–0.25 M H_2SO_4 or 0.3–0.5 M CH_3COOH with an NBS concentration of 8 μg ml^{-1}. Since the difference in absorbance between the sample and the blank was found to be highest for the addition of HCl, subsequent studies were performed in 0.25 M HCl. In order to obtain a linear relationship between the concentration of added NBS and the corresponding decrease in the absorbance of CB (40 μg ml^{-1}), experiments were performed on 0.25 M HCl with varying amounts of NBS. As the decrease in absorbances was found to be linear up to 10 μg ml^{-1} of NBS, subsequent studies were performed with 40 μg ml^{-1} of CB and 10 μg ml^{-1} of NBS in 25 ml of 0.25 M HCl. Time spans of 5–20 min for the reaction between the drug and NBS in the first step and 2–30 min between NBS and CB in the second step resulted in a constant and maximum difference in absorbance of the test and blank solutions. Hence, reaction periods of 10 and 5 min were maintained in subsequent studies of the first and second steps, respectively. The colored product was found to be stable for 5 h after the attainment of maximum intensity at 540 nm.

In order to establish the optimum volume of Na_2CO_3 solution in method D, the drug was allowed to react with F–C reagent in the presence of 1.0–13.0 ml of 10% Na_2CO_3. Constant absorbances were obtained with 8.0–10.0 ml, hence 9.0 ml was chosen as the routine addition. A volume of 2.0 ml of F–C reagent was found to be optimal. An increase in the volume of F–C reagent (> 2.0 ml) led to precipitation. Reversing the order of addition of reagents i.e., Na_2CO_3 plus F–C, had no influence on color formation. Maximum color intensity was attained within 5 min after the addition of Na_2CO_3 solution. The color product was found to be stable for 4 h after the attainment of maximum intensity at 770 nm.

The above optimum experimental conditions were incorporated in recommended procedures for color development. Beer's law was found to be valid over the concentration ranges given in Table 1 at appropriate λ_{max}.

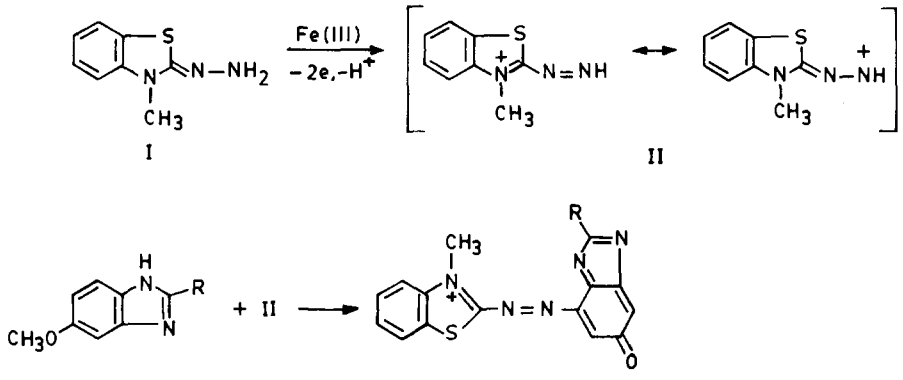
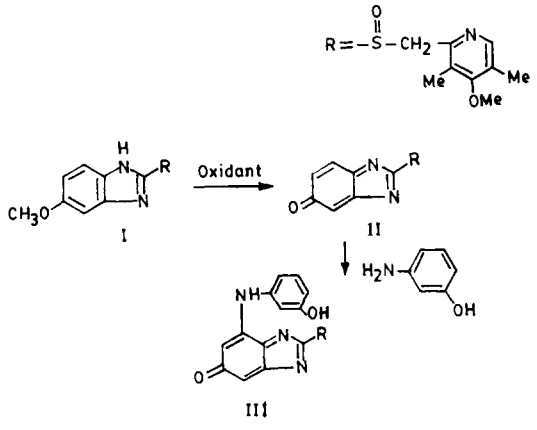


Scheme 1.

2.7. Analytical data

Beer's law limits, molar absorptivity, Sandell's sensitivity, detection limits [14], regression equation, and correlation coefficients obtained by least squares treatment of these results are given in Table 1. Precision of each method was tested by analysing six replicate samples containing (7.5, 16.0, 1.2 or 6.0 μg ml^{-1}) of pure drug for methods A, B, C and D, respectively. The percent standard deviation and the percent range of error at 95%, confidence level of each method are given in Table 1.

Commercial formulations (Capsules) containing OMZ were successfully analysed by the proposed methods. The value obtained by the proposed and reference methods for the pharmaceutical preparations were compared statistically by the *t*- and *F*-tests and found not to differ significantly. As an additional demonstration of accuracy, recovery experiments were performed by adding a fixed amount of the drug to the preanalysed formulations. These results are summarised in Table 2. The ingredients usually present in pharmaceutical preparations of OMZ did not interfere with the proposed analytical methods.



Scheme 2.

2.8. Chemistry of colored species

Several substituted Benzimidazoles [omeprazole (OMZ), albendazole (ABZ), mebendazole (MBZ), fenbendazole (FBZ) and astemizole (AZ)] were tested with reagents MBTH-Fe(III) (method A) or *m*-AP-CAT (method B). It was noticed that color development only occurred with OMZ. The failure of ABZ, MBZ, FBZ and AZ to develop colors with the proposed reagents indicate the necessity to have a 5-OMe group in the benzimidazole moiety.

Method A: under these reaction conditions MBTH (I) on oxidation with Fe(III) loses two electrons, and one proton forming an electrophilic intermediate (II), which is the active coupling species. Of this species, 1 mol, undergoes electrophilic substitution with OMZ to form a colored product (III), shown in Scheme 1.

Method B: omeprazole reacts initially with the CAT to produce the highly reactive and less stable intermediate as with *P*-Phenetidine (*P*-ethoxy aniline) [15]. The intermediate may react further with *m*-aminophenol to give 7-substituted product, as shown in Scheme 2.

Method C: NBS provides molecular bromine at low concentration in polar media [16]. This reacts with the drug resulting in either oxidation, substitution, or addition depending upon the functional group present in the drug. Probably a mixture of reproducible products are produced under the specified experimental conditions. The remaining molecular bromine is involved in bromination reaction with the dye (CB) to form a brominated dye which is colorless. The mole-ratio of the reaction between NBS and OMZ under the experimental conditions has been found to be 1:3.

Method D: color formation following the reaction of F–C reagent with OMZ in method D may be explained in the following manner based on the anology with reports of the earlier workers [12,17]. The mixed acids in the F–C preparation involve the following chemical species.

$3H_2O, P_2O_5 \cdot 13\ Wo_3 \cdot 5\ MoO_3 \cdot 10\ H_2O$ and

$3H_2O, P_2O_5 \cdot 14\ Wo_3 \cdot 4\ MoO_3 \cdot 10\ H_2O$

OMZ probably affects a reduction of 1, 2 or 3 oxygen atoms from tungstate and/or molydate in F–C reagent (Phosphomolybdotungstate), thereby producing one or more of the possible reduced species which have a characteristic intense blue color.

3. Conclusion

The order of sensitivity among the proposed methods and UV reference method (R) in the determination of OMZ is C > D > A > R > B. The λ_{max} order of D > A > C > B > R. Although the molar absorptivity of one of our methods (B) was somewhat less than that of the reference method, the λ_{max} of all the four proposed methods were considerably higher than that of the reference method. The higher λ_{max} of the proposed methods is a decisive advantage since the interference from the associated ingredients shall be far less at higher wavelengths. Moreover, no visible spectrophotometric method has been reported to date. Thus, all the proposed methods are simple, sensitive and useful for the determination of OMZ in pure samples and pharmaceutical formulations. They provide a wide choice, depending upon the need of the specific situation.

Received 11 July 1996; received in revised form 28 October 1996; accepted 29 October 1996

Abstract

A precise and accurate graphite furnace atomic absorption spectrometric method for the determination of mercury in urine was developed. Samples were subjected to hydrolysis with nitric acid. Then, mercury in the sample was complexed by dithizone and extracted by cyclohexane. Mercury concentrations were determined against a urine-matched calibration curve. Coated graphite notched partition tubes (Varian) and forked pyrolytic platforms (Varian) were used. The detection limit of the method ($x_{blank} + 3\ SD_{blank}$) was 1 μg l^{-1}. The between run precision CV's were 4.7 and 3.4% for urine with a mercury concentration of 48.2 and 156.2 μmol l^{-1}, respectively; the within run precision CV's were 8.9 and 2.9% for urine with a mercury concentration of 17.0 and 172 μg l^{-1}, respectively. © 1997 Elsevier Science B.V.

Keywords: Graphite furnace; Mercury; Pyrolytic platform

1. Introduction

In the past, mercury was an important constituent of drugs, but nowadays its use is gradually decreasing. Concentration of mercury in air, soil and water have been increasing because of greater utilisation of fossil fuels and for the expanded use in industry and agriculture. Apart from industrial exposure, the major source of elemental mercury for humans is dental fillings (Hg/Ag amalgam) [1]. A recent study [2] showed that amalgam fillings contribute considerably to plasma and urine mercury concentration.

The potential hazard of human exposure to mercury is well known. The novel 'Alice's adventures in wonderland' refers to 'Mad Hatters' who were hat makers gone mad due to exposure to mercury used in cleaning felt hats. With regard to toxicity, three major chemical forms of the metal must be distinguished: mercury vapours (elemental mercury); salts of mercury; and organic mercurials. Elemental mercury, salts of mercury and aryl mercurial compounds, containing a labile Hg–C bond, possess the same toxicity with formation of divalent mercuric cations. In contrast alkilmercurial (e.g., methylmercury) are metabolised slowly.

PII S0039-9140(96)02162-5

There is a linear relationship between plasma concentration and urinary excretion of mercury after exposure to vapour [3]. The concentration of mercury in urine has been used as measure of the body burden of the metal. In contrast, the excretion of mercury in urine is a poor indicator of the amount of methylmercury in the blood, since it is eliminated mainly in faeces.

Mercury in urine can be measured using a potentiometric method [4], gas-chromatographic methods [5–7], cold vapour atomic fluorescence spectrometry method [8], and by atomic absorption spectrometry with the cold vapour technique [9–12]. The latter has several advantages such as lower detection limits, less time consuming sample preparation, higher sample throughput due to a shorter measurement cycle times and the procedure is full automated. But for this technique, additional accessories, specifically designed for measurement of mercury, are required. With our method we tried to determine Hg without this apparatus, but using the capacity of mercury to bind sulphidric groups. Dithizone was used successfully as stabilising agent in the furnace [13], and it is one of the complexing agents most commonly used for mercury [14–16]. The complex is generally extracted with chloroform or carbon tetrachloride. In this work we combined both the complexing capacity of dithizone with cyclohexane extraction. The latter was used because of its easier recovery due to its lower density with respect to water.

2. Materials and methods

2.1. Instrumentation and apparatus

For all measurements a Varian SperctrAA-300 atomic absorption spectrometer with graphite tube atomizer and programmable sample dispenser was used. The spectrometer was equipped with a Zeeman background corrector for the correction of non specific signal. Mercury hollow cathode lamp, graphite notched partition tubes and graphite forked pyrolytic platform were obtained from Varian (Torino, Italy).

2.2. Reagents and materials

Suprapur nitric acid, water pro analysis and cyclohexane were obtained from Merck (Milano, Italy). Diphenylthiocarbazone (dithizone) was obtained from Sigma, mercury (II) chloride 99.5%, mercury (II) nitrate monohydrate 98% and standard solution of mercury 995 μg ml^{-1} in 1% nitric acid were obtained from Aldrich (Sigma-Aldrich, Milano, Italy). Two stock standard solutions of 4 and 20 μg l^{-1} in 1% nitric acid using polypropylene tubes from PBI International (Milano, Italy) were prepared daily [17] from the latter.

Methylmercury (II) chloride (1 g l^{-1} standard solution in water) was purchased from Alfa Products (Karlsruhe, Germany). All glass tubes (PBI International) were acid-washed with 1 M nitric acid solution and rinsed three times with water.

2.3. Samples

Urine was collected at random time from a volunteer group of men and women (ages 20–40) with no professional exposure in polypropylene containers, 10 ml were put in polypropylene tubes, capped and stored at 4°C for a maximum of 48 h. The amount of creatinine ranged from 0.8 to 1.5 g l^{-1}. To monitor the accuracy and precision of analytical procedure a Lyphocheck Urine Metal Controls (Biorad, Milano, Italy) was used. The control is prepared from human urine with added trace elements and heavy metals. The lyophilised urine samples were reconstituted with distilled water and stored at 2–8°C for 5 days according the reported instructions.

2.4. Samples and standards preparation

Sample, 4 ml, were pipetted into glass tubes. Standard additions calibration curves were prepared adding different volumes of the stock standard solutions to 4 ml of urine from two donors without neither professional exposure nor dental fillings. Blank solutions were prepared using 4 ml of water. Nitric acid 65%, 500 μl were added to each tube, and, after mixing, were capped and incubated at 95°C for 90 min.

Table 1
Time/temperature program

Step no.	Temperature °C	Time s	Gas flow l min^{-1}	Read command
1	90	5.0	3.0	No
2	180	5.0	3.0	No
3	180	5.0	3.0	No
4	180	2.5	0.0	No
5	1400	1.0	0.0	Yes
6	1400	3.0	0.0	Yes
7	2700	1.1	3.0	No
8	2700	2.0	3.0	No
9	80	15.0	3.0	No

After cooling, 2 ml of a dithizone saturated solution in cyclohexane were added. The mixture was vigorously shaken for 30 s and then, after separation, the upper phase was transferred to a clean glass.

2.5. Instrument conditions

The monochromator was set at 253.7 with a slit width of 0.2 nm. Lamp current was 5 mA and measurements were recorded both in peak height and peak area mode. The samples were injected into the furnace at the temperature of 90°C (hot injection) with a rate of 0.7 μl s^{-1}. The volume of the injection was 25 μl.

3. Results and discussion

Usually the traditional furnace methods are not recommended for mercury because it is a very volatile metal. In order to decrease its volatility many matrix modificators have been proposed as palladium [18,19], strong oxidising agents [20] and complexing agent with sulphidric groups [13–16]. In our procedure, dithizone is responsible both of the extraction of the metal from a complex matrix (i.e., urine) and of a decreasing of volatility during the pre-atomisation step. In fact the determination of mercury in aqueous solution with the same time/temperature program do not give appreciable absorbance values. Every modification of time/temperature program do not increase the absorbance values. In Table 1 is presented the time/temperature program. As indicated on the char/atomisation curves in Fig. 1, the maximal char temperature that could be used without loss of sensitivity was 200°C, while the best atomisation temperature was 1300–1400°C.

We used coated graphite notched partition tubes and forked pyrolytic platforms. With the same time/temperature program a decreasing of the absorbance value was observed using coated graphite partition tubes. With such tubes the optimum of atomisation temperature was observed at 800°C. The resulting values were the same with respect to the values obtained with pyrolytic platform but they were characterised by a greater peak broadening (Fig. 2).

Dithizone forms hydrophobic complexes with most of the divalent or trivalent metal ions. Copper (10–70 μg 24 h^{-1}) and zinc (150–1300 μg 24 h^{-1}) are the most common metal ions in urine:

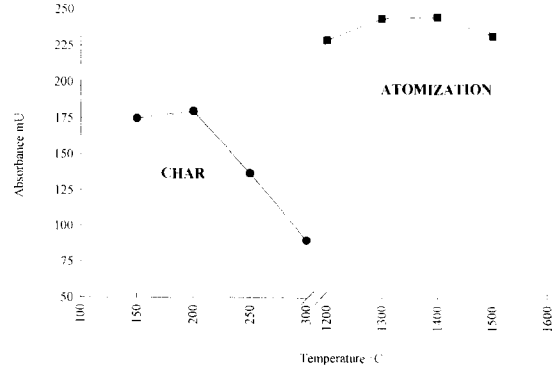

Fig. 1. Char and atomization temperature curves of the determination of mercury in urine.

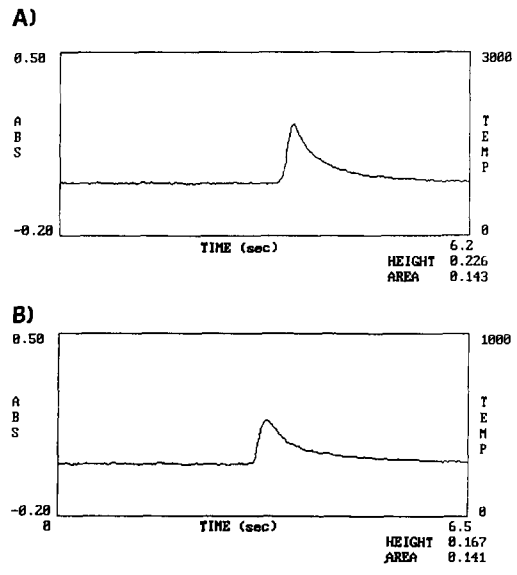

Fig. 2. (A) Atomic signal from pyrolytic platform (char temperature: 180°C, atomization temperature 1400°C); (B) Atomic signal from coated partition tube (char temperature: 180°C, atomization temperature 800°C). Height, A; Area, A·s.

but it was found that even high concentrations of both ions (300 μg l^{-1} for copper and 2000 μg l^{-1} for zinc) did not interfere with mercury determination with this method.

Nitric acid did not show an oxidising action to give dithizone a change in complexing capacity. But it was important to separate the organic phase from the urine after the extraction. In fact after 30 min the separated dithizone solution did not show significant absorbance variation, while the part in contact with urine showed a reduction of 10%.

The detection limit of the method, calculated as $X_{blank} + 3SD_{blank}$, was 1 μg l^{-1}. Solutions for 20 different calibration curves were prepared adding different volumes of the daily prepared stock standard solutions to urine from donors without neither professional exposure nor dental fillings. The recorded absorbances for no-spiked samples were below the threshold value. The results obtained in peak area and peak height mode were compared. The response was linear up to 200 μg l^{-1}. Both the systems give a good correlation factor (r) and reproducible slopes between the different calibration (peak area: average correlation factor $r =$ 0.9993, CV% = 0.08 and average slope 1.27, CV% = 0.07; peak height: average correlation factor $r = 0.9995$, CV% = 0.07 and average slope 1.74, CV% = 5.84). In order to test the proposed method in routine work, different furnaces with different degree of use were utilised. These furnaces were previously used both for mercury in urine determination and for determination of other analytes in different matrices (blood, urine, serum, plasma). The increase in life time of use led to wider peaks with lower peak heights, resulting in higher coefficient of variation. In Fig. 3 typical calibration curves are shown.

After 48 h of storage at 4°C no significant variation of concentration were measured. Urine added with Hg^{2+} in the linearity range and stored for the same time gave 98–101% recoveries. The within-run precision (measure of repeatability) and the between run precision (measure of reproducibility) were measured considering two concentrations of mercury with quality controls. For the between-run precision Bio Rad Lyphocheck Urine metal control Level 1 (Lot. No. 60901) and Level 2 (Lot No. 60902) were used. For the within-run precision Bio Rad Lyphocheck Level 1 (Lot No. 58501) and Level 2 (Lot No. 58502) were used. Results are reported in Table 2.

Accuracy was evaluated comparing data obtained with the Bio Rad quality controls (Table 2) and evaluating the recovery from urine of different subjects added with mercury. In the urine

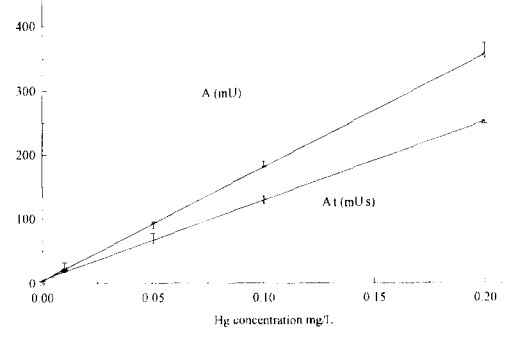

Fig. 3. Linearity of the calibration curve in urine in peak-area (□) and peak-height (○) modes using graphite tubes and platforms. Each point represents the mean ± S.D. of 20 calibrations. Char temperature, 180°C; atomization temperature, 1400°C. Instrumental settings as reported in the text.

Table 2
Precision

	Acceptable range (μg l^{-1})	Mean (μg l^{-1})	S.D. (μg l^{-1})	CV (%)
Between run ($n = 20$)				
Level 1	35.0--52.0	48.2	2.3	4.7
Level 2	116.0--174.0	156.8	5.3	3.4
Within run ($n = 4$)				
Level 1	13.0--20.0	14.9	1.3	8.9
Level 2	137.0--206.0	151.9	4.4	2.9

added with inorganic salts (mercury (II) nitrate and mercury (II) chloride) 98–101% of recoveries were obtained for all the concentrations in the linearity range. For metal organic compounds (methylmercury chloride), using the same procedure as for inorganic salts, the obtained recoveries were between 85–90% for 25 μg l^{-1}, 84–88% for 50 μg l^{-1} and 75–85% for 100 μg l^{-1} of methylmercury addition. During our work, 25 urine samples were tested. Results, ranging from 1 to 8 μg l^{-1} for 23 samples, collected from people with dental filling, were obtained while for two people without dental fillings results were below the detection limit. Though not statistically relevant, these results are in accordance with expected values and with other published papers [3,8,21].

All these data allow to consider this technique precise and accurate so that it makes possible a simple and fast quantification of mercury in urine even if the equipment necessary to the cold vapour technique is lacking.

Kinetic spectrophotometric determination of traces of sulfide

Afsaneh Safavi *, Zahra Ramezani

Department of Chemistry, Faculty of Sciences, Shiraz University, Shiraz, 71454, Iran

Received 15 May 1996; received in revised form 25 October 1996; accepted 29 October 1996

Abstract

A method for the determination of sulfide based on the addition reaction of sulfide with magenta at pH 7 and 25°C is described. The decrease in absorbance of magenta at 540 nm, its λ_{max}, over a fixed time is proportional to the concentration of sulfide over the range of 25–2500 ng ml^{-1}. The limit of detection was found to be 15 ng ml^{-1}. Ten replicate analysis of a sample solution containing 1.5 μg ml^{-1} sulfide gave a relative standard deviation of 0.8%. The effects of various cations and anions on sulfide determination have been reported and procedures for removal of interferences have been described. © 1997 Elsevier Science B.V.

Keywords: Kinetic spectrophotometry; Magenta; Sulfide determination

1. Introduction

Determination of sulfide is important particularly from biological and industrial point of view. Its extreme toxicity as hydrogen sulfide is well known. Conversion of amino acids to sulfide occurs in most microorganisms [1]. Sulfur can be converted to sulfide fairly readily by non enzymatic reactions [2]. Sulfides are also present in industrial effluents. Sulfur metabolizing organisms are responsible, at least in part, for several types of corrosion [3–5]. Evidence was obtained that the sulfide was generated by the action of sulfate reducing organisms. So sulfide determination is a measure of corrosion. In agriculture, sulfur compounds influence to a considerable extent on soil fertility.

Different classical and instrumental methods were used for sulfide determination including argentiometric titration of alkaline solution [6], complexometry [7], spectrophotometry [8], flow injection analysis [9,10], molecular emission cavity analysis [11] and so forth, but few are convenient for modern routine analysis, or have sufficient sensitivity.

Kinetic methods of determination of micro amounts of sulfide have been described [12–15]. In some of these methods the catalytic action of sulfide is used for the determination while in others an addition reaction of sulfide with a specific reagent is described. However, most of these methods suffer from interfering effects of other sulfur anions, or poor sensitivity and low linear dynamic range. Thus, more selective as well as sensitive methods are still required.

PII S0039-9140(96)02163-7

In this study a kinetic spectrophotometric method based on the addition reaction of sulfide to magenta at pH 7 is described.

2. Experimental

2.1. Reagents

All reagents were of analytical grade. Triply distilled water was used throughout. A stock solution of 1000 μg ml^{-1} sulfide was prepared daily by dissolving 0.3746 g of $Na_2S.9H_2O$ (Merck) in water and diluting to 50 ml. This solution was standardized using sulfide selective electrode. The results were consistent with those of iodometric titrations. Magenta solution (1.77×10^{-4} M) was prepared by dissolving 5.73 mg magenta in water and diluting to 100 ml. Phosphate buffer (pH 7) was used for pH adjustments.

2.2. Apparatus

Absorption spectra were recorded on a Philips PU 8750 UV-Vis spectrophotometer. Spectrophotometric measurements at a fixed wavelength were made on a PU 8625 spectrophotometer. The PU 8625 spectrophotometer was connected to a 386 personal computer through its RS-232C port. The change in absorbance by time was displayed on the screen. A mechanical stirrer (Janke and Kunkel GMBH KG, IKA-Werk) was used for mixing when using the procedure of data collection by computer. pH was adjusted by a 691 Metrohm pH meter. The temperature was kept constant at 25 ± 0.1°C by a thermostat (Colora, NB, Germany). All the solutions were previously brought to this temperature. The temperature was maintained constant in the reaction cell by circulating water at appropriate temperature around the cell compartment of the spectrophotometer during the experiment.

2.3. Recommended procedure

Two separate procedures were adopted. The first was based on the conventional fixed time method and the other was performed by direct data collection by computer and applying the slope method.

2.4. Fixed time method

Buffer, 1 ml, (pH 7) was added to the sample solution containing 0.125–12.5 μg sulfide in a 5 ml volumetric flask. The solution was diluted to about 4.5 ml and kept in the water bath at 25°C for 10 min. Then, 0.25 ml of 1.77×10^{-4} M magenta, previously brought to the same temperature was added to initiate the reaction and the solution was diluted to the mark with distilled water. The chronometer was turned on when the last drop of magenta was added to the solution. A portion of this solution was transferred to a glass cell within 30 s and the absorbance change at 540 nm was recorded for 2 min after initiation of the reaction.

2.5. Slope method using direct data collection by computer

Since the absorbance data was directly transferred to the computer, the solutions were prepared in 1 cm, 4 ml glass cell. In this case, 0.7 ml of phosphate buffer was added to a sample solution containing 0.09–8.75 μg sulfide in the cell. The solution was diluted to 3.3 ml by the addition of appropriate amounts of water. The cell was

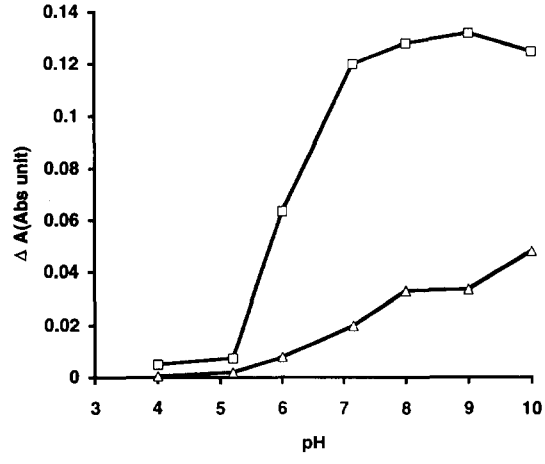

Fig. 1. Effect of pH on the reaction rate of 1 μg ml^{-1} sulfide (□) and blank (△).

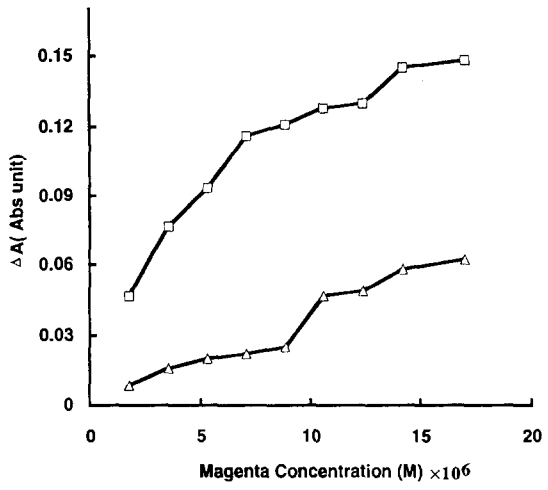

Fig. 2. Effect of magenta concentration on the reaction rate of 1 μg ml^{-1} sulfide (□) and blank (△).

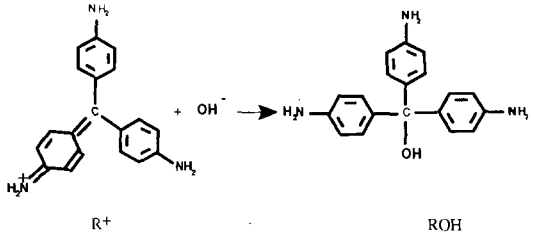
inserted in the cell compartment of the spectrophotometer, where its temperature was kept constant at 25°C. A mechanical stirrer was used to mix the solution within the cell. After 10 min, 0.2 ml of 1.54×10^{-4} M magenta was added to the cell, and the absorbance versus time data were collected by the computer. The slope of the plot of absorbance versus time was found during the first 2 min after starting the reaction.

3. Results and discussion

Magenta is an acid base indicator and exists in two forms, R^+ and ROH, depending on the pH of the solution [16].



At pH 6–8 addition of sulfide to magenta occurs at room temperature [17]. This causes a relatively rapid change of the color from purple to colorless even in the presence of small amounts of sulfide (ng ml^{-1}). The following optimizations were undertaken to achieve maximum sensitivity and large linear dynamic range.

3.1. Effect of variables

The decrease in the absorbance of magenta with and without sulfide was measured in the pH range 4–10, using either titrisol buffer, hydrochloric acid or sodium hydroxide solutions for pH adjustments. The effect of variation of pH on the rate of the reaction of 7.08×10^{-6} M magenta in the presence of 1.0 μg ml^{-1} sulfide is shown in Fig. 1. As it is obvious from the figure, the difference between blank and sample reaction rate was increased with increasing pH from 4 through 7, whereas this difference was decreased for pH values greater than 7. So pH 7 was used as optimum pH because of maximum difference between the rate of blank and sample reactions. Above pH 7 the rate of blank reaction is increased owing to the formation of ROH and thus, pH values greater than 10 were not tested.

Effect of magenta concentration on the reaction rate at pH 7 was studied. As it is shown in Fig. 2, there was an increase in the reaction rate when the concentration of magenta was varied from 1.77×10^{-6} to 1.70×10^{-5} M while at higher concentrations of magenta no considerable change in the reaction rate was observed. However, the rate of the blank reaction was also increased above 8.84×10^{-6} M of magenta. Thus, the optimum final concentration of magenta was chosen as 8.84×10^{-6} M.

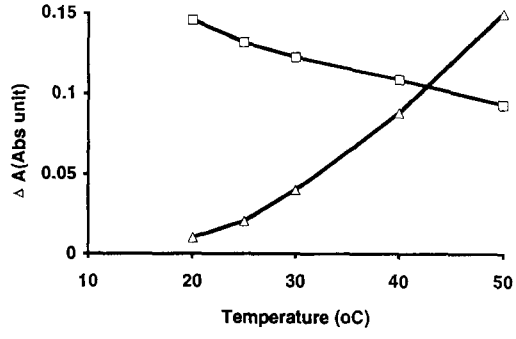


Fig. 3. Effect of temperature on the reaction rate of 1 μg ml^{-1} sulfide (□) and blank (△).

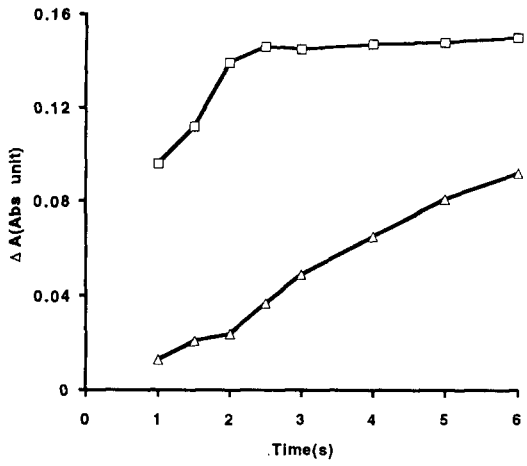

Fig. 4. Effect of measuring time on the reaction rate of 1 μg ml^{-1} sulfide (□) and blank (△).

The effect of ionic strength on the reaction rate was investigated. The ionic strength was varied from 0.02 to 0.7 M, using KCl solution. The results showed that this parameter had no effect on the reaction rate up to 0.2 M.

The effect of temperature was studied in the temperature range 20–50°C. Fig. 3 shows that the reaction rate of sulfide decreased with increasing temperature while the blank reaction rate increased. This deviation from Arrhenius equation could be due to instability of sulfide solution at higher temperatures or complexity of the reaction mixture [18]. Temperature of 25°C was used as the best working temperature, since at this temperature the difference between blank and sample reactions is large and 25°C is the ambient temperature at which it is very easy to work.

Table 1
Precision and accuracy of the method evaluated by fixed time analysis

S^{2-} (ng ml^{-1})	S^{2-}found (ng ml^{-1})	RSD% ($n = 10$)
150	134	2.10
400[a]	360	1.03
500	489	1.30
1000	950	1.00
1500	1460	0.80

[a] This amount of sulfide was added to a sample of tap water.

Table 2
Precision and accuracy evaluated by slope method

Sulfide concentration (ng ml^{-1})	Sulfide found (ng ml^{-1})	RSD (%)
50	50.8	1.80
500	536	1.12
1000	960	0.83
1500	1480	0.60

The effect of measuring time on the reaction rate was investigated (Fig. 4). The results showed that the first 2 min was the best working time at which maximum rate of reaction was achieved.

Optimum conditions chosen were as follows: pH 7; magenta concentration, 8.84×10^{-6} M; temperature, 25°C; measuring time, 2 min and λ_{max}, 540 nm.

4. Calibration

Calibration graphs were obtained by slope and fixed time methods. In fixed time method, the calibration curve was linear in the range 25–2500 ng ml^{-1} with equation of $\Delta A = 0.02925 + 0.097 \times 10^{-3}$ C and correlation coefficient (r) of 0.9986, where C is the concentration of sulfide in ng ml^{-1}. In the case of slope method, calibration curve is linear in the range of 25–2500 ng ml^{-1} with equation of $dA/dt = 1.128 \times 10^{-3} + 1.104 \times 10^{-5}$ C and correlation coefficient of 0.9991, where C is concentration of sulfide in ng ml^{-1} and dA/dt is the change in absorbance per second.

4.1. Precision and limit of detection

Both fixed time and slope methods were used to evaluate the precision, accuracy and detection limit. In each case a series of independent synthetic samples with fixed magenta concentration was used. In fixed time method the relative standard deviation, RSD, was in the range of 2.1–0.8% for sulfide concentration of 150–1500 ng ml^{-1} (Table 1). In the case of slope method, the RSD was in the range of 1.8–0.6% for sulfide concentration of 50–1500 ng ml^{-1} (Table 2). The

theoretical limit of detection, $Y_{DL} = Y_B + 3\ S_B$ [19] where Y_{DL}, Y_B, and S_B are signal of detection limit, blank signal and standard deviation of the blank, respectively, was 5 ng ml^{-1}. The experimental limit of detection was 15 ng ml^{-1} by both methods.

4.2. Interference study

To study the selectivity of the proposed method the effect of various cations and anions on the reaction rate of 700 ng ml^{-1} of sulfide at pH 7 was tested. The results are summarized in Table 3 with maximum tolerance limit for each ion.

4.3. Removal of interfering ions

Among the anions, sulfite and iodate interfere. Sulfite interference was eliminated by the addition of 1 ml of 0.1% formaldehyde to 5 ml of test solution prior to each measurement. The interfering effect of iodate was removed by the addition of 1 ml of 500 mg ml^{-1} I^- to 5 ml of test solution prior to each measurement.

Most of the cations that interfere in sulfide determination form insoluble metal sulfides. Interference effects of these cations were removed by the addition of iodide or hydroxide ions and filtering the solution prior to each measurement. Since cyanide did not interfere, the interfering effect of silver was removed by the addition of cyanide to form stable silver cyanide complex and thus preventing silver sulfide formation. The results are summarized in Table 4.

The proposed method offers good sensitivity for sulfide determination. As the results imply the fixed time and slope methods are comparable with each other. Higher precision of the latter may arise from the difference in data collection method. In the slope method large number of data was collected by the computer just after initiation of the reaction with two second time intervals. So the slope could be estimated with higher precision.

Table 4
The accuracy obtained after removal of interfering ions[a]

Interfering ion	Masking agent	S^2-found (μg ml^{-1})	RSD% $n = 3$
SO_3^{2-}(5)[b]	Formaldehyde(0.02%)	0.981	0.80
Ag^+(10)	CN^-(100)	0.970	0.72
Pb^{2+}(10)	OH^-(100)	1.03	1.63
Hg^{2+}(10)	I^-(100)	0.95	1.10
Hg^+(10)	I^-(100)	0.92	1.30
Cu^{2+}(20)	OH^-(200)	0.99	1.00
IO_3^-(10)	I^-(100)	0.974	0.98

[a] Sulfide concentration was 1 μg ml^{-1} in each case.
[b] The term in parenthesis are concentration of interfering ions or masking agent in μg ml^{-1} except for formaldehyde.

Table 5
Analysis of real samples by proposed method

Spring water	Proposed method (μg ml^{-1})	Standard method [20] (μg ml^{-1})	RSD %
Type 1	30.93	31.20	0.86
Type 2	29.07	29.41	1.00
Type 3	23.25	23.51	0.95

These are the results of ten replicate analysis.

5. Application

To evaluate the analytical applicability of the method, the recommended procedure was applied to the determination of sulfide in three different samples of spring water. The spring water sample was first treated with sodium hydroxide and filtered. The pH of the filtrate was then adjusted to about 7 with HCl. The recommended procedure was then applied using the standard addition method. The results (Table 5) show that the method is suitable for the analysis of real samples.

The effect of pulsed amperometric detection on penicillin G concentration profiles in a flowing-stream environment

Mark W. Lehmann, Marcelle R. Fahr, Lawrence E. Welch *

Department of Chemistry, Knox College, Galesburg, Illinois, 61401, USA

Received 6 August 1996; received in revised form 4 November 1996; accepted 5 November 1996

Abstract

It is well known that alterations of the times and potentials of each step within a PAD waveform can alter the sensitivity of the amperometric response, peak shape has also been found to vary with waveform adjustments. This work studied the variation in both peak heights and peak tailing as a function of waveform alterations for penicillin G oxidation in flow injection analysis. Large variations were found when the detection step and adsorption time were altered and smaller changes were observed during alterations of the other parameters. The major contribution to the tailing profile was inefficient removal of adsorbed analyte, which was subsequently retained until further PAD cycles. Alterations that improved the desorption efficiency led to reduced peak tailing, whereas alterations that hindered desorption caused an increase in tailing. The ability to minimize peak tailing will be advantageous for PAD usage with separation methods featuring ever-increasing resolution capability. © 1997 Elsevier Science B.V.

1. Introduction

Pulsed amperometric detection (PAD) has developed into a mature technique for determination of various organic compounds following liquid chromatographic separation. PAD utilizes a regular waveform that incorporates potential steps to perform anodic and cathodic cleaning following current measurement at a constant potential, insuring a reproducible detection environment for each detection period, even when in the presence of potentially passivating adsorbates [1]. This detection technique was originally applied for carbohydrate detection following a cation-exchange separation and post-column addition of NaOH by Hughes and Johnson [2,3] and carbohydrates remain the major application area for PAD today [4–6]. Significant development work has also been done utilizing PAD for detection of amines and amino acids [7,8] and organosulfur compounds [9,10]. Many very specific and narrowly focused PAD applications are appearing in the current literature [11,12], illustrating the maturity of the technique. A series of related detection waveforms are often grouped together with PAD under the designation of pulsed electrochemical detection (PED) [13]. These methods are similar

to PAD except that their current measurements are taken during a period where the potential is changing rather than being held constant as in PAD. Another recent development has been the application of PAD following separation by capillary electrophoresis (CE). As with PAD use following HPLC, the original applications with CE have been for detection of carbohydrates [14,15].

The penicillins are the most popular class of antimicrobial agents, having proven to have a tremendous positive impact on human health [16]. Studies in this laboratory have determined that the penicillins could be electrochemically oxidized on noble metal electrodes [17]. It was found that PAD could be successfully applied for penicillin detection, in either a direct or an indirect manner. Further work determined that this detection mechanism would operate properly following a reversed-phase separation on a C-18 column [18]. The PAD system was found to be compatible with a gradient solvent program that could separate a mixture of nine different penicillins. Methodology of a similar type was applied for determination of penicillins within bovine milk samples, and an on-column concentration scheme was shown to allow improved detection limits for these compounds [19]. Alternative PAD waveforms with four potential steps rather than the standard three were demonstrated using the penicillins as a model electrochemical system [20]. Summarizing from previous studies [17,20] and using the description of a PAD waveform given in Table 1, the electrochemical oxidation mechanism of the penicillins is proposed to occur as described henceforth. E1 is the detection potential where catalytic oxide (AuOH) is grown on the electrode surface, allowing oxidation of the penicillins previously adsorbed. The oxidation is thought to occur via an oxygen transfer from the oxide to the sulfur group within the penicillin. The second stage is a step to a more positive potential to initiate oxidative cleaning. The electrode is stepped to a potential whereby the higher, non-catalytic oxide (AuO) is formed on the electrode surface, accompanied by the desorption of adsorbed material ranging from analyte to carbonaceous free radicals. E3 steps the potential to a much smaller value, where the surface oxide is reductively stripped. Adsorption of the penicillin G occurs at this stage, through the sulfide group. Only adsorbed analyte is subsequently oxidized upon the return to the detection step. A similar mechanism has been proposed for the PAD oxidation of other organosulfur compounds [21–23].

Table 1
The standard waveform

E1 = 1500 mV	T1 = 0.333 s
E2 = 1600 mV	T2 = 0.333 s
E3 = −200 mV	T3 = 0.167 s

It is not unusual for PAD response to be very non-Gaussian in nature, typically displaying a tailing profile. Some of this can be attributed to chromatographic conditions and extra-column broadening, but even flow injection analysis experiments can produce tailing well beyond what can be attributed to flow-cell dead volume, etc. Tailing has been shown to occur for fixed potential (dc) amperometry in addition to pulsed amperometric trials [24] for sodium thiophosphate, and detector waveform alterations were noted to change the peak shape. Examination of a non-adsorbing analyte under similar conditions gave a response much closer to Gaussian, suggesting that adsorption was critical. Peak tailing has also been observed for amino acids using pulsed electrochemical detection and the observation was made that waveform alterations could alter the observed peak shapes [25].

Vandeberg et al. [26] showed that PAD determination of thiourea could produce peaks varying greatly in breadth depending on the detection potential chosen. The original PAD investigation of penicillins [17] noted that peak tailing was clearly in evidence for flow injection trials. It was postulated that this was related to the rates of the adsorption/desorption processes for the penicillin adsorbates at the gold electrode. Further work [20] has shown that the addition of a fourth potential step for pre-growth of catalytic oxide prior to the PAD detection step allows a waveform to be constructed that had less tailing character than that seen with standard 3-step PAD. It was noted that tailing was a greater problem with indirect PAD compared with direct PAD and that

the peak asymmetry factor (PAF) was useful as a quantitative measure of the degree of peak tailing. Despite clear evidence that the PAD waveform altered peak shapes, no in-depth study elucidating the relationship between the various PAD waveform parameters and peak shape has been performed. Our intention with this work was to examine how each parameter of the standard PAD waveform affected the peak shape and to determine the relationship between peak shape and peak size for injections of penicillin G.

2. Experimental

Penicillin G was purchased from Sigma (St. Louis, MO). All other solutions were made from reagent-grade chemicals from Aldrich (Milwaukee, WI), Baker (Phillipsburg, NJ) or Fisher (Pittsburgh, PA). Water was distilled and deionized before use as a solvent.

Flow injection analysis was done with a Waters 625 LC system (Milford, MA) and a Waters 464 Pulsed Electrochemical Detector. A 75 μl sample injection loop was employed with this system, and a flow rate of 0.7 ml min^{-1} was standard. The solvent for all flow injection work was 0.200 M acetate buffer (pH 4.7). Injected penicillin solutions during flow injection analysis trials were all solvent matched with the mobile phase to avoid having a system peak overlapping with the analytical peak. All mobile phases were vacuum filtered through an Alltech (Deerfield, IL) 0.20 μm nylon filter. The mobile phase mixtures were degassed further using a 15 ml min^{-1} helium sparge during the flow injection trials.

A thin-layer cell was utilized with a single gold working electrode having a diameter of 0.25 cm. The counter electrode was a stainless steel block mounted opposing the thin-layer cell, with the flow channel created by a teflon spacer between the two. The reference electrode was a Ag/AgCl. A BAS MF-2060 Polishing Kit was used to polish the working electrode, in addition potential cycling to the voltage limits of the system, as defined by the onset of solvent breakdown, was helpful to restore electrode activity following temporary losses of sensitivity.

Current integration was always during the final 16.7 ms of the detection step, as required by the detector. Detector signal polarity was inverted so that increased anodic response would produce peaks rather than troughs on the output plots. Output data was collected by a PC using LabCalc software (Galactic Industries, Salem, NH). The collection interval was synchronized with the potentiostat, such that a single data point was collected per PAD cycle.

3. Results and discussion

Peak size was determined by measuring peak height and measurements of peak asymmetry factors (PAF) were utilized to quantitatively describe the degree of peak tailing [27,28]. To find the PAF, a vertical trace is drawn through the Y maximum, then bisected by a second segment drawn perpendicularly at 10% of the maximum peak height. The segment length of the bisecting line from the intersection point to the right edge is divided by the segment length from the intersection point to the left, with the resulting ratio giving the PAF value. Originally developed for theoretical plate measurements in chromatography, the PAF was ideal for quantitating detector-related tailing in flow injection analysis [20]. Not all of the tailing was solely related to electrochemical events, tandem detector experiments with downstream ultraviolet detection found that dispersion of the sample during passage through the electrochemical flow cell and its associated fittings was enough to induce a small degree of tailing. By using a single solvent mixture, maintaining a constant flow rate and identical injection volumes, and using a single flow cell without any modification, tailing from this source was assumed to be constant throughout all experiments, allowing peak height and PAF variations to be attributed solely to PAD waveform changes and any corresponding alterations in the electrochemistry.

Initial studies found that although peak heights for a series of repetitive trials were fairly precise, the PAF measurements were a great deal more variable. To be able to interpret trends in peak shape based on PAF measurements, maximum

precision within sets of experimental data was a necessity. Data was collected in sets of 12 replicate trials, with all sets varying a given waveform parameter done during the same session. There was a considerable degree of day-to-day variability, underlining the importance of collecting an entire data set during a single session. The overall PAF trends remained consistent on a daily basis even if the value for a given set of conditions varied from 1 day to the next. Foley and Dorsey [29] have noted that the precision of peak asymmetry measurements increases as the peak becomes more asymmetric, this was confirmed experimentally for penicillin G. Thus, a relatively high penicillin G concentration, 1.00×10^{-2} M, was chosen to improve precision. The relationship between concentration and peak shape will be discussed at length below. Detector noise varied significantly as a function of solvent flow rate due to the lack of pump back pressure. Optimal response was found at a value of 0.7 ml min^{-1}, which was incorporated for all subsequent trials.

Initial measurements were made by displaying each peak on the computer screen and manually using the cursors to determine the peak heights and segment lengths necessary to calculate the PAF. Adaptation of an algorithm to instruct the data collection computer to automatically calculate both peak height and PAF was successful at providing improved precision. Further study of the PAF algorithm found that measuring a bisecting line at a height greater than the standard 10% limited the effect of baseline perturbations, producing a more precise set of PAF measurements for a given series of peaks. Measuring chromatographic figures of merit at the standard 10% height has been defended as advantageous for a number of reasons [29], including precision and simplicity. With the computer program doing the measurements, the simplicity angle does not come in to play. It is possible that measurements at 10% might be better given more ideal conditions (i.e., less baseline noise), however, the precision clearly increased until a maximum was achieved at 20% for the system being tested. This 20% value was utilized thereafter for all PAF measurements.

Although previous chromatographic trials had required the addition of organic modifier to an aqueous mobile phase [18–20], for simplicity, unmodified acetate buffer was chosen for the flow injection studies. A standard waveform, shown in Table 1, was chosen as a starting point for this work and a systematic variation of each waveform parameter was initiated while all of the other parameters were held constant. Observations of each parameter are discussed in turn below.

Based on observation of PAD peaks for penicillin G with a wide variety of waveforms, it is theorized that the tailing profiles are an artifact of inefficient electrode cleaning during the E2 (oxidative cleaning) and E3 (reductive cleaning) potential steps. Some analyte material and likely other adsorbates depending on solution composition, are not removed during the cleaning steps, carrying them over to the following PAD cycle. Other workers [21] have noted the very strong adsorption of organosulfur compounds to gold via their sulfur group. A strong adsorption would be more likely to give rise to this carry-over effect than for more weakly adsorbed species. This carry-over would result in the oxidized analyte for each step being composed of two types, analyte freshly adsorbed, and analyte carried over from the previous PAD cycle. If the cleaning were 100% efficient, then the amount of analyte adsorbed and oxidized would be solely a function of solution concentration, giving a Gaussian peak shape. The delay caused by adsorbate carry-over causes the analyte material to spend a greater amount of time on the working electrode on average, shifting the peak's center of mass to a later time and creating the tailing profile much like that seen for slow mass transfer from a stationary phase. Typically, an increase in the amount of analyte carry-over would be expected to increase peak height, assuming that carry-over adsorbate augments rather than replaces fresh adsorbate, the greater amount of adsorbed material will lead to a larger anodic signal. The proportion of fresh versus carry-over adsorbate, and therefore the peak shape, ultimately depends on the waveform parameters selected. It has been noted in the literature [23] that adsorption sites of varying types and strengths are present on Au. Due to surface roughness, there are likely a few sites where catalytic oxidation is hindered due to ge-

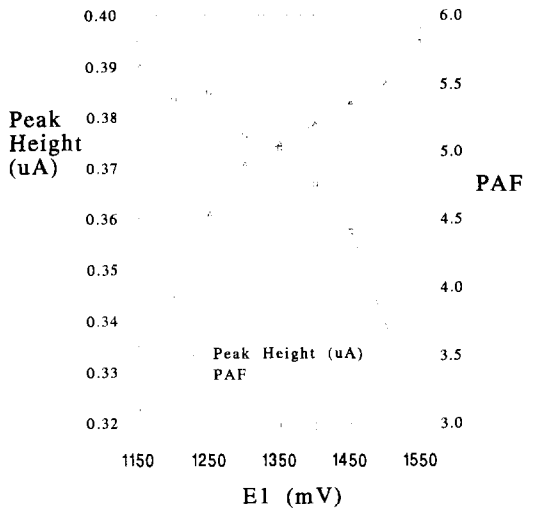

Fig. 1. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of E1. The other waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.00521. Relative standard deviation of PAF values = 0.0577.

ometry–desorption from here is presumably quite inefficient, creating severe tailing at the very end of each peak. This can be illustrated by observing peak shapes following mechanical polishing of the working electrode. Immediately following polishing, both the peak height and PAF values drop significantly. This is due to the polishing minimizing surface roughness, which cuts down on electrode surface area. The smaller surface area limits the degree of analyte adsorption and therefore reduces peak size. The peak shape improves because a more-level electrode surface allows the adsorbed penicillins greater access to active surface oxide groups. At greater times following the polish, both the peak height and PAF grow larger as the electrode surface regains its roughness.

3.1. E1

E1 was varied from 1150 to 1550 mV in 50 mV intervals. Average peak heights and PAF values for each voltage are displayed in Fig. 1. As expected, the peak heights became larger as E1 was increased. The rate of penicillin G oxidation is not particularly rapid [17], so by increasing E1, greater overpotential is applied, accelerating the reaction and producing a greater anodic signal. The PAF displays an inverse relationship with E1. The proposed oxidation mechanism for penicillin G predicts that analyte desorption accompanies oxidation. As E1 is increased and greater oxidation efficiency enabled, this should also result in more efficient analyte desorption. Less analyte is carried over to following PAD cycles, so the degree of tailing is reduced. Normally when the amount of carry-over adsorbate is reduced, the peak height would be expected to decrease as well, but in this circumstance the overpotential increase causes a large enhancement in oxidative efficiency, which more than offsets loss of carry-over material. At first glance, the trends seen in Fig. 1 suggest that the optimum value of E1 would be at an even greater value than the 1550 mV, as this gave the largest peaks and the smallest PAF values. This overlooks the fact that noise is not being considered along with the signal, and noise increases significantly as E1 is elevated. Reproducibility also suffers at large E1 values, as evidenced by a decrease in precision for the data sets. The reduced detector selectivity seen at larger E1 values might also be a concern for PAD usage in a chromatographic setting.

3.2. T1

T1 was varied from 0.166 to 0.516 s in intervals of 0.050 s. Average peak heights and PAF values for each time are displayed in Fig. 2. By holding at the detection potential for a longer time, it would be expected that a greater total amount of analyte would get oxidized during the detection step. Assuming desorption follows oxidation, this would result in less analyte carry-over to subsequent cycles, and therefore less tailing and a decrease in PAF as observed. The greater degree of oxidation would be expected to increase peak heights, but the experimental data shows a decrease, this can be attributed to the current sampling taking place only during the last 16.7 ms of the detection step. The oxidative current is well known to decay with time for PAD experiments [7], so a sampling at the very end of the detection step will yield smaller peaks as step length in

increased, even though a greater degree of oxidation takes place when the entire detection step is considered. One can interpret Fig. 2 to see a trade-off, where peak size and peak shape are antagonistic. LaCourse et al. [30] have observed the same trend in peak size while working with sugars in basic solution.

3.3. E2

E2 was varied from 1600 to 1800 mV in 50 mV intervals. Average peak heights and PAF values for each voltage are displayed in Fig. 3. As E2 is increased, the peak heights and the PAF values both were seen to increase. This would suggest that higher E2 values create a greater degree of analyte carry-over. Tailing would increase, and the peak height would also increase if this were indeed the case. This was a surprise, as the natural assumption was that increasing the E2 value would make the oxidative cleaning step more efficient, resulting in decreased carry-over of analyte to subsequent cycles. Although the trends are clear, it should be noted that the relative change of both peak height and PAF values as T2 is

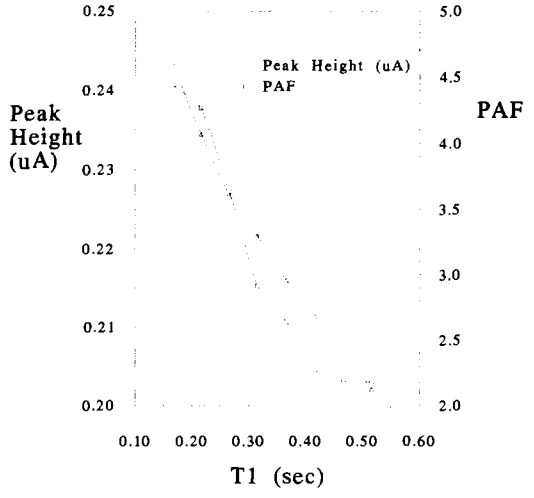

Fig. 2. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of T1. The other waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.00872. Relative standard deviation of PAF values = 0.0871.

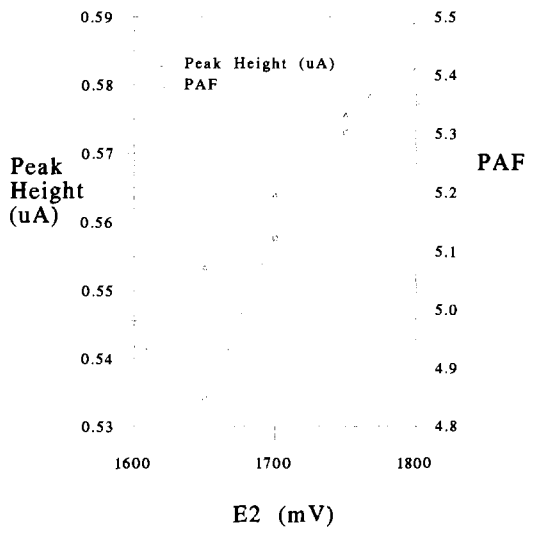

Fig. 3. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of E2. altered is much smaller than that seen for either E1 or T1. Extension of the E2 range downward to 1350 mV demonstrates that very little change for either parameter occurs below 1600 mV. A clear upward trend follows this region of little change, as can be seen in Fig. 3.

It would appear that at high E2 values, where a large overpotential for the formation of the higher surface oxide (AuO) exists, that cleaning is less efficient and more carry-over results. The best cleaning potentials would be in the lower-potential region, which corresponds to a much greater surface coverage of the lower surface oxide (AuOH). This would suggest that in this range that the continued presence of catalytic surface oxide allows penicillin oxidation to overlap into the E2 step, producing less carry-over following desorption of the oxidized material. This would produce the observed smaller peak heights and PAF values. At larger E2 potentials, the high degree of inactive higher oxide insures that no further oxidation takes place during this step. The large E2 value, however, does not appear to remove much of the adsorbed analyte, so much is

carried over for possible oxidation during the next cycle. The strong adsorption of the penicillins to the gold surface appears to allow them to remain on the surface during E2 potentials that would cause the release of most other organic adsorbates.

The loss of oxidative activity resulting from higher oxide production was not observed during the E1 variation due to the lower potential range employed and the fact that the oxide was much 'younger', having been grown during the step rather than carried over from a prior step as with the E2 variation. Coupling a very large E1 and T1 would allow production of significant quantities of the higher oxide much like seen with the E2 trials, but these values are outside the range tested and impractical for proper detector performance.

3.4. T2

T2 was varied from 0.166 to 0.516 s in intervals of 0.050 s. Average peak heights and PAF values for each time are displayed in Fig. 4. For the T2 variation, as the length of the oxidative cleaning

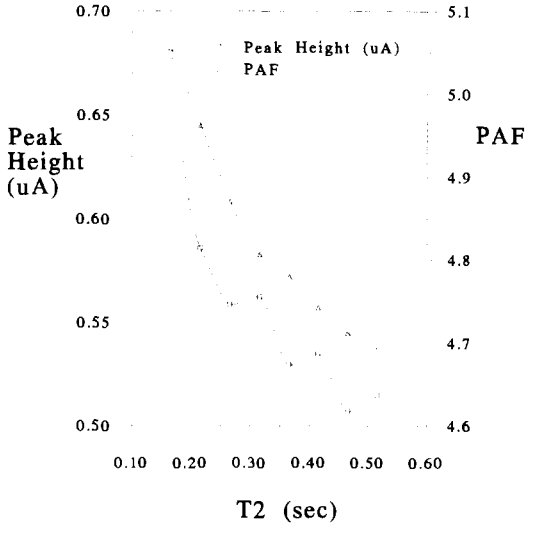

Fig. 4. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of T2. The other waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.00587. Relative standard deviation of PAF values = 0.0621.

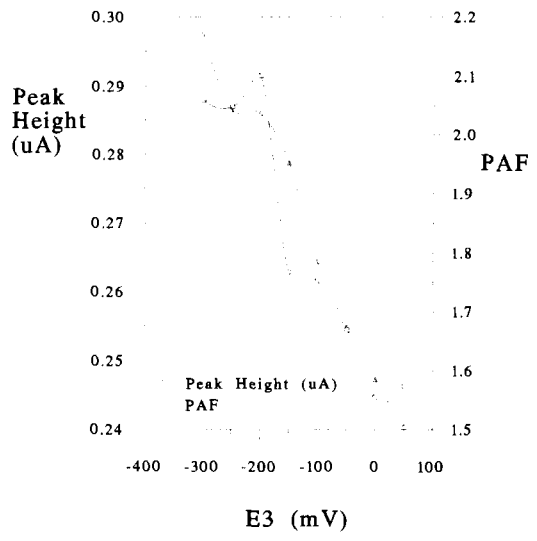

Fig. 5. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of E3. The other waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.0139. Relative standard deviation of PAF values = 0.0956.

period was increased, greater cleaning efficiency was expected. This would mean less carry-over of adsorbate, causing a decrease in peak height and less tailing at higher T2 values. The experimental data showed this behavior clearly. Short oxidative cleaning periods have been shown to produce greater tailing for amino acid samples in a prior study [25].

3.5. E3

E3 was varied from -300 to 50 mV in 50 mV intervals. Average peak heights and PAF values for each voltage are displayed in Fig. 5. As E3 was increased, the peak heights and the PAF values both showed a decrease. It was felt that all of the E3 values utilized were sufficiently small enough to not really alter the efficiency of reductive oxide removal. However, the amount of analyte adsorbed at this step was considered to be variable throughout this voltage domain. From the experimental data, both of the trends point out that the carry-over of adsorbed analyte is reduced as E3 is increased. The higher E3 voltages

lead to less efficient adsorption of analyte. If the cleaning efficiency is not changed, then making adsorption less efficient will create a smaller degree of carry-over, explaining the observed peak height and PAF trends. A more efficient adsorption will lead to greater electrode surface coverage of analyte, resulting in a change in response similar to what one would expect upon increasing analyte concentration, as discussed below.

3.6. T3

T3 was varied from 0.016 to 0.466 s in intervals of approximately 0.060 s. Average peak heights and PAF values for each time are displayed in Fig. 6. Prior studies have shown that peak size increases as the PAD adsorption step is extended to longer times, deviating only at very large time values as adsorbate saturation is approached [31]. The same trend is evident in Fig. 6, as both the peak height and the PAF are seen to increase. As with the E3 response, the trends are dictated by T3 alteration changing the efficiency of the adsorption without alteration of the cleaning effectiveness. Longer T3 values allow greater adsorption of analyte, so without a change in the cleaning, the analyte carry-over increases, resulting in larger peaks with a greater degree of tailing.

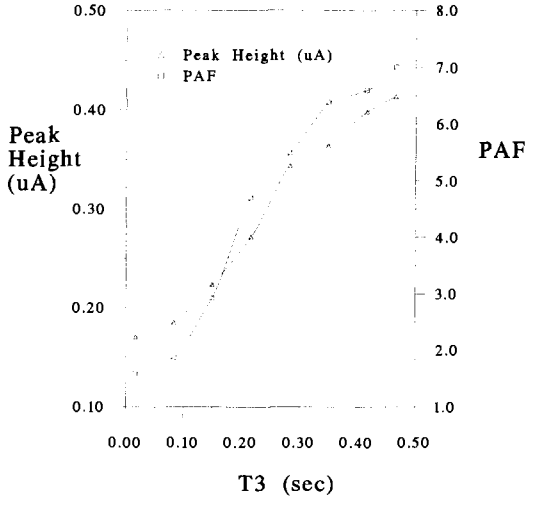

Fig. 6. Peak height and peak asymmetry factor (PAF) values for 1.00×10^{-2} M penicillin G injections as a function of T3. The other waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.00970. Relative standard deviation of PAF values = 0.0737.

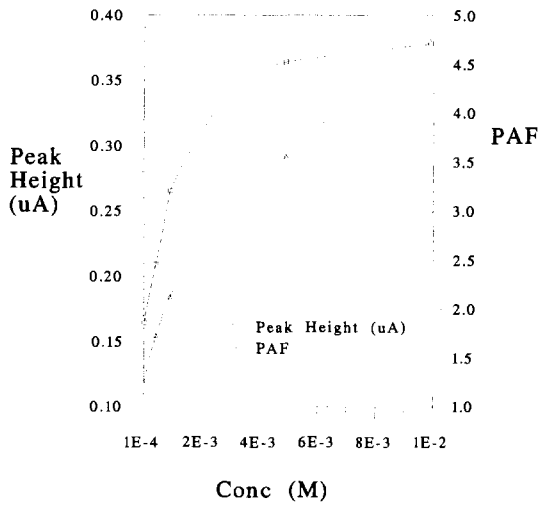

Fig. 7. Peak height and peak asymmetry factor (PAF) values for penicillin G injections as a function of concentration. The waveform parameters are held at their standard values (see Table 1). Relative standard deviation of peak heights = 0.00546. Relative standard deviation of PAF values = 0.0956.

3.7. Concentration

It is well known that the current versus concentration response for PAD is non-linear, except for examination of relatively small concentration ranges [32]. When viewed over a wide range, the response is linear at low concentrations, but then curvature occurs at higher concentrations as the current is less than the linear extrapolation. This is due to the crucial adsorption requirement for oxidation, creating an isotherm-like response resulting from the limited area available for adsorption. Our data confirmed that this type of response was present. The degree of peak tailing was also clearly a function of concentration, as can be seen in Fig. 7. Peak tailing was minimal at low concentrations, yet very significant at increased values. Variations in both peak height and PAF were present for low penicillin G concentrations as the various waveform parameters were

varied, but they were very slight and the data sets of low precision. Employing 1.00×10^{-2} M, as done above, allowed greater precision and easier visualization of the trends. The concentration dependence of the PAF is further evidence that the carry-over of adsorbed material is the root cause of peak tailing. At low penicillin G concentrations, the electrode surface coverage of adsorbed analyte will be quite small. The balance of the surface sites would be expected to grow surface oxide, which would be available for electrocatalytic oxidation via an oxygen transfer. At this low coverage value, there is a great likelihood that most of the adsorbed analyte has a nearby oxide site available to donate an oxygen, so the oxidation proceeds with great efficiency. Since the oxidative mechanism ends with desorption of the analyte, the efficient oxidation seen at these low concentration values would leave very little adsorbed analyte material behind, making carry-over minimal. Very little peak tailing results. However, as the concentration of analyte is increased, the penicillin G surface coverage becomes much larger. This leaves fewer sites available for oxide growth on the electrode surface. Under these conditions, the efficiency of oxidation is much lower, as many adsorbed analytes do not have an adjacent oxide available for oxidation. This contributes not only to the isotherm-like current versus concentration response, but it also results in fewer analyte molecules desorbed via the oxidative mechanism. The unoxidized analyte remains behind to be subjected to the E2 and E3 cleaning steps of the PAD waveform. Whereas the oxidative desorption process is very efficient, the cleaning from E2 and E3 is notably inefficient, and a clear function of waveform design. In any case, this inefficiency means that a good deal of the remaining adsorbate will not be removed and the carry-over to the following cycle is significant. As noted before, this carry-over is what leads to peak tailing. One can conclude that if all potential adsorbates are present at very low concentration, then there is little reason to be concerned with detector-generated tailing, but this will become an issue at higher concentrations.

4. Conclusion

As can be noted from the discussion above, waveform optimization in most cases makes size and shape antagonistic parameters, optimizing to maximize one will cause a degradation in the other. Optimizing for peak S/N instead of size tends to blur this relationship slightly, but it still exists most of the time. HPLC detector enthusiasts often try to maximize S/N, as detection limits are a common yardstick for detector performance. The antagonistic relationship between size and shape suggests that one might want to develop several waveforms, one featuring high sensitivity, one featuring minimized peak tailing and perhaps others of intermediate character.

While the trends determined within this study relate solely for direct PAD of a single analyte, it is expected that similar behavior would be observed for other PAD analytes that are detected via oxidation at the catalytic lower oxide of gold. The importance of the peak shape produced by a PAD waveform is likely to become a more significant issue. As HPLC efficiency increases and PAD is applied to capillary separation methods, detector response to narrow bands of analyte material, thus, greater detector resolution, will be required to keep pace. Avoiding detector-related peak tailing might be a crucial factor for such separations, and it should be noted that the high frequency waveforms necessary to accurately portray such narrow bands should suffer from worse peak shapes than the standard PAD waveforms for use with HPLC, especially given the PAF dependence on T1 and T2.

Abstract

Analysis of the total antimony in plant material was unsuccessful using the electrothermal atomic absorption spectrometry (ETAAS) conditions recommended by the instrument manufacturer. For this reason, an optimisation procedure utilising the Plackett-Burman method, simplex optimisation and visualisation of the generated response surface via principal components analysis, was carried out. The Plackett-Burman method was used to eliminate four of the initial variables chosen. Four variables (atomisation temperature, atomisation time, ash temperature and modifier concentration) were subsequently optimised using the composite modified simplex method and the results were visualised as a contour diagram, after reduction to two principal components. The optimised conditions were used for the analysis of both an acid digested pine needle standard reference material (NIST 1575) and a pond weed sample, collected from a contaminated site at Yellowknife Bay, Yellowknife, NWT, Canada. The total concentration of antimony present in the pine needles was statistically indistinguishable from the non-certified value, as was the value for the pond weed sample, compared with a value determined by neutron activation analysis (NAA). The results for the analysis of the pond weed sample by ETAAS agreed with those obtained from a subsequent analysis by inductively coupled plasma-mass spectrometry. © 1997 Elsevier Science B.V.

Keywords: Antimony; Electrothermal atomic absorption spectroscopy; Environmental samples; Simplex optimisation and Plackett-Burman design

1. Introduction

Antimony has been found in biological, geological and water samples [1–4], and its toxicity has led the United States Environmental Protection Agency (US-EPA) to consider it and its compounds priority pollutants [5]. Common techniques for determining the total amount of antimony include: inductively coupled plasma mass spectrometry (ICP-MS) or atomic emission spectroscopy (ICP-AES) and hydride generation, followed by different atomisation methods such as electrothermal or flame heated quartz tube atomic

PII S0039-9140(96)02168-6

absorption spectroscopy (HG-QT-AAS) [1–3]. The preconcentration of antimony hydride in a graphite furnace, followed by atomisation has recently been developed as another method of analysis [6,7].

All these methods give low detection limits, but ICP based methods are expensive for routine analysis. Hydride generation may not give 100% recovery when non-hydride forming species are present in the sample and is labour intensive. Electrothermal atomic absorption spectroscopy (ETAAS) is a widely used analytical tool for the determination of many trace metals, including antimony, in a wide variety of sample matrices [8–11]. The use of ETAAS for the determination of total antimony is cost effective and simple, but no formal optimisation of conditions has been reported for plant samples.

The very first studies [12] on the graphite furnace technique showed that the sample matrix has a pronounced effect on the absorbance signal observed for a particular element. These effects often lead to systematic errors when determining metals in complex organic matrices and result from substances not being fully volatilised prior to atomisation of the metal. Optimisation of instrumental conditions is therefore a prerequisite for development of an environmental analytical protocol using electrothermal AAS.

Until recently it was usual to optimise a system using a one-factor-at-a-time-approach, in which each variable but one is held at a low level and the response is evaluated at the lower and the upper level of the factor being tested. Each variable is treated in turn, until the response is maximised or minimised, depending on the system. This approach is far from adequate because there is no guarantee that an optimum response will be found, it requires a large number of experiments to be carried out and the presence of inter-relationships between the variables (e.g., modifier concentration and ash temperature) means that the optimum obtained will depend on the initial conditions chosen. Factorial experiments, in which all the factors are varied simultaneously according to a pre-set design, have also been used to optimise analytical systems. However, this approach is highly dependent on the levels of each factor and thus, it works best when some prior knowledge of the system is available. It also requires a large amount of experimentation when more than three variables are investigated.

Simplex optimisation is a highly efficient, multifactor, empirical feedback, optimisation procedure, that does not require the large number of experiments nor the initial variable information that is necessary with the two methods outlined above. This procedure 'homes in' on the optimum response region by driving the experiments in the direction of steepest ascent of the response surface. The optimum thus obtained is generally a local optimum, but some assurance that it is the overall optimum can be obtained by repeating the search from different starting conditions to see if the same conditions are reached.

Simplex optimisation is now routinely used as a method of maximising a response [13,14] or reducing interferences [15,16] in the analysis of trace elements. In the present work the use of the instrument manufacturer's recommended operating conditions [17] for the determination of antimony by ETAAS were completely unsuccessful, yielding no absorbance maximum. These conditions were: dry at 75°C for 5 s, then at 90°C for 60 s, then at 120°C for 10 s, hold at 120°C for 2 s, ramp to 2000°C in 1 s (maximum ramp rate), atomise at 2000°C for 3 s, clean at 2000°C for 1 s.

A two stage approach was used to optimise the experimental conditions used for the determination of antimony in plant material. The first part of the investigation involved the use of the Plackett-Burman method to screen a number of potential variables to select the most appropriate to optimise using the composite modified simplex method [18,19]. The principle advantages of this approach are that information concerning the significance of each variable is obtained (Plackett-Burman method) and the optimum conditions are efficiently reached, with less experimentation than would be necessary if none of the variables had been eliminated. Additionally, visualising the response surface eliminates the need for univariate searches around the optimum, which are often carried out to check that the optimum is correct. These goals are not possible using a one-step-at-a-time-approach, or a factorial experiment.

To check the accuracy of the developed methodology the concentration of antimony in a pine needle standard reference material (SRM), NIST 1575, was determined. The pond weed sample was acid digested and methanol extracted and these samples were statistically compared with results obtained by ICP-MS, as well as by neutron activation analysis (NAA).

2. Experimental

2.1. Reagents

Concentrated nitric and hydrochloric acids (both double sub-boiling distilled, Seastar Chemicals, Sidney, BC), concentrated sulphuric acid (Analytical grade, BDH Chemicals, Toronto, ON), and glacial acetic acid (Reagent grade, Fisher Scientific, Nepean, ON). Hydrogen peroxide (30%) (Assurance grade, BDH Chemicals, Toronto, ON), D-tartaric acid (Reagent grade, Allied Chemical Canada, Canada), palladium nitrate ($Pd(NO_3)_2 \cdot 2H_2O$, Reagent grade, Sigma, St. Louis, MO), citric acid (Certified, Fisher Scientific, Fairlawn, NJ).

Water was purified to a final resistivity of better than 1 M ohm (Barnstead Mega-Pure system, Barnstead/Thermolyne, Dubuque, IA). Methanol (HPLC grade, Fisher Scientific, Nepean, ON). A methanol/water (1/1 v/v) solvent mixture was used to extract the aqueous antimony species. Antimony metal (Certified, Fisher Scientific, Fair Lawn, NJ) and 1000 mg l^{-1} indium (Spectroscopy standard, High-Purity Standards, Charleston, SC).

The freeze dried pine needle standard reference material 1575, was obtained from the National Institute of Standards and Technology (NIST, Washington, DC). The pond weed sample (*Potomogetan pectinatus*) was collected from a site contaminated with mine tailings (Yellowknife Bay, NWT, Canada) as described previously [20] and freeze dried. The pine needle SRM (NIST 1575) was chosen as a representative standard reference material because it contains an uncertified antimony concentration of 0.2 mg kg^{-1}.

2.2. Preparation of samples and standards

The pine needles (1575), and pond weed were dried to constant weight and then acid digested. Acid digestions were carried out in duplicate by adding 3 ml of concentrated nitric acid, 3 ml of 30% hydrogen peroxide, and 1 ml of concentrated sulphuric acid to a 250 ml round bottom flask containing pine needles (0.5 g) or pond weed (0.25–0.40 g) and refluxed for 3 h as described elsewhere [21]. An additional pine needle digestion was carried out by heating 1 g of material with the above acid/hydrogen peroxide mixture, in a vial on a hot plate, at 90°C for 3 h. After the digestions were complete, the partially evaporated samples were diluted to 5 ml (pine needles) and 10 ml (pond weed) using deionised water.

Extraction of the pondweed was carried out by sonicating 0.5 g dry material with 10 ml methanol/water (1/1 v/v) for two samples, and 10 ml 0.2 M acetic acid for one sample. The sample and solvent were sonicated for 20 min, the mixture was centrifuged at 3000 rpm for 10 min and the supernatant was decanted. This was repeated five times and the combined extracts were evaporated under reduced pressure to dryness and made up to 5 ml with water.

A stock solution of 1000 mg l^{-1} antimony solution was prepared by dissolving 0.1000 g antimony metal in aqua regia and diluting to 100 ml with 1% D-tartaric acid. The 50 and 25 μg l^{-1} solutions for use in the standard additions determinations were prepared fresh daily from the stock.

The palladium modifier solution was prepared by dissolving 0.1083 g palladium(II) nitrate dihydrate in 0.5 ml of concentrated nitric acid and diluting to 100 ml with 2% citric acid solution to give a 1000 mg l^{-1} Pd solution. This stock solution was then diluted further with 2% citric acid solution to give the various concentrations needed for the experiments.

Indium solution was used as an internal standard in the ICP-MS determinations and was prepared by diluting an appropriate volume of a 200 μg l^{-1} standard solution so that the final concentration was 10 μg l^{-1} in each sample.

2.3. Instrumentation

An atomic absorption spectrometer (Varian Techtron Model 1275, Australia) fitted with an auto-sampler, graphite furnace and programmer (GTA-95) was used throughout this work. The antimony hollow cathode lamp (SpectrAA, Varian, Australia) was operated at 10 mA with a slit corresponding to a spectral bandwidth of 0.2 nm and the 217.9 nm line was monitored. Continuous background correction was by a deuterium lamp (Varian, Australia). Pyrolytically coated graphite tubes (Varian, Germany) were used.

The ICP-MS measurements were carried out using a VG PlasmaQuad 2 turbo plus instrument (VG Elemental, Fisons Scientific Equipment, Winsford, Cheshire, UK), operated at 1350 W RF power. Cooling, auxiliary and nebulizer gases (Ar) were at flow rates of 13.82, 0.69 and 1.00 l min^{-1}, respectively. Masses were monitored in the peak jumping mode by using m/z 115 (In) and 121 (Sb).

A real sample (pond weed digest diluted four times with deionised water) was used for the optimisation procedure outlined below. This sample was chosen, rather than an antimony standard, so that matrix and species dependent effects could be minimised and the antimony signal maximised.

The OPTIMA3 computer program [18,19] was used for the simplex calculations and the generation of experimental conditions. The principal components analysis was carried out by using Systat® 5.03 for windows (SYSTAT). Both of these programs were run under Windows® 3.1, on a DELL 466/M personal computer.

NAA was carried out as described elsewhere [20,22].

2.4. Plackett-Burman experiments

The initial variables chosen to be screened using the Plackett and Burman method were: dry time (Dt), dry temperature (DT), ash time (At), ash temperature (AT), atomisation ramp (AtR), atomisation time (Att), atomisation temperature (AtT) and modifier concentration (MC). This allowed for the use of three dummy variables and so had 3 df (see Table 1). Initial experiments carried out using longer ash and atomisation times (up to 15 and 7 s, respectively) resulted in a short graphite tube lifetime (60 firings), thus limits for these variables were chosen to minimise tube deterioration. The limits for all the variables were chosen so as to show a change in measured absorbance, which was the response measured, rather than to reflect conditions usually used for ETAAS.

After the first design was carried out, three variables (atomisation ramp, atomisation time and modifier concentration) were kept constant, whilst the effect of the other five variables were investigated using a $N = 8$ design (two dummy variables, 2 df) (see Table 2). The matrix designs, adapted from the method of Jones et al. [23], accompany the designations of variables in Table 1 and Table 2.

2.5. Simplex optimisation

The composite modified simplex (CMS) optimisation method described previously [18,19] was employed during this work. Having screened out the variables that did not have a significant effect on the response, the remaining four factors (atomisation temperature, atomisation time, ash temperature and modifier concentration) were optimised to provide the maximum antimony absorbance signal from a pond weed digestate. The upper and lower limits used in the CMS procedure as well as the stepsize for each variable are given in Table 3.

Five initial experiments were conducted and the conditions for each factor, as well as the resulting absorbance, were entered into the OPTIMA3 computer program. The next set of experimental conditions were generated and carried out, and the response was entered. The simplex progressed via a series of reflections, expansions, contractions or fit points, towards the optimum absorbance (see Table 4). The process was continued until the standard deviation of the five highest responses was less than the value of the stepsize of the absorbance (0.010), three times sequentially. To prove that the optimum values determined were not due to a local region of maximum response, the procedure was repeated with different starting

conditions; the same optimum conditions were found.

2.6. Visualisation of the response surface

The experimental results were analysed by using principal components analysis, as described in detail and with examples by Molinero [24]. Briefly, principle components analysis was used to reduce the four variables from the simplex optimisation to two new variables (principle components 1 and 2). The scores of these principle components give coordinates for all the experimental vertices. Thus, the vertices of the simplex previously represented by n variables, are now represented by two variables, and the responses are plotted against these variables, to generate the response surface. The relative significance of the effects of the original variables on the responses can be evaluated by considering the loading of each variable on each principle component, which indicates to what degree each principle component is influenced by each of the original variables. This approach provides visual information on the optimum and the response surface, which is not possible with the simplex

Table 3

search alone. The response surface can be studied to determine more information such as the presence or absence of ridge features or local maxima. It also helps to show other factor levels that could provide better experimental conditions in terms of lower temperature operating conditions, or less modifier, thus resulting in a more cost effective procedure.

Table 5
t Values for 12 and 8 variable designs used in the Plackett-Burman experiments

Variables	Dt	DT	At	AT	Att	AtT	AtR	MC
12	−1.58	2.55	−0.97	1.74	−4.46*	−0.83	−2.46	3.49*

3. Results and discussion

3.1. Plackett-Burman experiments

The results for the first Plackett-Burm experiment were used to obtain a minimum t value of 3.18 for a 95% confidence interval. Only the atomisation time and modifier concentration give t values above this and so are the only significant variables at this confidence level (Table 5). Birnbaun plots can be used to confirm or help clarify results obtained from such experiments, as explained in more detail elsewhere [23]. Briefly, deviance of points from a straight line indicate large variable effects [14]. In this instance, the Birnbaun plot (not shown) gives essentially a straight line and therefore does not help with the further interpretation of this experiment.

The second Plackett-Burman experiment was carried out by holding three factors constant and hence utilised five of the original variables and two dummies (2 df). The atomisation time and modifier concentration shown to be important by the first experiment were held constant at 0 s and 500 mg l^{-1}, respectively, in the hopes that any other significant variables might be revealed. The ramp rate was observed in these and preliminary experiments to give maximum results at higher speeds, as noted by Pergantis et al. [11] in their optimisation for arsenic. Instrumental constraints

[d] nsd: not significantly different at confidence level indicated.
[e] Four analytical replicates.

limited the ramp to 2000°C s^{-1} and this value was used for all subsequent experiments.

The results for the second experiment produced a minimum t value at the 95% confidence interval of 4.3 and the t values for the two variables, ash and atomisation temperature were greater, indicating that these variables have a significant effect on the antimony response. The Birnbaun plot in Fig. 1 shows that the ash and atomisation temperatures deviate from a straight line because of large variable effects, which confirms the significance of these variables.

Four variables: atomisation time, atomisation temperature, ash temperature and modifier concentration, were subsequently optimised by using the composite modified simplex procedure (CMS).

3.2. Simplex optimisation

A total of 29 experiments were carried out and the maximum response was reached after 23 experiments (see Table 4). The optimum parameters were found to be: atomisation temperature, 2200°C; atomisation time, 0 s; ash temperature, 1350°C; and modifier concentration, 400 mg l^{-1}. The simplex analysis was repeated from different initial conditions and the maximum response was: atomisation temperature, 2200°C; atomisation time, 0 s; ash temperature, 1450°C; and modifier concentration, 400 mg l^{-1}. These conditions were reached after 22 experiments from a total of 27. The conditions from the first optimisation are considered to be better for routine use, because the lower ash temperature is less destructive to the graphite cuvette.

The response surfaces generated from both searches are not identical, but the characteristic ridge feature of high absorbance is present in both (see Fig. 2 for the response surface generated from the first simplex). The results for the principle components analysis (PCA) indicate that the first and second principle components (PC) retain 43.8 and 31.5%, respectively of the original variance of the data. This is similar to values reported in previous work [24]. The results also demonstrate that the atomisation temperature and modifier concentration have the greatest influence on the first PC, whereas ash temperature has the greatest

Table 8
Comparison of the concentrations of antimony (mg kg^{-1} dry weight) in pond weed samples from Yellowknife, NWT, Canada

Sample	Determined by ETAAS ± S.D.[a]	Determined by ICP-MS ± S.D.[b]	Comparison[c]
Extract 1[d]	0.28 ± 0.04	0.222 ± 0.003	nsd at 95%
Extract 2	0.26 ± 0.02[e]	0.221 ± 0.002	nsd at 95%
Extract 3	0.28 ± 0.02	0.179 ± 0.003	nsd at 98%
Total digest 1	39 ± 5	32.6[f]	nsd at 98%
Total digest 2	40 ± 5	41.8[f]	nsd at 95%

Determination by optimised ETAAS and ICP-MS.

[f] No replication.

influence on the second PC. Generation of the response surface also eliminates the need to carry out univariate searches around the optimum to establish that it is correct.

Therefore, after carrying out the simplex optimisation twice, from two different starting conditions and then analysing each response surface using principle components analysis, it was felt that further univariate investigates of the optimum were unnecessary.

3.3. Analysis of samples by using the optimised temperature program

The optimised procedure (Table 6) was used to determine the antimony concentration in pine needle SRM and pond weed, by using ETAAS and the method of standard additions. The results obtained for analysis of the pine needles are shown in Table 7, along with a comparison to the reference value. The concentrations for pine needles, with an average observed concentration of 0.220 mg kg^{-1}, do not differ significantly from the non-certified concentration of 0.2 mg kg^{-1}.

The pond weed sample is from a contaminated site near a gold mine in the Northwest Territories, Canada. The concentration of antimony in this sample was determined by ICP-MS to verify the values obtained by ETAAS and the results are given in Table 8. The results for the two methods do not differ significantly, as shown by the statistical comparison. The concentration of antimony for each digestion does not differ significantly (95% level) from the value determined by neutron activation analysis of 41.2 mg kg^{-1}.

The aqueous phase soluble antimony species were extracted from the pond weed sample with 1/1 methanol/water (V/V), so that further analysis by speciation techniques such as HPLC-ICP-MS or HG-GC-MS [24] can be carried out. However, prior to this it is important to establish the total antimony concentration, both hydride and non-hydride forming, present in the extract. Although the values obtained for the methanol/water extracts after analysis by ETAAS and ICP-MS do not differ statistically, consistently lower values for the ICP-MS results were observed. This is probably due to matrix or solvent effects, as the ETAAS analyses were carried out by using the method of standard additions, whereas the ICP-MS analyses were carried out using external calibration with aqueous standards.

By the analysis of the SRM and the methanol/water extract the optimised ETAAS procedure for the determination of antimony has been shown to overcome any interferences due to the sample matrix and any differences due to the different antimony species present. In addition, the method can be used for any total antimony determinations in samples of plant origin.

Acknowledgements

The authors would like to thank Dr M. Dodd for provision of the pond weed samples and NAA results, Mr B. Mueller for help with ICP-MS analysis, Ms M. Winters for assistance with sample preparation and Dr A. Wade for comments on the manuscript. We would like to acknowledge Dr K.J. Reimer, Environmental Sciences Group, Kingston, Ontario and the Natural Sciences and Engineering Research Council of Canada for financial assistance.

Abstract

Two membrane inlet mass spectrometric (MIMS) methods for determining phenolic compounds in water are described and compared, namely direct analysis and analysis after acetylation of the phenolic compounds. Direct analysis of phenolic compounds in water is a very simple and rapid method and detection limits are relatively low (from 30 μg l^{-1} for phenol to 1000 μg l^{-1} for 4-nitrophenol). Analysis of phenolic compounds after aqueous acetylation is also a very simple and rapid method, and the detection limits are even two orders of magnitude lower than in the direct analysis. For example the detection limit of phenol acetate is 0.5 μg l^{-1} and that of 4-nitrophenol is 10 μg l^{-1}. The acetylation method was also tested in the analysis of phenolic compounds from contaminated surface water samples. © 1997 Elsevier Science B.V.

Keywords: Membrane inlet mass spectrometry; Phenolic compounds; Water analysis

1. Introduction

Phenol and related compounds are used in large amounts in industry (total world production capacity 1993 was 5.5 million tons [1]). As a result of emissions, accidents and other releases they are also present in the environment. Phenols are highly toxic and can cause serious taste and odour contamination and therefore their analysis at low concentrations is very important [2,3]. However, the analysis of phenolic compounds is difficult due to their high polarity. The separation of phenolic compounds from water by solvent extraction is especially difficult and the recoveries are not satisfactory. Many different analysis methods have already been tested but there is still a need for methods which are applicable to rapid on-line analysis, especially directly from water samples.

Direct measurement of phenolic compounds in water using high performance liquid chromatography (HPLC) is possible, but the detection limits are rather high, about 100 μg l^{-1} [4]. Several concentration methods may be used to obtain better overall detection limits. Solid phases such as C_{18} [5], polymeric sorbents [6], carbon black [7]

PII S0039-9140(96)02169-8

and alkaline anion exchanger [8] extraction enrichment are used to improve detection limits but these methods are all quite laborious. Continuous liquid–liquid extraction [9], on-line liquid chromatographic precolumn-based column-switching [10] and on-line membrane/liquid chromatographic analysis [11] have all given good results but special equipment is needed. Solid-phase microextraction [12,13] has also been applied to the analysis of phenolic compounds. Low detection limits with good precision were obtained, but the absorption time of one sample, about 40–50 min, limited the usefulness of the method for on-line applications. Various derivatives [14] have also been used to improve the chromatographic behaviour of phenolic compounds, mainly in gas chromatography. Acetylation of phenols after solvent extraction is one of the most frequently used derivatization techniques. Recent studies have shown that it is also possible to carry out acetylation in aqueous solution [15–17]. This derivatization method, followed by solvent extraction and gas chromatographic analysis, has produced much better results than the reversed order method, in which the phenols are first extracted and then derivatized, due to better recovery of the phenols. With the new method recoveries of about 100% could be obtained [15].

In this study the applicability of membrane inlet mass spectrometry (MIMS) to the analysis of phenolic compounds was studied. MIMS is an analytical method well suited to rapid on-line analysis. In the method the introduction of analyte into the mass spectrometer occurs through a polymer membrane, which is highly selective for organic compounds relative to water. MIMS is an excellent technique for monitoring gases and volatile organic compounds directly from aqueous solutions [18]. The main application fields are biochemical and environmental analysis [19–24]. Lauritsen et al. [25] have already used a modified MIMS method, Trap-MIMS, for the analysis of chlorophenols from water samples. In this method the membrane is kept cold during sample loading by the flow of sample, and when the sample flow is stopped the membrane is heated rapidly due to the heat of the filament, which subsequently causes rapid release of compounds adsorbed on the inside of the membrane into the ion source of the mass spectrometer. Good detection limits for larger chlorophenols (10 $\mu g\ l^{-1}$) were obtained, but the results for more volatile compounds such as phenol and 4-chlorophenol were less satisfactory.

In the present study the traditional MIMS method for the analysis of phenols from aqueous samples was characterized. Phenols were measured directly from aqueous solutions or after acetylation. Lower detection limits were obtained with the acetylation method. The acetylation method was also applied to the analysis of contaminated surface water samples and compared with a HPLC method.

2. Experimental

2.1. Reagents

The standard phenolic compounds: phenol [108-95-2], 3-methylphenol [108-39-4], 2,3-dimethylphenol [526-75-0], 2,4,6-trimethylphenol [527-60-6], 4-chloro-3-methylphenol [59-50-7], 2,5-dichlorophenol [583-78-8], 2,4,6-trichlorophenol [88-06-2], 2,3,4,6-tetrachlorophenol [58-90-2], pentachlorophenol [87-86-5] and 4-nitrophenol [100-02-7] were obtained commercially (from Riedel-de Haën, Merck, Analabs, Fluka and Dr Ehrenstorfer GmbH). For each standard compound a stock solution containing about 10 $g\ l^{-1}$ was prepared in methanol. Dilutions of the stock solutions were prepared using deionized water (Millipore, Milli-Q plus) as needed. Twice distilled acetic anhydride (Merck, distilled in the laboratory) and sodium bicarbonate (Riedel-de Haën) was used in the derivatization of samples and methanol (Rathburn, HPLC grade) was used as eluent in HPLC analysis.

2.2. Derivatization procedure

The derivatization procedure used was similar to that described by Coutts et al. [14]. Acetic esters of phenols were prepared in a 1000 ml separation funnel. $NaHCO_3$, 20 g, was dissolved in a water sample of 500 ml, and 1 ml of acetic

anhydride (twice distilled) was added. The separation funnel was shaken vigorously during the evolution of carbon dioxide (about 2 min), after which the samples were ready for analysis. The total derivatization time is about 5 min.

2.3. Mass spectrometric and liquid chromatographic conditions

Membrane inlet mass spectrometry: samples were analyzed using a Balzers QMG 421C mass spectrometer with a mass range of 1–500 amu and equipped with an open cross-beam electron impact (70 eV) ion source (Balzers Aktiengesellschaft, Balzers, Liechtenstein). Data were collected continuously either by measuring full mass spectra or by using a selected ion monitoring method. The latter method was used to determine detection limits and the linearity of response. The membrane inlet used was built at VTT Chemical Technology on the basis of the design of Lauritsen [26]. The membrane utilized was a methylsilicone sheet membrane (Specialty Silicone Products, Ballston SPA, NY, USA) with dimensions: thickness 100 μm and contact area 28 mm^2. During operation of the system a water stream was continuously supplied to the membrane inlet via a peristaltic pump (Ismatec IPS4, Ismatec SA, Switzerland), typically at a flow rate of 10 ml min^{-1}, and aliquots of sample solution (typically 50–100 ml) were injected into this stream as needed. Before passing of the flowing water stream through the membrane inlet, its temperature was equilibrated to 70°C using a heat exchanger, which in turn was heated with a circulating water bath (Lauda M3, MGW, Germany).

Liquid chromatographic experiments were carried out using a HPLC (HP 1090, Hewlett Packard, Palo Alto, CA, USA) in combination with an autoinjector, an autosampler and a diode array detector. A reversed phase analytical column (Hypersil 100 mm × 2.1 mm i.d., 5 μm) with a linear gradient elution (10% methanol/acidic water $\rightarrow$ 10 min 100% methanol, flowrate 0.4 ml min^{-1}) was used to separate compounds and a diode array detector (wavelength 225 nm) was used for detection.

2.4. Samples

Three surface water samples were analyzed using MIMS. The content of phenolic compounds in two of the samples was below the detection limit. The third sample was diluted 1:100 and acetylated before analysis. The pH of standard solutions measured without acetylation was about 5.5, the pH of deionized water. Pentachlorophenol was the only compound for which the pK_a value was lower than 5.5 and it was therefore partly ionized. This probably explains its poor detection limit without acetylation [27]. Before acetylation the pH of both standards and samples was adjusted to $\cong 8$ using $NaHCO_3$ [15].

3. Results and discussion

Electron ionization mass spectra of the standard compounds were measured by MIMS before and after acetylation (Table 1). Even at this early stage it was observed that the acetylated compounds could be measured at lower levels, since solutions of similar concentrations produced mass spectra with much better signal to noise ratios for the acetylated phenols than for the underivatized compounds. For underivatized phenols the base peak is most often the molecular ion, whereas in the case of acetylated phenols the base peak is the fragment ion formed by the loss of neutral ketene (CH_2CO). The relative abundance of the molecular ion of the acetylated phenols was typically in the order of 20% and it was lowest for pentachlorophenol and highest for 4-nitrophenol (4 and 70%, respectively). All the measured EI mass spectra agreed very well with the EI mass spectra published in reference mass spectral libraries [28]. As an example of this the EI mass spectra of 4-nitrophenol as measured by MIMS and redrawn from the Wiley reference library are presented in Fig. 1. The good agreement obtained in this case also demonstrated the good analytical capabilities of membrane inlet mass spectrometry. The typical fragmentation pathways of 4-nitrophenol acetate can easily be recognized from the spectra presented. The main fragmentation route starts with the loss of neutral ketene producing the fragment

ion m/z 139, which subsequently looses either neutral NO or NO_2 to produce fragment ions m/z 109 and 93, respectively.

The detection limits (Table 2) and the linear dynamic ranges for underivatized and acetylated phenols were measured using selected ion monitoring (SIM) method. Typically the base peak of the mass spectrum was used in the SIM method and a signal to noise ratio of 3 was used as a criterion for the detection limit determination.

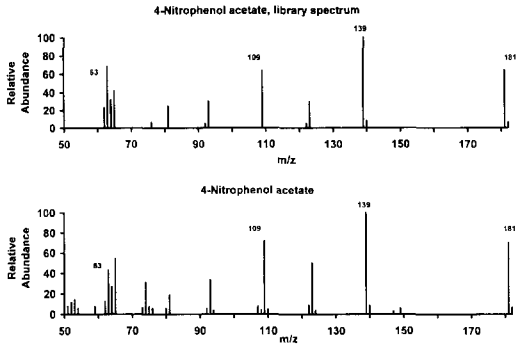

Fig. 1. Electron ionization mass spectrum of 4-nitrophenol acetate measured by membrane inlet mass spectrometry, and a mass spectrum redrawn from the Wiley mass spectra collection.

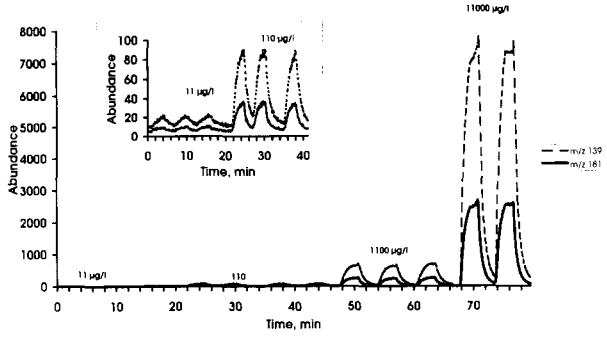

Fig. 2. Ion chromatograms of m/z 181 and 139 showing the MIMS response to successive injections of aqueous solutions of 4-nitrophenol (11, 110, 1100 and 11 000 µg l^{-1}).

Four or five different concentrations were used for the linear dynamic range determinations. From Table 2 it can be seen that acetylation significantly lowered the detection limits, especially in the case of 4-nitrophenol. The detection limit of four nitrophenol was lowered from 1000 to 10 µg l^{-1}. The effect is believed to be due mainly to two factors. Probably the most important of these is the change in the solubility of analytes in the methyl silicone membrane. The more polar underivatized phenols do not dissolve as well in the relatively non-polar membrane material as do the less polar acetylated phenols (i.e., the partition coefficient of acetylated compounds into the silicone is higher than that of underivatized phenols). Another effect is that the phenols with pK_a values below 5.5 (e.g., pentachlorophenol, pK_a 4.74 [13]) cannot be analyzed very well directly from water samples at the used pH values of the samples because they are in ionic form and ions do not dissolve in the methyl silicone membrane. This effect has earlier been reported in connection with SPME determinations of phenols from aqueous solutions [13]. For example pentachlorophenol was extracted by SPME 1.4-fold better at pH 2 than at neutral pH.

The linear dynamic ranges measured were typically about three orders of magnitude. An example of this is presented in Fig. 2, which shows

Table 2
Detection limits and linear dynamic ranges of some phenolic compounds measured by MIMS with and without acetylation

Compound	Detection limit µg l^{-1}	Linear dynamic range µg l^{-1}	Detection limit after acetylation µg l^{-1}	Linear dynamic range µg l^{-1}
Phenol	30	30–1000	0.5	0.5–300
3-Methylphenol	20	20–1000	1	1–300
4-Chloro-3-methylphenol	10	10–1000	1	1–300

2,4,6-Trichlorophenol	5	5–1000	1	1–300
2,3,4,6-Tetrachloropenol	10	nm	2	2–1000
Pentachlorophenol	60	nm	5	5–2500
4-Nitrophenol	1000	nm	10	10–10000

nm, Not measured.

selected ion monitoring data measured for successive injections of 4-nitrophenol acetate. The correlation coefficient of the calibration line calculated on the basis of the data was 1.00. The correlation coefficients of the calibration lines of all the other phenols were in the range of 0.996–1.00, demonstrating the good quantitative capabilities of membrane inlet mass spectrometry. It is also worthy of note that the average measurement time in Fig. 2 is about 7 min, which clearly demonstrates the potential of MIMS for rapid analyses.

Membrane inlet mass spectrometry was also tested in the analysis of complex phenol mixtures. A mixture mass spectrum of acetylated phenol, methylphenol, 4-chloro-3-methylphenol, 2,5-dichlorophenol, 2,4,6-trichlorophenol and pentachlorophenol is presented in Fig. 3. The concentration of each of the analyte was about 1 ppm. For all the analytes characteristics ions can be seen, i.e., the molecular ion and the ion formed by the loss of neutral ketene from the molecular ion. These ions are m/z 136 and 94 for phenol, m/z 150 and 108 for methylphenol, m/z 184 and 142 for 4-chloro-3-methylphenol, m/z 204 and 162 for 2,5-dichlorophenol, and m/z 238 and 196 for 2,4,6-trichlorophenol. For pentachlorophenol only the ketene loss ion, m/z 264, can been seen. These results clearly demonstrate that MIMS is capable of mixture analysis.

Some surface water samples taken from an area contaminated with phenolic resins were analyzed using both the acetylation method and the direct

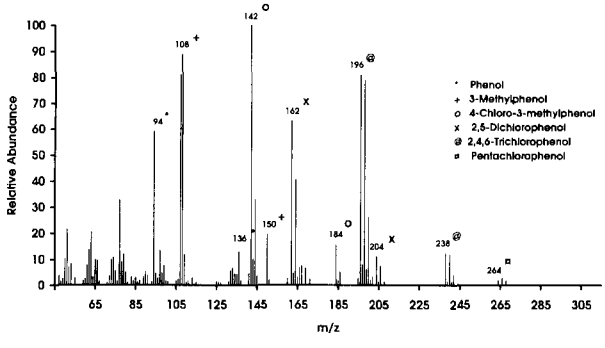

Fig. 3. Mass spectrum of a solution containing phenol, methylphenol, 4-chloro-3-methylphenol, 2,5-dichlorophenol, 2,4,6-trichlorophenol and pentachlorophenol. The characteristic ions of each compound are indicated.

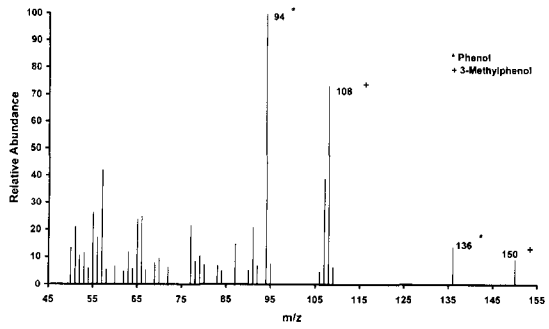

Fig. 4. Mass spectrum of a contaminated surface water sample measured after acetylation of the phenolic compounds.

HPLC method presented in the experimental section. The phenolic content of most of the samples were below the detection limits of both of the methods. Only in one sample measureable amounts of phenolic compounds were observed. For quantitative analysis this sample was diluted 1000-fold prior to analysis by MIMS, the HPLC analysis was carried out without any dilution. The mass spectrum measured for this sample is presented in Fig. 4. The characteristic ions of phenol actetate (m/z 94 and 136) and methylphenol acetate (m/z 108 and 150) can be recognized from the mass spectrum. The concentrations of these compounds were determined by an external standard quantitation method using the closest concentration of standard solution as calibrant. The concentrations of phenol and methylphenol in calibrant were 11.6 and 12.5 $\mu g\ l^{-1}$ and the peak heights of measured ions (m/z 94 and 108) were 13 300 and 6300 respectively. The peak heights of the same ions measured in diluted water samples were 39 000 and 13 000. The concentrations of phenol and methylphenol calculated on the basis of these numbers were 34 and 26 mg l^{-1}, respectively. With the HPLC method only phenol could be identified reliably, due to the large background eluting simultaneously with the methylphenols. The concentration of phenol obtained by the HPLC method was 36 mg l^{-1} which agrees very well with the MIMS determination.

In conclusion, acetylation of phenolic compounds directly in water with subsequent MIMS analysis is a very rapid and easy analytical method for the analysis of phenolic compounds in

aqueous solutions. The derivatization step adds only about 5 min to the direct MIMS analysis time of 5 min i.e., even with the derivatization step the analysis time of one sample is less than 20 min. The implementation of derivatization step in the flow injection analysis manner is also planned so that this method can also be used for on-line analysis. The detection limits obtainable with the acetylation method are 5–100 times lower than in the direct MIMS method in which phenols are not derivatized before analysis. For example detection limits of 0.5 μg l^{-1} for phenol and 10 μg l^{-1} for 4-nitrophenol were measured.

Determination of equilibrium states in multi-phase systems

Jarosław Chojnacki *

Technical University of Gdańsk, 80-952, Gdańsk, Poland

Received 1 July 1996; received in revised form 7 November 1996; accepted 13 November 1996

Abstract

Volume corrections in calculation of equilibrium state for multi-phase systems, as an extension from one-phase systems, have been described. The algorithms can handle with one, two, three or more phases of different volumes. Several applications of the algorithms to calculation of equilibrium concentrations of all species in two- and three-phase systems have been presented. Different possibilities of the determination of equilibrium constants from extraction data have been discussed. © 1997 Elsevier Science B.V.

Keywords: Computer programs; Equilibrium; Extraction; Multi-phase systems

1. Introduction

In the literature one can find many programs for determination of equilibrium concentrations [1] and equilibrium constants, e.g., most popular SCOGS [2], SUPERQUAD [3], or more recent SPECA [4] and SIRKO [5]. Practical use of them also have been examined [6]. However, the programs are designed for processing spectroscopic or potentiometric data. Application of them to all extraction data is not possible. Although there are old extraction oriented programs e.g., LETAGROP-DISTR [7], other, interactive computer programs are required. Moreover, new programs are more general and can describe multi-phase systems.

Mathematical formalism describing multi-reaction equilibria has been described in details by Kostrowicki and Liwo [8]. The formalism, although general considering the types of equilibria, was worked out for systems with many reactions, but only one-phase. More precisely: heterogenic (solid–liquid) systems were allowed, but only concentrations in one liquid phase were calculated. However, one can be interested in equilibrium concentrations in several liquid phases. Such necessity is in extraction, whenever phases (organic and aqueous) are of different volumes. If the volumes were equal, the system would be regarded as one-phase using the existing programs. Sometimes one can meet stable three-phase liquid extraction systems (e.g., Zn distribution in H_2SO_4-1-penthanol-toluol [9]). Other examples of three phase systems are liquid–liquid extraction with a solid deposit (e.g., extraction of metals in $AlCl_3$-HCl-H_2O-diisopropyl ether system [10]) or bulk

liquid membrane with two aqueous phases separated by one organic phase.

In the previous algorithms concentrations were inserted into balance equations. In systems with several phases, moles instead of molar concentrations must be used in balances. The necessary modifications in procedures are described in this work.

Programs for determination of equilibrium constants from extraction data are much less common. Many researchers investigating extraction equilibria use graphical procedures (e.g., see Fletcher and Flett [11]). Some use commercial programs for linear or multiple regression to support graphical procedures. Berger and Graff describe one-species extraction equilibrium in [12], while mathematical analysis of multiple-species extraction appeared in their next paper [13]. Extraction of many species in liquid–liquid systems were first analyzed by a specialized program by Rydberg et al. [14] by fitting of the measured metal concentration to a polynomial. Analysis of the extraction data by multiple regression has been presented e.g., by Jaycock et al. [15] or Apostoluk [16].

In most of those procedures there are no corrections of concentrations for progress of reactions. It is assumed that the experiment is arranged in such a way that addition of excesses of some reagents allows to neglect concentration changes caused by run of reactions. The correction is not trivial if there are several reactions to consider. Liem overcome that by applying an iteration procedure for finding the equilibrium concentrations for two-phase extraction systems, in the program LETAGROP-DISTR [7].

Presented programs EXTRAFIT and EXTRAPH are an extension of LETAGROP-DISTR towards systems with more than two phases and towards more types of equilibria. The advantage of the algorithms is that they accept wider spectrum of different equilibria, e.g., solid deposit formation/dissolution and use actual equilibrium concentrations corrected for run of reactions. This means that we can investigate systems with small stoichiometric excesses of reagents. The balance equations are created automatically according to chemical equilibria specified. There is no restriction regarding the number of phases or the number of species, or the number, or the type of reactions other than the capability of the applied computer.

2. Determination of equilibrium concentrations

It has been shown that multiple equilibria most conveniently can be expressed in language of linear algebra [17,18]. One may also study the simple example given in the application section. Consider a system of n components involved in m reactions. The equilibrium concentrations must satisfy equilibrium condition Eq. (1)

$$\mathbf{A} \ln \boldsymbol{C} = \ln \boldsymbol{K} \tag{1}$$

where: $\mathbf{A}_{m \times n}$, stoichiometric matrix; $\boldsymbol{C}$, vector of concentrations, $\boldsymbol{C} = [C_1, C_2,..,C_n]^T$, ln $\boldsymbol{K}$-vector of natural logarithms from stability constants, ln $\boldsymbol{K} = [\ln K_1, \ln K_2,..,\ln K_m]^T$.Additionally for one phase systems the following balance equations set must hold

$$\mathbf{Q}\boldsymbol{C} = \boldsymbol{T} \tag{2}$$

where: $\mathbf{Q}_{n-m \times n}$, balance matrix; $\boldsymbol{T}$, balance constants vector $[T_1, T_2,.., T_{n-m}]^T$.For multi-phase systems Eq. (2) must be replaced by Eq. (3)

$$\mathbf{Q}\boldsymbol{N} = \boldsymbol{T} \text{ or } \mathbf{QV}\boldsymbol{C} = \boldsymbol{T} \tag{3}$$

where: $\boldsymbol{N}$, moles vector, $\boldsymbol{N} = [\mathbf{V}_1 C_1, \mathbf{V}_2 C_2,..,\mathbf{V}_n C_n]^T$, $\mathbf{V}$, diagonal volumes matrix $\mathbf{V} = [\delta_{i,j}\mathbf{V}_i]_{n \times n}$ V_i, volume of the phase in which i species exists, $\delta_{i,j}$, the Kronecker δ (0 if $i \neq j$, 1 if $i = j$). We assume here that transfer of solutes does not induce significant volumes change and activity coefficients are constant in all phases.

Solving the system (1) + (3) can be accomplished by analogy to one-phase systems (1) + (2). This is a non-linear system which can be solved using Newton-Raphson iterative method. In multi-phase systems the volume matrix must be introduced in balances and in derivatives in the iteration process as described below. Also initialization of vector $\boldsymbol{C}$ needs volume corrections when calculations are carried out by varying progress of reactions.

(a) adjusting equilibrium while balances are held

This method is based on run of reactions until concentrations satisfy Eq. (1). Technically it means variation of m reaction numbers ϵ_i. In this procedure balances are satisfied because run of reactions do not change the balances. Definition of concentration as a function of progress of reactions for one-phase systems:

$$\boldsymbol{C} = \boldsymbol{C}^0 + \mathbf{A}^T\varepsilon \tag{4}$$

for multi-phase systems must be rewritten as follows:

$$\boldsymbol{C} = \boldsymbol{C}^0 + \mathbf{A}^T\mathbf{V}^{-1}\varepsilon \tag{5}$$

where: $\mathbf{V}^{-1} = [\delta_{i,j}\mathbf{V}_i^{-1}]_{n\times n}$; ε, reaction number vector $= [\varepsilon_1, \varepsilon_2, \ldots \varepsilon_m]^T$; $\boldsymbol{C}^0$, any vector satisfying balance equation, usually initial composition.There is an important orthogonality Eq. (8), [19] $\mathbf{QA}^T = 0$ which expresses mutual dependence of stoichiometric and balance matrixes. Due to orthogonality of matrices $\mathbf{Q}$ and $\mathbf{A}^T$ balance equations are automatically satisfied for any vector ε, $\mathbf{QV}\boldsymbol{C} = \mathbf{QV}\boldsymbol{C}^0 (= \boldsymbol{T})$.

Inserting Eq. (5) into Eq. (1) we get the following system of m unknowns:

$$\mathbf{A}\ln(\boldsymbol{C}^0 + \mathbf{A}^T\mathbf{V}^{-1}\varepsilon) - \ln \boldsymbol{K} = 0 \tag{6}$$

This can be solved by the Newton-Raphson method according to equations

$$\rho^{(l)}\Delta\varepsilon^{(l)} = \ln \boldsymbol{K} - \mathbf{A}\ln \boldsymbol{C}^{(l)} \tag{7}$$

$$\boldsymbol{C}^{(l+1)} = \boldsymbol{C}^{(l)} + \mathbf{A}^T\mathbf{V}^{-1}\Delta\varepsilon^{(l)} \tag{8}$$

where:

$$\boldsymbol{\rho}^{(l)} = \mathbf{A}^T M^{(l)} A,\quad M^{(l)} = [\delta_{k,j}\boldsymbol{C}_k^{(l)-1}\mathbf{V}_k^{-1}]_{n\times n}$$

$$\text{or } \boldsymbol{\rho}_{i,j}^{(l)} = \sum_{k=1}^{n} \frac{a_{i,k}\,a_{j,k}}{\boldsymbol{C}_k^{(l)}\,\mathbf{V}_k} \tag{9}$$

Here l is the iteration number. In the multi-phases case the derivative $\boldsymbol{\rho}$ contains volume correction. As the stop test $\|\ln \boldsymbol{K}\text{-Aln}\boldsymbol{C}\|_1 = 10^{-4}$ was applied.

Now, to start the iteration process we need a positive concentration vector to calculate $\ln \boldsymbol{C}$. Usually in starting conditions we have some zero concentrations. To overcome this we can take a component of zero concentration and advance a reaction which produces it to an extend allowed by amount of substrates.The details are as follows:

(1) Find first component i of zero concentration;
(2) Find first non-zero element $a[j,i]$ of the stoichiometric matrix in the column i corresponding to its name (j reaction will be run);
(3) Determine maximum reaction number ε_j that can be accomplished:

$$\varepsilon_j = \min_k \left\{ \underset{a[j,k]<0}{\forall} \frac{-\boldsymbol{C}_k\mathbf{V}_k}{a[j,k]} \right\},\ \text{if } a[j,i] > 0 \tag{10}$$

$$\varepsilon_j = \min_k \left\{ \underset{a[j,k]>0}{\forall} \frac{\boldsymbol{C}_k\mathbf{V}_k}{a[j,k]} \right\},\ \text{if } a[j,i] < 0 \tag{11}$$

Eq. (10) describes reaction toward products, Eq. (11) towards substrates. If $\varepsilon_j = 0$ because all $\boldsymbol{C}_k\mathbf{V}_k/a[j,k]$ have $\boldsymbol{C}_k = 0$, then probably the substrates will be produced in next reactions. So we must skip it this time and return to this reaction again after initiating others. Another possibility, no negative $a[j,k]$ in Eq. (10) (or no positive $a[j,k]$ in Eq. (11)), indicates usually solid phase solution/deposition or solvent self-ionization take place. It can be overcome by introducing special initialization for those reactions as $\varepsilon_j := \ln K_j/(\Sigma_k\, a[j,k])$ (j is the index of such a reaction).
(4) Replace all $\boldsymbol{C}_k$ with

$$C_k + \frac{1}{a[j,i]m}\frac{a[j,k]\varepsilon_j}{\mathbf{V}_k}$$

for $k = 1..n$, where: m, total number of reactions. Note, that we proceed with mth fraction of the available limiting component.
(5) If there are still some $\boldsymbol{C}_i = 0$, then repeat the previous four steps.The method gave good results in practice and seems general for all chemical systems. It is a modified, volume-corrected, version of the algorithm introduced by Kostrowicki and Liwo [8].

(b) adjusting balances while equilibrium is held.

Second method proceeds by changing amounts of reagents while equilibrium is hold until balance equations are satisfied. This implies that parameters proportional to $\ln\mathbf{C}$ are being varied while equilibrium condition is hold. Concentrations, which satisfy equilibrium condition, can be rewritten as:

$$\ln \boldsymbol{C} = \ln \boldsymbol{C}^* + \mathbf{Q}^T\tau \tag{13}$$

for any vector τ, if $\ln C^*$ is an arbitrary chosen solution of Eq. (1). As the consequence of orthogonality equation $\mathbf{AQ}^T = 0$, the equilibrium condition is always valid $\mathbf{A} \ln C = \mathbf{A} \ln C^* (= \ln K)$. Insertion of Eq. (13) to Eq. (3) gives non-linear equations system of $n - m$ order:

$$\mathbf{Q}\,\mathbf{V}\,(\exp(\ln C^* + \mathbf{Q}^T\tau)) - T = 0, \tag{14}$$

In the one-phase version there is no matrix **V**. This implies that for multi-phase systems we will get also different derivative σ in the iteration scheme. By analogy to one-phase algorithm equilibrium concentrations can be calculated by the following iteration scheme:

$$\sigma^{(l)}\,\Delta\tau^{(l)} = T - \mathbf{Q}\,\mathbf{V}\,C^{(l)} \tag{15}$$

$$\ln C^{(l+1)} = \ln C^{(l)} + \mathbf{Q}^T\Delta\tau^{(l)} \tag{16}$$

where:

$$\sigma^{(l)} = \mathbf{Q}\,\Lambda^{(l)}\mathbf{Q}^T,\ \Lambda^{(l)} = [\delta_{k,j}\mathrm{V}_k C_k^{(l)}]_{n\times n}$$

$$\text{or } \sigma_{i,j}^{(l)} = \sum_{k=1}^{n} q_{i,k}\,q_{j,k}\,\mathrm{V}_k\,C_k^{(l)} \tag{17}$$

As the stop test $\|\Delta\tau\|_1 = 10^{-4}$ has been chosen.

The balance matrix **Q** is calculated automatically from stoichiometric matrix **A** as described elsewhere [8]. Additionally some minor modifications of initialization of vector $\ln C^*$ were made in presented programs.

3. Determination of equilibrium constants from extraction experiments

Once the concentrations have been determined they can be used for evaluation of equilibrium constants from experimental data. In the extraction research it is common to measure equilibrium metal distribution and to measure equilibrium pH values. Another, less common, approach is to add large excess of a buffer and resign measuring pH. Both situations can be processed with the use of multidimensional calculations.

1. In the first case we assume the pH values are error-free and that we can combine them with the equilibrium constants. So, for each pH we have a specific, apparent equilibrium constants set, log K′. The log K′ is a sum of the log K and pH multiplied by the stoichiometric coefficient of $[H^+]$ for each reaction (see the examples in the following text). In this manner $[H^+]$ is placed on the right-hand side of equation and is no longer changed during the iteration process. Hence $[H^+]$ column is removed from the stoichiometric matrix, the balance matrix must be accordingly modified. It is immediately found as $\mathbf{Q} = [-((\mathbf{A}^L)^{-1}\,\mathbf{A}^R)|\mathrm{I}]$, where we defined partition of the stoichiometric matrix **A** into left and right parts as: $\mathbf{A} = [\mathbf{A}^L_{m\times m} \mid \mathbf{A}^R_{(n-m)\times m}]$, $\det\{\mathbf{A}^L\} \neq 0$. Here A denotes stoichiometric matrix after removal the hydrogen ion column. For practical reasons (less complicated equations) it is more convenient to fit total organic phase metal concentration than logarithm from distribution ratio (log D). Thus, the minimized function ϕ can be defined as:

$$\phi = \sum_{i=1}^{pn} w_i\,(\hat{C}_i^{tot} - C_i^{tot})^2 \tag{18}$$

where: *pn*, number of measurements; C_i^{tot}, total metal concentration in one (e.g., organic) phase in *i* experiment, hat stands for experimental value; w_i, statistical weight of *i*th measurement. Total metal concentration can be calculated as:

$$C_i^{tot} = \sum_{k=1}^{n} \beta_k C_{i,k} = \boldsymbol{\beta}\mathbf{C}_i \tag{19}$$

where $C_{i,k}$ denote concentration of *k* species in *i* experiment and β_k denote the number of metal atoms in *k* species molecule, if present in the analyzed phase. Thus, for each experimental point we can define pH-dependent equilibrium constants set, calculate C_i^{tot} and add squares of differences between calculated and measured values for all points obtaining the desired sum of squares [18]. Once we have done that we need to find such constants that minimize the sum. Minimization of the sum can be carried out by the Marquardt method. Multi-dimensional calculation has a convenient property of the possibility of calculating derivative $\boldsymbol{J}_{i,j} = \partial C_i^{tot}/\partial \ln K_j$ analytically [8]. For each point *i* we calculate vector $\boldsymbol{J}_{i,j}$, $j = 1,..m$. The formula is the following:

$$\boldsymbol{J}_{i,j} = \frac{\partial C_i^{tot}}{\partial \ln \boldsymbol{K}_j} = (\rho_i^{-1} A\beta)_j \tag{20}$$

Organic phase volume 0.1 l, aqueous phase volume expressed in litres. Columns contain equilibrium concentration in the system: K_2H, abbreviates hydrogenphosphates; KH_2, dihydrogenphosphates. Programs EQU (ε) and EQUT(τ) were used. Final results were obtained in less than 13 iterations.
M, mole l^{-1}; mM, millimole l^{-1}; μM, micromole l^{-1}; and pM, picomole l^{-1}.

where: ρ_i is derivative Eq. (9) in experimental point i. The minimization is carried out by the following iteration scheme:

$$((\boldsymbol{J}^T\mathbf{W}\boldsymbol{J})^{(l)} + \lambda I)\,\Delta X^{(l)} = \boldsymbol{J}^{(l)\,T}\mathbf{W}\,(\hat{\mathrm{C}}^{\mathrm{tot}} - \mathrm{C}^{\mathrm{tot}^{(l)}})$$

$$\ln \boldsymbol{K}^{(l+1)} = \ln \boldsymbol{K}^{(l)} + \Delta X^{(l)} \tag{21}$$

Where l is the iteration number and $\mathbf{W}_{\mathrm{pn}\times\mathrm{pn}}$ is the matrix of weights ($\mathbf{W}_{i,j} = \delta_{i,j}\mathbf{W}_i$). As the stop test $\|\Delta \mathrm{X}\|_1 \leq 10^{-4}$ was applied. Program, realizing this algorithm have been worked out and named EXTRAPH.

(2) If we can assume that pH is not affected by unknown variables, we can simply use function Eq. (18) and not-modified system $\mathbf{A}\ln \boldsymbol{C} = \ln \boldsymbol{K}$ to solve the problem. It is possible to create a bigger model system and optimize just a few unknown constants. Again, iteration scheme Eq. (21) can be used for chosen number of constants to vary s ($s \leq m$) with a shorter Jacobian $\boldsymbol{J}_{\mathrm{pn}\times s}$. This algorithm is realized by the program EXTRAFIT.

Third method can minimize extended sum of squares

$$\phi = \sum_{i=1}^{pn} w(\mathrm{C})_i(\hat{\mathrm{C}}_i - C_i)^2 + w(\mathrm{pH})_i\,(\mathrm{p}\hat{\mathrm{H}}_i - \mathrm{pH}_i)^2 \tag{22}$$

where: $w_i(C)$,w_i(pH), statistical weights for each C or pH measurement; C, total metal concentration in one phase, hat stands for experimental values; i, indexes measurements. Although most justified for statistical point of view, it has not been implemented yet. The work is in progress.

4. Application section

In order to illustrate the applicability of the derived algorithms I tested them on data obtained from simulation as well as from real-life extraction experiments. The original code was written in Turbo-Pascal v 6.0 and run on a simple IBM PC 486-DX2 computer.

The use of the programs is intuitive for every chemist. One must define equilibria expected in the system (the equation and the appropriate constant for each reaction) and specify initial concentrations of all chemicals. All the reactions can be

entered manually from keyboard in the same way they are usually written down. All matrixes are created automatically by the programs, however they can be modified manually in the input files with any ASCII—text editor. In the case of multi-phase reaction additionally volumes of each phase are to be introduced.

4.1. Calculation of equilibrium concentrations in the case of multi-reaction, multi-phase system

Example 1. Example of stoichiometric, balance and volume matrixes.
For simple aminoacid HA—acid/base reactions with extraction of HA we have two equilibria:

$$H^+ + A^- = HA(o),\ K_1 = \frac{[HA(o)]}{[H^+][A^-]}$$

$$H^+ + HA(o) = H_2A^+,\ K_2 = \frac{[H_2A^+]}{[H^+][HA(o)]}$$

which can be denoted as matrix **A** (substrates negative, products positive coefficients, charges omitted for clarity):

$$\begin{bmatrix} HA(o) & H_2A & A & H \\ 1 & 0 & -1 & -1 \\ -1 & 1 & 0 & -1 \end{bmatrix}$$

One can see that equations obtained by taking natural logarithm from equilibria constants:

$$\ln K_1 = \ln [HA(o)] - \ln [A] - \ln [H]$$

$$\ln K_2 = \ln [H_2A] - \ln [HA(o)] - \ln [H],$$

are equivalent to matrix notation $\mathbf{A} \ln \mathbf{C} = \ln \mathbf{K}$.If the organic phase has twice more volume then the aqueous phase, the **V** matrix will get the following form:

$$\mathbf{V} = \begin{bmatrix} HA(o) & H_2A & A & H \\ 2 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

The balance equations in this case have the following form (one of many possibilities):

$$V_o[HA(o)] + V_a[H_2A] + V_a[A] = n_A$$

$$V_o[HA(o)] + 2V_a[H_2A] + V_a[H] = n_H,$$

where: V_a, volume of the aqueous phase; V_o, volume of the organic phase.This is equivalent to matrix equation $\mathbf{QVC} = \boldsymbol{T}$:

$$\begin{bmatrix} 1 & 1 & 1 & 0 \\ 1 & 2 & 0 & 1 \end{bmatrix}$$

$$\begin{bmatrix} V_o & 0 & 0 & 0 \\ 0 & V_a & 0 & 0 \\ 0 & 0 & V_a & 0 \\ 0 & 0 & 0 & V_a \end{bmatrix} \begin{bmatrix} [HA(o)] \\ [H_2A] \\ [A] \\ [H] \end{bmatrix} = \begin{bmatrix} n_A \\ n_H \end{bmatrix}$$

Note: EQUT transforms matrix **A** to its Hermite normal form [18] [I|P] so in output generally you

Table 3

will obtain information about the transformed stoichiometric matrix.

Example 2. Consider a complicated system of two-phase liquid–liquid extraction. It is very laborious to calculate equilibrium concentrations of all reagents and the distribution ratio. This is true even if one knows which equilibria take place, knows their equilibrium constants and knows all balance concentrations. In this example we use an equilibria set comprised of two complex-formation, one acid–base and two extraction equilibria.

$$\begin{aligned} 2Ag^+ + 2\,HR(o) &= (AgR)_2(o) + 2\,H^+, & \log K &= 17.0,\\ Ag^+ + HR(o) &= AgR(o) + H^+, & \log K &= 6.8,\\ HPO_4^{2-} + H^+ &= H_2PO_4^-, & \log K &= 6.88,\\ Ag^+ + 2\,S_2O_3^{2-} &= Ag(S_2O_3)_2^{3-}, & \log K &= 12.72,\\ Ag^+ + 3\,S_2O_3^{2-} &= Ag(S_2O_3)_3^{5-}, & \log K &= 13.5 \end{aligned} \qquad (28)$$

where: HR denotes a thiol (tri-*t*-butoxysilanethiol), (o) means organic phase. First two constants were taken from preliminary results of the author's research. The other constants are taken from literature [20]. Initial concentration profile was: $C(Ag) = 0.0001$ mole l^{-1}, $C(HR) = 0.002$ mole l^{-1}, $C(Na_2S_2O_3) = 0.1$ mole l^{-1}, $C(K_2HPO_4) = C(KH_2PO_4) = 0.02$ mole l^{-1}, organic phase volume 0.1 l.

Program called EQU (by varying ε) have been used. Nevertheless, method which varies balance parameters τ (EQUT) has been also tested and yielded identical results in similar iteration numbers. The test runs are summarized in Table 1.

Example 3. Liquid–liquid extraction with solid deposit

Let us take a system with three reactions. Complex formation in the aqueous phase:

$$Ag + 2\,SCN = Ag(SCN)_2 \quad \log \beta_2 = 8.2$$

dissolution of solid AgSCN

$$Ag + SCN = 0 \text{ (nothing)} \quad \log K_{SO} = -11.97$$

and extraction of silver by a thiol HR into an organic phase

$$Ag + HR(o) = AgR(o) + H \quad \log K = 6.8 \qquad (29)$$

First two constants were taken from the literature [20], last one from preliminary author's results. All charges were omitted for clarity. Organic phase volume was 0.01 l, whereas aqueous phase was 0.1 l. Initial concentrations were 0.01 M SCN in the aqueous phase and 0.02 M of HR in the organic phase. Table 2 summarizes results of different silver dissolution from AgSCN when different acidities of the aqueous phase were applied. Program EQU and EQUT both gave rapid convergence within 10–13 iterations. It should be emphasized that the results are obtained very fast, with no need of manual derivation of D from complicated set of equations. Lowering of partition ratio D and deposit formation at high acid concentration, when silver was introduced to the organic phase, were experimentally observed by the author.

Example 4. Three phase system. Bulk liquid membrane.

Let us take a system composed of two aqueous phases of volume 0.1 l (phase 1) and 0.2 l (phase

Table 4

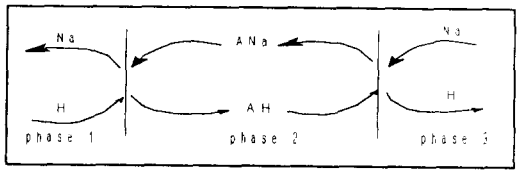
3), containing sodium and hydrogen ions, separated by a floating organic phase (phase 2) of volume equal to 0.01 l containing an organic ion carrier (in form of AH or ANa). Additionally assume two interface reactions:

$$Na(1) + AH(2) = ANa(2) + H(1),\ K = 10 \quad (30)$$

$$Na(3) + AH(2) = ANa(2) + H(3),\ K = 10 \quad (31)$$



Phase numbers are specified in brackets. Equilibrium concentrations in all three phases were calculated starting from different initial compositions. Test runs are specified in Table 3. One can notice that uniform distribution of species is not always obtained at the equilibrium. It is so only in the first case where there was no hydrogen ion gradient. Second run starts from evenly distributed Na, whereas third run starts from more sodium in the (3) phase. In both last cases, as a result of hydrogen removal from (3) phase, Na(3) concentration must be increased in this phase as the result of ion exchange.

4.2. Determination of extraction equilibrium constants

(1) Method with pH combined with equilibrium constants. Test run of EXTRAPH. As a model let us regard data from extraction of nickel (II) with decanic acid. Extraction model together with relevant constants were taken from [21]. The authors concluded that experimental data is best described by assumption of two extraction reactions:

Table 5
Determination of extraction constants from non-equal volume extraction experiments

Initial buffer components concentrations		Total silver in the organic phase, μmole l^{-1}		
$C(K_2HPO_4)$	$C(KH_2PO_4)$	Simulated	Perturbed	Recalculated
0.002	0.038	733.5	734.5	733.58
0.004	0.036	573.2	572.4	573.30
0.006	0.034	453.9	454.9	453.99
0.008	0.032	360.4	359.4	360.56
0.010	0.030	285.8	286.8	285.86
0.012	0.028	225.6	224.6	225.71
0.014	0.026	177.2	178.2	177.26
0.016	0.024	138.3	137.3	138.37
0.018	0.022	107.3	108.3	107.30
0.020	0.020	82.58	82.48	82.61
0.022	0.018	63.06	63.16	63.07
0.024	0.016	47.66	47.56	47.67
0.026	0.014	35.56	35.66	35.56
0.028	0.012	26.07	25.97	26.07
0.030	0.010	18.64	18.74	18.63
0.032	0.008	12.83	12.73	12.83
0.034	0.006	8.307	8.317	8.30
0.036	0.004	4.795	4.78	4.79
0.038	0.002	2.083	2.09	2.08

Organic phase volume was set as 0.1 l, aqueous 1 l. Initial concentrations: C(Ag) = 0.0001 mole l^{-1}, C(HR(o)) = 0.002 mole l^{-1}, $C(Na_2S_2O_3)$ = 0.1 mole l^{-1}.

$$Ni^{2+} + 3(HA)_2(o) = [NiA_2 4HA](o) + 2\,H^+,\ \log K_1 = -11.34$$
$$2\,Ni^{2+} + 4(HA)_2(o) = [NiA_2 2HA]_2(o) + 4\,H^+,\ \log K_2 = -19.15 \quad (32)$$

Thus, instead of the stoichiometric matrix **A** and the ln ***K*** vector of

$$\begin{bmatrix} NiA_2 4\,HA & [NiA_2 2\,HA]_2 & (HA)_2 & Ni^{2+} & H^+ \\ 1 & 0 & -3 & -1 & 2 \\ 0 & 1 & -4 & -2 & 4 \end{bmatrix} \begin{matrix} \ln K \\ \ln K_1 \\ \ln K_2 \end{matrix}$$

we use its reduced version, **A′** and a corrected ln **K′**:

$$\begin{bmatrix} NiA_2 4\,HA & [NiA_2 2\,HA]_2 & (HA)_2 & Ni^{2+} \\ 1 & 0 & -3 & -1 \\ 0 & 1 & -4 & -2 \end{bmatrix} \begin{matrix} \ln K' \\ \ln K_1 + 2\,pH \\ \ln K_2 + 4\,pH \end{matrix}$$

Recalculating of the constants' values from data in Table 4 leads to $\log K_1 = -11.354 \pm 0.008$ and $\log K = -19.140 \pm 0.006$.

(2) Method with no pH measurements, but with an excess of a buffer applied. Test run of EXTRAFIT. As an example a set of simulated extraction data with two phases of different volume was created, total metal concentration was disturbed by 1% and then the equilibrium constants were backward evaluated. The values of the constants were perfectly redetermined as is shown in Table 5. The system contained five reactions and can be described by the equations set.

Simulation values of the constants were: log K = [6.30,17.00,12.72,13.50,6.88]. Fitting two first constants to the disturbed data gave back: $\log K_1 = 6.2995 \pm 0.005$ and $\log K_2 = 17.0004 \pm 0.005$ while $\log K_1 = 8$ and $\log K_2 = 15$ were taken as initial values.

Possibility of using the algorithms

If we investigate a system with multiple equi-

libria, some of the constants may happen to be determined in different physical-chemical conditions than others. Sometimes the difference is in ionic strength, sometimes in temperature or in different supporting electrolyte. This specially can happen when we take into consideration many independently determined constants (e.g., acid–base constants together with complex formation). One possible solution is to choose experimental conditions to match those declared for most of the constants, and recalculate the other constants together with the searched equilibrium. Thus, some of the equilibrium constants will be processed as unknowns during the iterations until they best fit to the experimental data. Such a possibility give both EXTRAFIT and EXTRAPH.

5. Final remarks

I hope wider use of the programs will help chemists to deal with complicated systems. The examples given do not show all possible applications of the programs. So far little attention is given to distribution of species in three phase systems, partly because of difficulty of mathematical description. This seems to be of diminishing significance. As mentioned before, all matrixes are generated internally by the programs. A chemist must just define the chemical model and the equilibrium concentrations are calculated automatically without time-consuming manual derivation. Moreover, the concentrations can be used for determination of unknown equilibrium constants, even if the system is very complicated.

The tentative versions of the programs EQU, EQUT, EXTRAFIT and EXTRAPH are available from the author along with the source Pascal code upon request. The source codes can be downloaded from Internet at http://www.pg.gda.pl/~jarekch/.

Protonation equilibria of quinolone antibacterials in acetonitrile–water mobile phases used in LC

J. Barbosa *, R. Bergés, I. Toro, V. Sanz-Nebot

Department of Analytical Chemistry, Diagonal 647, 08028, Barcelona, Spain

Received 12 August 1996; received in revised form 22 November 1996; accepted 23 November 1996

Abstract

Ionization constants of nine quinolone antibacterials in acetonitrile–water mixtures containing 0, 5.5, 10, 16.3, 25, 30, 40, 50 and 70% (w/w) acetonitrile were obtained and assignment of these pK values to the several potentially ionizable functional groups was made. The variation of the pK values obtained over the whole composition range studied can be explained by consideration of the preferential solvation of electrolytes in acetonitrile–water mixtures. In order to obtain pK values in any of the unlimited number of possible binary solvent acetonitrile–water mixtures, relationships between pK values and different bulk properties (such as dielectric constant) were examined. The linear solvation energy relationships method, LSER, was applied to study the correlation of pK values with the solvatochromic parameters of acetonitrile–water mixtures. The equations obtained allow calculation of the pK values of the quinolone antimicrobials in any acetonitrile–water mixtures up to 70% (w/w) and thus permit the knowledge of the acid–base behaviour of these important antimicrobials in the widely used acetonitrile–water media. © 1997 Elsevier Science B.V.

Keywords: Acetonitrile–water mixtures; Liquid chromatography; Preferential solvation; Quinolones, dissociation constants

1. Introduction

Quinolone antibiotics are synthetic orally active, broad spectrum agents which are effective against resistant mutants of bacteria [1,2]. They all possess a carbonyl group in position '4', so are often referred to as 4-quinolones. These quinolone carboxylic acids are active against many gram-positive and gram-negative bacteria [3–5]. Increase in their antibacterial activity is greatly influenced by addition of the 6-fluoro and 7-piperazinyl groups to the molecule. The increased potency of the new fluoroquinolones has greatly expanded their potential clinical usefulness [6]. The antibacterial activity of quinolones is pH-dependent since they act by inhibition of bacterial DNA gyrase, a process which depends upon both the pH and concentration of the acid [7]. Therefore, the examination of protonation equilibria in quinolone solutions is essential in order to understand their antibacterial activity. Furthermore, the equilibrium constants of antibiotics are biologi-

cally important physicochemical parameters. These data are important for a thorough understanding of absorption, transport and receptor binding of these drugs at the molecular level.

Traditionally, water has been considered the solvent which best represents the biological conditions. Although this is a general assumption, a lower polarity has been detected in some biochemical microenvironments, such as active sites of enzymes and side chains in proteins, sometimes hidden in lower dielectric cavities [8–10]. In these cases, the selection of other solvents seems more recommendable in order to emulate properly the medium's real features. Among the wide range of eligible solvents, hydroorganic mixtures have been found especially suitable because they show simultaneously a low polar character and a partially aqueous content, as do all biological systems. In this work, acetonitrile–water mixtures were selected because of the different nature of their constituents, which provides solvent mixtures offering a wide range of features and behaviour.

Acetonitrile–water mixtures are used in many branches of chemistry, ranging from hydrometallurgy to liquid chromatography, from reaction media for synthesis to capillary electrophoresis. The acid–base behaviour of substances in these mixtures are, therefore, of considerable interest.

However, the infinite number of different solvent compositions which can be prepared from a particular binary system (e.g., acetonitrile–water) precludes determination of the pK values in all the compositions. Therefore, an equation which connected the pK value of an acid or base to the solvent composition would be very useful. The relationship between equilibrium constants and solvent composition in mixed solvents is not straightforward. The electrolytes can be preferentially solvated by any of the solvents present in the mixture. Preferential solvation will produce higher pK values than expected if the 'preferred' solvent has the lowest relative permittivity, or lower pK values in the contrary instance. In general, preferential solvation is a composite effect determined by solute–solvent and solvent–solvent interaction [11].

In the last years we have reported acid–base studies in acetonitrile–water mixtures concerning the standardization of the glass electrode in these mixtures and the determination of their autoprotolysis constant [12], the determination of ionization constants of pH reference materials in these media [13], the assignment of reference pH-values to primary standard buffer solutions for standardization of potentiometric sensors in acetonitrile–water mixtures [14,15] and the application of the quasi-lattice quasi-chemical (QLQC) theory [16,17] to the study of the preferential solvation of the hydrogen ions in these mixtures in order to clarify the acid–base behaviour of the solutes in these media [11].

Central to the study of acid–base equilibria in organic-water mixtures is the problem of how the solute species react to changes in the solvent that forms their solvation sphere. In order to characterize this important zone of the solvent, a group of solvatochromic parameters was proposed (π^*, α, β and E_T^N) and reported for acetonitrile–water mixtures [18–21]. π^* measures the polarity and polarizability of these solvents; α and β measure the hydrogen bond acidity and hydrogen bond basicity, respectively; the normalized Dimroth and Reichardt solvatochromic parameter, E_T^N, has a mixed nature and is sensitive to many solvent–solvent interactions [21].

The purpose of the present study is the determination of pK values of nine quinolone antibacterials in 0, 5.5, 10, 16.3, 25, 30, 40, 50 and 70% (w/w) acetonitrile–water mixtures according to the rules and procedures endorsed by IUPAC [22]. The variation of the pK values obtained over the whole composition range studied can be explained by tacking into account the preferential solvation of electrolytes in acetonitrile–water mixtures. In order to obtain pK values in any of the unlimited number of the possible binary solvent acetonitrile–water mixtures, relationships between pK values and different bulk properties (such as dielectric constant) were examined and the linear solvation energy relationships method, LSER, was applied to study the correlation of pK values with the solvatochromic parameters of acetonitrile–water mixtures. The equations obtained allow calculation of the pK values of the quinolone antimicrobials in any acetonitrile–water mixtures up to 70% (w/w) and thus permit the knowledge

of the acid–base behaviour of these important antimicrobials in the widely used acetonitrile–water media.

2. Experimental

2.1. Apparatus

Values of the emf of the potentiometric cell were measured with a CRISON 2002 potentiometer (± 0.1 mV) using a Radiometer G 202 C glass electrode and a reference Ag/AgCl electrode prepared according to the electrolytic method [23] and directly immersed in the solution to avoid the residual liquid junction potentials [12].

The glass electrode was stored in water when not in use and soaked for 15–20 min in acetonitrile–water mixture before potentiometric measurements. The stabilization criterion for the emf readings was 0.2 mV within 150 s; in all instances the electrode system gave stable and reproducible potentials within 5 min.

The reference electrode was stable for three months of continuous work. The E^0 values used here are the average of at least 15 standardizations. The standardization of the electrode system was carried out each time solvent media or electrodes were changed and the constancy of E^0 values was ensured by continual surveillance by means of periodical calibrations. The cell was thermostatted externally at 25 ± 0.1°C. The potentiometric assembly was automatically controlled with a microcomputer.

2.2. Reagents

Analytical reagent grade chemicals were used, unless otherwise indicated.

All the solutions were prepared by mixing doubly distilled, freshly boiled water, the conductivity of which did not exceed 0.05 μS cm^{-1}, and acetonitrile (Merck, chromatography grade). The quinolones used in this study are shown in Fig. 1 and were purchased from different pharmaceutical laboratories: Pipemidic acid (Almirall, Prodesfarma); Nalidixic acid (Impex Química, Sterling Winthrop); Norfloxacin (Liade, Boral Química); Enoxacin (Almirall); Flumequine (Sigma); Fleroxacin (Roche); Ciprofloxacin (Lasa); Cinoxacin (Impex Química, Dista); Ofloxacin (Hoescht).

Stock 0.1 and 0.02 mol l^{-1} potassium hydroxide (Carlo Erba) solutions were prepared with an ion-exchange resin [12] to avoid carbonation and standardized volumetrically against potassium hydrogen phthalate.

Stock 0.1, 0.03 and 0.01 mol l^{-1} hydrochloric acid (Merck) solutions were prepared and standardized titrimetrically against tris(hydroxymethyl)aminomethane (Merck).

2.3. Procedures

The quinolone pK values were determined potentiometrically by different analytical methods:

(i) by titration of appropriate solutions of quinolones in the acetonitrile–water mixtures studied, which also contained approximately 5×10^{-3} M KCl solution for the correct response of the electrode system. KOH solutions were used in the same solvent as titrant. The KOH solutions used as titrants were of different concentrations (0.1 M–0.02 M) depending on the solubility of the quinolones.

(ii) by titration of appropriate solutions of quinolones in the acetonitrile–water mixtures studied, using HCl solution as titrant. Again, the concentration of HCl solution was different depending on the solubility of the quinolones.

(iii) by titration of appropriate solutions of quinolones in the acetonitrile–water mixtures studied, which contained a measured excess of HCl solution using KOH solution as titrant. In this way, the quinolones are fully protonated at the beginning of the titration.

The differences existing in the literature about the assignment of the ionizable function groups justify the use of these different analytical procedures [24,25].

pK values were obtained from systematic measurements of the emf of the cell

$$\mathrm{Pt/Ag/AgCl/}\ \underset{\text{in acetonitrile - water}}{\mathrm{HA + A + Cl^-}}\ \mathrm{/Glass\ Electrode} \quad \text{A}$$

where HA and A are the acid and basic species, respectively, involved in the dissociation equilibrium studied. The emf, E, of this cell is directly

Fig. 1. Structures of selected quinolones.

related to the activities of the hydrogen and chloride ions in solution:

$$E = E^{\theta} + k \log(a_{H+} a_{Cl-}) \quad (1)$$

where E^{θ} is the standard emf of the cell and $k = (\ln 10)RT/F$. E^{θ} values were determined as in a previous study [12].Taking into account the general expression for the dissociation equilibria studied

$$K = \frac{c_A y_A c_{H+} y_{H+}}{c_{HA} y_{HA}} \quad (2)$$

the functional Eq. (3), which permits pK calculation, is obtained:

$$\frac{E^0 - E}{k} + \log \frac{c_{HA} y_{HA} c_{Cl-} y_{Cl-}}{c_A y_A} = pK \quad (3)$$

where c_{HA} and c_A are the molar concentrations of acidic and basic species, respectively; c_{Cl-} is the molar concentration of the ion chloride; and y_x the molar activity coefficient of species x. These values can be calculated through an extrathermodynamic assumption, i.e., a form of the classical Debye-Hückel equation,

$$py = \frac{AI^{1/2}}{(1 + a_0 BI^{1/2})} \quad (4)$$

where A and B are the Debye-Hückel constants; a_0 is the ion size parameter in the solvent mixture; and I is the ionic strength.

In compliance with IUPAC rules [22,26] the value of the a_0B produce in Eq. (4) is assigned at temperature $T = 298.15$ K by an extension of the Bates-Guggenheim convention [22,27], in terms of

$$(a_0B)_T = 1.5(\epsilon^W\rho^S/\epsilon^S\rho^W)_T^{1/2} \quad (5)$$

where ϵ is the dielectric constant, ρ the densities and the superscripts W and S refer to pure water and to the appropriate solvent mixture, respectively. Values of Debye-Hückel parameters A and a_0B at 25°C at different percentages of acetonitrile in admixture with water were reported in previous works [12,28].

The difference between the two ionization constants of the quinolones is not very high. Therefore, pK values were calculated in two different ways: considering the two equilibria independently and considering them simultaneously. In the latter case the calculation made use of a program written in PASCAL, pKPOT [29]. The least-square computer program, PKPOT, determines thermodynamic acid–base constants in aqueous and non-aqueous media, taking into account the activity coefficients of the species. These mathematical procedures also allow the determination of pK_a values in overlapping ranges ($pK_i - pK_f < 2$) and dissociation constants in very alkaline conditions. The procedures are based on the postulation of a chemical model, that is, the postulation of an initial set of species defined by their stoichiometric coefficients and formation constants, which are then refined in least square minimization.

Moreover, pK_a values were obtained in pure acetonitrile solvent for two acid species of two NIST standard buffers (acetic and citric acids) in order to study preferential solvation in acetonitrile–water mixtures. For this purpose the potentiometric system described previously [30,31] was used and the standard potential of the cell was determined by titration of picric acid solutions in acetonitrile with tetrabutylammonium hydroxide, as in a previous study [30].

3. Results and discussion

The emf, E, of cell A was measured at different concentrations of acidic, HA, and basic, A, species of quinolones in 0, 5.5, 10, 16.33, 25, 30, 40, 50 and 70% (w/w) acetonitrile–water solvent. 5.5, 16.3 and 25% (w/w) correspond to 7, 20 and 30% (v/v), respectively. For each quinolone various series of measurements were performed, making a total of more than 5600 independent measurements over the solvent interval explored. To simplify the tabulation and as an example, one series of measurements for one titration of norfloxacin and HCl acid solution in 10% (w/w) acetonitrile–water using KOH solution in the same solvent as titrant is shown in Table 1, where V_0 is the initial solution volume, V_{ei} the equivalence volumes, c_t the titrant concentration and E^0 the standard emf of cell. For each point of titration, E is the emf value measured, [H_2A] the concentration of fully protonated species, [HA] the concentration of intermediate species, [A] the concentration of basic species and y the molar activity coefficient.

Table 2 shows the ionization constant values determined using the pKPOT program for the series of nine quinolones studied in 0, 5.5, 10, 16.3, 25, 30, 40, 50 and 70% (w/w) acetonitrile–water mixtures and the respective standard deviations, s, together with pK values reported in water [32–34].

Quinolone analogues have several potentially ionizable functional groups, Fig. 1. Although in the literature there is no agreement on the assignment of the obtained pK values in water [24,32,35], extensive experimental data obtained in this study by potentiometric titrations of quinolone solutions with KOH and HCl, and of quinolones and HCl solutions with KOH, are in perfect agreement with the protolytic equilibria expressed in Fig. 2.

Six of the quinolone derivatives studies (1–6, Fig. 1) have two relevant ionizable functional groups, which means that their acid base chemistry involves two protons. In contrast, nalidixic acid, flumequine and cinoxacin have only one relevant ionizable functional group within the pH ranges of pharmaceutical or physiological importance. All the quinolones have a carboxyl group that is normally stronger acid than the ammonium group, and have a pK value of 6 ± 1 in water rich solvents. Therefore pK_1 values can be associated with the carboxylic acid function [33,36].

Nalidixic acid, pipemidic acid and enoxacin have naphtyridine rings and the other analogues

have quinolone rings. Their ring nitrogen does not have appreciable basicity in aqueous solutions [36] and neither in acetonitrile–water mixtures, as can be seen in the potentiometric titration curves of nalidixic acid, flumequine and cinoxacin. The pK_2 values can be associated to the presence of a piperazine ring (1–6, Fig. 1). Protonation occurs at N_4 of the piperazine ring over other apparently basic sites, as is proven by NMR measurements [36] and by the fact that N'_4-acetylnorfloxacin has only one proton binding group (carboxylate), since the molecule loses amine basicity due to the acetylation of N'_4 atom [36].

The pK_1 values associated with the carboxylic acid function for the compounds studied here were higher than those generally observed with carboxylic acids in water mixtures [13] (e.g., acetic acid in 30% (w/w) of acetonitrile has a pK = 5.63). This decrease in acidity can be attributed to an intramolecular H-bond formation with the neighbouring keto function resulting in stabilization of the protonation species [33]. The formation of an intramolecular hydrogen bond is supported by US and IR spectral data [37].

The pK_2 values of the four secondary amine type derivatives studied (ciprofloxacin, norfloxacin, enoxacin and pipemidic acid) are greater than those of the tertiary amines (ofloxacin and fleroxacin). These findings were consistent with reports in the literature for similar secondary and tertiary amines: piperazine, pK = 9.71 [38], and N-methylpiperazine, pK = 8.98 [39], in water. The more water molecules involved in the hydrate sphere of the protonated amine, the greater the

stabilization [40]. The protonated form of the secondary amine was stabilized by the greater number of water molecules involved in its hydration sphere when compared with the corresponding tertiary amine [33].

The variation of the pK_1 and pK_2 values of quinolones with dielectric constant is presented in Fig. 3 and Fig. 4, respectively. The variation is different for each substance although, in general, the pK values increase as the acetonitrile content increases. However, pK_1 values corresponding to dissociation of carboxylic acid vary differently from pK_2 ones.

The dissociation constant of a substance HA in a solvent S is related, by means of the Born model, with the dielectric constant of the medium, ϵ, by the following expression [41]

$$HA + S \leftrightarrows A^- + HS^+$$

$$pK_a = pK_a^0 - pK_{HS+}^0 - e^2(z-1)/(2.3r\epsilon kT) \qquad (6)$$

where K_a^0 and K_{HS+}^0 are the intrinsic dissociation constants of the substance and the protonated solvent in the vacuum, taken as standard state, r the average radius of the ions, e the electron charge, z the charge of the acid species HA and KT the energy of thermal agitation.

Eq. (6) shows that the medium affects the strength of an acid in two ways: when the acidity of the solvent, K_{HS+}^0, increases, K_a becomes smaller; and when the dielectric constant decreases, K_a decreases if $z \leq 0$, does not change if $z = 1$ and increases if $z > 1$.

For a series of solvents with similar acidity, the change in the dissociation constant can only be attributed to the change in dielectric constant, and Eq. (6) can be written as:

$$pK_a = A + \frac{B}{\epsilon} \qquad (7)$$

where A and B are constants for a given substance, assuming the radius of the ions, r, independent of the solvent composition.

Thus, the plot of the pK_a of neutral or anion acids versus the reciprocal of the dielectric constant in some solvents of similar acidity shows a straight line. These predictions are in agreement

with plots shown in Fig. 3 of the dissociation of carboxylic acids of the quinolones, pK_1 values.

In fact, Eqs. (6) and (7) apply only if all solvents show similar specific solute–solvent interactions, when changes in pK values can be attributed mainly to the change in dielectric constant.

For dissociation of the carboxylic acid of the quinolones, pK_1, the electrostatic interaction overwhelms the specific solvation and the pK_1 value increases with the percentage of acetonitrile, as Eq. (7) predicts.

However, in dissociation of a monocharged cation acid (such as the ammonium ions of the N'_4 of piperazine ring of quinolones, pK_2), there is no change in the number of charges ($HA^+ \rightleftharpoons H^+ + A$) and the change in the dielectric constant of the medium does not affect the dissociation process. In this instance, the dissociation depends only on the solvation of the different species by the solvents of the mixture.

The pK_2 values of quinolones in acetonitrile–water mixtures show low changes in the range 0% (w/w) to approximately 30% (w/w) of acetonitrile whereas at higher percentages of acetonitrile they increase with the percentage of acetonitrile, Fig. 4.

The change of pK_2 values corresponding to ammonium ions of quinolones with a percentage of acetonitrile could be explained by the fact that these dissociation constants depend on the solute–solvent interaction effects with the solvents of the mixture. Preferential solvation by water exists in acetonitrile–water mixtures [11] and is related to the structural features of these mixtures [42,43]. On the water-rich side, $x_{AN} < 0.15$, there is a region in which the water structure remains more or less intact: the acetonitrile molecules gradually occupy the cavities between water molecules without disrupting the water structure [43]. In this water-rich region there are not changes in the pK_2 of quinolones. This is in accordance with the previously obtained values of preferential solvation, δ_w, of hydrogen ions by water in acetonitrile–water mixtures [11]. The preferential solvation of hydrogen ions by water is positive, i.e., water molecules show a greater tendency to be in the immediate vicinity of a given hydrogen ion than acetonitrile molecules. In this water-rich region the structure of water remains constant, the solutes are preferentially solvated by water and the variations of pK_2 values are minimal.

In the range $0.15 \leq x_{AN} \leq 0.75$ there are clusters of molecules of the same kind surrounded by regions where molecules of both kinds are near each other. In this middle range of compositions there is also preferential solvation of hydrogen ions by water [11], which could explain the low slope of the linear variations of pK_2 values of quinolones versus x_{AN}. The boundaries of the regions are, of course, not sharp [18].

At $x_{AN} \geq 0.75$ the number of water clusters is low, and water–acetonitrile interactions that could be discounted in the middle range now become important. This may be considered as a region in which preferential solvation by water decreases [11].

Although the variation of the pK_1 values of quinolones obtained in acetonitrile–water mixtures with x_{AN} is linear with the mixtures studied, these pK_1 values, as well as pK_2 values, are lower than expected, giving the high pK value expected in the neat solvent acetonitrile. Preferential solvation in acetonitrile–water mixtures produce lower pK values than expected if the preferred solvent is water.

The deviation from the ideal dependence on the composition of the mixture indicates that the solvent composition in the neighbourhood of the solute may be different from that in the bulk. pK values of quinolones in acetonitrile neat solvent are not known, but in this study pK values of citric acid were determined in pure solvent and the pK value of acetic acid is obtained from literature [44]. These pK values were determined previously over the whole composition range of acetonitrile–water mixtures [13]. Fig. 5 and Fig. 6 show these pK values as a function of x_w, the bulk mole fraction of water, where the dashed line represents the expected variation of pK values between $x_{AN} \approx 0.5$ and pure acetonitrile solvent and the dotted straight line correspond to the ideal variation of the pK values. Fig. 5 and Fig. 6 also show pK_1 and pK_2 values of quinolones, respectively, versus x_w for comparison. The pK values obtained could be explained in terms of

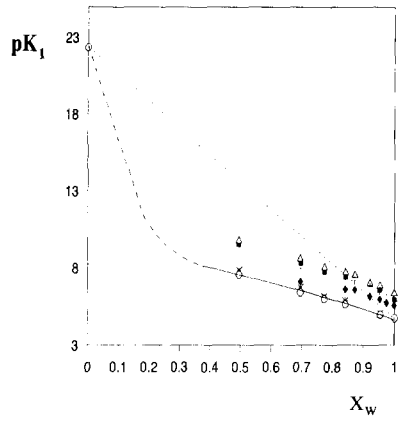

Fig. 5. pK_1 values versus mole fraction of water, x_w, in acetonitrile–water mixtures. ● Acetic acid; Remainder symbols as in Fig. 3.

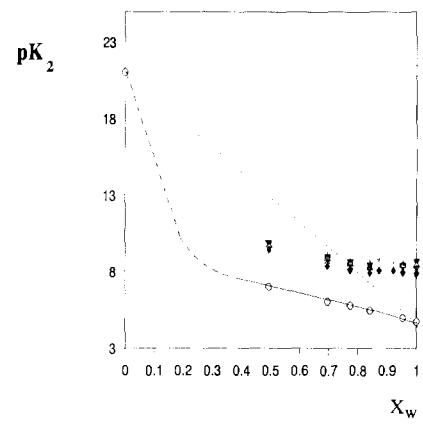

Fig. 6. pK_2 values versus mole fraction of water, x_w, in acetonitrile–water mixtures. ● Citric acid; $pK_1 = 14.86$ ($s = 0.04$), $pK_2 = 20.98$ ($s = 0.09$); Remainder symbols as in Fig. 3.

structural features and preferential solvation by water in acetonitrile–water mixtures. The slope of pK_1 values of quinolones versus x_w plot is greater than the pK_2 values versus x_w plot in the water-rich region because of the influence of ϵ.

In water-rich region $x_{AN} \leq 0.15$, pK_2 values do not vary in contrast with pK_1 values because of the influence of changes in ϵ. In the regions where water–acetonitrile mixtures show microheterogeneity $0.15 \leq x_{AN} \leq 0.75$, pK_1 and pK_2 values change but are lower than the theoretical ones because of the preferential solvation by water; a concave variation of pK versus x_w may be expected with an inflexion point at $x_w = 0.25$, where preferential solvation by water is maximal [11].

On the other hand, it is not self-evident that solvatochromic parameters are valid stand-ins for generalized solutes in binary solvent mixtures with regard to the properties they are supposed to measure. Preferential solvation in such mixtures may interfere more seriously with the ability of indicators to act as stand-ins for generalized solutes than in the case of single solvents. Progress has been made [18,45] and although this problem is not solved unequivocally, these investigations provide significant evidence of the general validity of the solvatochromic parameters. It is, therefore, of interest to examine the linear solvation energy

relationships (LSER) which explain any solute property varying with solvent composition as a linear combination of the microscopic parameters of the solvent responsible. The Kamlet-Taft [46] expression states:

$$XYZ = (XYZ)_0 + s\pi^* + a\alpha + b\beta \quad (8)$$

where α, β and π^* are the microscopic parameters previously described, XYZ is the solute property, XYZ_0 the value of this property for the same solute in a hypothetical solvent for which $\alpha = \beta = \pi^* = 0$ and a, b and c are the susceptibilities of the solute property studied to changes in α, β and π^*, respectively. This equation can include additional terms or some of its terms can become equal to zero, depending on the property of the solute to be described [47]. Values of the Kamlet-Taft solvatochromic parameters π^* [18,20], α [18,47] and β [18,19] for acetonitrile–water mixtures over the entire range of composition are known. Table 3 gives the relevant solvatochromic parameter values for the mixtures studied.

Several attempts were made to find the best form of the Kamlet-Taft equation to describe the variation of pK_1 and pK_2 values of quinolones in acetonitrile–water mixtures. Multiple regression analysis was applied to the pK data. All possible combinations of solvatochromic parameters, including Dimroth and Reichardt normalized parameter E_T^N, Table 3, were checked. The best fit was obtained when the three solvatochromic parameters α, β and π^* were used, yielding the general equations in Table 4. The linear solvation energy relationships obtained, permit to know the pK values of quinolones in any acetonitrile–water mixture up to 70% (w/w) acetonitrile. It could be of great practical interest to apply multiple regression analysis to the whole set of pK values of quinolones and the usual concentration by volume %(v/v), v, and weight %(w/w), w, as the intercept variables. In these cases the second order polynomials shown in Table 5 are obtained. The equations in Table 4 and Table 5 enable the pK_1 and pK_2 values of the quinolones studied in any binary solvent acetonitrile–water mixture up to 70% (w/w) acetonitrile to be known, and thus permit the interpretation of their acid–base behaviour in these widely used hydrorganic mixtures.

Liquid–liquid extraction separation of iron (III) with 2-ethyl hexyl phosphonic acid mono 2-ethyl hexyl ester

J. Jayachandran, P.M. Dhadke *

Inorganic Chemistry Laboratory, Department of Chemical Technology, University of Bombay, Matunga, Mumbai 400 019, India

Received 8 August 1996; received in revised form 21 November 1996; accepted 22 November 1996

Abstract

Liquid–liquid extraction separation of iron(III) with 2-ethyl hexyl phosphonic acid mono 2-ethyl hexyl ester (PC-88A) in toluene has been studied. Quantitative extraction of iron(III) with 5×10^{-3} M PC-88A in toluene is observed in the pH range 0.75–2.5. From the extracted complex species in the organic phase iron(III) was stripped with 1–4 M HNO_3, 1.5–4 M H_2SO_4 and 1.5–4 M HCl, and later determined spectrophotometrically by thiocyanate method. Separation of iron(III) was carried out with some of the first transition metals in binary and multicomponent mixtures. This method was extended for the determination of iron in real samples. © 1997 Elsevier Science B.V.

Keywords: Iron (III); Liquid–liquid extraction; PC-88A; Thiocyanate method

1. Introduction

During the last two decades, large number of workers have reported on the extraction of iron(III) from different aqueous media by organophosphorus extractants [1,2]. In recent years phosphonic and phosphinic acid extractants have been commercialised [3], and among these, the dialkylphosphonic acid, especially 2-ethyl hexyl phosphonic acid mono 2-ethylhexyl ester(PC-88A) has been widely studied [4,5]. It has been preferred as an extractant for the separation of rare earth elements due to the high separation factor between any two chemically similar rare earth elements [6,7].

The extraction of iron(III) from KSCN with tri-*n*-butyl phosphate(TBP) has been reported [8]. Bis-2-ethyl hexyl phosphoric acid (D2EHPA) is an excellent extractant for iron(III), though back extraction of iron(III) from organic phase is found to be very difficult [9,10]. The quantitative extraction of iron(III) was possible from nitrate media with 0.1 M mono-2-ethyl hexyl phosphoric acid in hexane [11]. The extraction of iron(III), iron(II) and titanium(IV) from acidic sulphate medium with Di-*o*-tolyl phosphoric acid in benzene-hexane-1-ol system was reported by Islam et. al [12].

Demopoulos et al. have reported synergistic extraction of iron(III) from H_2SO_4 solutions using mixtures of Kelex 100-PC-88A in varsol 140 [13], while Jiayong chen et al. carried out the extraction with the mixture of amine and PC-88A [14].

PII S0039-9140(97)02190-X

However, systematic investigation on the extraction of iron(III) with PC-88A are lacking.

2. Experimental

2.1. Apparatus and reagent

Elico model LI-120 pH meter with combined electrode was used for H^+ ion concentration and Elico model SL-150 UV/Visible spectrophotometer with 10 mm corex quartz cuvettes were used for absorbance measurements.

The stock solution of iron(III) was prepared by dissolving 8.634 g of $NH_4Fe(SO_4)_2\ 12H_2O$ in 1 l of distilled water containing concentrated sulfuric acid and it was standardised volumetrically [15]. The required concentration of iron(III) solution was prepared by appropriate dilution with double distilled water. PC-88A (2-ethyl hexyl phosphonic acid mono 2-ethyl hexyl ester) supplied by Daihachi Chemical Industry (Japan) was used without further purification. All other chemicals used were of analytical grade.

2.2. Procedure

An aliquot of the solution containing 5 μg ml^{-1} of iron(III) was taken for all experiments. For extraction studies, 10 ml of aqueous solution containing 50 μg of iron(III) was taken and its pH was adjusted with sulphuric acid and/or ammonium hydroxide. The solution was then transferred into a separating funnel and 10 ml of 5×10^{-3} M PC-88A in toluene was added to it and was shaken for 5 min. The two phases were allowed to separate. Iron(III) from the metal loaded organic phase was then stripped back with different mineral acids as stripping agents. The amount of iron(III) in aqueous phase was determined spectrophotometrically by thiocyanate method [16].

3. Result and discussion

3.1. Effect of pH on extraction

Iron(III) was extracted in the pH range of 0.1–5.0 with 5×10^{-3} M PC-88A in toluene. The extraction was found to be quantitative in the pH range 0.75–2.5, hence all extraction were carried out at pH 2.0. (Fig. 1).

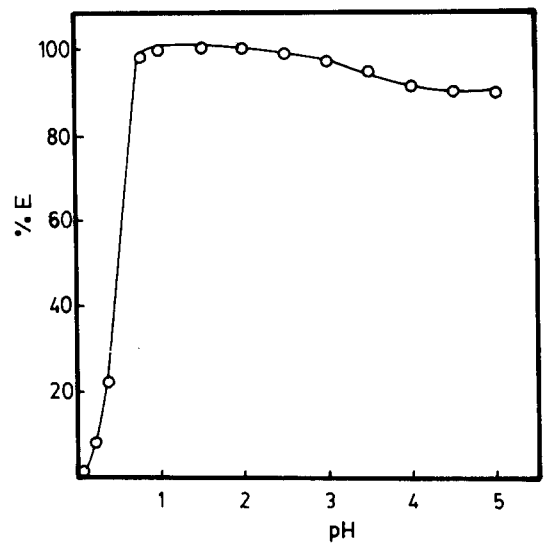

Fig. 1. Effect of pH on percentage extraction of iron(III) with 5×10^{-3} M PC-88A in toluene.

Table 1
Extraction as a function of PC-88A concentration

PC-88A conc (1×10^{-3} M)	% Extraction (E)	Distribution ratio (D)
0.10	7.5	0.08
0.25	11.3	0.13
0.50	16.5	0.20
0.75	30.1	0.43
1.0	45.9	0.85
2.5	60.9	1.56
3.0	65.4	1.89
3.5	88.7	7.87
4.0	90.9	10.09
5.0	99.2	132.0
10.0--100.0	99.9	999.0

Fe(III) = 50 μg, pH = 2.0.

Table 2
Effect of stripping agents on back extraction of iron

Stripping agents (M)	% Recovery								
	0.1	0.5	1.0	1.5	2.0	2.5	3.0	3.5	4.0
HNO_3	63.9	90.2	99.9	99.9	99.9	99.9	99.9	99.9	99.9
HCl	50.8	91.1	97.7	99.9	99.9	99.9	99.9	99.5	99.5
H_2SO_4	55.2	88.5	96.2	99.2	99.9	99.9	99.9	99.7	99.3

3.2. Effect of reagent concentration

Iron(III) was extracted with varying concentration of PC-88A in toluene from 1×10^{-4} to 1×10^{-1} M. The extraction was observed to be quantitative with 5×10^{-3}M of PC-88A in toluene (Table 1).

3.3. Extraction with various diluents

The extraction of Iron(III) was performed with 5×10^{-3} M PC-88A in different diluents. The extraction was found to be quantitative with toluene, xylene, benzene and chloroform as the diluents, while with hexane (90.9%), cyclohexane (96.2%), carbon tetrachloride (93.2%) and methyl-iso-butyl ketone (91.7%) the extraction was not quantitative. Toluene was preferred as best diluent for extraction, since it provided better phase separation.

3.4. Effect of various stripping agents

Iron(III) was back extracted from organic phase with various strength of mineral acids. The stripping of iron(III) was observed to be quantitative with 1–4 M HNO_3, 1.5–4 M HCl and 1.5–4 M H_2SO_4. Among these mineral acids HNO_3 was preferred as stripping agent as it facilitates the determination of iron(III) without the step of dry ashing (Table 2).

3.5. Equilibration study

The solution was shaken for a period ranging from 1 to 20 min. The extraction was quantitative with a minimum 4 min of shaking. Therefore, a 4 min period of equilibration was maintained.

3.6. Nature of extracted species

It was necessary to evaluate distribution constant (D) while varying extractant concentration to ascertain the nature of the extracted species. The composition of the extracted species was ascertained from the graph of log D versus log [PC-88A] at fixed pH 2.0. The slope obtained was 2.7 (Fig. 2). Hence the probable composition of the extractable species is 1:3 or $Fe(PC\text{-}88A)_3$.

3.7. Effect of various diverse ions

Iron(III) was extracted in the presence of a large number of metal ions. The tolerance limit was so set as the amount of foreign ion causing interference of $\pm 1\%$ in the extraction of iron. The alkali metals were tolerated a ratio of 1:50. Manganese(II), mercury(II), copper(II) and

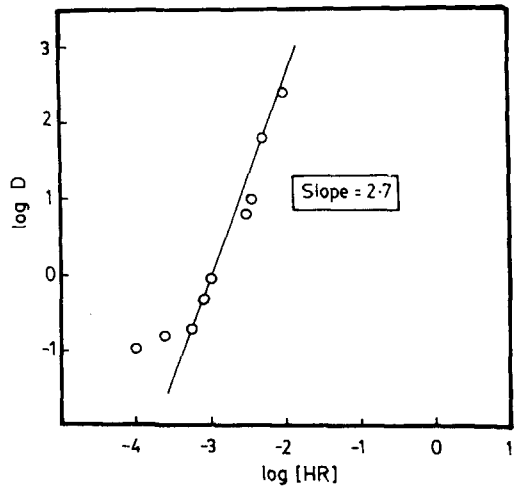

Fig. 2. Dependency of distribution ratio of iron(III) on PC-88A concentration in toluene (pH = 2.0)

Table 4
Analysis of samples containing iron

Samples	Metal present	Present	Found	% Recovery
Ilmenite ore	Fe, Ti	48.5%	48.2%	99.5
Pyrulosite ore[a]	Fe, Al, Mn	9.8%	9.7%	98.9
Monel metal[a]	Fe, Cu, Ni, Mn	1.5%	1.45%	96.6
Impheron injection	Fe	100 mg	99.9 mg	99.9
Fecontin-F tablets	Fe	100 mg	99.2 mg	99.2

[a] Al, Mn and Ni were separated after studying their extraction condition.

calcium(II) were tolerated in the ratio of 1:25. Chromium(VI), nickel(II) and lead(II) were tolerated up to a ratio of 1:10. Cobalt(II), vanadium(V), zinc(II), cadmium(II), rubidium(I), thallium(I), barium(II), indium(III) and osmium(VIII) were tolerated in the ratio of 1:4. Anions like chloride, sulphite, sulphate and perchlorate were tolerated at a ratio of 1:60 but acetate, EDTA, bismuth(III), silver(I) and arsenic(III) showed strong interference.

3.8. Separation of iron(III) from multicomponent mixtures

The mixture of iron(III), titanium(IV), cobalt(II) and chromium(VI) was resolved by first extracting iron(III) and titanium(IV) at pH 1.0 with 5×10^{-2} M PC-88A in toluene, during which cobalt(II) and chromium(VI) remain unextracted in the aqueous phase. From the organic phase iron(III) and titanium(IV) were separated by taking advantage of difference in stripping agents. Iron(III) was first stripped with 1 M HNO_3, followed by titanium(IV) with the mixture of 2 M H_2SO_4 and 3% H_2O_2 to get a quantitative separation. Cobalt(II) and chromium(VI) which remained unextracted in the aqueous phase were separated by first extracting cobalt(II) in acetate media with 5×10^{-3} M PC-88A in toluene. In acetate medium, chromium(VI) remained unextracted.

Copper(II) and zinc(II) were found to get extracted at pH 6.0 and 4.5, respectively with 2×10^{-2}M PC-88A in toluene [17]. Iron(III), zinc(II) and chromium(VI) from their mixture were separated by first extracting iron(III) at pH 2.0 with 5×10^{-3} M PC-88A in toluene and then zinc(II) at pH 5.0 with 2×10^{-2} M PC-88A in toluene where as chromium(VI) remain unextracted (Table 3).

4. Application

The proposed method was applied for the analysis of different samples containing iron (Table 4). The results conform to the labile claim and is free from interferences due to other excipient present in pharmaceutical formulation. Determination of iron in ilmenite ore and monel metal was carried out after separating titanium and copper respectively by the method given in Table 3.

5. Conclusion

The proposed method is simple, rapid and selective. It is advantageous over other existing method as follows:

1. Concentration of PC-88A (5×10^{-3} M) required is much less as compared with reagents like 8-hydroxyquinoline, acetylacetone and thenoyltrifluoroacetone.
2. Extraction is difficult with dithizone as iron(III) oxidizes the reagent and does not form a complex.
3. Various metals showed different extents of extraction with PC-88A in toluene at different pH and have difference in stripping power. These factor permitted the separation of iron(III) from commonly associated elements like titanium(IV), cobalt(II), chromium(VI), zinc(II) and copper(II) in binary, ternary and quaternary mixtures.
4. Equilibrium time required is much less, i.e., 4 min and much less concentration of stripping agent is required.

Acknowledgements

The authors are thankful to Professor S.M Khopkar, Emeritus Scientist (CSIR), Department of Chemical Technology, University of Bombay, for his help and inspiration in the research work and Dai-hachi Chemical Industries, Japan for the gift sample of PC-88A.

Abstract

Some podands, acyclic polyethers, were utilized as membrane active components to prepare Ag^+-selective polymeric membrane electrodes. The thiapodand-based electrodes exhibited considerable selectivity toward Ag^+ over other heavy metal ions including Cd^{2+}, Pb^{2+}, Cu^{2+} and Hg^{2+}. Also, good selectivity over alkali and alkali earth metal ions were observed. Response slopes, pH effects, response time, and signal baseline return of the sensor systems were studied in static mode and/or in a flow-injection system. The Ag^+-selectivity was explained by the soft–soft interaction of the Ag^+ ion with the sulfur donor atoms as well as the stacking interaction between aromatic end groups of the host molecule on complexation. © 1997 Elsevier Science B.V.

1. Introduction

Among various metallic ions, alkali and alkali earth metal ions (Li^+, Na^+, K^+ and Ca^{2+}) have been routinely measured by ion-selective electrodes (ISEs) in clinical applications [1–4]. Active components (ionophores) for the related ion-selective membranes are usually macrocyclic polyethers that contain oxygen and nitrogen atoms. The remarkable selectivity of such membrane electrodes toward these metal ions reflects the high affinity of oxygen- and nitrogen-containing coordination sites toward the cations. Nitrogen- and oxygen-containing cryptands have also been exploited for the measurement of Zn^{2+} and other heavy metal ions [5–7].

On the other hand, the multi-purpose nature of silver makes its analysis in, and recovery from, waste material of importance [8]. Soft coordination sites like sulfur seem to generate great affinity toward the d^{10} transition metal ions such as Ag^+ and Hg^{2+}. A group of polythiacrown ethers and acyclic polythia compounds have been utilized for the measurement of Ag^+ [9–11]. It is also found that some sulfur and/or nitrogen-containing calixarene-based PVC membrane electrodes exhibit good selectivity toward Ag^+ ion over alkali metal ions [12].

Fig. 1. Structures of some podand-type ionophores used in the preparation of Ag^+-selective membrane electrodes.

Here we describe the synthesis of some new podands, which contain two sulfur atoms in ether chain, and aromatic or lipophilic end groups (Fig. 1). These oxygen or sulfur-containing podands are employed as the active components for Ag^+-selective polymeric membranes. And the relation between the structure of ionophores and the selectivity are also discussed. The electrochemical properties of the podands as the Ag^+-selective ionophore are tested in static and flow-injection analysis (FIA) mode.

2. Experimental

2.1. Materials

The podands II and III were prepared as reported [13,14]. Podands I and IV were synthesized by the reaction of 1,8-dichloro-3,6-dioxaoctane with β-thionaphthol and n-nonylmercaptane in the presence of KOH in ethanol, respectively.

Podand I: β-thionaphthol and KOH were dissolved in boiling ethanol. Under reflux condition, 1,8-dichloro-3,6-dioxaoctane in ethanol was added dropwise. The mixture was refluxed for 12 h. After cooling to room temperature, the mixture was filtered and evaporated. The residue was dissolved in chloroform. To separate unreacted β-thionaphthol, the mixture was extracted several times with dilute NaOH. The organic layer was dried over $MgSO_4$, concentrated and purified by column chromatography over silica gel (eluent, n-hexane:ethylacetate 65:35 v/v; R_f value, 0.34; yield 50%; ^1H NMR ($CDCl_3$), 8.6–6.9 (m, 14H, aromatic C–H), 3.4–3.9 (m, 12H, CH_2OCH_2), 3.2–3.5 (m, 4H, $-SCH_2$); IR (KBr), 3010 (aromatic C–H, m), 2900 (aliphatic C–H, s) 1100 (alkyl C–O, s), 740 (allyl C–S, s) cm^{-1}).

Podand IV: n-nonylmercaptane and KOH were dissolved in boiling ethanol. Under reflux condition, 1,8-dichloro-3,6-dioxaoctane in ethanol was added dropwise. The mixture was refluxed for 16 h. The synthetic procedure was almost same as that used for podand I (eluent, n-hexane: ethylacetate 90:10 v/v; R_f value, 0.35; yield 65%; ^1H NMR ($CDCl_3$), 3.45–3.67 (m, 4H, OCH_2), 2.40–2.75 (t, 4H, SCH_2), 1.10–1.70 (m, 8H, CH_2), 0.83 (t, 3H, CH_3); ^{13}C NMR ($CDCl_3$), 70.98, 70.19 (OCH_2), 32.54, 32.42 (SCH_2), 22.43, 28.40, 29.63, 31.20 (CH_2), 13.93 (CH_3); IR (KBr), 2920 (aliphatic C – H, s), 1126 (alkyl C – O, s), 725 (allyl C – S, w) cm^{-1}).

Poly(vinyl chloride) (PVC) and potassium tetrakis(4-chlorophenyl)borate (KTpClPB) from Fluka (Ronkonkoma, NY) were used to cast the ISE membranes. A plasticizer, diisodecyl adipate (DIDA) was obtained from Scientific Polymer Products (Ontario, NY). Tetrahydrofuran (THF) was purchased from Aldrich (Milwaukee, WI) and purified over sodium before use. A Tris buffer solution consisting of 0.05 M Tris[hydroxymethyl]aminomethane (Trizma Base) (Sigma, St. Louis, MO) adjusted with HNO_3 solution to pH

[a] Numbers indicate wt.%.
[b] Roman numerals indicate the podands in Fig. 1.
[c] Data were obtained with three membranes. Slope values denote (mean ± S.D.).
[d] The slopes were calculated using the linear portion of the response curve (detection limits and 1 mM).

9.0 was used as the working buffer for the potentiometric measurements. Nitrate salts of analytical-reagent grade were employed for the preparation of metal ion standard solutions. The buffer and standard solutions were prepared with deionized water.

2.2. Preparation of polymer membranes and electrodes

PVC-based ISE membranes were prepared by the method of Simon et al. [15]. The membrane compositions in the present work are listed in Table 1. After allowing the membranes to cure, 5.5 mm diameter disks were cut out and placed in Phillis electrode bodies (ISE-561, Glasblaserei Moller, Zurich). As an internal filling solution, 1 mM $AgNO_3$ was used for all electrodes.

2.3. Static mode potentiometric measurements

Cell potentials were measured at ambient temperature (18°C). The potentiometric cell used was as follows: Ag/AgCl(s)/4M KCl saturated with AgCl/Tris buffer/sample solution/ion-selective membrane/1 mM $AgNO_3$/AgCl(s)/Ag. The ion-selective and Ag/AgCl reference electrodes were connected through a high impedance amplifier to an IBM AT-type computer equipped with an A/D converter. Sampling rate was adjusted to 1 Hz. This apparatus was used to determine the selectivity of each membrane toward Ag^+ ion over other cations in the static mode. Selectivity coefficients, $k^{pot}_{Ag/x}$, were obtained by using the separate solution method [16].

2.4. Flow-injection mode measurements

The arrangement shown in Fig. 2 was used to evaluate the performance of the podand-based PVC membrane electrodes in the IFA mode. A Phillips electrode body was fitted with a wall-jet type flow-through cap similar to that described

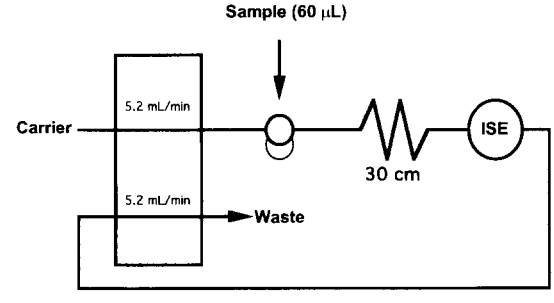

Fig. 2. Schematic of the membrane electrode-based flow-injection system.

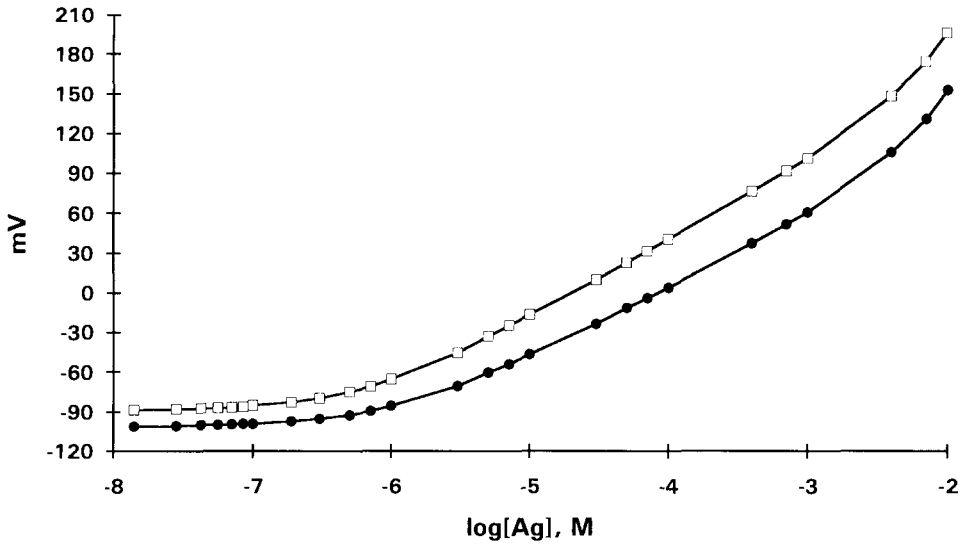

Fig. 3. Potentiometric Ag^+ ion response of the podand-based PVC membrane electrodes: (•) E1, (□) E2 in Table 1, respectively. Measurements were made in 0.05 M Tris buffer, pH 9.0.

previously [17]. The flow cap was connected to the injection valve by teflon tubing (0.012 in. i.d.). A peristaltic pump (Ismatech SA, Zurich) and a Rheodyne four-way rotary teflon valve (Model 7125) equipped with a 60 μl sample loop completed the flow-injection setup. The Tris buffer was used as the carrier stream. The Ag^+-selective and Ag/AgCl reference electrode were connected as described above. Sampling rate was adjusted to 2 Hz to observe delicate changes in the mV response.

3. Results and discussion

As with many ionophore-based membrane electrodes, the potentiometric response of the electrode toward Ag^+ ion depends on the concentration of the ionophore incorporated in the membranes. As shown in Table 1, increasing levels of the podand results in membrane electrodes (E1–E6) that exhibit larger slopes and lower detection limits. Approximately 6 wt.% of podands yielded electrodes with near-Nernstian response toward Ag^+ (55–60 mV per decade) over a wide range of Ag^+ concentrations. If the concentration of podand is higher than 6 wt.%, there was no clear advantage in terms of response slope and detection limits of the fresh membrane-based electrodes. Therefore, membranes doped with 6.0 wt.% podands were employed for further studies.

In addition, KTpClPB was used as an anionic additive in the membranes. KTpClPB is known to assist an ionophore's binding capability in many cation-selective membranes [18,19]. As can be seen in Table 1 for E7(I) and E8(II), however, there was no clear advantage of using the additive. Rather, it was revealed that those membrane electrodes showed slightly adverse effects in terms of detection limits and electrical signal to noise.

The equilibrium potentiometric response of the new podand-based PVC membrane electrodes E1(I) and E2(II) toward Ag^+ in the concentration range of 0–10 mM is shown in Fig. 3. Almost Nernstian slopes are observed in both type of electrodes. Surprisingly, unlike most membrane electrodes, the electrodes do not demonstrate a Donnan failure. Rather, there is an increase in slope at Ag^+ concentrations higher than 1 mM. These phenomena may indicate that there is a cooperative interaction between the ion and podand molecules as the concentration of podand-Ag^+ complexes increases in the membrane phase

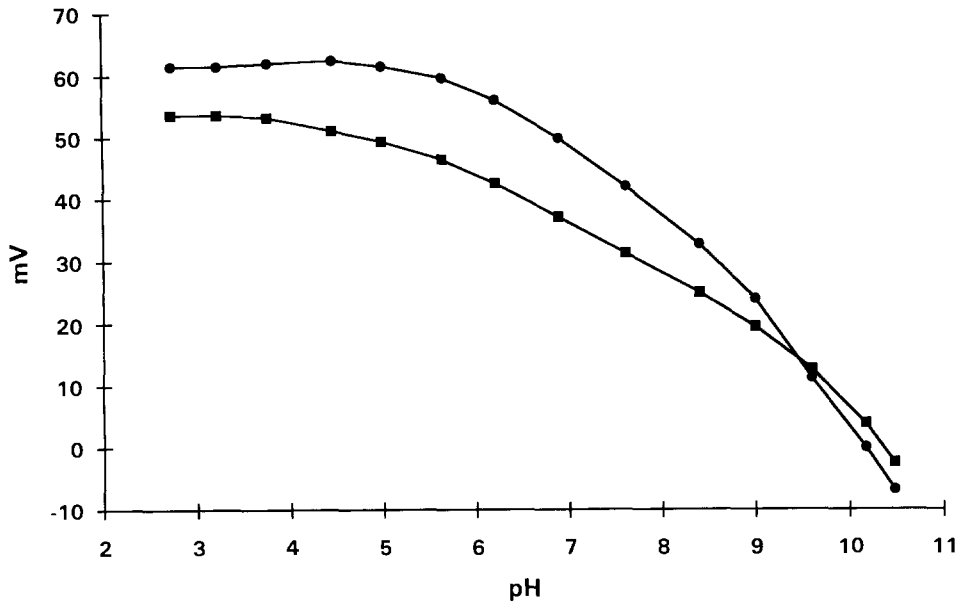

Fig. 4. Potentiometric pH response of the podand-based PVC membrane electrodes: (■) E1, (•) E2 in Table 1, respectively.

(see later discussion on mechanism). Response time of each electrode is short enough. Indeed time required to reach 90% of equilibrium mV values was less than 2 s.

Fig. 4 shows the pH response of E1(I) and E2(II) evaluated by titrating 0.05 M phosphoric acid with 0.1 M sodium hydroxide. These pH responses seem to ascribe to the competitive binding of proton (or hydrated water) to the ligands. Despite of the relatively minor pH response (< 10 mV per decade), 0.05 M Tris buffer, pH 9.0, was used throughout the whole work to dilute/carry sample standards to minimize H^+ interferences.

In terms of lifetime of the PVC membrane electrodes, more than 1 month of response stability was observed (see Table 1).

Table 2 provides the potentiometric selectivity coefficient data of some podand-based PVC membrane electrodes for the interfering cations relative to Ag^+. The data for thiapodand-based electrodes, such as E1(I), E2(II) and E10(IV) show the better response and selectivity to Ag^+ ion with respect to the most common monovalent and divalent metal cations than that of oxopodand, (III, E9). It is noted that oxopodands yield the lower selectivity toward each metal ion, undoubtedly reflecting the relatively poor coordination power of each oxygen donors toward Ag^+ ion.

Table 2
Static mode potentiometric selectivity coefficients[a], $\log k^{pot}_{Ag,x}$ of the podand-based membrane electrodes[b]

Cation	Electrode[c]			
	E1(I)	E2(II)	E9(III)	E10(IV)

Hg^{2+}	−3.9	−3.9	−3.1	−3.9

[a] Measured by the separate solution method at 1 mM cation concentrations in 0.05 M tris-nitric acid, pH 9.0.
[b] Membrane composition (E1–E10) is listed in Table 1.
[c] Roman numerals in parentheses indicate the podands in Fig. 1.

Among thiapodands, O_3S_2 donor set podand with benzyl end group (II, E2) seems to show the best response and selectivity to Ag^+ ion. Values of $\log k_{Ag/x}$ range from -3.4 for K^+ to -5.2 Ba^{2+}, Ca^{2+} and Co^{2+}. For the Hg^{2+} ion, the selectivity coefficient ($\log k_{Ag/Hg}$) was -3.9. Generally the Hg^{2+} ion is known as the most severely interfering ion for the membrane electrodes based on the thia cyclic and acyclic ionophores [10,11].

The presence of O_2S_2 donor set, as occurs in I(E1) and IV(E10) results in good selectivity toward Ag^+ ion. There is no improvement in the performance of the electrode on attaching the long chain to the sensor molecules, as would be expected from their increased lipophilicity.

The relation between the structures of podands and the performance of electrodes from E1(I), E2(II), E9(III) and E10(IV) in Table 2 could be explained by the combination of following two reasons.

The high selectivity toward Ag^+ is due to the high affinity of sulfur atoms in the ionophores. It is well known that the $Ag^+(d^{10})$ exhibits strong affinity toward sulfur derived ligands and show a remarkable preference for linear coordination [8,20]. To explain the Ag^+ ion selectivity of the membrane electrode based on these thiapodands it is essential to take into account all these effect. The monovalent or divalent metal cation tested as interference do not show the strong sulfur affinity or linear coordination preference, except Hg^{2+}.

In addition, improved results were obtained by modifying the aromatic end groups with benzyl groups (II, E2). In our previous NMR [21] and the thermodynamic [14] works, it was suggested that podand II-Ag^+ ion complexes can be stabilized by the partial stacking interaction between two flexible aromatic end groups to give the pseudo-cyclization. This extra stabilization effect by the stacking interaction seems to lead the higher selectivity for Ag^+ ion in membrane electrodes. It is instructive to consider the position of two sulfur atoms, and the size or the length of ether chain in podand I, II, and IV. Podand II is distinguishable in both cases. The inner position of two sulfur in podand II act advantageously to improve the complexation affinity due to the flexible nature of the terminals. Otherwise, it is not a matter of size of the podands, because there is enough flexibility to fit the size of given metal cations.

In summary, two sulfur atoms and flexible benzyl end groups in podand II give rise to increased discrimination for Ag^+ ion, simultaneously.

Fig. 5A shows the typical flow-injection response to Ag^+ ion when an E2 electrode is used as the detector in the FIA arrangement shown in Fig. 2. In the nonequilibrium flow-injection system, response slopes toward Ag^+ ion tend to be somewhat less than observed in static mode experiments (50 mV per decade). In addition, the time required to return completely to baseline potential limits the throughput of the system (20 samples h^{-1}) particularly when the system is exposed to higher concentrations of Ag^+ ion (e.g., greater than 1 mM). Although it shows a limited throughput the reproducibility was satisfactory. For five repeated injections of 1 mM aqueous standard, RSD was 0.7%. As were in the static mode the podand-based electrodes were found to give high selectivities toward Ag^+ over other cations. A typical data is shown in Fig. 5B. Note that the peak heights (ΔmV) for a series of 1.0 mM $AgNO_3$ standards containing different interfering metal ions are essentially the same.

4. Conclusions

We have reported on the potentiometric Ag^+-selectivity of polymer membranes doped with several podands. Considerable response and selectivity toward Ag^+ ion are observed for membranes doped with podands that contain sulfur in their main chain and/or aromatic rings in the tail. When incorporated into an optimal FIA system, the podand-based membrane electrode may serve as a suitable detector for measuring Ag^+ levels in various samples. With further modification of the podand structure, additional enhancement in the potentiometric selectivity toward Ag^+ ion would be possible. Real sample measurements as well as more mechanistic studies (e.g., binding constant measurements) are also warranted.

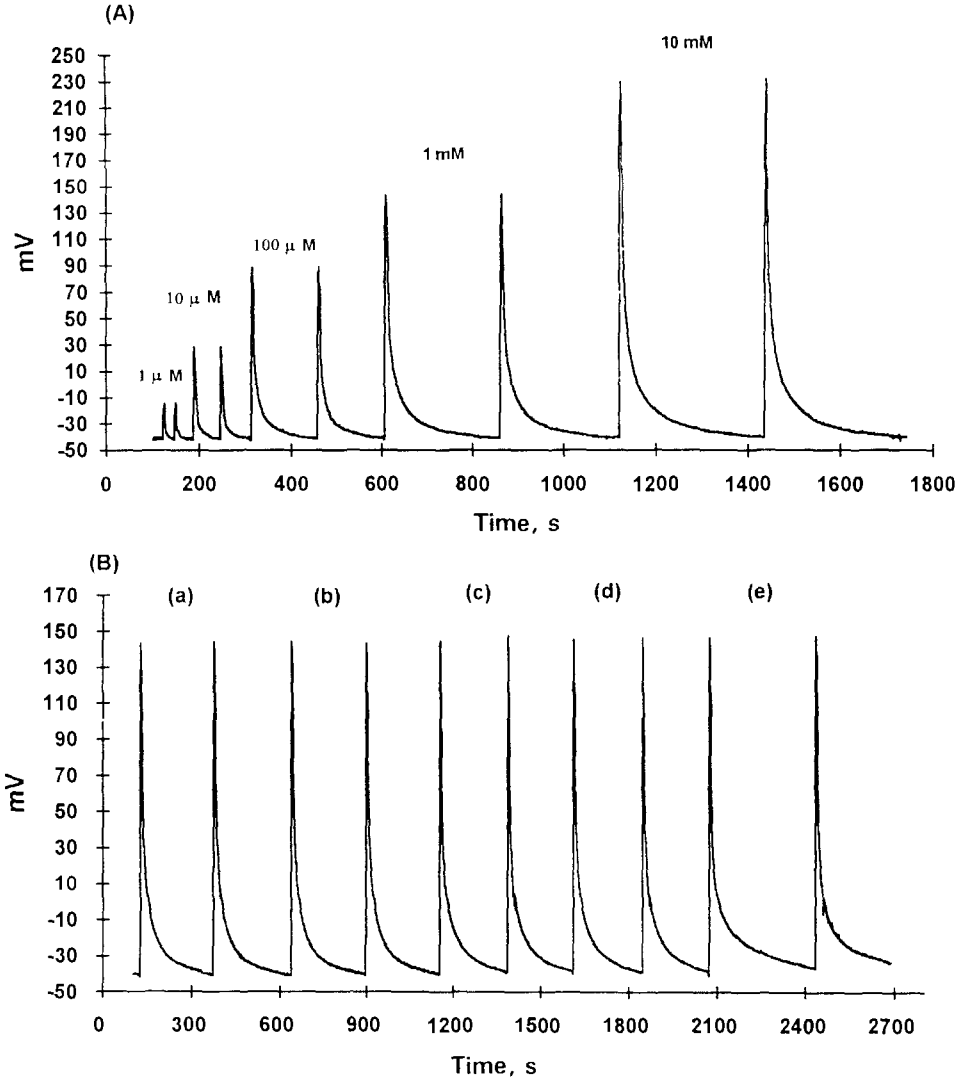

Fig. 5. (A) Potentiometric responses obtained for injections of Ag^+ standards in the FIA system with the podand II-based (E2 in Table 1) PVC membrane detector. (B) Responses for double injections of 1.0 mM $AgNO_3$ containing: (a) no other metal ion; (b) 1.0 mM $NaNO_3$; (c) 1.0 mM $Pb(NO_3)_2$; (d) 1.0 mM $Cu(NO_3)_2$; and (e) 1.0 mM $Hg(NO_3)_2$, respectively, using the Tris buffer, pH 9.0, as carrier stream.

Abstract

A highly water soluble disulfonated tetrazolium salt, 4-[3-(2-methoxy-4-nitrophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate sodium salt, was synthesized. The compound is reduced by NADH in good yields at neutral pHs in the presence of 1-methoxy PMS to produce the corresponding formazan dye that absorbs at 460 nm. The formazan is soluble to water at concentrations higher than 0.1 M. The tetrazolium salt thus proved to be useful as a sensitive chromogenic indicator for NADH. It is also applicable to cell proliferation assays as a cell viability indicator. © 1997 Elsevier Science B.V.

Keywords: Cell viability; Formazan; Lactic acid; Lactate dehydrogenase; Tetrazolium salt; Water solubility

1. Introduction

Tetrazolium salts, which produce highly colored formazan dyes upon NADH reduction, have been of broad application as chromogenic reagents for NADH both in clinical and cell proliferation/cytotoxicity assays. These assays are based on colorimetric quantification of NADH as a detection signal. A major disadvantage of tetrazolium salts, which limits further applications in the both area, is that formazan dyes are extremely water insoluble; colorimetric assays using the tetrazolium salt/formazan system thus suffer from a poor data reproducibility possibly due to a solubilizing process, and are often accompanied by adsorption of the dyes to the assay instruments which resulted in contamination.

In previous work [1–3], we reported a novel disulfonated tetrazolium salt, 4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate sodium salt (WST-1 in Scheme 1), that produces highly water soluble formazan with a solubility greater than 0.1 M. WST-1 is currently employed as a chromogenic indicator for cell's bio-reducibility in viability assays [4–9], rather than for use in the area of clinical chemistry where a higher sensitivity for NADH is required. The sensitivity of WST-1 has been improved in an analogous compound, 4-[3-(4-iodophenyl)-2-(2,4-

WST-8: R^1 = H; R^2 = NO_2; R^3 = OCH_3
WST-3: R^1 = NO_2; R^2 = I; R^3 = H
WST-1: R^1 = H; R^2 = I; R^3 = H

Scheme 1. NADH reduction of WST compound.

dinitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate sodium salt (WST-3) [10], that has a smaller reduction potential than WST-1 because of an additional nitro group (Scheme 1). The sensitivity of WST-3 for NADH is 2.5-fold greater than that of WST-1 at pH 7.4, and, in addition, it is less pH-dependent at important neutral pH range. [10] However, its stability, which is one of the key factors in exploring further applications, is much lower in aqueous solution, giving rise to a substantial increase of blank absorption even when refrigerated. An assumption that the lack of stability in WST-3 is attributable to the two nitro groups on the same benzene ring led us to design a new tetrazolium salt, 4-[3-(2-methoxy-4-nitrophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]

-1,3-benzene disulfonate sodium salt (WST-8), that bears each nitro group at different ring as well as a methoxy group instead of the electron-withdrawing iodo group of WST-3 (Scheme 1).

We describe herein the synthesis and the potential applicability of WST-8, which proved to combine the both advantages of high stability of WST-1 and high sensitivity of WST-3.

2. Experimental

2.1. Apparatus

Thin-layer chromatography (TLC) was performed on Kieselgel 60 F_{254} (Merck, Darmstadt, Germany) using a mixture of *n*-butanol, acetic acid, pyridine and water (4:1:1:2, v/v) as a developing solvent. Absorbance spectra were taken on a Shimadzu UV-210A spectrophotometer. Proton nuclear magnetic resonance (^{1}H-NMR) spectra were measured on a Bruker AC-200P spectrometer at 200 MHz using sodium 3-(trimethylsilyl)-1-propanesulfonate as an internal standard. The splitting patterns were designated as follows: s, singlet; and m, multiplet. IR spectra were recorded in KBr disks on a Hitachi 270-30 spectrometer. Electrochemical measurements were carried out with a Cypress computer-controlled system, model CS-1090/1087 (Lawrence, KS, U.S.A.) in a Tris–HCl buffer (pH 8.0) at a scan rate of 20 mV s^{-1} using a glassy carbon working electrode. Uncorrected melting points were obtained on a Yamato MP-21 melting-point apparatus.

2.2. Materials

1-Methoxy-5-methylphenazinium methosulfate (1-methoxy PMS) was obtained from Dojindo Laboratories (Kumamoto, Japan). Lactic acid lithium salt of greater than 97% purity (enzymatic assay) was purchased from Sigma (St. Louis, MO, U.S.A.). Lactate dehydrogenase isoenzyme (LDH-1 H_4, 98 + % homogeneous)) from human erythrocytes was also from Sigma as a suspension of a 2.1 M $(NH_4)_2SO_4$ solution at pH 6.0. NADH and β-NAD^+ were purchased from Oriental Yeast (Osaka, Japan). The solutions of tetrazolium salts were all prepared as an aqueous solution at a concentration of 1 mM. The following buffers were used: 50 mM citrate (for pH 5–6), 50 mM Tris (for pH 7–9). These buffers were obtained from Dojindo Laboratories. HeLa cells (human uterus carcinoma, Dainippon Phar-

maceutical Co., Tokyo, Japan) were cultured in a Dulbecco's modified Eagle's medium (DMEM) (Gibco Laboratories, NY, U.S.A.) supplemented with 10% fetal bovine serum (Gibco Laboratories) at 37°C and under 5% CO_2 in a CO_2 incubator.

2.3. Assay procedure for NADH

To a mixture containing WST-8 (0.1 mM) and 1-methoxy PMS (5 μM) in 5 ml of 50 mM Tris–HCl (pH 8.0), 0–50 μl of NADH (5 mM) was added to yield a final concentration of 0–50 μM. After the solution was incubated at 22°C for 5 min, the absorbance at 460 nm was measured against a blank prepared in the same manner without NADH addition. The pH of the solution was then raised to 12.5 by adding 100 μl of 4 M NaOH and the absorbance at 640 nm was measured.

2.4. Assay procedure for lactic acid

To a mixture containing a tetrazolium salt (1 mM), 1-methoxy PMS (20 μM) and β-NAD^+ (200 μM) in 5 ml of 100 mM CHES buffer (pH 8.8) was added 0–50 μl of lactic acid lithium salt (10 mM in water) to give a final concentration of 0–100 μM. After the solution was pre-incubated at 30°C for 5 min, 100 μl of LDH (20 U ml^{-1}) was added (final concentration = 0.4 U ml^{-1}). The solution was incubated at 30°C for 10 min; the absorbance was measured at 455 nm (for WST-8), 440 nm (for WST-1), 435 nm (for WST-3) or 340 nm (for UV method).

2.5. Cell proliferation assay

A hundred μl of HeLa cell culture in the logarithmic phase was inoculated onto a 96-well microtiter plate, and the plate pre-incubated for 24 h in a CO_2 incubator at 37°C. A 10 μl of the working solution containing WST-8 and 1-methoxy PMS (0.5 mM and 20 μM, respectively, as the final concentration) was added to each well; it was incubated for an additional 2 h. The absorbance of each well was measured at 450 nm with a reference wavelength at 650 nm with an M-UVmax microplate reader (Molecular Devices Corp., Menlo Park, U.S.A.). An aliquot was taken from the medium to count the number of the cells with a Bürker–Türk haemacytometer (Nitirin, Tokyo, Japan).

2.6. Syntheses

2.6.1. Disodium 4-[1-(2-methoxy-4-nitrophenyl)-5-(4-nitrophenyl) formaz-3-yl]-1,3-benzene disulfonate

Concentrated HCl (4 ml, 48 mmol) was added to a stirred suspension of 5-nitro-*o*-anisidine (2.7 g, 0.016 mol) in water (30 ml), and the suspension was cooled to 0°C. To this suspension was added sodium nitrite (1.2 g, 18 mmol) in water (20 ml) at 0–5°C. After being stirred at approximately 0°C for 30 min, the solution was added to a pre-cooled solution of 2,4-disulfobenzaldehyde-4′-nitrophenylhydrazone, disodium salt [1] (6.7 g, 15 mmol) in water (200 ml). Sodium hydroxide (2.6 g, 64 mmol) in water (40 ml) was added dropwise to the mixture while the temperature was kept at 0–5°C. The solution was stirred at this temperature for 2 h and then at room temperature for an additional 2 h. The reaction mixture was acidified (pH 2) with 3 M HCl and treated with activated charcoal. The reaction mixture was concentrated to roughly one quarter of its volume, which resulted in precipitation of the crude formazan product. The precipitate was collected, dissolved in hot water (400 ml), and re-treated with activated charcoal. The filtrate was concentrated (not to dryness). Addition of isopropanol yielded 5.9 g (63%) of the title compound as a dark-reddish powder. mp: > 300°C (decomp.); TLC: $R_f = 0.60$; ^{1}H-NMR (D_2O): δ 3.78 (3H, s, OCH_3), 7.51–8.21 (10 H, m, Ar), 8.42 (1H, s, NH); FAB-MS: m/z = 624 $[M]^+$.

2.6.2. 4-[3-(2-Methoxy-4-nitrophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate, sodium salt (WST-8)

Concentrated HCl (6.7 ml, 0.08 mol) and *n*-butylnitrite (4.1 g, 0.04 mol) were sequentially added to the formazan as obtained as above (5.0 g, 8 mmol) in methanol (250 ml). After being

stirred at room temperature overnight, the mixture was treated with activated charcoal. The filtrate was concentrated to dryness to leave an oily residue, to which was added tetrahydrofuran to prompt crystallization. The crude product was re-dissolved in water and re-treated with activated charcoal. Concentration of the aqueous solution gave an oily residue. Addition of ethanol and tetrahydrofuran yielded crystals, which were collected to give 2.2 g (45%) of the title compound as a light yellow powder. mp: >300°C (decomp.); TLC: $R_f = 0.55$; IR (cm^{-1}): 1620 (C = N), 1540 (NO_2), 1350 (NO_2); ^{1}H-NMR (D_2O): δ 3.65 (3H, s, OCH_3), 7.99–8.47 (10 H, m, Ar); FAB-MS: m/z = 601 $[M+H]^+$. Anal. Calcd. for $C_{20}H_{13}N_6O_{11}S_2Na$: C, 40.00; H, 2.18; N, 14.00. Found: C, 39.96; H, 2.41; N, 14.27.

3. Results and discussion

WST-8 was synthesized in a similar way as described for WST-1 [1] in a moderate overall yield from 4-formyl-1,3-benzene disulfonic acid disodium salt. Unlike WST-1, however, for which chromatographic purification of the precursor formazan is needed, the formazan of WST-8 could be readily purified by single crystallization with a good recovery.

In the presence of a catalytic amount of 1-methoxy PMS, an electron mediator, WST-8 is readily reduced by NADH to give an absorption at 460 nm in proportion to the NADH concentration. The absorption maximum (λ_{max}) corresponds to λ_{max} of its formazan (Fig. 1). The λ_{max} was longer than that of WST-1 (438 nm) or WST-3 (433 nm), and was largely shifted reversibly to 640 nm when the pH was raised to $\sim$ 12.5, where the molar coefficient (e) value was roughly 1.7-fold greater than the value at 460 nm. Fig. 2 clearly indicates this pH-dependent color change which is characteristic to sulfonated tetrazolium salts. It appears to be reasonable by analogy to WST-3 [10] to assume that imide double bond isomerization of the formazan nucleus, rather than deprotonation, gives rise to the reversible color change. The formazan of WST-8 has a smaller ε value of 3.07×10^4 at pH 8.0 and 460 nm than does WST-1 (3.70×10^4 at pH 8.0 and 433 nm), but it is roughly equal to that of WST-3 (3.01×10^4 at 438 nm). In addition to the ε value, the yield of the product formazan (y) is another important factor that accounts for the sensitivity of tetrazolium salts toward NADH. In an overall NADH reduction expressed as:

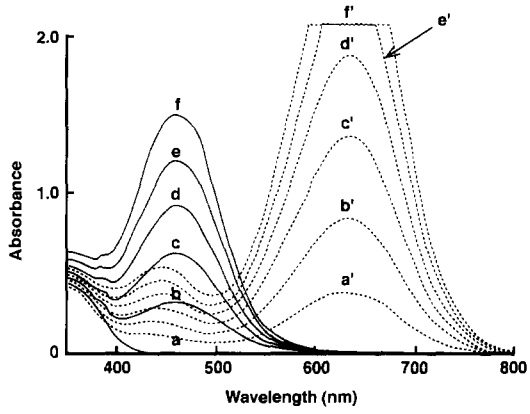

Fig. 1. Absorption spectra of WST-8 (0.1 mM) in the presence of increasing concentration of NADH and 1-methoxy PMS (5 μM). The spectra were taken after 5 min incubation at 22°C. Concentration of NADH (μM): a, 0; b, 10; c, 20; d, 30; e, 40; f, 50. Spectra a–f were taken at pH 8.0 and a'–f' are at pH 12.5.

$$T^+ + NADH \rightarrow F + NAD^+ ([T^+] > [NADH])$$

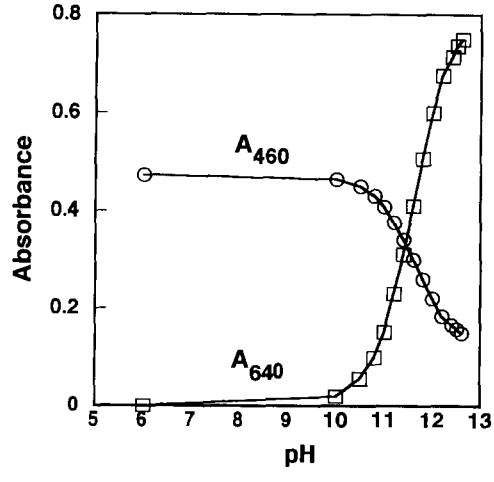

Fig. 2. Absorbance—pH profile of WST-8 formazan (15.4 μM) at different wavelengths. The pH was adjusted with 0.01 M NaOH.

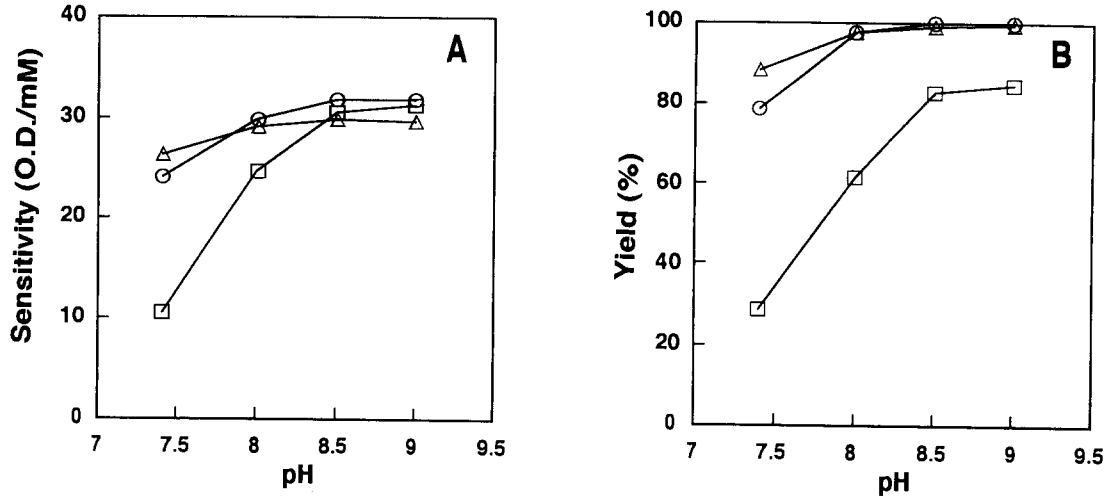

Fig. 3. Sensitivity—pH (A) and yield—pH (B) profiles of WST-8 in comparison with WST-1 and WST-3. ○: WST-8 (460 nm); □: WST-1 (438 nm); △: WST-3 (433 nm). The sensitivity ($\Delta A/\Delta$[NADH]) and the yield (Δ[F]/Δ[NADH]) of the NADH reduction were obtained based on the standard curves of absorbance (A) versus [NADH] that were taken as detailed in the experimental section.

in which T^+ and F stand for a tetrazolium salt and a formazan (= TH), respectively, the sensitivity for NADH is determined to be as follows:

$$\text{sensitivity} = \Delta A/\Delta[\text{NADH}] = \varepsilon(\Delta[\text{F}]/\Delta[\text{NADH}]) = \varepsilon y$$

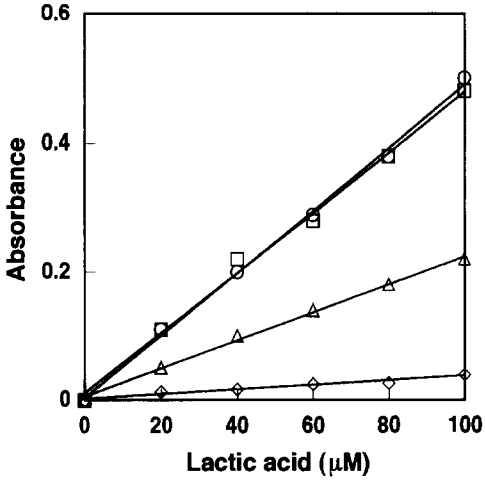

Fig. 4. Standard curves of lactic acid assays using WST compounds. See Section 2. ○: WST-8 (455 nm); □: WST-1 (440 nm); △: WST-3 (435 nm); ◇: UV method (340 nm).

where ΔA is the increase of the absorbance due to formazan formation. Accordingly, both the sensitivity and the yield of tetrazolium salts are given by the plot of the absorbance observed at λ_{max} of the formazan versus concentration of NADH. The sensitivities thus determined for WST-1, -3 and -8 at various pH values are shown in Fig. 3(A), in which good linearities of ΔA versus Δ[NADH] were observed ($r > 0.998$) for these tetrazolium salts, with within-assay coefficients of variation of less than 5% ($n = 5$) under conditions involving 0.1 mM tetrazolium salt and 0–50 mM NADH. Fig. 3(B) shows the yield of formazan as the function of pH, which is similar to the pH profile of the sensitivity (Fig. 3(A)) because ε values are almost constant at the observed pH range. In the figure, WST-8 is more readily reduced by NADH (larger yields) than is WST-1 particularly at important neutral pH range. At pH 8, for example, the NADH reduction of WST-8 takes place almost quantitatively whereas that of WST-1 is of approximately 60% efficiency. This greater reactivity of WST-8 compared with WST-1 toward NADH leads to a higher sensitivity of WST-8, despite the fact that it has a smaller ε value. Furthermore, the sensitiv-

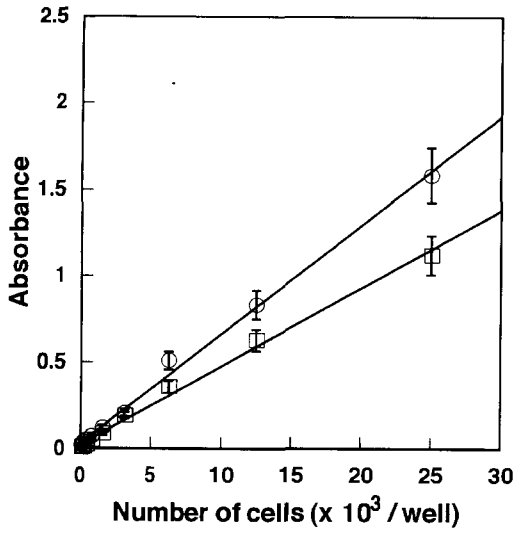

Fig. 5. Cell proliferation assays using WST-8 (○) and WST-1 (□) with HeLa cell line. The assay procedure is detailed in the experimental section.

ity of WST-8 is less pH-dependent. To our knowledge, WST-8 and -3 give the highest sensitivity for NADH among tetrazolium salts so far reported, with almost quantitative yields of reduction at pH higher than 8. However, electrochemical analyses did not support the greater reduction yield of WST-8, as its reduction potential was found to be nearly equal (− 0.37 V) to that of WST-1 (− 0.35 V).

Effects of addition of detergents and bovine serum albumin (BSA) on the sensitivity of WST-8 were also examined. Triton X-100, cetyltrimethylammonium bromide (CTMAB) and sodium dodecyl sulfate (SDS) were tested as a non-ionic, cationic and anionic detergent, respectively, in which SDS at the concentration of 0.1% (w/v) caused the sensitivity to be decreased 32%. The addition of BSA resulted in a similar decrease in the sensitivity; the presence of 1% (w/v) BSA caused a 22% decrease.

The reduction of WST-8 by NADH is very fast. Indeed, the reduction monitored at 460 nm completed within 5 min when it was run at pH 8.0 (50 mM Tris buffer) and 22°C using WST-8 (0.1 mM) and NADH (30 μM) in the presence of 1-methoxy PMS (5 μM); no decrease of the absorbance was observed once it reaches a plateau. The color thus developed was found to be stable for weeks at room temperature.

With the high sensitivity for NADH, we next examined the stability of WST-8 as an aqueous solution since the stability in aqueous solution becomes very important because of a growing demand to supply reagents as aqueous solution for ready use in clinical analyses. An increase of the blank absorbance of WST-8 (1 mM in 50 mM Tris buffer at pH 7.4) at 460 nm after 2 weeks at room temperature was 16% ($\Delta = 0.138$) of that of WST-3 at its λ_{max} under the same conditions, a value close to that of WST-1. The blank absorbance increase was less than 0.1 when the solution was refrigerated for 30 days. WST-8, therefore, combines advantages of the higher sensitivity from WST-3 and the greater aqueous stability of WST-1.

WST-8 was applied to the assay of lactic acid which is based on LDH-mediated dehydrogenation of the acid to pyruvic acid and NADH. Fig. 4 shows the standard curves of the tetrazolium salts for lactate, in comparison with a UV method that measures an increase of the absorbance of NADH directly at its λmax of 340 nm. Relative standard deviations for WST-8 determined by five separate runs for each point in the figure did not exceed 5%. The sensitivity of WST-8 toward lactic acid, as determined as $\Delta A/\Delta$[lactate] (O.D. mM^{-1}), was almost equal (4.86) to that of WST-1 (4.67), and was 2.2-fold larger than that of WST-3; it is sensitive enough to detect lactic acid in serum that ranges sub-mM to 2 mM. A poor sensitivity of WST-3 is partly due to a large background absorption as the sensitivity for NADH is comparable to those of WST-1 and -8.

We then turned our attention to using WST-8 as a viability indicator in cell proliferation assays. When HeLa cells were incubated with tetrazolium salts in the presence of 1-methoxy PMS, a linear colorimetric response was obtained in proportion to the number of viable cells with good correlation coefficients ($r = 0.9981$ and 0.9970 for WST-8 and WST-1, respectively) (Fig. 5). WST-8 gave 1.39-fold greater sensitivity than WST-1, for which increasing number of applications have been reported [4–9], under identical assay conditions.

In conclusion, WST-8 combines the best features of WST-1 and -3, being sensitive and stable. In addition, it is much easier to synthesize, which is a practical advantage to enable a cost-effective synthesis. We have also demonstrated that WST-8 has a great potential as a viability indicator in cell proliferation/cytotoxicity assays. Further application is currently underway.

Solvent extraction, spectrophotometric and inductively coupled plasma atomic emission spectroscopic (ICP-AES) determination of lanthanum(III) with crown hydroxamic acid

Yadvendra K. Agrawal *, Pranav Shrivastav

Chemistry Department, School of Sciences, Gujarat University, Ahmedabad 380 009, India

Received 17 July 1996; received in revised form 7 January 1997; accepted 8 January 1997

Abstract

A new crown hydroxamic acid, 5,14-*N*,*N*′-hydroxyphenyl–4,15-dioxo-1,5,14,18-tetraaza hexacosane (NHDTAHA) for the extraction and spectrophotometric determination of lanthanum(III) is described. Lanthanum(III) forms a yellow coloured complex with NHDTAHA, which is extracted with chloroform, having molar absorptivity 7.7×10^3 l mol^{-1} per cm at 372 nm. The system obeys Beer's law in the range 1.2–20 ppm of lanthanum. The extract is directly aspirated for ICP–AES measurements, the limits for estimation are 5–140 ppb of lanthanum. Lanthanum has been determined in monazite sand and standard samples. © 1997 Elsevier Science B.V.

Keywords: Crown hydroxamic acid; Inductively coupled plasma atomic emission spectrophotometry (ICP-AES); Monazite sand; Lanthanum(III); Spectrophotometry

1. Introduction

Liquid–liquid extraction technique is widely used for preconcentration and separation of various metal ions from an interfering matrix. Hydroxamic acids are superior reagents for extraction and spectrophotometric determination of metal ions [1–5]. In recent years the macrocyclic ligands, crown ethers, have been reported for metal complexation [6–10]. However, the methods for the extraction and determination of lanthanum with crown ethers suffer from low sensitivity and interference of diverse ions [11,12]. The direct atomic absorption and inductively coupled plasma emission determination of lanthanum is reported, but a prior ion exchange separation is required [13,14]. The complexities of lanthanum emission lines with large number of strong ionic lines cause some difficulties over line selection thereby causes overlaps and reduces the detection limits considerably [15,16]. The very low levels at which the lanthanum is sought and potential interference from major elements, have led to the use of separation method to remove the bulk of major elements and at the same time to concentrate the lanthanum from the samples into small volume of solution.

The use of strongly luminous flame is physically unpleasant and the photomultiplier receives high background radiation that can cause fatigue of the photo responsive surface of the cathode, even though the continuum radiation is not amplified. With this view a new crown hydroxamic acid is used for the extraction and simultaneous determination of lanthanum in presence of several diverse ions. The extraction removes the bulk of the major elements and at the same time concentrate the lanthanum into small volume of solution and the extract is directly injected into the plasma which increases the sensitivity and detection limit to several folds.

2. Experimental section

2.1. Apparatus

A Hitachi 3210 Spectrophotometer with matched 10 mm quartz cells was used for spectral measurements. Plasma Scan Model 710 Sequential Inductively Coupled Plasma Atomic Emission Spectrophotometer with Plasma Scan multitasking computer and peristaltic pump was used.

The following operating conditions were set for ICP–AES: Rf 27.12 MHz, incident power 2000 watts; GMK nebulizer; sample concentration 1 ng ml^{-1}; RF power 5 watts; observation height 14 mm; argon coolant flow rate 10 l min^{-1}; argon carrier flow rate 1 l min^{-1}; intergraph period 10 s; resolution 0.004 nm; peristaltic pump flow rate 1 ml min^{-1}; wavelength 394.91 nm.

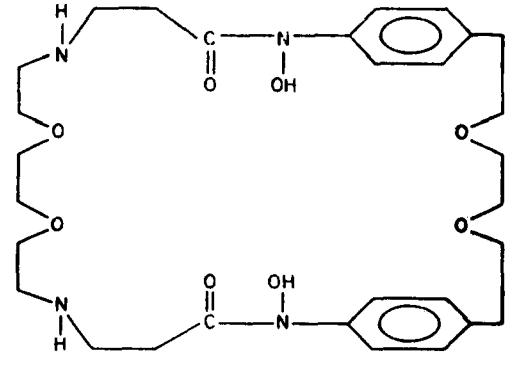
2.2. Reagents

All chemicals used were of analytical grades of BDH or E. Merck. The ligand 5,14-*N*,*N*′-hydroxyphenyl-4,15-dioxo-1,5,14,18-tetraaza hexacosane (NHDTAHA) (Scheme 1) was synthesized by reacting 3,6-dioxoctane-1,8-diphenylhydroxylamine with 4,15-diamino-4,-13-dioxohexadecane-1,16-dioic acid chloride [17] in etherial medium in presence of suspended sodium bicarbonate as described elsewhere [18]. Its 0.2% stock solution was prepared in acetone. A standard lanthanum solution was prepared by dissolving 2.276 g of lanthanum acetate hydrate in a litre of double distilled water in the presence of HCl. Its final concentration 7.20×10^{-3} M was determined volumetrically [19]. It was further diluted as and when required. Buffer solution of pH 9 was prepared by mixing 40 ml of 1 M HNO_3 and 100 ml of 15% triethanolamine [20].

2.3. Extraction procedure

An aliquot of sample solution containing 30–500 ppm of lanthanum was transferred into a 60 ml separatory funnel. 10 ml of 0.2% NHDTAHA in acetone was added. pH 9 was adjusted with 2 ml of buffer solution and the mixture was shaken with 15 ml of chloroform for 1 min. The organic extract was collected, dried over anhydrous sodium sulphate and transferred into a 25 ml volumetric flask. To ensure the complete recovery of lanthanum, the extraction was repeated, adding 5 ml of NHDTAHA along with 5 ml of chloroform. The sodium sulphate was washed with chloroform and the combined extracts and washings were diluted to the mark with chloroform. The absorbance of the organic phase was measured against the reagent blank at 372 nm. For ICP-AES determination the lanthanum-NHDTAHA chloroform extract was introduced into the plasma by peristaltic pump.

The values of the percentage extraction (%E) and distribution ratio (D) of lanthanum was cal-



Scheme 1. 5,14-*N*,*N*′-hydroxyphenyl-4,15-dioxo-1,5,14,18-tetraaza hexacosane hydroxamic acid (NHDTAHA).

culated at different pH and NHDTAHA concentrations.

3. Results and discussion

3.1. Absorption spectra, Beer's law and precision

The Lanthanum(III)–NHDTAHA complex has a maximum absorbance at 372 nm and reagent blank does not absorb at this wavelength. The system obeys Beer's law in the range 1.2–20 ppm of lanthanum, sensitivity 0.018 ppm and the molar absorptivity is 7.7×10^3 l mol^{-1} cm^{-1}. The regression analysis represent Conc. = 18.8 × Absorbance with correlation coefficient 1.00.

Under the optimum conditions for ICP–AES determination, a linear calibration graph was obtained between 5 and 140 ppb of lanthanum. The determination of standard solution containing 20 ppb of lanthanum gave a relative standard deviation of 2.5%. The detection limit, expressed as the concentration of lanthanum giving a signal equivalent to three times the standard deviation of the blank plus the net blank intensity, was measured to be 0.18 ppb.

3.2. Effect of pH and shaking time

The percentage extraction and formation of chelate is also influenced by the pH of the solution. Maximum extraction of lanthanum with NHDTAHA was obtained in the pH range 8.5–9.5 (Fig. 1). At both lower and higher pH the extraction was incomplete (Table 1). The extraction is instantaneous, however, 1 min shaking is sufficient for quantitative extraction of lanthanum.

3.3. Effect of NHDTAHA concentration

The influence of NHDTAHA was studied by extracting lanthanum (1.78×10^{-4} M) with different amounts of NHDTAHA. It has been observed (Table 2) that 10 ml of 3.62×10^{-3} M reagent NHDTAHA is quite adequate for the complete extraction of lanthanum. The lower concentration of NHDTAHA reduces the percentage extraction, while a large excess of reagent can be used without any difficulty.

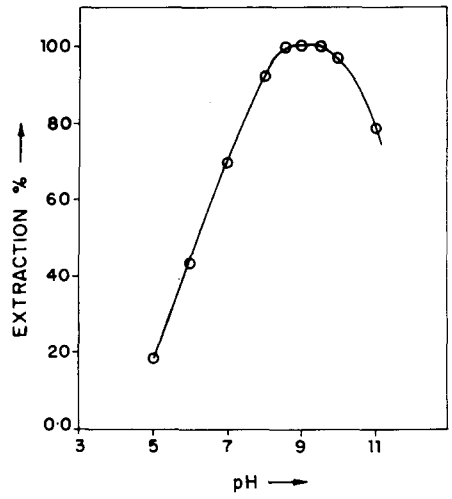


Fig. 1. Plot of percentage extraction of lanthanum against pH.

3.4. Stoichiometry of the complex

The composition of the Lanthanum(III)-NHDTAHA complex extracted into chloroform has been studied by slope ratio method [21] viz. by plotting a graph of logarithm of the distribution ratio of the metal ($\log D_M$) against the negative logarithm of ligand concentration ($-\log$ ligand).

Table 1
Effect of varying pH on the extraction of Lanthanum(III)–NHDTAHA complex

pH	Extraction (%)	Molar absorptivity (l mol^{-1} cm^{-1})
5.0	18.5	1.4×10^3
6.0	43.5	3.3×10^3
7.0	70.0	5.3×10^3
8.0	91.8	7.0×10^3
8.5	100.0	7.7×10^3
9.0	100.0	7.7×10^3
9.5	100.0	7.7×10^3
10.0	97.0	7.4×10^3
11.0	78.4	6.0×10^3

The lanthanum in the aqueous phase was determined by ICP-AES.
Solvent, chloroform; Lanthanum, 12 pm; NHDTAHA, 10 ml, 3.62×10^{-3} M in acetone; and λ_{max}, 372 nm.

Table 2
Effect of varying concentration of reagent for the extraction of Lanthanum(III)—NHDTAHA complex

NHDTAHA ($M \times 10^{-3}$)	$-\log$ (NHDTAHA)	Lanthanum conc. (M)		Log D_M
		$[La_{org}] \times 10$	$[La_{aq}] \times 10^{-4}$	
0.90	3.04	1.49	0.297	0.70
1.26	2.89	1.55	0.236	0.82
1.80	2.74	1.61	0.180	0.95
2.70	2.56	1.66	0.128	1.11
3.62	2.44	1.78	0.08	1.35
4.46	2.35	1.78	0.08	1.35

The detection limit for lanthanum is 8.0×10^{-6} M.
The lanthanum in aqueous phase was determined by ICP–AES.
Solvent, chloroform; pH, 9; and λ_{max}, 372 nm.

The extraction was carried out by taking a fixed amount of lanthanum with varying amounts of NHDTAHA. The plot of log D_M against $-\log$(ligand) gave a straight line of a slope 0.89 (Fig. 2), which indicates the composition of the complex is 1:1, thus 1 mol of ligand (NHDTAHA) is required for 1 mol of lanthanum. The NHDTAHA is having two hydroxamic groups (2L) and hence the expected structure of the complex is [La(OH)(2L)].

To get more information about the nature of the extracted complex, attempts were made to isolate it from chloroform extract. The extract was evaporated to dryness and subjected to elemental analysis. Further a known weight of the dry complex was digested with perchloric and nitric acid mixture and lanthanum content was determined by ICP–AES. The experimental results obtained for the complex are carbon 48.75%, nitrogen 7.41%, hydrogen 5.80% and lanthanum 18.65% and are comparable to the theoretical values for carbon 48.53%, nitrogen 7.54%, hydrogen 5.83% and lanthanum 18.71% which are in conformity with the complex formula [La(OH)(2L)].

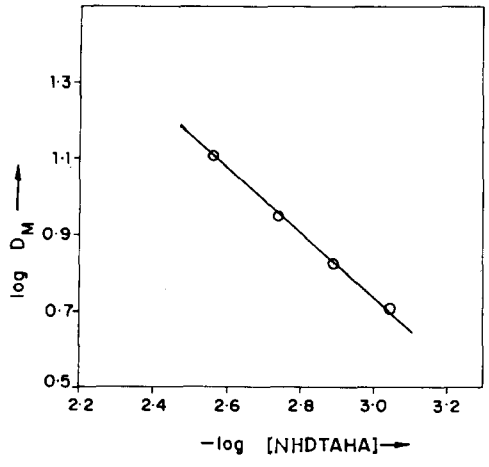

Fig. 2. Plot of distribution ratio of lanthanum [D_M] against crown hydroxamic acid [NHDTAHA].

3.5. Effect of solvents

The extraction was carried out with various solvents viz. chloroform, benzene, toluene and isoamyl alcohol. The results given in Table 3 show that the chloroform is the most appropriate solvent for the quantitative extraction of lanthanum.

Table 3
Effect of solvents on the extraction of Lanthanum(III)—NHDTAHA Complex

Solvent	Extraction (%)	Molar absorptivity ($l\ mol^{-1}\ cm^{-1}$)
Chloroform	100	7.7×10^3
Benzene	24	1.8×10^3
Toluene	29	2.2×10^3
Iso-amyl alcohol	[a]	—

Lanthanum, 2 ppm; NHDTAHA, 10 ml, 3.62×10^{-3} M in acetone; pH, 9; and λ_{max}, 372 nm.
[a] No extraction was obtained in iso-amylalcohol

Solvent, chloroform; Lanthanum, 10 ppm; NHDTAHA, 10 ml, 3.62×10^{-3} M in acetone; pH, 9; and λ_{max}, 372 nm.
[a] Stripped with sodium fluoride.
[b] Stripped with sodium oxalate.
[c] Reduced with sodium nirite.

3.6. Effect of diverse ions

Lanthanum was selectively separated and determined in presence of various metal ions viz. Th(IV), U(Vl), Zr(IV), Hf(IV), Sc(III) etc. Scandium, being extracted at a considerably lower pH with hydroxamic acids, is not interfering in the extraction of lanthanum. However, yttrium(III) (> 20 ppm), cerium(IV) (> 10 ppm), praseodymium(III) (> 20 ppm) and neodymium(III) (> 20 ppm) do interfere in the determination of lanthanum. The interference of cerium(IV) can be eliminated by reducing it to cerium(III) with sodium nitrite. Lanthanum, 12 ppm, in presence of 40 mg each of yttrium, praseodymium and neodymium is extracted either masking these with fluoride (1:20) and oxalate (1:1000; 1:1500), respectively or after stripping yttrium with 0.1 M sodium fluoride and praseodymium and neodymium with 2.5 M sodium oxalate. The results obtained are given in Table 4.

3.7. Determination of lanthanum in standard samples

Standard lanthanum samples were analyzed to test the reliability of the present method. The samples were digested in a mixture of perchloric

acid and nitric acid and evaporated to dryness. The residue was redissolved in 0.5 M perchloric acid and diluted to 250 ml with distilled water. An aliquot of this solution was taken for extraction and determination of lanthanum. The data are given in Table 5.

4. Conclusion

The present method is simple, sensitive and selective. Lanthanum(III) is first pre-concentrated by solvent extraction and then subjected to a versatile technique, ICP–AES, which enhances the sensitivity many folds (detection limit 0.18 ppb) compared with its non-extract estimation. The proposed method overcomes the problem of spectral interference due to matrix components, nebulizer blockage due to high solid content of the solution or analyte emission enhancement.

Abstract

The ion exchange behavior of Au and Pt on a new China-made macropore anion resin was studied using radiotracer technique. The conditions for adsorption and desorption, such as acidity, flow-rate and concentration of desorbing agents were studied carefully. Using the established method, the contents of Au and Pt in two Chinese ultrabasic SRMs were determined by ICP-MS and the results found in good agreement with the reference values.

Keywords: Au and Pt adsorption and desorption; HHY-10A macropore resin; ICP-MS; Radiotracer technique

1. Introduction

With an average concentration of 5 ppb [1] in the earth crust, platinum belongs to the category of the most rare naturally occurring elements. The omnipresent concentration of platinum in environmental and biological samples is estimated to lie in the ppt region, or even lower. There are only very few reliable data available about it, simply for the reason that no analytical procedures with sufficient detection sensitivity are yet existing.

Since the introduction of automobile exhaust catalytic cleaning, platinum has become a new environmental pollutant [2]. The concentration of Pt in ocean water has been reported to be higher than that existing in fresh water [3]. Thus, the concentration of Pt in ocean organisms is likely very high. Perhaps more and more intake of seafood will lead to an unexpected effect. This potential new impact to human health has initiated research to develop analytical methods for the Pt detection at very low levels.

Gold is an element coexisting with Pt generally in biological and environmental samples. Thus, it is convenient and hopeful to get the content of Au

simultaneously in analyzing Pt in a portion of sample.

Since the conventional analytical techniques, such as graphite furnace atomic absorption spectrometry (GFAAS) [4], instrumental neutron activation analysis (INAA) [5] and inductively coupled plasma-mss spectrometry (ICP-MS) [6] are not able to analyze Pt at such a low content, a preconcentration of Pt is necessary. Alt et al. [7] used MIBK extraction to preconcentrate Pt from biological and environmental materials, but this method is inconvenient in dealing with great amount of samples with low-level Pt. Parent et al. [8] reported an adsorption chromatography method with high recovery and minor interference of other elements, but the method is very time consuming. Ion exchange is a widely used method for separation due to its high adsorption capacity and unique selectivity, we selected it to preconcentrate Pt and Au from practical samples.

To develop the preconcentration procedures, radiotracer technique are very helpful because of its easy detection. ^{195m}Pt and ^{199}Au have suitable half-lives (^{199}Au 3.14d; ^{195m}Pt 4.02d) [9] and γ-ray energies(^{199}Au 158.38 keV; ^{195m}Pt 98.88 keV) [9] and can be produced from a kind of chemical only containing Pt. In this work, we studied the adsorption and desorption behaviors of ^{199}Au and ^{195m}Pt on a new China-made HHY-10A macropore anion resin. Since no biological or environmental reference materials with certificated values for Pt and Au is available up to date, we preconcentrated Au and Pt from China-made geological standard reference materials DZΣ-1 and DZΣ-2 and determined them by ICP-MS.

2. Experimental

2.1. Instruments and apparatus

A miniature nuclear reactor (China Institute of Atomic Energy); a γ-ray spectrometer system (HPGe detector of Nucleus, PCA-II-8000 multianalyzer, detection effect 25% and resolution 1.96 keV for 1332 KeV peak of ^{60}Co); a Teflon column (ϕ10 mm × 250 mm) with adjustable flow-rate and various plastic vials (ϕ5 mm × 35 mm; ϕ10 mm × 50 mm) for measuring the radioactivities.

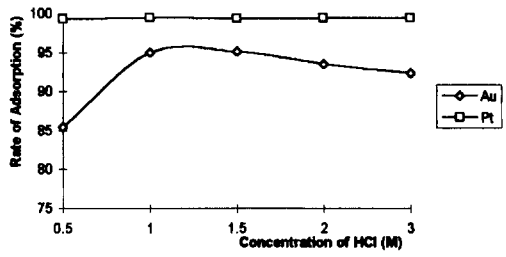

Fig. 1. Effect of HCl concentration on Au and Pt adsorption on HHY-10A resin (20 ml HCl, flow-rate 1.0 ml min^{-1}).

2.2. Radiotracers and other reagents

The radiotracers ^{195m}Pt and ^{199}Au are made of the same chemical reagent (H_2PtCl_6). The chemical, 300 mg was irradiated in the nuclear reactor for 5 h (neutron flux 5×10^{11} n cm^{-2} s), the ^{195m}Pt was formed via ^{194}Pt(n, γ) reaction, while the ^{199}Au via ^{198}Pt(n, γ)^{199}Pt, and followed by its β^- decay in the same time. After cooling for 24 h, the chemical was dissolved in 50 ml 0.5 M HCl as stock solution. All other reagents, such as HCl and thiourea, are A.R degree, and the water is deionized. The HHY-10A resin is a kind of macropore resin with Cl ionic form, it has a large exchange capacity (4.1 mmol g^{-1}) and a proper wet density (0.69 g ml^{-1}), its particle size, cross-linkage, specific surface, porosity and hole diameter are 0.3–1.2 mm, 4%, 38 m^2 g^{-1}, 0.54 cm^3 g^{-1} and 24.2 nm, respectively, and the functional group amido is bound to the polystyrene diethylenebenzene frame.

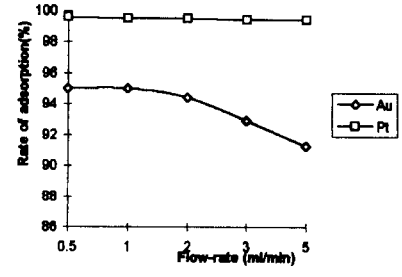

Fig. 2. Effect of flow-rate on adsorption of Au and Pt on HHY-10A resin (20 ml 1.0 M HCl).

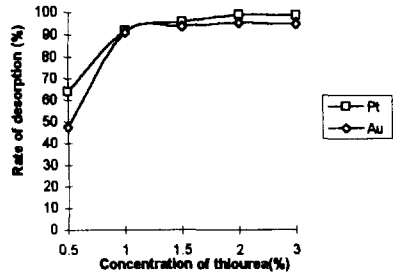

Fig. 3. Effect of thiourea concentration on desorption of Au and Pt on HHY-10A (20 ml thiourea, 1.0 ml min^{-1}).

2.3. Adsorption and desorption

The column was filled with about 1.0 g (20 mm high) pretreated HHY-10A resin, which was prebalanced with 0.5 M HCl overnight before use. Pipetted 1.00 ml of the stock solution into a 50 ml beaker, diluted it with 19.0 ml HCl which has a certain concentration. Transferred the diluted radiotracer solution into the column and adjusted the flow-rate to obtain a certain flow velocity, collected the eluent (2 ml each counting vial) and measured the radioactivity of ^{195m}Pt and ^{199}Au at the same time, 2 ml of the stock solution was used as the relative standard. Added the contents of Au and Pt in each vial together to get the total contents Au and Pt which were not been adsorbed, and then the contents of adsorbed Au and Pt could be calculated, the latter were used to calculate the adsorption rates of Au and Pt. After washing the column with 20 ml 0.5 M HCl at 2 ml min^{-1} velocity, desorbed Au and Pt with 20 ml thiourea solution of a certain concentration at a certain flow velocity, collected each 2 ml of the desorbed solution and measured ^{195m}Pt and ^{199}Au.

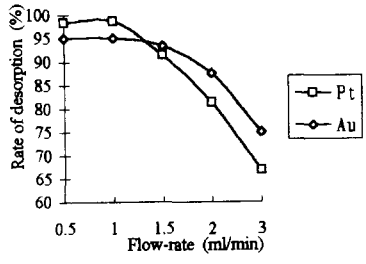

Fig. 4. Effect of flow-rate on the desorption of Au and Pt on HHY-10A resin (20 ml 2% thiourea).

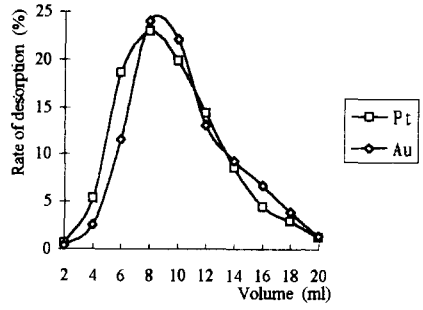

Fig. 5. Desorption curves of Au and Pt from HHY-10A resin (20 ml 2% thiourea at 1.0 ml min^{-1}).

Added the contents of Au and Pt in each vial together to get the total contents of Au and Pt desorbed, and then the desorption rates of Au and Pt were calculated. The stock solution, 2 ml, was used as the relative standard.

2.4. Analysis of SRMs

Pt and Au in some China-made geological standard reference materials ultrabasic DZΣ-1 and DZΣ-2 were preconcentrated using the above described method and determined with ICP-MS. Before preconcentration, 10.00 g of the samples were baked at 600°C for 1 h to oxide the organisms and dissolved in 100 ml aqua regia. Evaporated the solution to near dryness and drove HNO_3 off with 10 ml concentrated HCl, repeated twice. And then, dissolved the residue with 50 ml 1.0 M HCl and filtered it, washed the residue with another 50 ml 1.0 M HCl. After preconcentration, the solution containing Au and Pt was treated and the concentrations of Au and Pt were determined. The method of determination using ICP-MS was reported elsewhere [10].

3. Results and discussion

3.1. Adsorption acidity

The adsorption of Pt is almost complete in the range of 0.5–3.0 M HCl (1.0 ml min^{-1} flow-rate). Fig. 1 shows the effect of the HCl concentration on the adsorption percentage of Pt and Au. The

Table 1
The contets of Au and Pt in DZΣ-1 and DZΣ-2 ($n = 2$, ng g^{-1})

Samples	DZΣ-1 [10]		DZΣ-2 [10]	
	Experimental values	Reference values [10]	Experimental values	Reference values [10]
Pt	3.9	4	6.0	6
	4.8		7.1	
Mean	4.4 ± 0.5		6.6 ± 0.6	
Au	1.3	1.4	0.3	0.4
	1.9		0.8	
	1.6 ± 0.3		0.6 ± 0.3	

maximum adsorption of Au is at about 1.2 M HCl and the adsorption increases or decreases gradually with the concentration of HCl increasing before 1.2 M or decreasing after that. It is evident that the adsorption is less than 96% in any case, perhaps it is due to the change of Au valence during the nuclear decaying process. Most of the Au atoms exist as Au^{3+}, perhaps there is a minor existing in Au^{+}, whose ability to form complex ions is not as good as Au^{3+}. Thus, the adsorption rate of Au^{+} is less than Au^{3+} during the adsorbing stage. But generally speaking, the adsorption of Au is satisfactory.

3.2. Adsorption flow-rate

Each of the flow-rate tested (0.5–5.0 ml min^{-1}) has a almost complete adsorption of Pt (HCl concentration 1.0 M). Fig. 2 shows the recoveries of Pt and Au at different flow-rates. Obviously, Au can be adsorbed quantitively at a flow-rate of ≤ 2 ml min^{-1}.

3.3. Desorption conditions

Fig. 3 shows the recoveries of Au and Pt desorbed with 20 ml different concentration of thiourea (1.0 ml min^{-1} flow-rate) from the column. Evidently, Au and Pt can be desorbed quantitively by 20 ml 2% (w/w) thiourea and their recoveries are greater than 91% when 20 ml 1% thiourea is used as desorbent. Fig. 4 shows the effect of flow-rate on the desorption of Au and Pt (2% thiourea), it can be seen that the rate of desorption decreases dramatically when the flow-rate is greater than 1.5 ml min^{-1}, and the quantitative desorption happens only at the flow-rate not exceeding 1.0 ml min^{-1}. Fig. 5 describes the desorption curves of Au and Pt (20 ml 2% thiourea at 1.0 ml min^{-1}).

3.4. Precision and accuracy

At the optimum conditions (adsorption in 1.0 M HCl at 1.0 ml min^{-1}, desorption with 2% thiourea at 1.0 ml min^{-1}), using 1.0 ml radiotracer stock solution replicated the experiments for three times. The total recoveries of Au and Pt are $(92.3 \pm 2.6)\%$ and $(97.7 \pm 0.9)\%$, respectively. The analytical results for ultrabasic SRMs DZΣ-1 and DZΣ-2 are listed in Table 1, which are in good agreement with the reference values [10].

4. Conclusion

The radiotracer technique is very convenient and successful in establishing preconcentration procedure for Au and Pt. The HHY-10A anion resin is suitable for preconcentrating Pt and Au for the quantitative adsorption and easy desorption at the optimum conditions we experimented. The SRMs analytical results agreed with the reference values very well.

A selective optical chemical sensor for *o*-nitrophenol based on fluorescence quenching of curcumin

Ying Wang [1], Ke-Min Wang, Guo-li Shen, Ru-Qin Yu *

Department of Chemistry and Chemical Engineering, Hunan University, Changsha, 410082, People's Republic of China

Received 19 July 1996; received in revised form 10 January 1997; accepted 20 January 1997

Abstract

An optical chemical sensor has been prepared for the selective determination of *o*-nitrophenol in aqueous solutions based on the fluorescence quenching of curcumin in PVC membrane. The sensing mechanism of the proposed sensor for *o*-nitrophenol has been discussed in detail. The fluorescence changes of sensing membrane resulted from an associated complex formation between curcumin and *o*-nitrophenol. In pH 4.8 buffer solution, the sensor responds linearly in the measuring range from 1.0×10^{-2} mol l^{-1} to 1.5×10^{-4} mol l^{-1}, and the experimental detection limit is evaluated to be 8.0×10^{-5} mol l^{-1}. A stable signal was obtained within less than 1.5 min. Under the optimum conditions, the sequence of selective response to the sensing membrane is *o*-nitrophenol > 2,4-dinitrophenol > *m*-nitrophenol > *p*-nitrophenol > 2,4,6-trinitrophenol. Phenol, aniline as well as other ions have less effect on the fluorescence of the sensor. The reproducibility for the determination of *o*-nitrophenol is better than 1%, and the response is reversible. The sensor can be used for the determination of *o*-nitrophenol in water samples. © 1997 Elsevier Science B.V.

Keywords: Curcumin; Fluorescence quenching; Optical sensor

1. Introduction

In recent years, owing to the development of a large variety of devices and techniques of the optical fiber sensing and its potential advantages over electrochemical sensing, the interest in the development of optically based chemical sensors has been increasing considerably. A common feature of this kind of sensors is that an immobilized reagent phase changes the optical properties upon interaction with an analyte. Therefore, the selection of immobilized reagents plays the central role in the development of the optical chemical sensors. The sensing materials in optode membrane based on fluorescence described in the literature include polycyclic aromatic hydrocarbons [1,2], laser dyestuff compounds [3], hydroxyquinoline compounds [4], and some newly synthesized fluorescence reagents [5]. In this work, an organic chromogenic reagent curcumin widely used for the measurement of trace boron in various samples is employed as the sensing material in optode

membrane utilizing its excellent fluorescence property and high lipophilicity.

Though different kinds of optical fiber chemical sensors have been reported in the literature measuring various species important for environmental monitoring such as ammonia [6], sulfur dioxide [7], nitrogen dioxide [8], organochlorinated compounds [9], nitro-compounds [10,11], and humidity [12], to our knowledge, however, no sensors have been reported for the determination of *o*-nitrophenol.

The monitoring of nitrophenols is essential for environmental pollution control and industrial applications. In the past, after being reduced and transformed into azostuffs, the compounds formed were detected with spectrophotometry or polarography [13]. More recently, nitrophenols are determined with GC or HPLC [14–16]. Questions remain, however, as to how to realize the on line and continuous determination of *o*-nitophenol with a non-destructive device such as an optical chemical sensor.

We discovered that *o*-nitrophenol in buffer solution of pH = 4.8 can strongly quench the fluorescence of curcumin. A new sensor using curcumin as sensing material for the selective determination of *o*-nitrophenol has been prepared. The sensor can respond selectively, rapidly and reversibly to *o*-nitrophenol. These analytical characteristics make it possible to determine *o*-nitrophenol in mixtures containing appropriate amounts of other nitrophenols. The analytical results obtained by recovery measurement are satisfactory.

2. Experimental

2.1. Apparatus

All fluorescence intensities were measured with a Hitachi M-850 fluorescence spectrophotometer equipped with a xenon lamp. For measuring fluorescence quenching, the excitation and emission wavelengths were set to 426 and 512 nm, respectively.

2.2. Chemicals

Unless otherwise stated, all solutions were prepared from analytical-reagent grade with redistilled water. For membrane preparation, the following reagents were purchased and used without further purification: high relative molecular mass poly(vinyl chloride)(PVC)(Zhuzhou Chemical Plant), tetrahydrofuran(THF) (Shanghai Chemical Reagent Corporation), curcumin (The Third Reagent Plant of Shanghai), tricresyl phosphate (C.P. The First Reagent Plant of Shanghai). Test solutions of *o*-nitrophenol were prepared by dilution of the stock standard solution. Acetate buffer solution (pH = 4.8) was prepared by dissolving 50 g of sodium acetate trihydrate in 500 ml of water, adding 34 ml of 6 mol l^{-1} acetic acid and diluting to 1 l.

2.3. Procedure

2.3.1. Membrane preparation

A medium containing 4.0 mg of curcumin, 50 mg of PVC, 100 mg of tricresyl phosphate was dissolved in 2 ml of THF. By means of a spin -on device [1], a membrane of approximately 4 μm thickness was cast onto a 35 mm diameter quartz plate.

2.3.2. Measurement of o-nitrophenol

Two identical membranes were subsequently mounted in the specially designed flow-through measuring cell [1]. About 3.4 ml of sample solution was aspirated by a syringe. Fluorescence measurements were completed under batch condition. The limiting fluorescence intensities F_b and F_s of the optode membrane were detected in pH = 4.8 blank solution and in 4.0×10^{-2} mol l^{-1} *o*-nitrophenol, respectively.

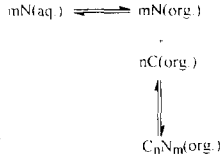
For the selectivity evaluation, the separate solution method (SSM) [17] was used to estimate the selectivity of the *o*-nitrophenol sensor with respect to other nitrophenols. The effect of other potential interferents on sensing performance was also tested.

3. Results and discussion

3.1. Principle of operation and quenching mechanism of o-nitrophenol

We discovered that *o*-nitrophenol can strongly quench the fluorescence of curcumin in the PVC membrane. Fig. 1 shows the fluorescence spectra of the optode membrane incorporating curcumin in pH = 4.8 buffer solutions containing various concentrations of *o*- nitrophenol. The fluorescence spectra were recorded at excitation wavelengths from 360 to 480 nm and emission wavelengths from 460 to 600 nm. It is apparent that the increase of *o*-nitrophenol concentrations causes a significant decrease in the fluorescence intensity of curcumin.

In order to explain the aforementioned phenomenon in the view of complex formation, we supposed that curcumin in the plasticized PVC membrane phase (org.) with *o*-nitrophenol in the aqueous solution (aq.) forms a *m*:*n* complex, the over-all equilibrium can be described as:



$$\text{i.e., } nC(org.) + mN(aq.) \rightleftharpoons C_nN_m(org.) \quad (1)$$

where C and N represent curcumin and *o*-nitrophenol, respectively. There is an equation as follows [1]:

$$\frac{\alpha^n}{1-\alpha} = \frac{1}{nKC_C^{n-1}[N]^m} \quad (2)$$

where C_C is the total concentration of curcumin in the membrane, [N] is the concentration of *o*-nitrophenol in aqueous solution, α (relative fluorescence value) is the ratio of the free curcumin concentration, [C], to the total concentration of curcumin present in the membrane, C_C, i.e.,

$$\alpha = \frac{[C]}{C_C} \quad (3)$$

and K is the equilibrium constant of the reaction described by Eq. (1). Relative fluorescence value α can also be derived from Eq. (3) that

$$\alpha = \frac{F - F_s}{F_b - F_s} \quad (4)$$

where F_b and F_s are the limiting fluorescence intensities when the optode membrane contacted with the blank solution and 4.0×10^{-2} mol l^{-1} *o*-nitrophenol solution, respectively. F is the fluorescence intensity of optode membrane exposed to the different concentrations of *o*- nitrophenol solutions. Obviously, Eq. (2) provides the basis for quantitative determination of *o*-nitrophenol.

It can also be seen from Eq. (2) that when the stoichiometric ratio of the complex changes, the relative fluorescence value α with various concentrations of *o*-nitrophenol has different functional relations. The fitted curves (1) in Fig. 2 by changing the ratio of *m* to *n* and adjusting the over-all equilibrium constant K was the best one to represent the experimental data. In other words, the complex ratio of *o*-nitrophenol to curcumin is 1:1.

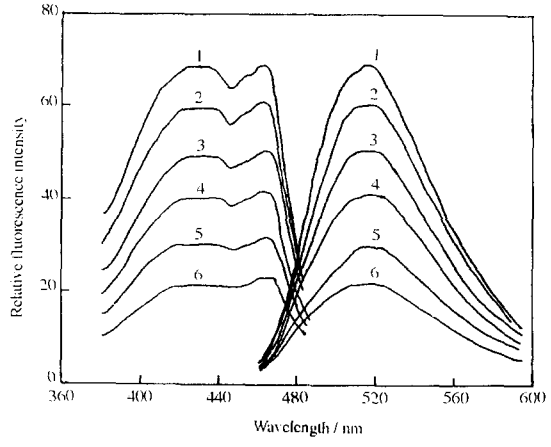


Fig. 1. Fluorescence spectra of the optode membrane after equilibrium with different concentrations *o*-nitrophenol solutions buffered at pH = 4.8. (5 nm bandwidth for excitation and emission, $\lambda_{ex} = 421$ nm and $\lambda_{em} = 520$ nm). 1. Reagent blank; 2. 2.5×10^{-4} mol l^{-1}; 3. 5.0×10^{-4} mol l^{-1}; 4. 1.0×10^{-3} mol l^{-1}; 5. 1.8×10^{-3} mol l^{-1}; and 6. 2.5×10^{-3} mol l^{-1}.

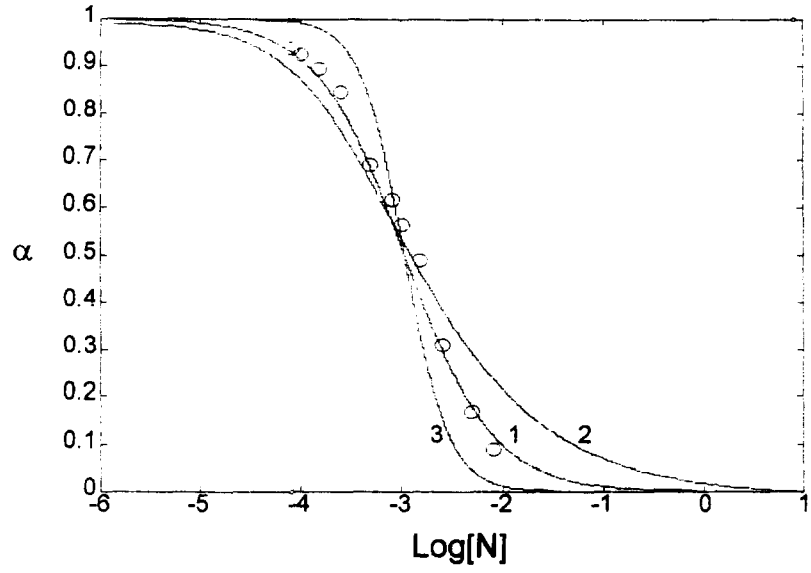

Fig. 2. Fitting the experimental data to Eq. (2). 1. $m:n = 1:1$, K = 800 (best fit); 2. $m:n = 1:2$, K = 150 000; and 3. $m:n = 2:1$, K = 650 000.

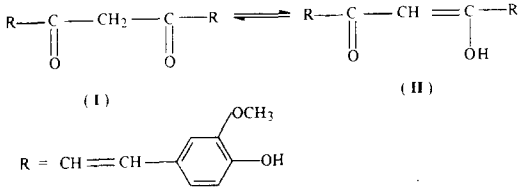
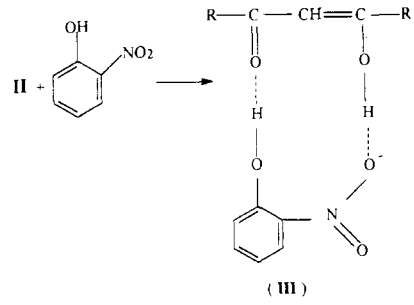
Curcumin is able to emit a strong yellow-green fluorescence. It usually exists in the keto (I) or enol (II) forms, i.e.,



It is possible for hydroxyl or carbonyl groups to form associated complexes by the means of hydrogen-bonds with some compounds containing hydroxyl or nitro group.

As the stoichiometric ratio of *o*-nitrophenol to curcumin is proved to be 1:1 and *o*-nitrophenol exists mainly in the molecular form at pH 4.8, it seems that the hydroxyl and nitro-groups in *o*-nitrophenol simultaneously associate with the carbonyl and hydroxyl groups of II through hydrogen-bonds to form non-fluorescent ground state complex (III). i.e.,



The formation of the cyclic structure III causes the fluorescence quenching of curcumin.

3.2. Membrane composition

The membrane composition was optimized by selecting appropriate plasticizers. Plasticizers must be selected so as to obtain a transparent and

flexible membrane, which has the maximum response to *o*-nitrophenol. The sensing membranes made of the different plasticizers such as tricresyl phosphate, dinonyl sebacate, butyl phthalate and didecyl phthalate were prepared. The membrane consisting of tricresyl phosphate shows the best results. The amount of curcumin giving the maximum sensitivity to *o*-nitrophenol is 2–4 mg. The optimum sensing membrane shows a linear response to *o*-nitrophenol in the range from 1.0×10^{-2} to 1.5×10^{-4} mol l^{-1}.

3.3. Influence of the acidity on o-nitrophenol sensitivity

The blank fluorescence of the sensing membrane itself was found to be independent of pH from 1.0 to 8.0. Solutions at pH > 8 caused the curcumin to be dissolved out from the PVC membrane. Fig. 3 shows the changes in relative fluorescence value α of the sensing membrane with the different pH in the presence of 1.0×10^{-3} mol l^{-1} *o*-nitrophenol. Because the ionization of *o*-nitrophenol was inhibited at pH < 6, α remained a constant. The extent of *o*-nitrophenol ionization was increased at pH > 6 so that the ability to form hydrogen-bonds with curcumin in the membrane was weakened and α increased. In our experiment, a HOAc–NaOAc buffer solution of pH 4.8 was used.

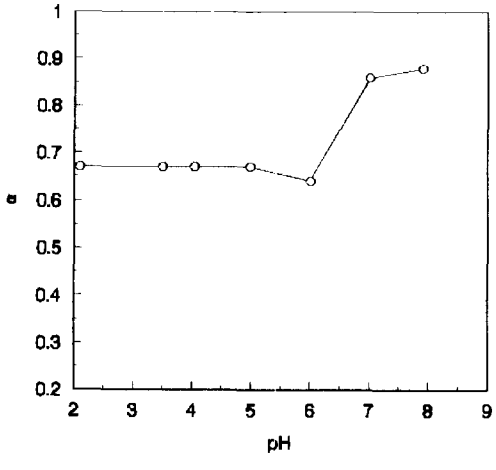


Fig. 3. Response of optode membrane at the different pH.

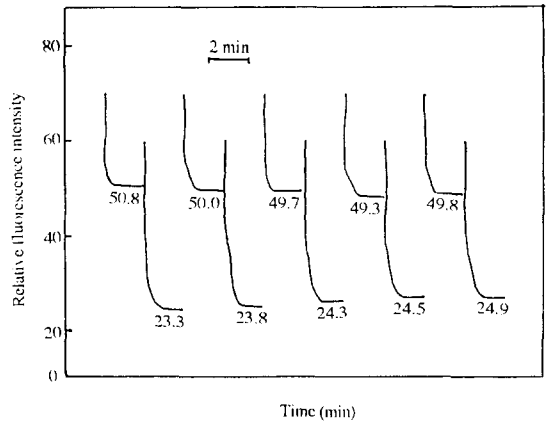

Fig. 4. Response of *o*-nitrophenol optode membrane versus time after a concentration step changing between 5.0×10^{-4} mol l^{-1} and 1.8×10^{-3} mol l^{-1}.

3.4. Reproducibility and response time

The reproducibility of the optode membrane consisting of curcumin in the determination of *o*-nitrophenol was evaluated by repetitively dipping the sensor into two sample solutions. Fig. 4 shows the fluorescence intensities change versus time recordings for the *o*-nitrophenol optode membrane. The present sensor shows good reproducibility and reversibility. Five determinations at 5.0×10^{-4} mol l^{-1} and 1.8×10^{-3} mol l^{-1} *o*-nitrophenol produced standard deviations of 0.55 and 0.62, respectively. Stable readings were obtained within ca. 1.5 min.

3.5. Short-term stability

Short-term stability for the optode membrane in 5.0×10^{-4} mol l^{-1} *o*-nitrophenol solution buffered at pH = 4.8 was measured over a period of 6 h. From the fluorescence intensities taken every 30 min ($n = 12$), a mean value of 48.3 and a standard deviation of 1.45 were obtained. During this period of time there was no evidence of significant leakage of reagent from the membrane and changed in response. The sensor was immersed in a HOAc–NaOAc buffer solution of pH 4.8 when not in use.

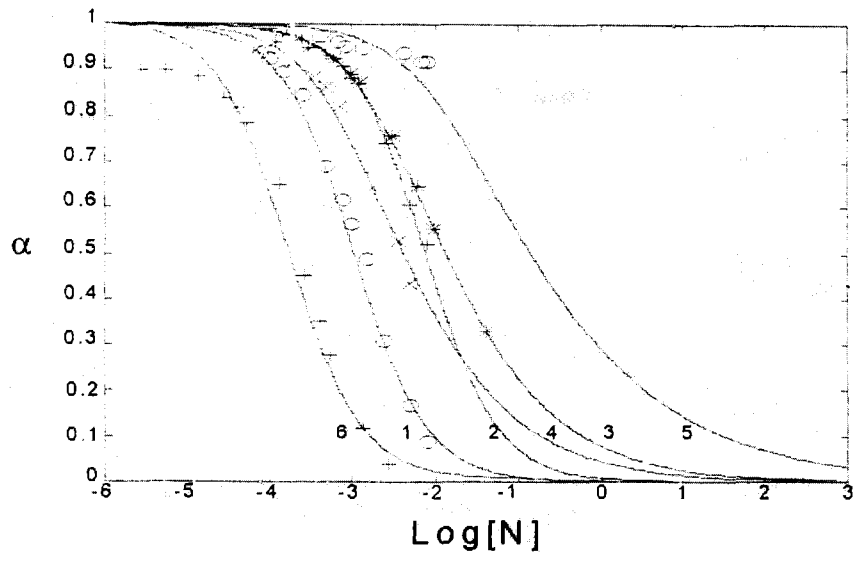

Fig. 5. Dependence of relative fluorescence values α on the various concentrations of nitrophenols. The curves were fitted according to Eq. (2). 1. *o*-nitrophenol (*m*:*n* = 1:1, K = 800); 2. *m*-nitrophenol (*m*:*n* = 1:1, K = 120); 3. *p*-nitrophenol (*m*:*n* = 1:2, K = 13000); 4. 2,4-dinitrophenol (*m*:*n* = 1:2, K = 4000); 5. 2,4,6-trinitrophenol; and 6. 2,4,6,-trinitrophenol (*m*:*n* = 1:1, K = 5000, 1.5 mol l^{-1} H_2SO_4 medium).

3.6. Measurement range, equilibrium constant and detection limit

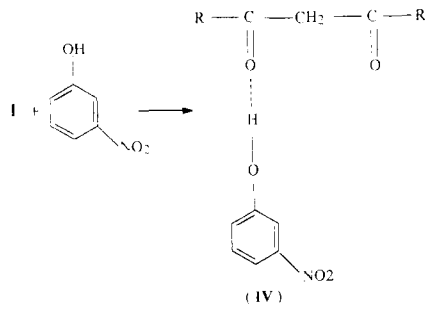
As mentioned above, Fig. 2 shows that the curve referring to 1:1 complex ratio and K = 800 is the best one fitted to the experimental data. The best fitted curve can be served as the calibration curve for the determination of *o*-nitrophenol. A practically usable range for quantitative determinations covers 1.0×10^{-2}–1.5×10^{-4} mol l^{-1} of *o*-nitrophenol with a detection limit of 8×10^{-5} mol l^{-1}.

3.7. Selectivity

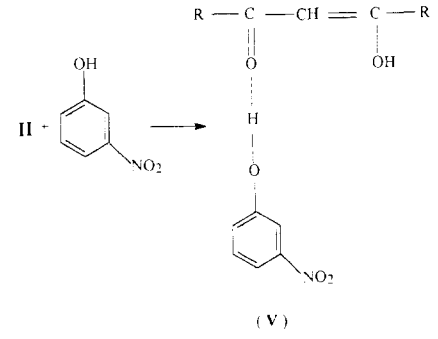
To investigate the influences of nitrophenols similar to *o*-nitrophenol structure on the optode membrane, the separate solution method (SSM) was employed. It is supposed that curcumin in plasticized PVC membrane phase (org.) forms *m*:*n* complexes with other nitrophenols in the aqueous solution (aq). According to the similar method as mentioned above, the best fitted curves (2), (3), (4), (6) for *m*-nitrophenol, *p*-nitrophenol, 2,4-dinitrophenol in the buffer solution of pH 4.8 and 2,4,6-trinitrophenol in 1.5 mol l^{-1} H_2SO_4 medium were obtained. The stoichiometric ratio for *m*-nitrophenol-curcumin complex is 1:1 and the complex compositions for *p*-nitrophenol and 2,4-dinitrophenol with curcumin are 1:2. It is obviously from Fig. 5 that the response sequence for nitrophenols to curcumin is *o*-nitrophenol > 2,4-dinitrophenol > *m*-nitrophenol > *p*-nitrophenol > 2,4,6-trinitrophenol under the experimental conditions tested.

As described above, *o*-nitrophenol can form an associated complex (III) with curcumin in the PVC membrane, while it is difficult for *m*-nitrophenol, *p*-nitrophenol and 2,4-dinitrophenol to form complexes similar to III owing to steric hindrance. From the view of stoichiometric ratios of *m*-nitrophenol, *p*-nitrophenol and 2,4-dinitro-

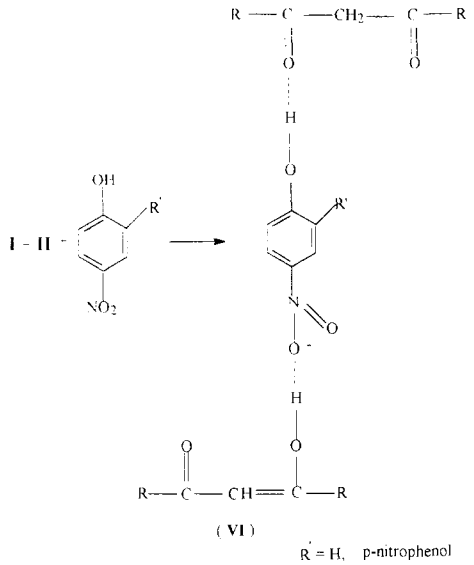
phenol to curcumin, one may assume that *m*-nitrophenol form the associated complex (IV) or (V) and *p*-nitrophenol and 2,4- dinitrophenol form the associated complex (VI) or (VII). i.e.,



(IV)



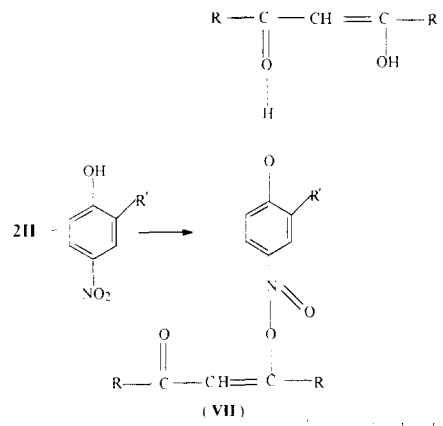
(V)



(VI)

R' = H, p-nitrophenol

R' = NO_2, 2,4-dinitrophenol



(VII)

R' = H, p-nitrophenol

R' = NO_2, 2,4-dinitrophenol

The quenching relatively strong by *o*-nitrophenol comparing to other nitrophenols seems to be related to more favorite complex forming sites for *o*-nitrophenol.

2,4,6-trinitrophenol has a structure similar to *o*-nitrophenol. However, it tends to dissociate more completely at pH 4.8 and is mainly in the anion form, which may not form associated complex with curcumin. The quenching effect of 2,4,6-trinitrophenol is much weaker than that of *o*-nitrophenol.

It was observed, however, 2,4,6-trinitrophenol can strongly quench fluorescence of the sensing membrane in 1.5 mol l^{-1} H_2SO_4 medium. In such medium, 2,4,6-trinitrophenol exists in the molecular form and forms an 1:1 associated complex with curcumin.

The effect of other potential interferents such as aniline, phenol and some ions were also tested for their possible co-occurrences in environmental samples with *o*-nitrophenol. No significant interferences were observed if a tolerance of less than $\pm$ 5% relative error in the determination of 1.5×10^{-3} mol l^{-1} *o*-nitrophenol was considered. Table 1 summaries the results obtained. The practical application of the optode membrane based on curcumin for the determination of *o*-nitrophenol seems really feasible.

Table 1
Effect of different interferents on the fluorescence signal of the optode membrane[a]

Interferent	Concentration (mol l^{-1})	Fluorescence change value $\Delta F = (F_2 - F_1)$[b]	Relative fluorescence change value(%) $(\Delta F/F_1) \times 100$
Phenol	4.50×10^{-3}	0.900	3.67
Aniline	6.00×10^{-3}	−0.500	−2.04
Nitrobenzene	1.00×10^{-3}	−0.700	−2.85
NaCl	1.00	−1.00	−4.08
KCl	1.00	0.300	1.22
$NaNO_3$	1.00	−0.300	−1.22
$CaCl_2$	0.80	−1.00	−4.08
$MgCl_2$	0.80	−1.10	−4.49
$Pb(NO_3)_2$	8.00×10^{-3}	0.900	1.23
$Cu(NO_3)_2$	7.00×10^{-3}	−0.200	−0.80
$CoCl_2$	5.00×10^{-2}	−0.600	−2.45
$FeCl_3$	1.00×10^{-2}	0.900	3.67
$ZnCl_2$	1.50×10^{-3}	0.900	3.67
$NiSO_4$	5.00×10^{-3}	−0.600	−2.45
$HgCl_2$	1.50×10^{-3}	0.300	1.22
$CrCl_3$	5.00×10^{-3}	−0.500	−2.04

[a] Each sample solution contained a fixed *o*-nitrophenol concentration 1.5×10^{-3} mol l^{-1}. The fluorescence intensities were recorded after the sample solutions have contacted with the membrane for 2 min.
[b] F_1 and F_2 are the fluorescence intensities of the optode membrane contacted with the 1.5×10^{-3} mol l^{-1} *o*-nitrophenol solutions without and with interferents, respectively.

Table 2
Determination of *o*-nitrophenol in tap water sample

Sample	Analyte and interferents added (10^{-3} mol l^{-1})					*o*-NP found[a] (10^{-3} mol l^{-1})	Recovery (%)
	o-NP	*m*-NP	*p*-NP	2,4-DNP	2,4,6-TNP		
1	1.00	0.80	1.20	0.50	1.50	1.08	108
2	1.00	0.50	1.20	0.30	1.50	1.04	104
3	1.00	0.20	1.20	0.15	1.50	1.01	101
4	0.50	0.20	0.60	0.15	1.50	0.501	104
5	0.50	0.50	0.60	0.15	1.50	0.50	108
6	0.50	0.20	0.60	0.30	1.50	0.505	110

o-NP, *o*-nitrophenol; *m*-NP, *m*-nitrophenol; *p*-NP, *p*-nitrophenol; 2,4-DNP, 2,4-dinitrophenol; 2,4,6-TNP, 2,4,6-trinitrophenol.
[a] An average of three determinations.

3.8. Determination of o-nitrophenol in water samples

To examine the recovery for the *o*-nitrophenol determination in the presence of other nitrophenols, the tap water samples with different amounts of nitrophenols added were analyzed. The recovery was 101 –108% (Table 2).

Book reviews

Stat-100, version 1.22 Biosoft, Cambridge, 1996. £99.00, US$199.00.

Stat-100 is a general purpose statistical analysis program for Microsoft Windows. It is accompanied by a comprehensive 161-page manual (with an index) and on-line help is available during program execution. The minimum requirements are: a 386 cpu, Windows 3.1 (or later), VGA monitor (or better), at least 4 Mb of ram and a minimum of 6 Mb of hard disk space for the program files. I installed the program, on a personal computer with a pentium cpu and Windows 3.1, plus the sample files without any problems. As the name implies, more than 100 procedures are offered for processing, analysing and presenting data. There is a STAT-100 native format but spreadsheet files can also be imported from, or saved as, Excel files. The maximum size of the STAT-100 spreadsheet is stated to be 262 144 cells.

The techniques covered include parametric and non-parametric analytical statistics, analysis of variance, linear regression analysis and survival data analysis. The usual set of descriptive statistics (mean, standard deviation, max and min values, skewness, etc.) is calculated in one easy operation. Numerous data transformations are possible, e.g. converting absorbance to log absorbance or temperature to reciprocal temperature - these are easily performed and include polynomial, probability and trigonometric transforms. In addition the expected range of spreadsheet operators and functions are also available.

Graph types include line, pie, bar, scatter, box-whisker charts and 3D plots. Fits can be made to polynomial, logarithmic, exponential and power functions. These numerous plots are easily annotated and various graph styles can be created. The graphs can be printed or saved and, if required, exported as Windows bitmaps or metafiles. The many options available for graph plotting take some time to explore and once the desired format is obtained it can be saved as a template. I found that this template worked well when the graph filled the whole screen. I also found it possible to incorporate several plots on the one set of axes.

I completed the tutorial in the manual with the correct results but occasionally found the indicator for a data range, e.g. $B$1:$B$10, appearing in the output. This caused no problems for graph labelling as editing options are comprehensive—in this case editing the 'legend text' removed the range label. Care is required to ensure that the order of data entry is correct, e.g. select X values first then Y values for line graph plotting but select Y values first then X values for simpler linear regression. I also tried many of the tests on offer (ANOVA, Student's t, Chi-squared, Mann-Whitney U, etc.) and found that the learning curve soon became horizontal. Producing the required results with this program is an easy task.

Overall an excellent program with a helpful manual that will enable you to quickly perform probably all the statistical calculations you will ever need. Try the free demonstration disk from Biosoft which can be downloaded from the Internet (http://www.cityscape.co.uk/biosoft/).

A Manual for the Chemical Analysis of Metals, by T.R. Dulski, ASTM, West Conshohocken, PA, 1996, xiv + 251 pp., US$89. ISBN 0-8031-2066-4.

This book is a comprehensive laboratory manual that deserves to become a best-seller in the metal analysis community. The book is a treasure trove of information, providing extensive and up-to-date references on all aspects of the analytical process. Furthermore, the author is a gifted writer and as evidence of this I confess to packing the book for my summer vacation. The book is divided into 5 sections that progress from Materials (laboratory design, equipment and reagents) to Samples (sampling, sample preparation and dissolution in acids) and thence to Separations followed by Measurement (gravimetry, titrimetry, absorption/emission spectroscopy etc.) and, finally, a section on Quality (reference materials, calibration, validation, statistics, good laboratory/administration practices and personnel). The book concludes with a series of Appendices that provide at-a-glance information on the chemical behaviour of analytes and strategies for their analysis.

It is the width of subject material and the depth to which it is treated that makes this book so valuable and unique. In addition to this the book is ruggedly bound—an important consideration for a laboratory manual. Finally, the really good news for cash strapped laboratories is that all this can be yours for a mere $89.

EqCaL for Windows, by L. Lackman, Biosoft, 1996. £125.00.

The package supplied includes a well presented manual which accompanies the disk containing the program which is for use with Windows 3.1 or later versions. The terminology used, both in the manual and the disk, for accessing and using the program should present no problems to those who are familiar, with Windows 3.1. To operate the system the user will need a 386SX or higher processor with a minimum of 4 Mb of memory and 1 Mb of free disk space. Installation proved very straight forward. The system is well designed and does take the tedium out of the cumbersome, time consuming calculations required for determining the equilibrium concentrations of the individual components in, for example, buffer solutions, chelation or binding interactions and other complex multiple equilibria reactions. To use this program the user must have prior knowledge of both the equilibrium constant and the balanced chemical equation for each of the reactions involving the components of the solution from which all the species present at equilibrium are formed. It will not cope with the ionic strength effects on the equilibria of the addition of ionic components not taking part in the equilibria.

The readily understandable manual clearly explains both the conventions using the EqCal program and how to use EqCal. The instant 'user friendly' Help facility in the program supplies the operational answers to any difficulties the user may have with the program.

Data input is comparatively straight forward. The sample session included in the manual is a particularly good guide to the on screen information and data/calculation handling facilities. It would have been helpful to have included in the manual a typical screen output for the equilibrium and total concentration calculations for the components present. On screen editing of the data and equations, and the storage and retrieval of the final templates and calculated values is easily done. The final results can be customised using display fonts and then printed out. The on screen data can also be easily copied into the clipboard for future pasting into a spreadsheet or wordprocessor.

A high quality presentation which does exactly what it claims to do.

Biosensor and Chemical Sensor Technology - Process Monitoring and Control, edited by K.R. Rogers, A. Mulchandani and W. Zhou, American Chemical Society, Washington, DC, 1995, xii + 187 pp., US$52.95. ISBN 0-8412-3330-6.

This American Chemical Society symposium volume emphasizes the application of biosensors and chemical sensors to monitoring bioproceses. It is divided into two sections. The chapters in the first section describe sensor technologies in various states of development with the common feature that they involve a biological recognition element. The second section describes the application of sensor technologies to bioprocessing monitoring. Each section has a short introductory chapter by the editors.

The first section includes seven chapters on sensor technology. Chapter 2 describes the use of an acoustic immunosensor as an HPLC detector. However, the slow response of immunosensors is detrimental to the separating power of HPLC and the selectivity should render a prior separation unnecessary so it is difficult to see how this will emerge as an important methodology. Chapter 3 is a short but comprehensive review on antibody basics as they relate to immunosensing. Chapter 4 describes the application of evanescent wave fibre optic biosensor technology developed at the Naval Research Laboratory, under the supervision of Fran Ligler, to environmental monitoring. Chapter 6 describes a method for detecting polyaromatic carcinogens based on competitive intercalation with a fluorescent dye using a DNA segment as the recognition element. Chapter 7 describes a chemically modified electrode that involves hydrogen peroxide reduction catalyzed so that it can be carried out at low potential. This device can be coupled to oxidase enzymes that catalyze hydrogen peroxide to yield a family of biosensors. Chapter 8 describes the use of enzyme cycling procedures to make measurements at subnanomolar concentrations. Chapter 9 describes a fructose electrode based on fructose dehydrogenase. While far from comprehensive, the chapters in the first section provide a representative selection of current biosensor research.

The second section emphasizes the application of sensing technology to bioprocess control. It contains two chapters on spectroscopy, including chapter 9 on chemical sensors for pH and oxygen based on fluorescence lifetimes measured by phase techniques and chapter 12 showing that near infrared spectroscopy can selectively measure glutamine and asparagine in water and can potentially be used to measure these substances non-invasively in bioprocesses. It also contains two chapters on the automation of flow injection analysis systems for bioprocess monitoring. Chapter 13 involves automation of several enzymatic methods while chapter 16 describes immunoassay automation. Chapter 11 describes the use of a enzymatic penicillin sensor to monitor penicillin production by fermentation. Chapters 14 and 15 show how conventional measurements of turbidity and chemical concentrations can be used to optimize and predict the output of bioprocesses.

What is striking about this book is how rarely the biosensor technologies described in the first section appear in the section that emphasizes the practical. The only exception to this is the use of a penicillin electrode based on penicillinase and this was done off-line rather than directly in the formation. The lesson here is that biosensors are not yet the practical solution for most bioprocess applications.

The quality of the papers is generally good and the book is recommended for scientists who wish to keep abreast of recent developments in biosensor research and bioprocess monitoring.

Announcement

28th ISEAC: 28th Annual International Symposium on Environmental Analytical Chemistry

Geneva, Switzerland,
2–5 March 1998

The aim of this 28th Symposium is to actively encourage progress in methods, instrumentation, applications and to facilitate the transfer of know-how in different fields. It is targeted at scientists, analysts, manufacturers, end-users and post-graduate students.

Tentative main topics of the Symposium:

—Analyzing trace polar products in the environment
—New extraction, separation and instrumental techniques
—Chiral separations in environmental analysis
—Micro-Total Analysis Systems (μTAS)
—In situ measurements and speciation
—Quality assurance issues for environmental analysis for harmonization within EC and non-EEC countries
—Environmental and education
—Other topics

All topics will be introduced in plenary lectures and invited research lectures followed by brief research presentations and posters. An exhibition of scientific equipment will also be organised.

A short course on Sample Handling and Analysis of Organic Pollutants will be organised in Archamps, France, 27–28 February 1988.

For further details contact:

Fibre-optic pesticide biosensor based on covalently immobilized acetylcholinesterase and thymol blue

Roberto T. Andres, Ramaier Narayanaswamy *

Department of Instrumentation and Analytical Science, UMIST, P.O. Box 88, Sackville Street, Manchester M60 1QD, UK

Received 30 May 1996; accepted 16 August 1996

Abstract

A fibre-optic based on immobilized acetylcholinesterase is described and its application in the detection of carbamate and organophosphate pesticides through enzyme inhibition measurements is discussed. The bioactive component of the sensor consists of acetylcholinesterase covalently immobilized on preactivated isothiocyanate glass mixed with thymol blue indicator bound on aminopropyl glass and the sensor was constructed by packing a thin layer of the glass bead mixture at the tip of a bifurcated fibre-optic sensor head, which was then integrated with a flow-through cell. The response of the sensor to acetylcholine was highly reproducible (RSD < 2%) and readily reversible. The sensor exhibited a linear response to acetylcholine in the concentration range 2.5–25 mM ($r^2 = 0.992$). Inhibition plots obtained for test organophosphate (paraoxon) and carbamate (carbofuran) pesticides exhibited concentration-dependent behaviour and showed linear profiles in the concentration ranges 5×10^{-8}–5×10^{-7} M for carbofuran and 5×10^{-7}–5×10^{-6} M for paraoxon. The detection limits, calculated at $I_{10\%}$, are 1.5×10^{-8} M (3.1 ppb) and 1.1×10^{-7} M (24.7 ppb) for carbofuran and paraoxon, respectively. The regeneration of paraoxon-inhibited sensor was possible using 2-pyrimidine aldoxime, while repetitive substrate injection was necessary to reactivate the carbofuran-inhibited optrode. The factors affecting the inhibition and reactivation processes were investigated.

Keywords: Acetylcholinesterase; Enzyme inhibition; Fibre-optic biosensor; Pesticide biosensor

1. Introduction

The development of cholinesterase-based biosensors has been actively pursued in recent years. These devices have found use in the determination of acetylcholine, a biomolecule which plays an important role in nerve impulse transmission in the peripheral and central nervous systems. Some authors [1–3] have already demonstrated their practicability in real sample analysis, e.g. in the determination of acetylcholine in cerebrospinal fluid and brain tissue extracts. Their application to other biological materials such as plasma and erythrocyte samples is also widely envisioned [4–6].

A more major interest on cholinesterase-based biosensors lies in their applicability in the analysis

of organophosphate and carbamate compounds. These are compounds that commonly find utility as pesticides in agriculture or household insecticide products and as chemical warfare agents. The toxicity of these compounds is commonly attributed to their inhibition effects on cholinesterase enzymes. In the development of pesticide biosensors based on cholinesterase enzymes, the measurement of inhibition also provides the analytical basis for the sensing of these toxic substances.

Two types of cholinesterase enzymes exist, both of which have proved useful for biosensor construction. They can be distinguished as acetylcholinesterase (also called true cholinesterase or choline esterase I) and acylcholine acylhydrolase (also referred as pseudocholinesterase or choline esterase II and comprises other cholinesterases, including butyrylcholinesterase) [7]. Physiologically, acetylcholinesterases exist in the erythrocytes, lungs and spleen, nerve endings and in the grey matter of the brain and they are involved in nerve impulse transmission. The second type of cholinesterases can be found in the liver, pancreas, heart, white matter of the brain and serum, although their biological role is unknown. Both types of enzymes display high sensitivity to the inhibition by organophosphate and carbamate compounds and have been found to be equally useful in the construction of pesticide biosensors.

The measurement of enzyme inhibition in pesticide biosensors has been performed using a variety of transducers and enzyme substrate systems. The most commonly used transducers have been pH-sensitive devices, such as glass pH electrodes [8–11], ion-selective field-effect transistors (ISFETS) [12–16] and metal–metal oxide electrodes [10]. These potentiometric devices monitor the changes of pH during an acetycholinesterase-catalysed hydrolysis of acetylcholine or butyrylcholine. Lower pH changes are detected for the enzyme sensors inhibited by pesticides. Another type of potentiometric sensor, based on a butyrylcholine-sensitive plasticized poly(vinyl chloride) membrane, has also been recently used as a transducer for an organophosphate pesticide biosensor [17]. The use of solution conductivity as a means of determining cholinesterase activity in pesticide sensors has also been exploited. A conductometric thin-film transducer [18] and an ion-responsive impedance sensor [19] have been utilized as transducers in these cases.

Amperometric devices have also become popular transducers for pesticide biosensors. Enzyme inhibition in these systems is normally assessed using either acetyl- or butyrylthiocholine as the substrate reagents, both of which hydrolyse to produce the electrochemically detectable species, thiocholine [20–24]. A different substrate, 4-aminophenyl acetate, which yields 4-aminophenol as the electroactive species, has also been shown recently to be a useful reagent for a pesticide biosensor [25]. Amperometric enzyme-based sensing of pesticides is more commonly performed, however, using a bi-enzymatic reaction (between acetyl- or butyrylcholinesterase and choline oxidase) and hydrogen peroxide detection [26–31], as described in the following equations:

$$\text{acetylcholine} + H_2 \xrightarrow{\text{acetylcholinesterase}} \text{acetic acid} + \text{choline} \quad (1)$$

$$\text{choline} + 2O_2 + H_2O \xrightarrow{\text{choline oxidase}} \text{betaine} + 2H_2O_2 \quad (2)$$

$$H_2O_2 \xrightarrow{\text{anodic oxidation}} O_2 + 2e^- + 2H^+ \quad (3)$$

Current is measured as a result of H_2O_2 oxidation; acetylcholinesterase inhibition by organophosphate and carbamate compounds leads to a decrease in the current.

Optical-based pesticide biosensors have also been described in recent years. However, accounts concerning these devices are not as numerous as those for electrochemical sensors despite the advantages they offer (e.g. no direct electrical connections, possibility of remote sensing and ease of miniaturization). Wolfbeis and Koeller [32] reported the first fibre-optic device based on immobilized acetylcholinesterase that has been applied for sensing pesticides, although this was not a biosensor in a 'true' sense. It consists of acetylcholinesterase immobilized on nylon beads and packed in a reactor column. A buffered proprietary substrate solution is passed through the column, where it is converted from a red solution into a blue dye upon action by the enzyme. The

colour change is detected, using a yellow LED as light source and a photodiode detector, as the effluent passed through a flow cell, fitted with optical fibres arranged in a transmittive mode. An analogous device was also later reported by Trettnak et al. [33], but activated aminopropyl glass was utilized as the immobilizing support for the enzyme and 2-(2-acetoxy-5-methylphenylazo)-*N*-methyl-1,3-thiazolium methosulphate was used as the specific chromogenic substrate for the assay.

Rogers et al. [34] reported the first fibre-optic anti-cholinesterase biosensor, which was constructed by immobilizing a fluorescein isothiocyanate-tagged acetylcholinesterase (FITC–AChE) on quartz fibres. During acetylcholine hydrolysis, the pH-dependent fluorescent signal generated by FITC–AChE present in the evanescent zone of the fibre surface is quenched by the protons produced, thereby allowing the measurement of enzyme activity. The biosensor was able to detect the carbamate insecticides bendiocarb and methomyl and the organophosphates echothiphate and paraoxon in the nanomolar to micromolar range, but malathion, parathion, and dicrotophos were not detected even at millimolar concentrations. Hobel and Polster [35] described another acetyclcholinesterase-based optical biosensor for pesticides. The enzyme, together with a FITC-modified dextran, were immobilized in a thin polyacrylamide gel layer, which was in turn covalently fixed in front of a functionalized bifurcated optical fibre. As before, the measurements were based on the fluorescence changes brought about by pH shifts during substrate hydrolysis. The detection of the carbamates aldicarb and carbofuran was demonstrated using this sensor.

In this paper, a fibre-optic pesticide biosensor different to those described above and based on an immobilized acetylcholinesterase and reflectance measurement is described. The bioactive reagent layer of the biosensor consists of acetylcholinesterase covalently bound on isothiocyanate glass mixed with thymo blue covalently immobilized on aminopropyl glass, and reflectance measurements are derived from the colour change of the pH-sensitive indicator during the enzyme action on acetylcholine. The response characteristics of the biosensor to acetylcholine are first presented, followed by its application to carbamate and organophosphate determination. The factors affecting the inhibition and reactivation processes are also discussed.

2. Experimental

2.1. Materials

Acetylcholinesterase (EC 3.1.1.7, Type VI-S from electric eel, lyophilized, 225 units mg^{-1} solid, AChE), acetylcholine chloride (AChCl), isothiocyanate glass (Sigma G4893, average pore size 50 nm, 200–400 mesh, 39 μmol isothiocyanate g^{-1} glass), aminopropyl glass (Sigma G4643, average pore size 50 nm, 200–400 mesh, 81 μmol amine g^{-1} glass) and tris(hydroxymethyl)aminomethane–HCl (Tris) were obtained from Sigma Chemical (St. Louis, MO, USA). Potassium dihydrogenphosphate, hydroxylamine, 2-pyrimidine aldoxime methiodide (2-PAM) (99%), thymol blue sodium salt, morpholineethanesulphonic acid (MES) and diethyl 4-nitorphenyl phosphate (technical 90%) (paraoxon) were purchased from Aldrich Chemical (Gillingham, Dorset, UK). Carbofuran was acquired from Riedel-de Haën (Seelze, Germany). Formaldehyde solution (37–40%) was obtained from BDH–Merck (Poole, Dorset, UK). All other reagents were of analytical grade, unless stated, otherwise, and were used as received.

2.2. Immobilization of indicator reagent and acetylcholinesterase

The bioactive reagent phase of the optical pesticide biosensor consists of covalently immobilized acetylcholinesterase enzyme and thymol blue indicator. The immobilization of acetylchoinesterase (AChE) was performed through covalent binding on preactivated isothiocyanate glass. A typical batch immobilization procedure consists of mixing 10 mg portions of the isothiocyanate glass, 50 μl of acetylcholinesterase solution (made by dissolving 0.5 mg of AChE in 1.5 ml of water) and 350 μl of 0.05 M borate buffer (pH 8.5) in a small

glass vial (5 × 1 cm i.d.). The mixture was then kept in a refrigerator for at least 2 h to allow the covalent binding of the enzyme. Subsequently, the glass material was repeatedly washed with cold distilled water and then with 0.1 M phosphate buffer (pH 7.0) to remove unbound enzyme reagent.

Thymol blue was immobilized on aminopropyl glass support through a condensation reaction with formaldehyde. About 200 μl of 10 mM formaldehyde, prepared in 0.1 M MES solution, was first added to a 10 mg portion of the glass beads, followed by 200 μl of 5 μM aqueous thymol blue solution, in a small, stoppered glass vial. The mixture was carefully swirled then stored in a preheated oven (50–60°C) for at least 48 h to effect the covalent binding of the indicator. Subsequently, excess indicator solution was carefully decanted, then the glass beads were thoroughly washed, first with 2 M NaCl then alternately with copious amount of buffer solutions of pH 10.0 and 2.0, followed by distilled water to remove weakly bound or unbound indicators. The glass beads were also subjected to intermittent (3–5 times) and short ultrasonic agitation (ca. 10 s) during the washing procedure to facilitate a more thorough removal of excess indicators.

2.3. Sensor construction and flow-cell configuration

The sensitive enzyme reagent phase of the optical biosensor was prepared by homogeneously mixing 10 mg portions of each of the glass-immobilized acetylcholinesterase and thymol blue indicator preparations. When not in use, this reagent mixture was stored in a refrigerator under 0.1 M phosphate buffer solution (pH 7.0). To construct the optical sensor, an aliquot of the reagent phase was pipetted out and deposited in the microwell (100–150 μm deep and 1.55 mm diameter) of a specially fabricated fibre-optic probe head (Fig. 1). The beads were blotted dry, then carefully packed until a thin and compact glass layer was produced. The glass materials were then retained in place using a fine nylon mesh, which in turn was supported by a plastic tube. The fibre-optic probe was inserted into a flow cell assembly, which was machined from a Perspex cylinder (1 cm diameter × 1 cm high). The flow cell device incorporated two 19G (20 × 1 mm o.d.) stainless-steel needles, positioned diametrically opposite each other, to serve as the solution inlet/outlet. The bottom end of the flow cell was also fitted with a white PTFE plug (at a 1.5 mm distance from the probe tip) to provide a reflective surface backing. The internal volume of the flow cell is approximately 25 μl.

2.4. Flow manifold configuration and measurement procedure

The flow manifold utilized for the characterization of the fibre-optic acetyklcholinesterase-based biosensor and for performing pesticide analysis is depicted in Fig. 2. For the initial characterization studies, the first two valves remained in the load position and only the third valve was activated for

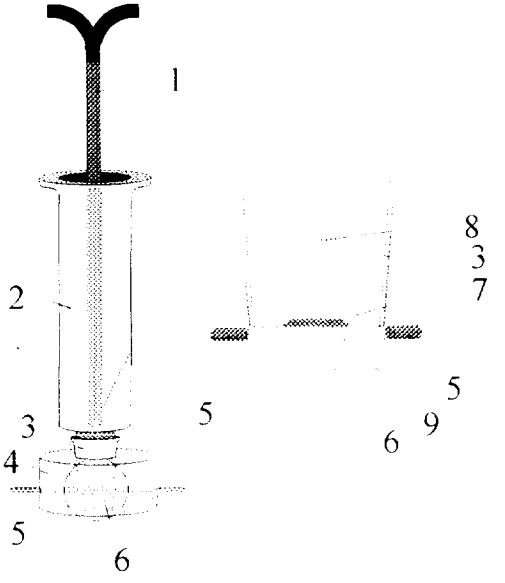

Fig. 1. Configuration of fibre-optic biosensor and flow cell set-up: 1, bifurcated optical fibre bundle; 2, plastic syringe cylinder; 3, plastic body of syringe needle; 4, poly(methacrylate) cylinder; 5, 19G gauge syringe needles; 6, white PTFE cylinder as reflector; 7, glass bead mixture (containing immobilized acetylcholinesterase and thymol blue) packed in a microwell; 8, bare 32-fibre plastic optical fibre bundle; 9, nylon mesh support.

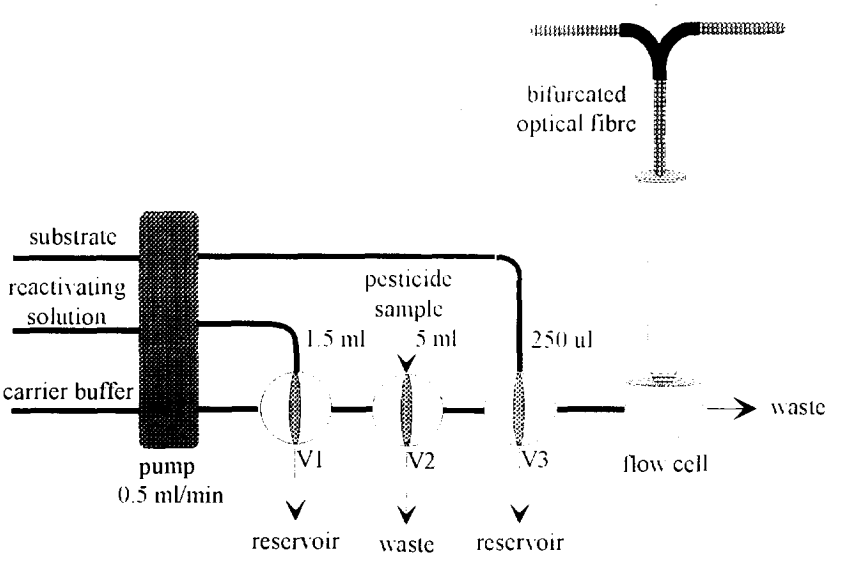

Fig. 2. Flow manifold used for sensor characterization and inhibition measurements. Carrier buffer = 7.5 mM Tris buffer (pH 7.5), reactivating solution = 0.1 mM 2-PAM; substrate = 100 mM acetylcholine; pump = Watson Marlow Model 202U Peristaltic pump; V1–V3 = injection valves (Rheodyne 5020); tubings used = Teflon of 0.8 mm i.d. except for the sample loop of V2 (1.6 mm i.d.).

the introduction of substrate solutions. Pesticide determination was performed using a measurement cycle involving the following: measurement of initial enzyme activity, pesiticide sampling, measurement of inhibited sensor signal, reactivation using a regenerating agent, measurement of reactivated sensor response and subsequent sampling of another pesticide solution. The detailed procedure is as follows: with all valves in the load position, the baseline signal was first allowed to stabilize by continuously pumping the carrier buffer solution (7.5 mM Tris buffer (pH 7.5)) across the sensor. The initial acetylcholinesterase activity was then measured by injecting replicate samples of the substrate solution (100 mM acetylcholine prepared in the Tris buffer) through valve 3. At the onset of peak recovery in the last substrate injection, valve 3 was returned to load position and the pesticide solution was injected to the flow system using valve 2. After the sample solution plug had completely passed through the flow cell (typically after 10–12 min) and when the baseline level had been regained, valve 2 was switched back to the load position and the substrate was injected through valve 3 to measure the inhibited enzyme activity. At the onset of peak recovery, valve 2 was returned to the load position and the regenerating solution was then introduced via valve 1. The baseline was allowed to recover and the 'regenerated' enzyme activity was measured again by the reintroduction of acetylcholine solution, while valve 1 was switched back to the load position. The whole measurement cycle was repeated for sampling other pesticide solutions. The percentage inhibition (or reactivation) at each measurement step was evaluated using the expression

$$\text{inhibition}(\%) = [(E_0 - E)/E_0] \times 100 \quad (4)$$

where E_0 is the initial uninhibited sensor response and E is the inhibited (or reactivated) sensor response.

The fibre-optic measuring system employed in these studies is the same as that described previously [36] and measured light intensities from the optical sensor are expressed as voltage output.

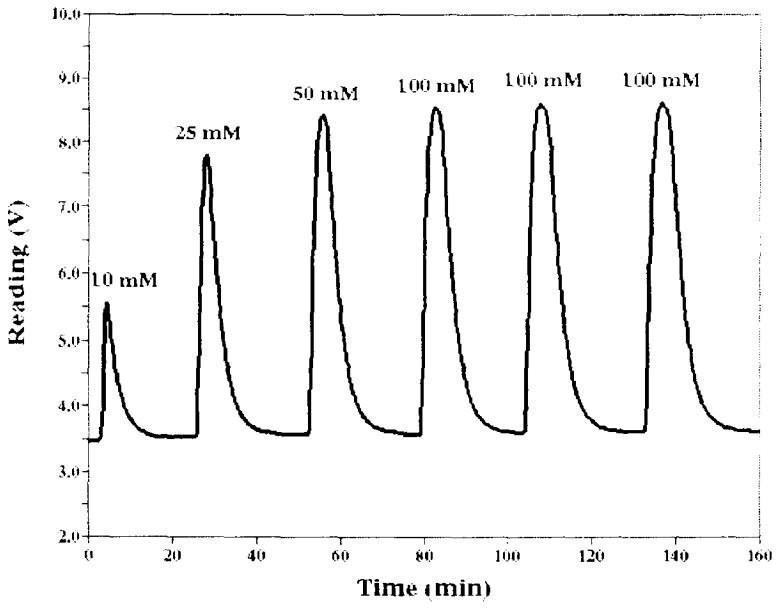

Fig. 3. Sample response curve of the acetylcholine optical biosensor.

3. Results and discussion

3.1. Sensitivity to acetylcholine

Acetylcholine was utilized as the test substrate for the characterization of the enzyme optrode and for the assay of its immobilized enzyme activity. Acetylcholine, introduced into the enzyme sensor, is biocatalytically hydrolysed into acetic acid and choline. It is generally accepted [37,38] that the hydrolysis of acetylcholine occurs in three steps and may be expressed by the following reactions:

$$\underset{\text{acetylcholine chloride}}{CH_3COOCH_2CH_2N^+(CH_3)_3Cl^-} + \underset{\text{acetylcholinesterase}}{AChE} \rightleftharpoons [\underset{\text{acetylcholine–acetylcholinesterase complex}}{CH_3COOCH_2CH_2N^+(CH_3)_3Cl\text{–}AChE}] \rightarrow \underset{\text{acetylated acetylcholinesterase}}{AChE\text{-}OOCHCH_3} + \underset{\text{choline chloride}}{HOCH_2CH_2N^+(CH_3)_3Cl^-} \quad (5)$$

$$\underset{\text{acetylated acetylcholinesterase}}{AChE\text{-}OOCHCH_3} \xrightarrow{H_2O} \underset{\text{acetic acid}}{CH_3COOH} + \underset{\text{free acetylcholinesterase}}{AChE} \quad (6)$$

The enzyme and the substrate first combine to form the Michaelis enzyme–substrate complex. The acetyl group then transfers to the serine group in the active site of the esterase molecule to form the acetylated enzyme and the first product (choline chloride). The third step involves the rapid hydrolysis of the acetylated enzyme to produce the free enzyme and the second hydrolytic product (acetic acid). The liberated acetic acid causes a pH decrease in the local environment of the enzyme optrode that can be detected by the immobilized pH indicator. This pH change is manifested as a colour change (blue green to yellow) in thymol blue, thereby leading to the increase in the reflected light intensity (measured at 600 nm) for the sensor.

A test sensor response curve illustrating the peaks obtained for varying concentrations of acetylcholine and replicate injections of the substrate is shown in Fig. 3. The concentration-dependent peaks and reproducible signals obtained here illustrate the feasibility of the measurement approach and the usefulness of the fibre-optic sensor design.

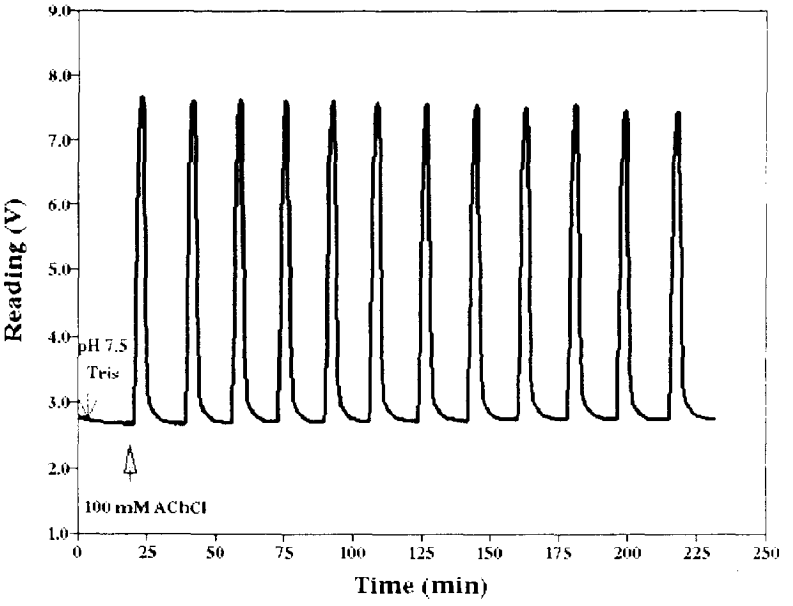

Fig. 4. Response of acetylcholine optrode to repetitive injection of 100 mM acetylcholine.

3.2. Reproducibility of response to acetylcholine

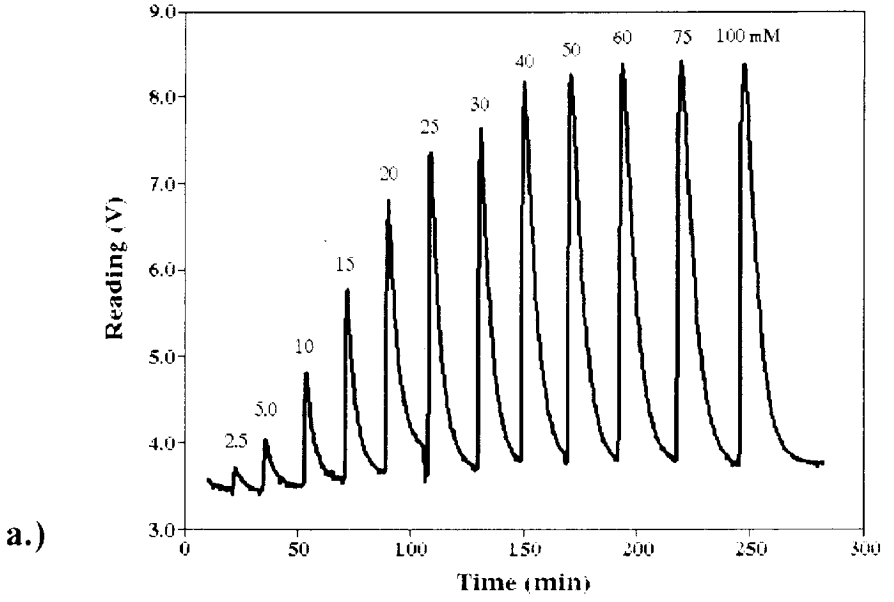
The reproducibility of the optrode response to repetitive injection of acetylcholine was then investigated. The applicability of the acetylcholinesterase-based sensor to pesticide determination depends on its reproducible response to the substrate solution. This requirement arises from the fact that the detection process involves the comparison of the enzyme activity before and after the exposure to the inhibitor. The change in sensor response should therefore be attributed to the inhibitor and not to the poor or non-reproducible sensor performance.

The response of the acetylcholine optical sensor on a periodic exposure to 100 mM acetylcholine chloride is depicted in Fig. 4. The response was fairly reproducible (RSD = 1.83% for $n = 12$), although it suffered from a small drift in the peak heights (about 1.6% h^{-1}). It was initially thought that the slow deterioration in the enzyme optrode response was due to product inhibition, brought about by drastic changes in pH during the enzyme reaction. Consequently, replicate measurements were also performed using a more dilute acetylcholine concentration (50 mM) and a reagent phase with a lower enzyme loading. However, no improvement was seen in the reproducibility tests for the optrode under these conditions. In fact, in some instances, the precision was worse for these sensors; although this was more attributable to the less perfect packing of the enzyme reagent phase at the fibre tip and the sporadic disturbances caused by bubbles that become entrapped in the flow cell and cause scattering in the light.

Nonetheless, provided that the reagent phase had been washed thoroughly (to remove weakly bound enzymes), that the glass beads are well packed at the sensor tip and that the bubbles in the flow stream were found to be absent or were carefully removed when they became entrapped in the flow cell, then the obtained precision of the sensor response is acceptable for inhibition measurements. The best precision achieved would already allow the distinct recognition of a pesticide sample that would cause at least a 3.7% inhibition in the response (2δ) of the enzyme optrode.

3.3. Acetylcholine calibration curve

The time–response curve of the enzyme op-



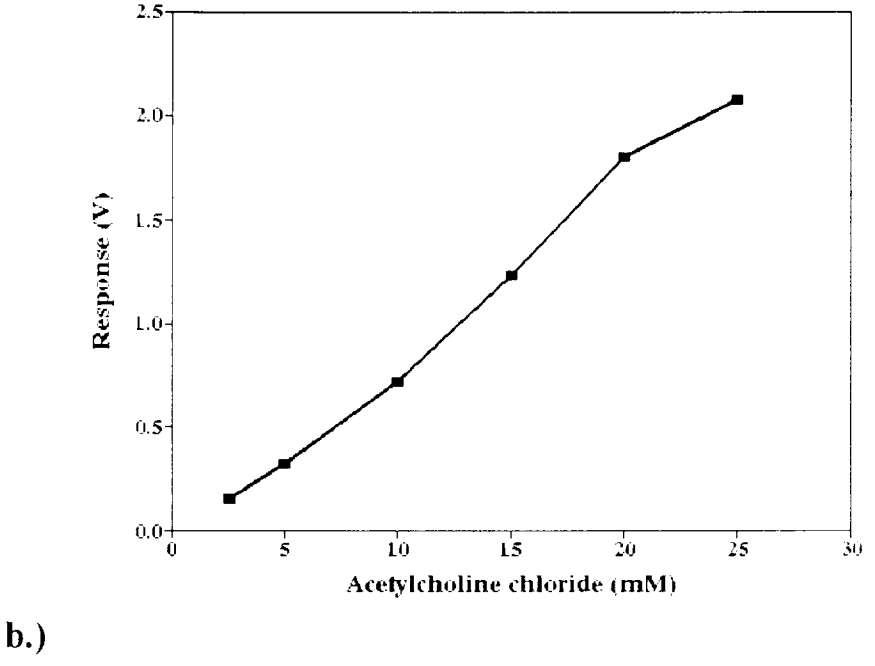


Fig. 5. (a) Time–response curve of acetylcholinesterase-based optrode to various concentrations of acetylcholine; (b) corresponding calibration curve in its linear response range.

trode during exposure to various concentrations of acetylcholine chloride is shown in Fig. 5(a) and the corresponding calibration curve is depicted in Fig. 5(b). Depending on the substrate concentra-

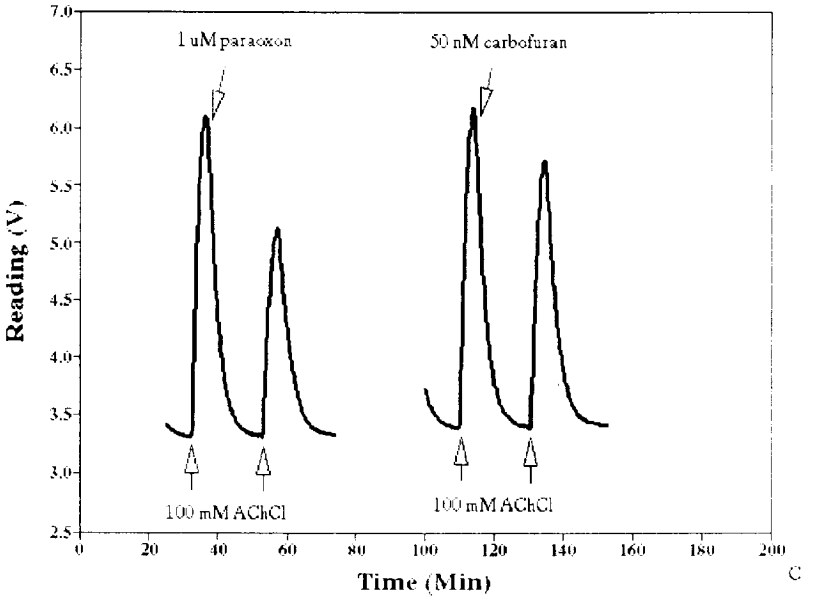

Fig. 6. Time–response curve of acetylcholine optrode before and after exposure to an organophosphate (paraoxon) and a carbamate (carbofuran) pesticide. The points of injection of the substrate and pesticides are indicated by the arrows.

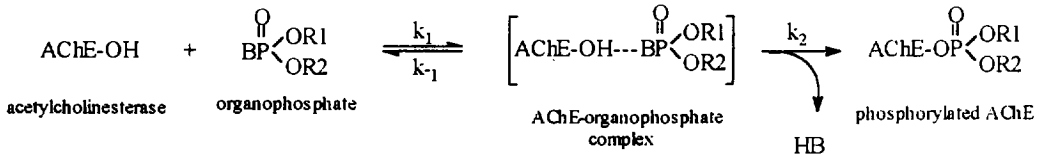
tion, it takes around 1.3–2.5 min to reach the maximum peak signal and around 15–20 min to recover the baseline level. The signal response, measured as the peak height, was linear with respect to acetylcholine concentration in the range 2.5–25 mM ($r^2 = 0.992$) and levelled off at concentrations > 40 mM. There was no sign of inhibition due to excess substrate, within the concentration range 0–100 mM, contrary to the normally observed behaviour of solubilized acetylcholinesterase enzyme [39].

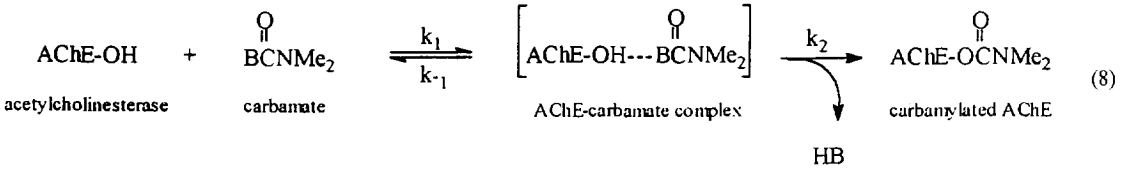
3.4. Determination of carbamate and organophosphate pesticides

3.4.1. Detection principle

Fig. 6(a) and (b) show the test response curves for the acetylcholinesterase-based optrode before and after the exposure to an organophosphate compound (paraoxon, 1 μM) and a carbamate (carbofuran, 50 nM). The reduced responses obtained after the introduction of the pesticides illustrate the possibility of detecting organophosphate and carbamate compounds using the acetylcholinesterase-based fibre-optic biosensor described here. The inhibition of acetylcholinesterase is normally attributed to the acylation of the serine –OH in the active site of the enzyme by these compounds [39,40]. The reaction with acetylcholinesterase is analogous to the enzyme–substrate reaction, whereby a Michaelis enzyme–pesticide complex is first formed, followed by the transfer of the pesticide acyl groups to the serine –OH of the enzyme, and the concomitant release of the side product HB, as depicted in Eqs. 7 and 8.



(7)



(8)

However, unlike the acylated ester formed from the choline ester, the rate of hydrolysis of the phosphorylated and carbamylated acetylcholinesterases was very slow. Consequently, when these acylated enzymes are reacted again with the natural enzyme substrate, acetylcholine, a lower pH change would be detected since the enzyme remains inhibited. The difference in the pH changes before and after the pesticide treatment of the sensor thus, provides information on the amount of the pesticide and can be utilized for its analysis.

3.4.2. Factors affecting the inhibition measurement

Substrate concentration can have a significant influence on the measured degree of inhibition for the acetylcholinesterase optrode, because both organophosphorus and carbamate pesticides act as competitive inhibitors and bind to the same active site of the enzyme on which the hydrolysis of the substrate (acetylcholine) takes place [39]. Thus, with a high concentration of the substrate, the inhibition by the pesticides may be hampered. This is obviously a concern in procedures wherein the inhibition and the measurement of enzyme activity are carried out simultaneously or where the pesticide sample and the substrate solution are both present in the reaction solution. In the procedure adopted in this work, however, the enzyme–substrate reaction is only initiated after a preincubation of the sensor in the pesticide sample. This ensures that there is no competition between acetylcholine and the pesticide and that the inhibition is maximized. High substrate concentrations can then be utilized for the enzyme assay. It also avoids the problem of having to contend with low optrode signals obtained at low substrate concentrations. In fact, in order to provide an accurate measure of the enzyme activity of the optrode, the substrate concentration should be high enough and into the saturation concentration range for the immobilized enzyme. In view, of this, an acetylcholine concentration of 100 mM is used for establishing the reference optrode signal and for the measurement of pesticide inhibition.

Flow-rate and sample volume are two of the experimental variables which are expected to have an effect on the sensitivity of the pesticide measurements. Large sample volumes favour greater contact time between the enzyme optrode and the pesticide sample, and thus can lead to higher enzyme inhibition. A similar situation is achieved when the flow-rate is low. However, as it has been observed that a low flow-rate results in longer sensor response times and consequently a low sample throughput, it is necessary to compromise the selected flow-rate condition for inhibition studies. It was therefore decided to adopt a flow-rate of 0.5 ml min^{-1} and a sample volume of 5 ml. This combination allows a reasonable sample contact time of 10 min between the sensor and the pesticide sample. Moreover, with these settings, the sample consumption is low, while the sensor response is maintained high and reasonably rapid.

3.4.3. Reactivation of pesticide-inhibited enzyme optrode

It is desirable for a pesticide-inhibited acetylcholinesterase-based optrode that its enzymic activity be recovered easily and efficiently. This will allow a more economical use of the sensor and facilitates its easier handling. However, results have shown that for an optrode that has been exposed to paraoxon, a spontaneous or rapid recovery of the enzyme activity was not very likely. Even a repetitive exposure to substrate solution did not provide a significant improvement in the enzyme reactivation. This can be ascribed, of course, to the strong ester linkage between the diethyl phosphate group and the serine moiety of the enzyme. Significant restoration in the enzyme optrode signal was only attained after the sensor has been treated with 2-PAM, which is a reagent commonly used for the

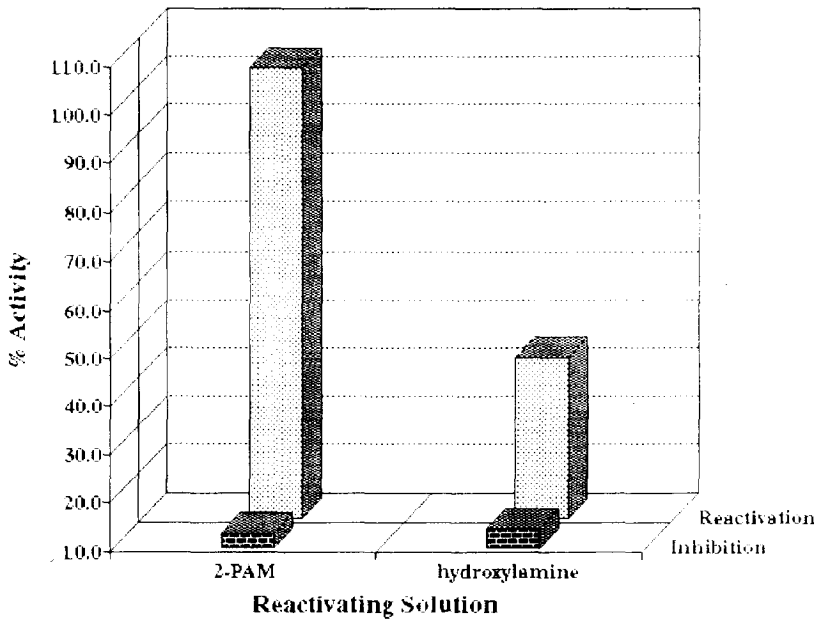


Fig. 7. Comparison of the reactivation efficiency of 2-PAM and hydroxylamine towards a paraoxon-inhibited acetylcholinesterase-based optrode.

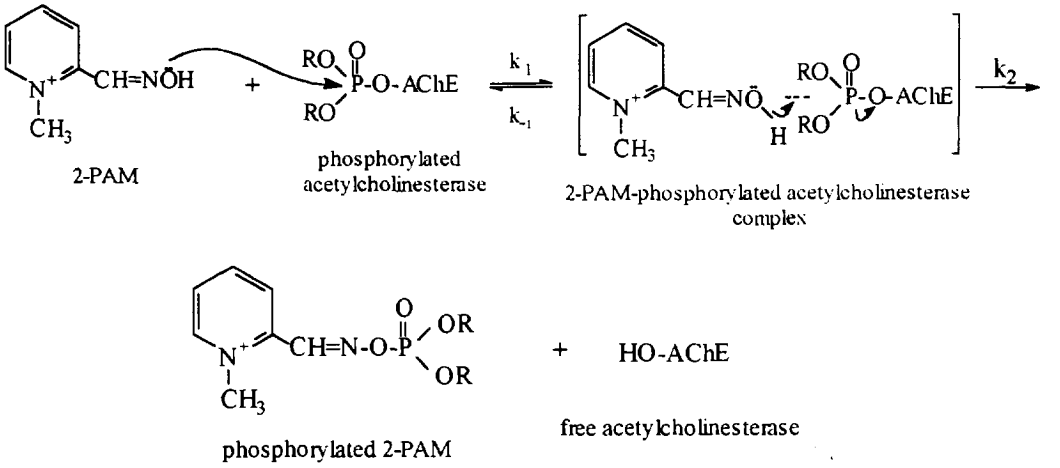
reactivation of organophosphate-inhibited cholinesterase enzymes [37]. It is generally believed that the reactivating effect of this reagent is due to its strong nucleophilic character, which makes it reactive towards the electrophilic phosphorus atom of the phsophorylated enzyme. In doing so, it displaces the enzyme from its attachment to the phosphorus, hence yielding the free and active form of the acetylcholinesterase again. This is illustrated in Eq. 9.



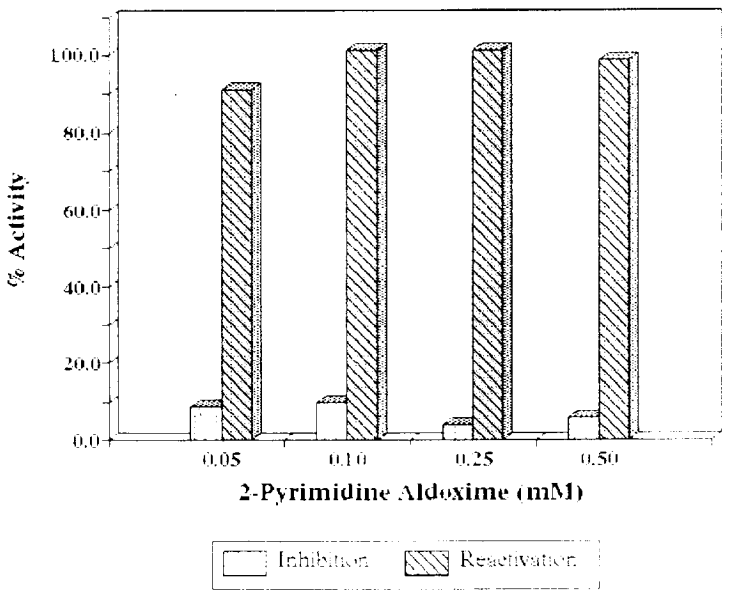


Fig. 8. Effect of the 2-PAM concentration on the efficiency of reactivation of acetylcholine optrode inhibited by 10 μM paraoxon.

However, as the phosphorylated oxime is known to be a potent inhibitor of the enzyme itself [37], it is necessary that a prolonged exposure of the immobilized enzyme with the former also be avoided, although with the relatively rapid decomposition of the phosphorylated 2-PAM and the continuous flow system employed in this study, the immediate removal or deactivation of the phosphorylated oxime is rather assured.

The efficiencies of hydroxylamine ($HONH_2$) and 2-PAM as reactivating reagents for a phosphorylated acetylcholinesterase optrode were also compared. A 10 μM paraoxon solution was used as the test pesticide solution and 2-PAM and hydroxylamine solutions, prepared at the same concentration (1 mM) and under similar pH conditions, were used as the reactivating agents. The results (Fig. 7) showed that 2-PAM is a more efficient regenerating agent than hydroxylamine. This can be traced to the better nucleophilic property of the oxime compared with the hydroxylamine. The good reactivating property of 2-PAM is also believed to be due to the cationic centre of the aldoxime [37]. This part can attach to the anionic site of the inhibited enzyme and thus arranges an easier and more proximate interaction between the nucleophilic –OH and the phosphorylated esteratic site.

Reactivation test were also performed on a carbamate-inhibited enzyme optrode. However, unlike the paraoxon-inhibited sensor, a recovery in the enzyme activity of the carbofuran-inhibited optrode is evident even on exposure alone to the substrate solution, albeit the reactivation was slow. This behaviour attests that the inhibition of the acetylcholinesterase optrode by the carbamate was reversible in nature, unlike that of the paraoxon inhibition. Unfortunately, however, the rate of regeneration of the carbofuran-inhibited optrode remained slow even after the introduction of 1 mM hydroxylamine or 2-PAM. A tenfold increase in the concentration of the nucleophilic reagents did not provide a significant improvement in the sensor regeneration either.

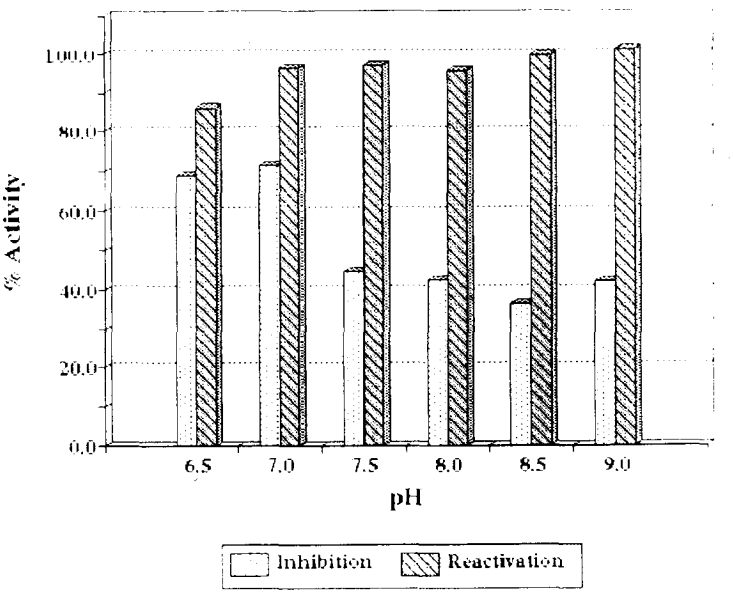

Fig. 9. Effect of pH on paraoxon (10 μM) inhibition and 2-PAM (1 mM) reactivation of the acetylcholinesterase-based optrode.

3.4.4. Factors affecting the reactivation

Having chosen 2-PAM as the reactivating reagent, solutions with various concentrations of this reagent were then prepared in order to compare its reactivating efficiency on the paraoxon-inhibited acetylcholinesterase-based optrode, using 10 μM paraoxon as the test inhibitor solution. The results (Fig. 8) suggest that 0.1 mM 2-PAM is sufficient to bring about a significant regeneration of a highly inhibited acetylcholinesterase optrode.

The influence of pH on the inhibition of the acetylcholine optrode by paraoxon and its reactivation by 2-PAM were also investigated. Tris buffers (7.5 mM) of varying pH (6.5–9.0) were made and were also used to prepare the various paraoxon (10 μM), 2-PAM (1 mM) and acetylcholine chloride (100 mM) working solutions. The results (Fig. 9) showed that the inhibition due to paraoxon increases with increasing pH and exhibits an apparent maximum at pH 8.5. The efficiency of reactivation by 2-PAM also improves with increase in pH. These changes can be attributed to the variation in the changes in ionization of the binding and catalytic sites of the enzyme, the inhibitor, the reactivator and the substrate as the pH is modified. As a result, the interaction between the enzyme and inhibitor of enzyme and reactivator is also expected to change. Although it seems that high pH (e.g. pH 8.5) appear to be favourable for the inhibition or regeneration reactions, the relative substrate response of the sensor at this pH is low. Measurements at this pH will thus be less precise. Furthermore, the prepared organophosphate and carbamate solutions are also unstable at high pH as they become more susceptible to hydrolysis [41]. Consequently, it was decided to conduct further inhibition and reactivation studies at pH 7.5, in order to maintain sensitive inhibition, efficient reactivation, high substrate response and stable pesticide samples.

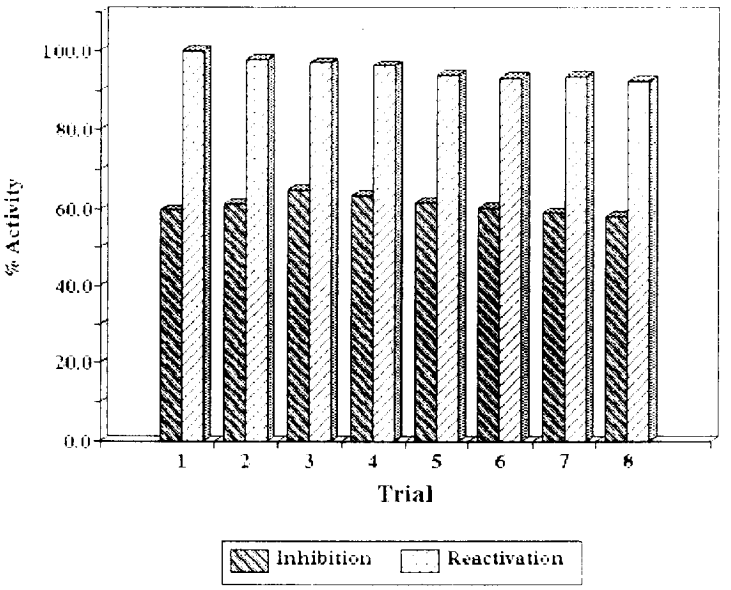

Fig. 10. Reproducibility of the inhibition of acetylcholinesterase-based optrode by 1 μM paraoxon and its reactivation by 0.1 mM 2-pyrimidine aldoxime.

3.4.5. Reproducibility of inhibition and reactivation

The reproducibilities of the inhibition measurement and the reactivation process for the acetylcholinesterase optical biosensor were also evaluated. The enzyme optrode was alternately reacted with 1 μM paraoxon and then regenerated using 0.1 mM 2-PAM. The results of the study are presented in Fig. 10. The inhibition and reactivation steps for paraoxon were fairly reproducible ($RSD_{inhibition} = 3.7\%$ for $n = 8$ and $RSD_{reactivation} = 2.8\%$ for $n = 8$). The precision and efficiency of the reactivation process can probably be improved by using 2-PAM solutions of slightly higher concentration.

An analogous inhibition and reactivation procedure for carbofuran (0.1 μM) yielded less reproducible responses ($RSD_{inhibition} = 5.8\%$ for $n = 4$ and $RSD_{reactivation} = 4.1\%$ for $n = 4$). These less precise inhibition data can be partly ascribed to the variations in the period allowed for sample and buffer stream elution before the substrate is again injected into the sensor. Ideally, a prompt introduction of the substrate, immediately after the tail of the sample stream has completely passed the sensor head, is necessary in order to obtain accurate inhibition measurement. However, in several instances, it was necessary to delay the substrate injection slightly to allow a more complete baseline recovery. Unfortunately during this delay, regeneration of the sensor can proceed owing to the reversible nature of the enzyme–carbamate interaction. Hence a slightly lower inhibition will be recorded.

3.4.6. Assay of organophosphate and carbamate pesticides

In order to demonstrate the usefulness of the acetylcholinesterase-based optical biosensor in the analysis of pesticides, its response to different concentrations of an organophosphate (paraoxon) and a carbamate (carbofuran) pesticide were determined. Stock pesticide solutions (1.5×10^{-3} M paraoxon and 1.0×10^{-3} M carbofuran) were prepared by dissolution of the reagents in acetone, and standard solutions were made by appropriate dilution in (7.5 mM) Tris buffer solution (pH 7.5). Response curves were obtained through a measurement cycle involving

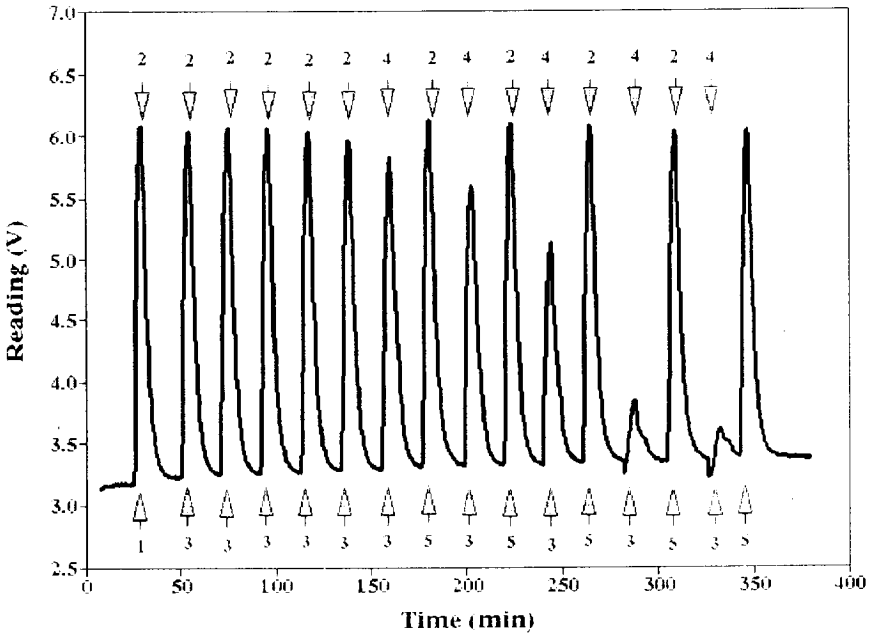

Fig. 11. Time–response curve of acetylcholinesterase-based optrode showing the inhibition by different concentrations of paraoxon and reactivation by 2-pyrimidine aldoxime. The arrows indicate the point of injection of substrate (1, 3, 5), pesticide (2) and reactivating agent (4). The measurement procedure generally consists of (1) preliminary measurement of uninhibited sensor response, (2) sampling of pesticide, (3) measurement of inhibited response, (4) reaction with reactivating agent, (5) measurement of reactivated response and (2) subsequent sampling of another pesticide sample.

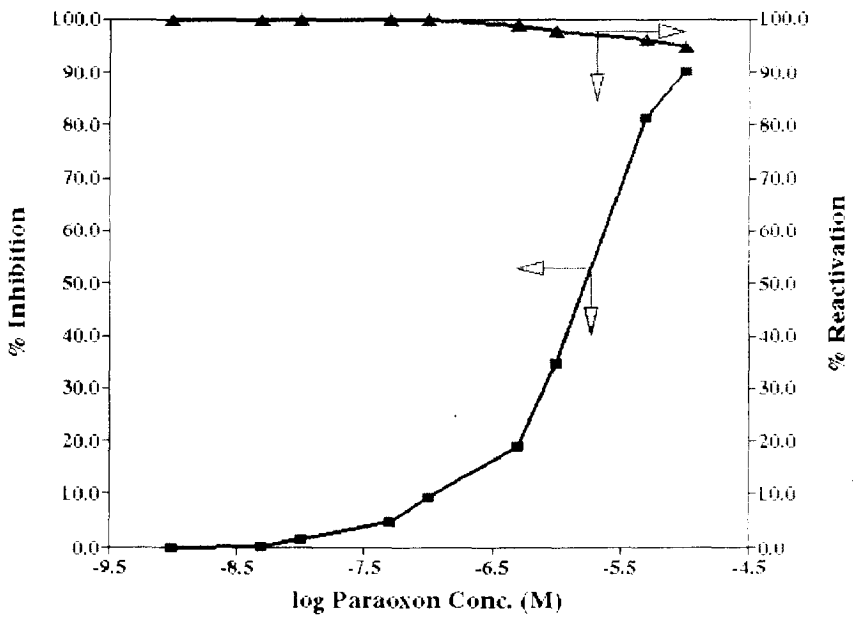
the alternate determination of acetylcholinesterase activity, sample exposure, measurement of inhibited signal, reactivation and remeasurement of enzyme activity. The time–signal profile showing these measurement cycles for paraoxon determination is shown in Fig. 11. The corresponding calibration curves for paraoxon and carbofuran are illustrated in Fig. 12(a) and (b). Both plots appear sigmoidal and exhibit linear response in the concentration ranges 5×10^{-8}–5×10^{-7} M for carbofuran and 5×10^{-7}–5×10^{-6} M for paraoxon. The detection limits, taken as the concentration at which the inhibition is 10% [10], i.e. $I_{10\%}$, are 1.5×10^{-8} M for carbofuran and 1.1×10^{-7} M for paraoxon.

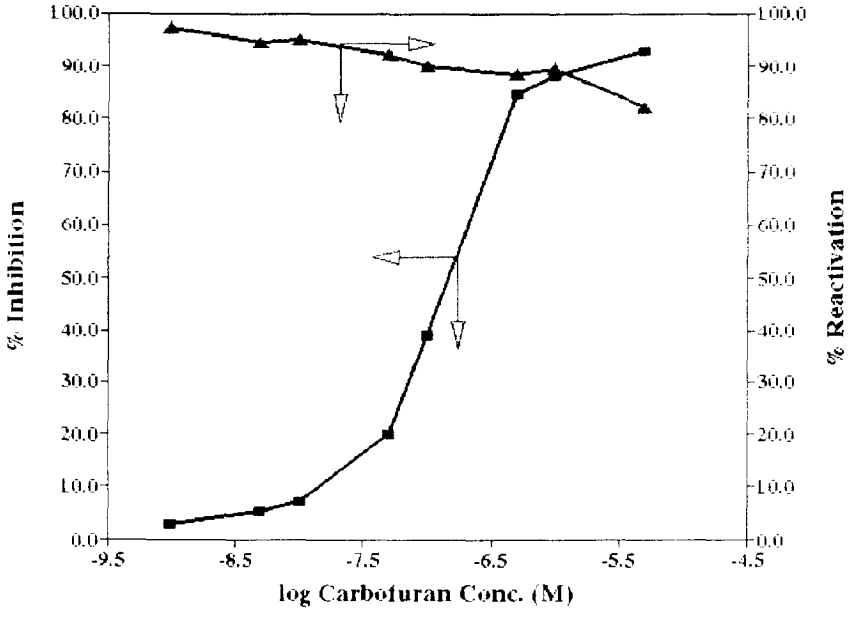
The plots also show the corresponding efficiency of the reactivation steps during the measurement cycles. A highly efficient recovery of acetylcholinesterase activity is obtained throughout a wide range of increasing paraoxon concentrations using 0.1 mM 2-PAM as the reactivating agent. On the other hand, the response of the biosensor was deteriorating during the determination of the carbamate, and this due to the incomplete reactivation at each regeneration cycle. However, the regeneration appears viable and can probably be improved by prolonging the sensor's exposure time to the substrate.

4. Conclusion

The construction and characterization of a fibre-optic biosensor based on controlled-pore glass-immobilized acetylcholinesterase and a colorimetric pH indicator (thymol blue) have been described and its application to pesticide analysis



a.)



b.)

Fig. 12. Calibration plots showing the variation of percentage inhibition with pesticide concentration and the corresponding percentage reactivation at each pesticide concentration: (a) paraoxon; (b) carbofuran.

has been investigated. The enzyme optrode exhibited good sensitivity towards acetylcholine, with a linear response in the concentration range 2.5–25 mM. The response was fully reversible and highly reproducible (RSD < 2%), further meriting its employment in the determination of pesticides based on enzyme inhibition. Parameters such as pH, flow-rate, substrate concentration and sample volume were noted to affect the inhibition process thus need to be optimized. Inhibition measurements using carbofuran and paraoxon as representative carbamate and organophosphate pesticides proved successful. The log [pesticide] vs. percentage inhibition plots exhibited a concentration dependence and were linear in limited concentration ranges. The detection limits, measured at $I_{10\%}$, are 1.5×10^{-8} M (3.1 ppb) for carbofuran and 1.1×10^{-7} M (27.1 ppb) for paraoxon. To achieve better sensitivity in the sensing process, an increase in the pesticide incubation time, e.g. through an increase in the sample volume, decrease in sample flow-rate or performing stopped-flow operations, can be further explored. By utilizing other sources of cholinesterase enzymes, better detection limits may also be achieved. Alfthan et al. [42] observed that cholinesterase preparations of different mammalian origins differ in sensitivity to pesticide inhibition.

The regeneration of the inhibited enzyme optrode has been possible, permitting its practical utility as a pesticide biosensor. Inhibition by an organophosphate pesticide (paraoxon) was effectively rectified by treatment with 2-pyrimidine aldoxime. The regeneration of carbamate-inhibited enzyme optrode was simpler and only entailed treatment with the substrate solution. The rate of signal recovery was slow, however.

As with other cholinesterase-based biosensors, the enzyme optrode described in this work does not selectively respond to a particular pesticide species, but to a wide range of organophosphate and carbamate pesticides. Hence, when exposed to a mixture of pesticide samples, it will most likely respond to the sum of inhibitory effect of the different inhibitors. It is therefore more useful as a screening device for cholinesterase-inhibiting pesticides, rather than being concerned with the determination of a particular pesticide. It can be applied as a general monitor for pesticide contamination in environmental water samples, drinking water, agricultural products, foodstuffs and many other samples.

Abstract

The quantitative capabilities of a system that combines a chiral selective separation mode with polarimetric detection (CSS/PD) were investigated in terms of the ability to quantitate enantiomeric mixtures even under conditions of poor chromatographic resolution. The laser-based polarimetric detection system can provide a rotational sensitivity on the order of 10 μdeg corresponding to a minimum measurable quantity of 10 ng for a compound with a specific rotation of 100 deg $(g/ml)^{-1}$ dm^{-1}. For the chromatographic studies, peak height and peak area were measured as analytical descriptors of the bimodal response function of this polarimetric detector. Analyses of the dansylated enantiomers of the amino acids phenylalanine, threonine, and valine have shown that chromatographic resolution and specific rotation are important factors affecting the shape of the polarimetric response curve. With CSS/PD, enantiomeric materials can be quantitated at both low and high enantiomeric excess (ee) even at resolutions of 0.3–0.4. © 1997 Elsevier Science B.V.

Keywords: Chiral separation; Enantiometric mixtures; Polarimetric detection

1. Introduction

The 1980s proved to be an important decade in the development of chiral separations, particularly with respect to liquid phase-based methods. In spite of the usefulness of indirect methods that produce separable diastereomers via derivatization with a chiral reagent, direct methods that involve chiral mobile phase additives (CMPA) and chiral stationary phases (CSP), have been vigorously pursued. The primary advantages of these methods over diastereomer formation are the reduced time per analysis, and the greatly reduced sample handling requirements of the instrumental methods. A considerable amount of work has been devoted to the design and utilization of chiral stationary phases and recent developments have revolutionized this area of separation science. Chiral separation techniques have especially benefited research in biotechnology and the pharmaceutical industry due to the importance of precise characterization of pharmaceutical materials of interest.

Several recent reviews [1–5] have summarized the progress in the field of enantiomeric separations. The emergence of the concept of chirality developed from studies by Pasteur on the relationship between optical activity and the spatial arrangement of atoms in a molecule. With the initial formulation of the structural requirements of chiral recognition by Dalgliesh, subsequent studies on the theory of enantioselective complexation have spurred the development of chiral stationary phases. In systematic studies of chiral recognition, Pirkle et al. [6–9] have validated the 'three-point rule' by implicating a minimum of three simultaneous interactions that must take place between the chiral stationary phase and at least one of the enantiomers. One of these interactions must be associated with a stereochemical dependence, that is, at least one of the three is either absent or significantly altered by replacing one enantiomer with its antipode without any conformational changes in either component. As summarized in the reviews cited above, thousands of compounds have been studied and separated using primarily the five different categories of commercially available chiral stationary phases that include ligand exchange, affinity, helical polymer, Pirkle or 'brush type,' and chiral cavity phases.

While HPLC has become an efficient technique for enantiomeric separations, the importance of polarimetric detection [10–12] has been noted as an adjunct to chromatography in the improvement of a chiral separation, and in enantiomeric purity determinations when only partial separation can be achieved. Since the separation of sugar standards and pressed juice samples by Boehme [13] using a commercially available polarimeter, substantial improvements have been reported with the introduction of a laser-based polarimeter [14]. Detection limits as low as 11 ng for fructose have been reported by Bobbitt and Yeung [15,16] using a microbore reverse-phase system with an argon-ion laser-based polarimeter. Such improvement was due to the increased efficiency of the chromatographic system and high frequency modulation which made it possible to detect an optical rotation of 1 μdeg. In one of the first reports of the use of a polarimetric detection system for enantiomeric purity determinations, Yeung and Reitsma [17,18] studied samples of amino acids separated using a cation exchange column. It was shown that the laser-based polarimeter was more sensitive than the RI detector and that the sensitivity of the technique could be increased by precolumn derivatization of amino acids with dansyl chloride in order to increase their specific rotation. Subsequently, using a diode-laser polarimeter, Lloyd et al. [19] tested a laboratory prototype optical rotation (OR) detector using the enantiomers of tryptophan. Polarimetric detection limits of 1 μg and $\pm$ 1% purity determinations at the 50 μg injection level were reported using a Spherisorb ODS column.

Whether or not a chiral separation has occurred is perhaps the most fundamental information a polarimetric detector can provide due to the opposite signs of the resulting peaks. An enantiomeric separation can be confirmed by coupling the UV and polarimetric detectors in series and measuring the ratio of the peak areas (or heights) of the UV and OR signals. This ratio should be constant for the two probable enantiomeric peaks [20]. In dealing with measurements of enantiomeric purity, Mannschreck et al. [21], invoked the role of UV and OA detectors connected in-series with the purpose of having the UV detector respond to the total amount of analyte and using the chiroptical detector to assay the proportion of each enantiomer in a mixture. The calibration factors obtained using a polarimetric detector for the *R* and *S* enantiomers, however, are not necessarily identical in the analysis of compounds with small specific rotations, or for mixtures with small enantiomeric excess (ee) due to refractive index-related effects [22]. While response functions were linear, the negative and positive signals did not coincide at zero ee.

Many studies reported during the past two decades have designed CSPs for the optimum separation of compounds as either the free enantiomers or as derivatized forms. These CSPs, however, while exhibiting excellent performance specifications for the compounds for which they were optimized, tend to be expensive and limited in their application. The utility of these chiral HPLC techniques to ascertain enantiomeric ratios and optical purities in mixtures is appropriate

only when baseline, or near baseline separation of the enantiomeric pair is achieved. Even in situations when adequate resolution is available, peak shape and detector sensitivity can limit the quality of the enantiomeric determination. Further, column failure, as manifested by decreased resolution can occur through various mechanisms including irreversible adsorption and stationary phase conformational changes. When the resolution decreases below baseline or near baseline, the ability to accurately quantitate the enantiomeric pair is substantially compromised. To enhance the quantitative capabilities of conventional enantiomeric separation methods, a chiral selective separation mode was interfaced with a polarimetric detection system (CSS/PD). To test the combined CSS/PD system, a series of dansylated amino acids were used as models to test the effect of chromatographic resolution and specific rotation on the quality of the data. Both peak area and peak height will be evaluated as analytical descriptors in this quantitation scheme. The influence of chromatographic resolution and specific rotation on the accuracy and precision of the enantiomeric data will be determined.

2. Experimental

2.1. Reagents

The dansylated amino acids (Dns-D- and L-Phenylalanine, Dns-L-Threonine and Dns-L-Valine), as well as the underivatized forms (D-Threonine and D-Valine) were obtained from Sigma (St. Louis, MO). Dns-D- and L-Phenylalanine were available in the free acid form while Dns-L-Threonine and Dns-L-Valine were purchased as cyclohexylammonium salts. The derivatizing agent, 5-[Dimethyl-amino]naphthalene-1-sulfonyl chloride (DnsCl) and the HPLC solvents acetonitrile and methanol were also obtained from Sigma.

2.2. Derivatization of amino acids

The procedure for the derivatization of amino acids for use in UV detection was reported by Tapuhi et al. [23]. DnsCl was dissolved in acetonitrile (1.5 mg/ml) while the amino acid was dissolved in 40 mM lithium carbonate buffer adjusted to pH 9.5 with HCl. A 1 ml volume of the DnsCl solution was rapidly added to 2 ml of the amino acid solution, the mixture was shaken for 2 min and then allowed to stand overnight at room temperature (22–23°C). Termination of the reaction was accomplished by adding 100 μl of a 2% ethylamine hydrochloride solution. Containers were wrapped with aluminum foil to exclude light.

For polarimetric detection, the quantity of the derivatizing agent as well as the amino acid, was increased to 0.0500 and 0.0250 g, respectively. DnsCl was dissolved in 20.0 ml of acetonitrile while the amino acid was dissolved in 10.0 ml of 40 mM lithium carbonate buffer adjusted to pH 9.5. The mixture was heated to about 55°C for 1 h and reactions were terminated using the 2% ethylamine hydrochloride solution. Solvents were evaporated at the same temperature under a vacuum.

Concentrations for the derivatized samples (Dns-D-Threonine and Dns-D-Valine) were determined using known concentrations of the corresponding Dns-L-amino acid and UV absorption spectroscopy.

2.3. Determination of specific rotation

Samples of commercially available, dansylated amino acids (DNS-L- and D-Phenylalanine, DNS-L-Threonine and DNS-L-Valine) were dissolved in a 70/30 (v/v) acetonitrile/NH_4NO_3 solvent mixture at a level of 0.100 g/10.00 ml. Specific rotations were obtained using a conventional polarimetric system at a measurement wavelength of 488.0 nm. The specific rotation of each compound was calculated from α, the actual rotation measured, c, the concentration of the solute in grams per ml of solution, and l, the pathlength, in decimeters.

2.4. Chromatographic analysis

The 25 cm × 4.6 mm i.d. Cyclobond column was purchased from Astec, Inc. (Whippany, NJ). The stationary phase for this column is a chiral

β-cyclodextrin chemically bound to a spherical gel support through a non-nitrogen-containing spacer arm. The preparation and characterization of this stationary phase has been described by Armstrong and DeMond [24].

Enantiomeric mixtures of D and L dansylated amino acids were prepared using different D to L ratios: 1/0, 0/1/, 1/1/, 1/2/, 2/1, 1/3, 3/1, 1/4, 4/1. In these mixtures, the total amount (L + D) of amino acid dissolved in the methanol solvent was prepared such that the amount of material injected with the polarimetric detection system was 15 μg for phenylalanine, 40 μg for threonine and 60 μg for valine using a 20 μl injection loop. With UV detection, the concentration of all three samples was set at 1.50 mg/250.0 ml. All separations were achieved at a flow rate of 1.00 ml/min using a degassed solvent system consisting of combinations of acetonitrile and NH_4NO_3. Since baseline separation for DNS-D and L-Phenylalanine was obtained with a solvent system of 80/20 acetonitrile/NH_4NO_3 [25], other solvent systems were prepared, for example, 70/30, 50/50 and 40/60, to decrease resolution. For the 40/60 solvent, the [NH_4NO_3] was 0.10 M.

2.5. UV and polarimetric detection

The UV detector (Shimadzu, Kyoto, Japan, model LC-6), was equipped with a solvent delivery module, a UV-VIS spectrophotometric detector and a CR 601 integrator. The laser-based polarimetric detection system has been described in detail previously [14,26], a schematic of which is given in Fig. 1. Briefly, the light source was an argon ion laser, (Lexel, Palo Alto, CA, model 85), mounted on a 4 × 6 ft. optical bread board. The source light was polarized by passing through a pair of Glan–Thompson polarizing prisms (Karl Lambrecht, Chicago, IL, model MGT-E8) and modulated using an in-house constructed Faraday cell driven by a signal generator (Wavetek, model 190). The modulation and detection cells had volumes of 1.1 ml and 28.57 μl, and pathlengths of 0.850 and 0.3826 dm, respectively. The polarized light passing through the analyzer was detected with a photomultiplier tube (PMT (Hamamatsu, Middlesex, NJ, model 928) powered by a high-voltage supply (Bertran Associates, Associates, Hicksville, NY, model 215). The signal from the PMT was demodulated, amplified and digitized using a lock-in amplifier (Stanford Research Systems, Palo Alto, CA, model SR 510). The digitized data were transferred to a PC computer over an IEEE interface (National Instruments, Austin, TX, model PC-2A) for storage and analysis. The Faraday coil used as an internal standard was made from a 10 cm × 0.125 o.d. piece of stainless-steel tubing wrapped with 8000 turns of a 30 AWG magnet wire (Bendon, Geneva, IL). A DC current of 0.266 A produced a rotation of 2.86×10^{-4} degree, as determined by Faraday's Law [26].

A minimum of three determinations for each enantiomeric mixture were obtained for both the UV and polarimetric detectors at all resolutions and L/D mixtures tested.

3. Results and discussion

This study sought to explore the potential of polarimetric detection for the quantitation of enantiomeric mixtures partially separated by a chiral-selective separation mode. The unique bi-

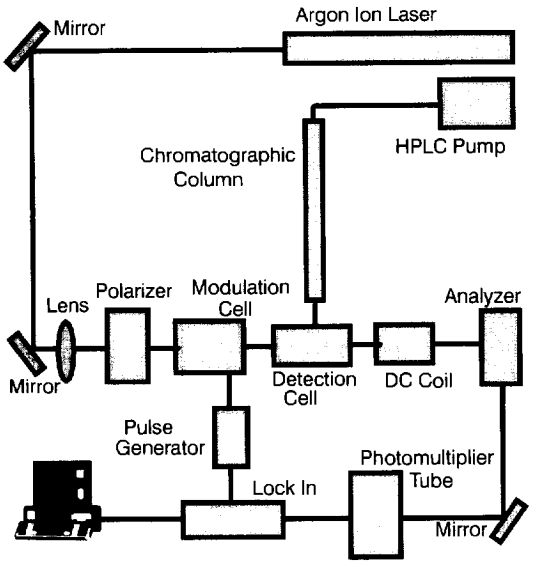

Fig. 1. Schematic of the laser-based polarimetric detection system.

modal response of the polarimetric system to the differing rotational properties of an enantiomeric pair may allow quantitative information to be obtained even under conditions of poor chromatographic resolution. This polarimetric response is expected to be equal in magnitude but opposite in sign for a given pair of enantiomers. Therefore, in contrast to a detection system which only provides a response in the same direction for an enantiomeric pair, the polarimeter provides a distinct and well defined zero crossing point which can be used to attribute peak area or height to the respective enantiomers in a quantitation protocol.

To evaluate the potential of this combined technology for enantiomeric quantitation, it is necessary to investigate the effect of specific rotation, chromatographic resolution and the mass ratio of the two enantiomers on the quality of the quantitative information extracted from the bimodal polarimetric response. Therefore, the dansylated derivatives of phenylalanine, threonine and valine were separated using a cyclodextrin column under varying conditions of chromatographic resolution. The three amino acid derivatives chosen provide specific rotations that vary by an order of magnitude, and in their sign of rotation.

Sample chromatograms obtained using either UV or polarimetric detection for the separated enantiomers of Dns-Phenylalanine are shown in Fig. 2 and Fig. 3. Fig. 2 shows the chromatograms of L and D Dns-Phenylalanine obtained from separate injections of the enantiomers with the L peak eluting earlier than the D peak. Fig. 2 also shows the DC reference signal that appears about 1 min after injection, and a peak disturbance due to the solvent at about 3 min. Fig. 3 shows the expanded chromatograms of the mixed enantiomers obtained using UV and polarimetric detection. The interesting feature of the polarimetric detector is seen in the unique bimodal response pattern, which is different from the unimodal response obtained with UV detection. As shown, since the L and D enantiomers rotate the plane of polarized light in opposite directions, the chromatograms obtained using polarimetric detection exhibit opposing signals for the L and D peaks. Unlike the unimodal response obtained using UV detection, the bimodal response pattern provides a

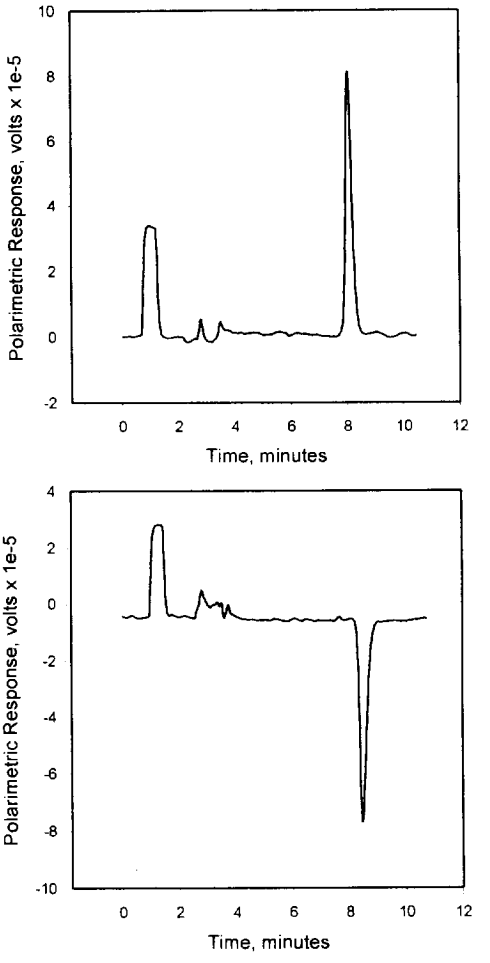

Fig. 2. Polarimetric detection of Dns-Phenylalanine. The peaks corresponding to the L and D enantiomers obtained using an 80/20 eluent system are shown in A and B, respectively. A DC reference signal produced by a DC coil appears at ~1 min and the peak disturbance due to solvent, at ~2 min.

well-defined crossing point between the two enantiomers that can serve as a reference in the determination of peak height and area. In combinations other than 1:1, such as 1:3 or 3:1 for the L and D enantiomers, the chromatogram obtained using polarimetric detection would clearly show this crossing point which would not be seen in a chromatogram obtained using UV detection. It should also be noted that the peaks obtained using UV and polarimetric detection as shown in the chromatograms in Fig. 3, do not elute exactly

at the same time due to differences in the length of connecting tubing and in the volumes of the cells used for the two detectors.

While a baseline separation of Dns-Phenylalanine enantiomers has been reported with the use of ACN/NH_4NO_3 [25] and MeOH/water [27] solvent systems, preliminary experiments identified conditions designed to decrease the resolution of the dansylated amino acid enantiomers by decreasing the organic content of the mobile phase.

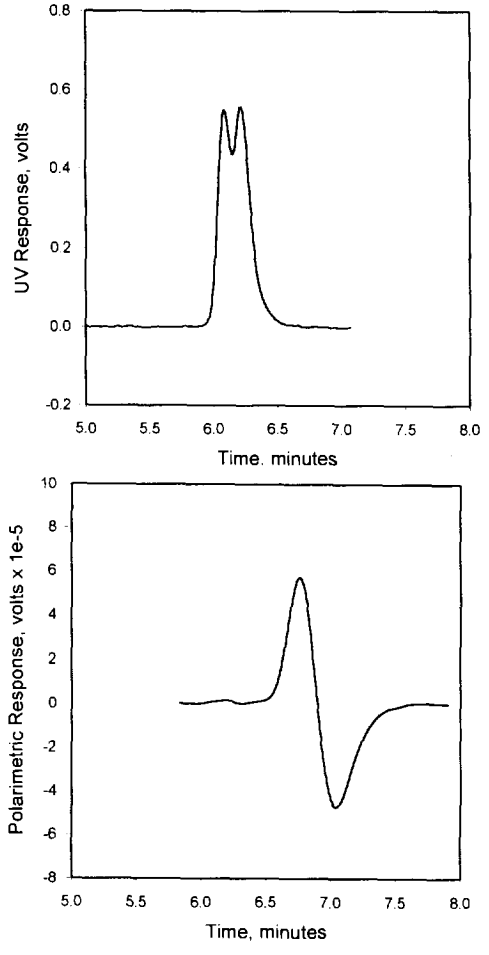

Fig. 3. UV and polarimetric response curves for Dns-Phenylalanine. The chromatogram in A was obtained using UV detection while B was obtained using polarimetric detection. Both chromatograms represent a 1/1 mixture of L and D enantiomers obtained with a 50/50 eluent system. Quantities injected were 0.12 and 15.0 μg for UV and polarimetric detection, respectively.

Tables 1–3 show the combinations of ACN/NH_4NO_3 used and the resulting retention time and resolution data for all pairs of enantiomers studied. The 60/40 combination was used with valine due to difficulties encountered in the elution of the enantiomers using the 80/20 eluent system. The decreased resolution available by decreasing the organic content of the mobile phase was an important part of this study and it allowed the capabilities of the CSS/PD system to be studied even under conditions of poor chromatographic resolution. As shown, the 80/20 eluent system was the most efficient in resolving the dansylated enantiomers of the amino acids as compared with the other eluent systems.

Peak height and area constitute the basic analytical descriptors utilized in many chromatographic analyses. While peak area has been generally considered a more 'fundamental' measurement as compared with peak height, uncertainties in the determination of baselines and peak boundaries have subjected peak area measurements to precision problems [28]. Studies have indicated that while peak area adequately correlates with the concentration of a component eluted from a column, the precision of a peak height measurement is significantly better than that of area even with the use of modern digital equipment [29]. Foley also noted that for tailed peaks of equal area, the errors in peak height are less than those in peak area [30]. In a 10:1 area ratio, it was found that a peak height measurement was more accurate than an area measurement when the small peak was eluted first, regardless of the tailing involved. When the small peak was eluted last, peak height determination was only superior if tailing was absent [31].

As analytical descriptors for the three dansyl amino acids, peak height and area were correlated with enantiomer fraction and these results are given in Table 4–6, and graphically presented in Figs. 4 and 5. Correlation coefficients were larger for peak height than for peak area, regardless of the magnitude of the chromatographic resolution. For Dns-L-Phenylalanine, the correlation coefficients for peak height and area using the 40/60 eluent were 0.993 and 0.981, respectively. With the 80/20 eluent where the resolution was higher,

Table 1
Retention time and enantiomeric resolution for Dns-Phenylalanine

[b] Resolution obtained using polarimetric detection.

the correlation coefficients for the same parameters were 0.996 and 0.995. With the latter eluting D enantiomer, these numbers were 0.984 and 0.987 for the 40/60 eluent and 0.996 and 0.987 for the 80/20.

The larger correlation coefficient observed for phenylalanine is most likely due to its larger optical activity when compared with the other species studied and the reduced quantity of material injected into the chromatographic system. Using the 70/30 eluent system, the specific rotations of Dns-Phenylalanine, Dns-Threonine and Dns-Valine were (− 131), (− 18.7) and (+ 65.3) deg $(g/ml)^{-1}$ dm^{-1}, respectively. The amount injected for phenylalanine was 15.0 μg as compared with the 40.0 and 60.0 μg amounts for threonine and valine, respectively. The commercially prepared Dns-Phenylalanine enantiomers also were obtained in a more pure form than the Dns-Threonine and Dns-Valine, which were synthesized prior to study. The derivatizing agent may interfere with the elution of the enantiomers, although it is not visible in the chromatograms obtained with the polarimetric detection system because of the absence of a chiral structure in the derivatizing agent. The use of the 80/20 eluent with UV detection of Dns-Valine in a preliminary study showed the fusion of the peak corresponding to the unreacted derivatizing agent with the enantiomeric peaks. This overlap was severe enough such that an accurate determination of resolution was not possible with UV detection.

In order to assess the efficiency of the CSS/PD, limits of quantitation for the enantiomers of Dns-Phenylalanine, Dns-Threonine and Dns-Valine were determined at different regions of enantiomeric excess (ee). The (ee) is defined as the difference between the proportions of the two enantiomeric components in the mixture divided by their total. For example, a 0% ee is equivalent to a racemic mixture, whereas, a 60% ee represents an 80:20 or 4:1 ratio of enantiomers. In the interest of this study, a − 40% ee represents a 30:70 ratio of the L and D enantiomers.

Tables 7–9 show the limits of quantitation (LOQ) for the enantiomers of dansylated phenylalanine, threonine, and valine at the regions of ee cited above. The LOQ represents the allowable values of x based on a linear calibration

Table 5
Correlation coefficient (r) for peak height and area with mass fraction of enantiomer for Dns-Threonine

Eluent[a]	L PK height	L PK area	D PK height	D PK area
40/60	0.996	0.998	0.985	0.997
50/50	0.991	0.994	0.993	0.982
70/30	0.994	0.998	0.997	0.991
80/20	0.992	0.984	0.987	0.993

[a] ACN/NH_4NO_3 (0.025 M, pH 4.0) except for the 40/60 (0.10 M, pH 4.0).

Table 6
Correlation coefficient (r) for peak height and area with mass fraction of enantiomer for Dns-Valine

Eluent[a]	L PK height	L PK area	D PK height	D PK area
40/60	0.992	0.991	0.987	0.985
50/50	0.996	0.994	0.994	0.994
60/40	0.998	0.991	0.984	0.993
70/30	0.995	0.989	0.986	0.997

[a] ACN/NH_4NO_3 (0.025 M, pH 4.0) except for the 40/60 (0.10 M, pH 4.0).

model and the standard error of the slope. In the 80/20 eluent system with Dns-Phenylalanine as the analyte, a 0.30 L enantiomeric fraction would fall in the range of 0.30–0.32, a 50% L, 0.49–0.52 and 80%, 0.77–0.83, when analysis was made in terms of peak height. In the 40/60 eluent, these values would correspond to 0.29–0.32, 0.48–0.53, and 0.77–0.85, respectively. With peak areas, the ranges include 0.30–0.32, 0.50–0.54, and 0.78–0.84, respectively, for the 80/20 eluent, and 0.27–0.33, 0.47–0.57, and 0.77–0.85, respectively, for the 40/60 eluent. Values for the D enantiomer were comparable over these ranges. Based on the correlation studies concerning peak height and area for all three derivatized samples at all resolutions, the LOQ indicate a value of 1–2% ee at the −40% ee level for peak height and peak area regardless of the magnitude of the correlation coefficient. At 0% and 60% ee, where the L/D ratios were 1/1 and 4/1, respectively, the LOQ was at the 3–5% ee level.

The unique feature of this study lies in the precision of the quantitative information available at these % ee levels. A limit of quantitation of 0.30–0.32, for instance, signifies a minimum quantity of 2% ee that can be measured using either peak height or area as the analytical descriptor. This limit of quantitation suggests the usefulness of the CSS/PD in quantitating enantiomers in a mixture under conditions of poor chromatographic resolution. For these limits, the resolution between the enantiomeric pair was 0.32, 0.47, and 0.34 obtained using the 40/60 eluent for phenylalanine, threonine and valine,

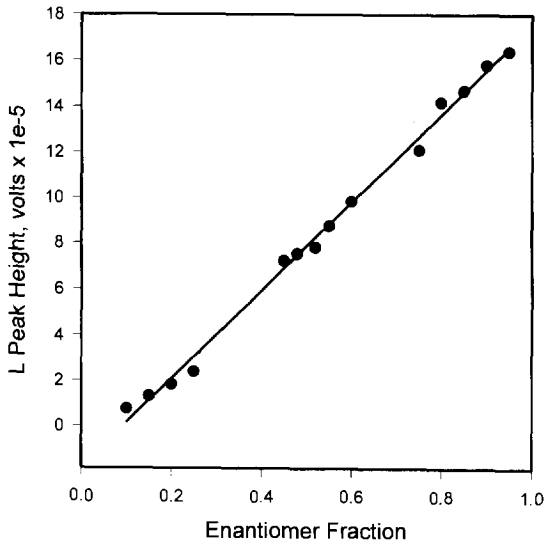

Fig. 4. Correlation of enantiomeric fraction and peak height for Dns-L-Phenylalanine. Eluent: 70/30 ACN/NH_4NO_3 (0.025 M, pH 4.0).

respectively. As compared with results obtainable using UV detection, where extensive overlap of the enantiomeric peaks precludes quantitation at these resolutions, the combination of the chiral selective separation mode with polarimetric detection, as demonstrated in this study provides significant advantages for the analysis of biological materials and pharmaceuticals. The limits of quantitation are at the level of injection reproducibility for manual injection. Further improvements would be expected in an automated injection system used with the CSS/PD technique.

This work has shown this technique to be useful for quantitating low levels of enantiomers ($\sim$ 1–2% ee), as compared to UV detection. What utility does polarimetric detection for incompletely resolved enantiomers have when compared with polarimetric detection with both no enantiomeric separation and with complete enantiomeric separation?

Polarimetric detection of enantiomers without separation is most useful when sufficient quantities of each enantiomer are available in pure form ($\geq$ 99.5% ee) for calibration purposes. Measuring the purity of these enantiomers requires an enan-

tiomeric separation, implying that the method of quantitating the enantiomers without separation may no longer be needed. A recent example illustrating the utility of enantiomeric quantitation without separation has been reported [32]. It may be true that enantiomeric quantitation without separation is often of limited utility as compared with these other two polarimetric detection modes.

The utility of polarimetric detection with complete enantiomeric separation is probably more clear cut: the bimodal signal is perhaps the most confirmatory evidence that an enantiomeric separation has indeed taken place. However, obtaining and maintaining baseline resolution of some enantiomers can be problematic, so there can be a complicated methods development strategy. Perhaps one clear advantage of polarimetric quantitation of partially resolved enantiomers is that it still provides a bimodal signal, just as with polarimetric detection with completely resolved enantiomers, but may permit shorter and simpler chromatographic methods development.

4. Summary and conclusions

It has been shown that the combination of a chiral selective separation mode with polarimetric detection (CSS/PD) can be used to quantitate enantiomeric mixtures even under conditions of poor chromatographic resolution. The bimodal response function of the polarimetric detector provides a well-defined crossing point between the two enantiomers which can then be used as a reference in the determination of peak height and area.

Analyses of the dansylated enantiomers of the amino acids phenylalanine, threonine and valine have shown higher correlation coefficients for peak heights than for areas with mass fraction of enantiomer. In addition to the concentration ratio

of the L and D enantiomers, specific rotation and chromatographic resolution constitute the important factors that affect the shape of the polarimetric response curve. For most resolutions studied, the LOQ was at, or near the RSD of the injection method used.

Work on the pharmaceutical application of the CSS/PD technique involving the enantiomeric analysis of DOPA and propranolol is in progress.

Received 13 June 1996; received in revised form 6 November 1996; accepted 13 November 1996

Abstract

The binary and mixed ligand complexes of some alkaline earth and transition metal (II) ions with dipicolinic acid (DPA) as a primary ligand and the biologically important secondary ligand (glycine), were studied using potentiometric technique. The acidity constants of the ligands were determined and used for determining the stability constants of the complexes formed in aqueous solutions under the experimental conditions ($t = 25°C$, $\mu = 0.1$ M $NaNO_3$). The dissociation constants of DPA were also determined in various water + dioxane mixtures under the same experimental conditions. It is concluded that a pronounced change in the pK values is observed as the solvent is enriched in dioxane. The values of $\Delta \log K$ have been evaluated and discussed. In addition, the chelation mode of ternary complexes was ascertained by conductivity measurements. © 1997 Elsevier Science B.V.

Keywords: Binary and ternary complexes; Dipicolinic acid; Potentiometric and conductometric studies

1. Introduction

Over the years there has been a steadily increasing interest in the complexes of pyridine derivatives [1–4] arises due in part to their physiological properties. The importance of pyridinecarboxylic acids stems from their presence in many natural products (alkaloids, vitamins, coenzymes, etc.). They are also of great interest to medicinal chemists because of the wide variety of their physiological properties displayed by the natural and synthetic acids. It is well known that complexes of metal ions are among the prominent interactions in nature [5,6], and the glycine residue is an important and versatile binding site of protein. Among pyridine dicarboxylic acids, dipicolinic acid seems to have the best chelating properties because it is terdentate.

As a continuation of our research program oriented to study binary and ternary complexes of biological importance, [7–11] the present work reports the formation and characterization of binary and mixed ligand complexes of the type M^{II}-DPA–glycine, where M = Mg, Ca, Sr, Ba, Cu, Co, Ni, Zn, Mn or Cd ions.

2. Experimental

2.1. Materials and solutions

Dipicolinic acid was obtained from Fluka. The reagent was repeatedly recrystallized from water, dried at 115°C, and checked by its melting point (250°C). Stock solutions were prepared by dissolving precisely weighed amounts of the anhydrous acid in suitably bidistilled water. Glycine was also provided by Fluka. The metal salts were provided by BDH as nitrates or chlorides. All solutions of metal (II) ions were prepared and standardized complexometrically by EDTA using suitable indicators [12]. Dioxane was of high purity (spectro grade product). Carbonate-free sodium hydroxide (titrant, prepared in 0.1 M $NaNO_3$ solution) was standardized potentiometrically with KH-phthalate solution (Merck AG). Nitric acid and NaOH were from Merck p.a.

2.2. Apparatus

Potentiometric pH measurements were carried out on solutions in a double-walled glass vessel at 25°C ± 0.1°C using a Griffin pH J-300-010 G Digital pH meter. The temperature was controlled by circulating water through the jacket, from a constant temperature bath. The cell was equipped with magnetic stirrer and a tightly fitting rubber stopper, through which an Amel 882 delivery dispenser, readable to 1 μl, and electrode system were inserted. The electrode system was calibrated in terms of hydrogen-ion concentrations instead of activities. Thus, all constants determined in this work are concentration constants.

Conductance of solutions was measured with PTI-10 Mini Digital Conductivity and temperature meter.

2.3. Procedure and measuring techniques

The following solutions were prepared and titrated potentiometrically against standard carbonate- free NaOH (0.1053 M) solution:(a) 0.04 M HNO_3 (5 cm^3) + 0.50 M $NaNO_3$ (10 cm^3)(b) (a) + 0.01 M DPA (5 cm^3)(c) (b) + 0.01 M M^{II} (2 cm^3)(d) (a) + 0.01 M glycine (5 cm^3)(e) (d) + 0.01 M M^{II} (2 cm^3)(f) (a) + 0.01 M M^{II} (5 cm^3) + 0.01 M DPA (5 cm^3) + 0.01 M glycine (5 cm^3)The total volume was adjusted to 50 cm^3 by adding double-distilled water in each case. All pH-metric titrations were performed at 25°C and $\mu = 0.1$ M ($NaNO_3$). An Irving and Rossotti pH titration technique [13] with modifications [14,15] was used to determine the protonation constants of the ligands and formation constants of the metal complexes. The equilibrium constants were calculated from six independent titration curves. The errors given in Table 1 and Table 2 are three times the standard error of the mean or the sum of the probable systematic errors, whichever is the larger.

Mixture (g) was titrated conductometrically against 0.1 M NaOH solution: g, 0.01 M Cu^{II} (10 cm^3) + 0.01 M DPA (10 cm^3) + 0.01 M glycine (10 cm^3).

3. Results and discussion

Dipicolinic acid, H_2L, can be further protonated as the acidity of the medium increases forming a monopositive species, H_3L^+. However, in the pH range utilized, this cationic form always proved negligible as checked previously using spectrophotometric technique [16].

The first and second proton association constants of neutral DPA were determined potentiometrically in aqueous solutions, under the experimental conditions ($t = 25$°C, $\mu = 0.1$ M

Table 1
pK_a values of dipicolinic acid in aqueous dioxane media ($t = 25$°C, $\mu = 0.1$ M $NaNO_3$)

Solvent composition %v/v	pK_1	pK_2
0.00	2.32 ± 0.05	4.53 ± 0.06
10	2.68 ± 0.04	5.15 ± 0.07
20	2.81 ± 0.07	5.45 ± 0.04
30	3.02 ± 0.04	5.67 ± 0.08
40	3.28 ± 0.06	5.98 ± 0.05
50	3.65 ± 0.08	6.32 ± 0.06
60	3.96 ± 0.08	6.75 ± 0.05

The pK_a values were calculated from pH titration data without correction.

Cd			6.75[a]	4.30 ± 0.05	1.65 ± 0.08	8.40	−2.65

[a] The values were previously determined by Anderegg using pCu-method [21], at 20°C, $\mu = 0.1$ M ($NaNO_3$).

$NaNO_3$). The values obtained (Table 1) are in a good agreement with the literature values [17].

In order to shed more light on the dissociation of DPA in various water + organic solvent mixtures, dioxane (an aprotic nonionizing coorganic solvent) was chosen. The observed increase in the pK_a values of DPA upon enrichment of the solvent with dioxane may be attributed to a lowering of the dielectric constant ($\varepsilon = 76.55$, 60.03 for 10 and 60% v/v solvent composition, respectively at 25°C) which increases in turn the fraction of associated ions to form Bjerrum ion pairs [18] and higher aggregates such as triple ions and dipole aggregates [19]. In this medium, free ions have very low concentration and acidity phenomena are governed largely by ionic association reactions, as previously reported by Kolthoff and Bruckenstein [20]. The pK_a values of DPA in aqueous dioxane media are listed in Table 1.

The stability constants of normal 1:1 binary complexes of DPA with alkaline earth metal ions have been determined. The values obtained (Table 2) agree well with those previously reported [21]. The stabilities decrease in the order Ca(II) > Sr(II) > Ba(II) > Mg(II).

In the cases of the 1:1 transition metal ions complexes with dipicolinic acid the acid strength of the complexing agent combined with the great stabilities of the complexes made the determination of stability constants by the pH method very inaccurate. The values of stability constants are taken from the work of Anderegg [21] using a copper amalgam electrode (p^{Cu}-method) as shown in Table 2.

The second association constant of glycine was determined, the obtained value (9.76) agree quite well with that previously reported [22].

The stability constants of glycine complexes with Mg, Cu, Co, Ni, Zn or Cd ions, agree well with literature values [22–25]. The disagreement found for the values of Ca, Sr, Ba or Mn complexes my be attributed to the different methods and ionic strength used for determination [23,26,27].

For the formation of the ternary complexes of the selected bivalent metal ions in presence of DPA = A and glycine = L, the following equilibria may be considered:

$$M + A \rightleftarrows MA$$

$$MA + L \rightleftarrows MAL$$

$$k_{MAL}^{MA} = \frac{[MAL]}{[MA][L]} \quad (1)$$

Here complex formation is considered to take place in a stepwise manner, i.e., the secondary ligand, glycine, starts complexation after the complete formation of the binary 1:1 complex of DPA. Representative titration curves for ternary systems investigated are shown in Fig. 1 and Fig. 2. The formation constants obtained are reported in Table 2.

The relative stability of the ternary complexes as compared with that of the corresponding binary complexes can be quantitatively expressed in different ways. The most suitable comparison is in terms of Δlog K, which represents the difference in stabilities for the addition of ligand L to the 1:1 MA complex and to the aquated metal ion as shown by Eq. (2) [28].

$$\Delta \log K = \log K^{MA}_{MAL} - \log K^{M}{}_{ML}$$

$$= \log K^{ML}_{MLA} - \log K^{M}_{MA} \quad (2)$$

The overall stability constant β^{M}_{MAL} which must be determined experimentally, is connected to K^{MA}_{MAL} by Eq. (3):

$$\log K^{MA}_{MAL} = \log \beta^{M}_{MAL} - \log K^{M}_{MA} \quad (3)$$

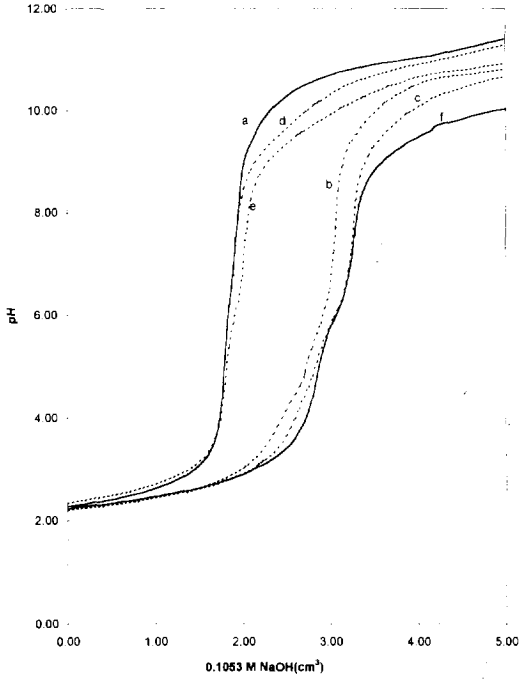

Fig. 1. Titration curves for the Ca^{++}–DPA–gly. system

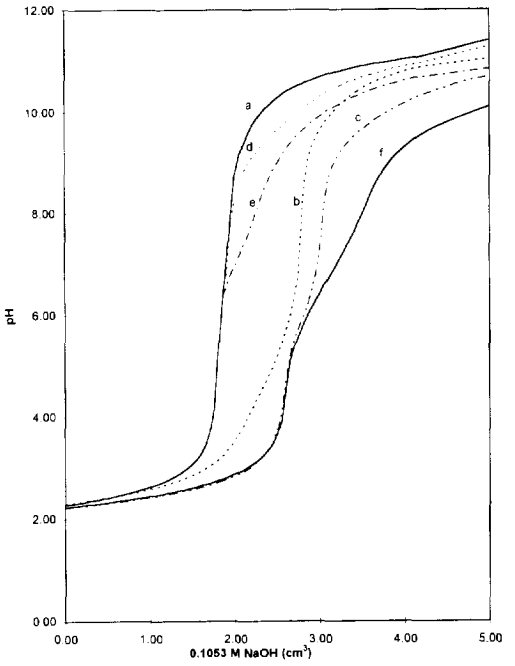

Fig. 2. Titration curves for the Ni^{++}–DPA–gly. system.

It is observed, that in general, Δlog K for the investigated ternary complexes is negative as expected from the statistical considerations (Table 2). There is π acidic character in the primary ligand (DPA), due to the possibility of M → Nπ bond formation. This behaviour is similar to that observed previously in [M-dipyridyl-L] complexes [14,29].

The conductometric titration curve of the ternary complex containing copper (II) with DPA and glycine (Fig. 3) shows an inflection at a = 2, probably corresponding to the neutralization of protons resulting from the formation of Cu-DPA binary complex. Between 2 < a < 3, the slight increase of conductance is due to the formation of the ternary complex and is associated with the release of a proton from the secondary ligand (glycine). Beyond a = 3, the conductance increases more uniformly due to the presence of excess sodium hydroxide.

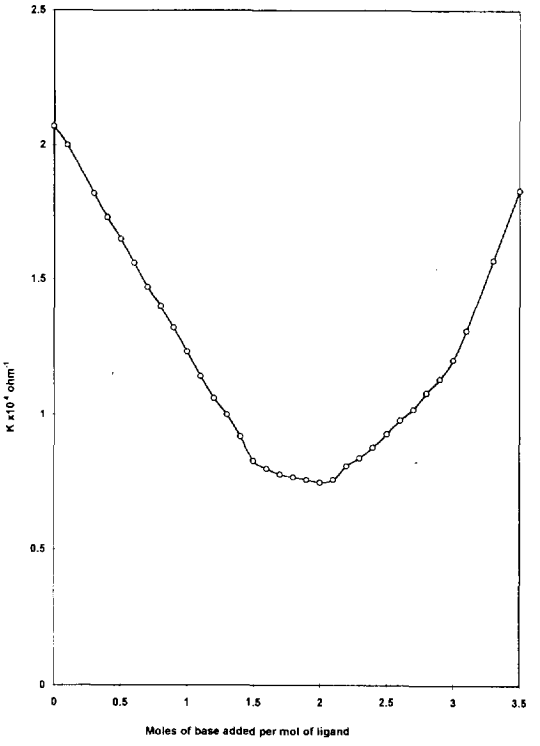

Fig. 3. Conductometric titration curve of Cu^{++}–DPA–gly. system.

The separation of gold by selective extraction of $HAuBr_4$ using a poly(tetramethylene) ether glycol impregnated filter

Richard Oleschuk, Art Chow *

Department of Chemistry, University of Manitoba, Winnipeg, MB, R3T 2N2, Canada

Received 18 October 1996; received in revised form 2 December 1996

Abstract

The separation of gold(III) by selective extraction on an organic- impregnated filter (OIF) was studied. Gold was found to be rapidly extracted into the active polytetramethylene ether glycol (polyTHF) layer of the filter from strongly acidic solutions of HBr, as the $HAuBr_4$ complex. Quantitative extraction of gold from solution was obtained with flow rates up to 600 ml min^{-1} through the 10.75 cm^2 OIF and at ng ml^{-1} concentration levels. The extraction is shown to be dependent on the solution flow rate and HBr concentration as well as the filter pore size, thickness and porosity. Gold can be eluted from the filter by converting it into the $AuBr_4^-$ complex using a KBr solution. The separation of gold is demonstrated from simple binary metal mixtures involving iron and cadmium, as well as from a more complicated matrix, gold ore solution. © 1997 Elsevier Science B.V.

Keywords: Ether glycol; Gold; Selective extraction

1. Introduction

Classical solid phase extraction (SPE) is the selective partitioning of one or more components between a solid and liquid phase. Sorbent material can be made for a specific analyte or analytes in order to extract only certain components in a mixture, or it can be modified so that only the compounds of interest are not sorbed on the solid phase material. The extraction of metals is performed using either a chelating sorbent or by employing solution conditions to form complexes that are extractable onto the solid sorbent.

Extractable metal complexes can be formed using complexing agents such as crown ethers [1–4], or by attaching bulky ligands to a molecule followed by extraction onto a hydrophobic sorbent. The extent of formation for a complex is determined by the stability constant of the complex and the relative concentrations of the complexing agents present in solution. Gold(III) is a soft Pearson [5] acid so it prefers to form complexes with bulky non-polar ligands. Gold(III) in the presence of sufficiently high chloride and bromide concentrations forms either the $AuCl_4^-$ or $AuBr_4^-$ (Eq. (1)) complex, respectively [6,7]. These complexes are stable in aqueous solutions [8,9] at a pH lower than 6. Both complexes are weak acids that become protonated at sufficiently low

pH (Eq. (2)) to form the extractable $HAuCl_4$ [10,11] and $HAuBr_4$ complexes in the following equilibrium.

$$Au^{3+} + 4Br^- \rightleftharpoons AuBr_4^- \quad (1)$$

$$AuBr_4^- \rightleftharpoons HAuBr_4 \quad (2)$$

Gold has been shown to be extracted as either the $HAuCl_4$ or the $HAuBr_4$ complex by diethyl ether [12], isopropyl ether [13] and polyurethane ether-type foams [14] and elastomers [15]. Each of these compounds possess ether linkages (-O-) in their structures. Preliminary experiments have shown that gold is also extracted from an HBr solution into the compound polytetramethylene ether glycol (polyTHF) (Fig. 1) which also possesses an ether linkage in its structure.

By impregnating a porous polytetrafluoroethylene filter with polyTHF, the gold complex, $HAuBr_4$, can be rapidly extracted from solution as it passes through the impregnated filter. This device is termed an organic-impregnated filter (OIF). The immobilisation of polyglycols in the pores of a filter has also been used by Ho [16] to prepare supported liquid membranes for the removal of organics from aqueous solutions.

The rapid gold extraction is shown to be both selective and quantitative. Once extracted the gold can be eluted by an analogous process to the extraction. The gold complex is converted to the de-protonated $AuBr_4^-$ complex where it is stripped from the surface of the active layer and consequently removed from the filter. In this paper, the use of an organic-impregnated filter for the selective removal of gold from solution is demonstrated. The effects of the HBr concentration, the flow rate, the filter pore size and the filter porosity on the extraction of gold from HBr solutions will be described. The recovery of the gold, and the ability of the OIF to preconcentrate and separate gold in simple binary metal mixtures and from gold ore will be investigated.

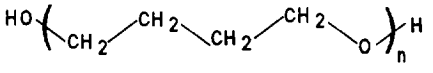

Fig. 1. Polytetramethylene ether glycol (polyTHF).

2. Experimental section

Polytetramethylene ether glycols (polyTHF's) of nominal molecular weights 650, 1000 and 2000 ± 50 g mol^{-1} were provided as samples by BASF. $NaAuCl_4$ was supplied by Johnson-Matthey and hydrobromic acid by Anachemia. Sodium hydroxide was purchased from Mallinckrodt and potassium bromide from British Drug Houses (BDH). All chemicals were reagent grade or better. Gold ore was obtained from Kirkland Lake Mine in eastern Ontario, Canada. All water used was purified by a Barnstead Nanopure™ II system using reverse osmosis-treated feedstock. A Varian Liberty 200 ICP emission spectrometer was used for the multi-element determinations made when performing the separation of gold from gold ore. Inter-element correction was used when overlapping emission lines were present. Atomic absorption was performed using a Varian SpectrAA-20 atomic absorption spectrometer equipped with an Instrumentation Laboratory Visimax™ hollow cathode lamp and an air-acetylene flame. The wavelength observed was 242.8 nm with a slit width of 1.0 nm. Two different types of polytetrafluoroethylene filters were used to prepare the OIF. Both filters were supplied by Millipore™ with the following specifications: pore size 5.0 μm, 47 mm diameter, 60% porosity and thickness 125 μm, (catalogue # LSWP04700) and pore size 3.0 μm, 47 mm diameter, 85% porosity and thickness 200 μm, (catalogue # FGLP04700).

The OIF was prepared by first liquefying the PolyTHF at 65°C in an oven for approximately 15 min. PolyTHF is a waxy solid at room temperature requiring softening to facilitate impregnation. The filter to be impregnated was first weighed and placed in a standard Millipore™ HPLC filtration device. Then 3–5 ml of PolyTHF was poured into the filtering receptacle. Vacuum was applied to the filter flask to pull PolyTHF through the filter until all the polymer in the filtering receptacle had been either passed through, or coated on the filter. The filter was then removed from the HPLC filtering apparatus and any excess PolyTHF beaded on the surface gently removed from the poly-

tetrafluoroethylene filter by pressing with a Kimwipe™. The organic-impregnated filter was weighed and was then ready to be used for extraction. The impregnation process yielded a filter with an active area of 9.6 cm^2 and requires less than 10 min of preparation time.

PolyTHF forms the active layer of the OIF in the gold extraction. The preparation process leads to an average loading of 50 and 100 mg of PolyTHF on the 5.0 and 3.0 μm pore size material, respectively. The larger loading on the 3.0 μm filter is due to the increased thickness and porosity of this filter compared with the 5.0 μm filter. PolyTHF coats the entire surface of the filter, penetrates into the pores of the filter and then solidifies. Scanning electron microscopy revealed that there are still holes visible on the surface of the OIF facilitating the passage of liquid through the filter. The presence of holes after the impregnation is essential for adequate flow through the filter because otherwise the filter would be clogged and unusable. Smaller pore size filters (0.2 and 0.5 μm) were impregnated and tested but the impregnation step led to clogging of the pores.

All gold solutions were prepared from a 500 mg l^{-1} standard prepared by dissolving $NaAuCl_4$ in 0.1 M HCl. The gold ore used in the gold ore separations is from the Kirkland Lake Mine in eastern Ontario, Canada. Gold ore solutions were prepared by first digesting the ore in aqua regia for a period of 1 week. The nitric acid portion of the mixture was then removed by evaporation while adding small aliquots of concentrated HCl. The acid content of the mixture was lowered by then boiling this solution while adding aliquots of deionised water. Finally the solution was filtered using Whatman™ No. 42 filter paper to remove the silicates not dissolved in the acid.

Samples were prepared and spiked with gold to the concentrations: 0, 1, 2, 5 mg l^{-1} Au. These solutions were made to 2.0 M HBr to facilitate the formation of the $HAuBr_4$ complex. The eluting solutions were prepared by dissolving KBr in deionised water and adjusting the pH with sodium hydroxide.

Once the OIF had been prepared it was placed in a standard HPLC filtration apparatus and clamped into place. The gold-containing solution was then placed in the filtering receptacle and a vacuum applied to the bottom filter flask to obtain the desired flow rate of the gold solution. The average flow rate was then calculated by dividing the time required for filtration by the volume of solution filtered. After the solution had passed through the OIF, an aliquot of the filtrate was taken for further analysis and the solution was placed again in the filtering receptacle and the filtration/extraction process repeated until the desired number of passes through the OIF had been completed. Once extracted the gold was eluted from the filter by passing the eluting solvent through the filter and collecting the filtrate for analysis.

3. Results and discussion

3.1. Extraction of $HAuBr_4$ with an OIF

Gold in the presence of suitable HBr concentrations forms the $AuBr_4^-$ complex [7]. The complex is a weak acid and at low pH becomes protonated.

$$HAuBr_4 \rightleftharpoons \overline{HAuBr_4}$$

*overline indicates the species present in the polyTHF layer of the OIF

We have shown previously [15] using polyurethane ether-type membranes that, the $HAuBr_4$ complex is responsible for the extraction of gold which is present at high HBr concentrations.

Fig. 2 shows the extraction of gold from several 100 ml solutions containing 5 μg ml^{-1} Au with increasing HBr concentrations. The solutions were each passed through the filter at 100 ml min^{-1}. The extraction of the solution containing 0.01 M HBr showed 50% of the gold still remained in the filtrate after one pass through the filter. Conversely, the extraction of gold from the solution containing 1.0 M HBr showed that the gold is quantitatively removed from the solution after only one pass through the OIF at 100 ml min^{-1}. The larger the HBr concentration, the greater the percentage of gold present in the extractable form. A greater percentage of the gold

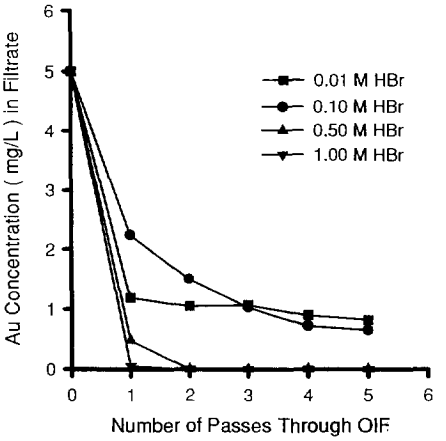

Fig. 2. The extraction of gold from solutions containing increasing HBr concentrations. Experiment was performed on 100 ml of solution at a flow rate of 100 ml min^{-1} through a 5.0 μm OIF.

being present in the extractable form leads to more of the gold being removed after one pass through the filter.

The extraction of gold can be followed both by the development, and loss, of an orange hue ($\lambda_{max} = 374$ nm) on the filter, and in the gold solution, respectively.

The effect of flow rate on the extraction of gold was tested using the 5.0 μm filter (Fig. 3). Several 100 ml solutions of 5 mg l^{-1} Au in 2.0 M HBr were passed through a 5.0 μm filter at different

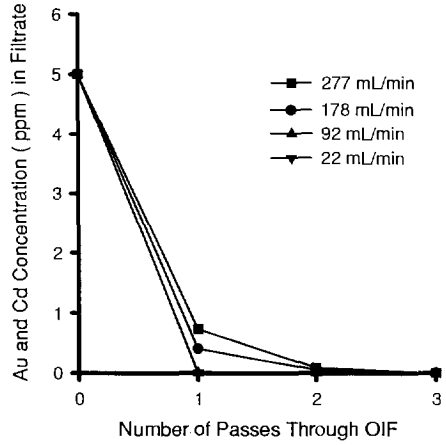

Fig. 3. The extraction of gold from 2.0 M HBr solutions using different flow rates with a 5.0 μm OIF.

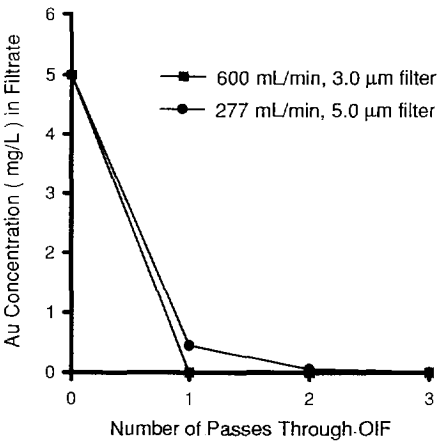

Fig. 4. The effect of using filters with different physical characteristics: ■ pore size 3.0 μm porosity 85% and thickness 200 μm, ● pore size 5.0 μm, porosity 60% and thickness 125 μm.

flow rates ranging from 22 to 277 ml min^{-1}. At flow rates of approximately 200–300 ml min^{-1}, 85–90% of the Au is removed from solution after one pass, and is quantitatively removed after two passes through the OIF. At flow rates of 92 ml min^{-1} and below the gold is quantitatively removed after only one pass through the OIF. The faster flow rates do not allow sufficient contact time for all of the gold to be extracted from solution. A comparison of the effect of flow rate on the extraction of gold for both the 5.0 and 3.0 μm filters is shown in Fig. 4. The 3.0 μm filter (thickness 200 μm, 85% porosity) has a greater thickness and porosity than the 5.0 μm filter, (thickness 125 μm, 60% porosity). The larger thickness and porosity leads to a greater loading of polyTHF on the surface of the filter which gives improved extraction performance. Even at a flow rate of 600 ml min^{-1}, the 3.0 μm OIF quantitatively removes the gold from solution. The extraction of gold is an extremely fast process as the actual contact time for the solution on the filter is extremely short. Filters with smaller pore sizes (i.e., 0.5 and 0.2 μm) were made but they became plugged after coating with polyTHF and did not allow sufficient solution flow.

Different molecular weights of polyTHF were tested ranging from 650–2000 g mol^{-1}. There appears to be no difference in extraction efficiency

between the different molecular weights. However, although there was no difference in the extraction efficiencies, the larger molecular weights had the advantage of being more viscous and more resistant to creep. Creep is the process by which a polymer undergoes a slow change of shape or a flowing action when subjected to a constant force. For the experiments performed in this paper, the polyTHF (M.W. 1000) used showed very little creep as measured by the slight weight loss incurred by an OIF for the duration of an experiment.

The capacity of the OIF was determined by passing several 100 ml solutions of 100 mg l^{-1} Au in 2.0 M HBr through the OIF until no further gold was extracted from solution. It was determined that greater than 0.5 mg of gold could be extracted for every mg of polyTHF loaded onto the filter.

3.2. Recovery of gold from the OIF

In solid phase extraction the recovery of an extracted analyte is important to the final analysis of a particular species. The gold can be recovered from the OIF in a similar manner to which it was extracted. The extraction of the gold into the active layer of the OIF dependent on the formation of the $HAuBr_4$ complex which is readily extractable into the active polyTHF layer held on the surface of the OIF. If the complex is not protonated it is not extracted into the organic layer. Conversion of the protonated complex at the surface of the polymer layer, to the deprotonated complex, leads to the elution of gold from the OIF.

$$\overline{HAuBr_4} \rightleftharpoons AuBr_4^- + H^+$$

* over line indicates species present in the polyTHF layer on the OIF.

The gold can be recovered with efficiencies of 95–100% at a flow rate of 10 ml min^{-1} using a solution of 0.5 M KBr adjusted to pH 10. The recovery of gold requires a flow rate that is substantially slower than that used for the extraction step. Once the $HAuBr_4$ is extracted, the complex diffuses throughout the polyTHF layer. Elution from the OIF requires the deprotonation of the gold complex. Only complexes present at the surface of the polymer layer are deprotonated by the change in elution solution and then subsequently removed, which induces a concentration gradient within the polyTHF layer. This gradient causes more gold complex to diffuse to the surface of the polyTHF layer where it can deprotonate and be subsequently removed. The recovery process is diffusion-limited, requiring flow rates of approximately 10 ml min^{-1}, roughly 10% of that of the extraction step. Eventually all of the gold on the filter is removed by the constant deprotonation of complexes that were formerly deeper within the polymer layer. The thin layer of polyTHF on the OIF is preferential to a disk made entirely of polyTHF. The thin layer allows faster elution of the extracted species. If the filter were made entirely of polyTHF or the applied layer made extremely thick, the filter would possess a greater capacity for the gold species, but would suffer from the extremely long elution times required to allow the complexes to diffuse to the surface.

The elution solvent was adjusted to a pH of 10 to neutralize any residual acid that was present on the filter. If this pH adjustment is not made then gold recoveries are not quantitative because the residual acid present on the filter and filter equipment lowers the pH of the eluting solution enough to inhibit the deprotonation of the $HAuBr_4$ complex. Consequently some of the gold will remain in the polyTHF layer.

The gold can also be removed from the filter by removing the entire polymer layer from the filter. Washing the filter with acetone will dissolve the polyTHF layer and remove it from the polytetrafluoroethylene filter. The filter can then be reused by impregnating it again with polyTHF.

3.3. Preconcentration using the OIF

Gold is usually found in low concentrations (μg l^{-1}) in natural waters and gold ore. Therefore it is often valuable to concentrate as well as separate gold from other species prior to analysis. The OIF can be employed to concentrate gold by extracting gold present at low concentrations in a large volume of solution, and then eluting the gold using a small volume of solution. A 2.0 l solution

of 125 μg l^{-1} Au in 2.0 M HBr was passed through a 5.0 μm OIF at a flow rate of 100 ml min^{-1}. The gold complex was then eluted from the filter using 100 ml of 0.5 M KBr adjusted to pH 10. Under these conditions the quantitative recovery of the gold should produce a gold concentration of 2.5 μg ml^{-1} in the eluting solvent. The concentration of the gold in the eluting solvent was found to be 2.4 μg ml^{-1}. This corresponds with a 96% recovery of the gold and a 20-fold increase in concentration compared with the original solution. The experiment shows that gold can be concentrated from solution onto the OIF even when initial concentrations are low.

3.4. Extraction of gold in the presence of other metals

Acyclic polyethers are relatively weak and unselective at complexing metal ions [17]. Only metals that can be made hydrophobic by either attaching hydrophobic ligands or by complexation can be extracted. The separation of gold from other metals in solution is possible if gold is the only metal that can form an extractable neutral complex with the HBr. Gold was shown to be quantitatively and selectively extracted from binary metal mixtures. An example of a binary mixture separation is gold from cadmium shown in Fig. 5,

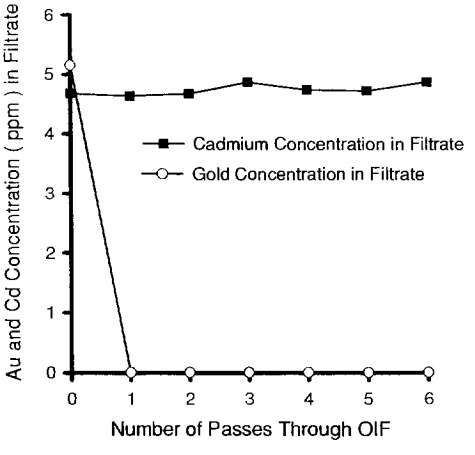

Fig. 5. The separation of gold from cadmium using an OIF. Experiment was performed on 100 ml of solution at a flow rate of 100 ml min^{-1} through a 5.0 μm OIF.

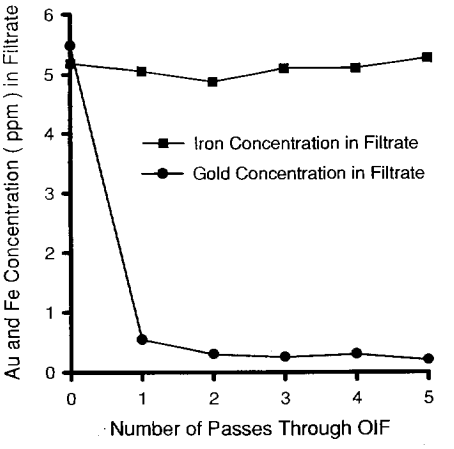

Fig. 6. The separation of gold from iron using an OIF. Experiment was performed on 100 ml of solution at a flow rate of 100 ml min^{-1} through a 5.0 μm OIF.

which demonstrates the effectiveness of the OIF as a separation device for the separation of gold from other metals. A 100 ml solution containing 5 mg l^{-1} Au, 5 mg l^{-1} Cd in 2.0 M HBr was passed through a 5.0 μm OIF at a flow rate of 100 ml min^{-1}. After one pass through the filter all of the gold was quantitatively removed from the solution and extracted onto the OIF, while none of the cadmium was extracted and it remained in the filtrate even after several passes of the solution through the OIF. The slight variation in cadmium concentration between each pass can be attributed to analytical errors. In this case gold is the only one of the two metals that is able to form an extractable complex under these conditions. In Fig. 6 the separation of gold from iron is shown. A 100 ml solution of 5 mg l^{-1} Au and 5 mg l^{-1} Fe in 2.0 M HBr was passed through a 5.0 μm OIF at a flow rate of 100 ml min^{-1}. In this case more than 95% of the gold is removed from solution after one pass through the OIF while the iron is left in the solution. In this binary metal mixture both Au and Fe are able to form hydrophobic extractable complexes in HBr. The stability constants of the $HFeBr_4$ complex dictate that much higher HBr concentrations [18] than those used would be required in order to form the extractable $HFeBr_4$ complex. Under these conditions gold is the only metal that can be extracted.

3.5. Separation of gold from gold ore

The ability to extract gold quantitatively and selectively in the presence of other metals has been demonstrated for relatively simple systems with binary metal mixtures. To demonstrate the ability of an OIF to separate gold from a more complicated matrix we attempted the separation of gold from a gold ore solution. The gold ore solution was prepared as described in the experimental section. The results of the separation of gold from a gold ore solution spiked with 1 mg l^{-1} Au are shown in Table 1. The metals analysed were chosen by performing an initial scan of several metals suspected of being present in the gold ore. If a metal was present in detectable concentrations it was further analysed for in the resulting samples. The gold ore from the Kirkland Lake Mine is known to possess a large concentration of pyrite which is indicated by the very large iron concentrations in the samples.

Fig. 7 shows the concentrations of gold and iron present in the spiked gold ore sample at different stages of the separation. Even though iron was present in concentrations 300 times as large as gold, the gold was still selectively extracted and removed from solution to the point where it was below the detection limits of the ICP after one pass through the filter. This indicates that the OIF can separate gold from solutions where large concentrations of possible interfering ions are present. The concentrations of the other metals do not change even after several passes through the OIF which demonstrates that none of these are extracted under the experimental conditions used. None of the metals present in the Canadian ore sample were co-extracted with the gold complex. Ore samples from different regions possess different metal compositions which may lead to interferences.

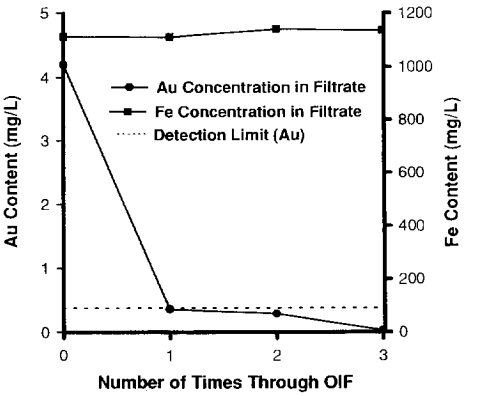

Fig. 7. The concentration of gold and iron present in the filtrate for the separation of gold from gold ore solution. Experiment was performed on 100 ml of solution at a flow rate of 100 ml min^{-1}.

Table 1
Concentration of metals present in the filtrate at different stages of the gold ore separation

No. of times through OIF	Metal concentration (mg l^{-1})			
	Au	Mn	Cu	Zn
Stock	4.2	26.78	1.03	1.41
1	0.36	26.45	1.05	1.40
2	0.30	27.36	1.15	1.48
3	0.03	26.58	1.13	1.49

The analysis of the eluting solution showed a 93% recovery of the extracted gold from the filter and virtually undetectable amounts of other metals present. The separation results of other gold ore solutions were similar. In each of the separations the gold was removed from solution by the OIF and the gold recovered using an eluting solution. The results of the gold ore separation indicates that there does not appear to be a competing ion effect between the other metals and gold, even though some of the metals are present in significantly higher and lower concentrations than gold.

4. Conclusions

A polytetrafluoroethylene filter impregnated with polyTHF can rapidly and quantitatively sep arate gold from HBr solutions that flow through it. The separation is due to the formation of the $HAuBr_4$ [7] complex in HBr solutions, and subse-

quent extraction into the PolyTHF layer on the OIF. The rate of extraction was found to increase with an increase in HBr concentration because of increased formation of the extractable species. The filter type effects the performance of the OIF with filters having larger porosity and greater thickness performing better because of the increased surface area and loading of PolyTHF.

The extracted gold can be removed from the OIF using an analogous process to the extraction. The protonated complex, $HAuBr_4$, can be eluted from the filter by converting it to the anionic, $AuBr_4^-$ complex using a 0.5 M KBr solution; the deprotonated form of the complex is not soluble in PolyTHF. Since only those complexes at the surface of the organic layer can be deprotonated, the elution process is diffusion-limited and requires reduced solution flow rates compared with the extraction to obtain recoveries greater than 95%.

The separation of gold from a number of other metals shows that the OIF can be used to separate gold from metals that cannot form extractable complexes in the presence of HBr. The separation of gold from gold ore solution demonstrates the ability of the OIF to separate gold from matrices that are quite complex. This method is inherently simple and rapid compared with other techniques currently available and can be expanded to include other metals.

Received 1 July 1996; received in revised form 18 November 1996

Abstract

A new method of efficient rotating gold-film glassy-carbon electrode preparation prior to the determination of As(III) and As(V) in seawater by anodic stripping voltammetry (ASV) is described. Factors affecting sensitivity and precision including pH, deposition time and potential, rotation and scan rate, and the nature of working electrode were investigated. Electroinactive As(V) was reduced to As(III) by gaseous SO_2 prior to ASV determination. For a deposition time of 4 min the determination limit was approximately 0.19 ppb. Precision of the proposed method was very good (RSD = 2–0.6% at 1–5 ppb) and a relatively good accuracy determined by analysis of certified reference seawater (CASS-1) and seawater samples spiked with an arsenic standard solution, was also obtained. © 1997 Elsevier Science B.V.

Keywords: Anodic stripping voltammetry; Arsenic; Gold-film plated electrode; Seawater

1. Introduction

The concentrations of As(III) and As(V) in the environmental samples are of considerable interest because of their potential toxicity, carcinogenic, and geochemical properties. The toxicological, physiological, and geochemical behavior of arsenic is dependent on its oxidation states [1,2]. Since the concentration of arsenic in normal natural water systems is in the range of ppb or sub-ppb levels, it is very important from the analytical point of view to develop a sensitive and reliable techniques capable to determine not only nanogram levels of arsenic but also their respective species.

Hydride generation techniques in conjunction with atomic absorption spectrometry and inductive-coupled plasma atomic emission spectrometry have been frequently used for the sensitive determination of arsenic [3,4]. Some environmental water samples have been reported [5–7] which contained methylated arsenic compounds in the amounts as high as 16–54% of total arsenic. The presence of methylated arsenic compounds can produce errors in speciation of inorganic arsenic(III) by hydride evolution directly into a

spectral detector. The coexistence of metallic elements predominantly in periodic groups VIII and Ib and the mutual interactions of the volatile hydride-forming elements can cause interference as well [3]. On the contrary, electrochemical methods can distinguish between the different oxidation states of arsenic and have a great sensitivity. The instrumentation required is relatively simple and generally costs far less than that required for spectrochemical techniques. Arsenic determinations have been made using classical dc polarography [8], differential pulse polarography [9,10], single-sweep polarography [11], cathodic stripping voltammetry [12–14], and anodic stripping voltammetry [15–21]. All of the aforementioned approaches are subject to interferences and not sensitive enough for the direct determination of different arsenic species in seawater. The development of differential pulse anodic/cathodic stripping voltammetry considerably improved the sensitivity and accuracy of trace elements determination in various media.

Several different electrode materials have been used for the arsenic determination by stripping voltammetric techniques. Sadana [12] and Holak [13] used the hanging mercury drop electrode with the aid of Cu(II) or Se(IV) to preconcentrate As(III) by the way of forming intermetallic compounds on the electrode in the deposition step. Owing to the limitation of sensitivity of the method and the arsenic peak appeared as a shoulder on the hydrogen reduction wave, it was found to be of little analytical utility for seawater analysis. Davis et al. [19] reported a 'reductillation' process for separation of arsenic from possible interfering substances in the sample matrix prior to ASV determination using the pyrolytic graphite tube with a thin electroplated gold film as a working electrode. By the way of the reductillation-ASV procedure, the measurement of arsenic at the nanogram level was possible. This method seems to require too many manipulations that should be avoided in trace analysis. Kuwabara et al. [21] performed an anodic stripping voltammetric method for arsenic using co-deposition with copper on a rotating platinum electrode. A more complicated voltammogram was obtained and the calibration curve did not pass through the zero point. The anodic-stripping voltammetric determination of arsenic at copper-coated glassy-carbon electrode developed by Jaya et al. [15] still can not be used to analyze arsenic in seawater due to too high determination limit.

According to Forsberg et al. [22], gold is the most suitable electrode material for determination of arsenic because of high hydrogen overvoltage and better reversibility of the electrode reaction in both the plating and stripping step. However, the response of gold electrode is very strongly dependent on the past history, pretreatment, and the oxide films formation. Stationary glassy-carbon electrode coated with gold film [18] and rotating solid gold electrode [20] was used for determination of arsenic, and the detection limits obtained were 0.56 and 0.2 ppb, respectively.

Besides the mentioned limitations of the gold-film electrode, an extremely high chloride concentration in seawater samples is also a detrimental factor. In order to avoid the possible variation of the gold-film electrode sensitivity a new way of gold-film preparation is developed and applied to an anodic stripping voltammetric method for the direct determination of arsenic in seawater with a rotating gold-film glassy-carbon electrode. Factors likely to affect the stability of electrode response and method sensitivity, including: acidity, deposition potential, deposition time, rotation rate, scan rate, the electrode reaction, and the reduction step of As(V) to As(III) are investigated. Furthermore, the equation for the limiting current during deposition of As(III) onto the rotating gold-film electrode is discussed. The effect of dissolved organic substances which might interfere with the determination of arsenic and the sample preservation conditions are also reported.

2. Experimental

2.1. Reagents

High-purity sulphuric acid (18 M) and hydrochloric acid (9.5 M) were used without further purification. Both chemicals were Suprapur (Merck, Germany). Hydrazinium chloride was of analytical reagent grade (Merck).

Standard solutions of As(III) were made up by dissolving 0.132 g of primary As_2O_3 standard in the minimum amount of conc. NaOH (Suprapur, Merck), adjusting the pH to about 3.5 with HCl, and diluting to 100 ml with H_2O. A 5 ppm of hydrazinium chloride was added to prevent oxidation of As(III) to As(V). Solutions with 1000 ppm of As(III) stored at 4°C were stable for at least 1 month when checked against a freshly prepared standard solution. Standard solutions of As(V) were prepared from 1000 ppm As(V) Merck standard solution. The required standards were prepared daily by dilution of the stock solutions. The electrode was plated with 40 ppm gold chloride (atomic absorption standard, Fisher, USA) diluted with 1 M H_2SO_4.

2.2. Apparatus

All experiments were carried out with a BAS 100B Electrochemical Analyzer (BAS, West Lafayette, IN, USA) interfaced with an Intel 486DX personal computer. Data analysis was conveniently done with the software available with this instrumentation. The voltammograms were recorded with a FPG-310 color plotter. The electrochemical cell consisted of a 1/4" glassy-carbon electrode (GCE, BAS, USA), an Ag/AgCl with saturated KCl reference electrode (BAS, USA), and a platinum wire. The instrument was also fitted with a Teflon purge tube for deaerating of the solution with prepurified nitrogen and directing the nitrogen flow above the solution.

2.3. Gold-film electrode preparation

Before each deposition of a gold film, polish the electrode with alumina powder (0.5 μm diameter) and wash it successively with nitric acid and double-distilled water. Submerge the electrode in 40 ppm gold(III) solution and leave in open circuit during a 5 min purge with nitrogen. After ensuring that gas bubbles are not lodged on the surface of the glassy-carbon electrode (GCE), apply -0.2 V potential to the electrode for 4 min. Since the gold deposited on GCE as a brown powder from stirred solution and as a lustrous plate from quiescent solution, the plating was done in a quiescent solution. For optimum reproducibility, the electrode was replated (make-up) at 0.5 V for 10 s between each measurement and the electrode was washed with the same seawater sample before re-merge into the electrolytic cell.

2.4. As(III) determination

A 8 ml of seawater sample solution and 2 ml of conc. HCl were transferred to the cell and then the solution was deaerated with pure nitrogen for 5 min. After the gold film electrode has been prepared by aforementioned process, the sample cell was put into place for the determination, which was carried out at -0.3 V and the rotating rate of 5000 rpm for 4 min. After deposition, the rotation of electrode was turned off and left for 30 s at -0.3 V that the solution became quiescent. Stripping was carried out in the differential pulse mode starting at -0.3 V with a scan rate of 30 mV s^{-1} in positive direction. Other operation parameters of the polarographic analyzer included a pulse width of 50 ms and a pulse height of 50 mV. Duplicate determinations were performed on the sample solution before standard addition.

2.5. As(V) determination

Seawater sample solution, 40 ml and 10 ml of conc. HCl were transferred to a flask which is then closed with a Teflon stopper having holes for sulphur dioxide in- and outlet. The solution was heated in a water bath set at 80°C. Sulphur dioxide was passed through the solution for 10 min. The sample was then cooled to the room temperature and 5 ppm of N_2H_4 was added and bubbled with nitrogen for 30 min. Evaporation losses were made up with H_2O. The final volume of the solution was 50 ml. All of the operation parameters for voltammetric determination are the same as above (see Section 2.4).

3. Results and discussion

3.1. Characteristics of As(III) at gold-film plated electrode

Arsenic can occur in natural water in four

oxidation states (− III, 0, III, V), however, the main oxidation states of arsenic are As(III) and As(V) [23]. Generally, As(III) and As(V) are, respectively, electrochemically active and inactive in most media [23,24]. A number of supporting electrolytes was studied and HCl was found to be the most suitable, sensitive, and the narrowest peak was obtained (i.e., the charge-transfer reaction is fastest) [9,23,24].

From the cyclic voltammetry study of the gold-film plated electrode in seawater acidified with HCl, shown in Fig. 1, relatively well defined reduction and oxidation peaks were observed indicating the possibility of use such a gold-film electrode for the determination of As(III) in seawater by ASV.

The changes of peak current and peak potential in seawater acidified with various concentration of HCl are given in Fig. 2. The peak current increases and peak potential shifts to more negative with increasing HCl concentration. According to Arnold [25], the As(III) species present in aqueous solutions contained HCl at increasing concentration are found to be consistent with the existence of the following species:

H_3AsO_3, $As(OH)_2^+$, $As(OH)_2Cl$, $As(OH)Cl_2$, $AsCl_3$

Since $As(OH)_2Cl$ and $As(OH)Cl_2$ are though to be the actual species which take part in the electron-transfer reaction on the electrode [24], the deposition efficiency of As(III) become higher as the amount of $As(OH)_2Cl$ and $As(OH)Cl_2$ increases with increasing of HCl concentration. Moreover, it is noteworthy that more chloride ions tightly bound in double layer around the electrode act as a bridge between the arsenic ion and the electrode makes the redox reaction more reversible [24,26]. From above descriptions, the conversion of As(III) species and the occurrence of chloride ion-bridge may explain the corresponding positive shift of peak potential and increasing peak current. For analytical purposes, the optimum HCl concentration was ca. 2 M.

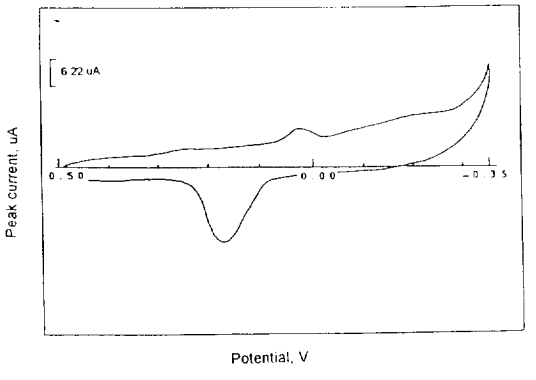

Fig. 1. Cyclic voltammograms of As (III) in seawater acidified with HCl. (8 ml seawater + 2 ml HCl, 5 ppb As (III)).

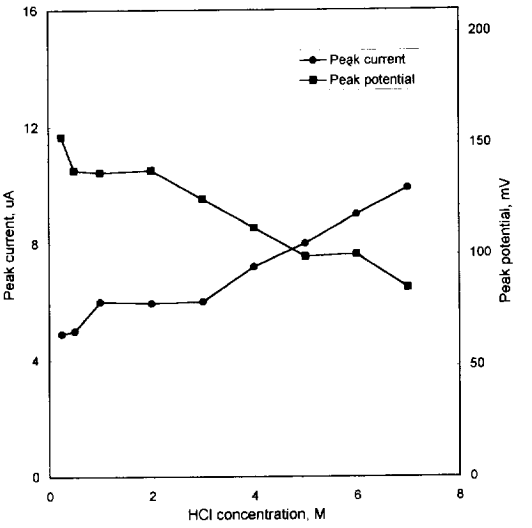

Fig. 2. Effect of HCl concentration on the peak current and peak potential. (8 ml seawater + 2 ml HCl, 5 ppb As(III), scan rate = 30 mV s^{-1}, rotation rate = 5000 rpm, deposition time = 30 s).

3.2. Gold-film electrode sensitivity

The decline of sensitivity of the gold electrode (solid or plated film) between each successive determination of the same solution has been widely discussed and many treatment procedures have been applied before or between sample runs [18,20,22,26–28]. However, all of the procedures applied were found to be unsatisfactory. From the obvious degradation of gold film on the used

electrode, it can be concluded that the gold film on the electrode was lost (dissolved) because of the tendency for complex formation between the gold and chloride ion. The same observation has also been reported by Baumann et al. [28] and Delahay [29]. The possible mechanism of declining sensitivity was deduced as follows: the plated gold film was oxidized in the sample solutions (seawater + HCl) contained high concentration of chloride ion to give the complex auric chloride ion ($AuCl_4^-$) [29], thus, the active gold surface for the deposition of arsenic was reduced and the reproducibility of the stripping peaks became disadvantageous. For the sake of solving the problem mentioned above, a 'make-up' procedure was developed, i.e., the original active surface area was restored between each run through replating the electrode with gold solution containing no chloride ion. Additionally, because impurities on electrode exert a profound effect on current-voltage curve when gold electrode was used for trace arsenic determination, gold electrode have to be pretreated. Among the possible interfering elements, copper was found to cause the most serious interference problem. In addition to having nearby oxidation peak (0.33 V), copper and arsenic have been shown to combine strongly [21], and the presence of even a slight excess of copper greatly reduces electrode response to arsenic [22]. In order to make up the gold-film on the electrode and get rid of codeposited copper simultaneously, 0.5 V potential was used as a make-up potential.

3.3. Effect of the deposition potential and deposition time

In fact, because anodic stripping voltammetry consists of a series of controlled-potential electrolysis steps, the sensitivity is dependent on the concentration of an interested element deposited on/in the electrode, and therefore the length and efficiency of the deposition (preconcentration) step becomes critical. The dependence of peak current on deposition potential was shown in Fig. 3. The deposition potential -0.3 V was chosen due to no apparent difference in peak current occurs in the range of -0.4– -0.2 V and the formation of H_2 bubbles become possible after -0.35 V.

Since elemental arsenic is a very poor conductor of electricity, the peak current of arsenic was found to be limited when the active surface of the electrode was fully covered with elemental arsenic [23]. The dependence of peak current on deposition time for seawater containing 5 ppb arsenic was shown in Fig. 4. The peak current reached a limiting height indicating the electrode surface saturated arsenic at the deposition time greater than 4 min. The levelling effect of peak current is concerned with the surface area of the electrode, the length of the deposition time, the stirring efficiency, and the concentration of arsenic(III). Owing to the concentration of arsenic in seawater is around 1.0–3.7 ppb [30], a deposition time of 4 min was used in this study to prevent possible error resulted from the electrode surface saturation.

3.4. Rotation rate effect

The sensitivity of stripping voltammetry strongly depends on the amount of substance deposited at the electrode, for which the rate of the substance flux from the bulk of the solution toward the electrode (i.e., the hydrodynamic conditions) is a predominant determinate. If a chemi-

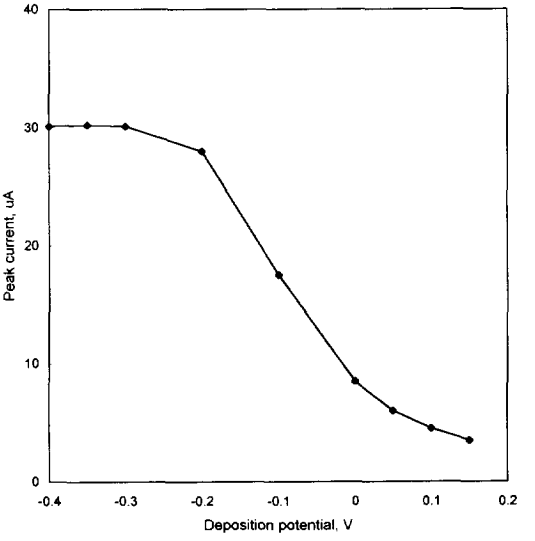

Fig. 3. Effect of the deposition potential on the peak current. (8 ml seawater + 2 ml HCl, 5 ppb As(III), scan rate = 30 mV s^{-1}, rotation rate = 5000 rpm, deposition time = 30 s).

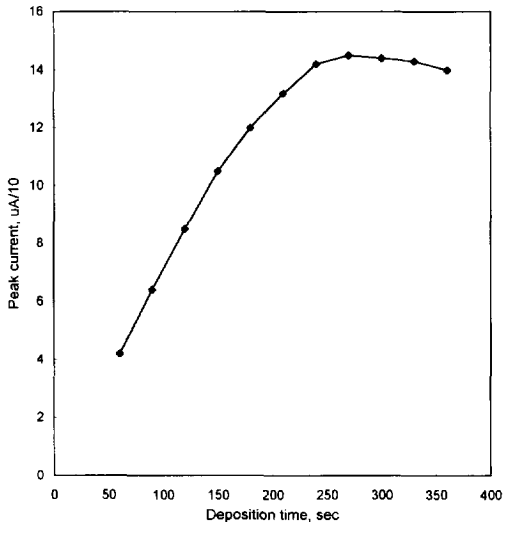

Fig. 4. Effect of the deposition time on the peak current. (8 ml seawater + 2 ml HCl, 5 ppb As(III), scan rate = 30 mV s^{-1}, rotation rate = 5000 rpm).

cal reaction is involved in the overall electrode process, it also affects the sensitivity through its reaction rate, the character of reaction products, and solubility of the compounds formed. According to Wang [31], the deposition current (I_L) as well as stripping peak current (I_P) at the rotating disk electrode is proportional to ω^{α} (where ω is the rotation rate and α is a constant dependent on the characteristics of the hydrodynamics and electrode configuration). For the laminar flow conditions, α usually ranges from 0.3 to 0.5. Frequently, α is found to be 0.5 when mercury film electrode is used and a reversible reaction is conducted [32]. In this study (as shown in Fig. 5) α was found to be 0.35 when gold-film electrode was used for As(III) deposition.

3.5. Scan rate effect

It was found that the stripping peak current was proportional to the square root of scan rate and agreed with the relationship between peak current (I_P) and scan rate (v) (in accordance with the equation $I_P = 2.74 \times v^{1/2}$) for mercury film electrode system [30]. Even if better sensitivity at higher scan rate was obtained, a broader and more ill-defined peak also resulted. For the determination of trace As in seawater, a scan rate of 30 mV s^{-1} was finally chosen to provide the necessary sensitivity and well-defined stripping peak.

3.6. Effect of hydrazinium chloride

Since As(III) can be oxidized in solution with a high Cl^- concentration and low pH [20], a continuous decrease of peak current was found during a series measurement of As(III) in the same samples with the proposed procedure. With the view of improving the poor reproducibility resulted from the oxidation of As(III) to As(V), different amount of hydrazinium chloride was added to the solutions. After an addition of hydrazinium chloride as the antioxidant, the reproducibility was apparently improved, but on the other hand, the background current elevated as more concentrated hydrazinium chloride was added. A 5 ppm of hydrazinium chloride addition of which the declining percentage of the peak current is 0.1% was chosen as compromise value. In seawater samples containing 5 ppm of As(III) the precision obtained was 6% for four duplicate analyses.

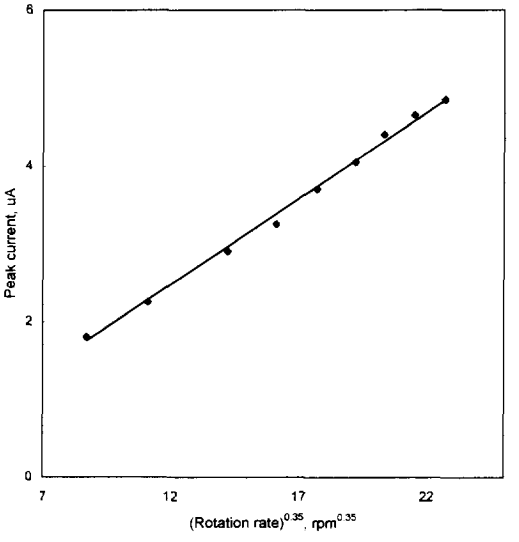

Fig. 5. Effect of the rotation rate on the peak current. (8 ml seawater + 2 ml HCl, 5 ppb As(III), scan rate = 30 mV s^{-1}, deposition time = 30 s).

According to the developed experimental procedure, a wide linear range for As(III) concentrations from 1 to 1100 ppb was achieved (in accordance with the linear equation $Y = 615.3 \times X - 7.4$, $R^2 = 0.999$). The determination limit was defined as the lowest concentration of As(III) which can be distinguished from the background current by the used measuring system. The concentration of As(III) in surface seawater is so low (0.05–0.02 ppb) that we can treat such a sample as 'blank'. The determination limit was obtained through addition of various concentration of As(III) into seawater sample and measured in the optimized conditions. The determination limit under the conditions used in this study was 0.19 ppb.

3.7. Interferences

Copper [21] and antimony(III) [30] have been found to present the most serious interference problem when gold-film electrode was used to determine As(III) by ASV. Fortunately, an observation that those elements contained in seawater do not interfere with the arsenic determination was reported [20]. Naturally occurring in seawater organic compounds such as humic acid and surfactant appeared to interfere in the determination of As(III), as shown in Fig. 6. Because the total amount of dissolved organic material in the open sea will not exceed 2 ppm and the concentration of humic acid is less than 0.11 ppm [33], no noticeable interference may be expected in open-seawater sample analysis according to the experimental data. With a view to avoid possible interference coming from the dissolved organic compounds and variation of the gold film electrode, the standard addition method was also used for a calibration.

Because the alkylated forms of arsenic are electroinactive, the determination of As(III) should be accurate. It is possible that the determination of As(V) can be interfere by the coexistent MMA (monomethylarsenic) after reduction [34]. However, because the concentration of MMA in surface seawater is extremely low (0.004 ppb) [2], the interference from reduced MMA can be negligible.

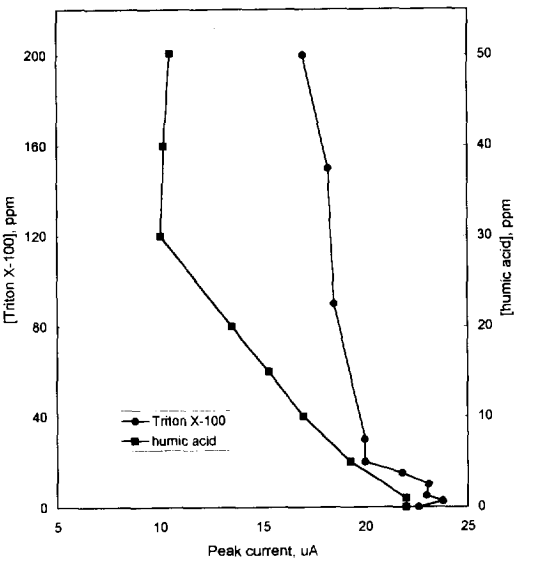

Fig. 6. Effect of the dissolved organic compound on the peak current: (a) humic acid; (b) Triton X-100. (8 ml seawater + 2 ml HCl, 5 ppb As(III), scan rate = 30 mV s^{-1}, deposition time = 30 s, rotation rate = 5000 rpm).

3.8. Sulfur dioxide reduction of As(V)

The same reduction procedure reported by Bodewig et al. [20] was used to reduce As(V) into As(III) in seawater. In order to ensure that no arsenic would be lost through splatter and volatilization, a closed system was used for reduction. However, the aforementioned make-up potential (0.5 V) used for the determination of 'natural' As(III) did not work here any more; meanwhile, the used gold-film plated on the electrode became tarnished and the analytical sensitivity got worse. Alternatively, −0.1 V was used as make-up potential, so that reproducible results could be obtained for SO_2 reduced samples.

Passivation may have involved adsorption of gold sulfite, $Au_2(SO_3)_3$, on the electrode during measurement, which resulted from the reaction between auric chloride ion around the electrode surface and dissolved sulfite originated from gaseous SO_2 reduction [35]. It has been reported that gold deposits in the form of discrete particles at active sites of a carbon surface and the condition of the substrate (i.e., glassy carbon electrode) can affect the activity of the gold deposition [36].

Table 1
Results of arsenic determination in water samples[a]

Sample	Added, ppb	Found, ppb	Recovery, %
Deionised water	5 ppb, As(III)	5.06 ± 0.04	101
Seawater	5 ppb, As(III)	5.00 ± 0.03	100
Seawater	5 ppb, As(V)	6.71 ± 0.03	101
Seawater	—	1.64 ± 0.01[b]	—
CASS-1	—	1.01 ± 0.02[b] (1.04 ± 0.07)[b]	97

Roman numerals in parenthesis indicate the certified value for CASS-1 sample (Nearshore Seawater Reference Material provided by National Research Council, Canada).
[a] 8 ml seawater + 2 ml HCL, 5 ppb As(III), scan rate = 30 mV s^{-1}, deposition time = 30 s, rotation rate = 5000 rpm.
[b] Total arsenic.

Through adsorption of gold sulfite on the electrode surface, some portions of the electrode become passivated (electrically isolated) and the sensitivity become worse. In view of restoring original activity -0.1 V was used as make-up potential instead of 0.5 V for the following experiments.

3.9. Preservation of seawater samples

Several studies [14,37–44] on the preservation of As(III) and As(V) in natural water prior to the analysis have been reported, but the different preservation methods appeared to be inconsistent. To the author's knowledge no suitable preservation conditions for As(III) in seawater sample have been reported until now. However, the preservation that maintains integrity and stability of samples is a prerequisite to the successful analytical determinations. In this study, the effective preservation conditions for As(III) and As(V) in seawater samples were established.

Adsorption on the wall of container, redox reactions, and the uptake by microorganisms present in the samples may cause the alteration of the distribution among arsenic species. It has been proven previously [44] that no adsorption occurs on the surface of polyethylene containers. In order to inhibit possible redox reactions and the activity of microorganisms, hydrazinium chloride and hydrochloric acid were used as preservatives for As(III) and As(V) in seawater. No significant loss of As(III) and no distinguishable reduction of As(V) into As(III) could be observed over a period of 6 days. For the analytical purposes, 5 ppm of hydrazinium chloride and 1:80 (V/V) hydrochloric acid were chosen as preservation media for the following experiments.

3.10. Analytical application

Andreae [45] has predicted that the concentration ratio of As(V) to As(III) of seawater is 10^{15}–10^{24} based on the thermodynamic equilibrium calculations. However, the redox reactions between As(III) and As(V) are biologically mediated and affected by complicated coexistent components [46]. In the oxygenated seawater, the As(V)/As(III) concentration ratio from 22 to 100 and the concentration of ca. 1.5 ppb of total arsenic in surface seawater were reported [6,47,48], therefore, the concentration range of As(III) in seawater could be presumed to be 0.05–0.02 ppb. Unfortunately, the proposed procedure was not sensitive enough for direct determination of As(III) in seawater, but the total amount of arsenic (As(III) + As(V)) can be certainly given, as shown in Table 1. The analytical results of standard reference seawater sample (CASS-1) and spiked samples are in a good agreement with the certified value and spiked concentrations. The open ocean water sample (Philippine Sea 3°45′ N, 124°01′ E), reported to contain 1.5 ppb arsenic [48], was analyzed by the described procedure and yielded 1.64 ppb of total arsenic (average of four independent determinations) with the standard deviation of ± 0.01 ppb.

4. Conclusion

In this study a new gold-film electrode preparation method for the determination of As(III) and total arsenic at the nanogram level in seawater by using rotating gold-film plated electrode for anodic stripping voltammetry was developed. An electrode make-up procedure was proved to be valid, and the extraordinary relationship of electrode rotating rate and deposition current for arsenic depositing from seawater onto a rotating gold-film electrode was observed. Additionally, efficient preservation conditions for As(III) and As(V) in seawater were established. The determination limit was 0.19 ppb of As(III) for a deposition time of 4 min and the precision, and accuracy of the method were very good. This technique has been successfully applied to the analysis of seawater samples and may be useful to study arsenic speciation in water samples.

Abstract

The simultaneous determination of copper and zinc in human plasma and urine by inductively coupled plasma mass spectrometry (ICP MS) is discussed. The performances of a cross-flow nebulizer and a direct-injection nebulizer (DIN) were compared. Flow-injection-DIN-ICP MS analysis of clinical samples using 1–2 μl samples was optimized. Isobaric interferences were discussed and were demonstrated to be eliminated for the ^{65}Cu and most of the Zn nuclides. The need for standard addition to compensate for signal suppression in the case of some serum samples was indicated. Results obtained by ICP MS using calibration with aqueous standard solutions were found to be in good agreement with those obtained by flame AAS for a batch of real blood plasma and urine samples. The methods developed were validated by analysis of several standard reference materials. © 1997 Elsevier Science B.V.

Keywords: Copper; FIA, Direct Injection Nebulizer; ICP MS; Serum; Urine; Zinc

1. Introduction

The levels of copper and zinc in plasma and urine have been extensively investigated for four decades and are now used for the early diagnosis of certain illnesses [1]. The mean values of Cu and Zn in healthy individuals are around 1 μg ml^{-1}. They can be readily determined by many instrumental methods; the analyses are usually done by flame or graphite furnace atomic absorption spectrometry (AAS) [2]. Inductively coupled plasma mass spectrometry (ICP MS) has been playing an increasingly important role in analytical laboratories owing to the possibility of direct, simultaneous and multielement trace analysis [3–5]. The determination of copper and zinc in clinical samples by this technique has been reported to be plagued by several spectral interferences and to be

PII S0039-9140(97)00009-X

hard to be carried out with a quadrupole instrument [6–9]. The use of a high resolution magnetic sector instrument has been proposed but its high cost limits considerably its availability [9].

The objective of this paper is to consider a recent generation quadrupole ICP mass spectrometer for the simultaneous determination of copper and zinc in plasma and urine. A cross-flow and a direct injection nebulizer have been discussed in terms of sample throughput (flow-injection analysis), sample consumption and interferences. Particular attention has been given to the validation of the procedures developed in order to enable their use for routine analysis in a busy clinical laboratory.

2. Experimental

2.1. Instrumentation

The ICP mass spectrometer used in this work was the ELAN 6000 (Perkin-Elmer SCIEX, Concord, Ontario, Canada). The sample introduction systems used included a Ryton™ spray chamber fitted with a cross-flow nebulizer (Perkin-Elmer), and a model Microneb 2000 direct injection nebulizer (DIN) (CETAC, Omaha, NE). For the cross-flow nebulizer, the samples were fed by means of a Minipuls 3 peristaltic pump (Gilson) which also served for draining the spray chamber. For the DIN the samples were fed by means of a metal-free gas displacement pump (GDP) (CETAC) through a 50 μm i.d. capillary. Samples were injected using a six-port injection valve made of PEEK. A 20 μl sample loop was used. Smaller sample volumes (part of the sample loop volume) were injected by controlling the load time. Disposable polyethylene vials (OSI, France) were used.

Table 1
Signal acquisition and valve parameters for continuous-flow and flow-injection measurements using direct injection nebulization ICP MS

Parameter	Continuous flow	Flow injection
Scan mode	Peak hopping	Peak hopping
Sweeps/reading	10	3
Readings/replicate	3	25
Replicates	3	1
Dwell time per amu	100 ms	70 ms
Internal standard	10 μg l^{-1} Y	10 μg l^{-1} Y
Process signal profile	Average	Maximum Baseline readings: 5
Valve parameters		
Sample loop	250 ml	20 or 50 μl
Load time	45–60 s	5–8 s
Injection time	60 s	1–2 s
No. of injections	1	1–10

Flame AAS measurements were carried out with a Model 3100 PE atomic absorption spectrometer (Perkin-Elmer).

2.2. Samples and standards

Samples were prepared in disposable polyethylene vials under clean room conditions (Class 10 000). For all preparations, 18 MW Milli-Q water (Millipore, Bedford, MA) and Suprapure® HNO_3 (Merck, Darmstadt, Germany) were used. Standard stock solution of copper and zinc was prepared by a 250-fold dilution of the commercial standards (1 g l^{-1}) of Cu and Zn with a 2% nitric acid. The stock solution of yttrium was also obtained from Merck.

Reference materials. NYC S1 Human serum (Nycomed Pharma Norway, Seronorm™) was purchased from Promochem (Molsheim, France). Biotrol human serum and human urine (level 1 and 2) were purchased from BioRad (Ivry-sur-Seine, France) and Merck-Clevenot (Nogent-sur-Marne, France), respectively.

2.3. Analytical procedures

Cross-flow nebulizer. The RF source power used was 1.0 kW and the sample uptake rate was 1 ml min^{-1}. The torch X-Y position was adjusted manually to maximize the signal for yttrium. The operating ICP MS conditions (nebulizer gas flow and lens voltage) were optimized daily in the range of 0.7–1 l min^{-1} and 6–8 V, respectively, using a standard (incorporated in the software) automatic procedure. Calibration curve was pre-

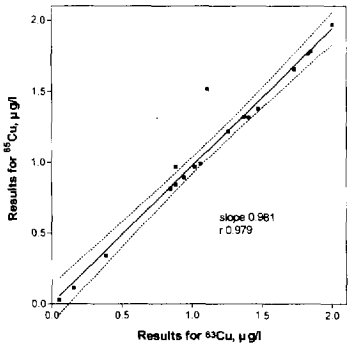

Fig. 1. Correlation ($\alpha = 0.95$) of the results obtained for the determination of copper in serum and urine by ICP MS using the different nuclides for quantification. ^{63}Cu versus ^{65}Cu.

pared by diluting the stock solution to obtain standard solutions at concentrations 0.2, 1, and 2 mg l^{-1}, respectively. Serum and urine samples were diluted 20-fold and 10-fold, respectively, with 0.05% HNO_3. Internal standard (Y-89) was added at the 10 µg l^{-1} level to the diluent.

Direct injection nebulizer. The RF source power used was 1.2 kW. The X-Y position of the ICP torch was adjusted first to maximize the signal for yttrium. Then, the position of the DIN capillary was optimized with the same objective. The fine-tuning was performed by the optimization of the GDP pressure (in the range 300–370 psi) and the nebulizer gas pressure (between 50–80 psi). The nebulizer makeup gas was optimized from the software of the ICP mass spectrometer between 0 and 300 ml min^{-1}. The lens voltage was tuned as described above. The DIN was operated either in the continuous-flow mode or in the flow-injection mode. For the latter the signal acquisition conditions were reoptimized. The parameters for data acquisition are summarized in Table 1. Calibration was performed as described above.

3. Results and discussion

Human serum is a rather difficult matrix for ICP MS. It contains 6–8% of proteins and about 1% of inorganic components, causing important spectral interferences up to m/z = 97. Urine contains less proteins, but also the concentrations of Cu and Zn are 5–20 times lower. The levels of Cu and Zn are sufficiently high to remain quantifiable by ICP MS after a 10–20-fold dilution. Standard precautions (class 10 000 clean room conditions and ultrapure water and acids) must be obeyed to avoid contamination problems. The choice of sample vials is critical. Among several types of polyethylene disposable vials tested those from OSI, France were found to produce the lowest (practically negligible) contribution to the blank signal. They could be used without the preliminary rinsing.

Serum and urine matrices affect strongly the element signal and are responsible for a considerable (up to 75%) signal suppression. Internal standard is thus necessary if external calibration with aqueous solutions is considered.

3.1. Isobaric interferences in ICP MS analysis for copper and zinc

Copper. Copper has two stable isotopes ^{63}Cu and ^{65}Cu with relative abundances of 69.2 and 30.8%, respectively. The former nuclide (m/z = 62.93) is interfered with the ion: $^{40}Ar^{23}Na$ (m/z = 62.95). This interference gives rise to an apparent concentration of Cu of ca. 10 µg ml^{-1} which is comparable with the actual concentration in plasma and is too large to be appropriately corrected for [4,8]. The latter nuclide (m/z = 64.93) is interfered by the ion: $^{32}S^{16}O_2^1H$ (m/z = 64.97)

which shows the apparent Cu concentrations of only 7% of the actual content of this element. High resolution (of 3000) was recommended to separate these interferences form the analyte peak [9]. An alternative is the use of size-exclusion LC to remove low-molecular-weight species ($ArNa^+$ and PO_2^+) that cause interference at m/e 63 [10].

Zinc. It has three major stable isotopes: ^{64}Zn (48.63%), ^{66}Zn (27.9%), and ^{68}Zn (18.75%). The determination of Zn in serum with quadrupole ICP MS is hampered by interferences caused by S-containing polyatomic ions for all the above nuclides. The most abundant ^{64}Zn is seriously interfered by $^{32}PO_2^+$ and $^{32}S_2^+$ [5]. In practice ^{66}Zn is chosen in the literature for which quadrupole ICP MS shows interferences by $^{34}S^{16}O_2^+$, $^{33}S^{16}O_2H^+$ and $^{32}S^{16}O^{18}O^+$, accounting for an apparent Zn content of around 0.66 μg ml^{-1} in serum which is half of the normal serum Zn level. ^{68}Zn was proposed alternatively [5].

3.2. Analysis using continuous cross-flow nebulization

Determination of copper. Fig. 1 shows that with the ICP mass spectrometer used in this work there is no difference between the results obtained using the different Cu isotopes. It means that, contrary to the literature [10], at the 1 μg l^{-1} level neither of the Cu nuclides is affected by the polyatomic interference probably owing to the PlasmaLok™ interface available on the instrument used. For the urine samples, however, results obtained using ^{63}Cu are ca. 20–30% higher than those with ^{65}Cu independent of the concentration level. This has to do with the fact that urine samples are run less diluted and the formation of the polyatomic ion of Ar with Na becomes more likely. Consequently, the ^{65}Cu should be chosen.

Fig. 2 shows that ICP MS gives consistent values with flame AAS. Table 2 shows that the Cu concentrations obtained for the certified sera and high level urine are in excellent agreement with the certified value. Also the low level urine is fully acceptable but in this case significant day to day variations are observed.

Determination of zinc. Fig. 3 shows that there is no difference in terms of result obtained regarding the nuclide chosen for quantification (^{66},^{67} or ^{68}Zn). Like in the case of copper, at the 1 μg l^{-1} level investigated none of the Zn nuclides is affected by the polyatomic interference probably owing to the PlasmaLok™ interface available on the instrument used. Contrary to copper, however, this is also true for the urine samples investi-

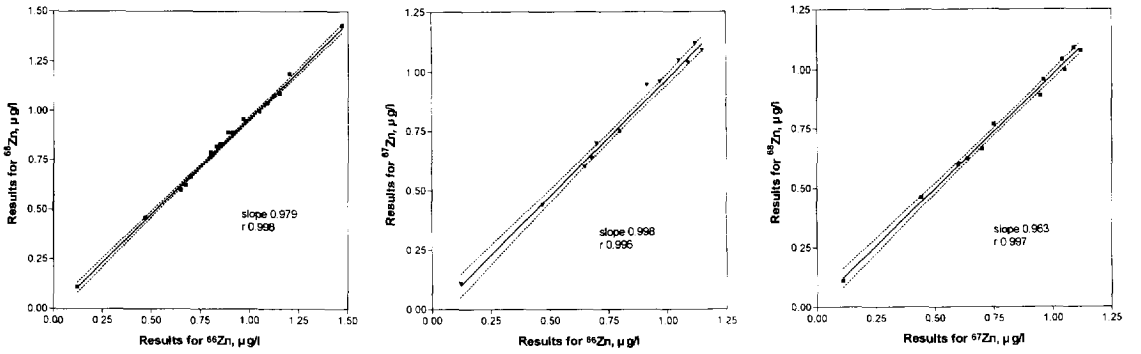

Fig. 3. Correlation ($\alpha = 0.95$) of the results obtained for the determination of zinc in serum and urine by ICP MS using the different nuclides for quantification. (a) ^{66}Zn versus ^{67}Zn; (b) ^{68}Zn versus ^{66}Zn; (c) ^{68}Zn versus ^{67}Zn.

gated. The ^{67}Zn and ^{68}Zn have been used in this work.

Fig. 4 shows that ICP MS gives consistent values with flame AAS. The reason for the few outliers was not established since it was not possible to re-run the samples with both techniques once again. Table 2 shows that the Zn concentrations obtained for the reference sera and reference urine are in agreement with the certified value.

3.3. ICP MS analysis with direct injection nebulization

The DIN is a microconcentric nebulizer with no spray chamber; it nebulizes the liquid sample directly into the central channel of the ICP torch [11]. Compared with conventional nebulizers it offers 100% sample introduction efficiency into the ICP, accommodation of low sample introduction flow rates (10–100 µl min^{-1}), an extremely small internal volume (< 2 µl) and fast sample washout with minimal memory effects.

Optimization of the DIN. The installation of the DIN required making a hole in the torch box of the ELAN 6000 mass spectrometer to enable the entrance of the nebulizer make-up flow. The virtual difference in the principle of operation between the DIN and the conventional nebulization systems makes it necessary to re-optimize the operational ICP MS parameters upon each and every installation of the DIN. Attempts to find a series of parameters once-for-ever were unsuccessful. The operational parameters (flow-rate, nebulizer gas flows, capillary position and lens voltage) were tuned on the every-day basis by the trial-and-error method to maximize the signal. RF source power was set at 1.2 kW which is higher than in the case of the cross-flow nebulization. Under the optimized conditions (Table 1) the sensitivity of the DIN-ICP MS for the nuclides: ^{23}Mg, ^{103}Rh, ^{134}Ba, ^{137}Cs and ^{208}Pb was a factor of two higher than that obtained with the cross-flow nebulizer. Note that the manufacturer's specification of the sensitivity is at 50% of that obtained with the cross-flow nebulizer. The relative standard deviation (for signals not limited by counting statistics) was 1–2%.

Analysis of clinical samples in the continuous-flow mode. It was found out that the introduction

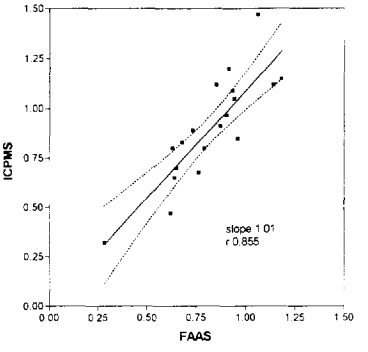

Fig. 4. Correlation ($\alpha = 0.95$) of the results for the determination of zinc in serum and urine between flame AAS (another laboratory) and ICP MS.

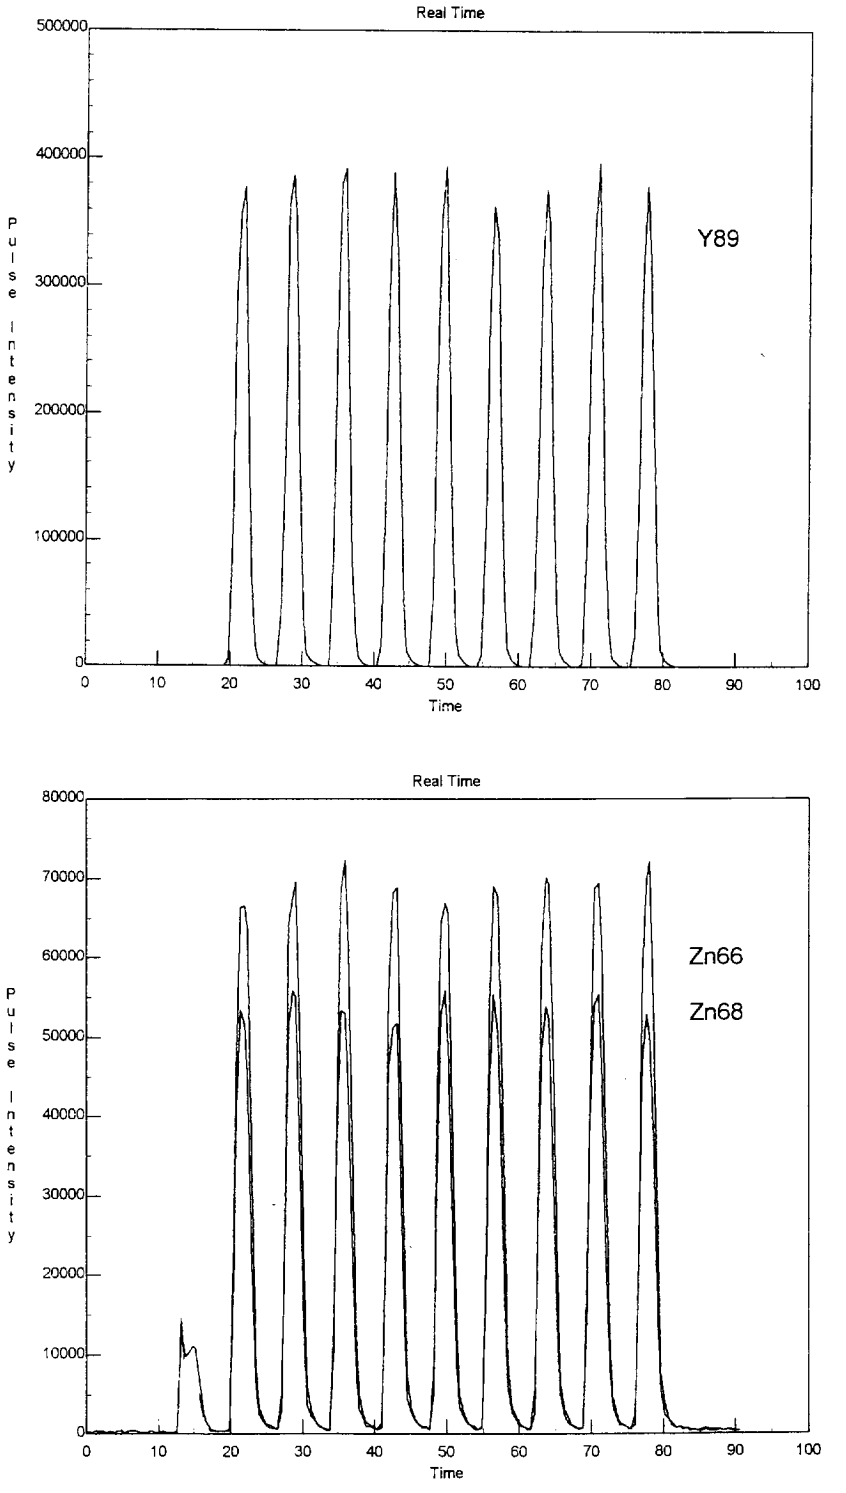

Fig. 5. Profile of the signal in a serum sample obtained by FIA-DIN-ICP MS for (a) zinc, (b) 10 ng ml^{-1} of Y (internal standard).

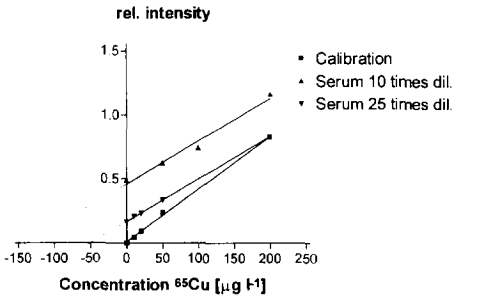

Fig. 6. External calibration and standard addition graphs for the determination of Cu in the Seronorm serum. (a) aqueous solution; (b) serum diluted ten times; (c) serum diluted 25 times.

of undiluted urine and, especially, of blood plasma samples led to the blockage of the DIN capillary after several seconds. Diluted (10–20-fold) samples could be fed for a couple of minutes but the signals decreased gradually and the results showed poor precision (RSD > 5%). This was found to be due to the adsorption of the serum proteins on the wall of the DIN capillary and thus to the gradual decrease in the nebulization efficiency. The use of the 0.1% Triton solution as the carrier and/or as the sample diluent was found to have no effect. It was therefore attempted to solve the above problems by discrete sample introduction (flow injection mode) with rinsing the capillary with the carrier solution between the subsequent injections.

Analysis of clinical samples in the FI mode. The injected volume was controlled by the sample load time from the sample loop. At the carrier flow-rate of 100 µl min^{-1} a 2 s load time (necessary to reach a peak height equal to the height of the continuous-flow signal) corresponds to a 2 µl injection. An example signal profile of a serum sample is shown in Fig. 5. The stability of signal measured as a relative standard deviation ($n = 5$) of the peak-height is 3–5%. If corrected for internal standard it can be reduced below 1%. The first peak should be, however, discarded since it may be due to some residual cross-contamination.

Matrix effects were investigated by comparing the slope of the calibration graph with that of the standard addition graph for ^{65}Cu and ^{68}Zn. A significant difference was observed for copper in the Seronorm serum sample which is illustrated in Fig. 6. Indeed, the value obtained with external calibration (0.94 ± 0.03 µg ml^{-1}) is different from that (1.17 ± 0.11 µg ml^{-1}) obtained by the method of standard additions. This suggests the existence of an interference which is characteristic to Cu and cannot be corrected by the internal standard. Indeed, for yttrium the slope of the straight line signal versus concentration is the same for aqueous and serum solutions. This interference cannot be removed by diluting the serum samples as shown in Fig. 6. The origin of this interference is hypothesized to be sorption of the protein-bound copper on the wall of the DIN capillary since once in the plasma protein-bound copper and free copper are ionized in the same way owing to the high temperature.

The results of the analysis of serum and urine samples using FIA-DIN-ICP MS were validated using the same reference materials as discussed above. The results (Table 3) show good agreement between the certified and obtained values when

Standard deviation calculated on the basis of five independent measurements.
[a] Value obtained by the method of standard additions.

the eternal calibration with aqueous solutions was used except the copper concentration in the Seronorm serum for which standard addition is recommended.

4. Conclusion

It is concluded that ICP MS is a rapid and reliable technique for the determination of Cu and Zn in serum and urine. The spectral interferences evoked earlier in the literature are minimized with the latest generation of ICP MS instruments but nevertheless the agreement of data from obtained using different isotopes should be a prerequisite for the validation of the results obtained. In some cases matrix can affect the analyte and the internal standard in a different way so standard addition runs may be recommended. The most important advantage of ICP MS is its being the ideal technique for the validation of AAS data. Other advantages include lower detection limits, and lower sample consumption and higher sample throughput in flow-injection mode.

Abstract

A multi-sensor cell containing a new photo-cured calcium ion selective electrode sensor is reported. Four membranes containing different components are prepared to determine the one with optimum selectivity and sensitivity. This is shown to consist of the *N,N,N',N'*-tetracyclohexyl-3-oxapentanediamide ligand (ETH 129) as the ionophore, 2-nitrophenyl octyl ether as the plasticiser and tetradodecyl ammonium tetrakis(4-chlorophenyl) borate as the lipophilic additive. The photo-curing process is applied after coating a thin membrane on a silver wire as substrate transducer to produce the calcium sensor. The curing process is demonstrated to be faster (1 min) than previous methods and does not require a nitrogen atmosphere for reproducible production of membrane response characteristics. Four sensors constructed with the identical optimum membrane are shown to function reproducibly in a multi-sensor flow-through cell using the steady-state mode of flow measurement, and an average calibration slope of 28.5 ± 0.4 mV change per activity decade is observed over a log-linear concentration range between 0.01 and 10 mM. The sensor is also shown to respond to changes in pH. Hence, in the flow injection potentiometric mode, a constant carrier buffer composition of pH 8.3 is required for accurate potentiometric calcium determinations. The sensor is used to determine calcium in water samples by flow injection potentiometry. The accuracy of the electrode determination relative to atomic absorption spectroscopy was in the range 5–9% for three different water samples.

Keywords: Calcium selective electrodes; Flow injection potentiometry; Multi-sensor mode; Photo-cured membrane

1. Introduction

Multi-sensor potentiometric response has been previously reported to have advantages in potentiometric flow analysis cells [1–4]. Three modes of application are possible: (1) where additive response of multiple identical sensors provides improved sensitivity and detection limits; (2) where different ion sensors can be incorporated into a flow through cell to provide simultaneous determinations; and (3) for applications [5,6] in field-portable instrumentation for flow injection potentiometry (FIP). The application of membrane selective electrodes in a multi-sensor cell, however, have been less successful due to high

impedance ISEs and electronic problems of cross-talk between analog-to-digital channels caused by unshielded circuitry. Diamond et al [7] has discussed this problem, and has described successful multi-sensor potentiometric measurements using the batch injection analysis technique.

This study concerned the development of a new photo-cured membrane for a calcium ion selective electrode (ISE) which was tested in a multi-sensor flow-through cell for response characteristics. At present, the preferred liquid polymer membrane for manufacture of ISEs is poly(vinyl chloride) (PVC). Commercial companies have a considerable number of cation and anion selective electrodes available based on PVC membranes which are durable and flexible, and have been applied to solid-contact type electrodes [8].

Miniature electrodes referred to as 'coated wire electrodes' [8] have also been reported for a range of PVC based anion and cation selective electrodes. The disadvantages of PVC based liquid polymer membranes are that they can take up to 2 days to manufacture due to the solvent-cast method, they can experience significant electrode signal drifting when used as a solid-contact electrode, and they exhibit poor adhesion to a solid substrate surface [9]. The poor adhesion of a PVC membrane in a solid-contact configuration presents a problem with continuous on-line monitoring, when eventually the membrane peals-off.

The use of UV photo-curing of a bisphenol A epoxy diacrylate based membrane cross-linked with an acrylate ester is an alternative method for the rapid manufacture of liquid polymer membranes. These membranes are mechanically stronger than PVC membranes [10–19], but the photo-curing of acrylate based membranes can take up to 40 min and requires a nitrogen atmosphere.

Photo-cured membranes developed at present include calcium [10,11,16,17], potassium [12,15], pH [13], nitrate [14], lithium [18] and sodium [19]. Most of these were utilised in the FIP mode. Most of these have employed up to 30% (w/w) of plasticiser [10–13,16–19] compared with about 65% (w/w) of plasticiser required for PVC membranes [20]. The use of less plasticiser in photo-cured membranes leads to other advantages [3–6,10–13]. There is an increase in the mechanical strength of photo-cured membranes compared with PVC membranes, making photo-cured membranes more reliable for flow-through measurements. There is also a decrease in the water uptake of the membrane which minimises electrode signal drift, improves the adhesion to metallic substrates and eliminates the need for volatile solvents such as THF in the manufacture.

Plasticisers of a high dielectric constant, such as 2-nitrophenyl octyl ether ($e = 24.2$), are preferred for divalent-selective electrodes since they improve the determined selectivity over monovalent ions [21]. The major disadvantage with some of the above-mentioned photo-cured membranes, in particular the calcium-selective electrode, was their inability to employ 2-nitrophenyl octyl ether as the plasticiser. The nitro group is known to inhibit the photopolymerisation process by acting as a free radical scavenger when using the benzophenone type of photoinitiator [11,15]. This can be overcome by introducing a small drop of the 2-nitrophenyl octyl ether plasticiser onto the surface of the photo-cured membrane and allowing it to permeate the membrane [11,18,19]. This procedure improves the response and the selectivity of photo-cured membrane based ISEs, however, there is no control of the amount of plasticiser introduced into the photo-cured membrane.

Recently, there has been a report of a photo-cured nitrate ISE that employed 2-nitrophenyl octyl ether plasticiser in the pre-cured mixture, thereby controlling the amount of plasticiser in the membrane [14]. In this case, photo-curing was made possible by the use of a photoinitiator mixture that contained diaryliodonium chloride and 9,10-phenanthrenequinone, and the photo-curing process was completed in 1 min. This membrane was photo-cured on to a solid-contact electrode and was also photolithographically attached to an ion-sensitive field effect transistor.

This paper presents the evaluation of a new method for preparing a photo-cured calcium ISE, and the reproducibility is determined in a four-sensor flow-through cell for FIP. There are a number of advantages demonstrated for the method of membrane preparation using 2-nitrophenyl octyl ether as the plasticiser and

Table 1
Photo-cured membrane compositions investigated in this study

Membrane components	Ca1 (w/w %)	Ca2 (w/w %)	Ca3 (w/w %)	Ca4 (w/w %)
Ebecryl 600	50.0	49.2	49.0	48.4
HDDA	25.0	24.6	24.5	24.2
9,10-Phenanthrenequinone	0.5	0.8	0.6	0.7

KClTPB	—	—	1.0	0.9

N,N,N′,N′-tetracyclohexyl-3-oxapentane diamide (ETH 129) as the ionophore. Although this is not a new ionophore, it was shown to be applicable in a faster preparation procedure in which the photo-curing process is completed in 1 min without the use of a nitrogen atmosphere. The photo-cured calcium ISE exhibited characteristics making it ideal for FIP measurements, and was applied successfully to determine calcium concentration in a range of water samples. Finally, reproducibility of the membrane preparation method and the precision of peak height measurements for four sensors in the multi-sensor mode of operation in FIP were demonstrated, without the problem of cross-talk.

2. Experimental

2.1. Materials

Metal chloride salts used in this study were all of analytical reagent grade. In addition sodium hydrogen carbonate (BDH, AnalaR), sodium acetate (BDH, AnalaR) and Ultrapure water (Barnstead Ultrapure water system, 18.0 MΩ) were used in this study.

The polymer mixture of the photo-cured membrane prepared in this study consisted of bisphenol A epoxy diacrylate (Ebecryl 600), obtained from UCB Chemical Sector (Belgium) and 1,6-hexanediol diacrylate (HDDA) obtained from Aldrich. The ionophore used was *N,N,N′,N′*-tetracyclohexyl-3-oxapentane diamide (ETH 129) and the lipophilic additives used were potassium tetrakis(4-chlorophenyl)borate (KClTPB) and tetradodecylammoniumtetrakis(4-chlorophenyl)borate (TAClTPB), the photoinitiator mixture consisted of 9,10-phenanthrenequinone and diphenyliodonium chloride and the plasticisers were 2-nitrophenyl octyl ether (NPOE) and bis(2-ethylhexyl)phthalate (BEHP), were all obtained from Fluka.

2.2. Electrode preparation

The composition of each of the pre-cured membrane mixtures prepared in this study are given in Table 1. The pre-cured membranes were each applied directly with a thin nylon brush onto four silver electrode substrates, each of 0.8 mm i.d., in the multi-sensor flow-through cell used in a portable battery-powered flow injection analyser described previously [5]. The coated electrodes were then exposed to UV radiation (250 W, $\lambda =$ 300 nm) for 1 min in the open atmosphere. A minimum of two membranes were prepared and evaluated for each of the compositions listed in Table 1, and identified as Ca1, Ca2, Ca3 and Ca4. All photo-cured membranes produced were hard and clear, and the resultant photo-cured calcium ISEs were conditioned in 100 mM calcium chloride solution overnight prior to any measurements.

2.3. Potentiometric measurements

Steady-state and FIP measurements were performed using four sensors in an eight-sensor flow cell developed in a previous study [5]. The multi-sensor flow cell contained two separate flow channels: (1) for the eight electrodes that were arranged in the wall-embedded configuration [22]; and (2) for the Ag/AgCl reference electrode that was prepared by anodising the silver electrode [23], and both flow channels were merged down stream.

Steady-state measurements were performed by continuously pumping each standard solution into the flow channel containing the photo-cured electrodes. The reference solution used was 10 mM potassium chloride with all steady-state measurements. The FIP measurements were performed by injecting a fixed sample volume into a carrier solution that travels over the surface of the photo-cured membrane and the reference solution was 10 mM sodium chloride. The carrier solutions used in FIP measurements were 10 mM sodium acetate buffer at pH = 5.5 and 7.0, and 10 mM sodium hydrogen carbonate buffer at pH = 8.3, whereby, the calcium standards solutions matched the carrier solutions. The injection sample volume used throughout this study was 200 μl.

In steady-state and FIP modes, electrode potentials were acquired using an analog-to-digital converter similar to that described previously [5,6,24] were displayed in real time and saved on a Macintosh Powerbook 145B computer. The data acquisition software was Satod© Ver. 1.46 and was written in Think C by J. Morgan (University of New South Wales, Sydney, Australia). Data was analysed and graphed by IGOR Ver.1.28 (AD Instruments, Sydney, Australia). The calcium ion activities were calculated using the Debye-Hückel equation [25].

2.4. Determination of membrane resistances

The membrane resistances of the photo-cured calcium ISEs were determined in a 100 mM calcium chloride solution, with each sensor connected to a Fluke 75 multimeter (John Fluke Mfg., USA) versus a platinum electrode. The 100 mM calcium chloride solution was continuously recirculated through the multi-sensor flow cell while measurements were performed.

3. Results and discussion

3.1. Calcium ion response

The four photo-cured membrane electrodes prepared (Ca1–Ca4, Table 1) were investigated to compare the response of each when exposed to calcium solutions. The characteristic performance of each of the ISEs is summarised in Table 2. Ca3 and Ca4 ISEs exhibited an inferior response to calcium in the steady-state mode compared with the Ca1 and Ca2 ISEs. Calibration curves for the four types of calcium ISEs are presented in Fig. 1.

The Ca3 and Ca4 ISEs were clearly sub-Nernstian when compared with the Ca1 and Ca2 ISEs in pure calcium chloride in the steady-state mode. The main difference in the membrane compositions of the photo-cured membranes was that Ca3 and Ca4 membranes both contained the lipophilic additive potassium tetrakis(4-chlorophenyl) borate, and the Ca1 and Ca2 membranes contained tetradodecyl ammonium tetrakis(4-chlorophenyl) borate. This observation indicates that tetradodecyl ammonium tetrakis(4-chlorophenyl) borate was more suited as an anion suppressing agent for photo-cured membranes that contain the NPOE plasticiser than the potassium tetrakis(4-chlorophenyl) borate.

The absence of anion suppressing agents in these photo-cured calcium membranes results in ISEs that respond to anions such as chloride. This observation was likely due to the formation of the

Table 2
Response behaviour of the photo-cured calcium ISEs prepared in this study

Calcium ISE	Electrode slope (RSD)	Log-linear range, mM
Ca1	27.7 (2.1%)	0.01–10
Ca2	28.8 (2.4%)	0.01–10
Ca3	20.7 (8.9%)	0.01–1
Ca4	13.5 (10.3%)	0.01–1

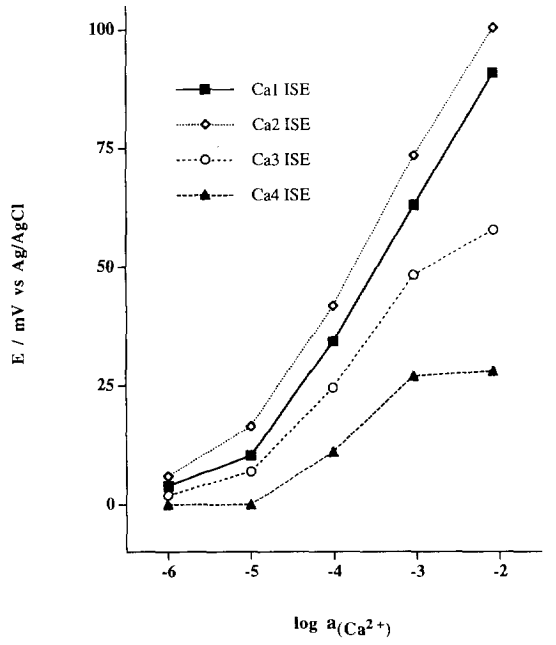

Fig. 1. Calibration curve observed for the photo-cured (Ca1–Ca4) calcium ISEs in the steady-state mode in pure calcium chloride solution.

positively charged calcium-ionophore complex in the membrane phase which electrostatically attracts sample anions, hence, the observed anion response. This also indicates that photo-cured epoxydiacrylate polymer contains no endogenous anionic sites to assist in counterbalancing the positively charged calcium-ionophore complex in the membrane phase.

The Ca1 and Ca2 electrodes were therefore used in further studies on FIP response characteristics in a multi-sensor flow-cell configuration used in a portable battery-powered flow injection system developed in our laboratories [5,6,24]. There was no observable cross-talk between the Ca1 and Ca2 membrane based ISEs, since the electronic circuitry employed in this study was contained in a single carry-case and shielded cables were used to carry the individual ISE signals which were displayed by the computer, as demonstrated in previous work [5,6]. Potentiometric application and evaluation of these photo-cured membranes of high resistance (greater than 10 MΩ) in either the steady-state or FIP modes was made possible employing the multi-sensor based portable flow injection analyser [5]. Typical membrane resistance for all the photo-cured calcium membranes produced in this study were in the range of 10 and 1 MΩ, depending on the thickness of the prepared membrane.

The Ca1 and Ca2 ISEs exhibited an electrode slope of 27.7 ± 0.6 and 28.8 ± 0.7 mV change per activity decade, respectively in pure calcium chloride solution. The log-linear range observed for the Ca1 and Ca2 ISEs were between 0.01 and 10 mM and a detection limit of 1.0 μM in pure calcium chloride solution in the steady-state mode. Fig. 2 illustrates a typical response curve for the step change in concentration for the Ca2 ISE. The time taken for Ca1 and Ca2 ISEs to achieve 90% steady-state were each 5 s making these photo-cured membranes ideal for FIP measurements. The observed baseline drifts for the Ca1 and Ca2 ISEs were about 5 mV per week,

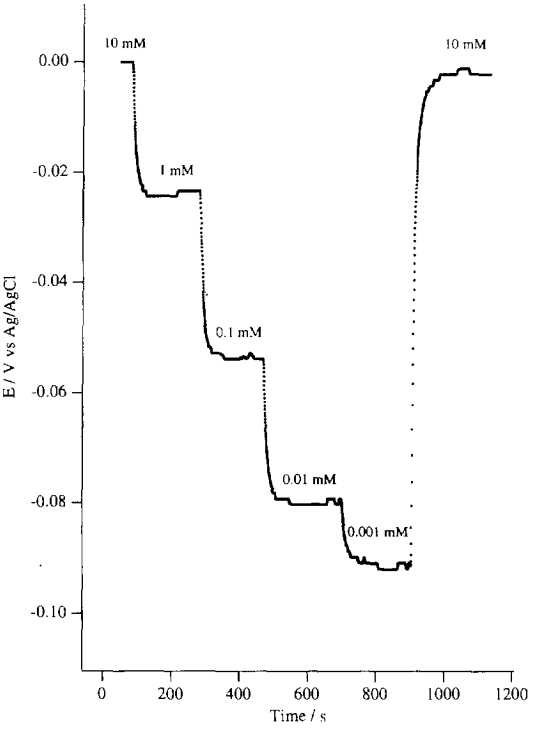

Fig. 2. Typical response curve observed for the Ca2 ISE for the step-change in concentration ranging between 0.001 and 10 mM calcium chloride.

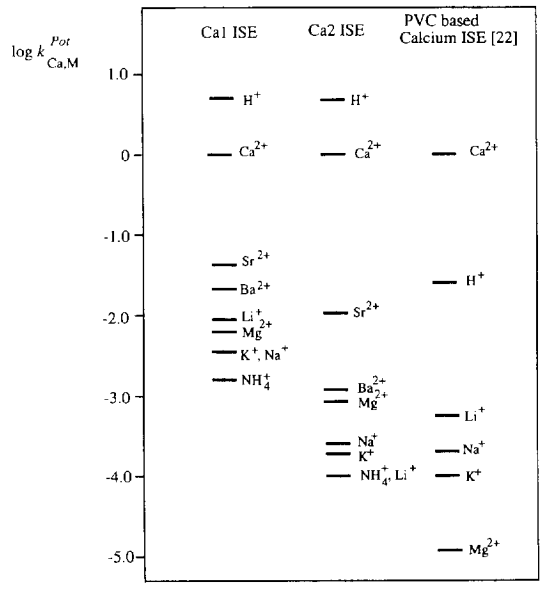

Fig. 3. The selectivity coefficients for the photo-cured Cal and Ca2 ISEs in this study compared to previously reported PVC based calcium ISE.

and both calcium ISEs were stored in 100 mM calcium chloride solution when not in use and were still operational after 3 months.

3.2. Selectivity of Cal and Ca2 ISEs

The selectivity coefficients for the Cal and Ca2 ISEs were determined using the matched potential method [26]. Fig. 3 shows the selectivity coefficients for the two photo-cured membrane based calcium ISEs Cal and Ca2 and a previously reported PVC based calcium ISE employing the same ionophore. The Ca2 ISE was generally more selective against interfering ions than the Cal. Generally, polar plasticisers such as NPOE having a high dielectric constant ($\varepsilon = 24.2$) are used in liquid polymer membranes of divalent cation ISEs in order to increase the selectivity of the determined ion over monovalent cations [21]. The plasticiser mixture employed for the Cal membrane consisted of 50% BEHP ($\varepsilon = 4.2$) and 50% NPOE, while the plasticiser used for the Ca2 membrane was NPOE alone as in Table 1. Since the overall polarity of the Cal membrane was lower than that of the Ca2 membrane, the inferior selectivity observed for the Cal ISE was expected.

The observed selectivities over the magnesium ion for the Cal and Ca2 based ISEs were inferior to a previously reported PVC membrane for calcium employing the same ionophore [27]. The Cal and Ca2 ISEs experienced severe interference from the hydrogen ion, but this was not detrimental to the calcium ion response. The Ca2 ISE exhibited adequate selectivity over sodium, potassium and magnesium ions for potentiometric calcium measurements in a range of water samples. However, the pH of the standards and samples must be the same.

Fig. 4 shows the calibration plot for the Ca2 ISE measured in the steady-state mode with solutions of different pH. Using a 10 mM sodium acetate buffer at pH = 5.5, there was a negligible response to calcium ions. In 10 mM sodium acetate buffer at pH 7.0 and in 10 mM sodium hydrogen carbonate buffer at pH 8.3, the electrode slopes were 22.5 ± 0.9 and 24.5 ± 0.5 mV

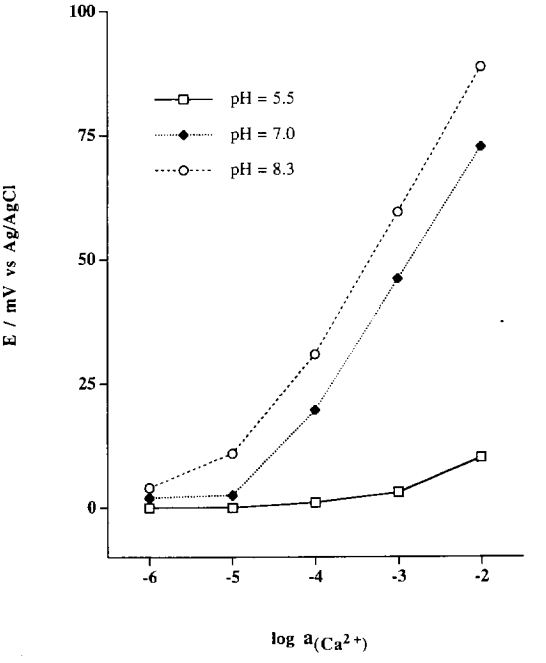

Fig. 4. Calibration curve observed for the photo-cured Ca2 ISE in the steady-state mode with calcium chloride solutions in 10 mM sodium acetate buffer at pH 5.5 and pH 7.0, and 10 mM sodium hydrogen carbonate buffer at pH 8.3.

per activity decade, respectively, and the observed log-linear range was between 0.5 and 10 mM calcium in the steady-state mode. Clearly, to perform reliable potentiometric measurements with this ISE, the pH must be ≥ 7.0 and there must be a pH match between the standards and the samples.

There are three possible sources of the hydrogen interference experienced by the Ca1 and Ca2 ISEs: (1) the epoxyacrylate membrane exhibited some pH sensitivity; (2) the lipophilic additive (tetradodecyl ammonium tetrakis(4-chlorophenyl) borate) was sensitive to pH; or (3) the ETH 129 ionophore was degraded after exposure to the UV radiation. Each point will be discussed in turn.

There have been numerous photo-cured epoxyacrylate based anion and cation-selective electrodes employing various ionophores and plasticisers (including NPOE), and none of these membranes have experienced any hydrogen interference [10–12,14–19]. A blank photo-cured membrane of similar composition to the Ca2 membrane, but without the ETH 129 ionophore, exhibited no pH response. It is therefore unlikely that the epoxydiacrylate polymer base and the lipophilic additive, tetradodecyl ammonium tetrakis(4-chlorophenyl) borate, contributed to the pH interference shown in this study. This eliminates the photo-cured epoxyacrylate polymer base for contributing to any pH interference of the Ca1 and Ca2 ISEs and the tetradodecyl ammonium tetrakis(4-chlorophenyl) borate additive.

In a previous study, oven-curing (90°C for 30 min) of a silicon rubber based calcium ISE which contained the ETH 129 ionophore resulted in an electrode response that was sub-Nernstian due to degradation of the ionophore [28]. In a different study, the room-temperature curing of a plasticised silicon rubber membrane employing the ETH 129 ionophore produced a calcium ISE that was comparable with the PVC based calcium ISEs [29].

A PVC calcium ISE based on the ETH 129 ionophore and the potassium tetrakis (4-chlorophenyl)borate lipophilic additive was prepared as described previously [27] and then exposed to UV radiation under the same conditions as the Ca1 and Ca2 ISEs. The PVC based calcium ISE exhibited a significant pH interference similar to that observed for the Ca1 and Ca2 ISEs. Clearly, curing of liquid polymer membranes containing the ETH 129 ionophore above room temperature results in a calcium ISE that shows some inferior electrochemical properties when compared with any liquid polymer membrane prepared at room temperature. We therefore believe that some degradation of the ETH 129 ionophore occurs on UV curing which raises the temperature of the membrane above room temperature and that this leads to the observed pH interference. The excellent selectivity observed against monovalent ions suggests that the extent of degradation is not great.

3.3. Flow injection potentiometric measurements with the Ca2 ISE

The photo-cured Ca2 ISE was fast responding, exhibited excellent adhesion to the silver substrate and was mechanically strong, thus making it ideal for FIP measurements. The carrier was 10 mM sodium hydrogen carbonate buffer (pH = 8.3). Typical peaks observed for four photo-cured Ca2 ISEs in the FIP mode are presented in Fig. 5 after baseline offsetting for each calcium ion electrode response. The precision of triplicate peak heights range between 1.0 and 4.0% (RSD). The mean electrode slope observed for the 4 Ca2 ISEs was 25.4 ± 0.4 mV change per activity decade which demonstrates the reproducible manufacture of the Ca2 membrane. The log-linear range observed for the Ca2 ISE was between 0.5 and 10 mM and the detection limit was 0.01 mM calcium in a 10 mM sodium hydrogen carbonate background in the FIP mode. The FIP response observed for the Ca2 ISE was 70% of the steady-state response.

To demonstrate the accuracy of the Ca2 ISE in the FIP mode, three types of water samples were analysed for their calcium content: (1) with low levels of calcium ions that would be near the detection limit of the Ca2 ISE (Tap water); (2) with similar levels of calcium and magnesium ions (Summit Mineral Water); and (3) with a higher calcium level than that of magnesium (Evian Mineral Water). Table 3 presents the results of the water analysis which were in agreement with atomic absorption spectroscopy measurements.

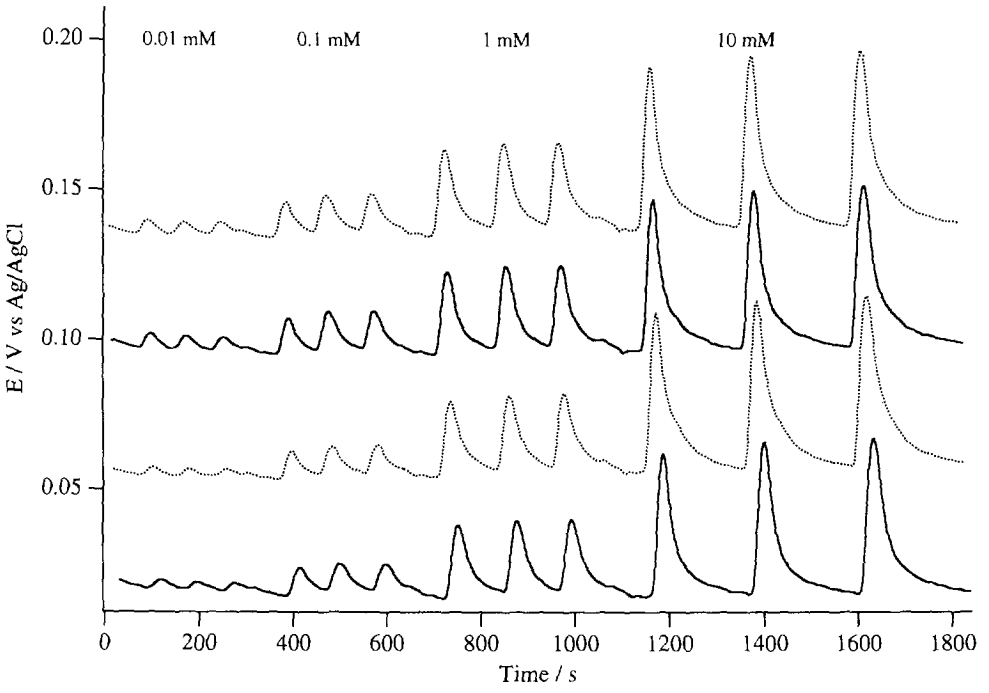

Fig. 5. Typical peak height responses observed for four photo-cured Ca2 ISEs, carrier stream was 10 mM sodium hydrogen carbonate (pH = 8.3) and reference stream was 10 mM sodium chloride, total flow rate was 2.5 ml min^{-1}, and the sample volume was 200 ml.

4. Conclusions

The development of a photo-cured Ca2 membrane using 2-nitrophenyl octyl ether as the plasticiser and tetradodecyl ammonium tetrakis(4-chlorophenyl)borate as the lipophilic additive has been shown to give superior potentiometric characteristics when compared with the other photo-cured calcium ISEs investigated in this study. A hard and transparent membrane was produced after a 1 min photo-curing process without the use of a nitrogen atmosphere compared with other reported photo-cured membranes which employ a benzophenone type photoinitiator requiring up to 40 min photo-curing under the nitrogen atmosphere [10–19]. Photo-curing membranes in ambient air which contained 2-nitrophenyl octyl ether plasticiser was made possible by employing a photoinitiator mixture containing 9,10-phenanthrenequinone and diphenyliodonium chloride. Good reproducibility of the calibration slope (1.4% RSD) was obtained in the multi-sensor flow cell design with four sensors coated with the same Ca2 membrane in the FIP mode. The peak height precision in the multi-sensor design for FIP ranged between 1 to 4% depending on the concentration injected.

Table 3
Calcium determination of various water samples by FIP and atomic absorption spectroscopy (AAS), ($n = 3$)

Water sample	Ca2 ISE mg l^{-1} (RSD)	AAS mg l^{-1} (RSD)	Labelled mg l^{-1}
Evian mineral water	71.2 (2.1%)	78.2 (0.3%)	78
Summit mineral water	16.0 (4.1%)	15.2 (0.3%)	18
Tap water	5.3 (4.2%)	5.6 (0.2%)	1–5[a]

[a] Expected range.

Significant interference by hydrogen ions was observed with all photo-cured membranes and it is proposed that a slight degradation of the ETH 129 ionophore in the photo-cured membranes after exposure to the UV light had occurred. The present photo-cured calcium ISE was used to determine calcium levels in various water samples in the FIP mode, whereby, a 10 mM sodium hydrogen carbonate (pH = 8.3) carrier was used. The results were in good agreement with atomic absorption spectroscopy.

Spectrophotometric determination of hydrogen peroxide by using the cleavage of Eriochrome black T in the presence of peroxidase

Min Zhu, Xuemei Huang, Liuzhan Liu, Hanxi Shen *

Department of Chemistry, Nankai University, Tianjin, 300071, People's Republic of China

Received 28 August 1996; received in revised form 11 December 1996; accepted 23 December 1996

Abstract

A new hydrogen donor for peroxidase, Eriochrome black T, was reported for the first time. Steady-state catalytic velocity depends upon enzyme and substrate concentrations, and a Michaelis–Menten K_m value of 1.72×10^{-5} mol l^{-1} and a V_{max} value of 4.43×10^{-3} s^{-1} were measured at pH 8.6. Trace amount of hydrogen peroxide (2×10^{-7}–1.0×10^{-5} mol l^{-1}) was determined in aqueous solution by using the cleavage of Eriochrome black T catalyzed by peroxidase. The method is simple and practical, with high sensitivity and enzymatic activity. © 1997 Elsevier Science B.V.

Keywords: Catalytic cleavage; Eriochrome black T; Peroxidase; Spectrophotometric determination of H_2O_2

1. Introduction

The spectrophotometric determination of hydrogen peroxide by reaction with a chromogenic hydrogen donor in the presence of peroxidase has been widely accepted in the analysis of biological samples. Various kinds of hydrogen donors have been recommended for this purpose, such as phenol derivatives [1–6], aniline derivatives [7–12], and leuco dyes [13,14]. However, aniline-4-aminoantipyrine system proceeded only in an acidic medium, so its application was limited during the determination of hydrogen peroxide in the presence of oxidases, such as cholesterol oxidase. The maximum absorbance of phenol-4-aminoantipyrine system was located at 500–520 nm, which was often susceptible to interference by bilirubin in serum, that had an absorption band in a range of 380–530 nm [15]. In addition, its limited analytical sensitivity was a common disadvantage. The determination of hydrogen peroxide requires submicro molar limit of detection when hydrogen peroxide is produced from samples catalyzed by some oxidases, such as monoamine oxidase and uricase, or originated from the supermicro amount of sample. Leuco dye, such as leuco crystal violet and patent blue violet could be substituted for them with a spectacularly high sensitivity, but it also proceeded in acidic conditions (pH $\leq$ 4.5) for the reason of solubility and

PII S0039-9140(97)00012-X

itself was easily oxidized by oxygen dissolved in water. In this paper, a new hydrogen donor for peroxidase, Eriochrome black T (EBT, 7-nitro-4-[(1-hydroxy-2-naphthonol)azo]

-1-naphthalenesulfonic sodium), was advocated for the first time. On the basis of oxidation cleavage of EBT, a simple and practical spectrophotometry was applied in the determination of hydrogen peroxide, with high sensitivity (ε_{max} is 5.51×10^4 l mol^{-1} per cm), wide working range and without coupling reagent.

2. Experiment

2.1. Chemicals

Horseradish peroxidase (HRP, E.C.1.11.1.7, ≥ 250 IU mg^{-1}, RZ > 3.0) was purchased from Sino-American Biotechnology Company and prepared to 2.5×10^{-7} mol l^{-1}. Hydrogen peroxide solution for analysis was freshly prepared by appreciate dilution of a stock solution, which was standardized by potassium permanganate. EBT was recrystaled twice before used and applied in 2.8×10^{-3} mol l^{-1} of stock solution and preserved at 4°C. 1-Phenyl-3-methyl-5-pyrazolone (PMP) was prepared in 0.01 M. Kolthoff [16], Tris–HCl and Glycine–NaOH buffer solutions were applied in pH 5.6–11.0. All other reagents were of analytical grade commercially available. All aqueous solutions were prepared in twice deioned water.

2.2. Apparatus

All spectrophotometric measurements were done with a Shimadzu UV-240 spectrophotometer in standard cells with 10 mm pathlength (Tokyo, Japan).

2.3. Procedure

In a 10 ml colorimetric tube, 2.5 ml buffer solution (pH 8.6), 0.4 ml EBT, 0.2 ml HRP, and a different amount of H_2O_2 standard solutions were added and diluted to the mark. The mixture was incubated at 50°C for 5 min, with the control sample without H_2O_2. The absorption spectra of both resulting solution and control sample were recorded and their absorbance differences at the wavelength of maximum absorbance (615 nm) were measured with the spectrophotometer.

3. Results and discussion

3.1. Reaction of EBT and H_2O_2 catalyzed by HRP

It was reported that 1-phenylazo-2-hydroxynaphthalene (Sudan I) was oxidized slowly by HRP/H_2O_2 to be the product of the oxidative splitting of this azo dye (30 min–3 h), which can be considered to lead to the formation of the benzenediazonium ion and quinone [17]. In our experiment, oxidation cleavage of EBT, which is the derivative of Sudan I, in the presence of HRP/H_2O_2, was investigated, as shown in Fig. 1. Absorption band of 615 nm at pH 8.6 (curve 1) disappeared immediately (0.5–3 min) at room

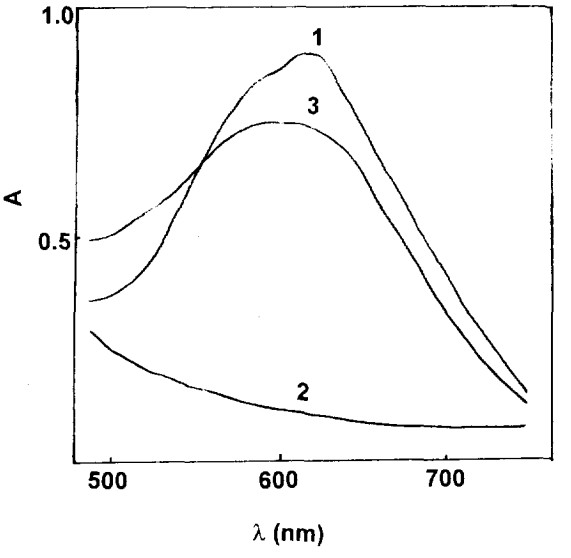

Fig. 1. Absorption spectra of EBT (1.0×10^{-4} mol l^{-1}) aqueous solution before (2) and after (3) addition of PMP (2×10^{-4} mol l^{-1}), in the precence and absence (1) of HRP (2×10^{-8} mol l^{-1}). The concentration of H_2O_2 was 2.5×10^{-5} mol l^{-1}. The solution was incubated at 50°C for 5 min, pH 8.6.

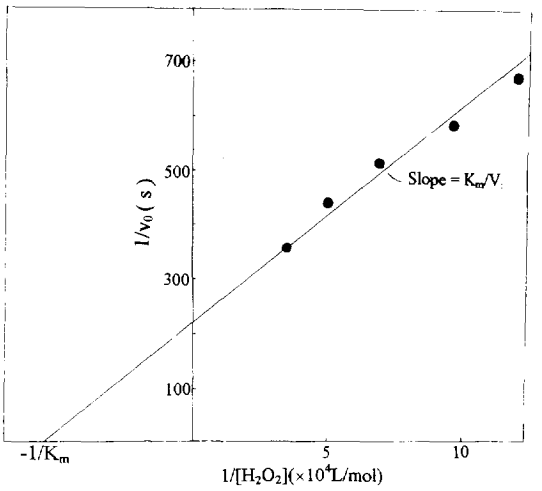

Fig. 2. Lineweaver–Burk plot The concentration of EBT was 1.1×10^{-4} mol l^{-1} at pH 8.6 and 25°C.

temperature or 50°C under the experimental condition, and no apparent absorption band was observed in the range of 500–750 nm (curve 2), which indicated that the conjugated double bond system was destroyed, probably due to the cleavage of covalent bond between –N=N– group and phenyl or naphthol group. The formation of the benzenediazonium ion in the EBT-HRP-H_2O_2 system was identified by its azo coupling with PMP. An absorption band at 550–650 nm was seen immediately after the benzenediazonium ion sensitive reagent, PMP, was added in the resulting solution (curve 3).

3.2. Determination of velocity and constants of enzyme reaction

The mechanism of enzyme action was not clear when EBT was used as the substrate for the peroxidase. It was necessary to measure velocity and constants of the enzyme reaction, in order to describe the enzyme mechanism further. The approach was to make the concentration of the substrate, EBT, excessive greatly and constant. Then the enzyme reaction was a single substrate reaction, and Michaelis–Menten behavior was observed. Thus, by Lineweaver–Burk plot, an approximately straight line is obtained, as shown in Fig. 2.

With its intercept and slope, it could be concluded that maximum velocity, V_{max} was $4.4(\pm 0.3) \times 10^{-3}$ s^{-1}, and Michaelis constant K_m was $1.7(\pm 0.2) \times 10^{-5}$ mol l^{-1}. Since $V_{max} = K_{cat}[E]_0$ ($[E]_0$ is the initial concentration of enzyme), the conversion constant K_{cat} was $2.0(\pm 0.1) \times 10^6$ $(\text{mol } l^{-1})^{-1}$ s^{-1}, and specificity constant K_{cat}/K_m was $1.2(\pm 0.1) \times 10^{11}$ $(\text{mol } l^{-1})^{-2}$ s^{-1}.

3.3. Optimization of experimental parameters

EBT is unstable in strong acid solution. As pH increased, the maximum wavelength shifted from 560 to 620 nm [18], and absorbances were measured at various maximum wavelengths. The effects of pH on relative enzyme activity and sensitivity were studied, with results shown in Table 1. Comparisons of the sensitivities would be made in terms of the following equation:

$$\frac{\Delta A_{\lambda\text{max of test pH}}}{\Delta A_{\lambda\text{max of pH 8.6}}} = \text{Factor} \quad (1)$$

Kolthoff, Tris–HCl and Glycine–NaOH buffer solution systems were compared and the EBT exhibited higher sensitivity and initial velocity at Kolthoff buffer solution. Measurement could be preceded in a range of pH 8.4–9.0. Both relative enzyme activity and relative absorbance differences were highest at pH 8.6, and the product of fading reaction was also more stable in a weakly basic condition.

There were few studies for the influence of temperature on enzyme activity [2–14], although there was much interest in horseradish peroxidase as a analytical reagent previously. Most of Trinder system and anline–aminoantipyrine system proceeded in the condition of 37°C [9–12] or at room temperature [5–8], following the Trinder's results in 1969 [1]. No experimental temperature was provided in literatures [13,14] when leuco dye was recommended as a substrate for routine assays. However, it was found by Bauminger [19] that higher absorbences were obtained at 45°C than at 37°C in phenol-4-aminoantipyrine system. In a previous paper [20], 40°C was identified as optimal when ascorbic acid was used as a substrate for the HRP.

Table 1
Effect of pH on initial rates and the sensitivity

	pH	λmax (nm)	v_0 ($\times 10^{-3}$ s^{-1})[a]	Factor[b]	t (min)[c]
Kolthoff	5.6	567	1.01	0.296	2
	7.0	604	2.76	0.515	2
	7.6	612	2.90	0.524	5
	8.2	612	5.25	0.702	5
	8.4	615	8.97	0.901	5
	8.6	615	10.7	1.00	10
	8.8	615	9.51	0.956	10
	9.0	617	5.55	0.915	10
	10.0	592	2.03	0.753	2
	11.0	592	0	—	—
Tris–HCl	7.6	612	2.51	0.508	2
	8.2	514	4.10	0.737	3
Glycine–NaOH	8.6	605	4.75	0.455	3
	9.2	605	5.04	0.633	3

[a] Initial rate, $[H_2O_2] = 1.0 \times 10^{-5}$ mol l^{-1}, $[HRP] = 5.0 \times 10^{-9}$ mol l^{-1}.
[b] Factor is defined in Eq. (1).
[c] Stable time of resulting fading product.

The impact of temperature on enzyme activity in the present system was examined when it varied from 20 to 70°C (Fig. 3). Enzyme lost more than 50% of its activity when temperature was above 70°C or below 20°C. Fig. 3 shows that relative enzyme activity increases with temperature, arriving at a maximum in the range of 45–60°C. Further increase in temperature leads to the decrease of velocity because of the partial denaturation of the enzyme. Thus, the reaction temperature for the following experiment was 50°C, and reaction was completed within 3 min.

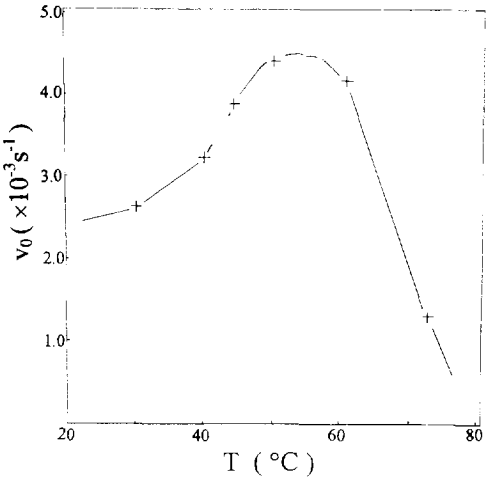

Fig. 3. Influence of temperature on relative enzyme activity. The concentration of HRP and H_2O_2 were 2.5×10^{-9} and 1.0×10^{-5} mol l^{-1}, respectively, pH 8.6.

Reaction time was directly related to HRP concentration. From experimental results, the reaction would be completed within 1 min when 1.0×10^{-8} mol l^{-1} enzyme was applied, and it would be completed within 10 min when 2.5×10^{-9} mol l^{-1} enzyme was used. So the concentration of HRP in a range of 2.5×10^{-9}–1.0×10^{-8} mol l^{-1} was recommended in the enzymatic assay.

The stability of the EBT stock solution was examined, and it was compared with Trinder reagent, aniline-4-aminoantipyrine system and leuco dye. Absorbance at experimental wavelength (505 nm) of phenol-4-aminoantipyrine

Table 2
Stability test of EBT

Day	A/A_0	$\Delta A/\Delta A_0$
1	1.00	1.00
10	0.93	0.99
30	0.88	0.99
60	0.80	0.96

Table 3
Results of recovery experiments

Sample	Added $\times 10^{-6}$ mol l^{-1}	Found $\times 10^{-6}$ mol l^{-1}	Recovery $\times 10^{-6}$ mol l^{-1}	%
1	0	4.12 ± 0.02	—	—
	2.00	6.06 ± 0.04	1.94 ± 0.02	97.0 ± 1.0
	4.00	8.16 ± 0.03	4.04 ± 0.01	101.0 ± 0.3
2	0	0.43 ± 0.01	—	—
	2.00	2.33 ± 0.02	1.90 ± 0.01	95.0 ± 0.5
	4.00	4.39 ± 0.02	3.96 ± 0.01	99.0 ± 0.3

stock solution was up to 0.075 from 0.030 after 15 days, and that of aniline-4-aminoantipyrine was up to 0.433 from 0.054 after 20 days [6]. High sensitive reagent, leuco dye was stable only for 24 h when stored in a dark bottle [14]. Table 2 shows the stability of EBT stock solution. A_0 is the absorbance at the maximum wavelength of EBT solution and ΔA_0 is the absorbance difference in the determination of 1.0×10^{-5} mol l^{-1} H_2O_2 with freshly prepared EBT reagent. A is the absorbance of EBT solution and ΔA is the absorbance difference with the EBT reagent which is stored for some day. From the results shown in Table 2, EBT exhibited good storage characteristics, in that there was no notable impact on measurement, although the absorbance at maximum wavelength decreased about 20% after 2 months.

3.4. Analytical characteristics

The calibration graph for the determination of H_2O_2 was obtained under the optimum reaction conditions. The range of linearity for the relationship between ΔA and concentration of H_2O_2 was 2×10^{-7}–1.0×10^{-5} mol l^{-1}. The regression equation and correlation coefficient of calibration graph for H_2O_2 was $\Delta A = 0.051(\pm 0.006) + 5.51(\pm 0.03) \times 10^4 C$ and $\gamma = 0.9987(\pm 0.0008)$, respectively. Calculated from the regression equation, the molar absorption coefficient of the EBT-HRP-H_2O_2 system was $5.51(\pm 0.03) \times 10^4$ l mol^{-1} per cm, which was 2.5–10 times better than that of the Trinder system [1,2]. The relative standard deviation was 0.4% for the determination of 1.0×10^{-5} mol l^{-1} H_2O_2 ($n = 8$).

Standard solutions of the test H_2O_2 were mixed to prepare mixture sample. The recovery experiments were carried out and the results were listed in Table 3.

The interferences of foreign ions to the determination of H_2O_2 (1.0×10^{-5} mol l^{-1}) in the EBT-H_2O_2-HRP system were studied, as shown in Table 4. When added at levels greater than those given, all the ions listed caused negative errors.

Determination of carboxylic acid vapour by a thickness-sheer-mode acoustic wave sensor coated with crown ethers

Cao Zhong, Gao De, Lei Zheng-Gang, Lin Hui-Gai, Yu Ru-Qin *

College of Chemistry and Chemical Engineering, Hunan University, Changsha, 410082, People's Republic of China

Received 20 August 1996; accepted 2 January 1997

Abstract

The frequency response sensitivities for 39 organic vapours by thickness-sheer-mode (TSM) acoustic wave sensors coated with monobenzo-15-crown-5 (B15C5), monobenzo-18-crown-6 (B18C6) and dibenzo-30-crown-10 (DB30C10) have been reported. It shows that crown ethers are the most efficient adsorptively active material for sensing carboxylic acid vapour, particularly B15C5 can be used for sensing formic acid vapour. The B15C5 based sensor possesses good reproducibility, high stability and short response time with wide linear detection range and a low detection limit down to 0.0201 mg l^{-1} (about 5.70 ppm, V/V) of formic acid vapour while coating with 12 μg of B15C5. There is no significant interference from other organic vapours except for some nitrogen containing compounds such as diethylamine, pyridine and *N,N*-dimethylformamide, and carboxylic acid homologues such as acetic and propionic acids. The effect of humidity is easily controllable. Compared with acid–base titration method, the sensor can be used for the determination of HCOOH vapour with recovery rate of 98.4 ~ 103.8%, the analytical results are in good agreement with those obtained by the more time consuming acid–base titration method. © 1997 Elsevier Science B.V.

Keywords: Crown ethers; Organic vapours; Thickness-sheer-mode acoustic wave sensor; Carboxylic acid

1. Introduction

Carboxylic acids are toxic atmosphere pollutants, especially formic acid, which may be causing shock, pneumonitis, severe corrosive effects in the respiratory and gastrointestinal tract and irritative effects on eyes, skin and mucous membranes of human beings and animals. The maximum acceptable level of formic, acetic, and propionic acid vapours' exposure in the industrial atmosphere are 5 ppm (9 mg m^{-3}), 10 ppm (25 mg m^{-3}), and 10 ppm (30 mg m^{-3}), respectively [1,2]. Hence it is very important to develop sensitive analytical methods for monitoring carboxylic acids in particular formic acid. To date the existing methods for detecting formic and other carboxylic acids include acid–base titration [3,4], ion chromatography [5,6], high-performance liquid chromatography [7], capillary electrophoresis [7],

* Corresponding author. Fax: +86 731 8824525.

PII S0039-9140(97)00016-7

absorptiometry [8], spectrofluorimetry [9] and enzymatic assay [10,11]. Most of these methods are laborious and time-consuming and hardly applicable for on-line monitoring carboxylic acids including formic acid.

Recently, coated thickness-sheer-mode (TSM) acoustic wave sensors have shown promising potential to be used as simple, inexpensive, and portable devices with high mass sensitivity for the detection of toxic atmospheric pollutants such as acetic acid [12], formaldehyde [13,14], toluene [15], SO_2 [16], and NO_2 [17], etc. The principle of the TSM device is that the decrease in resonance frequency of an AT-cut quartz crystal vibrating in the thickness sheer mode (ΔF, Hz) is proportional to the increase in mass of a foreign substance adsorbed onto its surface (ΔM, g), derived from the Sauerbrey equation [18]

$$\Delta F = -2.3 \times 10^6 F_0^2 \frac{\Delta M}{A} \quad (1)$$

Here F_0 is the fundamental frequency of the quartz plate (MHz), A is the surface area of the quartz crystal coated (cm^2). From Eq. (1), a mass sensitivity of about 400 Hz μg^{-1} for a 9 MHz crystal and a sensitivity of 2600 Hz μg^{-1} for a 15 MHz crystal is obtained. The vibrating quartz crystal is in fact an extremely sensitive mass detector, whose theoretical detection limit is about 10^{-12} g for foreign substances absorbed [19].

The coated TSM acoustic wave gas sensors usually possess high sensitivities, low detection limits and long useful lifetimes with macromolecular compounds and polymers as adsorptive coating materials [20–24]. There is few attention paid to the analytical application of macrocyclic polyether such as crown ether coated TSM gas sensors [24–27]. In the presented paper, the response characteristics for 39 organic solvent vapours are investigated by TSM detectors coated with monobenzo-15-crown-5 (B15C5), monobenzo-18-crown-6 (B18C6) and dibenzo-30-crown-10 (DB30C10), respectively, showing that crown ethers are efficient adsorptively active materials for sensing carboxylic acid vapours, in particular B15C5 is very suitable for sensing formic acid vapour. Therefore, an inexpensive and portable TSM device coated with B15C5 may be used for detecting formic acid vapour with potential on-line or on-site applications.

2. Experimental

2.1. Apparatus and materials

The schematic diagram for the experimental assembly is shown in Fig. 1. The measuring chamber consist of a glass vessel with a volume of 535 ml. It included two way pipes with valves for incoming and outgoing gases, a stainless steel nozzle sealed and furnished with silicone rubber for injection of samples. A small customized magnetic fan was mounted on the bottom of the vessel that was used to homogenize the gas inside the chamber before detection, and a fixed magnetic stirrer (Model 78-1, Nanhui Telecommunication Equipment Factory, Shanghai) with its transformer and regulator placed outside the chamber for inductively driving the fan. The measuring chamber was kept at 24 ± 0.5°C by using a thermostatted water bath. The AT-cut quartz crystal (12.5 mm diameter) vibrating in the thickness sheer mode was placed in the sealed measuring chamber with a fundamental frequency of about

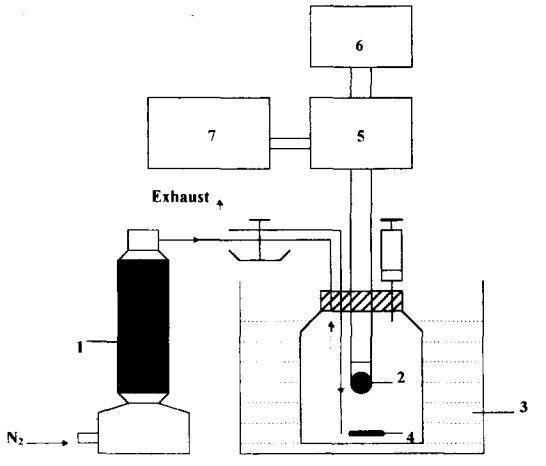

Fig. 1. The schematic diagram for the experimental assembly. 1, Anhydrous $CaCl_2$; 2, coated TSM acoustic sensor; 3, thermostatted water bath; 4, magnetic stirring fan; 5, TTL oscillator; 6, d.c. voltage regulator; 7, digital frequency counter.

9.3125 MHz, having silver-plated electrode (6 mm diameter) on each side (Model JA-5, Chengxing Radio Instruments, Beijing). The crystal electrode holder was direct connected to a laboratory-made oscillator build with a Transistor-Transistor Logic (TTL) circuit which was powered with a regulated power supply. The applied voltage was kept constant at 5 V dc for all measurements. The output frequency of the oscillating quartz crystal was monitored by using a digital frequency counter with a resolution capacity of 0.01 Hz (Model 1992/SS3380, Sijiazhuang Radio Instruments).

The adsorptively active materials applied to the crystal surface were monobenzo-15-crown-5 (B15C5), monobenzo-18-crown-6 (B18C6) and dibenzo-30-crown-10 (DB30C10) obtained from Neijiang Chemicals (Sichuan). All solvents were of analytical-reagent grade or laboratory-reagent grade which were refined and stored in sealed bottles with some pieces of drying anhydrous calcium sulfate before measurement.

2.2. Coating method

A solution about 1% by weight of each coating material was prepared using a high volatile organic solvent such as tetrahydrofuran. The solution was coated onto both sides of a crystal first by dipping and then by syringe dropping method in order to load desired amount of coating material and the solvent was evaporated with the aid of a blower. The process was repeated until a homogeneous film with an appropriate amount of coating ($4 \sim 50$ μg) dispersed on the crystal surface was formed. The coated TSM acoustic sensor was thus prepared, which was placed in a desiccator with anhydrous silica gel and activated charcoal holding while not used.

2.3. Detection procedure

In the measuring chamber, the stabilized coating fundamental frequency (F_1) of the coated TSM sensor was measured in an air or nitrogen atmosphere, which was dried and cleaned by passing through the anhydrous calcium chloride drying column. Then the appropriate amount of solvent sample was injected into the measuring chamber with a micro syringe. With the sensor coming into adsorption equilibrium with the sample vapour, the output frequency of the sensor was read (F_2). The frequency shift value of the sensor was obtained by the equation:

$$\Delta F = F_1 - F_2 \quad (2)$$

All measurements were performed at room temperature of 24 ± 0.5°C.

3. Results and discussion

3.1. Sensor's response sensitivities and selectivities

The TSM acoustic sensor coated with B15C5, B18C6, and DB30C10 were tested by exposure to 39 different organic solvent vapours. Their response sensitivities are listed in Table 1, showing that crown ethers are the efficient adsorptively active material for sensing of carboxylic acid vapours, in particular B15C5 possesses high sensitivity for formic acid vapour, which may be attributed to the formation of relatively strong hydrogen bonds RCOOH···O (crown ether) between carboxylic acid and crown ether resulting in greater adsorption than other organic solvents. With the molar mass of an acid molecule increased, the sensitivity of the sensor increases due to higher mass of individual molecule adsorbed on the coated TSM crystal. Similar regularity is true for other organic homologues of alcohol, ketone, acetate and aromatic hydrocarbon, etc., Fig. 2a–2c show that the sensitivity of the sensor response toward three carboxylic acid homologues in terms of the response curve slope has the following sequence: B15C5 > DB30C10 > B18C6. Compared with DB30C10 and B18C6, B15C5-coated sensor possesses excellent linear response characteristics for formic acid. It seems that this is due to monolayer adsorption, while possible multilayer adsorption might lead to non-linear responses to such species as acetic and propionic acids. B15C5 as the best adsorptively active material for the determination of formic acid vapour has taken as the subject of detailed investigation of the response characteristics of the TSM sensor of interest.

Table 1

[a] The coating mass of each crown ether was 12.5 μg.

For a TSM acoustic sensor, the selectivity coefficient (K_{ij}) for an organic species i with respect to interferant j may be simply defined as the ratio of corresponding sensitivities, i.e., $K_{ij} = S_j/S_i$. The selectivity coefficient of the B15C5 coated sensor for formic acid with respect to other organic compounds are given in Table 1. No significant interference is observed from organic solvent vapours such as alcohol, ketone, ether, ester, alkane, and aromatic hydrocarbon compounds except for some nitrogen containing compounds such as diethylamine, pyridine and *N*,*N*-dimethylformamide, and carboxylic acid homologues such as acetic and propionic acids.

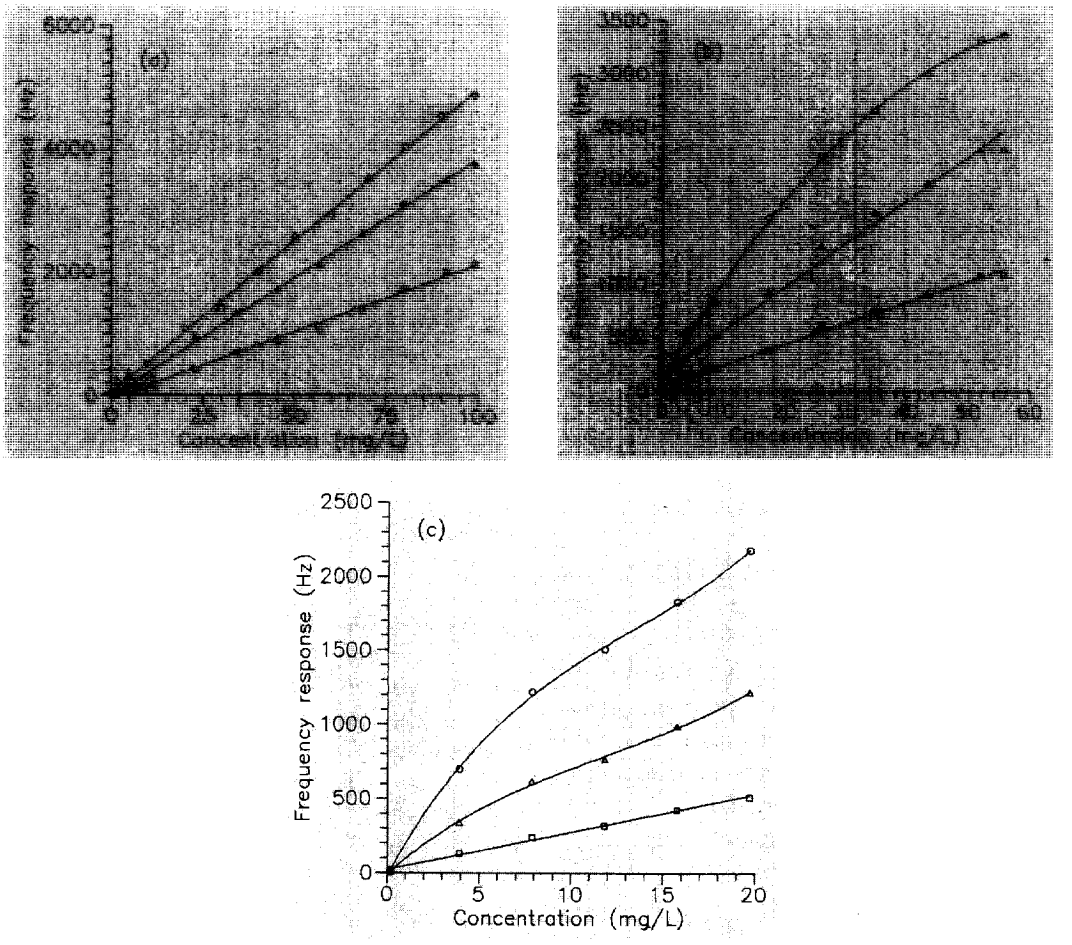

Fig. 2. The response curves of TSM acoustic sensors exposing to carboxylic acid vapours including; (a) formic acid; (b) acetic acid; and (c) propionic acid. The sensor surface was coated with 12.5 μg of B15C5 (○), B18C6 (□), or DB30C10 (△).

3.2. Relation between coating mass and linear response characteristics

The amount of B15C5 coated on the crystal surface had a significant influence on the linear response characteristics of TSM sensor for formic acid assay. The crystal with more B15C5 coated on its surface exhibited a larger frequency shift response for the same concentration of formic acid vapour. The optimum amount of B15C5 to be applied to the crystal was determined experimentally. Fig. 3 shows that the sensitivity of the B15C5 coated TSM acoustic sensor increases as the amount of the B15C5 coating increases due to an increased probability of interaction between the B15C5 coating material and the HCOOH molecules. One could not, however, take the full advantage of this phenomenon, as the increased amount of coating tended to lead poor linearity which seemed to be related to the thickness and homogeneity of the coating. The response curves of the TSM sensors coated with different amount of B15C5 exposing to formic acid vapour are shown in Fig. 4. It has been shown that about 12 μg of B15C5 coating is sufficient for obtaining satisfactory linear response characteristics. When TSM crystal with 12 μg of B15C5 coating was exposed to formic acid vapour, the linear response
