range of the sensor was 2.01 ~ 99.3 mg l^{-1} with the slope of 49.4 Hz mg^{-1} per l (24 ± 0.5°C), the regressive coefficient was 0.998 ($n = 12$). In addition, the same sensor could also be used for the determination of formic acid vapour of lower concentration. When the sensor was exposed to HCOOH vapour with the concentration of 0.100 ~ 2.01 mg l^{-1}, a roughly linear response could be obtained, though the regression line was

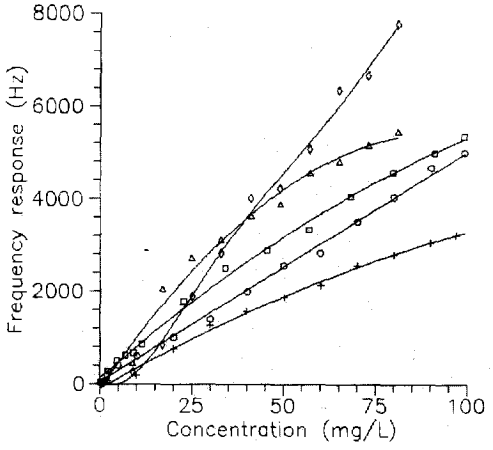

Fig. 4. The response curves of the TSM sensors coated with different amount of B15C5 exposing to formic acid vapour. Amount of coating are: 4.21 μg (+); 11.9 μg (○); 17.1 μg (□); 34.5 μg (△); and 40.5 μg (◇ >.

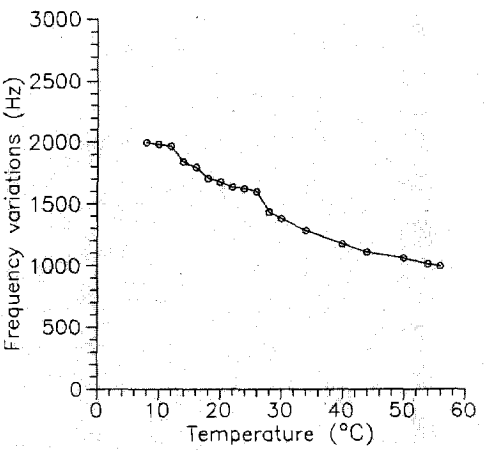

Fig. 5. Effect of temperature on the TSM sensor coated with 12 μg of B15C5 upon exposure to 30.1 mg l^{-1} HCOOH vapour.

only quasi-linear in this range and it was not the extrapolation of the aforementioned major lower concentration linear response range. The sensitivity in the lower concentration range was 103 Hz mg^{-1} per l (24 ± 0.5°C) with the regressive coefficient of 0.997 ($n = 11$), and the detection limit approached 0.0201 mg l^{-1} (equivalent to about 5.70 ppm, V/V).

3.3. Effect of cell temperature

The effect of temperature in the range of 8 ~ 56°C on the TSM crystal coated with 12 μg of B15C5 upon exposure to 30.1 mg l^{-1} HCOOH vapour is shown in Fig. 5. The frequency shift response decreased with increasing temperature from 8 to 56°C, indicating that the adsorption of HCOOH by the coating decreases with the increase of temperature. The variation of the sensor response within the temperature range from 18 to 26°C was relatively smooth. For all measurements in practical application, it is recommended that the temperature be controlled at 24 ± 0.5°C.

3.4. Influence of humidity

The effect of water vapour on the TSM sensor response was investigated in detail. Fig. 6 shows

the relation between relative humidity and the frequency shift responses when the TSM acoustic sensors coated with 11.9 and 12.4 μg of B15C5 were exposed to HCOOH vapours of different concentrations. The recorded lines were parallel to each other, which possessed good linearity with a slope of 3.84 ± 0.20 Hz/% RH ($n = 5$). The influence of moisture on the detection of HCOOH vapour seemed to be easily controllable.

3.5. Reproducibility and stability

The frequency response data of the TSM sensor coated with 12 μg of B15C5 alternatively (for nine times) exposing to HCOOH vapour of two concentrations of 10.0 and 20.1 mg l^{-1} are listed in Table 2. The relative standard deviations of the sensor response were 2.94% and 2.66%, respectively, showing that the sensor possesses good reproducibility for the determination of HCOOH vapour.

When the sensor was also exposed to 30.1 mg l^{-1} HCOOH vapour continuously for 3 h and the response data was recorded every 5 min, the standard deviation of the sensor response was ± 24.61 Hz ($n = 36$), the frequency drift of the sensor was less than ± 8.21 Hz/h (24 ± 0.5°C), showing that the sensor possesses good stability.

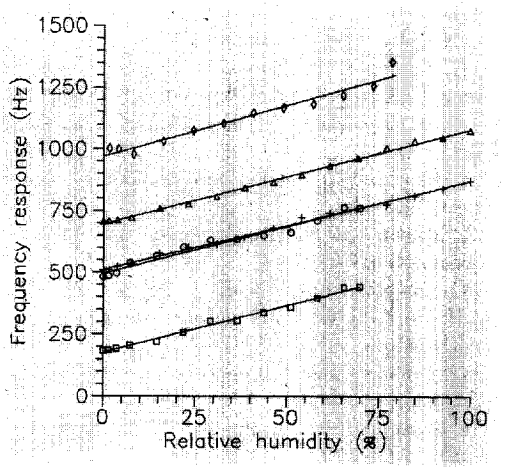

Fig. 6. Effect of relative humidity on the frequency response of the TSM acoustic sensor coated with B15C5: (i) 11.9 μg of B15C5: ○, [HCOOH] = 8.40 mg l^{-1}; △, [HCOOH] = 12.3 mg l^{-1}; and (ii) 12.4 μg of B15C5: □, [HCOOH] = 1.84 mg l^{-1}; +, [HCOOH] = 8.40 mg l^{-1}; ◇, [HCOOH] = 17.9 mg l^{-1}.

Table 2
Reproducibility of the TSM acoustic sensor coated with 12 μg of B15C5

No.	Frequency shift response (ΔF, Hz)[a]	
	10.0 mg l^{-1} HCOOH	20.1 mg l^{-1} HCOOH
1	622.66	1104.62
2	623.14	1109.23
3	613.60	1092.82
4	609.72	1104.07
5	604.94	1098.77
6	604.25	1096.70
7	573.99	1067.16
8	583.77	1109.63
9	584.47	1020.00
A.V.	602.28	1089.22
S.D.	17.70	28.97

[a] The sensor was alternatively exposed to low (left) and high (right column) HCOOH concentration samples.

3.6. Reversibility and useful lifetime

The response time of the TSM sensor coated with 12 μg of B15C5 was of the order of 2 min. When the HCOOH concentration was very low such as 0.2 mg l^{-1}, the sensor's response time was about 1 min. When the HCOOH concentration was very high such as 20.0 mg l^{-1}, the sensor's response time was about 3 min, as it took longer time for the adsorption of HCOOH vapour by the coating material to reach equilibrium. If the sensor was purged by dry nitrogen with the flow rate of 200 ml min^{-1}, it could restore to its initial coating fundamental frequency (F_1) in 2–4 min. The sensor seems to possess good reversibility. The sensitivity of the sensor decreased by 4.66% after 30 day continuous use. It decreased by 16.8% after 40 day continuous use. Therefore, the practical useful lifetime of the sensor was about 1 month.

3.7. Preliminary analytical application

The proposed sensor was applied to the determination of the HCOOH concentration in air

Table 3
Results of the determination of the formic acid concentration obtained by using the TSM sensor and by the acid–base titration method

HCOOH added (mg l^{-1})	HCOOH determined (mg l^{-1})[a]		Recovery of TSM sensor method (%)
	Acid–base titration method	TSM sensor	
1.00	1.03 ($\pm$0.03)	0.999 ($\pm$0.04)	99.9
2.00	1.97 ($\pm$0.08)	2.01 ($\pm$0.07)	100.5
3.00	3.04 ($\pm$0.09)	2.98 ($\pm$0.06)	99.3
5.00	5.08 ($\pm$0.04)	4.98 ($\pm$0.08)	99.6
10.00	9.85 ($\pm$0.06)	9.84 ($\pm$0.11)	98.4
20.00	19.58 ($\pm$0.05)	20.77 ($\pm$0.19)	103.8

[a] The data in the parenthesis are the standard deviations ($n = 4$).

with appropriate amount of HCOOH added, and the results were compared with those of acid–base titration method. Table 3 shows the results obtained by using the TSM sensor coated with 12 μg of B15C5 as well as by the acid–base titration method. The recovery of the TSM sensor method was from 98.4 to 103.8%, showing that the application of the proposed TSM sensor for monitoring HCOOH vapour in air is quite feasible. The accuracy of the sensor's method is comparable with that of the much more time-consuming chemical analysis method.

Abstract

A novel and expeditious approach for direct determination of phenols in water and waste waters based on solid-phase extraction coupled on-line to a flow injection analysis (FIA) manifold is described. The method employs on-line preconcentration of the phenols in an acidified sample (pH = 2.0) onto a 3 cm × 3 mm column packed with Amberlite XAD-4 resin. The phenols are subsequently eluted from the resin into a flowing system with an alkaline solution (pH = 13) by actuating a switching valve; the eluted analytes were then quantified spectrophotometrically as the products of reaction with 4-aminoantipyrine (4-AAP) and potassium ferricyanide on passing through the flow-cell of a detector. The proposed method has a linear calibration range 0.01–1 μg ml^{-1} of phenol, with a detection limit of 0.004 μg ml^{-1} (S/N = 3) and a sample throughput of 12 h^{-1}, investigated with a 4.4 ml sample volume. The relative standard deviation is 2.4% for 0.2 μg ml^{-1} of the analyte. The sensitivity offered by the procedure was higher by a factor of 13 than that provided by a conventional flow injection analysis method. The analytical scheme of the proposed system is much simpler than its conventional manual counterpart due to the fact that it combines trace enrichment, sample clean-up, derivation and detection in one analytical set-up. The high speed, ease of use and automation, selectivity, and relative freedom from random contamination by sample handling make this method ideal for the phenols monitoring in water and waste waters. © 1997 Elsevier Science B.V.

Keywords: Amberlite XAD resin; Flow system; Phenols; Solid-phase extraction; Waste water

1. Introduction

Phenolic compounds are a sort of common and important water pollutants [1]. They are often taken up from waste waters discharged from a variety of industrial sources, e.g., the manufacture of dyes, papers, plastics, drugs and antioxidants. Phenol and its derivatives have been found toxic to most aquatic life and mammals, and could impart objectionable tastes and odors to both drinking water and fish even at very low concentrations; the adverse effects of phenols are even more hazardous when they are become chlori-

nated. As a result, the maximum allowed levels of total phenolic compounds in a wide range of industrial wastes and natural waters are regulated by legislation in each country. The highest volatile phenols limits are normally set at a few ng ml^{-1}–sub-μg ml^{-1} range for different grades of environmental quality standards. For example, in China, maximum volatile phenols levels of 0.5 and 1 μg ml^{-1} are permitted for grade 1 and grade 2 standards of petroleum and chemical industrial effluents, respectively [2]. Hence, the development of new efficient assaying and monitoring methods for phenol and its derivatives in environmental waters to obtain reliable analytical data for regulatory and other purposes is of great interest.

A variety of analytical method for phenols determination have been established so far. Usually, chromatographic methods (HPLC [3,4] and GC [5,6], with or without derivation) are often applied for the selective determination of individual substituted phenols, but they normally involve solvent extraction for sample pre-treatment, which is complex, costly, time-consuming, and their use on-line for continuous monitoring or control is impractical. Electrochemical techniques such as cyclic voltammetry have also been used as suitable for the same purpose [7]. Spectrophotometric methods [8,9] are more conventionally and frequently employed for the determination of the sum of the compounds possessing a phenolic moiety (phenols index), among which the method based on the oxidative coupling of phenols with unblocked para-position and 4-aminoantipyrine (4-AAP) in an alkaline solution has been long-known. This method has been adopted by many countries as an approved official standard method for phenols assay [10,11]. While the method seems to be satisfactory, the procedure of which is rather complex and hazardous, and involves extensive sample clean-up processes such as stream distillation, liquid–liquid extraction, addition of masking agents etc., being time-consuming, tedious and sources of bias or accidental errors. Moreover, chloroform is used in color extraction in order to obtain desired sensitivity, which is expensive to disposal of and a major pollutant to the environment.

With the movement toward automation in phenols determination and monitoring, more and more research is being done with continuous flow systems in general and flow injection analysis (FIA) as coupled to continuous separation techniques such as distillation device and liquid phase extraction approach in particular [12–15]. These methods, however, have several limitations such as long start-up and line-out period, large on-line volume, low reproducibility etc., the sensitivity of the existing methods is not yet high enough to reliably measure phenols with concentration below a few parts per billion level in real samples; moreover, the use of chloroform is not avoided in most cases [13,14]. It is obvious that all these problems put serious constraints on the available phenols determination methods and that better analytical procedures are required.

Solid-phase extraction (SPE) appears to be a very promising alternative to the liquid–liquid extraction and related techniques, since it can be used for eliminating complex matrix and for trace enrichment [16]. The use of SPE for sample clean-up and enrichment of phenols from water for HPLC analysis, either in an on-line or off-line fashion, has achieved great success [17–21]. However, the combination of SPE and FI manifold is virtually exclusively related to the on-line enrichment of trace metal elements and species differentiations, as reviewed by Welz [22].

In a recent paper, Frenzel, et al. [23], have developed an FI method using solid sorbent (C_{18} bonded silica material) to retain the imine product of the oxidative coupling between phenols and 4-AAP, which is located in a flow-cell of on-column optical detector or in a mini-column in front of the detector. The sensitivity achieved is greatly enhanced due to the fact that all colors formed in the flow system was concentrated to a very small area of the support that was monitored in-situ by the detector or eluted to pass through the detector cell by a discrete volume of methanol. However, since the solid-phase absorbent located downstream of the reaction coil, it also retained the color formed by aromatic amines and related interfering substances. So the interference problem inherent in the standard method system was not efficiently eliminated there.

This paper describes a new FIA assembly with on-line SPE for phenols determination suitable for laboratory and field analyses. The aim of the present study is to develop a method being able to directly and accurately determine concentrations of the analyte over a range which spans the discharge consent levels, i.e., a few ng ml^{-1} to low μg ml^{-1} range. We have combined the simple chemistry of 4-AAP method with the ease of automation of flow injection analysis and the preconcentration abilities of Amberlite XAD-4 resin column. The sample is introduced by a volume-based injection fashion, and a mini-column loaded with Amberlite XAD-4 resin which is inserted into the FIA manifold is used for implementing trace enrichment and for undesired sample matrix removal, simultaneously. By introducing a relatively large sample volume, phenols are enriched onto the column from an acidified sample (pH = 2). Aromatic amines, dissociated at this pH, are not adsorbed by the resin, so they are isolated from the analytes; other inorganic substances are removed as well at this stage, rendering the procedure nearly specific toward the analyte. The elution is effected by taking advantage of the ionization properties of the phenolic compounds. By using a NaOH solution of pH 13.0, rapid and complete desorption can be achieved, so no organic solvent is required. The proposed procedure does not require complicated instrumentation and the operation is simple and fast. A critical evaluation of the optimal conditions for operation of the proposed method is present here with special emphasis on sensitivity, selectivity, responsibility to various phenol derivatives, and comparison of results provided by the proposed method and its manual standard counterpart for real sample analyses.

2. Experimental section

2.1. Apparatus

A Gilson Minipuls-2 peristaltic pump (France) was used throughout the investigation. A syringe was used for loading sample into the loop of an injection valve manually. A 756-UV/Vis spectrophotometer (Yixing, China) furnished with a Hellma 178.12 QS flow cell (18 μl inner-column, 10 mm path-length) and connected to an XWT-104 chart recorder (Shanghai, China) was used for absorbance measurements and for resulting transient FI signals recordings. One Rheodyne 5041 six-way injection valve fitted with a sample loop (volume adjustable) and another eight-port low-pressure rotary valve modified to a switching valve that fitted with two XAD-4 resin columns of the same dimensions were also used.

Teflon tubing of 0.8 mm (i.d.) was used to construct the flow manifold except sample loop was made of Tygon pumping tubes. Pumping tubes of various diameters were made of Tygon.

2.2. Reagents

All reagents used in this study were of analytical reagent grade and used as received. Water used was deionized distilled one. Carrier solution was of HCl solution at pH 2 unless notified especially. Eluent was of 0.1 M NaOH (pH = 13).

Stocking phenol solution and standard working solutions. Stocking solution containing 1000 μg ml^{-1} was obtained by initial dissolution of accurately weighed 1 g phenol (Shanghai Chemical Reagent Company) in a few ml of 1 M NaOH solution and diluting to 1000 ml with water. It was stored in a refrigerator at 4°C and was stable for at least 2 weeks. Standard working solutions of various concentrations were prepared daily by appropriate dilutions of aliquots of the stock with HCl solution at pH 2. Other phenolic compounds tested in this study were prepared similarly using commercially available products.

R_1-color reagent. 4-aminoantipyrine, 1.0 g (Shanghai Chemical Reagent Company) was dissolved in 1000 ml buffer solution.

Buffer solution (pH 8.5). A buffer solution of pH 8.5 was prepared by dissolving 10.7 g NH_4Cl and 4.0 g NaOH in 980 ml of water, the pH of which was carefully adjusted by adding a few ml of 1 M HCl or 1 M NaOH solution; the solution was made up to 1000 ml.

R_2-oxidant. 2.0 g of $K_3Fe(CN)_6$ (Shanghai Chemical Reagent Company) was dissolved in 1000 ml of water, a few drops of 1 M NaOH was added to adjust the pH to 11.0.

2.3. Column preparation

Amberlite XAD-4 resin was purchased from Fluka (Rohm and Hass) at 20–40 mesh, it was then ground and sieved to get 40–80, 80–120, and over 120 mesh, respectively, for testing. Glass tubes of 3 mm i.d. were cut into pieces of 2.5, 3.5 and 5.5 cm long. A typical procedure for the 3.0 cm long column preparation was as follows: to one end of the column a small glass wool plug was inserted, a water–ethanol (2:1) slurry of XAD-4 resin was then aspirated into the column to obtain a 3 cm long resin bed. A second portion of glass wool was plugged to another end to embed the loaded resin in order to prevent material losses. The column was connected with Teflon tubings (i.d. = 0.8 mm) and integrated into the FIA system, short pieces of suitable Tygon pumping tubes were used as connecting sleeves. The column so prepared was filled with water–methanol (2:1), any air bubbles possibly existed in the resin bed should be carefully driven out at this step. It was further washed successively with methanol, water, 0.01 M HCl, water, 0.01 M NaOH and water to remove impurities, and was made ready for FIA use. All columns thus remained serviceable for at least 4 months. The columns with 2.0, 3.0 and 5.0 cm length packed with different granularities (40–80, 80–120, over 120 mesh) of resin were made and tested in this study.

2.4. Sample pre-treatment

Water samples should be analyzed shortly after their collection (normally less than 4 h); otherwise, they should be stored at 4°C to minimise the possibility of biodegradation of the phenols. First, 100 ml of water was passed through a glass microfiber filter (Whatman) to remove any suspended particles; the clear filtrate was then adjusted to pH 2.0 using a few drops of 12 M HCl, and made ready for injection. For colored waste water sample, however, a predistillation step as described in [10] is recommended prior to analysis.

2.5. Manifold and proce dures

In Fig. 1, a schematic outline for the on-line solid-phase extraction/FIA manifold is given. The manifold consisted of two distinct blocks, namely, the preconcentration/separation unit for sample pretreatment and the flow assaying system for the phenols determination based on the 4-AAP method. The former was used to accomplish trace phenols enrichment and bulk sample matrix separation simultaneously. It was constructed from one peristaltic pump which produced the flow rates depicted in the manifold, and a Rheodyne 5401 six-port injection valve fitted with a 4.5 ml sample loop, a eight-port low pressure Teflon rotary valve accommodated two XAD-4 resin columns of the same dimensions in the two loops. The sample loading flow rate selected here was 1.8 ml min^{-1}. A flow-rate above this value is not recommended because the back-pressure from the column which is increased with the increase of flow rate may make the peristaltic pump difficulty to keep a constant value of the flow rate. Fig. 1 also shows the two positions the eight-port valve can take: one for retention and the other for elution. In the remainder of the manifold, the effluent from the preconcentration column was first confluenced with a 4-AAP (in buffer of pH 8.5) stream (denoted by R_1 in Fig. 1), then subsequently merged with an oxidant stream ($K_3Fe(CN)_6$, denoted by R_2 in Fig. 1). The high flow rate ratio of eluting stream to R_1 and R_2 (1.8:0.4:0.4) was chosen to minimise the diluting of the sample plug. The dye thus formed along reactor coil (RC) was monitored by a spectrophotometer at $\lambda = 490$ nm on passage through the flow cell. Peak height was used for the analytical measurements.

The operational scheme was as follows: in the first step, SV was set to loading position for column 1, elution position for column 2. The water sample or standard solution, containing 0.01–1.0 μg ml^{-1} of phenols at pH 2.0, was injected into the carrier stream of the flow system via injection valve (IV). The injected sample was thus driven and passed through the column 1, where adsorption of phenols took place, and the sample matrix was driven to waste on leaving the

Insert denotes the another valve position of SV. S, sample; C, carrier (HCl solution of pH 2.0); P, four channel peristaltic pump; W, waste; IV, injection valve; SV, switching valve fitted with two columns loaded with XAD-4 resin; FC, spectrophotometer fitted with a flow-cell; MC, 30 cm long mixing coil; RC, 60 cm long reacting coil; E, eluent (pH 13.0); R_1, 0.1% 4-AAP solution in buffer of pH 8.5; R_2, 0.2% $K_3Fe(CN)_6$ solution (pH 11.0).

column. Meanwhile, the eluting stream of pH 13.0 was pumped to flush column 2 continuously and merged to the phenols determination flowing system to give rise to a base-line zero-set on continuous passage through the detector cell. In the second step, SV was turned to eluting position for column 1, loading position for column 2; the eluent (0.1 M NaOH) back-flushed column 1 to desorb the phenols from resin and swept the analytes to the reaction and determination flowing system for measurement, within ca. 1.0 min, the eluted analyte is detected as a peak at the spectrophotometer and is quantified. Simultaneously, while column 2 was flushed by an acidified carrier, and the loop of IV was filled with the next sample, the loaded sample was injected into carrier and passed through column 2. After the signal of previous sample fell to the baseline, SV was switched again and the desorption of column 2 occurred, allowing the start of a new determination cycle.

3. Results and discussion

The chief advantage of the manifold used (Fig. 1) is that both trace enrichment and sample clean-up processes, as well as the determination procedures, were accomplished in the same setup. Adjustment of the sample pH to a suitable value enabling minimization of interference substances retention and maximization of retention of the analytes on the resin column is a key strategy for sensitive and selective determination of the analytes. To optimize the system, main efforts were focused on the conditions for sample loading and phenols eluting from the column, as well as the analytical flow system which was coupled on-line with the preconcentration and separation unit in order to obtain highly sensitive, accurate and reproducible results with minimal sample handling and maximal possible sample throughput.

Table 1
The analytical signals obtained at different sample pHs (phenol = 0.5 μg ml^{-1})

Sample pH	1	3	5	8	10	11	12	13
Signal (absorbance)	0.29	0.29	0.29	0.29	0.25	0.16	0.10	0.02

3.1. Preconcentration and separation system

3.1.1. Selection of the absorbent

The use of solid-phase sorbents as concentrating agents to adsorb and separate phenolic compounds from sample matrix has been well-documented. Commonly used sorbents are charcoal, alkylsilane-modified silica, macroreticular porous polymers. According to Galceran et al. [24], poly-(styrene-divinylbenene) (PS-DVB) offers better retention and selectivity for polar aromatic compounds such as phenols than C_{18} bonded silica, while Amberlite XAD resins is typical material of the former. In a previous paper [25], we have investigated the phenol collection efficiency of different types of XAD resins in terms of their breakthrough volume, and found XAD-4 resin offers the best sample capacity, the resin was then chosen in this study. In order to optimize the preconcentration and separation processes, we have studied the effects of sample pH, resin size, column length, and loading rate on the adsorption of phenols from water onto the resin.

3.1.2. Sample pH

The sample pH for the system was determined to satisfy two criteria: maximization of retention of the analytes and minimization of interferents retention on the column. Thus, the effect of varying the sample pH over the range 1–13 was studied by using a 3 cm × 3 mm column packed with 80–120 mesh XAD-4 resin, a standard solution of 0.5 μg ml^{-1} of phenol and a solution containing 1000 μg ml^{-1} of aniline was used separately at a loading flow rate of 1.8 ml min^{-1}. The results obtained are shown in Table 1. We found that the pH range for optimal phenol uptaking was at 1–10, at pH values above 10.0, the signals decreased obviously, and at pH 13.0, no retention of phenol on the column was observed, which fitted well to that reported previously [25]. While another test using 1000 μg ml^{-1} of aniline showed that the positive interference from this interferent decreased with decreasing sample pH; the effect was canceled at a sample pH below 3.0. Thus, in order to eliminate the aromatic amines and related substances, which are ionized and hence not retained on the resin at a low pH, a sample of pH 2.0 was chosen, and the same value was adopted for the carrier accordingly (washing cycle).

3.1.3. Column length and resin granularity

An optimal inside diameter of ca. 3.0 mm was adopted throughout according to Resing and Mottl [26]. Our initial experiments with a 10 cm long column packed with commercially available XAD-4 resin in the particle size range 20–40 mesh indicated there was less than 10% phenol uptake (recovery) when a 4.5 ml standard phenol solution (1.0 μg ml^{-1}) passed through the column at conditions mentioned above, possibly due to the channelling of water flow in the column and the short contact time between the resin and the sample containing phenols. This prompted us to test the ground resins as the absorbents for phenols enrichment. Thus, we constructed three columns of different lengths (2, 3 and 5 cm bed length), using 40–80, 80–120 and over 120 mesh XAD-4 resin, respectively, to assess the effect of column length and resin granularity on the retention of phenol. We evaluated the characteristics of these columns with respect to the sample capacity. The results are showed in Fig. 2. The data indicated that more sensitive with smaller granularity for phenol determination, however, due to high pressures produced during sample loading for an over 120 mesh resin column, which might influence the loading flow rate, an 80–120 mesh resin was preferred for further investigations. Fig. 2. also shows that a longer column resulted in a slightly reduced signal, indicating no break-

through occurred during sample loading. The reducing of the signal when a longer column was used compared with a shorter one (5 cm versus 3 cm) was believed to be a result of dispersion, but too short a column ($\leqslant 2$ cm) also resulted in the reduction of the signal, thus we have subsequently adopted a target column (3 cm) for all further studies.

3.1.4. Sample volume and washing time

In this study, we have selected a sample volume of 4.4 ml, a loading flow rate was set at 1.8 ml min^{-1}, thus it took ca. 2.5 min (taking into consideration the sample dispersion in the carrier and column) for complete concentrating the phenols onto the resin. With respect to the matrix removal, another 1.5 min washing period was kept in order to wash out the sample matrix and undesired co-existing interferents; adding a loop-loading time of ca. 1 min, a total period of 5 min was required before it was turned to eluting position. As mentioned above, two identical columns were equipped in the manifold allowing them to be operated in an alternative fashion, thus the time required for elution was overlapped with the loading time, resulting in an estimated sampling throughput of 12 h^{-1}.

3.1.5. Elution

According to literature [16], the adsorbed phenols could be recovered by elution with an organic solvent such as methanol, ether, acetone, ethyl acetate etc. However, in this study, we found these solvents were unsuitable for the system, since they provided abnormal signals resulting from the refractive disturbances when an interface between the continuously flowing organic solvent stream and the interstitial water volume present in the column passed through the detector cell. Thus, we tried to elute the adsorbed phenols from the resin using an aqueous solution of appropriate pH. The effect of the eluent pH was studied by varying this parameter at a range of 11–13, which were adjusted with 1 M NaOH solution. It was found that, at pH 11, the peak signal had a long tail, about 3 min was required for the signal to return to baseline, indicating the slow elution kinetics, moreover, low sensitivity was obtained; at pH 12.0, the peak was yet much wide; at pH 13.0, the peak became narrow, the signal returned to baseline within 40 s, and the sensitivity obtained was the highest. An eluent with pH 13.0 was adopted for rapid and sensitive measurement as a result. An eluent with pH higher than 13.0 was not recommended because it gave rise to a noise baseline.

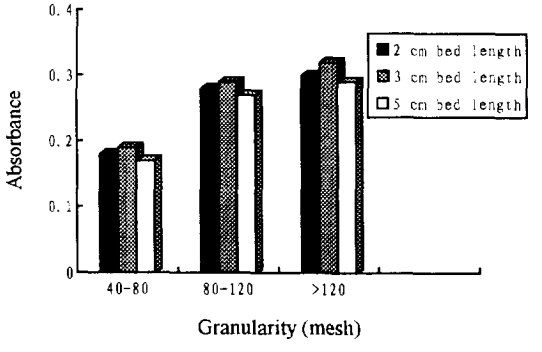

Fig. 2. Influence of the resin bed length and resin granularity on the determination of phenols. [phenol] = 0.5 μg ml^{-1}; sample volume = 4.4 ml.

3.2. Optimization of the flow analysis system

The effects of chemical and flow variables of the 4-AAP based flow system was similar to those observed in a normal FIA and independent of the sample treatment unit used. Consequently, such variables were optimized by using a three-channel flow injection manifold similar to that reported by Moller and Martin [13], except that a carrier was of an aqueous solution with pH 13.0, according to the eluting conditions as discussed above.

3.2.1. Oxidant (R_1)

$K_3Fe(CN)_6$ and $Na_2S_2O_8$ were tested in the concentration range of 0.1–2% (w/v) and 0.1–5% (w/v), respectively. When $Na_2S_2O_8$ was used as the oxidant, it provided less sensitive and reproducible results and very high concentration (saturated solution) was required for the maximal signal; while $K_3Fe(CN)_6$ was more conveniently adopted to give higher sensitivity. We found, at room temperature, MC = 30 cm, RC = 60 cm, and at a reasonably low concentration of the

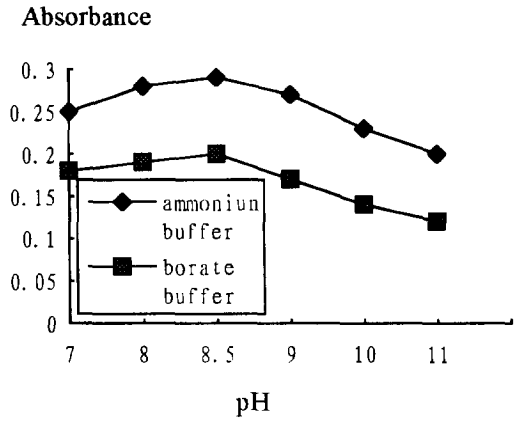

Fig. 3. Influnce of the buffer compositions and pH on the sensitivity for phenol determination. [phenol] = 0.5 μg ml^{-1}; NH_4Cl and borate: 0.2 M.

oxidant (0.2%, w/v), the reaction got complete shortly. A higher concentration resulted in no further increase of sensitivity, so a 0.2% $K_3Fe(CN)_6$ was preferred for great sensitive and reproducible results.

3.2.2. 4-AAP concentration

The effects of 4-AAP concentration was studied by varying it from 0.025 to 0.4%. It showed that the signal increased with the increment of 4-AAP concentration until 0.1%, after which, the sensitivity decreased slightly. It might be caused by the reaction between excess 4-AAP and the oxidant, leading to a high background absorbance. So a 0.1% 4-AAP concentration in buffer was set.

3.2.3. Buffer

According to literature, the optimal pH of the buffer must keep at 10.0 ± 0.2 in order to obtain reproducible results and keep interference minimum. The lower buffer pH used here (pH 8.5) is driven by the need to compensate the higher pH of the effluent containing the analyte. We have tested two kinds of buffers, $H_3BO_3 + NaHCO_3$ and NH_4Cl-$NH_3 \cdot H_2O$ at different composition concentrations. We found the optimal pH of buffer to be 8.5, but signal responses obtained by using ammonium buffer was generally higher than that when borate was used as a buffer, as shown in Fig. 3. A buffer containing 0.2 M NH_4Cl-$NH_3 \cdot H_2O$ (pH 8.5) proved to give the best reproducible results and highest sensitivity, the value was adopted as a result.

3.3. Response of phenolic derivatives

The response of the 4-AAP method to other phenolic compounds was the subject of several investigations [13,15]. The response factors of various phenol derivatives using 4-AAP in FI approach reported in literature are quite controversial. Moller and Martin reported that the relative responses of substituted phenols with respect to the phenol response were considerably lower under FIA dynamic conditions compared with the conditions of the manual assay [13]. Frenzel et al. argued that the response factors obtained under FIA conditions were almost identical with the literature values [15]. Our system differs with Frenzel only in that an on-line solid-phase extraction column was introduced in our manifold. Since the column uptake might show different kinetics for a variety of phenols, it is therefore of interest to re-exam how substituted phenols would be taken up on the column and reacted under the flowing condition compared with the available standard manual assays and normal FIA counterpart. Results of our studies are shown in Table 2, which indicates that the relative response of substituted phenols in percent with respect to the phenol on an equimolar basis by the proposed method is compared favorably with those obtained under both a standard manual method and a normal FIA method, except that the data provided by *o*-amino-phenol were generally lower for the proposed method compared with that of normal FIA without prior distillation, this was due to the presence of additional amino group in the parent compounds that were ionized at low pH (pH 2), thus was not extractable at all on the solid absorbent. Nevertheless, when a standard method including prior distillation procedure was applied, the result obtained agreed well with that provided by the proposed method.

Table 2
Comparison of response factors obtained for various phenols

Compound	Response (%)		
	Normal FIA	Proposed method	Standard method
Phenol	100	100	100
o-Chlorophenol	94	93	92
m-Chlorophenol	92	92	91
o-Cresol	88	85	85
m-Cresol	85	86	86

o-Nitrophenol	25	24	22
1-Naphthol	56	55	56
o-Aminophenol	55	<1	<1[a]

[a] With stream distillation.

3.4. Study of interferences

Some major inorganic and organic species usually present in water and waste water were studied as potential interferents with the phenol determination in order to testify the interference eliminating capability of the on-line solid phase extraction manifold. The limits were taken as the largest amount of foreign species yielding a relative error (with respect to pure standard phenol of 0.5 μg ml^{-1}) less than ± 5% in the peak height. Table 3 shows the tolerated limits for interferents accompanying phenol of 0.5 μg ml^{-1} using the proposed method and normal FIA. It allows us to conclude that almost none of the ions and common species tested at their usual concentrations in natural or treated waste waters interfered with the detection. While at least five kinds of species, i.e., aromatic amines, sulfide, sulfite, hypochlorite, and nitrite, were reported to be potential interferents in the standard method, which are normally eliminated by prior distillation at an acidified condition.

The lack of interferences exhibited in the proposed method is due to the adoption of a preconcentration and separation column as described above. When sample is adjusted to pH 2.0, interferents such as aromatic amines, if present in a given sample, may be dissociated and hence not retained onto the XAD column; other inorganic substances like sulfide, sulfite etc., are impossible to be retained on a non-ionic copolymer, XAD resin, they are feasibly removed during loading and washing cycles, and thus do not interfere at reasonably high concentrations. An exception was that when a colored sample is to be analysed, a predistillation step is yet required due to the color of bulk sample matrix would be irreversibly retained on the column and then interfere with the separation and detection.

Table 3
Study of interferences with the determination of 0.5 μg ml^{-1} of phenol by proposed method and normal FIA

Interferent	Normal FIA (ppm)	Proposed method (ppm)	Interferent	Normal FIA method (ppm)	Proposed method (ppm)
Aniline	<5	>500	PO_4^{3-}	20	>2000
3-nitro-aniline	<100	>2000	CO_3^{2-}	20	>2000
2,5-dichloroaniline	<10	>1000	NO_3^-	20	>2000
4-chloroaniline	<100	>2000	ClO^-	<1	50
3-amino phenylformic acid	<10	>1000	Zn^{2+}	<1	>1000
2-aminophenylamine	<1	>100	S^{2-}	<1	40
3-aminophenylamine (above added as R-NH_3^+ Cl^-)	1	>100	SO_3^{2-}	<1	40
Ca^{2+}	15	>2000	Fe^{3+}	10	>2000
Mg^{2+}	15	>2000	Fe^{2+}	10	>2000
Cu^{2+}	<1	>1000	NO_2^-	5	500
NH_4^+	20	>2000			

3.5. Calibration curves, detection limit and repeatability

When a sample volume of 4.4 ml was adopted, a calibration curve obtained could be expressed by a linear regression equation: $A = 0.547\ C\ (\mu g\ ml^{-1}) + 0.026$ ($n = 8$, $r = 0.993$, S.E. $= 7.35 \times 10^{-3}$), where A is the measured signal in absorbance; C the concentration of the analyte; n the number of standard samples tested; r the regression coefficient; and S.E. the standard error. The peak height obtained was proportional to phenol concentration from 0.01 to 1 $\mu g\ ml^{-1}$; the precision or repeatability, expressed as relative standard deviation (r.s.d.), was 2.4% ($n = 11$) for 0.2 $\mu g\ ml^{-1}$ of phenol standard solution. The detection limit was estimated to be 0.004 $\mu g\ ml^{-1}$ (S/N = 3). For comparison, we also constructed a normal FIA manifold which was similar to that reported by Moller and Martin [13] for phenol determination. A sample injection volume of 300 μl was set. We obtained a linear regression equation: $A = 0.0418\ C\ (\mu g\ ml^{-1}) + 0.012$ ($n = 8$, $r = 0.9997$, S.E. $= 8.16 \times 10^{-4}$); the calibration linear range was 0.05–15 $\mu g\ ml^{-1}$ of phenol; a detection limit of 0.02 $\mu g\ ml^{-1}$ and a r.s.d. of 2% were obtained. Thus, it could be concluded that a 13-fold increase of sensitivity compared with the normal FIA is achieved for the proposed method in which an on-line preconcentration and separation step was included, while repeatability is comparable with that of normal FIA.

3.6. Analysis of water and waste water samples

The ultimate test of the proposed method was to apply it to the analysis of real samples, so ten different local environmental water samples (including six industrial waste waters, three river waters, and one tap water) were tested in three different ways, i.e., the proposed method, normal FIA method, and approved standard manual method [10]. The correlation of phenols results obtained with the normal FIA and the approved standard method, as shown in Fig. 4a, yield $r = 0.940$, with an intercept of 0.19 ± 0.03 and a slope of 1.88 ± 0.10, indicated the results provided by the normal FIA method were generally higher,

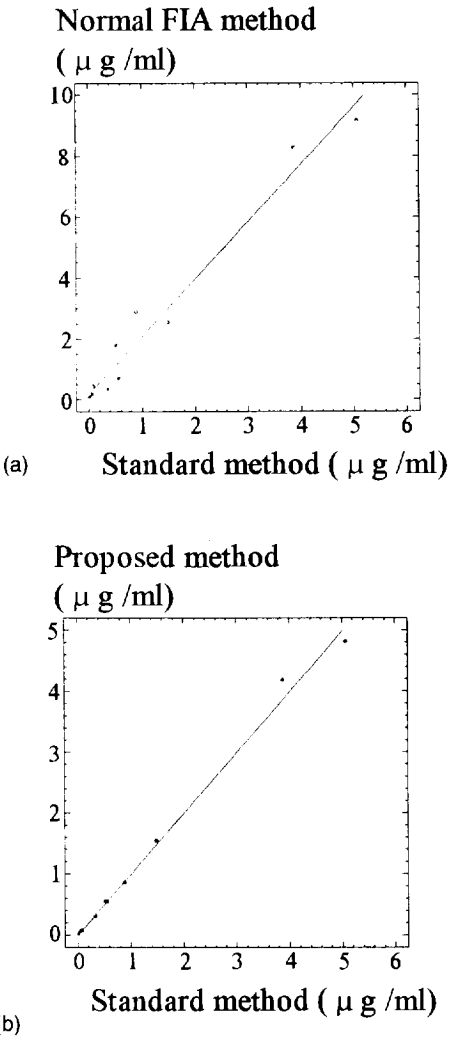

Fig. 4. Comparison of the phenols values measured by normal FIA method (4a), proposed method (4b) and a standard method for real samples.

thus suggesting the presence of systematic errors [27]. This is believed to be the results of interferences existing in the sample matrices contributing to the phenol index. While the correlation of phenols analyses by the proposed method and the approved official standard manual method, as shown in Fig. 4b can be described by a linear regression equation with a slope of 0.994 ± 0.027, an intercept of 0.0012 ± 0.0563, and a regression coefficient $r = 0.997$, which testifies the consis-

tency between two methods. Thus, it allows us to conclude that the proposed method could be reliably applied to the real sample analyses and provide the results in good agreement with those provided by the approved official standard method.

4. Conclusion

Flow injection with on-line solid-phase extraction approach resulted in significantly enhanced sensitivity and selectivity for the phenol index determination. It could provide the results in less than 5 min from sample introduction, which was ideally suitable for large-scale screening and on-site routine monitoring the trace pollutants in water and waste water samples. Detection limit achieved is similar to or better than that of the available standard method, even with liquid extraction. The method allows one to directly enrich and quantify phenols in a variety of waters in the presence of relatively high concentrations of interferents. It could eliminate pretreatment procedures such as distillation or extraction, which is required by other conventional methods due to the integration of the trace enrichment and sample clean-up into a single analytical scheme in an on-line fashion. The use of large quantities of expensive and environmentally harmful organic solvents is also avoided. We have found that the sensitivity for phenols essay was benefited from the using of a smaller particle size of the resin, but was worth nothing to use a longer preconcentration column. We also found that the major phenol derivatives have the response factors agreed well with those of available standard method.

Immobilization of uricase to gas diffusion carbon felt by electropolymerization of aniline and its application as an enzyme reactor for uric acid sensor

Shunichi Uchiyama *, Harukuni Sakamoto

Department of Environmental Engineering, Saitama Institute of Technology, 1690 Fusaiji, Okabe, Saitama 369-02, Japan

Received 28 August 1996; received in revised form 31 December 1996; accepted 3 January 1997

Abstract

Electropolymerizations of aniline and pyrrole solutions containing uricase at a neutral pH was performed to immobilize the enzyme on the surface of the gas diffusion carbon felt, and a selective uric acid sensor was fabricated by combining immobilized enzyme carbon felt and an oxygen electrode with oxygen gas permeable membrane. This carbon felt has a desirable feature for uricase sensing because an extremely efficient supply of oxygen for the enzymatic reaction can be realized due to its porosity permitting a transfer of oxygen. The current response time required from when sample is added until when current reaches the steady-state value is < 5 min. The calibration graph of uric acid showed a linear line in a concentration range from 1×10^{-5} to 4×10^{-4} M with a detection limit of 4×10^{-6} M. © 1997 Elsevier Science B.V.

Keywords: Aniline; Pyrrole; Uricase; Carbon felt

1. Introduction

Recently, an electropolymerization technique has been used to prepare the enzyme electrode [1–5]. In general, it is well known that an electropolymerization film is produced on the surface of electrode material such as glassy carbon, carbon paste or noble metals (Pt, Au) by electrooxidation of monomers such as pyrrole or aniline. Most of these electrodes can detect the reduced form of the enzyme, the electroactive enzymatic reaction product such as hydrogen peroxide or the consumed oxygen accompanied by an oxidase reaction. However, amperometric uric acid sensor with uricase membrane prepared by immobilization of enzyme during electropolymerization has not been reported, mainly because conducting polymer is not produced at a neutral pH and the electropolymerization electrode loses its electric conductivity. Furthermore, highly sensitive and selective detections of these species would be difficult because the side reactions of interferences might be occurring by amperometry at these electrode surface. Recently, poly(*o*-aminophenol)-modified carbon paste electrode for uric acid has

* Corresponding author. Tel.: +81 485 856839; fax: +81 485 856004.

PII S0039-9140(97)00023-4

been reported [6], but enzyme is not immobilized during an electropolymerization, because 0.1 M acetic acid (denature of enzyme may take place at pH 5) is used as an electrolyte.

A porous carbon felt used in this research consists of fine carbon fibers (diameter 10–20 mm) and has an excellent property for oxygen permeability because of its porosity. Recently, it has been demonstrated that amperometric response of glucose sensor using the gas diffusion carbon cloth electrode is much higher than that using gas impermeable electrode such as glassy carbon. The amplification of the current response is based on its extremely efficient supply of oxygen for the enzymatic reaction [7].

In this work, a carbon felt was chosen as a gas diffusion electrode material for electropolymerizations of aniline and pyrrole. Novel biosensing devices consisting of this porous enzyme reactor and a polarographic type oxygen electrode are fabricated to improve the selectivity and sensitivity. A carbon felt electrode has been employed as effective electrode material for controlled potential coulometry [8] and amperometry [9] by us, but the electrooxidation of hydrogen peroxide at this electrode material is highly irreversible [10], then the detection of oxygen is reasonable way for this type of biosensor.

2. Experimental

As an electrolyte for electropolymerization, 3 ml of 0.1 M KCl solution (pH 7) containing 0.1 M aniline or pyrrole and 2 mg of uricase (EC 1.7.3.3, Sigma, 4.53 U mg^{-1}, optimum pH 9.0) are used. A round porous carbon felt (Nippon carbon Ltd., GF-20-3F, baked at 2000°C, 0.5–2 mm thickness, 10 mm diameter) with platinum (0.5 mm diameter) wire lead and a gold wire (0.5 mm diameter) were used as working and counter electrodes, respectively, and a saturated calomel electrode was used as reference electrode. The electrode potential of the carbon felt was maintained at a constant potential (+ 0.7 V vs. SCE) by a potentiostat (Nikko Keisoku NPOT-1) and polymerization was performed by electrolyzing for 5 min. The electropolymerization carbon felt was washed with a distilled water and then fixed on the oxygen gas permeable membrane of an oxygen electrode by an electrode cap and this electrode was employed as an uric acid sensor. The electrode potential of the gold working electrode of Clark oxygen electrode (Denki Kagaku Keiki, Ltd.) was maintained at + 0.7 V vs. Ag/AgCl electrode. The solution in which the uric acid sensor is tested (0.1 M phosphate buffer solutions) was stirred with a magnetic stirrer. The chemicals used in this experiment were reagent grade. The carbon felt consists of the carbon fibers that possess a hydrophilic property and it has been estimated as an effective electrode material for rapid electrolysis [11].

3. Results and discussion

The sensing principle of uric acid electrode is schematically shown in Fig. 1. The oxygen consumed, accompanied by the enzymatic reaction occurred at the surface of the carbon fiber, is detected at a gold electrode of an oxygen electrode. Electropolymerization polyaniline prepared at a neutral pH is known to be an electroinactive polymer [12] in contrast to polypyrrole. In fact, the oxidation current of aniline decreases with electrolysis time because of the coating of this electroinactive polymer on the electrode surface

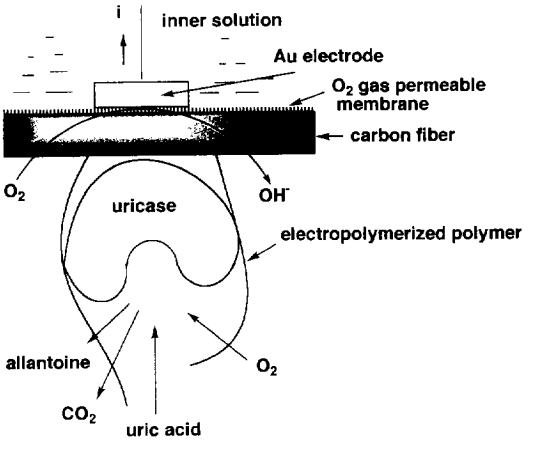

Fig. 1. Schematic sensing principle of uric acid by the present sensor.

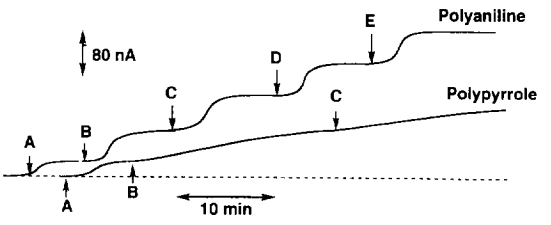

Fig. 2. Typical current responses of uric acid obtained by enzyme electrodes using carbon felts coated with polyaniline and polypyrrole. Addition of uric acid concentration, A: 0.01 mM, B–E: 0.02 mM.

and the oxidation current was decreased during electropolymerization from the initial current (several hundreds mA) to several mA after 20 min (total charges are about 0.1 coulomb) has passed. Therefore, this electropolymerization carbon felt is not adequate for an amperometric sensing device.

The typical current responses of uric acid obtained by the polyaniline and polypyrrole electrodes are shown in Fig. 2. These results show that uric acid gives the significant current responses in the case of polyaniline and it was found that uricase could be immobilized on the surface of the carbon fiber by electropolymerization of aniline. In the case of polypyrrole, the current responses of uric acid are also apparently observed, however, the rate of the current response is very slow and rapid sensing of uric acid has not been realized. This fact indicates that uricase can be immobilized to the surface of the carbon felt by an electropolymerization of pyrrole, as same as that of aniline, however, the current response time becomes very large, mainly because the transfer rate of uric acid to the active site of the immobilized enzyme is slow, probably due to a steric effect of polypyrrole coated on the surface. The current response of uric acid reaches the steady-state values after each addition of 2×10^{-5} M uric acid within 3 min when the thickness of the carbon felt is 0.5 mm. In contrast, no oxygen decrease was observed when uricase is not immobilized into the polyaniline or polypyrrole membrane, and it was confirmed that the present electrodes work as biosensor for uric acid. Uricase is well known to be the enzyme with an excellent specificity to uric acid, and no current responses of other species such as glucose or L-ascorbic acid were observed.

The current response of uric acid decreases linearly as decrease in oxygen concentration in the sample solution, then, the oxygen supply by the addition of buffer solution to the sample solution is needed to obtaine accurate analytical results for biological fluids such as urine.

From the results above, it can be recognized that an effective uric acid sensor can be fabricated by combining electropolymerization carbon felt and a Clark type oxygen electrode using aniline monomer. The uric acid electrode prepared using aniline polymerization retained its enzyme activity for 5 days and the activity was decreased at half value after 7 days. The calibration graph of uric acid exhibited an excellent linear concentration range from 1×10^{-5} to 4×10^{-4} M with a sensitivity of 2.5 μA mM^{-1}. The relative standard deviations of the steady state current responses are decreased according to increase in uric acid concentration, and the relative standard deviation ($n = 5$) of 1×10^{-4} M uric acid was found to be 3%.

The current response of uric acid is increased according to increase of the electrode potential of electroporimerization, but the side reactions such as oxygen gas evolution are increased and the electropolymerization was then carried out at + 0.7 V vs. SCE throughout the experiment.

It can be considered that the response time of the present electrode is highly dependent on the thickness of the carbon felt membrane, and the

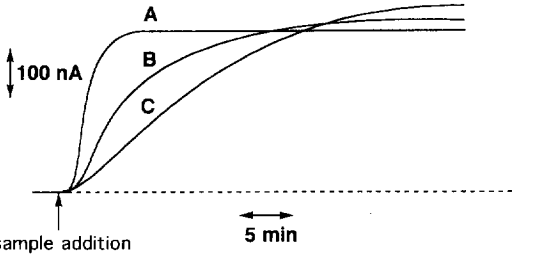

Fig. 3. Effect of the thickness of the carbon felt in the present sensor on the current response of 1×10^{-4} M uric acid.

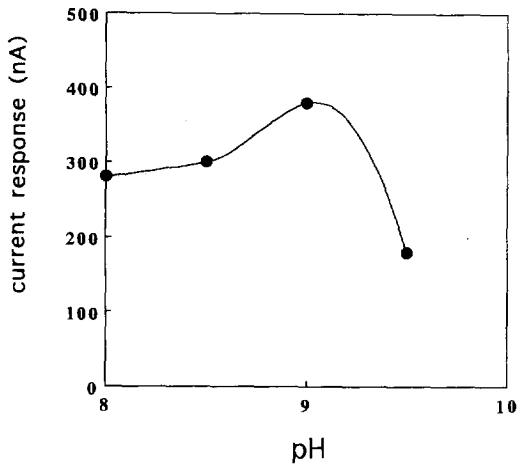

Fig. 4. Effect of pH on the 1×10^{-4} M uric acid response obtained by the present sensor. Thickness of the carbon felt: 0.5 mm.

effect of the thickness of the carbon felt on the current response is shown in Fig. 3. These results indicate that the rate of the current response of uric acid becomes larger as decrease of the thickness of the carbon felt, mainly because the mass transfer rates of oxygen and uric acid become faster. The time required from the sample addition to reach the steady state current response value of 1×10^{-4} M uric acid is found to be 5 min when 0.5 mm carbon felt was employed. Therefore, it has been estimated that the reasonable rapid responses can be obtained by the present sensor.

The effect of pH on the uric acid response is shown in Fig. 4, the maximum current response was obtained at pH 9.0 and this fact indicates that the structure change of enzyme due to an immobilization would not be occurring because the optimum pH of free uricase activity (pH 9.1) is about the same value. The current response characteristics of the present sensor are compatible with those of conventional uric acid electrodes with uricase membrane fabricated by the other methods [13,14].

The electropolymerization method has been found to be very powerful technique for enzyme immobilization during electropolymerization, but many electropolymerization polymers prepared at a neutral pH range are electroinactive and electrode becomes an insulator, although the electropolymerization polymers produced at acidic media (< pH 1), in which many redox enzymes unfortunately lose their activities, are electroactive. It is therefore desirable although not always essential, to use neutral aqueous solutions in the electropolymerization process [15]. In this work, the electropolymerization carbon felt was then used as a gas diffusion enzyme reactor and not an electrode of uric acid sensor, and oxygen electrode was used as an detector to avoid this problem.

From the results and discussion, it was found that the electropolymerization technique for immobilization of enzyme can be successfully applied to the biosensor based on gas sensing electrode with gas permeable membrane, using an enzyme reactor of porous carbon material. The combination of other gas sensing electrode such as ammonia or carbon dioxide electrode with the electropolymerization carbon felt would be expected to be an effective technique for fabricating various type of biosensors.

Reproducibility of the nonlinear regression fit to the FTIR spectra of lysozyme[1]

Thomas F. Kumosinski *, Joseph J. Unruh, Harold F. Farrell Jr.

U.S. Department of Agriculture, ARS, Eastern Regional Research Center, 600 East Mermaid Lane, Wyndmoor, PA 19038, USA

Received 25 September 1996; received in revised form 22 January 1997

Abstract

Controversy exists concerning the influence of experimental artifacts on the number of component FTIR vibrational bands which may be resolved from the amide I and II envelopes of proteins in water. Whether these bands represent unique populations of vibrating protein groups in a particular global 2° structure or whether the bands are due to instrumental and environmental fluctuations has been addressed, T.F. Kumosinski and J.J. Unruh, Talanta, 43 (1996) 199–219. The repeatability of the methodology and the apparent uniqueness of the nonlinear regression fits are addressed in this study. We obtained a series of the spectra of lysozyme, and carried-out nonlinear regression analysis of each spectrum. Coefficients of variation (COV) were calculated for the wavenumber and area values of assigned component peaks obtained. Low COVs obtained attest to the precision of the methodology and the apparent uniqueness of the nonlinear regression fits. This methodology for acquisition and analysis of protein FTIR spectra yields results with good precision. © 1997 Elsevier Science B.V.

1. Introduction

FTIR analysis of proteins and peptides as a method for estimation of their global secondary structure has become a valuable tool for protein biochemists [1,2]. While this methodology is used more frequently, controversy exists in the areas of how to carry out the experiments and analyze the results. Whether to obtain the spectra in the real-world environment of H_2O with a difficult subtraction routine, or in the potentially structure changing environment of D_2O [2,3] with an easier subtraction routine is still debated. The best method for analysis of the results is also in debate. Many methods and combinations for analysis are available to choose from; these include: nonlinear regression analysis; second derivative analysis; Fourier self-deconvolution; and basis-set factor analysis. The pros and cons of the above considerations have been discussed elsewhere [4,5].

Recently we reported an FTIR methodology with which we obtained the spectra of 14 proteins in H_2O, analyzed the data using the second derivative and nonlinear regression methods, and compared the results with the known X-ray crystallographic data [1]. Differences of 2–4% for the periodic structures of helix, extended, irregular and turn were observed between the FTIR and X-ray results. Thus the accuracy of the method is firmly founded. An additional consideration would be the reproducibility (overall precision) of the spectral acquisition and the uniqueness of the nonlinear regression analysis. Here we present a validation study showing the reproducibility and uniqueness of the results using our reported methodology [1] with the well characterized protein lysozyme.

2. Experimental

2.1. Materials and solutions

Water was Type I grade obtained from the NANOPURE system (Barnstead, Dubuque, IA). Lysozyme (chicken egg white) and PIPES (potassium salt) were from Sigma (St. Louis, MO). Any other chemicals were of reagent grade or better. The CaF_2 windows and 6 μm Mylar® spacer were from SPECAC (Smyrna, GA). The buffer solution was 25 mM PIPES (potassium salt) with pH adjusted to 6.65 using concentrated HCl. After pH adjustment the buffer was filtered through a 0.22 μm Nylon filter (Sigma), and stored at 5°C. Two Lysozyme solutions were made—one at 3% (w/w) and one at 1.5% (w/w)—in the PIPES buffer, then filtered through 0.22 μm DVDF filters (Sigma) and stored at 5°C. The concentration of the lysozyme solutions were verified by UV spectrometry (ϵ_{280} = 36000) [6] on a Beckman DU-7 (Fullerton, CA) instrument.

2.2. Infrared measurements

The procedures and equipment were as previously reported—collecting 4096 double-sided interferograms (each with 16384 data points), which were co-added, phase-corrected, apodized (Happ-Genzel function), and fast-Fourier transformed [1]. The following minor exceptions to the methodology were made: a 6 μm Mylar® spacer was used in place of the 12 μm Teflon spacer; the sample cell's temperature was controlled at 25°C using SPECAC's electrical heating jacket (part # 20707, SPECAC); and the lysozyme solution was 3% (w/w) in 25 mM PIPES·K, pH = 6.65 in place of 4% in an imidazole buffer. To test repeatability, a spectrum was acquired each day for 5 days with the sample cell being disassembled and cleaned daily.

2.3. Data analysis

The buffer subtraction procedure used to obtain the protein spectra has been reported elsewhere [1]. Briefly, after obtaining the absorbance spectra for the protein and buffer solutions the protein spectra (amide I and II region) were obtained by subtracting the buffer spectra from the respective protein solution spectra in the 2000–1350 cm^{-1} region. Subtractions were performed interactively using the subtraction function in the Sx software of the Nicolet 660 data system. The scaling factor (FCR) was individualized during each subtraction by adjusting the FCR parameter value until the region from 2000 to 1700 cm^{-1} was as flat as possible. Next, the water vapor absorption was subtracted from the protein spectra using the 2nd derivative method [7].

The data analysis procedure of our previously reported methodology was changed slightly [1]. Here, the Fourier-self deconvolution spectra were not calculated because the choice of values for the parameters is controversial and the results thus questionable. We found more acceptable analyses could be obtained using only the second derivatives and the nonlinear regression fits of the original spectra. As previously reported, the starting wavenumbers for the ABACUS [8][2] curve fitting program were chosen from the second derivative

[2] Version F.1 is available on the internet from QCPE (their program number 652) or directly from ERRC. Persons desiring the program may use FTP, connect to 'ceres.arserrc.gov', and use the account 'anonymous' which requires no password. They would then select directory 'abacusf' and download all files. Installation instructions and user documentation are also provided.

of the original spectrum. To increase the probability that the resulting fit was not a local minimum and the unique fit to the data, the original spectrum was fit twice, once starting from below the experimental values (where $Y_{exp} - Y_{theoretical}$ is positive) and once starting from above the experimental values (where $Y_{exp} - Y_{theoretical}$ is negative). Convergence to the same model from both starting positions was one criterion for an acceptable fit. The starting peak heights for the 'below fit' were chosen so that the composite sum was at least 25% below the original spectra absorbance plot, and the starting peak heights for the 'above fit' were similarly chosen to be 25% above the original spectra absorbance plot. The starting half-width at half-height was three for all peaks. While just the peak heights were adjusted to obtain two different starting points, it should be emphasized that all peak parameters (height, half-width at half-height, and wavenumber) as well as the baseline were permitted to float during the nonlinear regression analysis. A more detailed discussion of the nonlinear regression analysis can be found in our previous report [1].

Three criteria were required to be met before the results of the curve-fitting were considered acceptable. First, the lowest RMS (root-mean-square) value obtainable had to be reached. Acceptable RMS values were usually of magnitude 10^{-5} for spectra with maximum absorbance values in the 0.05–0.09 range. Second, the below and above fits should converge to the same model. Third, the second derivative of the composite sums should overlie the second derivative of the original spectra. Only when all three of the above criteria were met was the curve-fitting result considered acceptable.

χ^2 instead of the RMS could also be evaluated as a means to determine the best nonlinear fit, since it includes the effects of adding more parameters to the model. For our ABACUS program, χ^2 and the RMS are equivalent when the model has a fixed number of peaks as it does in our case for any individual fit of a model to the data. In the case where more or less peaks may be needed in the model, we use an F-test to statistically evaluate the change in the number of parameters (i.e., the number of peaks). This part of the methodology is discussed in more detail in our previous report [1].

3. Results and discussion

3.1. Spectral acquisition

Fig. 1 shows the spectra (amide I and II region) obtained on each of 5 different days for lysozyme. In all but one case the spectra are nearly identical. The one exception sample was prepared at half the concentration. This spectrum was included in the curve-fitting analysis to consider variance with concentration. With the exception of the 1.5% lysozyme spectra the upper four spectra nearly overlie each other, except in the 1500–1400 cm^{-1} region. We can not explain this but have not noticed differences in this region to effect the nonlinear regression analysis of the 1700–1500 cm^{-1} region. We have noticed though that small changes in the FCR during buffer subtraction have a greater effect in this region than the 1700–1500 cm^{-1} region.

During the 5 days of the study, the ambient temperature of the analysis room changed slightly (68–72°F) and the humidity changed greatly (27–56% relative humidity). As can be observed these environmental changes had little effect on the obtained spectra, and the presence of an H_2O vapor spectra are not observed in the final protein

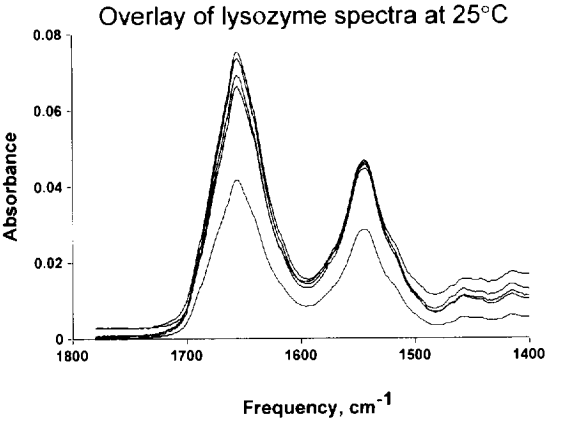

Fig. 1. Overlay plot of lysozyme spectra obtained as described in text.

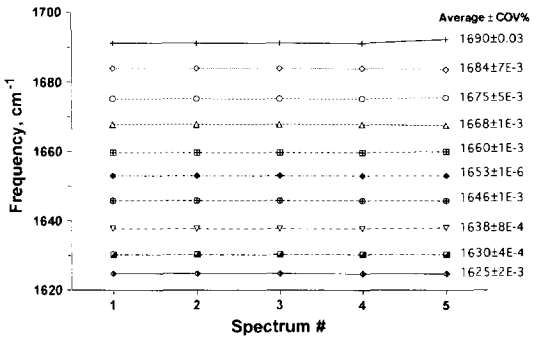

Fig. 2. Graph of the wavenumbers obtained from the nonlinear regression analysis of the spectra in Fig. 1 versus the day of acquisition.

spectra obtained. Daily cleaning and reassembly of the cell showed a variation in the pathlength to be approximately 1.5% Coefficient of variation (COV).

3.2. *Curve-fitting—nonlinear regression analysis*

Two points of evaluation were considered to determine if the curve-fitting procedure leads to repetitive results. First, if the resultant wavenumbers for the component peaks from the fit turned out to be the same for each of the five spectra; and second, if the resultant areas for the component peaks turned out to be the same for each of the five spectra.

Fig. 2 demonstrates the first case. There the wavenumbers found for the amide I of the spectra from each of the 5 days are plotted versus the day number. Nearly flat horizontal lines are obtained. This shows the repeatability of the curve-fitting procedure to obtain the same wavenumbers for different spectra of the same sample. Beside each plotted line is listed the average wavenumber ± COV%. The COV for the wavenumbers varies from 0.000002 to 0.03%—indicating very precise results for the wavenumbers. Repeatable wavenumbers show that defining the structural elements in the model for the secondary structure is precise for lysozyme, and will probably be precise for most other proteins analyzed. A more stringent test for repeatability of analysis will be found by comparing the areas for each wavenumber's component peaks.

Table 1 lists the areas of the component peaks obtained for each day's analysis. The standard deviations are good, an average COV of 7.86% (range 1.78–26.71%) is obtained for days 1–5. This shows acceptable repeatability. The greatest variation occurs in the day 5 results, where all the data for this day approach being considered outliers. Day 5 is the sample prepared at 1.5%, to test the effect of concentration on the results. If the results of day 5 are not included, the averages obtained only change slightly (last column in Table 1), while the average COV changes to 2.39% (range 1.36–4.97%). Eliminating the day 5 results greatly improves the precision of the methodology. Our first report [1] concerned itself with the accuracy of this methodology when comparing the results to X-ray crystallographic data. In that report we only analyzed 3–4% protein solutions. Therefore, until more data at lower concentrations is accumulated for a number of proteins, we suggest that a minimum absorbance value of 0.06 should be obtained for the amide I in order to ensure good repeatability of the nonlinear regression fit and ultimately the secondary structural model obtained for the protein.

4. Conclusions

FTIR analysis of lysozyme for its global secondary structural model in water (H_2O) using nonlinear regression to obtain the component wavenumbers and areas is a precise methodology. The only caution to be observed for the methodology is the absorbance value obtained for the amide I envelope. We found the absorbance of the amide I should be at least 0.06 in order to obtain precise results using the current instrumentation we have (the Nicolet model 740 spectrophotometer). Newer generation spectrophotometers (for example the Nicolet 860) have better signal-to-noise ratios, and would probably be capable of precisely analyzing protein spectra with the amide I absorbance at values less than 0.06.

Our previous work showed the methodology used in this report to be accurate for the 14 proteins studied [1] when compared with the X-ray crystallographic results. Combined with the

Table 1
Percent area values found

precision analysis reported here, the methodology presented to analyze for the global secondary structure of proteins in H_2O is both accurate and precise. We recommend that researchers carrying out secondary structural analysis of proteins using FTIR of the protein in H_2O perform a validation analysis as reported here on a model protein (like lysozyme) before attempting to analyze proteins of unknown structure.

Preparation and analytical properties of a chelating resin functionalized with 1-hydrazinophthalazine ligand

Rita Pathak, G.N. Rao *

Department of Chemistry, IIT Delhi, Hauz Khas, New Delhi-110016, India

Received 19 November 1996; received in revised form 13 January 1997; accepted 20 January 1997

Abstract

A poly[styrene-co-(divinylbenzene)] resin (XAD-4) functionalized with 1-hydrazinophthalazine ligand has been prepared and its analytical properties investigated. The pH dependence of sorption of metal ion on the resin has been determined for Cu(II), Ni(II), Co(II), Zn(II), Cd(II), Pb(II), Fe(III) and Cr(III). Trace amounts of these metal ions were quantitatively retained on the resin and recovered by eluting with 1 mol l^{-1} hydrochloric acid. The resin was found to be selective for Fe(III) and its separation from other metal ions was carried out effectively. Metal ions concentrations were determined using AAS. © 1997 Elsevier Science B.V.

Keywords: Atomic absorption spectrometry; Chelating resin; 1-hydrazinophthalazine; Iron(III); Metal sorption

1. Introduction

Chelating resins have found increasing utility for separation and concentration of metal ions at trace levels, because of their selectivity. A number of chelating resins containing various functional groups (e.g., ethylenediamine tetraacetic acid [1], iminodiacetic acid [2–4] etc.) have been reported. Vernon and Eccles used chelating resin formed with *N*-substituted hydroxylamine [5]. We have reported chelating resin containing bicine [6] functional group.

Polyamines like ethylenediamine, diethylenetriamine, etc., form an important class of chelating ligands. Several authors have studied the modification of synthetic resins with linear polyamine ligands [7–10]. More recently Blain et al. have applied a chelating resin, chelamine, for preconcentration of trace metals from sea water with high selectivity [11].

Synthesis of chelating resins having good selectivity is a subject of continuing interest and importance. 1-Hydrazinophthalazine, a hydrazino type ligand capable of chelating interactions utilizing the α-nitrogen of the hydrazine residue and the nitrogen doners of phthalazine substituent. Thus, it presents a favourable environment for coordination with the metal ion. 1-Hydrazinophthalazine has been reported to form stable complexes with Fe(III), Cu(II) and Zn(II), while it has negligible affinity for Ca(II), Mg(II) and Mn(II) [12]. Ruggieri et al. have used 1-hydrazinophthalazine as a sensitive reagent for the determination

* Corresponding author. Fax: +91 11 6862037.

PII S0039-9140(97)00026-X

of Fe(III) [13]. Takaoka et al. have reported a similar reagent, di-2-pyridylmethanone 2-(5-nitro)pyridyl hydrazone for sensitive and selective spectrophotometric determination of trace iron [14]. Hence it was considered interesting to incorporate this ligand on to a polymeric support and study its analytical potential. In the present work, the macroporous resin poly styrene-co-divinylbenzene (XAD-4) has been functionalized using 1-hydrazinophthalazine ligand. The resin have been characterized and sorption behaviour of different metal ions on the resin has been studied.

2. Experimental

2.1. Instrumentation

An ECIL (Hyderabad, India) AA 4139 microprocessor controlled atomic absorption spectrometer was utilized for determining metal concentration; an ELICO (Hyderabad, India) digital pH meter (LI-120) was used for pH measurements. A mechanical shaker with incubator (Scientific, New Delhi, India), 200 strokes min^{-1} was used for carrying out equilibrium studies. Infrared (IR) spectra were recorded on a Nicolet-5DX Fourier transform IR spectrophotometer (Madison, USA), in potassium bromide pellets.

2.2. Reagents

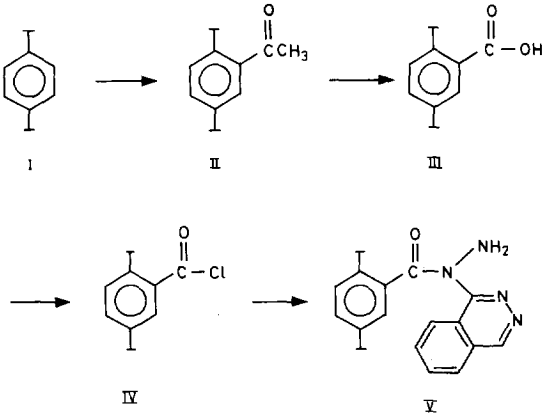
The stock metal ion solutions were prepared by dissolving analytical reagent grade metal nitrates, chlorides or sulfates in double distilled water or the matrix acid. All the metal ion solutions were standardized using standard methods [15]. Poly (styrene-co-(divinyl benzene)] resin (Amberlite XAD-4) was obtained from Fluka (Buchs, Switzerland) and 1-hydrazinophthalazine from Sigma (U.S.A.). The following buffers were used to control the pH of the solution: hydrochloric acid-glycine (pH 1–3), acetic acid-sodium acetate (pH 3–5); disodium hydrogen phosphate-potassium dihydrogenphosphate (pH 5–8); and sodium borate-hydrochloric acid (pH 8–9).

2.3. Synthesis of XAD_4-1-hydrazinophthalazine

Styrene divinyl benzene copolymer (XAD-4) was functionalized by a slight modification of the method reported by Fritz et al. [1], (Scheme 1). XAD-4 beads (10 g) were first acylated by refluxing with acetic anhydride (20 ml) and anhydrous aluminium trichloride (1 g) in petroleum ether (60–80°C) at 70°C for 30 h. The product was filtered off and washed with 50 ml of hexane. The intermediate product (II) was stirred in 500 ml of water containing 8.5 g of potassium permanganate and 10 g of sodium hydroxide at 40°C for 1 h. The product was filtered off, washed with water and then treated with (1 + 1) hydrochloric acid. The subsequent carboxylic form (III) was refluxed with 50 ml of thionyl chloride at 60°C for 0.5 h. The intermediate resin (IV) was refluxed with 1-hydrazinophthalazine (1.5 g) and sodium ethoxide (0.2 g) in dry dimethylformamide at 100°C for 12 h. XAD_4-1-hydrazinophthalazine resin formed, was filtered off, washed with methanol, water, acetone and dried. A pale yellow resin was obtained. A total of 20 g resin was prepared. The 200–250 mesh fraction of the resin was collected through standard sieve and was used for metal sorption studies.

2.4. Effect of pH on metal ion uptake

The effect of the pH on the metal ion uptake was studied by a batch equilibration technique.



I II III IV V

Scheme 1.

Metal ion solution (50 ml, 50 μg ml^{-1}) was shaken with 100 mg of resin for 1 h. The pH of the metal ion solution was adjusted prior to equilibration over the range 2.0–9.0, with buffer solution. After the equilibration, the concentration of the metal ion remaining in the solution was determined by AAS. The concentration of metal ion was also determined in the eluent after desorbing the metal ion with 1 M hydrochloric acid. Sorption experiments were carried out in duplicate each time.

2.5. pH dependence of trace metal ion uptake

A 50 ml volume of buffered solution containing 5 μg ml^{-1} of metal ion was shaken with 100 mg of resin for 1 h in a glass stoppered bottle. The resin was filtered off and the concentration of the sorbed metal ions was determined after eluting out with 1 M HCl (10 ml) and diluting the resultant sample solution to 50 ml with distilled water.

2.6. Resin capacity

The capacity of the resin was determined by shaking the excess of metal ion [50 ml; 100 μg ml^{-1} for Cu(II), Ni(II), Fe(III), Zn(II), Cr(III) and Co(II) and 200 μg ml^{-1} for Pb(II) and Cd(II)] with 50 mg of resin for 6 h at the optimum pH of sorption. The resin was filtered off and the concentration of the remaining metal ion in the solution was determined by AAS. The capacity of the resin was also checked after soaking the resin in 1 M HCl–1 M NaOH for 24 h.

2.7. Equilibrium time

To determine the time of equilibrium for the metal ion under investigation, the metal ion solution (50 ml, 10 μg ml^{-1}) at a constant pH was sampled in six bottles. These bottles were removed from shaker at regular intervals of time and concentration of the sorbed metal ions was determined. The duplicate values agreed with a precision of $\pm 2\%$.

2.8. Effect of diverse ions

The effect of diverse ions viz. potassium, magnesium and calcium ions on the recovery of various metal ions from aqueous solution was studied. For this, standard solutions of 50 ml of Cu(II), Zn(II), Pb(II) and Fe(III) (1–5 μg ml^{-1} each) containing manifold amounts of the foreign ions as interferents were analysed.

2.9. Concentration and separation of metal ions

A batch equilibration method was used to concentrate the trace metal ions. Sample solutions (250–500 ml) containing 0.1 μg ml^{-1} metal ion were adjusted to the optimum pH of sorption with buffer solution. The solution was then shaken with 100 mg of resin for about 10 min. Sorbed metal ions were eluted with 1 M hydrochloric acid (10 ml) and the concentration of the metal ion in the eluent was determined using AAS.

Based on the sorption behaviour of metal ions on XAD_4-1- hydrazinophthalazine resin at different pH values, separation of Fe(III) from various other metal ions were carried out in binary mixtures by column method. A funnel-tipped glass column with a length of 6 cm and i.d. of 0.5 cm was used for separation purposes. The dry resin (0.5 g) was loaded into the glass column, immersed in the buffer solution and 50 ml of metal ion solution containing Fe(III) (10 μg ml^{-1}) and other metal ions (10 μg ml^{-1}) was passed through the column at a flow rate of 2.0 ml min^{-1}. The sorbed metal ion was desorbed from the resin with 1 M HCl (10 ml). Concentration of Ni(II), Cu(II), Co(II), Zn(II) or Pb(II) was determined in the effluent by AAS.

XAD_4-1-hydrazinophthalazine was also used for separation and analysis of Fe(III) in synthetic samples (N.B.S., SRM-1632 and NKK, No. 920).

3. Results and discussion

The resin was synthesized according to Scheme 1 and the incorporation of 1-hydrazinophthalazine into the polymeric matrix was established by IR spectra (Fig. 1) and chemical analysis.

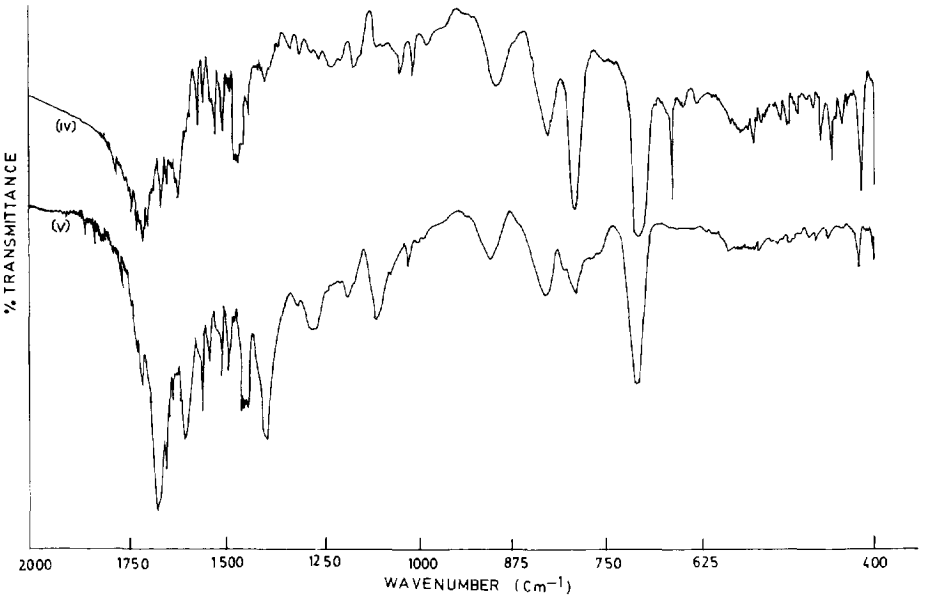


Fig. 1. Infrared spectra of resins (KBr disk): IV, acid chloride resin; and V, 1-hydrazinophthalazine resin.

The final resin (V) did not have C–Cl band at 670 cm^{-1} supporting Scheme 1. It is further indicated by a upper shift in the absorption band corresponding to a carbonyl group (1740–1765 cm^{-1}) in the spectrum of resin (IV) (acid chloride form) probably resulting from Fermi-resonance between the C=O band and the overtone of a longer wavelength band near 875 cm^{-1} [16]. The ligand is attached to the polymer through the secondary amine group. This is indicated by disappearance of the band corresponding to secondary aryl N–H (at 3220 cm^{-1}). All other characteristic band of pure ligand were present in the final resin(II).

Fig. 2 shows the scheme for coordination of the metal ion with the ligand. 1-Hydrazinophthalazine acts as bidentate ligand coordinating through α-nitrogen of the hydrazine moiety and one of the nitrogen of the phthalazine ring [17], resulting in the formation of a stable five membered ring.

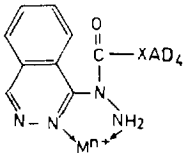

Fig. 2. Co-ordination of metal ion by the ligand.

Nitrogen analysis of the resin gave a value of 8.05% nitrogen. Assuming that all nitrogen is part of intact 1-hydrazinophthalazine group, the capacity for the metal ion should be 1.44 mmol g^{-1} of resin. The values actually obtained are reported in Table 1.

Fig. 3 shows the sorption behaviour of Cu(II), Ni(II), Zn(II), Co(II), Pb(II), Cd(II), Fe(III) and Cr(III) as a function of pH using XAD_4-1-hydrazinophthalazine resin. Sorption of Fe(III) be-

Table 1
Metal uptake capacity

Metal ion	pH	Capacity ($\pm$S.D.) mmol g^{-1} of resin)
Cu(II)	6.51	1.24(0.02)
Zn(II)	7.05	0.74(0.01)
Fe(III)	4.52	1.32(0.01)
Pb(II)	6.52	0.86(0.02)
Ni(II)	8.54	0.82(0.02)
Cd(II)	7.52	0.96(0.01)
Co(II)	8.03	0.85(0.02)
Cr(III)	8.84	0.62(0.02)

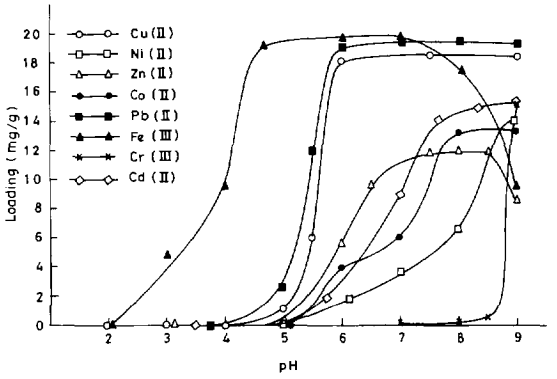

Fig. 3. Effect of pH sorption with 1-hydrazinophthalazine resin.

gins at lower pH (around pH 3) compared with other metal ions and attained a limiting value at pH 4. For Pb(II) and Cu(II) no uptake was observed till pH 5 but increases sharply beyond pH 5.5. Other metal ions showed gradual increase in sorption with increasing pH and the optimum uptake was observed in the higher pH region. These curves shows that the resin shows high selectivity for Fe(III) and its separation from other metal ions could be carried out by gradient elution. For example at pH 4.0 Fe(III) would remain on the resin while other metal ions would be eluted. Resin also shows fairly good selectivity for Pb(II) and Cu(II), and their separation from Ni(II), Co(II), Zn(II), Cr(III) etc., could be carried out by batch or column method.

Fig. 4 shows the effect of pH on the uptake of trace metal ions. This is to determine the pH value other than the optimum pH of metal sorption, at which metal ion can be quantitatively removed from the solution. Complete sorption was obtained in the following pH region for various metal ions, (4.2–8.5) for Fe(III); (5.8–9.0) for Cu(II); (6.5–8.5) for Zn(II); (7.7–9.0) for Co(II); (8.0–9.0) for Ni(II); (5.6–9.0) for Pb(II); (7.5–9.0) for Cd(II), and (> 9.0) for Cr(III).

The capacity of the resin for various metal ions was determined at optimum pH of sorption and data is listed in Table 1, along with the standard deviation. The capacity of the resin for Cu(II) was found to be 1.24 mmol g^{-1} which is higher than some of the previously used chelating resins having similar groups (e.g., chelamine resin [11], 1.0 mmol g^{-1}; 8-hydroxyquinoline on fractogel [18], 0.29 mmol g^{-1}; diamine on silica gel [19], 0.47 mmol g^{-1}).

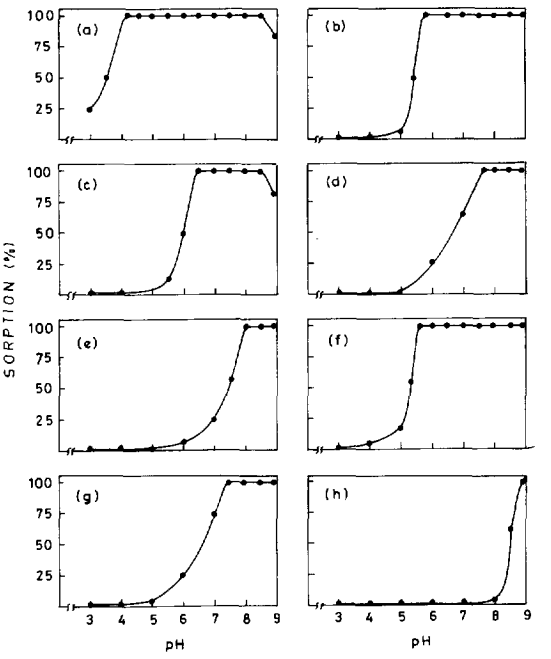

Fig. 4. PH dependence of the uptake of trace metal ions: (a), Fe(III); (b), Cu(II); (c), Zn(II); (d), Co(II); (e), Ni(II); (f), Pb(II); (g), Cd(II); and (h), Cr(III).

Equilibration time of the resin was determined for Cu(II), Ni(II) and Fe(III) and results are plotted in Fig. 5. Equilibration of the resin with

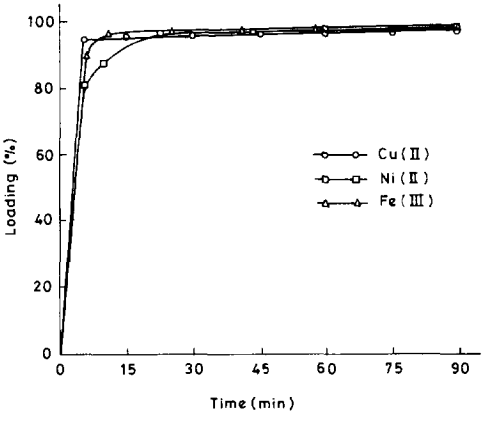

Fig. 5. Rate of uptake of metal ions.

Table 2
Effect of diverse ions

Interfering ions	Recovery (%)			
	Cu(II)	Pb(II)	Zn(II)	Fe(III)
Ca (50 μg ml^{-1})	98.5	99.4	98.9	98.4
Mg (50 μg ml^{-1})	101.0	99.2	99.1	100.2

the metal ion is sufficiently rapid, allowing the resin to be used in a packed column. Copper(II) and Ni(II) are extracted up to 90% within 5 min of their interaction with the resin, while Fe(III) reaches 81% extraction level in 5 min. Other metal ions also showed similar behaviour.

The presence of alkali and alkaline earth metals have no effect on the recovery of metal ion from the solution. Table 2 shows the recovery rates of metal ions in the presence of manifold amount of these foreign ions.

This suggests the suitability of this resin for trace concentration of metal ions from natural samples that have a high concentration of alkali and alkaline earth metals, e.g., sea-water, pond water, etc. The capacity of the resin is also high enough for use in the simultaneous concentration and determination of several metal ions. The resin has a high mechanical and chemical strength and no significant change in the hydrogen-metal exchange capacity was observed on using the resin after recycling.

The resin was used for preconcentration of various metal ions from aqueous solutions and the results are reported in Table 3.

Metal ions could be enriched up to 50 times with XAD_4-1- hydrazinophthalazine resin. Separation of Fe(III) has been carried out from other metal ions in various mixtures and the results are reported in Table 4.

At pH 4.2 resin selectively takes up Fe(III), while other metal ions viz Cu(II), Ni(II), Pb(II), Zn(II) or Co(II) passed through the column. Sorbed Fe(III) was eluted out with 1 M hydrochloric acid (10 ml). Analysis of sea water for Fe(III) is important and requires very rapid and sensitive method. Analytical methods like those involving solvent extraction-graphite furnace atomic absorption detection are time consuming and relatively inconvenient as large volumes of the sample solution have to be treated. The classical chemiluminescence method using luminol-H_2O_2 system along with chelating resin concentration was found to be promising [20]. But chemiluminescent detection is not specific for Fe(III) and ions like Cu(II), Co(II), Ni(II), Mn(II) etc., interfere. Therefore, chelating resin having good selectivity for Fe(III) over other metal ions are attractive. As Fe(III) was retained relatively at lower pH on XAD_4-1-hydrazinophthalazine (Fig. 3), its suitability for the separation of iron from other metal ions was evaluated by its application on various synthetic samples like coal (N.B.S., SRM- 1632) and Al alloy (NKK, No. 920).

3.1. Separation and determination of iron in synthetic samples

An aliquot of the pretreated sample solution was taken [21] and was passed through the column at pH 4.2. Iron retained on the column was eluted with 1 H HCl. The results are given in Table 5.

Amount of Fe(III) recovered agreed well with the certified value. Other metal ions were not detected in the eluent (1 M HCl) showing separation is possible.

Table 3
Preconcentration of metal ions (amount of metal ion taken 0.1 μg ml^{-1})

Metal ion	Sample volume (ml)	Metal ion found[a] (μg ml^{-1})

4. Conclusion

The sorption studies of XAD_4-1-hydrazinophthalazine indicates its potential for enrichment and separation of various metal ions from aqueous solution. Resin has shown high selectivity for Fe(III) and its separation from other metal ions has been carried out effectively. Several other separation like Cu-Ni, Cu-Co, Cu-Zn, Pb-Co, Pb-Ni, etc., are feasible on resin by control of pH.

Received 4 September 1996; received in revised form 20 January 1997; accepted 22 January 1997

Abstract

N-*p*-(*n*-, *iso*- and *tert*-)Butylbenzoyl-*N*-phenylhydroxylamine (HL) was synthesized to evaluate the steric effect of the substituent on the mutual extraction separation of representative lanthanoids(III) (Ln). Lanthanoids(III) were all found to be extracted with compounds as self-adducts of the form $LnL_3(HL)_2$. It was found that the structure of the substituents in *N*-*p*-butylbenzoyl-substituted *N*-phenylhydroxylamine is closely related to the separation factor for the pair of Yb/Eu. The separation factors for a pair of Eu/Yb with these compounds decreased in the order of *tert*-butyl derivative > *iso*- > *n*-, with a decreasing Taft's E_s value, that is, with an increasing steric effect of the substituent group. The correlation between the separation factor and the stereochemical shape of the substituent was also investigated. © 1997 Published by Elsevier Science B.V.

1. Introduction

High-purity lanthanoid(III) metals are widely used as various functional materials such as electronic, optical and magnetic materials. The use of these metals is increasing annually [1]. However, it is very difficult to mutually separate lanthanoids(III), because of their similar chemical properties. The first general separation procedures, introduced in the 1950s, were based on complexation-enhanced ion exchange processes [2]. However ion exchange processes are costly as they require a chelating agent such as EDTA for stripping into the mobile phase, and these processes are also unsuitable for large-scale commercial production. In the mid-1960s, liquid–liquid extraction processes were introduced, and today all large-scale commercial production is performed by this process [2]. However, the extractant currently used is not sufficient for the mutual separation of lanthanoids(III). A large number of extraction steps in a continuous countercurrent process in a non-

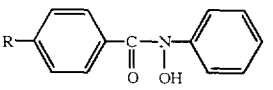
a) Structure of compounds:



polar organic liquid are necessary to obtain high-purity lanthanoids(III), even with bis(ethylhexyl)hydrogen phosphate (D2EHPA) and 2-ethylhexyl hydrogen(2-ethylhexyl)phosphonate (PC-88A), which have been reported to have high separation efficiency [3].

Recently, the relationship between the steric effect of the extractant and separation efficiency was noted, and studies were mainly carried out with organophosphorus extractants having a bulky substituent [4–10]. Danesi et al. reported the effect of the structure of the alkyl substituents on the selectivity for the cobalt(II) and nickel(II) with dialkylphosphoric, alkyl alkylphosphonic and dialkylphosphinic acids [4]. Yuan et al. reported the steric effect of the extractant on the extraction behaviors of rare earth elements with a series of acidic organophosphorus extractants [5–7]. Ohto et al. reported the steric effect and the effect of ethereal oxygen on selectivity and extractability of rare earth elements with several kinds of new organophosphorus extractants [8,9]. Ishida et al. also reported the structural effect of extractants on the extraction behavior of rare earth metals with a series of alkyl cyclohexyl hydrogenphosphates [10].

In the present paper, we report the correlation of selectivity with Taft's E_s value, representing the steric effect of substituents, as well as the stereochemical shape of the substituent with *N*-*p*-(*n*-, *iso*- and *tert*-)butylbenzoyl substituted *N*-phenylhydroxylamine as the extractant.

2. Experimental

2.1. Reagents

The extractants were newly synthesized by the reaction of the corresponding acid chlorides with *N*-phenylhydroxylamine, as previously reported [11]. Crude products were purified by recrystallization from ethanol and water, and were dissolved in chloroform just prior to use. All the chemical formulas of *N*-benzoyl-*N*-phenylhydroxylamine (BPHA) and its butyl derivatives, and analytical results for nitrogen determined by the Kjeldahl method are shown in Table 1. Stock solutions containing lanthanoids(III) were prepared from chloride salts (Aldrich Chemical) and standardized by complexometric titration using Xylenol Orange as a indicator. Chloroform was washed three times with distilled water just prior to use. The buffer solution included 0.025 mol dm^{-3} tris(hydroxymethylamino)methane (THAM) and was prepared so as to cover a pH range of 7.4–9.1, and 0.085 mol dm^{-3} sodium tartrate solution was added to prevent the hydrolysis of lanthanoids(III). All other reagents were of analytical grade and were used without purification.

A Hitachi Model U-3210 spectrophotometer was used to determine metal concentrations after extraction. An Iwaki V-SN shaker was used to equilibrate the solutions. A Hitachi-Horiba F-7AD pH meter, calibrated daily at 4.01 and 6.86 using buffer solutions provided by Toa Denpa, was used for all measurements.

2.2. Procedure for distribution of lanthanoids(III)

The distribution of lanthanoids(III) between chloroform and water was examined as a function of each reagent and hydrogen ion concentration.

A 10 cm^3 portion of a buffered lanthanoid(III) solution with an initial concentration of 1.92×10^{-5} mol dm^{-3} containing 0.034 mol dm^{-3} tartrate ions and an equal volume of the reagent in chloroform solution was equilibrated in a 50-cm^3 vial by vigorous shaking for 1 h, a time period which was found to be adequate for the attainment of equilibrium. The pH at equilibrium was measured after phase separation. An aliquot of the organic phase was shaken with a 0.1 mol dm^{-3} sodium formate-formic acid buffer at pH 4.05. The concentration of the lanthanoid(III) back-extracted into the aqueous solution was determined by the Arsenazo III method [12]. The lanthanoid(III) concentration in the aqueous phase was calculated by using a material balance technique.

3. Results and discussion

3.1. Extraction equilibrium of lanthanoid(III)

The stoichiometries for chelate extractions and extraction constants of lanthanoids(III) with *N*-*p*-(*n*-, *iso*- and *tert*-)butylbenzoyl-*N*-phenylhydroxylamine were obtained based on the relationships of log D vs. pH and log D-3pH vs. $\log [HL]_O$, so-called 'slope analysis'. The results of slope analysis are summarized in Table 2 except the data for BPHA, which was already reported [13]. From these data, all of the slopes of log D vs. pH for the representative tervalent lanthanoids(III) (La, Pr, Eu, Ho and Yb) were found to be close to three, indicating that the extracted species contain three L^- ions, since three hydrogen ions are released during their formation. However, the ex-

[c] Ref. [13].

tracted species are not simple chelates. In Table 2, plots of log D-3pH vs. log $[HL]_O$ at a constant pH are linear with slopes close to five. As previously reported by Hori et al. [12], tartrate species, and lanthanoid(III) is present in the aqueous phase largely as its ditartrate complex, LnT_2^-. These results indicate that the stoichiometry for chelate extractions involving adduct formation can be expressed as

$$LnT_2^- + 5HL_O \rightleftharpoons LnL_3(HL)_{2,O} + 3H^+ + 2T^{2-} \quad (1)$$

where T^{2-} is the tartrate dianion and LnT_2^- is the tartrate complex of the lanthanoid(III), which exists in solution. The experiments were carried out at a constant concentration (C_T) of 0.034 mol dm^{-3}. The distribution ratio (D) of the lanthanoid(III) for chelate extraction equilibrium (Eq. (1)) is given by

$$D = \beta_3 K_{DC} K_a^3 \beta_{2HL} [HL]_o^5 / K_{DL}^3 K_f C_T^2 [H^+]^3 = K'_{ex}\, \beta_{2HL} [HL]_o^5 / [H^-]^3 \quad (2)$$

and

$$\log D = \log(K'_{ex}\, \beta_{2HL}) + 3pH + 5 \log [HL]_o \quad (3)$$

where K_a and K_{DL} are the acid dissociation constant and distribution constant of the reagents, respectively. β_3 and K_{DC} are the overall aqueous formation constant of LnL_3 and its distribution constant, respectively. K_f is the overall aqueous formation constant of LnT_2^- and β_{2HL} is the adduct formation constant of the following reaction:

$$LnL_{3,o} + 2HL_o \rightleftharpoons LnL_3(HL)_{2,o} \quad (4)$$

The conditional extraction constant (K'_{ex}) is related to the extraction constant (K_{ex}) in the following manner:

$$K_{ex} = K'_{ex}\, K_f\, C_T^2 = \beta_3\, K_{DC}\, K_a^3 / K_{DL}^3 \quad (5)$$

The values of log ($K_{ex}\, \beta_{2HL}$) and the pH values at half extraction ($pH_{1/2}$) for the reagents studied are given in Table 3 and compared with the values obtained for BPHA [13]. The separation factors (defined as the difference in log ($K_{ex}\, \beta_{2HL}$)) for the Pr/Eu and Eu/Yb pairs are also given in Table 4 along with that for BPHA. It was found that the lanthanoids(III) were extracted with each butyl derivative as a self-adducted chelate, $LnL_3(HL)_2$, containing two neutral adduct molecules in extracted species, although only one neutral adduct molecule for the BPHA system was found [13].

Table 4
Comparison of separation factor for Eu/Pr and Yb/Eu with BPHA and its butyl derivatives

Compound	Extracted species	Log (SF)		E_s value for substituent[a]
		Eu/Pr	Yb/Eu	
n-Butyl	$LnL_3(HL)_2$	1.87	0.90	−0.39
iso-Butyl	$LnL_3(HL)_2$	1.81	1.38	−0.93
tert-Butyl	$LnL_3(HL)_2$	1.85	1.77	−1.54
BPHA[b]	$LnL_3(HL)$	1.82	1.16	1.24

[a] Ref. [16].
[b] Ref. [13].

3.2. Correlation of extractability or separation factor with Taft's E_s value

For estimating the steric effect of the substituent in the organic reaction, the steric constant, E_s, was defined by Taft [14] as $E_s = \log(k_X/k_H)$, where k refers to the rate constant for the acid hydrolysis of esters of the $X-CH_2COOR$ type. Hence, $E_s = 0$ when $X = H$, i.e., when the group attached to the ester function is CH_3 [15]. The larger steric effect of the substituent, the smaller is the E_s value of the substituent. The steric constant, E_s, for each substituent [16] is shown in Table 4. As described above, since the same extraction stoichiometries with each butyl derivative hold, the values of $\log(K_{ex}\ \beta_{2HL})$ and log (SF) for each butyl derivatives can be directly compared with each other. The $\log(K_{ex}\ \beta_{2HL})$ values for Eu and Pr with these derivatives in Table 3 decrease with decreasing E_s values for the substituents, that is, with an increasing steric effect of the substituents: *n*-butyl derivative > *iso*- > *tert*-. However, the opposite order was found for the extraction of Yb with these derivatives: *n*-butyl derivative < *iso*, < *tert*-. If the $\log(K_{ex}\ \beta_{2HL})$ value is mainly influenced by a steric hindrance of the substituent, $\log(K_{ex}\ \beta_{2HL})$ values for Yb with these butyl derivatives should be still more same order as that of Eu and Pr, since Yb has the smallest ionic radii in the lanthanoids(III) studied. Probably the factors other than steric effect of substituent for the extraction of Yb may affect. These results suggest that selectivity in the extraction of lanthanoids(III) is influenced by introducing these butyl groups into BPHA. Separation factors (SF) for the two pairs Pr/Eu and Eu/Yb were chosen to represent selectivity in the lighter and heavier members of the lanthanoids(III). The log (SF) value for the pair Pr/Eu is approximately constant value (1.8) for *n*-, *iso*- and *tert*-butyl derivatives as shown in Table 4. However, the log (SF) values for a pair of Eu/Yb increase in the order of *tert*-butyl derivative > *iso*- > *n*-, with decreasing E_s values, that is, with an increasing steric effect of the substituent group. The steric effect of the substituent for the separation of lanthanoids(III) was observed for the pair Eu/Yb, which has smaller ionic radii than that of Pr.

3.3. Correlation of the separation factor with the stereochemical shape of the substituent

Taft's E_s constant is generally used as a numerical definition of the steric substituent effect in an organic reaction. However, this value is inappropriate as a parameter for representing the shape of the substituent. Verloop et al. have attempted a multiparameter approach to steric interaction of organic compounds with macromolecules or drug receptors [17]. They have selected five dimensions defined by the length and width of the substituent, and have developed a computer program using van der Waals radii, standard bond angles and length, and reasonable conformations to define the space requirements of the substituent. Fig. 1(a and b) illustrates a procedure for determining the

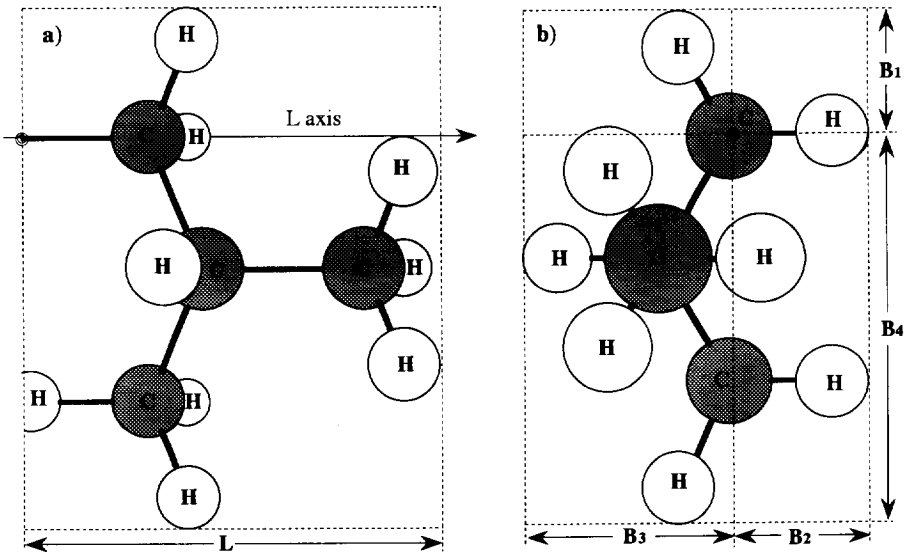

Fig. 1. Projection of the *iso*-butyl group: ◎ denotes the center of carbon in the benzene ring bonded to the *iso*-butyl group.

five dimensions by projecting an *iso*-butyl group. The length dimension, L, is defined as the length of substituent along the axis of the bond between the α-carbon atom of the *iso*-butyl group and the carbon atom in the benzene ring bonded to the *iso*-butyl group as shown in Fig. 1a. The four width dimensions, B_1–B_4, are determined from the distance at their maximum point perpendicular to this attachment bond axis and each other. B_1 is the smallest and B_4 is the largest width as shown in Fig. 1b. As these L and B values, we have employed the numerical values already reported by Verloop et al. [17]. The correlation between the E_s value and L or B_4 for butyl groups is shown in Fig. 2. L and B_4 parameters show relatively good correlations with the E_s value, indicating a steric effect of the branching of butyl substituents on the stereochemical shape of the substituent. However, a correlation of the E_s value with B_1, B_2 or B_3 was not observed. A relatively good inverse correlation between Log (SF) for Eu/Yb and L or B_4 for each butyl substituent was also observed as shown in Fig. 3. These results indicate the validity of the steric effect of branching of the butyl group on the selectivity of butyl derivatives and the possibility for evaluation of selectivity on the basis of L and B_4 for the substituent. Correlations of log (SF) with L/B_1 and log (SF) with B_4/B_1 are also shown in Fig. 4, where both L/B_1 and B_4/B_1 indicate asymmetry in the shape of the substituent. The log (SF) value for Yb/Eu gave the largest value

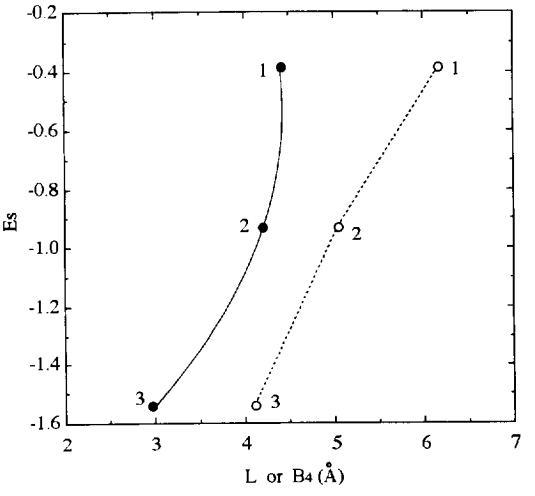

Fig. 2. Relationship between E_s and L or B_4. Dotted line, L; solid line, B_4; 1, *n*-butyl derivative; 2, *iso*-butyl; 3, *tert*-butyl.

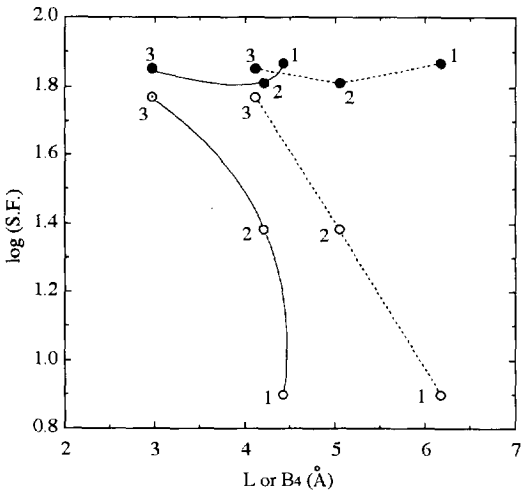

Fig. 3. Relationship between log (SF) and L or B_4. Dotted line, L; Solid line, B_4; white circle, Yb/Eu; black circle, Eu/Pr; 1, *n*-butyl derivative; 2, *iso*-butyl; 3, *tert*-butyl.

(1.77) with the *tert*-butyl derivative having developed branching structure and spherical in shape in the butyl derivatives studied. As is apparent from Fig. 3 and Fig. 4, introducing a substituent with the appropriate branching to BPHA that may cause a steric hindrance is a good means of improving the selectivity of HPHA for the extraction of heavy lanthanoids(III). Two neutral adduct molecules in the extracted species were included and these two neutral molecules may bond to metal ions with hydrogen bonds with the other ligands in some way. The configuration in space of neutral molecules may be expected to have an effect on the steric hindrance by substituent groups on the ligand. However, such an effect on steric hindrance was not considered in the present studies, although the effect of the length and width of the substituent on steric hindrance was investigated as shown in Fig. 1. The configuration in space of neutral adduct molecules will appear only by analysis with other separate experiments, such as X-ray diffraction.

In conclusion, the extractant plays an important role in mutual separation of lanthanoids(III). The results obtained in this study provide useful information on ligand design for the mutual extraction separation of lanthanoids(III).

Analytical assessment of the oscillating chemical reactions by use chemiluminescence detection

Rafael Jiménez-Prieto *, Manuel Silva, Dolores Pérez-Bendito

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

Received 27 November 1996; received in revised form 7 February 1997; accepted 10 February 1997

Abstract

This paper introduces the chemiluminescence (CL) detection in oscillating reaction-based determinations using the analyte pulse perturbation technique, a straightforward and expeditious approach to deriving quantitative analytical information from oscillating chemical reactions. The behavior of the H_2O_2–KSCN–$CuSO_4$-NaOH oscillating system in the presence of luminol was examined by using the proposed detection method and the classical potentiometric technique. Some analytical and practical aspects of both detection systems are discussed. A new analytical method for the determination of vitamin B_6 based on the sequential perturbation produced by different amounts of this substance on the oscillating chemical system was also developed in order to assess the potential of CL detection for routine analyses. The calibration curve thus obtained was linear over the range 0.5–2.0 μmol of vitamin B_6, and the precision and throughput were also quite good (3.04% as RSD and nine samples h^{-1}, respectively). The proposed method was validated by determining the vitamin in pharmaceutical preparations. © 1997 Elsevier Science B.V.

Keywords: Oscillating reaction; Analyte pulse perturbation technique; Chemiluminescence detection; Vitamin B_6; Pharmaceutical preparations

1. Introduction

Some far-from-equilibrium chemical systems exhibit an oscillating behaviour as a result of their complex mechanisms including and autocatalytic step [1]; such systems are usually referred to as oscillating reactions. The use of these reactions has been the focus of much research in the area of theoretical and experimental chemical kinetics in recent years [2,3]. From the first paper about the quantitative use of oscillating reactions published in 1978 by Tichonova et al. [4], some studies on the analytical applications of chemical oscillators have been developed [5–8].

The analyte pulse perturbation (APP) technique was developed fairly recently in order to facilitate the use of oscillating chemical reactions in routine quantitative analytical determinations [9]. It uses a continuous-flow stirred tank reactor (CSTR) to maintain oscillations for a long time (a few hours), thereby providing an inexhaustible indicator system for successively added analyte pulses; by contrast, classical determinations based on a closed system entail restarting the

oscillating system for each new determination [4,6,7,10,11].

Research has shown that analytes exhibit various types of interactions with the H_2O_2–KSCN–$CuSO_4$–NaOH oscillation chemical system; thus, sodium thiosulphate [9] and vanillin [12] diminish its oscillating amplitude and period, whereas gallic acid [13] and ascorbic acid [12] increase its amplitude, and reduced glutathione [14] and paracetamol [12] increase its period. These responses are linearly correlated with the analyte concentration in the injected sample—those for glutathione and paracetamol fit a second-order polynomial equation, however. The APP technique also allows the resolution of mixtures of species such as gallic acid and resorcinol [15]. It has become a solidly established tool for quantitative routine determinations including those of vanillin, paracetamol and ascorbic acid in foods and pharmaceutical samples [12].

Oscillations are usually monitored potentiometrically (with a platinum electrode). However, the H_2O_2–KSCN–$CuSO_4$–NaOH system also exhibits oscillations in colour (between yellow and colourless), in the dissolved oxygen concentration [16] and, as shown more recently, in chemiluminescence in the presence of luminol [17,18].

The purpose of this work was to broaden the scope of application of the APP technique in oscillating reaction-based determinations by using a chemiluminescence (CL) detection system. To this end, we compared the performance of potentiometric and CL detection by use of the APP technique and then undertook the determination of vitamin B_6 in pharmaceutical preparations by use of this novel detection methodology in far-from-equilibrium dynamic systems.

2. Experimental

2.1. Reagents

All reagents used were supplied by Merck in analytical reagent grade. Bidistilled water was used to prepare the solutions: (1) (1.5 M hydrogen peroxide), (2) (0.15 M sodium thiocyanate, 0.15 M sodium hydroxide and 1.95×10^{-3} M luminol) and (3) [6.0×10^{-4} M copper(II) sulphate]. The analyte solutions (sodium thiosulphate, gallic acid and paracetamol) were also prepared in bidistilled water, as were vitamin B_6 solutions.

2.2. Apparatus

The instrumental set-up used is depicted in Fig. 1. The oscillating assembly comprised a 10-ml glass reaction vessel (CSTR) fitted with a thermostated jacked connected to a Selecta 6000484 thermostat, an Eyela RC-2 magnetic stirrer for homogenization, a Gilson Minipuls-3 4-channel peristaltic pump (3 of the channels were used to deliver the reactants and the fourth to keep the volume of reaction mixture in the CSTR constant), a remote control for operating the pump that allowed instantaneous switching between several preset flow-rates, and a Metrohm Dossimat 665 autoburette for injection of analyte pulses.

The CL detection system consisted of a Hitachi F-2000 fluorescence spectrophotometer the sample compartment of which was used to accommodate the CSTR and magnetic stirrer, and a PC-AT 12 MHz compatible computer equipped with a PC-Multilab PCL-812PG 12-bit analog-to-digital converter (ADC) for data acquisition and processing. Poly(vinyl chloride) pumping tubes and PTFE tubing for the manifold were also used.

2.3. General procedure for CL-based determinations

The CSTR, thermostated at 27.5°C, was loaded with the three reagent solutions (1–3), delivered by the peristaltic pump, to a final volume of 9.0 ml, and the mixture was homogenized by the magnetic stirrer. Then, the flow-rate was reset to the working conditions, viz. an overall reactant feed flow-rate of 0.9 ml min^{-1} (i.e. 0.3 ml min^{-1} through each reactant channel), the reaction products being removed at the same rate. After steady oscillating conditions were obtained, the system was perturbed by injecting micro-analyte volumes. Sodium thiosulphate, gallic acid and paracetamol were assayed in this way for comparison to potentiometric detection. Changes in the oscillation amplitude and period by effect of the perturbations

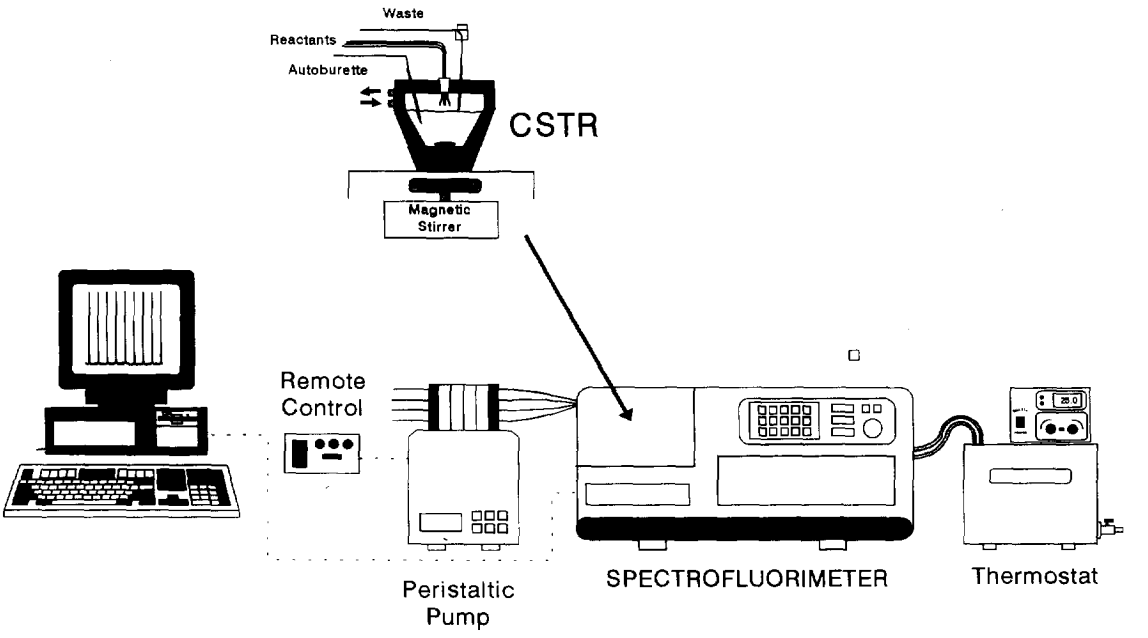

Fig. 1. Experimental set-up for implementation of CL oscillating reaction-based determinations.

were used as measurements in order to construct pertinent calibration graphs. Data were acquired and processed by using software developed by the authors in Microsoft QuickBasic v. 4.0 language.

2.4. CL determination of vitamin B_6

The CSTR, thermostated at 25°C, was filled, in this sequence, with 2.1 ml of 1.0 M hydrogen peroxide, 1.4 ml of 0.1 M sodium thiocynate, 1.05 ml of 0.1 M sodium hydroxide, 1.4 ml of 1.0×10^{-3} M copper sulphate and 1.0 ml of 7.0×10^{-3} M luminol, the mixture being homogenized by magnetic stirring. Without delay, the peristaltic pump was actuated to deliver the three reactant streams—the overall feed stream was 0.6 M in H_2O_2, 4.0×10^{-2} M in NaSCN, 3.0×10^{-2} M in NaOH, 2.0×10^{-4} M in $CuSO_4$ and 1.0×10^{-3} M in luminol—at a constant flow-rate of 1.8 ml min^{-1}. As soon as the signal and time increments for the oscillations levelled off, variable volumes (a few microlitres) of sample or standard containing also variable amounts of vitamin B_6 in the rage 0.5–20 μmol were sequentially injected. Perturbations decreased the amplitude of the oscillating cycle by a factor proportional to the amount of vitamin B_6 injected. After the system response was recorded, the flow-rate delivered by the pump was raised to 4.65 ml min^{-1} for 150 s in order to expedite restoration of the steady state. Then, the initial flow-rate (1.8 ml min^{-1}) was reset—such an abrupt rise was facilitated by the fact that the oscillating state was not lost under the working conditions used. After the steady state was regained, the system was ready for a new determination.

3. Results and discussion

The copper(II)-catalysed oscillating reaction between hydrogen peroxide and sodium thiocyanate has been widely studied by Orbán in 1986 and 1990 and Luo et al. in 1988 [16,19,20]; who propose that the mechanism for this oscillating reaction consists of 30 kinetic steps involving 26 independent variables [21]. The centerpiece of the mechanism of this reaction, which contains the key of the oscillation, is the positive and negative feedback loops on which the autocatalytic process

Table 1
Effect of experimental variables on the oscillating system, with potentiometric and CL detection

[a] Data from Jiménez-Prieto et al. [9].

relies. Thus, the positive feedback loop produces the yellow superoxy copper(I) complex:

$$OS(O)CN^* + Cu^+[SCN^-]_n \rightarrow OS(O)CN^- + Cu^{2+} + nSCN^-$$

$$H_2O_2 + Cu^{2+} + OH^- \rightarrow HO_2 - Cu(I)_{yellow} + H_2O$$

which disappears in the negative feedback loop:

$$HO_2 - Cu(I)_{yellow} + nSCN^- \rightarrow Cu^+[SCN^-]_n + HO_2^*$$

the concentration of species $Cu^+[SCN^-]_n$ being crucial for this feedback network.

The light-producing reactions of luminol have been the subject of much research and are thus widely documented [22–25]. However, oscillating chemiluminescence (viz. that produced by addition of luminol to the H_2O_2–KSCN–$CuSO_4$–NaOH oscillating system) is an intriguing phenomenon that was only recently described in the literature [17]. Although the information gathered from the few studies carried out so far on the interaction of luminol with this oscillating system necessitates some refining [18], it can be ascribed as:

$$HO_2 - Cu(I)_{yellow} + LumH^- \rightarrow Cu^{2+} + 2OH^- + Lum^{*-}$$

Such a peculiar oscillating system has not yet been used for analytical determinations. In this work, we examined its analytical performance in combination with the analyte pulse perturbation (APP) technique and compared it with that of potentiometric detection. As a result, a new analytical method for the determination of vitamin B_6 in pharmaceutical preparations was developed to validate the proposed use of CL oscillating-reaction based methods for routine analyses.

3.1. CL vs potentiometric detection of oscillating chemical reactions

The interaction of luminol with the H_2O_2–KSCN–$CuSO_4$–NaOH oscillating system was examined with a view to its subsequent use for developing analytical determinations in combination with the APP technique. Thus, the effect of experimental variables potentially influencing the system performance was thoroughly assessed and the results compared with those obtained with potentiometric detection. The oscillating amplitude and period were the two measured parameters used in both cases.

Table 1 shows the results of this comparative study. As can be seen, the oscillation period exhibited a similar behaviour with both potentiometric and CL detection; however, the oscillation

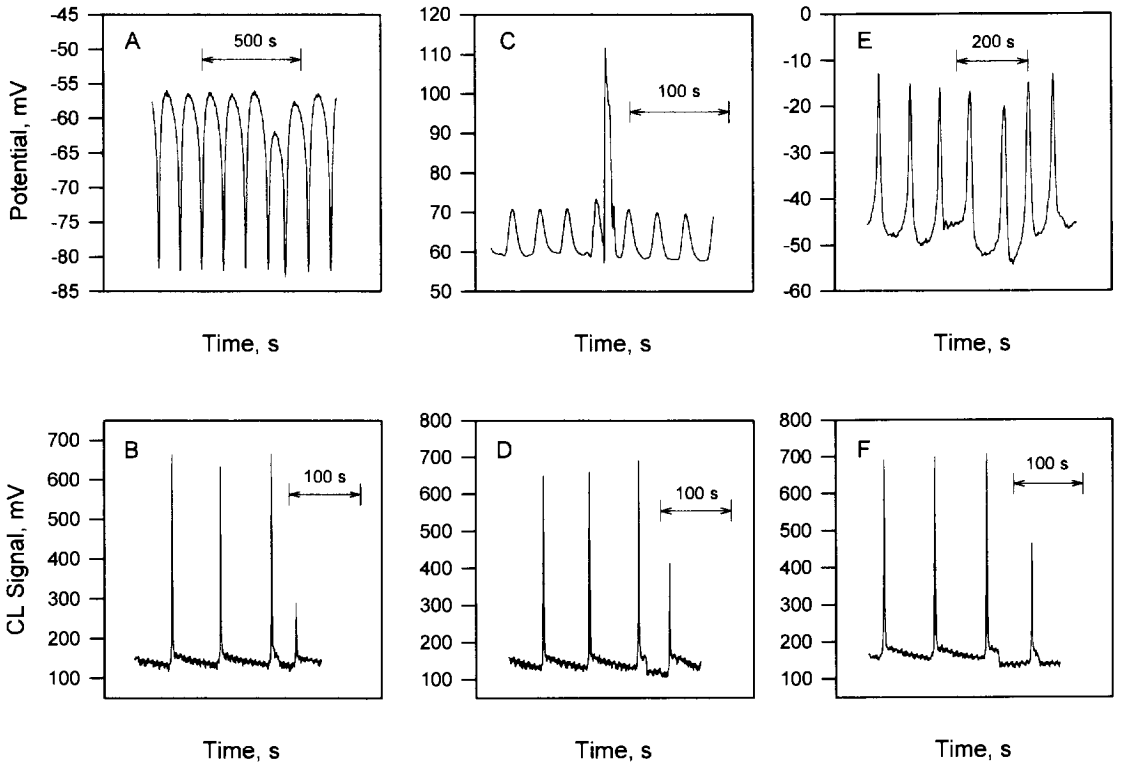

Fig. 2. Time course of oscillations for the H_2O_2–KSCN–$CuSO_4$–NaOH system in the absence and presence of perturbations with (A) and (B) sodium thiosulphate, (C) and (D) gallic acid, and (E) and (F) paracetamol, with potentiometric and CL detection in the presence of luminol.

amplitude response was different for hydrogen peroxide and temperature. The optimum value for each variable in the CL detection study was selected with three criteria in mind, namely: (a) maximizing the stability of the oscillating system over time; (b) maximizing the oscillation amplitude; and (c) ensuring that the oscillation period would allow the effect of perturbations on it to be accurately determined.

The high similarity in the behaviour of the oscillating period –the most important feature of an oscillating system whatever the detection system used—in relation to changes in the experimental variables suggests a coupled interaction between luminol and the oscillating system. In fact, considering that oscillations coincide in colour (between yellow and colourless) and in CL, then one can assume the yellow superoxy copper(I) complex to act as a catalyst in the oxidation of luminol by hydrogen peroxide. On the other hand, the differences observed for the hydrogen peroxide concentration and temperature in comparing the oscillation amplitude responses can be ascribed to a substantial effect of these variables on the optimization of the CL luminol reaction—the stability of the oscillating system over time is compromised in no way, however. The similar effects of copper on the oscillation amplitude and period with both potentiometric and CL detection, and hence the seemingly null influence of this variable on the CL luminol reaction—despite its catalytic effect on it—can be ascribed to the high concentration of copper in the reaction medium: the reaction was thus poisoned, so increasing the copper concentration decreased the CL amplitude, similarly as in potentiometric detection.

Under the selected experimental conditions, the oscillating curve was perturbed by using several

amounts of various analytes, viz. sodium thiosulphate, gallic acid and paracetamol, which were chosen because each responded differently to perturbations of the oscillating system with potentiometric detection and thus afforded comparison with CL detection. Fig. 2 shows the typical responses thus obtained and their potentiometric counterparts. The responses were analysed in terms of the oscillation amplitude and period of the perturbed system for each analyte tested. Table 2 gives the analytical figures of merit for the proposed method and those obtained with potentiometric detection. Detection limits were taken to be the analyte concentrations giving analytical signals equal to three times the standard deviation ($n = 30$) of the oscillation amplitude or period in the absence of perturbation (blank) [26]; also, the throughput was calculated from the time needed for the system to recover after each perturbation.

The results shown in Fig. 2 and Table 2 allow one to draw several interesting conclusions, namely:

1. As a rule, the detection limit and dynamic linear range was similar or better with CL detection except for gallic acid. This analyte exhibited a peculiar behaviour; the large increase in the amplitude with potentiometric detection (Fig. 2C) was more likely the result of the electroanalytical properties of this compound, which presumably forms a complex with copper in the medium [13], than of its interaction with the oscillating system since a perturbation by itself can never increase the oscillation amplitude. In this respect, CL detection is a more reliable means for assessing interactions between analytes and the oscillating system. On the other hand, the reactivity sequence obtained for the analytes (sodium

thiosulphate > gallic acid > paracetamol) may be directly related to their reducing power.

2. CL detection provided poorer precision (as RSD) than potentiometric detection as the likely result of instrumental differences. Thus, the sharp change in CL signals (Fig. 2) results in some inaccuracy in locating its maximum. While the acquisition rate was more than adequate (the maximum A/D sampling rate was 30 kHz), the performance was constrained by the spectrofluorimeter's time constant, which directly influenced the analog signal provided by the instrument.

3.2. New approach to analytical determinations: the CL quantitation of vitamin B_6

After both detection methods were assessed, the potential of CL oscillating reaction-based determinations for routine analyses was evaluated with the determination of vitamin B_6 in pharmaceutical preparations.

The addition of variable amounts of vitamin B_6 to the CSTR where the H_2O_2–KSCN–$CuSO_4$–NaOH-luminol oscillating reaction was developed decreased the amplitude of the cycles following the perturbation to an extent proportional to the analyte concentration in the sample. Fig. 3 shows a typical oscillation sequence obtained for the proposed chemical system in the absence and presence of vitamin B_6 perturbations. Fig. 3 shows the system oscillating in the steady state (zone A), its response to the perturbations (zone B) and the situation after the steady state conditions were restored (zone C).

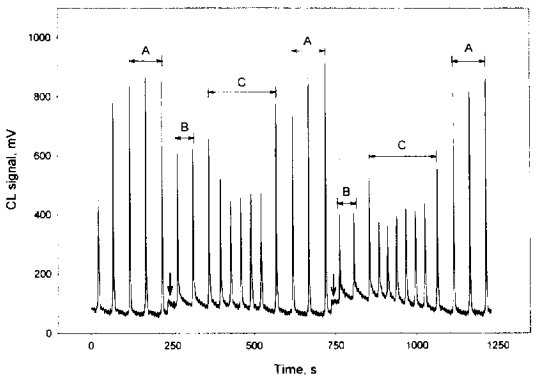

Fig. 3. Typical profiles for the proposed CL oscillating reaction in the presence and absence of a vitamin B_6 perturbation. Arrows indicate the times at which oscillations were perturbed. Zones A–C correspond to the oscillating steady state (A), the response of the oscillating system to the perturbation (B), and (C) recovery following the perturbation.

3.2.1. Influence of experimental variables

The effects of the variables potentially influencing the behaviour of the oscillating system were thoroughly studied in the presence and absence of perturbations. The measured parameter used for this purpose was the ratio of the oscillating amplitude before and after each injection. The optimum value of each variable met the following two conditions: (a) it allowed the system to oscillate undisruptedly and to recover its steady state after each perturbation; and (b) the system response to vitamin B_6 perturbations was maximal and so was the sensitivity of the method.

Fig. 4 illustrates the influence of the different variables studied—their optimum values are given in Section 2. Some selected values did not correspond to the maximum value of the measured parameter (e.g. 2.0×10^{-2} and 1.5×10^{-2} M as the concentration of NaSCN and NaOH, respectively) because a compromise between sensitivity in the determination of vitamin B_6 and stability of the oscillating system must be made. Thus, lower concentrations of both reactants caused the system to lose some stability on each injection.

One other influential variable—not shown in Fig. 4—was the reactant feed rate, the effect of which was examined over the range 0.44–5.31 ml min^{-1}. The oscillation amplitude of both the unperturbed and the perturbed system were found to decrease with increase in this rate, with no net effect on the amplitude ratio. The oscillating period also decreased with increase in the feed rate. Because the system response was not affected, the optimum flow-rate value was taken to be that resulting in an appropriate oscillation period in the steady state, viz. 1.8 ml min^{-1}. On the other hand, the flow-rate used to restore the steady-state conditions after each perturbation was the highest possible in order to shorten the restoration time with no loss of the oscillating state –

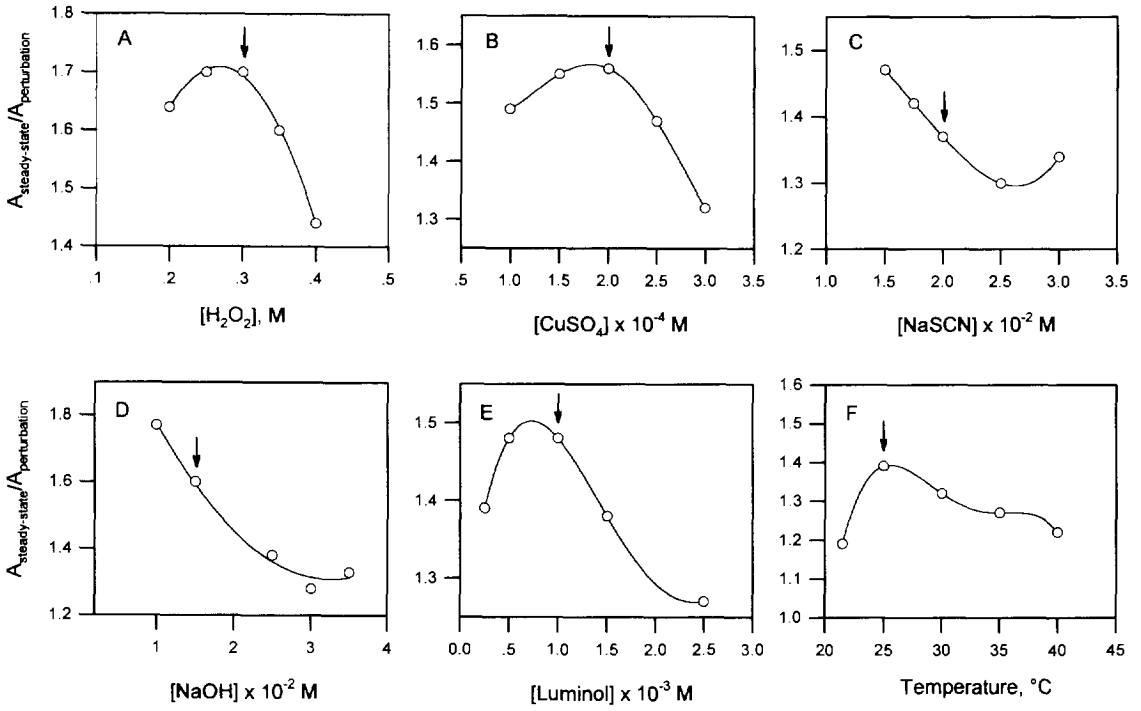

Fig. 4. Influence of the concentrations of hydrogen peroxide (A), copper sulphate (B), sodium thiocyanate (C), sodium hydroxide (D) and luminol (E), and of temperature (F), on the oscillating reaction in the presence of vitamin B_6. Arrows indicate the selected values for the variables.

not even with the most concentrated sample. As shown in the Experimental section, such a rate was set at 4.65 ml min^{-1} and applied for 150 s.

3.2.2. Determination of vitamin B_6

The oscillating system was perturbed with microvolumes of sample containing variable amounts of vitamin B_6 (pyridoxine) between 0.5 and 20 μmol as described in Section 2. The measured parameter was the amplitude of the second response cycle (see zone C in Fig. 3). A plot of oscillation amplitude against analyte concentration was linear throughout the range studied.

Table 3
Analytical figures of merit of the determination of vitamin B_6 with the proposed CL method

Dynamic linear range (μmol)	0.5–20
Detection limit (μmol)	0.1
Precision (RSD) (%)[a]	3.04
Throughput (samples h^{-1})	9

[a] From 11 determinations of 5 μmol of vitamin B_6.

Table 3 gives the analytical figures of merit for the determination. As can be seen, the proposed method is quite precise. Its throughput was calculated from the time needed for the system to regain its initial state after each perturbation; the result, 9 samples h^{-1}, confirms the goodness of the APP technique for the intended purpose.

The potential interfering effects of structurally related species was also investigated. To this end, a fixed amount of pyridoxine (5 μmol) was injected jointly with variable amounts of pyridoxylamine, pyridoxal-5-phosphate, pyridoxal and 4-pyridoxic acid. All were found to interfere with the determination—particularly pyridoxamine, above an interferent-to-analyte ratio as low as 0.0015; this can be ascribed to its reducing power and the presence of primary amino groups in its structure, which probably had a marked dis-

turbing effect on the oscillating reaction [21]. These results are of a high interest with a view to developing sensitive determination methods for various pyridoxine derivatives, which could be used as a useful alternative to other liquid chromatographic detection systems.

3.2.3. *Applications*

We assessed the potential of the proposed method for determining vitamin B_6 in real samples of special interest. For this purpose, we selected several pharmaceutical preparations including pyridoxine as the active principle or a secondary ingredient. The nominal value in each preparation was used as reference—with provision for potential errors made in the manufacturing process—because the basic aim was simply to demonstrate the usefulness of the method for routine analyses of this type of sample.

The sample preparation procedure was quite simple. Thus, solutions were all made in bidistilled water and the amount of sample used was dictated by its pyridoxine concentration. In those cases were dissolution was incomplete, the sole additional treatment required was filtration to a clear solution, an appropriate aliquot of which was subjected to the above-described procedure. The Trofimilina sample, a phospholipid homogenate and hence of oily texture, was dissolved in chloroform and then extracted for vitamin B_6 with bidistilled water.

The results obtained are given in Table 4. As can be seen, they were quite consistent with the nominal values. No separation of the species accompanying vitamin B_6 in the preparations studied was needed.

The simplicity, expeditiousness and precision of the proposed method as regards sample pretreatment, and the good results it provides, make oscillating chemical systems and chemiluminescence determination useful couples for determining species in real samples of interest.

Received 8 November 1996; received in revised form 24 January 1997; accepted 7 February 1997

Abstract

Collection and elution method for inorganic anion on protonated chitin has been applied to the spectrophotometric determination of molybdenum (VI). The molybdenum (VI) is collected as molybdate ion on a column of chitin in weak acidic medium which is easily eluted with a small volume of 0.1 M ammonia buffer solution (pH 10). The molybdenum (VI) in the eluent is determined by bromopyrogallol red-Zephiramine method spectrophotometrically. Beer's law is obeyed over the concentration range of 0.1–0.8 μg of molybdenum (VI) in 1 ml of eluent at 634 nm. The apparent molar absorptivity is 6×10^4 dm^3 mol^{-1} cm^{-1}. The tolerance limits for WO_4^{2-}, VO_3^-, CrO_4^{2-} and Fe (III) is low, that is, 1–100 times that of molybdenum (VI), but some metal ions and common inorganic anions do not interfere in concentration range of 1000–5000 times that of molybdenum (VI). The present method can be applied to the determination of molybdenum (VI) in natural water samples. © 1997 Elsevier Science B.V.

Keywords: Trace molybdenum; Chitin; Molybdate ion

1. Introduction

Molybdenum is one of the important elements for many organisms and has a wide distribution throughout nature. It is difficult, however, to determine molybdenum directly in natural samples, especially water samples because of its low concentration level. Therefore, the preconcentration methods for the determination of trace molybdenum have been developed using solvent extraction [1–6] and solid-phase extraction on various supports, including controlled pore glass [7], sephadex gel [8], anion-exchange resin [9,10], polyurethane foam [11], chelating resin [12–14], activated carbon [15] and silica gel [16].

Attention has been paid to the preconcentration of some inorganic ions as their various species on a natural polymer chitin. The spectrophotometric methods for some metal ions have been developed after the collection and elution of their colored

* Corresponding author. Fax: +81 157 2247719.

PII S0039-9140(97)00051-9

metal complexes on a chitin in the presence of suitable counter ions [17–20], in which their colored metal complexes were rapidly collected on chitin and readily eluted with a small volume of the suitable eluents. The functionalyzed chitin containing dithiocarbamate group has been also synthesized and used for preconcentration of some metal ions [21].

On the other hand, it is known that chitin acts as anion exchanger in acidic medium (Fig. 1). This property of chitin was applied to the determination of some metal ions with atomic absorption spectrometry after preconcentration as their maleonitriledithiolate [22] and 1-nitroso-2-naphthol-3,6-disulfonate [23–25] anionic chelates, and to the spectrophotometric determination of phosphate and iron after collection and elution as their phosphomolybdenum blue anion and 8-hydroxyquinoline-5-sulfonate anionic chelate [26,27].

In this paper we report on the spectrophotometric determination of molybdenum (VI) following the collection and elution as molybdate ion on protonated chitin, and the color reaction by bromopyrogallol red (BPR)-tetradecyldimethylbenzylammonium chloride (Zephiramine) method [28] in the eluent as shown in Fig. 1. The proposed method was applied to the determination of molybdenum (VI) in natural water samples.

2. Experimental

2.1. Reagents and apparatus

A commercially available purified chitin powder (FUNAKOSHI, Japan) was washed successively with a 1 M hydrochloric acid solution, distilled water and methanol; it was then kept at 40°C for 24 h in a vacuum dry oven.

Standard molybdenum (VI) solution (1 mg/ml) was prepared by dissolving accurately weighed 0.5044 g of analytical grade sodium molybdate dihydrate (Wako Pure Chemical Industries, Japan) in water and diluting to volume in a 200-ml standard flask and was further diluted as required. Bromopyrogallol red (DOJINODO LABORATORIES, Japan), Zephiramine (DOJINODO LABORATORIES, Japan) and other chemicals used were of analytical grade.

All absorbance measurements were made with a Hitachi U-2000 spectrophotometer with a black cell (light-path lengths 10 mm × light-path widths 2 mm, inner volume about 1 ml). A Hitachi-Horiba Model F-7_{AD} pH meter was used for all pH measurements.

2.2. Standard procedure

To a 100-ml of solution containing up to 0.8 μg of molybdenum (VI), add 1 ml of 0.1 M acetate buffer solution (pH 4.5). Then pass the solution through a chitin column (polyethylene column, 6 mm i.d. × 60 mm long, 50 mg of chitin) fitted with a porous polyethylene disk with a 20-μm pore size at a flow-rate of 10 ml min^{-1}. Elute molybdenum (VI) with 1 ml of 0.1 M ammonia buffer solution (pH 10) from chitin. To the eluent, add 0.05 ml of 10 M HCl, of 0.1 M Zephiramine and of 0.03 (w/v)% BPR with a micro-pipette, respectively, and then after 20 min, measure the absorbance of the solution at 634 nm against water.

3. Results and discussion

3.1. Overall capacity

The overall capacity for molybdenum (VI) as molybdate ion on protonated chitin at pH 4.5 was examined by batch equilibration of 50 mg of chitin with a 100-ml of solution containing 5×10^{-5} M of molybdenum (VI). The equilibration

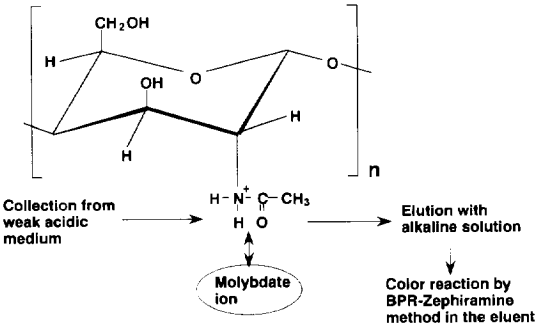

Fig. 1. Collection and elution scheme of molybdenum (VI) as molybdate ion on protonated chitin.

could be achieved by agitating for over 60 min. After filtration, the amounts collected for molybdenum (VI) were decided comparing the concentration of the solutions before and after equilibration by BPR-Zephiramine method spectrophotometrically. The overall capacity for molybdenum (VI) calculated on chitin were 50.56 μmol g^{-1}. The capacity is sufficient to collect a 0.01-μmol level of molybdenum (VI) (equal to 0.8 μg), though its capacity is less than that of common anion-exchange resin.

3.2. Color reaction in eluent

In preliminary work, some spectrophotometric methods for molybdenum (VI) were investigated. The BPR-Zephiramine method was selected for the determination of molybdenum (VI) in the eluent because of the simplicity for procedure and the sensitivity for the determination of molybdenum (VI). The optimum conditions for the color reaction by the BPR-Zephiramine method in the eluent were examined using the molybdenum (VI) standard solution. The maximal and constant absorbance of the eluent was obtained in the concentration over 0.04 ml of 10 M HCl, 0.04 ml of 0.1 M Zephiramine and 0.03 ml of 0.03 (w/v)% BPR, when used 1 ml of the eluent contained 0.8 μg of molybdenum (VI). These reagent conditions for the color reaction in the eluent were modified from original BPR-Zephiramine method [28], and chosen as described in the standard procedure. Fig. 2 shows the typical absorption spectra of the ternary complex of molybdenum (VI) and reagent blank. All absorption measurements were carried out at 634 nm as the ternary complex showed the maximum absorbance at 634 nm against water in this study.

3.3. Collection and elution of molybdenum (VI) as molybdate ion on chitin

Fig. 3 shows the effect of pH on the collection of molybdenum (VI) on chitin. The distribution curve of each species of molybdate, also shown in Fig. 3, was calculated using the acidic dissociation constants of H_2MoO_4 ($pK_{a1} = 2.4$ and $pK_{a2} = 3.8$) [29]. Molybdenum (VI) was quantitatively collected from aqueous solution over a pH range of 4–6. It is likely that the collection percentage for molybdenum (VI) on chitin decreases due to the decrease in the amount of the anionic species of molybdenum (VI) with protonation down to pH 4 as shown in Fig. 3, and due to the decrease in the amount of the effective protonated chitin beyond pH 6. In this study, the optimum pH of the solution for the collection was adjusted to be 4.5 by adding 1 ml of 0.1 M acetate buffer solution.

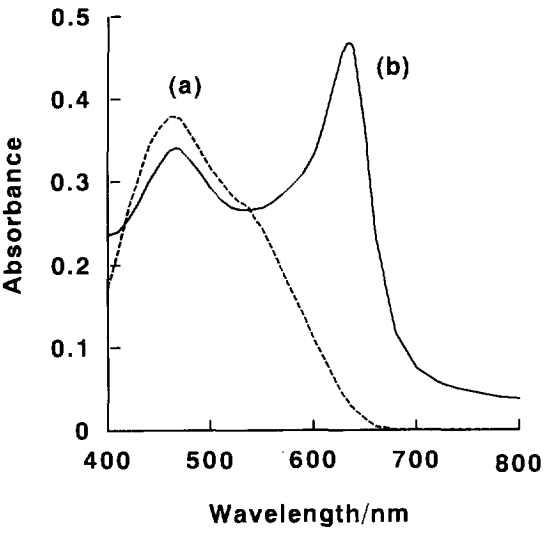

Fig. 2. Absorption spectra of the reagent blank and Mo-BPR-Zephiramine ternary complex in eluent. Condition as the standard procedure for 0.8 μg of molybdenum (VI): (a) reagent blank (Reference: water); (b) the ternary complex (Reference: water).

Collection from a 100-ml of solution containing 0.8 μg of molybdenum (VI) on a column with various amounts of chitin over the range of 10–65 mg was examined. Molybdenum (VI) was quantitatively collected on a column containing up to 40 mg.

The effect of flow rate on the collection was examined. The flow rate of sample solution for the collection was varied from 5 to 25 ml min^{-1}. The column was aspirated over 5 ml min^{-1}. Molybdenum (VI) was quantitatively collected up to 20 ml of the flow rate.

Recoveries of 0.8 μg of molybdenum (VI) from various volumes over the range of 100–500 ml of sample solution were examined. Molybdenum

(VI) was quantitatively collected in this range; up to 500-fold concentration could be easily achieved.

The elution of molybdenum (VI) collected on a column of chitin was examined using alkaline solution, mainly 0.1 M ammonia buffer solution over a pH range of 8–10 (Fig. 4), because molybdenum (VI) as molybdate ion was largely collected by the electrostatic interaction between the anionic species and the surface of the protonated chitin (Fig. 1). The elution of molybdenum (VI) was not quantitative with the ammonia buffer solution, pH 8 due to insufficient neutralization of the protonated chitin, while molybdenum (VI) was quantitatively eluted with the ammonia buffer solution, pH up to 8.5. In this study, 0.1M ammonia buffer solution, pH 10 was used. Molybdenum (VI) collected on the chitin was readily eluted with 1 ml of the eluent within 1 min.

Five successive collection and elution cycles with 0.8 μg of molybdenum (VI) on the same chitin gave almost identical results.

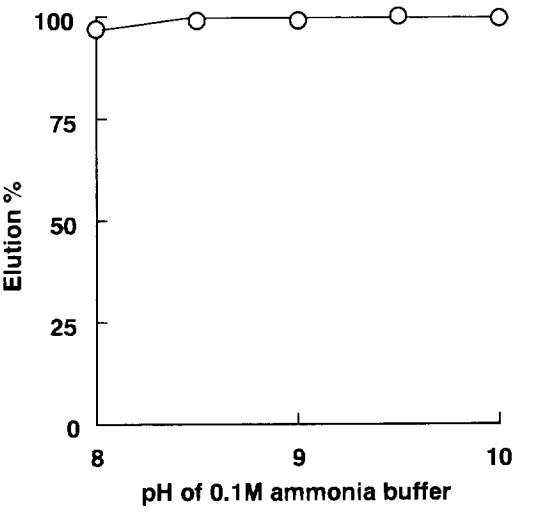

Fig. 4. Effect of pH of eluent on elution of molybdate ion from chitin. Eluent: 1 ml of 0.1 M ammonia buffer solution; Molybdenum (VI): 0.8 μg.

3.4. Calibration curve, and precision

The calibration curve obtained by the standard procedure was linear over the concentration range of 0.1–0.8 μg of molybdenum (VI) in 1 ml of the eluent. The apparent molar absorptivity was 6×10^4 dm^3 mol^{-1} cm^{-1}. The relative standard deviation was 2.31% for 0.4 μg of molybdenum (VI) (5 measurements).

Table 1
Effect of diverse ions on the determination of 0.4 μg of molybdenum (VI)

Ion added	Ion/Mo (VI) tolerated
F^-	5000
NO_3^-, EDTA	4000
Cl^-, ClO_4^-, SO_4^{2-}, PO_4^{3-}, AsO_4^{3-}, NO_2^-, Ca^{2+}, Mg^{2+}, Al^{3+}, Mn^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+} [a] NH_4^+, L-ascorbic acid	1000
Fe^{3+} [a]	100
CrO_4^{2-} [b]	10
WO_4^{2-}, VO_3^-	1

[a] 1600 μg of EDTA added.
[b] 400 μg of L-ascorbic acid added.

Table 2
Analytical results for molybdenum (VI) in tap and natural waters

Sample	Mo (VI) added (μg)	Mo (VI) found (μg)	Recovery (%)
Tapwater	0.00	ND	—
	0.10	0.105	105.0
	0.15	0.161	107.3
	0.20	0.211	105.5
Riverwater	0.00	0.097	—
	0.10	0.195	97.0
	0.15	0.245	98.7
	0.20	0.297	100.0
Spring water	0.00	ND	—
	0.10	0.102	102.0
	0.15	0.149	99.3
	0.20	0.197	98.5

Each sample volume, 100 ml; ND, not detected.

3.5. Effect of diverse ions

Table 1 shows the effect of diverse ions. The tolerance limit was taken as being the amount causing an error ± 3% in the absorbance of the eluent for molybdenum (VI) alone. For the determination of 0.4 μg of molybdenum (VI), Fe (III) in concentration up to 100-times, and CrO_4^{2-} in concentration up to 10-times that of molybdenum (VI) were tolerated when EDTA and L-ascorbic acid were added, respectively. The tolerance limits for WO_4^{2-} and VO_3^- were low, and it might cause the competitive adsorption on protonated chitin. The common anions, Al (III), Ca (II), Mg (II), Mn (II), Cu (II), Pb (II), Zn (II), NH_4^+, EDTA and L-ascorbic acid did not interfere in concentration up to 1000- to 5000-times that of molybdenum (VI).

3.6. Application

The method described was applied to the determination of molybdenum (VI) in tap water and natural water samples around our Kitami city. The samples were analyzed after filtration with a 0.45-μm cellulose acetate membrane filter. To a 100-ml of each sample, added a known amount of molybdenum (VI), and 1600 μg of EDTA to prevent the effect of Fe (III) and Pb (II), mainly. The percentage of recovery was estimated from the determination of molybdenum (VI) in the eluent. The results are summarized in Table 2. The recovery of molybdenum (VI) added for the each water sample was almost complete. Thus, this method is particularly effective for the determination of molybdenum (VI) in natural water.

In conclusion, the presented method has the advantages of simplicity, rapidity and a high concentration factor on the preconcentration procedure, and makes possible to determine molybdenum (VI) at ppb level. The proposed method may be also applicable to the spectrophotometric determination of other oxo-anions after the collection and elution on protonated chitin.

Determination of enantiomeric purity by simultaneous dual circular dichroism and ultraviolet spectroscopy

Péter Horváth, András Gergely, Béla Noszál *

Semmelweis University, Institute of Pharmaceutical Chemistry, Hôgyes Endre u. 9. Budapest H-1092, Hungary

Received 29 July 1996; received in revised form 3 February 1997; accepted 14 February 1997

Abstract

A method is described for the determination of enantiomeric composition. The ellipticity and absorbance of the sample are measured simultaneously by CD and UV spectroscopies, and the resulting G value is determined. G is an intensive physico-chemical parameter, a close derivative of anisotropy factor. Its magnitude is identical with opposite sign for enantiomers. The experimental G value is concentration-independent, as long as both absorption and ellipticity are linear functions of concentration. The analytical procedure introduced here is simple, rapid, and inexpensive, even though it includes calibration with standards of established enantiomeric composition. Provided the sample contains some UV-active contaminant(s), the method can be used after achiral chromatographic purification. By virtue, the method lacks several sources of error, arising normally from concentration inaccuracies. Applicability of the principles is tested by the example of phenylglycine and mandelic acid. Advantages of the method allowed the determination of phenylglycine enantiomer purity with an accuracy of 0.1%. © 1997 Elsevier Science B.V.

1. Introduction

Optical purity is the state of matter in living organisms [1], with far-reaching consequences in life sciences. As such, it is an increasingly significant quality control criterion in pharmaceutical, biochemical and related industries.

The optical purity of substances can be determined with and without separation techniques.

Of the methods, using separation techniques, HPLC is certainly the most widely used one, as described by Souter (1991, pp. 418–421) [2]. All enantiomeric separations are based upon diastereomeric weak interactions with homochiral reactants. Such homochiral counter-molecules can be proteins [3,4] or chiral modifiers (amino acid- [5,6] or amine- and alcohol derivatives [6]) of the stationary phase, or asymmetric additives (cyclodextrin [7] and amino acid derivatives [8]) in the eluent. Chiral pre-column reagents can also be used to produce covalent diastereomeric derivatives [9–11], which can then be separated under achiral circumstances as well.

For the identification of asymmetric compounds, chiroptical detectors offer a relatively

* Corresponding author. Fax: +36 01 2170891; e-mail: nosbel@hogyes.sote.hu

PII S0039-9140(97)00058-1

new way. The combination of HPLC separation and CD or ORD detection has recently been reviewed [12,13]. Dual detector systems in a serial fashion have also been connected to HPLC. Such systems include a refractive index or UV spectrometer to measure the sum of the enantiomers, whereas polarimetric, CD or fluorescence-detected CD techniques monitor the enantiomeric excess [14–17]. Vibrational CD is a candidate to become a detector of high chiral and chemical identification capacity [18,19]. Other separation techniques, such as capillary zone electrophoresis was also shown to be appropriate to characterize enantiomeric composition, with the advantage of short analysis time, while remaining reasonably sensitive [20,21]. Thin layer chromatography can be an inexpensive alternative in some cases as well [22,23].

Concerning non-separation methods, NMR is the most frequently used one (Souter, 1991, pp. 422–423) [2], in which chiral shift reagents [24,25] serve to form diastereomeric complexes. Ladányi et al., have developed a thermoanalytical method to determine the enantiomeric composition of selegilin [26].

The inherently distinctive chiroptical methods, and the role of polarimetry has been summarized by Schurig [27]. The sensitivity of enantiomeric determinations can be enhanced by derivatization with chromophore groups [28]. Optical purity of amino acids was determined by ORD and CD spectroscopy of their mixed complexes formed with other chiral ligands [29]. Purdie et al., have developed a method based upon ligand substitution reaction, to characterize enantiomeric composition in epinephrine mixtures [30].

Here we describe the application of anisotropy factor, measured by single cell, single solution dual spectroscopy, to determine enantiomeric composition, without the physical separation of the enantiomers.

2. Experimental section

2.1. Reagents

Phenylglycine and mandelic acid isomers were obtained from Fluka. The enantiomeric purities were declared to be above 99% while the chemical purities were above 99.9%. No further purification was carried out. For the accurate determination of the enantiomeric compositions with HPLC, CHIREX D-Penicillamine chiral column (Phenomenex) was used. By this method, the L-phenylglycine impurity in D-phenylglycine was found to be 0.19%, whereas the D impurity in the L-isomer was below 0.05%. The L-isomer was therefore accepted as a standard reference material (SRM). In case of mandelic acid, the D-isomer contained 0.27% of L-isomer, while in the L-isomer, the quantity of the D-isomer could not be determined by the above method. The reason is that the peak of the minor D-isomer is highly covered by the peak of the earlier eluted major L-isomer. All solutions prepared for spectrometric measurement were made in 1 M HCl as solvent.

2.2. Instrument

The spectroscopic measurements were carried out on a JASCO J-720 type spectropolarimeter, using single cell technique, detecting simultaneously UV absorption plus ellipticity or optical rotation dispersion signals. The spectra of the materials were recorded in wavelength mode, while the ellipticity and the absorbance in 'Time' mode. The measurements in 'time' mode were carried out employing the following parameters:

Time for data registration: 60 s, resolution: 0.5 s, accumulation: 3 ×, cell: 10 mm cylindrical cell from Hellma, band width: 2 nm.

Following the threefold accumulation, the mean of 180 data points, the standard deviation as well as the G factor were calculated with MS Excel 5.0 program. The standard deviation of the ellipticity values were found to be approximately 0.25 mdeg, while a typical standard deviation of the absorption was 0.0005 absorbance unit. Further calculations were aided by the program-package STATISTICA 4.5 for Windows.

3. Theory

G-value, a concentration-independent parameter is a derivative of absorbance (see the denominator of Eq. (1)) and ellipticity (see the numerator). Also, it is proportional to the anisotropy factor, g [31,32], as given in Eq. (1).

$$G = \frac{[\Theta] \times c \times l}{\epsilon \times c \times l} = \frac{[\Theta]}{\epsilon} = 3298g \quad (1)$$

Eq. (1) shows that G is a wavelength-dependent intensive, intrinsic parameter of a chiral chemical entity. For the two enantiomers, it has the same numerical values with opposite sign. The value of G can be calculated if simultaneous determination of ellipticity and absorbance of the sample is feasible. Eq. (1) also shows the two most important features of G:

1. As long as both ellipticity and absorbance are linear functions of concentration (which is normally the case) the G value is independent of the concentration.
2. The G value is a function of enantiomeric composition.

Thus, we can conclude that CD/UV dual spectroscopy and the resulting anisotropy factor are a tool for concentration-independent determination of enantiomeric composition.

Concentration of the minor (contaminant) enantiomer ($C_{cont\%}$) can be calculated as follows:

$$C_{Cont\%} = \frac{G_{pure} - G_{obs}}{2G_{pure}} \times 100 \quad (2)$$

where G_{pure} is the G value for the pure, major enantiomer, G_{obs} is the actual observed value of the measurement in question.

This principle can be utilized for analytical purposes in a number of ways. For example, the use of single solution, single cell, double spectroscopy eliminates several traditional analytical errors arising normally from weighting and dilution, and also from differences in cell quality. If the sample contains some CD- or UV-active contaminant(s) previous purification or chromatographic separation is needed. The chemical and optical impurities of the substances, however, are also indicated by the experimental G value. The analytical exploitation and practical aspects of the principle will be illustrated by D- and L-phenylglycine and D- and L-mandelic acid, as described below.

4. Results and discussion

The experimental ellipticity and absorbance values are linear functions of concentration, unless association processes or technical artifacts occur. Taking into consideration that the observed ellipticity and absorbance are generally different in different state of protonation (Fig. 1), it is important to keep the compound studied in an unchanged protonation form. Also, the solvent must be chosen carefully, otherwise undesired homo- and heteroassotiations can be formed, resulting in distortion of linearity [33].

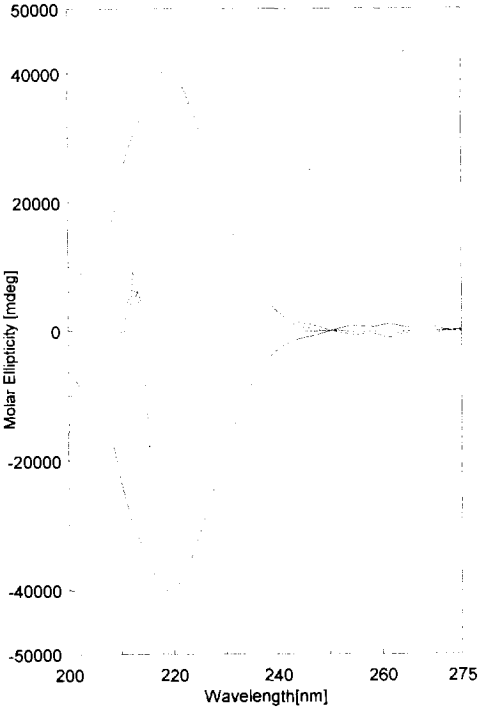

Fig. 1. CD spectra of phenylglycine and mandelic acid enantiomers. Spectrum extrema and molar ellipticities at extremum wavelengths are −40 153 at 218.6 nm for D-phenylglycine (——), 40 247 at 218.6 nm for L-phenylglycine (– – –), −35 903 at 221.6 nm for D-mandelic acid (• • •), 35 934 at 221.6 nm for L-mandelic acid (– • – – • –) and −22 950 at 218.6 nm for Na-D-mandelate (– ••– ••–), respectively.

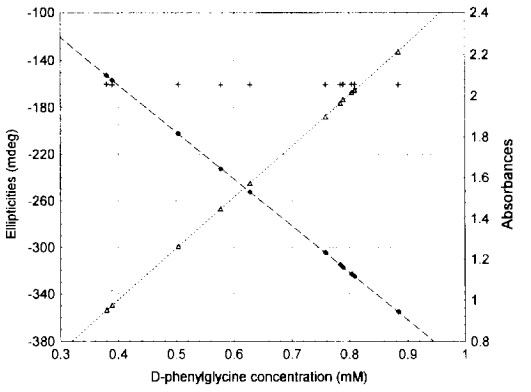

Fig. 2. Measured ellipticities (◆), absorbances (△) and calculated G values (+) vs. D-phenylglycine concentration in mM (C_D). Equations of the best fit are: $\Theta = -0.12 + (-401.56 \times C_D)$; $r = 0.99998$ (left axis). $A = -0.001 + (2.509 \times C_D)$; $r = 0.9999$ (right axis). Mean of $G = -160.3 \pm 0.2$; (left axis).

Fig. 1 shows the CD spectra of phenylglycine and mandelic acid. The chirally perturbed phenyl chromophore L_B band (250–270 nm) is of low intensity and provides poor conditions to determine the anisotropy factor. Around 220 nm, the Cotton effect is much more favorable, phenylglycine and mandelic acid were therefore measured at their 218.6 and 221.6 nm respective maxima in all subsequent measurements.

Concentration-independence of the anisotropy factor was verified as follows: L-phenylglycine solutions were in the dilution range of 0.2–1.0 mM, using 1.0 mM stock solution. The G parameters were calculated from the ellipticity and absorbance values in the same sample, yielding an unquestionably linear function in the 0.3–0.9 mM concentration range. For concentration above 0.9 mM, the absorbance was too high, and the concomitant background noise made the anisotropy factor also noisy. Data in the 0.3–0.9 mM range and the pertinent regression parameters are in Fig. 2. Clearly, the values are independent of concentration. Analogous results were found for D-phenylglycine.

The anisotropy factors for enantiomers were proved to be of identical magnitude with opposite sign, as theory predicts. The verification procedure was as follows: the actual molar ellipticity curves are in Fig. 1. The digitized spectrometer readings were divided by the actual molar concentrations. The resulting respective Θ_S, A_S standardized ellipticity and absorbance and G values are collected in Table 1. For phenylglycine, the A_S values of the isomer pairs do not differ significantly. This identity is also indicative of the similarity of their chemical purity. The Θ_S values show significant difference at $P = 0.1\%$ ($t = 4.56$), while the G values show significant difference at $P < 0.1\%$ ($t = 13.21$). The L-enantiomer impurity in the D-form was found to be 0.09% by ellipticity-difference measurement, whereas from difference of the G values is 0.15%. The latter result is in good agreement with the HPLC data (0.19%).

In the case of mandelic acid, none of the Θ_S, A_S or G values show significant differences. This suggest that the amount of D-isomer in the L-form is approximately the same as the L-isomer in the D-form (0.27%). Thus, on the basis of the G values, the enantiomeric composition can be determined directly.

D- and L-phenylglycine stock solutions ($C_D = 0.8097$ mM and $C_L = 0.7917$ mM) were mixed in various proportions. The G values of each solution are plotted against the % of the D isomer (Fig. 3(a)). The straight line intercepts the 'x' axis at 50% composition (racemic mixture). Linearity proves that no detectable homo- or heteroassociation takes place, and it can also serve as an analytical calibration curve. Since deviations from straight line are not discernible on Fig. 3(a), we also plotted residuals in Fig. 3(b). The random distribution of the residuals supports the hypothesis of linearity. The A_S value was also calculated with regards to the full concentration of the phenylglycine solutions. Thus, the obtained value of 2.505 ± 0.002 is practically the same as values given in Table 1.

For several analytical purposes, determination of small amounts of impurities have great importance. In many cases, however, highly purified standards of both enantiomers are not available. Instead, reasonably purified substances with validated amount of contaminants can be obtained. We have therefore made a test analysis under such circumstances.

A contamination standard was prepared containing 1.097% L-phenylglycine while L-impurity

Table 1
Standardized ellipticity (Θ_S), standardized absorbance (A_S) and G values for phenylglycine and mandelic acid enantiomers

	D-phenylglycine ($n = 65$)	L-phenylglycine ($n = 16$)	D-mandelic acid ($n = 59$)	L-mandelic acid ($n = 21$)
Θ_S	-401.8 ± 0.5	402.5 ± 0.6	-359.4 ± 0.5	359.6 ± 0.5
A_S	2.506 ± 0.004	2.503 ± 0.004	2.563 ± 0.005	2.568 ± 0.004
G	-160.3 ± 0.2	160.8 ± 0.1	-140.2 ± 0.3	140.1 ± 0.2

Θ_s, standardized ellipticities; A_S, standardized absorbances; G, Θ/A.

in the 'pure' D-isomer was 0.192%. After measuring ellipticities, absorbances and G values, calibration equations were found to be as follows: $\Theta = -325.305 + 42.994 \times C_L$ and $G = -161.949 + 9.45 \times C_L$ respectively, where C_L is the concentration of the L-isomer in percent. The analytes of known amounts of contaminants were prepared. After the measurements of the ellipticities and absorbances of these samples, the Θ and G values were substitued into the respective equations. As a result, calculated C_L values were obtained. The differences between the theoretical and experimental impurities are shown in Table 2. The maximum deviation is approximately 0.03%. The mean of deviations is irrespective of Θ or G function as a source, whereas the standard deviations favor the G values.

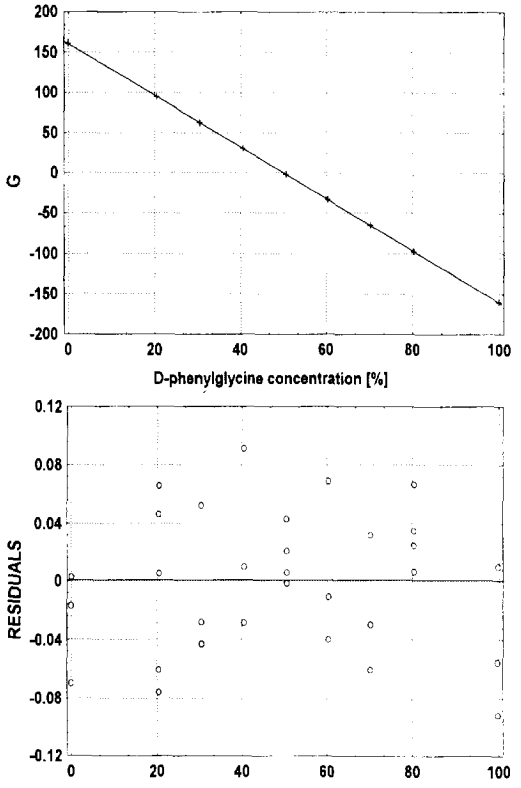

Fig. 3. G values against % of D-phenylglycine (top) and related residuals (bottom).

5. Conclusion

The method presented here is suitable for the determination of enantiomeric composition, including cases when the minor component is impurity only. This method determines anisotropy factor by using single cell, single solution dual spectroscopy, and its rapidity and accuracy makes it inexpensive, and eminently suitable for routine quality control purposes. Anisotropy, the measured quantity is a concentration-independent parameter, which eliminates concentration-related errors. Nevertheless, the measurement provides the traditional absorbance and ellipticity data as well, thus concentration values can also be obtained. Compared to HPLC, its disadvantage is that at least one standard of definite purity is needed for calibration.

Analysis of EDTA and DTPA

Mika Sillanpää *, Marja-Liisa Sihvonen

Helsinki University of Technology, Laboratory of Inorganic and Analytical Chemistry, FIN-02150 Espoo, Finland

Received 21 November 1996; received in revised form 28 January 1997; accepted 14 February 1997

Abstract

In this paper, analytical techniques for the determination of ethylenediaminetetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA) are reviewed. These compounds, especially EDTA, are used as metal chelating agents in several industries. As they are likely to be poorly degraded in waste water treatment plants, significant amounts of EDTA and DTPA are released into natural waters. The overview consists of comparing chromatographic, electrochemical, spectrophotometric, titrimetric and atomic absorption methods and their applicability to the determination of EDTA and DTPA in different matrices. © 1997 Elsevier Science B.V.

Keywords: EDTA; DTPA; Determination

1. Introduction

Aminopolycarboxylic acids, e.g. ethylenediaminetetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA), are widely used in industry, detergents, foods and agriculture. The industrial applications include metal, textile, leather, rubber, pharmaceutical, food and polymer production among others. In Finland, however, pulp and paper industry is obviously the dominant user of EDTA and DTPA.

Pulp and paper mills utilise EDTA and/or DTPA to inactivate metal ions which catalyze the decomposition of added bleach. If totally chlorine free (TCF) processes will be applied in wider extent, as the trend is at the moment, and if EDTA and DTPA are not replaced by other complexing agents, their use will significantly increase in the future. This raises concern of their ultimate release to the aquatic environment.

Complexing agents EDTA and DTPA have been analyzed by a variety of analytical methods. The earliest reports applied spectrophotometric and titrimetric methods, but later different forms of chromatography, being far more sensitive, have widely replaced these methods. Also, some electrochemical methods have been used for EDTA and DTPA analysis. The following review discusses and compares the applicability of the methods presented in the literature for the analysis of EDTA and DTPA with the main emphasis in waste and natural water applications.

2. Liquid chromatography

EDTA has been determined in a wide variety of sample matrices by liquid chromatography (LC). These include waste waters [1–3], natural waters [1,4–7], sediments [7], fertilizers [8], chemical cleaning solutions [9], radioactive waste solutions [10], boiler water [11,12], drinking water [5], foodstuffs [13–17], vancomysin formulations [18], micronutrients [19], and anaesthetic parental solutions [20].

On the other hand, the LC applications for DTPA determination are much fewer in number: it has been analysed in natural waters [1], waste waters [2,3,21], fertilizers [8], and micronutrients [19].

In recent years, there has also been increasing interest in using these chelating agent for trace metal separations and metal–chelate analysis by reversed phase (RP)-HPLC or by ion chromatography (IC). This can be performed by utilising EDTA in sample pretreatment [20,22–26] and EDTA or DTPA solutions as eluents [27–34]. In addition, lanthanoid EDTA complexes have also been separated and determined by HPLC [35].

The separation of different metal-EDTA or metal-DTPA complexes in reversed-phase columns is analytically a challenging task due to the structural similarity of the complexes. However, some authors have succeeded in separating several metal complexes of EDTA [6,22,23].

Most common trace metal-EDTA complexes can be separated and determined at the $\mu g\ l^{-1}$ level in river water according to a recent report [6]. Unfortunately, in the case of the methods presented in Knox and Shibukawa [22] and Jen and Chen [23], the detection limits for different Me-EDTA compounds were not given [22], or were far too high for the natural water applications (ranging between 1.4–66 $mg\ l^{-1}$) [23]. Using the method presented in Jen can Chen [23], it is also unlikely that the other complexes than Fe(III)-EDTA could be detected even in waste waters, that is to say, without further preconcentration.

From the environmental point of view, the speciation of EDTA and DTPA complexes in aquatic media is of crucial importance. But, no HPLC speciation studies of metal-DTPA complexes exist until now, at least to our knowledge.

In LC methods, the separation of the analytes (EDTA and/or DTPA) are performed either by RP columns or by ion chromatography (IC). In the case of RP technique, ion-pair reagent is added to the mobile phase to convert the target compounds into neutral components. Usually, the increase in retention is achieved by this step. In the case of ion chromatography, EDTA and DTPA are polyvalent anions with high affinity to anion-exchange resin and can thus be analysed by IC.

Table 1 presents the characteristics of the LC methods described in the literature for the EDTA and DTPA analysis. It can be observed that in different methods, there exist extremely wide variety of detection limits ranging between 0.8 $\mu g\ l^{-1}$ and 0.8 $g\ l^{-1}$. However, usually the detection limits are at low $mg\ l^{-1}$ level.

EDTA and DTPA have been found at concentrations of few $mg\ l^{-1}$ in waste waters and 2–100 and 2–15 $\mu g\ l^{-1}$ in natural waters, respectively. Generally speaking, most methods are not suitable to natural water monitoring due to the lack of sensitivity. Two of the LC methods provide low enough detection limits (around 1 $\mu g\ l^{-1}$) for fresh and sea water applications [5,7], but the time-consuming enrichment step is required. On the other hand, LC can conveniently be applied to analysis of, e.g. foodstuffs, where low detection limits are not required.

Preconcentration is performed by evaporation [5,7]. In addition to preliminary enrichment, the increament of loop volume is another relatively simple way of lowering the detection limits. The loop volumes vary between 10 and 200 μl.

Ultraviolet (UV) detection is the most commonly used detector with three exceptions: Chinnick utilised visible light at 760 nm due to the matrix interferences caused by the other UV absorbing compounds [36]. Dai and Helz [1] analysed complexing agents in their free acid form and thus the detection was based on amperometric detection to minimise interferences of metal ions. Ye and Lucy [116,117] used fluorescence detection with postcolumn formation of a ternary complex, which proved to be relatively sensitive, as can be observed form Table 1.

Table 1
Characteristics of the LC methods for the determination of EDTA and DTPA in various matrixes

Reference	Analyte	Matrix	Complex	Loop (μl)	Method	Detector	L.O.D.
[38]	EDTA, DTPA	Water		10	RP	Visible light (760 nm)	584 mg l^{-1} for EDTA and 788 mg l^{-1} for DTPA
[4]	EDTA	Water	Fe(III)	50	IC	UV (258 nm)	0.2 mg l^{-1}

[3]	EDTA, DTPA	Waste and natural water	Fe(III)	25/150	IC	UV (260 nm)	0.1 mg l^{-1} in waste water (loop: 25 μl); 0.01 mg l^{-1} in surface water (loop: 150 μl)
[26]	EDTA	Pore water	Co(II), Co(III)	25	IC	Visible light (535 nm) and electrical conductivity	0.18 mg l^{-1} for Co(II)-EDTA and 0.54 mg l^{-1} for Co(III)-EDTA

Table 1 (continued)

Reference	Analyte	Matrix	Complex	Loop (μl)	Method	Detector	L.O.D.
[115]	EDTA, DTPA	Waste water	Fe(III)	20	RP	UV (260 nm)	0.5 mg l^{-1} for both compounds
[116]	metal-EDTA	Natural water		50	RP	Fluorescence	0.1 μmol l^{-1} for Pb-, Zn-, Cu- and Cd-EDTA
[117]	EDTA	Ophthalmig drug	Cu(II)	20	RP	UV (250 nm)	
[118]	EDTA	Ophthalmic cleanser	Fe(III)		RP	UV (254 nm)	0.2 mg l^{-1}
[119]	EDTA, DTPA	Natural water	Lu(III)	50	RP	Fluorescence	7 μg l^{-1} for EDTA and 15 μg l^{-1} for DTPA
[7]	EDTA	Natural water and sediment	Fe(III)	200	RP	UV (258 nm)	0.9 μg l^{-1} (preconcentration step)

In most cases, however, EDTA and DTPA are converted into Cu(II) or Fe(III) complexes in sample pretreatment step and analysed at the UV region. It should be noted that, many authors have not, for some reason, analysed Me-EDTA or Me-DTPA complexes at their absorption maximum [2,8,17,19,20,22,37]. De Jong et al. reported that better selectivity was obtained at high wavelengh (300 nm), even though the response was weaker [17]. In addition, paying attention to the pH dependence of the stability of the metal complexes of EDTA and DTPA, unfavourable pH conditions were used in some papers [1,6,10,11].

Iron forms the strongest complexes with EDTA and DTPA [38,39] and thus in most applications the analytes are converted into their stable Fe(III) complexes [2–5,7–9,18,20,21,40,41,44]. Some authors have determined complexing agents as their Cu(II) complexes [10,17,19]. This procedure provides higher retention and thus better resolution of the analytes from the sample matrix, but is susceptible to the interferences arising from those metal ions, which form more stable complexes with EDTA and DTPA than copper.

In summary, LC determination of EDTA and DTPA can be applied in many matrices, as indicated in Table 1. However, without enrichment step, it is unlikely that LC is suitable for natural waters in which the concentrations are expected to be below detection limits. Interestingly, speciation study of metal complexes has received attention, which is of importance when estimating their environmental fate and ecotoxicological effects.

3. Gas chromatography

Gas chromatography (GC) requires volatility of the compounds to be determined. EDTA, DTPA and their metal complexes are most commonly converted into methyl, ethyl, propyl or butyl esters to obtain volatility. This makes sample preparation procedure time-consuming and labour intensive. In addition, need of manual work makes the pretreatment step susceptible to errors. Methyl esterification is most commonly applied (Table 2). Silylation is also reported by Suback and James [45], but difficulties arise when salts are present [46], as is the case, e.g. in sea water.

Table 2
Characteristics of the GC methods for the determination of EDTA and DTPA

Reference	Analyte	Matrix	Sample amount	Ester	Method	Garrier gas	Detector	L.O.D.
[47]	EDTA, DTPA	Waste water	5 ml	Methyl	GLC	Helium	FID	10 μg l^{-1}
[46]	EDTA	Steam propulsion system	10 ml	Butyl	GLC	Helium	FID	
[59]	EDTA	Pickled vegetable	10 g	Methyl	GLC	Nitrogen	FID	
[48]	EDTA	Natural water	25 ml	Ethyl	GLC	Nitrogen	FID	15 μg l^{-1}
[62]	EDTA	DTPA		Methyl	GLC	Helium	FID	0.05%
[49]	EDTA	Aqueous media		Methyl	GLC		FID	
[50]	EDTA, DTPA	Waste and natural water	5 ml	Methyl	GC	Nitrogen	FID	5 μg l^{-1} for EDTA and 40 μg l^{-1} for DTPA
[51]	EDTA	River water		Butyl	GC	Helium	MS	
[52]	EDTA	Aqueous rince	25–100 ml	Methyl	GC	Helium	FID	25 μg l^{-1}
[60]	EDTA	Tinned bean	25 g	Methyl	GC	Nitrogen	FID	5 mg kg^{-1}
[53]	EDTA	Aqueous media	Methyl/propyl		GC	Hydrogen	FID/NPD	
[54]	EDTA	Natural and drinking water	50 ml	Methyl	GC	Hydrogen	NPD	
[55]	EDTA, DTPA	River water		Propyl	GC	Nitrogen	MS	1 μg l^{-1} (enrichment step)
[2]	EDTA, DTPA	Waste and natural water	10 ml	Propyl	GC		MS	1 μg l^{-1}
[58]	EDTA	Mixed nuclear waste		Methyl	GC			
[56]	EDTA	Waste water	50 ml	Butyl	GC	Helium	MS	
[57]	EDTA	River water, sediment, fish	100 ml, 1–10 g	Methyl	GC	Helium	MS	6.2 μg l^{-1} level
[120]	EDTA, DTPA	Natural water	10 ml	Ethyl	GC	NItrogen	NPD	3 μg l^{-1} for EDTA and 12 μg l^{-1} for DTPA

Most GC methods were developed for EDTA analysis. There are only very few GC methods which provide the possibility for the simultaneous determination of EDTA and DTPA (Table 2). The reported object of the most existing gas chromatographic methods has been the determination of EDTA or EDTA and DTPA in natural and waste waters, as well as in aqueous solutions in general [47–58]. By GC, EDTA has also been determined in nuclear waste [59], foodstuffs [60,61], steam propulsion systems [46], as an impurity of DTPA [62] and in sediments and fishes [57].

Due to the evaporation to dryness of aqueous samples, the simpliest way to decrease detection limit is to increase sample volume. However, an increase in sample volume leads to prolonged sample preparation times. Evaporation step is required, as extraction of EDTA and DTPA into organic solvents is difficult due to their hydrophilic nature.

As a general trend, it can be conferred that the more recent GC methods provide lower detection limits than earlier ones. However, it must be remembered that also more sensitive mass selective (MS) and nitrogen phosphorus detectors (NPD) have widely replaced flame-ionization detectors (FID) which were applied in earlier reports (Table 2). The detection limits are approximately three decades lower than in HPLC methods in general (in other words, at low $\mu g\ l^{-1}$ level).

In conclusion, GC analysis is suitable when high sensitivity is required, i.e. for environmental samples. GC is also successfully applied for foodstuffs. The sample preparation procedures consist of several steps which increase the total analysis time. Total amount of complexing agents are measured as their esters. Therefore speciation studies are not possible, in contrast to LC. EDTA and DTPA form extremely stable complexes with metals, especially with Fe^{3+}. As these compounds are used to bind metal ions in industrial and agricultural applications, metals can interfere, at least to some extent, the esterification step. However, in many of the studies presented above, the interference of metal ions has not received sufficient attention.

4. Electroanalytical methods

Several electrochemical applications for EDTA determination has been developed. Only Horacek and Pribil [63] and Yoshimura [64–66], using potentiometry and voltammetry, have analysed EDTA and DTPA simultaneously. In addition, Yoshimura used PbO_2 electrode as an indicator electrode and observed that there is a linear relationship between the peak-to-peak heights and the stability constants of the lead complexes [64]. Therefore, it was inferred that the peaks were due to complex formation.

Methods for EDTA analysis include polarography [67–69], differential pulse polarography (DPP) [70,71], potentiometry [72,73], one-drop square-wave polarography [74], differential pulse anodic stripping voltammetry (DPASV) [75,76], differential pulse cathodic stripping voltammetry (DPCSV) [77] and potentiometric stripping analysis (PSA) [78]. The details of the methods described in literature are presented in Table 3.

Methods for natural and waste water analysis developed by Voulgaropoulos et al., provide the lowest detection limits ($0.1\ \mu g\ l^{-1}$) ever presented for EDTA determination [75,76]. Concentrations below this level have most likely only negligible environmental relevance. Unfortunately, the methods were developed for the nitrilotriacetic acid (NTA) and EDTA determination, while DTPA was excluded. In addition, it is reported that these methods are affected by the nature of the electrolyte present in solution and its concentration [78].

Generally speaking, the most recent methods [75–78] prove superiority to earlier ones in terms of sensitivity. If EDTA was found in natural waters by these methods, it was present at relatively low $\mu g\ l^{-1}$ level with one exception: the highest natural water concentration of EDTA ever presented in literature ($900\ \mu g\ l^{-1}$) was found in river water 1 km away from the point source [78].

The electrochemical methods presented in the literature for the EDTA and DTPA determination are well suited to the aquatic environment, such as waste and natural waters. Selectivity is poor in some electrochemical methods and simultaneous

Table 3
Characteristics of the existing elecrochemical methods for the analysis of EDTA and DTPA

Reference	Method	Analyte	Matrix	Indicator electrode	L.O.D.	Remarks
[63]	Potentiometry	EDTA, DTPA	Aqueous media		15 mg l^{-1}	Fe(III) complex
[69]	Voltammetry	EDTA	Aqueous media	Carbon	15 mg l^{-1}	
[73]	Potentiometry	EDTA	Detergent			Zn(II) complex, no differentiation between EDTA and NTA
[70]	DPP	EDTA	Phytoplancton media	DME	1.5 mg l^{-1}	Cd(II) complex
[71]	DPP	EDTA	Phytoplancton media	DME	0.6 0.9 mg l^{-1}	Cd(II) complex
[72]	Potentiometric	EDTA	Aqueous media	Perchlorate selective	2.2. mg l^{-1} catalytic titration	
[68]	Voltammetry	EDTA	Aqueous media	DME	15 μg l^{-1}	V(V) complex
[64]	Voltammetry	EDTA, DTPA	Aqueous media	MnO_2	30 mg l^{-1} for EDTA	
[65]	Voltammetry	EDTA, DTPA	Aqueous media	PbO_2	30 mg l^{-1} for EDTA	
[74]	One-drop square-wave polarography	EDTA	Aqueous media	DME/TFME	21 μg l^{-1}	
[66]	Voltammetry	EDTA, DTPA	Aqueous media	MnO_2 and PbO_2	30 mg l^{-1} for EDTA	
[75]	DPASV	EDTA	Natural waters	HMDE	0.1 μg l^{-1}	Bi(III) complex, indirect, Fe(III), Cu(II), Cl interfer
[77]	DPCSV	EDTA	Aqueous media	HMDE	3 μg l^{-1}	Cl, Br, Cu(II), Fe(III), Zn(II) interfere
[78]	PSA	EDTA	Natural and waste water	Glassy carbon	1 μg l^{-1}	Bi(III) complex, indirect
[76]	DPASV	EDTA	Natural and waste water	HMDE	0.1 μg l^{-1}	Indirect

Table 4
Characteristics of the spectrophotometric methods for the determination of EDTA and DTPA

Reference	Analyte	Matrix	L.O.D.	Remarks
[88]	EDTA	Fruit juice		Direct
[89]	EDTA, DTPA	Aqueous media		Indirect
[90]	EDTA	Aqueous media	0.3 mg l^{-1}	Direct, Fe(III) complex
[91]	EDTA	Freshwater	10 μg l^{-1}	Co(III) complex, preconcentration step
[92]	EDTA	Aqueous media	30 μg l^{-1}	Indirect, Mn(II) complex
[93]	EDTA	Aqueous media	750 μg	Direct
[94]	EDTA	Human urine	0.74 μg	Direct, interferences reported
[95]	EDTA	Aqueous media	3.0 mg l^{-1}	Indirect, Cu(II) complex
[96]	EDTA	Aqueous media	370 μg	Direct
[97]	EDTA	Aqueous media		Fe(III) complex
[98]	EDTA	Aqueous media	3 mg l^{-1}	Indirect
[99]	EDTA	Aqueous media	18.6 mg l^{-1}	Direct
[100]	EDTA, DTPA	Aqueous media	0.3 mg l^{-1}	Indirect
[101]	EDTA	Food	0.5 μg g^{-1}	Fe(III) complex, 20 g of sample
[121]	EDTA	Aqueous media		Cu(II) complex with chrome azurol S
[102]	EDTA	Food	3.4 μg l^{-1}	Zr(IV) complex with Alizarin Red S

detemination of chelating agents complicated. In natural waters, ligands, e.g. humic substances or other anthropogenic complexing agents than the analytes, can interfere. In addition, many anions and cations often present in natural waters also interfere [73,74]. On the other hand, most electrochemical methods are simple, inexpensive, rapid and sensitive.

5. Other methods

There exist several early reports [79–98] for EDTA determination by spectrophotometric procedures, but only few recent ones [99–101]. Again, only two of these methods can be directly applied to the DTPA determination [89,100]. These spectrophotometric methods are based on forming a metal–chelate complex and measuring its amount either directly or indirectly.

Most of these procedures do not differentiate between complexing agents, are subject to interferences and are not sensitive enough for trace analysis. On the other hand, the rapidity and simplicity are the unquestionable advantages.

The characteristics of the methods are presented in Table 4. In addition to aquatic media in general, EDTA has been determined in fruit juices [88], human urine [94] and foods [101]. Detection limits are usually at the low mg/l range and thus inappropriate for, e.g. natural water applications. However, the most recent paper presents the procedure which involves the reaction of EDTA with Zr(IV) and Alizarin Red S. This method gives a detection limit (3.4 μg l^{-1}) which is well compatible with chromatographic methods and thus should be paid attention in the case of natural water applications.

Some titrimetric methods are available for the determination of EDTA at low mg l^{-1} level [103–105]. These procedures have equal disadvantages as the colorimetric methods: interference by other complexing agents and low sensitivity.

Capillary electrophoresis (CE) is suited for the analysis of charged hydrophilic compounds. It offers efficient separation being relatively matrix-independent. However, the application of CE for EDTA and DTPA determination has not received sufficient attention so far.

EDTA has been used as a complexing agent in a carrier solution with the aim of alkali and alkaline–earth metal separation and determination by CE in tap and river waters as well as urine and serum samples [106,107]. Also, some heavy metals (Cr, Fe(III), Cu and Pb) have been simultaneously determined as their EDTA complexes

by CE in waste waters [108]. One paper presents a method for the determination of DTPA and its metal complexes (Fe(III), Bi, Cu, Pb and Ni) in waste waters [109]. With this procedure, it was found that Zn-DTPA, Ni-DTPA and Cu-DTPA comigrate and that the resolution between Pb-DTPA and Mn-DTPA is poor. Detection limits were found to be 0.2, 1.4, 0.7, 0.3 and 1.3 mg l^{-1} for Fe-DTPA, Bi-DTPA, Cu-DTPA, Pb-DTPA and Ni-DTPA, respectively. Chelating agents, including EDTA and DTPA, were separated and determined in tank waste simulant by CE as their Cu^{2+} complexes according to a recent report [122]. Detection limits were 2.9 mg l^{-1} for EDTA and 7.9 mg l^{-1} for DTPA. The free pentaacetic DTPA, as a major degradation product of the dianhydride of DTPA, has been determined using CE by another recent report [110]. UV absorbance detection was used in these methods.

The advantages of CE include the possibility for metal speciation studies, short analysis time and high separation efficiency. The applications include pharmaceutical use of DTPA and waste waters. Effective preconcentration procedure would make CE an important tool for heavy metal speciation investigations in natural water applications.

In addition, some procedures for indirect determination of EDTA by atomic absorption methods have been reported [111–114]. The lower limit of analysis is between 0.1–0.3 mg l^{-1} depending on method. Although they are relatively rapid and simple, they provide low selectivity, if other chelating agents are present. As a well-known fact, the speciation of heavy metals is of crucial importance when estimating their bioavailability and environmental fate in general. Hence, these methods can mainly be used for determining the complexing capacity of waste and natural water samples.

6. Conclusions

The chromatographic methods seem the most suitable for the EDTA and DTPA determination. There exists wide variety of matrices in which these compounds have been analysed either by LC or GC. However, waste and environmental samples as well as foodstuffs are the main objects. When the expected concentration is relatively high, as is the case with, e.g. foods, detergents and waste waters, HPLC might be favorable over GC. The sample preparation procedure for HPLC is simple and, in most cases, the required selectivity and sensitivity is achieved. In addition, no significant interferences were observed. Importantly also, the speciation of metal complexes, which is of vital importance from environmental point of view and in some industrial application, such as pulp and paper industry, could be studied by HPLC. The GC analysis of EDTA and DTPA is quite well-known and is very suitable for routine monitoring of complexing agents in natural waters due to high sensitivity. However, all GC procedures require a time-consuming sample preparation step and only the total concentration can be measured. On the other hand, there exist some relatively recent methods, based on either DPASV, PSA or spectrophotometry, which are well compatible with chromatographic methods in terms of sensitivity and simplicity. CE is also promising technique for the determination of EDTA and DTPA as well as their metal complexes in a variety of matrices. Other methods show relatively limited applicability.

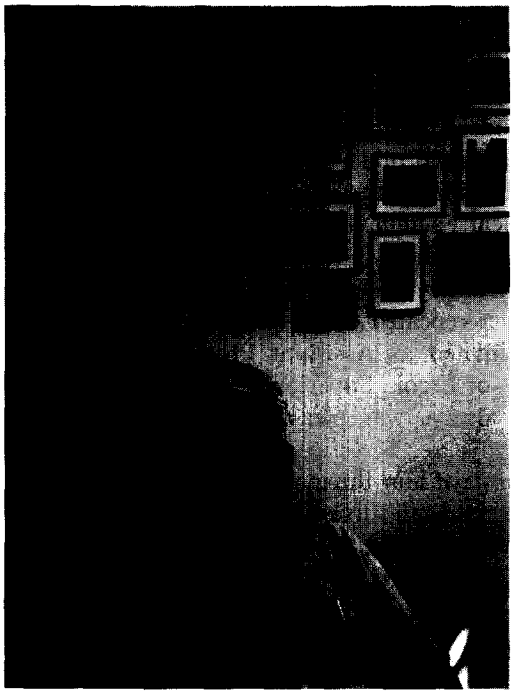
In Memoriam



Professor Henrique Bergamin Filho

On December 14th 1996, a few days after receiving one of the highest Brazilian awards (Comenda da Ordem do Merito Cientifico), the scientist Henrique Bergamin Filho suddenly passed away, victim of a heart aneurysm. He was the intellectual mentor of the analytical chemistry group at CENA/USP, research father of several docents in different Brazilian Universities, lovely husband, father and grandfather, and exemplary citizen.

Professor Bergamin was internationally recognized, mainly for his research in the field of flow analysis, as he was concerned with the inception and development of Flow Injection Analysis (FIA). Without him, it is difficult to tell what FIA would have been today. Also, he experimented with atomic absorption spectroscopy (the first AAS instrument in South America was built by him in 1961, and was presented again at the First Rio Symposium on Graphite Furnace in 1988), and with atomic emission spectroscopy. Thus, his contributions evolved from atomic spectroscopy in the 1960s, to FIA-AAS and FIA-ICP-AES in the 1970s, and recently electrolytic dissolution spectroscopy. He liked to propose challenges, (e.g. automated merging zones, ion-exchange, solvent extraction, isothermal distillation, reagent immobilization, etc.), and this was the key to science development at CENA.

PII S0039-9140(97)00024-6

Besides science, his main hobby was photography. As he had his own laboratory since he was young, we believe that this feature had a large influence in his scientific comprehension of natural phenomena. Also, he was an expert in machining small pieces, both at home and in the laboratory.

Simplicity, creativity, intelligence, valorization of the human being, and availability to help were some of his personal characteristics, as can be realized from the following text, an adaptation of his autobiography prepared when he became a Member of the Brazilian Academy of Sciences [1]:

'Born in 1931. His father was a state civil servant and his mother a teacher in fundamental school. Home provided stimulating surroundings, as his father appreciated literature and music. There was in the house a hi-fi playing machine with an old motor: 10–12 turns of the handle sufficed for playing two 78 r.p.m. records! It was the first machine dismounted by him (actually, it was the second one, since the first was an alarm clock. His father became very angry and the clock remained dismounted). His father died when he was 11-years old, and his mother provided education for all their children and pushed them in the right direction. She died after her 91st birthday.

Dr Bergamin was a good student in fundamental and high schools. Before entering into University, his mother told him that his father would prefer if he became a doctor. This was a surprise, as Dr Bergamin was already looking for the best universities where he could learn chemistry. He did not get high enough a score to enter into the Medical Faculty. In Piracicaba, he was admitted in the Agricultural Faculty of the Sao Paulo University. He studied the four academic years with relative facility, mainly when disciplines such as physics, chemistry and mathematics were concerned. Other specific disciplines were more cumbersome, but he never repeated one.

After graduation, he was invited as Assistant Professor by R.A. Catani, full Professor of Chair # 10—Analytical Chemistry—of Escola Superior de Agricultura 'Luiz de Queiroz', USP, at Piracicaba. Dr Bergamin succeeded! He always was pleased with searching new things, solving problems, and teaching.

He married Therezinha who gave him three children: Henrique (today 36 years old), Denise (34) and Cynthia (32). They traveled abroad, and lived for one and a half years in Champaign-Urbana, Illinois, USA, working with H.V. Malmstadt, and about one year in Copenhagen, working with J. Ruzicka and E.H. Hansen. Back in Brazil, he worked at the Education Ministry and then organized the Analytical Chemistry Section at CENA/USP. Thereafter, he spent four years in the Amazon, directing the Instituto Nacional de Pesquisas da Amazonia. This was one of the most remarkable experiences of his life. He and his wife were always together, and his children visited him eventually, mainly during the holiday periods. Asked by J. Cousteau how and why a relatively successful chemist was directing a research institute in the Amazon region, he became astonished with his own answer: since he was a child, he was fascinated by explorers and explorations. And a secret wish: one day, to become one of them. Nowadays, he still lives well with the same wife, in the same house. He likes when the house is filled with children, grandchildren and friends, and hopes to live the next years in the same place in the same actual conditions'.

An analytical chemist of verve: George-Emil Baiulescu

J.D.R. Thomas [1]

4 Orchard Court, Gresford, Wrexham LL12 8EB, Wales, UK

Received 20 August 1996; accepted 3 September 1996

1. Introduction

Sixty-five is an age when distinguished people, like leading analytical chemists, are frequently honoured in one way or another. So it was in 1994 when I was asked to eulogize the contributions of Professor Richard P. Buck to electroanalytical chemistry [1]. It is my privilege to have been asked yet again to express appreciation of the contributions of another of the personalities of analytical chemistry. The honour of the special issue of Talanta on this occasion is Professor George-Emil Bailuescu, whose 65th birthday fell on August 4th, 1996.

George Baiulescu is well known for his work over a wide span of analytical chemistry, namely separations, colorimetry and spectrometry, ion-selective electrodes, environmental analysis and sampling. Additionally, he has been active in the field of education, and it was through such a contribution—as a plenary lecturer at The Royal Society of Chemistry's SAC 80: An International Conference on Analytical Chemistry at Lancaster, UK in July 1980, that I was to first meet George Baiulescu, but his works were known to me long before then. His lecture [2] with the esoteric title of 'Moral Ageing of Analytical Methods' reflected Baiulescu the philosopher, for George took on a broad view of analytical chemistry and reasoned the analysis of a sample in terms of the octahedron of analytical chemistry (Fig. 1) to demonstrate the areas of knowledge and experience demanded of a sound analyst.

Apart from the 'big slot' at Lancaster, George has filled many other significant engagements as plenary lecturer—at Sassari (Italy) (1976), Zaragoza (Spain) (1983), Chiba (Japan) (1991), Gdansk (Poland) (1986 and 1990) and Changchun (China) (1994). Doubtless, the list would be longer were it not for the frustrations of the ridiculous system of 'rationed' exit visas imposed by the former political system of Eastern Europe. George Baiulescu suffered from this, as illustrated by him being prevented from leaving Romania in

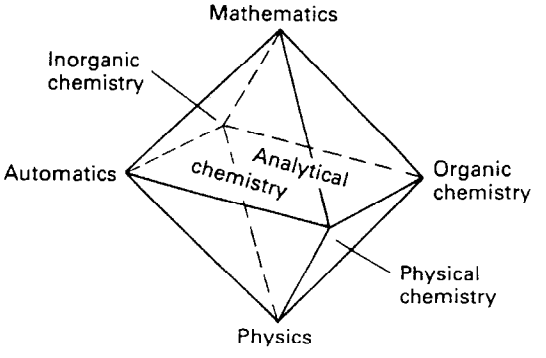

Fig. 1. The octahedron of analytical chemistry.

[1] The author is Emeritus Professor of Chemistry at the University of Wales, Cardiff; Visiting Professor at NEWI (An Associate College of the University of Wales), Wrexham; and Honorary Professor of the Faculty of Industrial Chemistry, University 'Politehnica', Bucharest.

PII S0039-9140(96)02178-9

November 1988 to deliver lectures on sampling for analysis at centres in the UK. This was not simply a case of an air ticket wasted, but rather—as also happened to others, an abuse of human dignity.

2. Education and experience

Baiulescu George-Emil took his BSc in 1954 from the Chemical Faculty of the University of Bucharest, and went on to be a researcher at the Centre of Chemical Researches (Department of Inorganic Chemistry) of the Romanian Academy of Sciences between 1954 and 1958. He then successively became assistant lecturer, reader and professor at the University of Bucharest, punctuated by a period at the National Institute of Chemistry. It was at the National Institute of Chemistry that I found him in September 1987, when I was the first British chemist to have visited Bucharest for some years. At the time George had just returned from Euroanalysis V which had been held in Paris.

After taking his PhD in 1960 and DSc in 1970, George—by the system in Romania, was in 1971 accorded with the authorization for directing PhD students. Twenty persons have completed this degree under his supervision.

3. Published works

In the field of separations, George's contributions are wide-ranging and relate to solvent extraction, ion-exchange, gas chromatography (GC), thin-layer chromatography (TLC), and HPLC. These are directed at advances in technique, such as new stationary phases in GC [3,4] and new vizualizing agents in TLC [5,6], as well as to the analysis of topical items and materials, such as PAHs [7], fruit extracts [8] and peptides [9].

Reaction analytical chemistry is an important feature of colorimetric and spectrophotometric analysis, and according to fashion of the time several of George's early papers are in this area, e.g. functional groups for osmium [10], palladium [11–13] and uranium (VI) [14,15]. Indeed, about a third of George's published titles relate to this area (mainly pre-1970), topped by some useful (post 1970) contributions in atomic absorption spectrometry [16,17], infrared spectrometry [18], spark mass spectrometry [19] and X-ray photoelectron spectroscopy [20].

While some of the spectrometric items relate to environmental analysis, e.g. analysis of lithium and manganese in Covasna and Harghita mineral waters [16] and colour measurement in the diagnosis of leaf diseases [21], George categorises his environmental analysis work as that of the analysis of gases in the air. Thus, there is the determination of ozone in ground level air [22] and various papers relating to determinations of atmospheric sulphur dioxide, such as by the use of reactive surfaces [23] and studies on reagents [24–26]. There are also papers relating to carbon monoxide [27,28] and nitrogen dioxide [29], and one on suspended particulates and their lead content [30]. Naturally, there is some reaction analytical chemistry and spectrophotometry underlying these items.

Potentiometry with ion-selective electrodes (ISEs) has attracted the attention of analytical chemists almost everywhere. It has led on from pioneering work—particularly in Hungary, Switzerland, UK and USA, and encouraged by the 1969 NBS Conference organized by Richard A. Durst in Washington, USA and the 1973 IUPAC Symposium organized by J.D.R. Thomas in Cardiff, Wales.

Further stimulation for researches on ISEs, as recently emphasized [31], has been given by the, by now, almost universal use of electrode-based blood electrolyte measurements seen as resulting from early work carried out in Philadelphia, Boston, Zürich and Cardiff. George Baiulescu was not to be left behind, and ISEs are to be seen as his equal second biggest area (with separations) of activity, enhanced by having Vasile Cosofret as an energetic partner. His attention, initially directed at metal cation ISEs, such as for copper(II) [32,33] and mercury(II) [34,35] has been given over to drugs and pharmaceutical systems, e.g. sulpha drugs [36], lidocaine [37], active components in intestopan [38] and imipramine [39].

4. Books

Ellis Horwood of Chichester did much to project East European analytical chemists to the world-wide community, and three of the five books co-authored by George Baiulescu were published by him. Among these, that on 'Applications of Ion Selective Membrane Electrodes in Organic Analysis' with V.V. Cosofret as co-author when published in 1977 (its Russian translation was published by Mir, Moscow in 1980) placed the Romanian group among world rankings in ISE research.

The two other books published by Ellis Harwood were 'Education and Teaching in Analytical Chemistry' by G.E. Baiulescu, C. Patroescu and R.A. Chalmers (1982) (Chinese edition in 1993), and 'Sampling' by G.E. Baiulescu, P. Dumitrescu and P.Gh. Zugravescu (1991) (Chinese edition in 1996). George's remaining two books are 'Physical Methods of Trace Analysis' co-authored by T. Nascutiu and published by Ed. Tehnica, Bucharest in 1974, and 'Stationary Phases in Gas Chromatography' co-authored by V.A. Ilie and published by Pergamon Press, Oxford in 1975.

5. Society and conference activities

To acknowledge his lecturing engagements at conferences outside of Romania, it is to be noted that George Baiulescu has taken on the role of organiser of several events in Romania. This has been facilitated by him being President of the Romanian Society of Analytical Chemistry—of which both he and Dr G.L. Radu have from time to time represented on the Working Party on Analytical Chemistry of the Federation of European Chemical Societies.

It was only on the occasion of the XIth National Conference on Analytical Chemistry in Ciuj-Napoca in 1992 that the first foreign lecturers were invited to these national Romanian events since that held in Brasov in 1971—the intervening 21 years being referred to as the 'dark period'. For the XIth, XIIth and XIIIth National Conferences at Ciuj-Napoca (1992), Constanza (1994) and Craiova (1996) respectively, George in his capacity as President and on behalf of SCAR (Societatea de Chimie Analitica din Romania) has welcomed many foreign lecturers of distinction, and these have been appreciative of their caring hosts.

The foreign guest lecturers have served to strengthen and add to the kind of international links, mentioned elsewhere [1], in which Richard P. Buck has been involved. The nature and extent of the involvement of these foreign lecturers invited by George Baiulescu on behalf of SCAR is summarized in a report [40] of the XIIth National Conference held in Constanza in 1994.

Having regard to the wide range of posters by Romanian analytical chemists at the SCAR National Conferences [40], it seems a pity that at least some of the Romanian authors are not encouraged to stand alongside the foreign guests on the lecturing podium in order to explain and enlarge on the work summarized in their posters. Now that George, through SCAR, has done the missionary work of having the international knowledge frontiers of analytical chemistry presented at these Conferences, there are indications that the XIVth Conference to be held in Piatra Neamt in 1998 (24–26th September) will have Romanian colleagues presenting their findings from the podium. The verve that George has for analytical chemistry will be well directed in promoting Romanian analytical chemistry by helping to bring this about.

6. Conclusion

Although his working life has been largely under a system where it was difficult to give vent to his kind of enterprising spirit, George-Emil Baiulescu has succeeded in adding to the status of analytical chemistry. In this, although it was by a quirk of circumstances, it has been an honour to have co-authored one of his papers [41].

By his enthusiasm and enjoyment of life, George has added a certain glitter to the pursuit of analytical chemistry. His qualities have assembled a wide circle of friends, spread over many countries. With him having now reached a significant milestone of life's journey, Professor George-

Emil Baiulescu is extended the best of good wishes. Long may his work prosper and friendship continue.

How to understand the response mechanism of ion-selective electrodes

Ernö Pungor

Institute for General and Analytical Chemistry, Technical University, Budapest, Hungary

Received 16 July 1996; received in revised form 23 October 1996; accepted 13 November 1996

Abstract

The present study breaks with the earlier mechanism of electrode potential on basis of experimental investigations and theoretical considerations. It rejects that the transport through the membrane produces the electrode potential and definitely proves that the electrode potential is created via surface chemisorption; i.e., the electrode potential is produced by a surface reaction. The reaction centres can be acid-base groups or complex formation groups (e.g., valinomycin or other alkaline earth metal complexing ligands). © 1997 Elsevier Science B.V.

Keywords: Chemisorption; Ion-selective electrodes; Surface reaction; Working mechanism of ISE-s

1. History

Nearly a century has passed since the time when it was found at some sorts of glass that they gave an electrochemical sign with respect to the acidity of the solution [1]. There was not found any explanation for this surprising discovery in the earlier theories. It was not clear, how a solid phase, at which any electron transitional reaction necessary to the potential response interpreted in case of metal phases cannot come true, gave an electrode potential response.

The researchers wished to find the answer for explanation by the first imaginable approach from a reaction of quite other type. In the experiment of Donnan [2], in which he separated two solutions—one of them was protein solution, the other was sodium–chloride solution—by a membrane, electrode potential was measurable, and it could be interpreted by supposition of equilibrium of charges and by supposition of ion equilibrium through the membrane. The entirely interpretable, clear picture of the Donnan reaction was adapted to the interpretation of the potential appearing on the glass electrode supposing appearance of charge transfer through the glass membrane. The external layer of the glass screen is swollen by the water solution in case of appropriate glass and through it was supposed the ion transport determining the potential. This transport idea has remained in the interpretation of glass electrodes with the difference that on the basis of precise layer analysis has been evident that the charge transporters can be only sodium ions, ion crystals.

In the 1930s a new change appeared in the interpretations in the way that Nicholski [3] introduced the term of ion exchange for the phenomenon observed by Lengyel and Blum [4]

PII S0039-9140(96)02183-2

potential given to high level of sodium ions in comparison to hydrogen ions. Nicholski interpreted it by that at certain ion concentration proportions the electrode responds to the activity of the formally not potential determining ionic species. By generalizing this idea the literature—first of all the educational literature—garbled this totally clear idea of the selectivity coefficient. The generalizing meant that it saw the basis of the effect of ion-selective electrodes in the ion exchange. Naturally, the Nicholski equation can be put down formally for the whole response function, and a wide domain of them, but in its mechanism the role of ion exchange gives only effect in the domain, where the two types of ions already disturb the response potential of each other. Even today there are in technical books equations attributing potential to the ion exchange, leaving aside that there is not any charge difference between the two sides of the equation being to put down. Although, if in a reaction new charges are not created or lost, then new potential response cannot emerge.

2. New phenomena

In the meantime several new electrodes were developed, and these were wished to be interpreted by the above principles, too. Transport through phase, as determinative process of potential was disclaimed by several experiences. One of the basic experiences is the response time figure determinable on the electrode investigation [5]. It was measurable that the response time of ion-selective electrodes is in general so short (20–40 ms) that this time is sufficient only for penetration onto the surface of the electrode through the fluid adhering to the surface of the electrode. Consequently, if we can speak about a kind of transport at such response times, it can contain in no way the ion transfer through the membrane phase.

A further result of experiments is that we separate space by a potassium-selective electrode so that on one side of the given surface potassium salt solution, on the other side distilled water can be found and considering the electrode membrane thickness as well as the ion transport being to calculate by the diffusion coefficient applied for one membrane phase, potassium ion does not appear on the water side of the membrane even during 8–10 times longer time, than could be calculated on the basis of the diffusion coefficient.

A further observation was, which we made with iodide membrane so that we prepared the electrode in a 'sandwich' form. We applied aluminium, platinum or silver, on the two sides iodide membrane electrodes. The speed of the potential response of such system was the same as that of the 'non-sandwich' membrane, and the E_0 value of the electrode remained the same.

We have proved by investigations of late years that the type of ions effecting potential of the glass electrode does not enter into the glass, but it takes part only in chemisorption on its surface [6]. Consequently it lies cross very fundamentally to the adaptation of analogies with the Donnan reaction.

We made experiments with help of reflection infrared spectrum [7], how deep does potassium ion penetrate into the potassium electrode. These penetration experiments of potassium ion in presence of very strongly lyophobic anion the depth of penetration is about 5–10 nanometre. Measurements of glass electrode by SIMS technique indicated the same depth adding that the depth distribution of gold atomized to the electrode was the same as that of the silver ion used at the experiment.

At the same time, if the lipophilic anion together with potassium is present, then the potassium ion can enter into the inside of the phase with help of a complexing agent. In this case at a high concentration of lyophobic anions we come to a condition, when the electrode is measuring the activity data of the lyophilic anions instead of that of potassium (Donnan maximum).

The observations concerning glass electrodes and electrodes with complexing agent can be attributed to the same experimental phenomena, namely to the chemisorption. In connection with chemisorption first of all the investigations of silver halides pointed out that by linkage of own ions onto the surface of the crystal a large electric field is emerging, which can considerably change the characteristics of the molecules adsorbed onto

the surface (constants of acid-base equilibrium, redox potential, face solubility product) and these data are measurable. Similarly the so-called related ions also establish adequate electric fields after their chemisorption [8]. In case of membranes with ion structure, the selectivity coefficients regarding the electrodes cannot only be interpreted, but also numerically defined on this basis [9].

In the new time of literature some authors are following the results described above. I have to emphasize the works of Umezawa et al. [10], P. Bühlmann et al. [11], who approached by the ATR-IR and SHG analyses the same phenomena, which we got earlier as results of ATT-IR.

Another question of ion-selective electrodes was analysed by Bakker et al. [12] and he interpreted the electrode selectivity coefficient. I would like to emphasize, too, that the selectivity coefficient bears only in that field an interpretation, where the disturbance function of the analysed ions arises. Therefore the equation, which can be written down without disturbing ion, can bear an interpretation only formally for the whole equation. At the same time Bakker et al. [13] analysed the interfacial potential method in details, too.

Specially remarkable is the publication, in which Buck et al. [14] deals with the transport mechanism. This publication is not understandable, because the potential through the membrane was described on a way, which was never controlled, but it was only assumed without any basis.

The results until now give that chemisorption developments on the surface of the membrane on the solution side, and hereby charge separation comes into being on the electrode and solution side. We demonstrated that the resistance of the membrane can be even infinitely high, but it changes the possibility of polarization only to such an extent that the input impedance of the measuring instrument will not be lower than the value of the measuring electrode system, about a 10 000-fold value.

Accordingly, the chemisorption will take place on the area of interface of the membrane electrode, the potential will emerge here, and the trajectories cannot be given through the membrane phase.

3. Interpretation of the phenomena

Specially remarkable is the result measured by us with help of valimomycin and bis crown ether membranes. It came out that the measured potential data were the same in case of both components. The energetics, which can be determined by the complex former, would have been different, if it had depended on the two complex formers. The energetics function is in connection with the charge separation energetics of the salt in the solution, and it can be expressed with help of the Gibbs function.

Accordingly, in case of lypophilic anion the chemisorption does not allow the penetration of the ion determining the potential into the membrane phase and in case of ion crystals it is from the beginning impossible that ion transport effected possibly by defect structure of the crystal plays a role in formation of electrode potential. The reaction itself producing potential is based upon charge separation in which the chemisorption regarding the given ion is bound on the electrode surface and the counter-ion is staying in the solution. We have to search for the energetic picture belonging to the establishment of the potential of the ion-selective electrode in the chemical potential of the ionic side in the solution, so we can put down, as follows:

$$-\Delta G = nFE$$

where ΔG is the chemical potential change, n is the charge of ion, F is the Faraday constant, E is the potential

The approach of Guggenheim established for ion-selective electrodes does not stand the proof. On the one hand the Guggenheim equation puts down two parameters changing in the same way and hereby the equation becomes fundamentally indefinable, because innumerable electrochemical potentials and galvanopotentials, which are, however, connected with each other, belong to the same chemical potential. On the other hand at the same time, if the components determining the potential can be found only on the surface of the membrane at the chemisorption, then there is no way to count with the potential data in the inside of the membrane.

The question arises that the Guggenheim approach is only then true, when we can put down the relation on the external layer of the membrane, as well as on the water phase and the area of interface closely connected with them.

If the ion determining potential can be forced through the membrane to pass the phase in form of ion transport, it is natural, if we apply an external electric field, which breaks down the potentials being established on the surfaces of the electrode, in this case the current intensity is adequate to the resistance of the electrode. Naturally, in this case the same component, which effects the chemisorption, as reagent can transport charges through the phase.

Solids, flow systems and atomic spectroscopy[1]

M. Valcárcel *, M. Gallego

Department of Analytical Chemistry, University of Córdoba, 14004 Córdoba, Spain

Received 29 July 1996; received in revised form 7 October 1996; accepted 14 October 1996

Abstract

An overview of major combinations and recent applications of the solids/flow systems/atomic spectroscopy trinomial is presented. Several representative examples, classified according to the role played by the solids (sample or active component of a chemical reaction or separation) are described. © 1997 Elsevier Science B.V.

Keywords: Atomic spectroscopy; Flow systems; Solids

1. Introduction

As in other scientific and technical areas, interfaces play a role of paramount significance in contemporary analytical chemistry. Some, including those with separation techniques, instruments and computers, and cooperation with other professionals in defining analytical problems, are crucial in several aspects. It is therefore unsurprising that much R&D analytical endeavour is being focused on establishing such interfaces.

This paper deals with different facets of the triple association of objects (solids), methodologies (continuous flow systems) and techniques (atomic spectroscopy); to this end, it discusses the double interfaces shown in Fig. 1 and describes several representative approaches to the joint use of the three elements according to the role played by the solid (as sample or an active component in the methodology) by way of practical examples. It is not the intension of the authors to present a review, but to emphasize the importance of this topic in today's and tomorrow's analytical chemistry.

2. Solids/atomic spectroscopy coupling

This association (Fig. 1A) is gaining increasing interest because it can dramatically help improve, simplify and automate the preliminary operations of the analytical process, a pending goal of today's analytical chemistry [1,2]. No doubt, the direct introduction of solid samples into atomic spectroscopic instrumentation minimizes the number of preparation steps involved and hence reduces time, human participation, expenses and hazards. Although some analytical properties (e.g., accuracy, precision, selectivity) have not reached an average high level, the advantages involved make this alternative of great practical interest. The main problems arise from the sample itself. Thus, each type of sample requires distinct working conditions; also, there can be significant differences even between batches of the same type of sample or difficulties to find appropriate standards (CRM) for a given methodology. Nevertheless, recent advances in this field warrant continuing endeavour. Laser ablation and direct sampling of solids and slurries [3] are typical examples of the efforts made in this direction.

3. Flow systems/atomic spectroscopy coupling

This combination (Fig. 1B) has reached a high degree of maturity thanks to both easy implementation and the excellent results obtained [4,5]. Good proof of the importance of this interface is the increasing availability of commercial continuous-flow modules for implementing a variety of functions (e.g., standardization, preconcentration) that are being launched by major instrument manufacturers as a way of boosting sales of atomic instruments. Flow systems are being routinely used for sample introduction. Several overviews of the performance of the FI-FAAS, FI-ICP/AES and FI-ICP/MS combinations have been published [6]. However, use of FI with ETAAS dates from much later than that with FAAS, obviously because of the discrete nature of ETAAS operations. Currently, semi-on-line techniques where the autosampler acts as an interface are gaining momentum; with on-line systems, samples are introduced into the furnace, usually dispensed by a pump via a sampling probe [5].

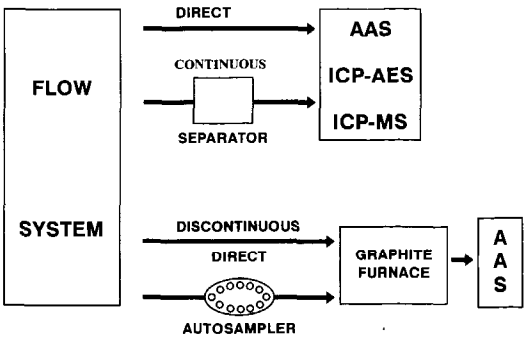

Fig. 2. Different ways of connecting (on-line or semi-on-line) flow systems and atomic spectrometers. For details, see text.

Fig. 2 shows different ways of connecting a continuous-flow system to an atomic spectrometer (AS). A direct combination is possible provided the two flow-rates involved are compatible. A continuous separator (gas–liquid, liquid–liquid, solid–liquid) can implement automatic preconcentration and interference removal. Somewhat more troublesome is connecting a flow system to an electrothermal atomization AS owing to the discrete functioning of the graphite furnace. Directly connecting the introduction arm to the flow system entails stopping the flow. On the other hand, the autosampler can be used as an interface between the continuous and discrete combined systems. Both choices can be considered semi-on-line connections.

4. Solids/flow systems coupling

The hydrodynamic character of flow systems make them theoretically incompatible with solids. However, solids and flow systems can be combined in many ways (see Fig. 3) because the former can act as samples, active components (sorbent, membranes, filters) of separations [7], ingredients (reagents, catalysts, products) of chemical reactions, and the sensing microzone of a flow-through sensor [8].

According to role, solids can be placed at different points in a flow-system, the most usual of which are as follows (Fig. 4):

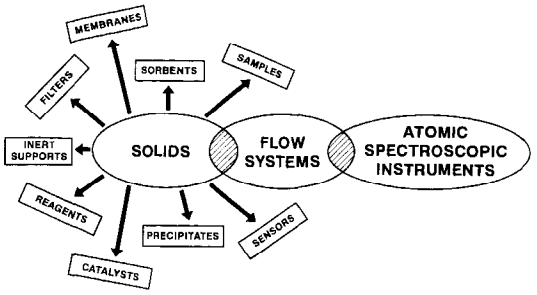

Fig. 3. Role of solids in flow systems connected to an atomic spectroscopic instrument.

1. Before the sample introduction point in order to condition the carrier (or reagent); prefilters, degassing units and redox minicolumns are usually placed in this zone.
2. Solid samples can be introduced on-line into a flow system in the form of slurries or by continuous leaching.
3. A minicolumn of sorbent material, and a dialysis or gas-diffusion unit can be placed in the loop of an injection valve through which the liquid sample or an accepting stream can be circulated.
4. A precipitate can be obtained in the reaction coil after mixing the analyte and reagent.
5. A separation unit (a liquid–liquid extractor, dialyser or sorption column, filter) furnished with an active solid (e.g., a membrane, sorbent, etc.) can be used between the mixing (reaction) coil and a continuous detector.
6. Finally, solids can be placed at the detection point in flow-through (bio)chemical sensors.

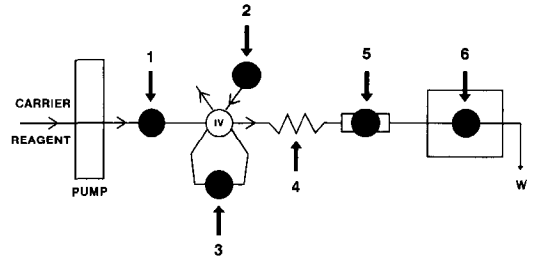

Fig. 4. Location of solids in flow (injection) manifolds. IV, injection valve; W, waste. For details, see text.

5. Solids/flow systems/atomic spectroscopy coupling

This triple association offers a great potential for solving analytical problems and enhancing basic and accessory analytical properties through a combination of the two above-described interfaces. Through representative approaches developed by our research group and applied to real samples, the most significant advances and prospects are discussed below, with special emphasis on the relevance of solids in this context.

5.1. Solids as samples

There are two general approaches to the direct introduction of solids into a coupled flow manifold/atomic spectrometer system. Continuous leaching of the analyte can be accomplished by applying electric or ultrasonic energy to a mini-reactor containing the solid sample. On the other hand, powdered or disperse solids can be introduced as slurries into the coupled flow system. It should be noted that the second alternative has been much more widely exploited.

Fig. 5 illustrates the ways real sample slurries can be introduced into a coupled flow system/electrothermal atomic absorption spectrometer (ETAAS) using an autosampler as interface; so, the sample from the flow system was collected in the cup of the autosampler instrument. According to the sample and analyte properties, a prior lyophilization step may be required. After the slurry is formed (e.g., by ultrasonic irradiation), a volume is introduced into the flow system, which can also receive several solution streams (e.g., carrier, digesting solution, chemical modifier, standards). This flow system can implement in an automatic way a variety of functions such as sample (slurry) volume measurement, dilution, addition of reagents, mixing (homogenization), standardization, filtration, and microwave digestion. The prepared sample is loaded into a cup of the ETAAS autosampler, where the metal ion concentration is determined in a discrete manner as usual.

Aluminium in milk dessert (yoghurt and custard) slurries can be determined by using an injec-

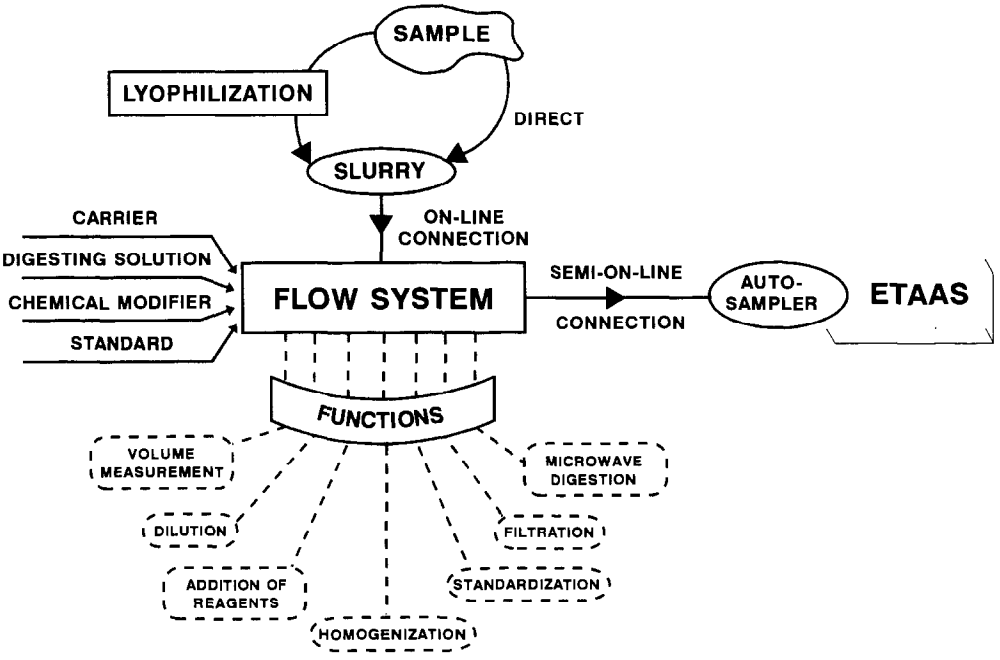

Fig. 5. Introduction of sample slurries into a flow system connected semi-on-line to an electrothermal atomic absorption spectrometer (ETAAS). For details, see text.

tor-commutator that facilitates the simultaneous introduction of two microvolumes (sample and standard) into two streams of 0.2% (v/v) nitric acid carrier that are merged with a chemical modifier (magnesium and palladium nitrate). The mixed solution (as slurry) is passed through a mixing chamber and then loaded into an autosampler cup for 120 s (2 ml). The turbulence arising from continuous dropping of the diluted/homogenized sample into the cups ensured adequate homogenization of the slurry. The results obtained are consistent with those provided by the classical dry ashing procedure and better than those of the wet ashing method, which exhibits severe contamination during sample preparation, as well as poor precision. The method was validated with a certified reference material (not-fat milk powder) from NIST [9].

The insertion of a paper disk sandwiched into a PTFE filter in the flow system allowed the direct speciation of aluminium [10] and selenium [11] in fruit and tomato juices, (i.e., the determination of the distribution of these elements in the suspended solids and in the aqueous phase of the foodstuffs). The ensuing methods are based on sequential, direct introduction of the juice slurry into two identical loops. In the first step, the contents of one loop are carried by a 0.2% HNO_3 stream, mixed with a magnesium (for Al) or palladium (for Se) nitrate chemical modifier solution and then filtered, the filtrate being loaded into an autosampler cup for determining the metal content in the liquid phase. In the second step, the contents of the other loop are flushed by the carrier and merged with the modifier stream, the mixture being loaded into another sample cup for the determination of the total metal content in the slurry; simultaneously, a stream of nitric acid washes the filter in the opposite direction. The metal content in the suspended solid is obtained by difference. The results obtained in the determination of the total metal content agree well with those obtained by the dry ashing method. This continuous methodology also allows one to dis-

criminate between the metal content in the solid and liquid phase; aluminium and selenium exist largely (60–90%) in combined forms in the liquid phase of fruit juices.

More complex samples entail implementing a new step in the flow system: microwave digestion of the slurry after mixing with a digesting plug (6 mol l^{-1} nitric acid). The use of air streams to transfer the sample to the microwave oven and an open system to collect the digested sample minimizes the well-know problems posed by digestion fumes. This methodology was successfully applied to the determination of aluminium [12] and selenium [13] in shellfish (mussels, clams, cockles, oysters and prawns) with excellent results. A parallel study was performed with lyophilized and unlyophilized samples of the same origin in order to check whether this typically tedious operation was necessary. The consistency between the two set of results revealed that the method can be directly applied with no lyophilization [13]. For aluminium, a correction factor must be used because the maximum recovery obtained was about 90%.

5.2. Solids as reaction ingredients

Solids can play an active role in analytical reactions taking place in coupled flow system, whether as reagents, catalysts or products (e.g., precipitates). Thus, they can be a permanent element of the flow system or be formed in situ. Analytes can be metal (ions) or organic species giving rise to direct or indirect determinations, respectively. Several examples illustrating these possibilities are described below.

The indirect determination of various oxidant drugs such as methadone [14], chloramphenicol [15] and chlordiazepoxide [16] can be accomplished by using a metal such as cadmium (uncoppered or coppered) or zinc packed in a minicolumn as reductant for specific organic groups such as keto, nitro and *N*-oxide to form alcohol, amine and azo functions, respectively. The stoichiometric amount of metal ion produced by passing the sample plug through the column is determined with an atomic absorption detector connected on-line to a straightforward flow injection manifold. The ensuing methods offer adequate sensitivity, selectivity and precision, and can thus be applied to pharmaceutical preparations and biological fluids. Recoveries range from 97 to 103%.

Over 90% of applications involving the formation, filtration, washing and dissolution of precipitates in continuous flow systems use an atomic absorption detector for direct or indirect determinations. The first such system was proposed by our research team in 1987 [17]. A variety of similar determinations have been reported ever since [5,18]. They are based on the reaction of a metal ion with an organic or inorganic anion and the retention of the precipitate on a filter. The continuous determination can be carried out on the metal excess in the filtrate (by measuring the difference between the initial concentration of the metal in the carrier and the concentration in the filtrate) or on quantitation of the metal contents in the precipitates. Thus, there are two different approaches depending on whether or not the precipitate is dissolved. Metal ions such copper, cobalt, nickel, lead, manganese and calcium, can be preconcentrated in these systems by forming a precipitate (a basic salt, or a quelate) and rapidly dissolving it after filtration; therefore, the procedure involves at least two steps. The indirect determination of halides in a variety of samples was achieved using silver ion as reagent; it even affords resolving a mixture of chloride and iodide ions in foodstuffs by selective dissolution of the silver chloride in ammonia [19]. A variety of organic anions of great practical interest can be indirectly determined in these continuous precipitation systems; typical examples include the determination of alkaloids (papaverine, strychnine and cocaine) using Dragendorff's reagent [20]; reducing sugars in wines using Fehling's reagents [21]; saccharin in mixtures of sweeteners with silver nitrate [22]; and tannins in wines and teas using the Folin-Ciocalteu reagent [23]. Coprecipitation without filtration was first reported by Fang et al., in 1991 [24]; the problems arising from the handling of a relatively large amount of precipitate in a flow system have been overcome by using knotted reactors as filterless precipitate collectors.

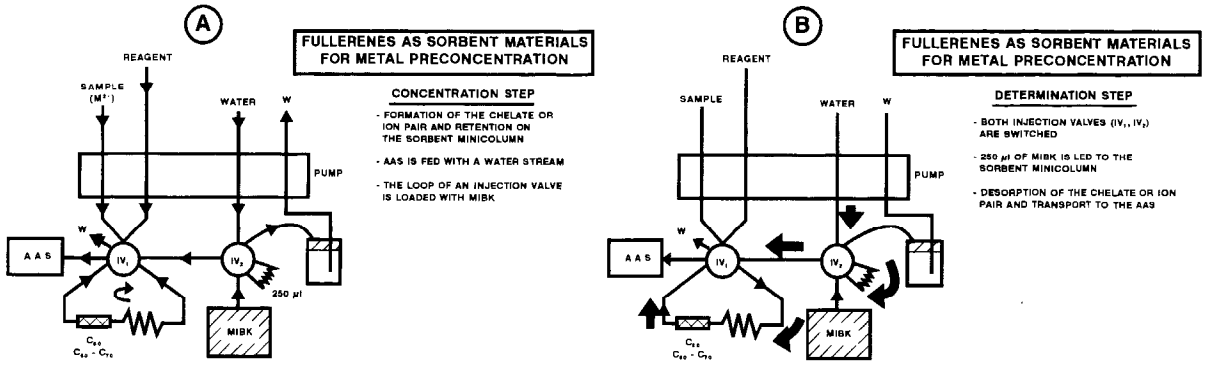

Fig. 6. Use of new sorbent materials (fullerenes) for the determination of metal traces by formation of chelates or ion-pairs. (A) concentration step; and (B) determination step. MIBK, methyl isobutyl ketone; IV, injection valve; W, waste; AAS, atomic absorption spectrometer. For details, see text. (Adapted from [25] and [26], with permission of the American Chemical Society).

5.3. Solids in continuous separations

The other way of using solids in flow systems coupled on-line to atomic spectroscopic instruments is by implementing non-chromatographic continuous separation techniques [7]. In this context, solids can act as filters in the above described continuous precipitation/dissolution systems; as membranes in dialysis, gas- diffusion and liquid–liquid extraction procedures; and as sorbents in solid-phase extractions. A detailed description of these approaches is beyond the scope of this paper (there are literally hundreds of publications on this topic) [2,5]. A survey of available literature can give the impression that innovation in such a widely explored field is virtually impossible. However, our group recently showed new ways for advancement. Thus, the use of new solid materials can open previously unexpected prospects. Such is the case of fullerenes as new sorbent materials for the concentration/determination of metal ions. Fig. 6 shows the manifold used for this purpose.

In the concentration step (Fig. 6A), the sample and ligand (and/or counter-ion) streams are continuously merged and passed through the loop of injection valve IV_1, and then sent to waste. A neutral chelate or ion-pair is formed in the reaction coil and retained on the sorbent minicolumn. The nebulizer of the atomic absorption spectrometer is continuously fed with a water stream. The loop of the second injection valve, IV_2, is loaded with methyl isobutyl ketone from a displacement flask. In the second step (Fig. 6B), both valves are simultaneously switched. The injected organic plug is led to the sorbent minicolumn, thereby effecting the rapid desorption of the chelate or ion-pair, which is directly transported to the nebulizer. A positive peak proportional to the concentration of the metal ion in the sample is obtained as a result.

Lead traces can be determined in this type of continuous manifold by using ammonium pyrrolidine dithiocarbamate (APDC) as ligand. For comparison, two systematic studies using C_{18} bonded silica and activated carbon as sorbents were also performed [25]. An amount of 50 mg of each sorbent material was packed into columns of 0.7–1.8 cm length (depending of the sorbent) and 3 mm internal diameter for all the experiments. The C_{60} fullerenes sorbent exhibited the highest preconcentration factor, lowest detection limit and widest pH range (at pH 0–5). The precision was similar for the three sorbents. Nevertheless, the most interesting feature of the new sorbent material is its selectivity. The effect of many common metal ions, that can form complexes with the chelating reagent (APDC), in the determination of cadmium and lead was listed in Table 1. In both

determinations the results obtained with C_{60} fullerene were compared with RP-C_{18} sorbent. As can be seen in Table 1, the selectivity was highest for C_{60} fullerene; this may have been the result of its larger surface area relative to C_{18}, in addition to its higher interstitial volume. The method is more favourable for the determination of cadmium than that for lead [25]. The selectivity of the fullerene sorbent was at least twice that of the C_{18} sorbent, for both elements. It is interesting to note that aluminium, iron, manganese and nickel are tolerated at concentrations thousands of times higher than that of lead, in contrast with the more modest ratios for RP-C_{18} [25].

The adsorptive potential of C_{60} and C_{70} fullerenes for the preconcentration of trace copper from aqueous solutions was also examined [26] using the formation of a neutral chelate with APDC, cationic chelates with 1,10-phenanthroline and neocuproine ligands forming ion-pairs with sodium dodecylsulphate, and an anionic complex with thiocyanate that in turn forms an ion-pair with dodecyltrimethylammonium bromide. The best analytical results (sensitivity and selectivity) were obtained with the neutral chelate and sorption on C_{70} fullerene thanks to its large surface area and high volume relative to C_{60} fullerene.

Table 1
Tolerated ratios of foreign cations to analyte in the determination of 10 or 50 ng ml^{-1} of cadmium or lead, respectively, with the APDC method

Foreign cation	Tolerated ratio			
	Cd determination		Pb determination	
	C_{60}	RP-C_{18}	C_{60}	RP-C_{18}
Al^{3+}	1000	600	1000	300
Zn^{2+}	1000	600	400	100
Pb^{2+}	1000	600	—	—
Mn^{2+}	1000	500	1000	200
Co^{2+}	1000	400	500	50
Cu^{2+}	1000	350	300	20
Fe^{3+}	1000	300	1000	20
Ni^{2+}	1000	200	1000	2
Sn^{2+}	800	400	400	100
Hg^{2+}	600	400	200	1
Cd^{++}	—	—	2	<1

6. Final remarks

The examples of the triple combination of solids, flow systems and atomic spectrometers briefly exposed in this paper, and many others not even mentioned for the obvious lack of space, demonstrate the possibility of expanding the scope of application of both flow systems and atomic spectroscopy, and of enhancing basic (sensitivity, selectivity and precision) and accessory analytical properties (expeditiousness, cost-effectiveness and personnel safety and comfort). The methodologies discussed have been validated by application to the resolution of real analytical problems.

Received 16 August 1996; received in revised form 1 October 1996; accepted 2 October 1996

Abstract

A general scheme is set up for the estimation of the impurity profile of bulk drug substances by the complex use of chromatographic, spectroscopic and hyphenated techniques. Several examples are presented as illustrations to the scheme from the authors' laboratory involving the use of chromatographic methods such as thin-layer-(TLC), gas-(GC), analytical and preparative high-performance liquid chromatography (HPLC), spectroscopic methods such as mass spectrometry (MS) and NMR spectroscopy as well as hyphenated techniques (HPLC/diode-array UV, GC/MS and HPLC/MS). In addition to summarizing earlier work, new examples are also presented: identification of an impurity (propyl 4-[diethylcarbamoyl(methoxy)]-3-methoxy phenylglyoxylate, **II**) in propanidid (**I**) and two unsaturated impurities in allylestrenol (**VII**) by GC/MS and HPLC/diode-array UV as well as estimation of the impurity profile of mazipredone (**III**) by HPLC/MS and HPLC/diode-array UV. © 1997 Elsevier Science B.V.

Keywords: Impurities; Propanidid; Allylestrenol; Mazipredone

1. Introduction

The estimation of the impurity profiles of bulk drug substances is one of the most important fields of activity in contemporary industrial pharmaceutical analysis [2]. In general impurities present in excess of 0.1% should be identified and quantified by sufficiently selective methods but drug registration authorities are increasingly interested in impurities in the range 0.01–0.1% [3] The main reasons for the increasing interest of drug manufacturers and drug registration authorities in the impurity profiles of bulk drug substances are as follows:

a. In the course of the development of a new drug or a new technology for manufacturing an existing drug it is essential to know the structures of the impurities: by possessing this information synthetic organic chemists are often able to change the reaction conditions in such a way that the formation of the impurity can be avoided or its quantity reduced to an acceptable level.

PII S0039-9140(96)02179-0

b. Having suggested structures for the impurities, they can be synthesized and thus provide final evidence for their structures previously determined by spectroscopic methods.

c. The material synthesized (or in exceptional cases isolated by large scale preparative column chromatography) can be used as an 'impurity standard' during the development of a selective method for the quantitative determination of the impurity and the use of this method as part of the quality control testing of every batch.

d. In the case of major impurities the synthesized or isolated material can be subjected to toxicological studies thus greatly contributing to the safety of drug therapy.

e. The impurity profile of a drug substance depends on several factors such as the synthetic route, reaction conditions, source and quality of the starting materials, reagents and solvents used during the synthesis, the purification steps, conditions of crystallisation, distillation, drying and storage of the endproduct, etc. For this reason in the hands of drug authorities the impurity profile of a drug substance is a good fingerprint to indicate the level and constancy of the manufacturing process of the bulk drug substance: even minor changes of the above listed factors may cause dramatic changes in the impurity profile.

As a consequence of the above points the impurity profile of a bulk drug substance has to be checked repeatedly not only during the research and development period but in addition in all cases when changes take place in the factors listed under e. above. For this reason the estimation of impurity profiles of bulk drug substances is a frequent task, especially in industrial analytical research and quality control laboratories. Taking into account the large time and labour consuming nature of these studies it is essential to find a strategy which enables the results to be achieved within the shortest possible time with the greatest possible certainty. The aim of this study is to introduce a general scheme for the rational use of chromatographic, spectroscopic and hyphenated techniques in drug impurity profiling studies and to present several examples from the authors' laboratory as illustrations to the scheme.

2. Experimental

2.1. Instruments and methods

UV spectroscopy. Varian Cary 3 double beam instrument.

NMR spectroscopy (^1H and ^{13}C). Varian VXR-300 and Varian UNITYplus 500 spectrometers. Chemical shifts in the text are relative to $\delta_{TMS} = 0.00$.

Mass spectrometry. VG-TRIO-2 and Finnigan MAT 95 SQ tandem spectrometers.

Gas chromatography. Hewlett-Packard 5890A and Gas chromatography/mass spectrometry (GC/MS). Fisons MD-800. Column for GC and GC/MS DB-5 MS (J and W) fused silica capillary (30 m × 0.32 mm × 1.0 μm). EI^+ 70 eV. Ion source temperature 240°C.

Propanidid. Temperatures: column (150°C for 9 min, 150–260°C at 10°C min^{-1}, 260°C for 10 min, 260–300°C at 10°C min^{-1}, 30 min at 300°C), injector and FID (250 and 300°C, respectively); split ratio 1:50.

High-performance liquid chromatography (HPLC). Hewlett-Packard 1090A equipped with an HP 1040 diode-array UV detector.

Propanidid. Column: 250 mm × 4 mm packed with LiChrospher Si-60 5 μm (Merck); eluent: hexane–methanol–2-propanol (90:8:2, v/v/v) at a flow rate of 1 ml min^{-1} at ambient temperature. Diode array detector set at 210, 282 and 320 nm or used in the spectrum scanning mode.

Allylestrenol. Column: 150 mm × 4 mm packed with Hypersil ODS 5 μm (Shandon); eluent: acetonitrile–methanol–water (64:18:18, v/v/v) at a flow rate of 1 ml min^{-1} at ambient temperature. Diode-array detector set at 210 and 240 nm or used in the spectrum scanning mode.

High-performance liquid chromatography/mass spectrometry (HPLC/MS). Waters 600/ Finnigan MAT 95 SQ.

Mazipredone. Column: 100 × 4.6 mm packed with Hypersil BDS C8 3 μm (Shandon); eluent: 25 mM ammonium acetate–methanol (65:35, v/v) at a flow rate of 1 ml min^{-1} at ambient temperature. Diode-array detector set at 240 nm or used in the spectrum scanning mode. The

mass spectrometer was used in the APCI (atmospheric pressure chemical ionisation) mode. Corona current: 4.8 μA. Temperatures: vaporizer 400°C, capillary 200°C. Sheath gas: nitrogen at 5.0 bar.

2.2. Samples

The investigated materials were laboratory or industrial samples from the Chemical Works of Gedeon Richter Ltd., Budapest.

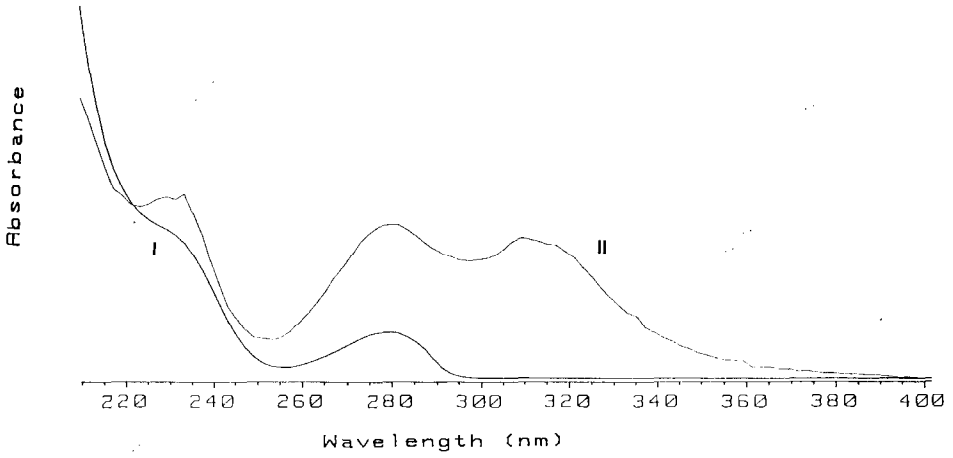

Fig. 2. Diode-array UV spectra of propanidid (**I**) and impurity **II**. See Section 2 for the HPLC conditions.

3. Results and discussion

3.1. General scheme for drug impurity profiling

As seen in Fig. 1 the procedure of impurity profiling begins with detecting the impurities on the thin-layer chromatograms, high-performance liquid chromatograms or gas chromatograms. (In the latter case caution is necessary since minor peaks originating from the thermal decomposition of the investigated drug material can easily be confused with real impurities.) The next step is to obtain as many potential impurity samples from the synthetic organic chemists as possible. These include the last intermediate of the synthesis, products of predictable side reactions and degradation reactions (if available). These samples should undergo retention matching with the previously detected impurities in the chromatographic systems where they were detected. The criterion for a positive identification is identical R_f or retention time in at least three different chromatographic systems selected in such a way that the separation mechanisms should be as different as possible. (In addition to the agreement of the retention data the TLC reflection spectra or the colour after visualization as well as the HPLC diode-array spectra, etc. should also be identical.)

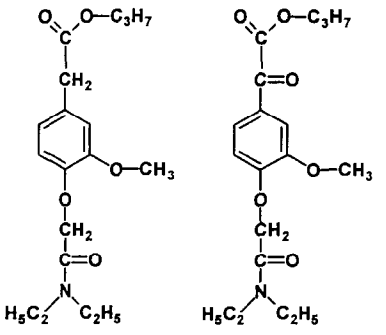
In the case of unsuccessful identification with standard samples the most reasonable way to determine the structure of the impurity starts with the investigation of the UV spectra, easily obtainable with the aid of the diode-array detector in the case of HPLC and the densitometer with reflection spectrum scanning facilities in the case of TLC. Although in the majority of cases the UV spectra of the impurities do not markedly differ from that of the main component, in some instances even minor differences are of diagnostic value and hence because of the ease of obtaining the spectra by means of the standard HPLC and TLC instrumentation, it is reasonable to try to draw as much conclusions from the UV spectra as possible. In exceptional cases (with full knowledge of the synthesis of the drug material) it is even possible to propose a structure for the impurity exclusively on the basis of the UV spectrum thus saving much time and efforts or at least the information thus obtained can be a useful complement to those obtained from the mass- and NMR spectra [4].

If the information obtainable from the UV spectrum is not sufficient, the next step in the procedure of impurity profiling is usually to take the mass spectrum of the impurity. Of course the most effective way to do this is to make use of the on-line GC/MS or HPLC/MS facilities available in the majority of laboratories dealing with impurity profiling. A great benefit of these techniques is that data can be obtained simultaneously on

several impurities down to the 0.01% level. An advantage of the GC/MS method is that reliable molecular weight value is obtainable using chemical ionisation and, in addition, information on fragmentation necessary for the solution of more complicated structure elucidation problems can also be obtained using the electron impact ionisation technique. A disadvantage is that due to volatility and thermal stability problems the possibilities of this method are limited. (The use of derivatization reactions widely used in other fields of GC/MS analysis is problematic here because the side-products of the derivatization reaction can be confused with the impurities.) An advantage of the HPLC/MS method [5] is its general applicability. A disadvantage is, however, that the ionisation techniques used in association with the generally used instruments (the older thermospray and the more up-to-date electrospray and atmospheric pressure chemical ionisation (APCI) techniques) usually give only molecular weight information. To obtain the fragmentation pattern highly sophisticated HPLC/MS/MS facilities are necessary.

It is worth mentioning that capillary electrophoresis (CE) is increasingly used in drug impurity profiling as an alternative to the above chromatographic techniques [6]. This technique can also be coupled with mass spectrometry [5].

If the hyphenated GC/MS, LC/MS or CE/MS facilities are not available, mass spectra can be taken on samples obtained from preparative or—



Scheme 1.

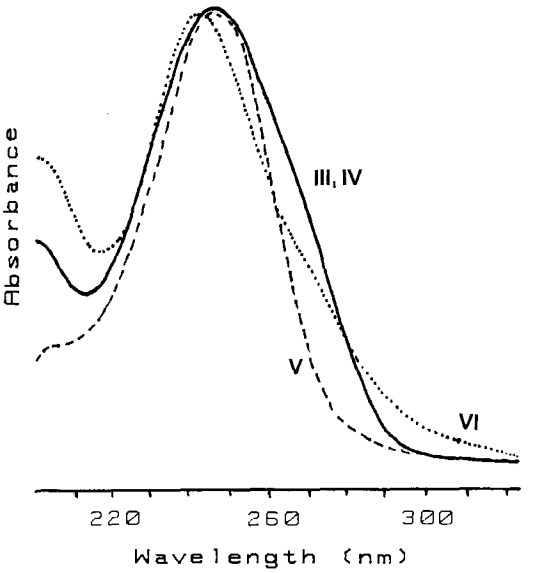


Fig. 3. Diode-array UV spectra of mazipredone (**III**) and impurities **IV**, **V**, **VI**. See Section 2 for the HPLC conditions.

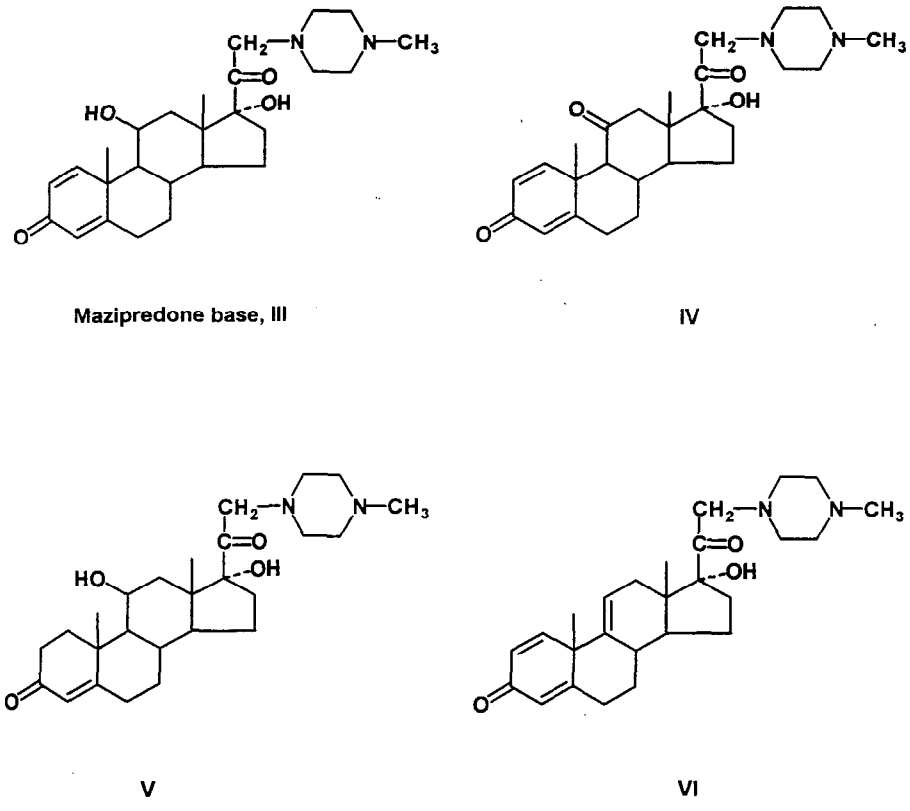
due to the high sensitivity of mass spectrometry—analytical TLC or HPLC.

In the majority of cases the information from the mass spectrum (together with the previously taken UV spectrum) is sufficient to propose a structure for the impurity. If not, NMR spectroscopy is the ultimate method for elucidating the structure of the impurity. Due to the limited sensitivity of this method NMR spectra are usually obtained on samples from preparative HPLC (or TLC) separation. Quite recently on-line HPLC/NMR instruments became commercially available [7]. This new hyphenated technique will certainly have a bright future in various fields, among them in drug impurity profiling.

The next step in the impurity profiling is the synthesis of the material with the proposed structure. The retention and spectral matching of the synthesized material (impurity standard) with the impurity in question is carried out as outlined above. In the case of successful matching the procedure of impurity profiling is terminated by working out selective quantitative methods for the determination of the impurity making use of the impurity standard.



Scheme 2.

The possibilities of spectroscopic techniques in drug impurity profiling without chromatographic separation are also worth mentioning. Spectra obtained by using high-resolution, highly sensitive NMR spectrometers and mass spectrometers with FAB or electrospray/APCI facilities are suitable to provide a fingerprint-like picture regarding the purity of the sample. In addition to this, in advantageous cases (especially if there is only one major impurity in the sample), conclusions can be drawn from the minor NMR signals regarding the structure of the impurity. Making use of the above mentioned MS facilities the molecular weight of the impurity can be obtained, if it differs from that of the main component, and this can also be a useful information in the course of the impurity profiling procedure. It has to be emphasized, however, that investigations of this type by no means substitute for the systematic chromatographic analysis in the search for the structures of the impurities.

3.2. Practical examples from the authors' laboratory

Characteristic examples where the UV spectra obtained by the HPLC diode-array UV detector were of diagnostic value are the structure elucidation of 3,17α-diethinyl-13-ethyl-3,5-gonadien-17-ol (an impurity in norgestrel with the characteristic *trans*-dienine UV chromophore) [1], identification of 9(11)-dehydro derivatives as impurities in oestradiol [8], ethinyloestradiol [9] and mestranol [10], where the difference between the spectra of the phenol-type main component and its α,β-unsaturated impurity is remarkable and on the basis of the UV spectra even to differenciate between the three regioisomers (Δ^6, $\Delta^{8(9)}$ and

$\Delta^{9(11)}$) was also possible. The discrimination between 4-ene-3-keto- and 1-ene-3-ketosteroids was also possible on the basis of the rather large difference between their UV maxima (228 and 237 nm in the apolar eluent of the normal-phase HPLC system used in this study) [11]. However, even minor differences can be of diagnostic value such as in the case of the identification of 8(14)-dehydronorgestrel as an impurity in norgestrel where the slight hypsochromic shift (2 nm) of the band of the α,β-unsaturated 3-keto group together with the remarkable band broadening is characteristic of 'through-space' conjugation with the $\Delta^{8(14)}$ double bond [9]. Another example of this type is the identification of 6α- and β- as well as 10β-hydroxy derivatives as impurities in norgestrel [11].

In the following examples the diode-array UV spectra together with the off-line mass spectra afforded sufficient evidence for the structure elucidation of various impurities. In an impurity of oestradiol (4-chlorooestradiol) the mass spectrum indicated the presence of a chlorine atom in the phenolic ring while its position was established on the basis of the UV spectrum [8]. Another example is the identification of propyl 4-[diethylcarbamoyl(methoxy)]-3-methoxy phenylglyoxylate (**II**) impurity (oxidative degradation product) in propanidid (**I**). The molecule peak of **II** from a GC/MS scan was at m/z 351 (t_R = 34.6 min) while the molecular weight of **I** is 337 (t_R = 30.5 min). In the normal phase high-performance liquid chromatogram of propanidid **I** appears at 11.9 min, while the peak of **II** is at 16.4 min. It is evident from the diode-array UV spectra of **I** and **II** in Fig. 2 and Scheme 1 that the reason for the difference of 14 units between the molecular weights of **I** and **II** is that in the latter the active methylene group of **I** between the phenolic ring and the propyloxycarbonyl group is oxidized leading to a highly conjugated ketone derivative .

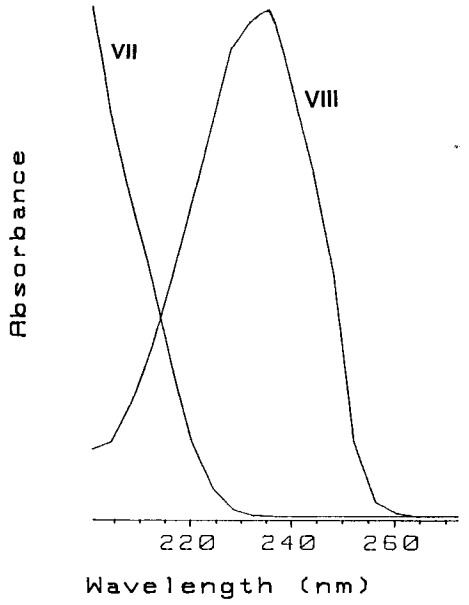


Fig. 4. Diode-array UV spectra of allylestrenol (**VII**) and impurity **VIII**. See Section 2 for the HPLC conditions.

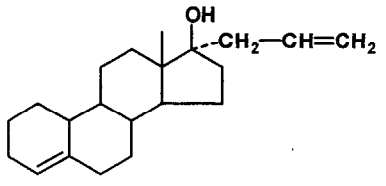
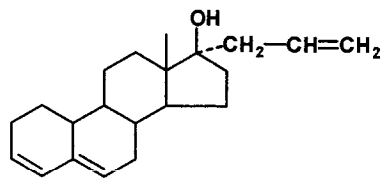
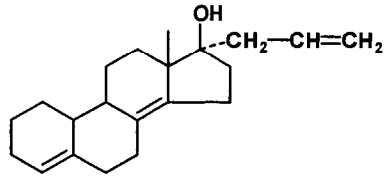
In the following the potential of the LC/MS technique supplemented with information obtained from diode-array UV spectra will be demonstrated on the example of the impurity profiling of mazipredone (21-deoxy-21-*N*-methylpiperazinyl-prednisolone hydrochloride, **III**), the water-soluble prednisolone derivative of the Chemical Works of Gedeon Richter Ltd., Budapest. Under the HPLC conditions described in Section 2 the retention time of mazipredone (**III**) is 30.7 min. In addition to minor trivial impurities such as prednisolone (retention time 24.9 min) and prednisolone-21-mesylate, the last intermediate of the synthesis (retention time 48.5 min) we report on the identification of three main impurities present in the range 0.1–0.4%. It is to be noted that under the APCI conditions described in Section 2 only the molecular weights of the protonated compounds are obtainable. The molecular weight of **III** is 442 (MH^+ = 443). The molecular weight of 440 of impurity **IV** eluting at 28.2 min indicates that the 11-hydroxyl group in **III** is replaced by a 11-ketone group.This is supported by the full identity of the diode-array UV spectra of **III** and **IV** [12] (Fig. 3 and Scheme 2). Impurity V (29.9 min) has a molecular weight of 444. It can be seen from its UV spectrum that the additional hydrogen atoms are at the 1 and 2 positions: the absorption maxima of 1,4-diene-3-keto and 4-ene-3-keto steroids are known to be at nearly the same wavelength but the bandwidth of the latter is much smaller [12–15]. The molecular



Allylestrenol, VII



VIII



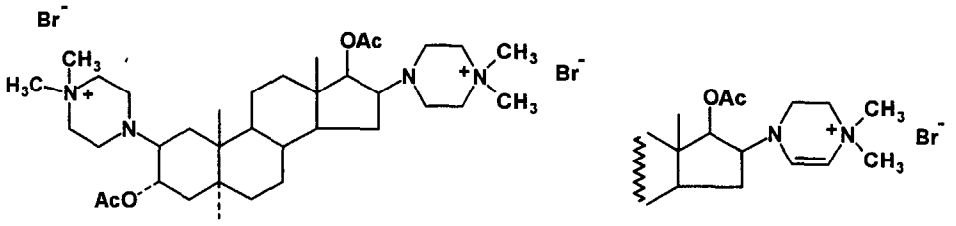
IX

Scheme 3.

weight of impurity **VI** (retention time 41.2 min) is 424. This indicates the loss of one molecule of water from the parent compound: either Δ^{16} or $\Delta^{9(11)}$ derivative. The hypsochromic shift observable in Fig. 3 is characteristic of the latter [12], the structure of which was proved by synthesis, retention and spectral matching. It is noteworthy that the characteristic molecular weights of the protonated forms of **IV–VI** (441, 445 and 425) could be estimated by direct APCI investigation of the contaminated sample of mazipredone without any chromatographic separation.

An example of the use of the GC/MS method is the impurity profiling of flumecinol (3-trifluoromethyl-α-ethyl-benzhydrol) [10,16,17]. This technique has also been successfully used (usually combined with other methods) in the impurity profiling of steroids, e.g. the identification of 3-deoxonorgestrel impurity in norgestrel [1], several impurities in 2-androstene-17-one (intermediate in the synthesis of pipecuronium bromide) [18] and in bulk cholesterol [19].

A recent example for the use of GC/MS supplemented by other spectroscopic techniques is the estimation of impurities **VIII–IX** in allyloestrenol (**VII**). The gas chromatographic retention times were as follows: **VII** 7.2 min, **VIII** 7.9 min, **IX** 6.3 min. The molecular weight of **VII** is 300 whereas those of **VIII** and **IX**, obtained from the GC/MS scans, is 298 indicating the presence of one additional double bond. The location of this in the structures of **VIII** and **IX** was estimated on the basis of the fragmentation pattern in the mass spectra and from NMR spectra obtained on samples isolated by preparative HPLC. The location of the additional double bond at the 8(14) position in **IX** is supported by a base peak at m/z 214 which is due to the cleavage of the C_{13}–C_{17} and C_{15}–C_{16} bonds (β-cleavage related to the 8(14) double bond). Further evidence is furnished by the NMR data. The chemical shifts (in $CDCl_3$) of the protons and carbons in the environment of the two bonds in the steroid nucleus are as follows. ^{1}H NMR: 1.09 (3 H, s, H-18), 5.44 (1 H, m, H-4); ^{13}C NMR: 21.7 (q, C-18), 120.1 (d, C-4), 130.8 (s,C-8), 136.2 (s,C-14), 140.0 (s,C-5). The base peak in the mass spectrum of **VIII** is the molecule peak. The intense fragment ion at m/z



Pipecuronium bromide, X XI

Scheme 4.

199 (88%) is due to the cleavage of the C_{13}–C_{17} and C_{14}–C_{15} double bonds. NMR chemical shifts (in DMSO-d_6) supporting the 3,5-diene structure are as follows. ^{1}H NMR: 0.81 (3 H, s, H-18), 5.42 (1 H, m, H-6), 5.64 (1 H, m, H-3), 5.95 (1 H, m, H-4); ^{13}C NMR: 14.4 (q, C-18), 122.7 (d, C-6), 126.4 (d, C-3), 129.5 (d, C-4), 136.2 (s, C-5). In the case of **VIII** the HPLC/diode-array UV spectral scan (see Fig. 4 and Scheme 3) also contributed to the structure of this conjugated *trans*-diene type impurity; (retention times: **VII** 12.8 min, **VIII** 8.1, **IX** 10.0 min).

Some examples for the complex use of chromatographic and spectroscopic techniques including NMR spectroscopy are, for example, the identification of two isomeric impurities (Z and E ethynodiol-3-acetate-17-(3′-acetoxy-2′-butenoate) in ethynodiol diacetate [20], epimeric 17α-hydroxy-17β-ethinyl and ethinyl-bridged dimeric derivatives in norethisterone [9,17], impurities with a methyl group attached to the aromatic ring of the main component in hexoestrol [10] and enalapril [20], isodanazol in danazol [21], 3-[2-(diaminomethyleneamino)thiazol-4-ylmethylthio]-*N*-cyano-propionamidine in famotidine [17], 2,5-bis-[(*N*′-cyano-*N*″-methyl)guanidino-ethyl-thiomethyl]-4-methylimidazole and 1,8-bis-[(*N*′-cyano-*N*″-methyl)guanidino]-3,6-dithiaoctane in cimetidine [22] as well as 3,17α-diethinyl-13-ethyl-3,5-gonadien-17-ol in norgestrel [1].

The last example merits special attention. NMR spectroscopy not only played a predominant role in the structure elucidation of 2′-dehydropipecuronium bromide (**XI**) impurity in pipecuronium bromide (**X**) but (due to the absence of signals in the ^{1}H-NMR spectrum of the latter in the 5.2–6.3 ppm range) the estimation of the doublets of the vinylic protons at 5.26 and 6.29 ppm enabled the impurity to be detected and even quantitated (using the internal standard method) down to the level of 0.5% in **X** without chromatographic separation [20] (Scheme 4).

Abstract

Fabrication and characterization of miniature, flexible, planar biosensors for monitoring L-lactate accumulation in an ischemic myocardium are described. Three configurations of Au-based electrodes were fabricated by a photolithographic technique on flexible polyimide Kapton® foil. All sensors are based on an immobilized lactate oxidase with amperometric detection of the enzymatically produced hydrogen peroxide at a platinum-electroplated-gold base electrode polarized at 0.5 V versus Ag/AgCl. An inner electropolymeric layer is used to prevent electrode fouling and to reject the interference effects of easily oxidizable molecules. In addition, a diffusion controlling outer layer that greatly enhances the linear dynamic range of the sensor, is obtained by casting a polyurethane external film. The developed sensor was evaluated in vitro and proved to have high selectivity, good operational stability, good accuracy and precision (average recovery = 102.3 ± 0.4% for control sera), fast response time (t_{95} = 20 s) and high upper limit of the linear dynamic range (25–80 mM, with sensitivity of 1.7–0.4 nA mM^{-1}, respectively at PO_2 = 15 mmHg). Subsequently, the sensor was brought into direct contact with the surface of the rabbit papillary muscle and used for continuous quantitative monitoring of extracellular lactate accumulation during no-flow ischemia. © 1997 Elsevier Science B.V.

1. Introduction

Lactic acid is an important metabolic product formed during anaerobic glycolysis as glucose is used for the generation of ATP [1,2]. Transsarcolemmal transport of lactate-anion and diffusion of lactic acid are believed to be important mechanisms regulating intracellular pH during cellular metabolic stresses such as anoxia, hypoxia, ischemia and chemical inhibition of mitochondrial function. Moreover, lactate anion-dependent mechanisms may contribute to cellular potassium loss during metabolic stress [3]. An understanding

PII S0039-9140(96)02175-3

of the relation between lactate and K^+ efflux during ischemia is particularly important because accumulating extracellular K^+ contributes significantly to the occurrence of lethal ventricular arrhythmias during myocardial infarction [4]. Although extracellular lactate and K^+ have been measured independently, a notable absence of appropriate methods for measuring extracellular lactate accumulation in the absence of myocardial perfusion has prevented the study of their interdependence. Such an interdependence has been proposed [5] but remains controversial [6–8]. For this reason, we have sought a novel sensor to determine lactate in an ischemic myocardium with sufficient temporal and spatial characteristics as to allow the future measurement of extracellular K^+ simultaneously.

In the last two decades, enzyme-based amperometric biosensors have played an increasing role in solving analytical and clinical problems [9–11]. Several enzyme electrodes for the electrochemical determination of L-lactate have been developed by using immobilized enzymes, such as: lactate dehydrogenase (cytochrome b2) (EC 1.1.2.3) [12,13], lactate dehydrogenase (EC 1.1.1.27) [14], lactate 2-monooxygenase (EC 1.13.12.4) [15] and lactate oxidase (EC 1.1.3.2) [16].

Lactate oxidase (LOD) has attracted a considerable degree of attention. It is widely used with different immobilization techniques such as crosslinking with bovine serum albumin and glutaraldehyde [17,18], entrapment behind a polymeric membrane [19], attachment to a preactivated membrane [20], entrapment in an electropolymeric film [21,22], entrapment in a photopatterned poly-HEMA hydrogel membrane [23], entrapment in a polyion complex layer [24], and crosslinking with isocyanate [25]. There are also several LOD-based sensors that employ non-physiological electron acceptors, instead of O_2, to communicate electrons between the redox center of lactate oxidase and the electrode surface [26–28].

Some of the previously reported lactate biosensors have been successfully applied in real samples. Subcutaneous microdialysis [19], suction effusion fluid [18] and double lumen catheter [29] are collecting techniques and were coupled with lactate probes for lactate monitoring in subcutaneous rabbit tissue, and blood of healthy volunteers, respectively. In addition, some other implantable lactate sensors were successfully used for lactate monitoring in subcutaneous rat tissue [17] and in the blood stream inside the right atrium of an anesthetized dog heart [30]. However, none of the previously reported sensors can be adapted for direct surface monitoring of extracellular lactate accumulation in ischemic rabbit papillary muscle. The needle type sensor described by Wilson [17] offers several advantages in terms of size, selectivity and stability. However, the cylindrical geometry of the needle sensor is not suitable for measurement on the muscle surface. With the needle type sensor, the active electrode area varies widely depending on whether the muscle is perfused or not. Moreover, the linear dynamic range (20 mM) of the needle sensors may be not enough to cover the expected high lactate concentration formed during extended periods of no-flow ischemia. With direct contact between the sensor and myocardium, there is no chance to dilute the accumulated lactate with any fluid. This is the reason that the expected lactate level is significantly higher than the blood lactate. Limitations associated with the needle sensor were solved by constructing the sensor on miniature flexible planar substrate with the active part of the sensor localized on one side, facing the muscle. The flexible nature of the substrate ensured good contact to the muscle surface without interference with the rhythmic beating. A sensitive optimized enzyme layer, along with efficient diffusion control outer layer, significantly enhanced the linear range.

Microfabricated-planar amperometric biosensors have several advantages over conventional enzyme electrodes: small size, low cost and mass production capability. Additionally, they can be fabricated on flexible substrates. Photolithographic technique has been used already in the fabrication of many biosensors [18,31,32]. In the present work, three different configurations of planar microelectrodes were fabricated on a flexible polyimide substrate (Kapton® DuPont) by the standard photolithographic technique. Optimization of the sensor structure will be discussed.

The characteristics and the reliability of the sensor for lactate monitoring in control sera using both batch and flow setup are presented. Finally, measurements of the accumulation of extracellular lactate in rabbit ischemic myocardium are given. This study, using the developed sensor, permits cardiovascular scientists to gain better understanding of the lactate-dependent mechanisms of ionic homeostasis.

2. Experimental

2.1. Materials and reagents

Lyophilized lactate oxidase (LOD), E.C. 1.1.3.2., from *pediococcus* species, 34 U mg^{-1}, L-lactic acid (sodium salt), bovine serum albumin (BSA, fraction V), glutaraldehyde (GA), 25% aqueous solution, L-ascorbic acid, acetaminophen, uric acid (sodium salt), were obtained from Sigma, St. Louis, MO. Hydrogen hexachloroplatinate (IV) (99.9%), potassium silver cyanide, *m*-phenylenediamine (*m*-PDA), urea, *l*-cysteine, and 1,3-dihydroxyacetone were obtained from Aldrich Chemical, Milwaukee, WI. The medical grade aliphatic polyurethane (PU, Tecoflex SG-85A) was a gift from Thermedics, (Woburn, MA). All other chemicals were of analytical reagent grade.

Stock lactate solutions (0.5 M) were freshly prepared every week, in a 0.1 M phosphate buffer (PB) of pH 7.2 and stored at 4°C when not in use. Lactate standard solutions used in FIA measurements were prepared in a 0.1 M PB containing 100 mmole l^{-1} NaCl. This buffer was used as a carrier stream in FIA system as well. All solutions were prepared with water from a Barnstead Nanopure II system.

2.2. Apparatus

All electrochemical experiments were performed with a Princeton Applied Research Model 363 Potentiostat/Galvanostat connected to a Princeton Applied Research Model 175 Universal programmer for potential scanning. The potentiostat was modified to measure lower current values (sensitivities down to 1 V nA^{-1}). Current-time plots, cyclic voltammograms and FIA signals were recorded on a Hewlett Packard Model 7015B X-Y-T recorder. A temperature-controlled circulating water bath (Haake B3) was used throughout the work. A Rabbit peristaltic pump (Rainin Instrument) was used to pump the carrier solution through a single flow stream FIA system. A manual sample injection valve (Rheodyne, Model 7125), fitted with either 50 or 100 μl injection loop was used for sample injection.

2.3. Sensor fabrication

2.3.1. Wafer fabrication

Three configurations of planar gold electrodes were batch fabricated on a flexible polyimide (Kapton,® DuPont) substrate (125 μm thick) as shown in Fig. 1; single site electrodes (area = 0.06 cm^2) (used for all the optimization and characterization studies), two-electrode (1.75 × 3.5 mm) and three-electrode (3.5 × 4.5 mm) miniature chips, respectively. The two-electrode chip consists of a working electrode (area = 2.25 mm^2) and a reference electrode (area = 3.13 mm^2). This chip was used for all papillary muscle experiments. The three-electrode chip consists of a working, counter and reference electrodes of areas 3.75, 5.25 and 0.5 mm^2, respectively. This chip was used with the wall-jet FI analysis. The fabrication steps were described recently in more detail [33]. Two thin layers of chromium and gold, respectively were sputtered onto the Kapton substrate. The Cr layer enhances the adhesion of gold to the substrate. A layer of positive photoresist (JSR, 1 × 700 10 CP) was applied to the gold layer and then standard UV-lithographic technique was used to define the desired shape of the electrodes. The photoresist was developed, gold and chromium layers were etched, and the photoresist was then removed from the patterned metal surface. A photodefinable polyimide (Du Pont, PI2721) was used to define openings for the electrode sites and the bonding pads. Finally, each electrode (or cell) was cut from the wafer and connected, through the bonding pads, to electrical wire by means of Ag epoxy (Epoxy Technology,). The electrical contacts were insulated using silicone rubber coating seal (Dow Corning 3140 RTV). The base Au

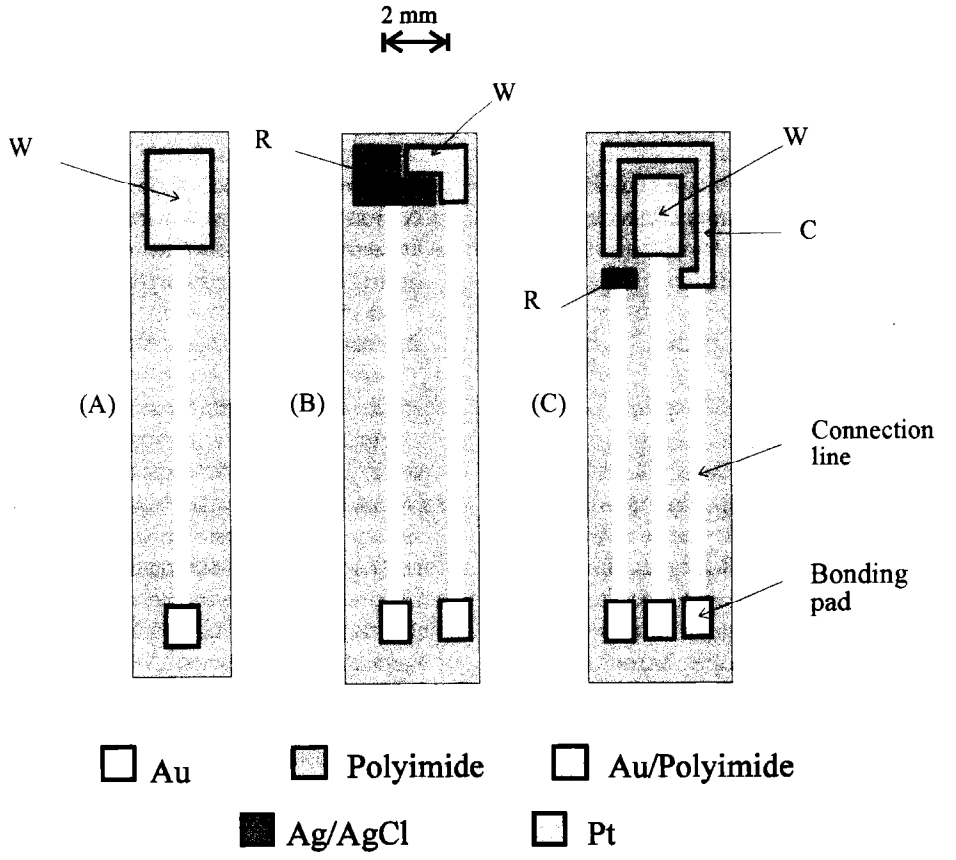

Fig. 1. Kapton-based substrates: single site electrode (A), two-electrode (B), and three-electrode chips. W, R and C refer to electrodes used as working, reference, and counter, respectively.

electrodes were then ready for further modification.

2.3.2. Electrochemical platinization

The platinization solution was prepared according to a well known method [34] as follow: 0.65 g $H_2[PtCl_6]$, 2.25 g $(NH_4)_2HPO_4$ and 4.73 g Na_2HPO_4 were dissolved separately each in ~10 ml water. The ammonium phosphate was added to the chloroplatinic acid with stirring. A yellow precipitate of $(NH_4)_2PtCl_6$ was formed; without filtering this solution, the sodium phosphate was added and the mixture was boiled gently with stirring for 2 h. The mixture was cooled and diluted to 50 ml with water. The electrodes for working or counter were electroplated by galvanostatic platinum deposition. A 5 cm diameter Pt mesh electrode was used as anode. Prior to plating, the gold electrodes to be platinized were cleaned by anodizing at 0.5 mA cm^{-2} for 25 s. in the same platinization solution. This bath was recommended for operation at 70°C with a current density of 2–5 mA cm^{-2} [34]. However, bright, smooth, and adherent platinum deposits were obtained at room temperature using a current density of 10–12 mA cm^{-2} for 5 min.

2.3.3. Electrochemical polymerization (inner layer formation)

Poly *m*-phenylenediamine film was prepared by electropolymerization using cyclic voltammetry. The film was grown from a gently stirred aqueous solution containing 10 mM *m*-PDA in 0.1 M PB pH 7.2. The potential was cycled from +0.2 to

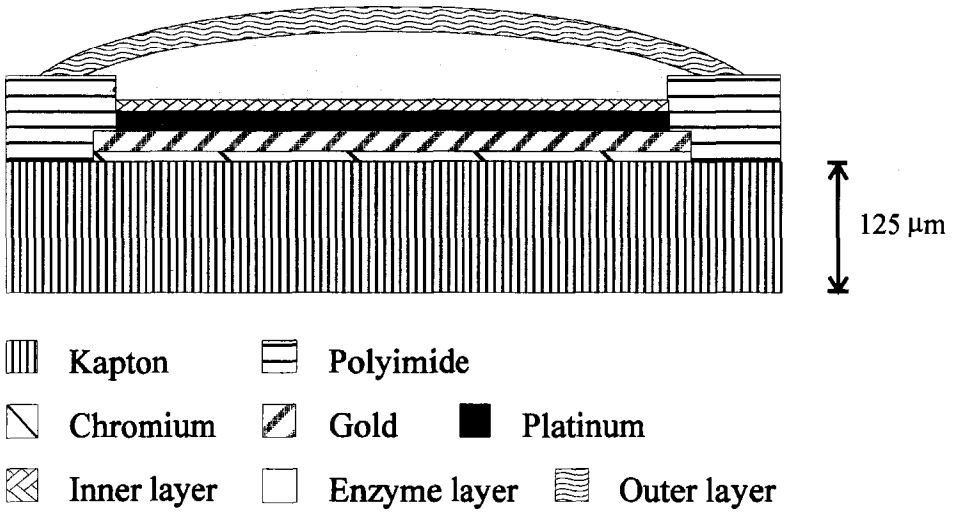

Fig. 2. Layer structure of the lactate biosensor.

+0.8 V versus Ag/AgCl at a scan rate of 2 mV s^{-1} for 12 cycles (2 h). The modified electrodes were washed with water and kept in 0.1 M PB at 4°C overnight. The selectivities of the electrodes towards common biological interferences, i.e., L-ascorbic acid, acetaminophen, uric acid, L-cysteine, urea, and 1,3-dihydroxyacetone were tested at 0.16, 0.16, 0.3, 0.1, 5.0, and 1.0 mM concentration level, respectively.

2.3.4. Enzyme layer (EL)

The immobilized enzyme layer was obtained by crosslinking LOD with BSA using GA. A 3 μl aliquot of a specified fresh enzyme mixture solution in PB was quickly syringed onto the electrode surface using a 5 μl syringe (Hamilton, Reno, Nevada). The enzyme layer was allowed to crosslink and to dry in air at room temperature for 1 h. The sensor was then washed thoroughly with water to remove excess reagents. The sensor was either stored in buffer at 4°C when not in use for EL optimization study, or dried in air for further modification with outer layer to complete the sensor construction.

2.3.5. Optimization of the enzyme layer

This study was done without inner polymeric layer. The term G/T was defined to reduce the number of variables to be investigated. G refers to the w/v% of glutaraldehyde and T refers to the total w/v% of LOD and BSA in the enzyme mixture solution. Initially, three sets of sensors (three in each) were prepared using different enzyme mixture solutions for which LOD was arbitrarily fixed at 6% (2 U μl^{-1}) and BSA was fixed at 5, 10, and 15% for the three sets, respectively. Among each set, G/T was adjusted to 0.03, 0.045 and 0.06, respectively. To study the effect of enzyme content, three different enzyme solutions were used containing 2, 4, and 6% LOD, respectively. BSA/LOD ratio was set at 1.4 and G/T ratio was set at 0.05. Finally, to study the effect of glutaraldehyde, three different compositions with 2% LOD—3% BSA and G/T of 0.05, 0.06 and 0.07, respectively were tested.

2.3.6. Outer membrane (OM)

To complete the construction of the sensor, a 3 μl aliquot of 1% w/v PU in pure THF was deposited above the enzyme layer by a microsyringe. The sensor was allowed to dry in air at room temperature for 5–10 min, washed with water and stored in PB at 4°C when not in use. A cross section of the whole layer structure of the sensor is shown in Fig. 2.

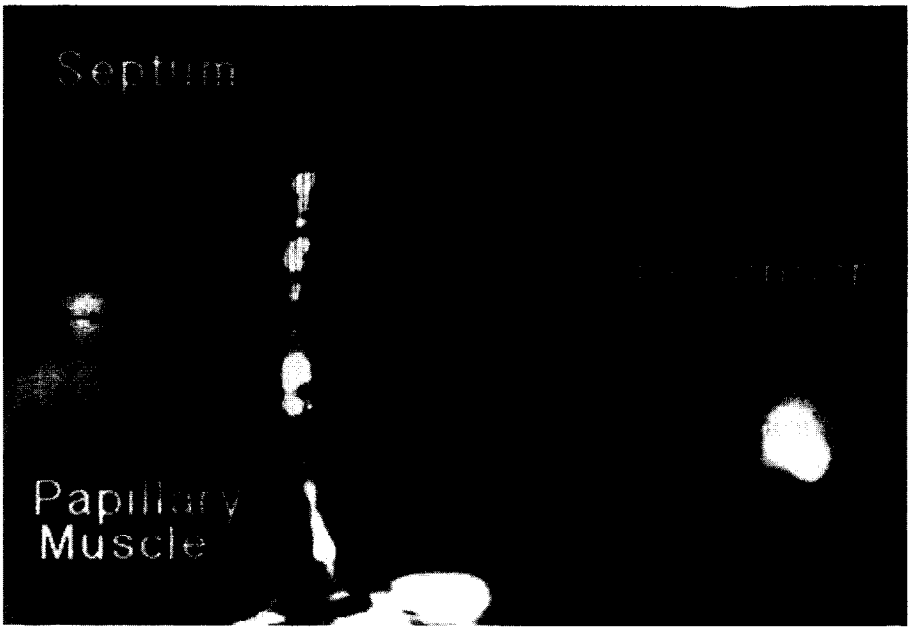

Fig. 3. The isolated arterially perfused RV rabbit papillary muscle is suspended in an artificial atmosphere and in contact with the two-electrode chip (the active part is behind the muscle). Pt counter electrode not shown in the field. The tendonous end of the muscle is fixed to a rigid hook with a suture. Electrical stimulation is delivered at twice diastolic threshold through a Pt wire affixed to the tendon. The scale bar represents 1 mm.

2.3.7. Miniature chips fabrication

The working and counter electrodes were platinized as before. The electrode that served as a pseudo reference was galvanostatically plated with silver from a 1% w/v solution of potassium silver cyanide using 5 mA cm^{-2} for 10 min. About 25% of this silver is electrochemically converted to AgCl in 0.1 M HCl. The inner polymeric film was grown on the working electrode as before. A 2 and 4 μl aliquot of the enzyme mixture solution (2% LOD-3% BSA-0.3%GA) was delivered by syringe onto the surface of two- and three-electrode chips, respectively, and spread with the syringe tip to cover all the electrodes. A 5 μl aliquot of PU solution was used for outer membrane formation.

2.4. Amperometric measurements

A conventional three-electrode system was used for all amperometric batch measurements. A Pt wire served as the counter electrode and a miniaturized Ag/AgCl electrode with flexible barrel (Cypress System, Lawrence, KS) was used as the reference, against which all potentials were referred in the present work unless otherwise stated. All experiments were performed in a 7 ml double-jacket-thermostated cell containing a magnetically stirred 4 ml PB at 25.0 ± 0.1°C. The working electrode was polarized at 0.5 V in all the measurement.

2.5. FIA setup

A three-electrode miniature chip was used in a single channel wall-jet flow injection system. A carrier solution consisting of 0.1 M PB containing 100 mmole l^{-1} NaCl was propelled by means of a peristaltic pump through PTFE tubings (0.8 mm i.d.) at the desired flow rate. The tubing ended with a horizontally mounted 8 cm glass capillary tube (6.6 mm o.d. and 1.0 mm i.d.). The length of the tubing from the injection valve to the capillary was 25 cm. The free end of the capillary was cut

at 90°. This end of the tube was brought into contact with the cell surface. The miniature chip was mounted in a vertical position with connection wires directed upward.

2.6. Lactate measurement in control serum

The human based control sera level I and II (Dade® Moni-Trol® ES Chemistry Control, Baxter Diagnostics) were constituted from the lyophilized preparation according to the manufacturer's recommendation. The manufacturer's mean values of lactate concentrations were 1.5 and 4.9 mM, respectively. A 3 ml PB aliquot was placed in the cell. After background current stabilization, a 0.5 ml aliquot of the serum sample without any treatment, was pipetted into the cell. When the current reached a steady value, the standard addition procedure was used to evaluate the lactate concentration level. The obtained results were compared with the results obtained with the established YSI 2700 SELECT Biochemistry analyzer equipped with YSI 2329 lactate membrane. For measurements with flow system, a 100 μl aliquot of the untreated serum sample was injected into the carrier stream and lactate concentrations were evaluated by direct calibration method.

2.7. Arterial perfusion of isolated papillary muscle

New Zealand white rabbits ($n = 5$) of either gender weighing 2–3 kg were heparinized (200 U kg^{-1}, i.v) and anesthetized with sodium thiopental (50 mg kg^{-1}, i.v.) in accordance with accepted guidelines for the care and treatment of experimental animals at the University of North Carolina at Chapel Hill. The heart was excised and arrested in cold Tyrode's solution (in mmol l^{-1}: Na^+, 149; K^+, 4.5; Mg^{2+}, 0.49; Ca^{2+}, 1.8; Cl^-, 133; HCO_3^-, 25; HPO_4^{2-}, 0.4; glucose, 20) for 20 s. The atria and left ventricle (LV) free wall were removed. The LV septal surface of the tissue was pinned to a wax plate in contact with Ag/AgCl ground electrode. The septal artery was visualized with a dissection microscope, cannulated and perfused with an perfusate composed of Tyrode's solution plus insulin (1 U l^{-1}), heparin (400 U l^{-1}), albumin (2 g l^{-1}), and dextran (M_r 70 000; 40 g l^{-1}). The time between cross clamping the aorta and perfusion was < 5 min in each experiment.

The cannula was fixed to the septal artery with a purse string suture and the septum was secured in a custom made experimental chamber [35]. The non-perfused portion of the right ventricle (RV) was excised and the papillary muscles were exposed. A long and symmetrical muscle was chosen and the tendon was attached to a rigid pin with a fine monofilament suture. The perfusate was pumped by a peristaltic pump (Digi-Staltic, Masterflex, Barrington, IL) through a custom made membrane gas exchanger in which partial pressures of O_2, N_2, and CO_2 of the perfusate were controlled [35]. The chamber was closed and the preparation was surrounded by humidified gas with the same composition as the perfusate. The pH of the perfusate was continuously monitored by a glass pH electrode positioned in the perfusion line before entering the septal artery. The amount of CO_2 was adjusted in the gas exchanger to yield a pH of 7.35 ± 0.05. The temperature of the papillary muscle was maintained between 36 and 37.5°C by passing the perfusate through a thermostated water bath before entering the cannula to the septal artery. The PO_2, PCO_2, HCO_3^- concentration and pH of the perfusate entering the cannula were confirmed by blood gas analysis (System 1304 pH/Blood Gas Analyzer, Instrumentation Laboratory, Lexington, MA). Intraarterial pressure was measured with a pressure transducer (Millar, Houston, TX) and continuously monitored on a strip chart recorder. The septal artery pressure ranged between 35 and 50 mmHg and was maintained by adjustment of the perfusion flow rate (approximately 1.0–1.5 ml min^{-1} g^{-1} tissue).

2.8. Measurement of extracellular lactate

Two-electrode chip with working electrode of (area 2.25 mm^2) and a Ag/AgCl pseudo reference electrode (area = 3.12 mm^2) was positioned in direct contact with the suspended muscle as shown in Fig. 3. A separate platinum wire, serving as a counter electrode, was positioned at the base of

the papillary muscle on the septal surface. A 0.7 Hz 5 pole Butterworth low pass filter was used to eliminate the noise resulting from the electrical pulse stimulation of the muscle. While the muscle is perfused the sensor is polarized at 0.5 V against the pseudo reference electrode. The background current was allowed to reach a stable value. Ischemia was induced by arresting flow. The volume fractions of O_2 and CO_2 in the recording chamber were measured using the gas analyzer. The magnitude of lactate accumulation was monitored by recording the change of the sensor output against the time after arrest of flow.

Ideally, the sensor should be calibrated under the same experimental conditions, namely, arrest of flow after infusion of a standard lactate solution. However, such a calibration will not be reliable because under no-flow conditions the muscle will generate lactate. In this way the standard value will be completely uncertain. For this reason the sensor calibration was performed under flow conditions. We believe that such in situ calibration is more accurate than the in vitro calibration approach which is accepted when a calibration under identical condition is not possible, e.g., with in vivo measurements. The sensor was calibrated in situ, by perfusing the muscle with perfusate containing lactate at 10 and 20 mM concentration levels, respectively. The current responses to the standard solutions were used to construct a two point calibration curve.

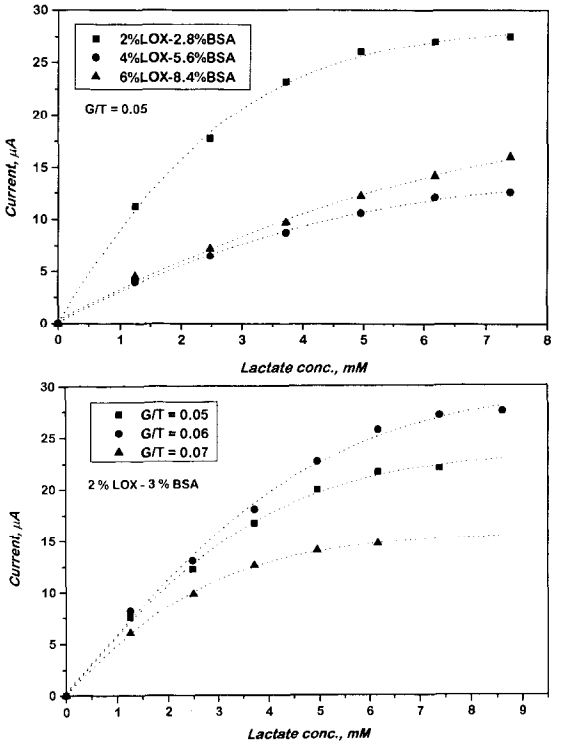

Fig. 4. (a) Effect of enzyme loading on the sensor response. (b) Effect of glutaraldehyde on the sensor response.

3. Results and discussion

3.1. Optimization of enzyme layer

Among many papers published for amperometric detection of lactic acid, only few papers [17,18,26,30,36] have adapted the crosslinking with BSA and GA as an immobilization technique for LOD. The reported ratios of LOD, BSA, and GA are widely varied, unjustified and sometimes incompletely mentioned [30]. In addition, Turner et al. [37] have published recently a paper on lactate, glutamate and glutamine biosensors. They immobilized LOD by mixing with hydroxyethylcellulose, and adapted glutaraldehyde crosslinking for the other two sensors. They apparently avoided crosslinking with glutaraldehyde as an immobilization technique. Moreover, Mulchandani et al. [38] have reported recently that LOD was not amenable to glutaraldehyde crosslinking. These observations suggested that LOD immobilization with glutaraldehyde crosslinking is not straightforward and requires a proper control of the enzyme mixture composition. This is the reason that the first step in this work was to find out the optimum composition of the enzyme layer. Enzyme layers obtained with BSA/LOD < 1 were found to be mechanically unstable and washed out from the electrode surface. BSA/LOD ratios in the range 1.4–1.5 showed very good mechanical stability and good adhesion to the polyimide substrate. With ratios greater than 1.7, the enzyme layer became undesirably thick and the response time became too long (50–60 s). The effect of enzyme concentration on the sensor response is shown in Fig. 4a. The response sensitivity is al-

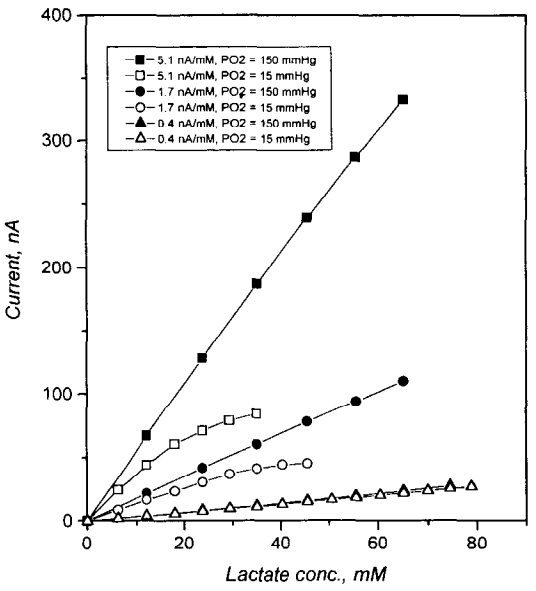

Fig. 5. Effect of sensitivity on the dependence of the sensor response on oxygen tension.

most halved on increasing the enzyme (and BSA) two-fold. This happens because the thickness of the enzyme layer is almost doubled as well. The decrease in sensitivity due to the increased enzyme layer thickness outweighs the increase in sensitivity due to the higher enzyme content. As a general trend, thicker enzyme layers lead to better linearity over a wide concentration range, but the response time is longer. A solution composition of 2% LOD-3% BSA was chosen for further work.

The effect of GA on the sensor response is shown in Fig. 4b. The trend shown in this figure is reproducible and G/T = 0.06 revealed the highest sensitivity. Smaller G/T ratio may lead to inefficient immobilization, while a higher ratio may lead to excessive crosslinking and blocking of some active sites of the enzyme. The critical dependence of the sensor response on the glutaraldehyde concentration in the enzyme solution is not a surprise if correlated with the above mentioned observations. Therefore, an enzyme mixture solution of composition 2% LOD-3% BSA-0.3% GA was proven to be the best among the ratios studied. Enzyme layers obtained with this ratios showed good adhesion to the substrate, high sensitivity (~ 8 μA mM^{-1}) and very short response time (< 5 s). These are the reasons that it is used throughout the subsequent work.

3.2. Interference rejection inner layer

Many approaches have been developed to enhance the selectivity of the H_2O_2 measuring system [24,39–42] in the presence of interferences. However, electropolymeric films provide many attractive features, such as self-limiting coverage, generation of very thin layers, strong adhesion to the electrode surface, ease of thickness control by changing the polymerization time, and convenience of automation. *m*-Phenylenediamine is one of the most successful monomers used for this purpose. Typical cyclic voltammograms (not shown) were obtained for oxidative electropolymerization of *m*-PDA from stirred 10 mM PB solution. The resulting film showed an efficient discrimination against ascorbic acid, uric acid, acetaminophen, etc., as we will discuss in the sensor selectivity section. On the other hand, a high permeability (80–90% of the bare Pt electrode response) to H_2O_2 was observed in comparison with the films obtained by casting cellulose acetate or Nafion solutions.

3.3. Diffusion control outer layer

Wilson et al. [17] have used a 5% PU solution in 98% tetrahydrofuran (THF)-2% dimethylformamide (DMF) and a wire loop technique to coat a needle-type lactate sensor with an outer diffusion layer. The described wire loop technique is not suitable for our planar sensors and 5% solution is too concentrated for the casting technique. The resulting sensor required very long time (10–20 days) to attain stable sensitivity and the upper limit of linear range is between 12 and 20 mM with sensitivity 2.8 and 1.1 nA mM^{-1}. On the other hand, we found that 1% PU solution in pure THF gives an efficient diffusion control outer layer and the sensor reached stable sensitivity in 12 h at 4°C. With almost the same sensitivity, the upper limit of the linear range is much higher as we will discuss below.

3.4. Characteristics of the sensor

Replicate sensors ($n = 30$) showed response sensitivities in the range of 1.5–3.6 nA mM^{-1} with a background current of 8 ± 3 nA. A typical sensor with sensitivity of 2.3 nA mM^{-1}, gave a linear dynamic range up to at least 140 mM in air equilibrated buffer, $r = 0.9997$. This high linearity is a result of a combination of a very sensitive enzyme layer and an efficient diffusion-controlling outer layer. The latter greatly reduces the flux of lactate ions that reach the enzyme layer. Sensors with higher and lower sensitivity ranges were prepared as well. In these cases, smaller (2 μl) or larger (4 μl) aliquots of PU solution (Section 2.3.6) were used, respectively, to form the outer layer. The sensor output is stable for 1 month when stored at 4°C when not in use. For longer periods, the linear range remains the same, but an increased sensitivity was observed due to the increase of permeability of the outer layer. About 10% increase in the sensor response was observed when the sensor is polarized in phosphate buffer at 37°C for 4 h. This is again due to the increased permeability of the outer layer. This relatively faster increase in the outer layer permeability is due to the higher temperature, because other sensors polarized for more than 8 h at 25°C did not show any significant change in the sensitivity. Operational stability at 37°C is adequate because the duration of the papillary muscle experiments does not exceed 2 h.

3.5. Effect of pH and temperature

The sensor output ($n = 3$) is stable to $3 \pm 0.5\%$ over the pH range 6.7–8.2. Outside this range, a relatively high background current was observed. The sensor showed a gradual increase in the sensitivity until it reached a maximum at 50°C. Then a slight decrease in sensitivity was observed from 50 to 60°C. The average temperature coefficient is 5%.

3.6. Sensor selectivity

The selectivity of the sensor towards some common interferences was tested. Addition of the combined maximum biological concentration of ascorbic acid, uric acid, acetaminophen, urea, L-cysteine and 1,3-dihydroxyacetone results in 6% increase of the signal obtained with 5 mM lactate solution with a sensor of 3 nA mM^{-1}. The high selectivity of the sensor is believed to be due to the combined effect of (1) the outer layer which reduces the flux of the analyte and interference molecules to the enzyme layer, and (2) the inner layer that selectively allows the small hydrogen peroxide molecules to reach the electrode surface to generate a signal nearly free from interferences. The sensor selectivity is maintained for about 12 days. For longer periods, the sensor started to show an increased response to the interferences (12–15% after 3 weeks).

3.7. Effect of oxygen tension

Since lactate oxidase catalyses the oxidation of lactate in the presence of oxygen as shown by the following equation:

$$\text{L} - \text{Lactate} + O_2 \rightarrow \text{Pyruvate} + H_2O_2$$

the sensor response should be oxygen dependent. Fortunately, the dependence of the sensor response on oxygen tension decreases with decrease of the sensor sensitivity [17,43,44]. Fig. 5 shows the calibration curves of three different sensors under high (150 mmHg) and low (15 mmHg) oxygen tension. Sensors with sensitivity of 5.1, 1.7 and 0.40 nA mM^{-1}, measured in air saturated buffers, showed linear dynamic ranges up to 8, 25, and 80 mM (at $PO_2 = 15$ mmHg), respectively. This is the reason that all the sensors used for extracellular lactate accumulation during induced ischemia experiments showed sensitivity < 1.7 mM nA^{-1} with linear dynamic ranges up to, at least, 25 mM under low oxygen tension required for the induced ischemia. Fortunately, such low sensitivities still allow successful measurement of the high extracellular lactate accumulation during no-flow ischemia under low oxygen tension which is the main objective of this work. However, sensors with reasonably higher sensitivies (5.0–11.0 nA mM^{-1}) obtained by using 2 μl aliquot of PU solution, will fit better any other application where no or fewer restrictions to the oxygen ten-

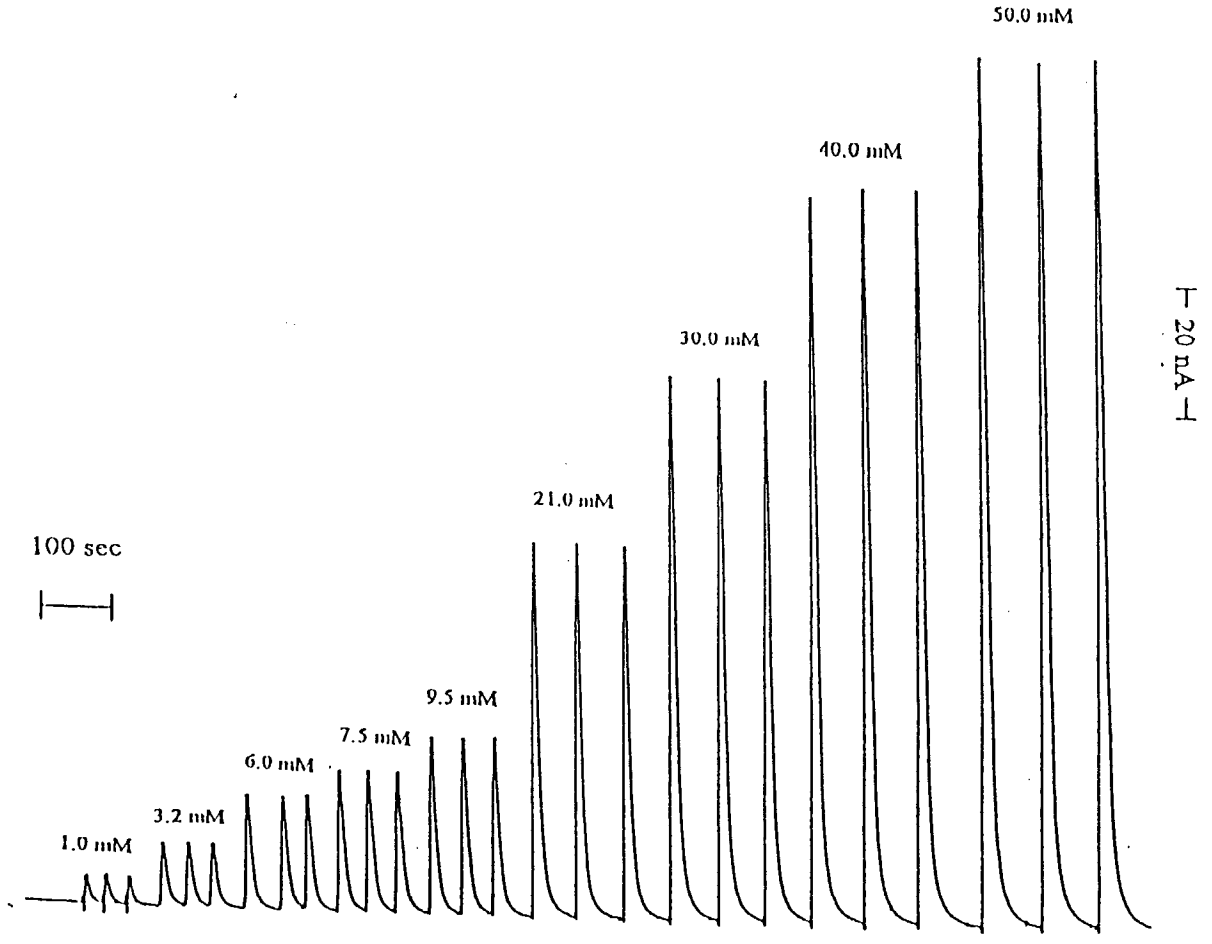

Fig. 6. Typical FIA signals.

sion and lactate concentration which is varying from sub- to several millimolar levels.

3.8. Flow injection analysis

A FIA setup, described in the experimental section, was used to evaluate the sensor response in a simulated wall-jet experiment similar to the setup described for lactate monitoring where the sensor is brought into direct contact with the muscle surface. A three electrode chip consisting of working, counter and reference electrodes was used in a single channel wall jet FIA setup. With a flow rate of 2 ml min^{-1}, and 100 μl injection loop size and a sensor sensitivity of 8.2 nA mM^{-1}, a linear range up to 30 mM was obtained. The sensor showed a good reproducibility ($1.5 \pm 0.5\%$), fast recovery time, and a very stable background current. Typical FIA peaks are shown in Fig. 6.

3.9. Lactate measurement in control sera

The reliability of the sensor for lactate monitoring in a biological complex matrix was assessed by determining lactic acid in a human based control sera which contain 42 constituents. The results obtained by both batch and FIA techniques were compared with those obtained with the YSI Biochemistry Analyzer. The excellent agreement (av-

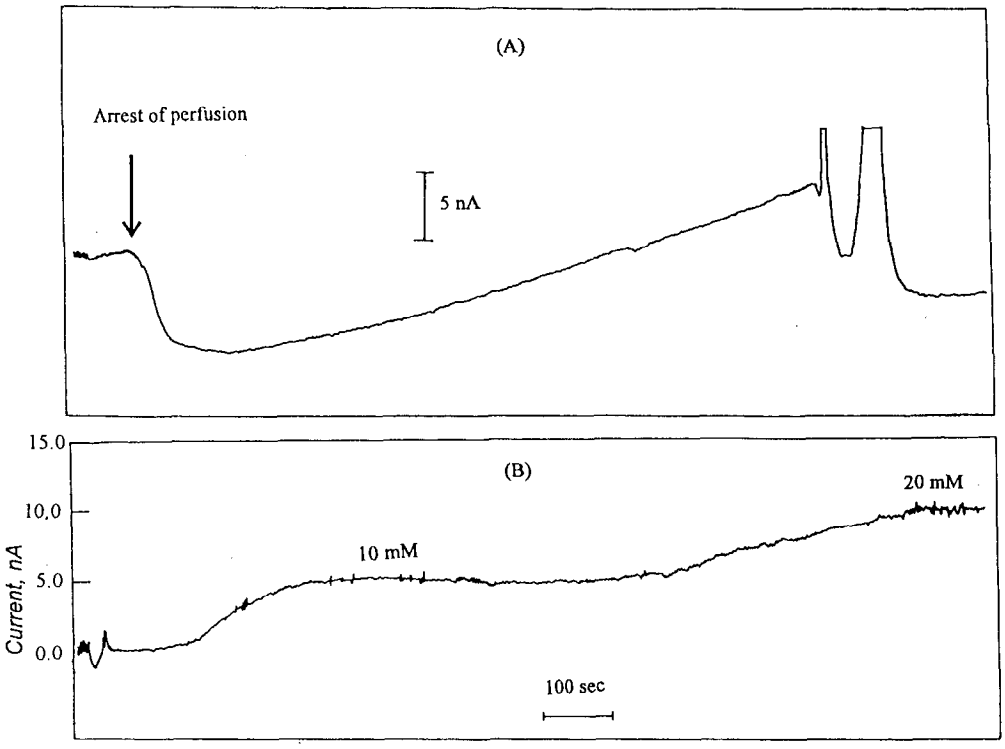

Fig. 7. Real time tracings of the sensor response during normal arterial perfusion, no-flow ischemia and reperfusion (A). An in situ sensor calibration (B).

erage recovery = 102.3 ± 0.4%) demonstrated that the sensor is reliable for simple, accurate, and rapid determination of lactic acid in real samples.

3.10. Time course and magnitude of the accumulation of extracellular lactate in rabbit ischemic ventricular muscle

The performance characteristics of the developed sensor, such as operational stability, high linearity under low oxygen tensions, high selectivity, fast response and reliability as a detector in a wall-jet flow system, suggest its successful use in continuous monitoring of the extracellular lactate accumulation in an ischemic rabbit papillary muscle. According to the authors' experience, this is the first report on continuous lactate monitoring using an amperometric sensor located in direct contact with the myocardium.

The layout of the two electrode chip (Fig. 1B) is designed to fit the dimensions of the papillary muscle. Within the same layout it is possible to make a three electrode pattern, however, the addition of the third electrode will lead to a smaller working and/or reference electrode area. At this stage of our work we sought a working electrode with a maximized area in order to measure lactate accumulation along the length of the entire papillary muscle.

The first attempt used the two-electrode chip in which the Ag/AgCl electrode served as both reference and counter. This configuration gave a very noisy and unstable response. However, when a separate Pt wire was connected to the muscle base, used as a counter, a stable response was obtained. The pseudo Ag/AgCl reference electrode was used successfully because the Cl^- ion concentration, in the solution perfusing the muscle, is nearly constant. The advantages of using

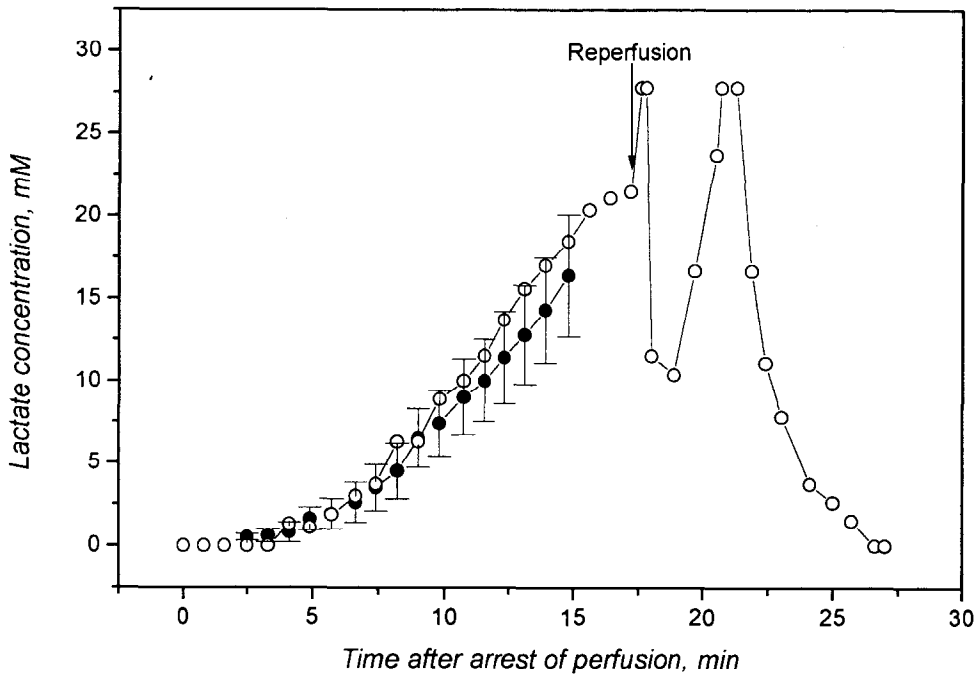

Fig. 8. Plot showing the accumulation of extracellular lactate during six episodes of 15 min of no-flow ischemia in five experimental animals. In these experiments PO_2 ranged from 24 to 250 mmHg but this did not significantly affect the accumulation of extracellular lactate. Reperfusion is shown for a single experiment for clarity because the time of repefusion differed among the individual experiments.

this arrangement are: (1) reproducible close position to the working electrode; and (2) saving the limited space around the muscle for other sensors such as oxygen, potassium sensors, etc., to be used for future studies (see Fig. 3). The sensitivity of the sensor chip placed on the papillary muscle was restricted to values < 1.7 nA mM^{-1}. The lactate content of the perfusate was measured and found to be zero prior to the onset of no-flow ischemia. As shown in Fig. 7, the arrest of perfusion resulted in an immediate shift in the baseline measuring 7.5 ± 1.5 nA. A new baseline was established within 1–1.5 min and this level was taken as the starting point for the measurement of the change in extracellular lactate concentration. Subsequently, lactate increased after a short delay. As shown in Fig. 8 the accumulation of extracellular lactate reached 16.4 ± 3.7 mM after 15 min of no-flow ischemia.

The maximal extracellular lactate concentration measured after 15 min of ischemia with the lactate sensor was substantially higher than the concentrations measured by microdialysis technique in ischemic canine heart (approximately 5 mM) [45]. This difference may be related to the methodologies or to the species studied. In contrast to the microdialysis technique, the developed lactate sensor does not damage the tissue and has direct contact to the extracellular compartment.

Reperfusion resulted in the prompt wash-out of the extracellular space. A transient increase in the current was noted after reperfusion and was similar in magnitude to the initial decrease observed immediately after arrest of perfusion. A second transient increase in current was measured 5–10 min after the onset of reperfusion. These phenomena were observed in each experiment. The mechanisms responsible for the initial decrease in current upon arrest of flow and the increase upon reperfusion are not fully understood at this time.

The second transient increase in current during reperfusion may result from washout of the lactate accumulation in the septum. Future studies will be needed to characterize these effects, although they do not interfere with the lactate measurement during the interval of no-flow ischemia.

4. Conclusion

The present miniature-three layered lactate biosensor, fabricated on a flexible planar substrate, shows many attractive features, such as miniaturization, flexibility, wide linear dynamic response range at low oxygen tensions, good stability, adequate sensitivity, fast response time and good selectivity. It was successfully used to monitor lactic acid in control sera by both batch and flow techniques and to measure extracellular lactate accumulation during no-flow ischemia. This novel lactate sensor will be a useful tool for further detailed studies in which both K^+ and lactate are monitored simultaneously for longer periods of ischemia, and to study lactate accumulation in hypoxic conditions, as well as conditions that simulate the boundary between normal and ischemic tissue. These conditions are characterized by low oxygen tensions and accumulation of potassium.

Calibration procedure for solid phase microextraction—gas chromatographic analysis of organic vapours in air

D. Gorlo, L. Wolska, B. Zygmunt, J. Namieśnik *

Department of Analytical Chemistry, Chemical Faculty, Technical University of Gdańsk, 80-952 Gdańsk, Poland

Received 16 August 1996; received in revised form 17 October 1996; accepted 13 November 1996

Abstract

A calibration procedure for solid phase microextraction—gas chromatographic (SPME-GC) analysis of organic vapours in air was described in which GC detector (MS in this case) signal is directly related to concentration of analytes of interest sampled by SPME. Gaseous standard mixtures used for the calibration were generated by means of a home-made permeation-type apparatus described elsewhere, W. Janicki et al., Chem. Anal., 38 (1993) 423 and modified to permit easy sampling of analytes on an SPME fibre. To establish sampling parameters, times for equilibrium partitioning of five selected organic compounds (carbon tetrachloride, toluene, chlorobenzene, *p*-xylene, *n*-decane) between gaseous mixtures and the fibre (fused silica fibre coated with 100 μm polydimethylsiloxane) were determined. For 10 min sampling time, the detector response and hence amount sampled on the fibre were linear functions of analytes concentration in a gaseous sample. © 1997 Elsevier Science B.V.

Keywords: Calibration; Gas chromatography; Microextraction; Organic vapours

1. Introduction

The dominant trend in present day environmental analytics can be related to the necessity to determine an increasingly wide range of pollutants on increasingly lower concentration levels in very complex matrices [2]. Hence, isolation and preconcentration of analytes of interest are usually necessary steps of the analytical procedure. Recently, a rapidly developing technique for this purpose is solid phase microextration (SPME) [3–10]. In the technique, sampling, isolation and enrichment are incorporated into a single step and use of solvents, which can be possible environmental pollutants, is eliminated. The technique can be applied to gases and relatively pure liquids by dipping an SPME fibre directly into an analysed medium; and to solid matrices and wastewater samples with grease, oil, and high molecular mass humic acids by analyte sampling from the headspace being at equilibrium with an original sample. The possible ways of sampling from different matrices are shown in Table 1.

In the case of SPME combined with gas chromatography, the fibre (with analytes extracted from the sample into stationary phase coated on it) is introduced into an injection port of a gas chromatograph. The analytes are thermally des-

orbed from the fibre and transferred by a carrier gas into a GC column for separation and then to a detector for quantitation.

However, SPME is an equilibrium method and analytical methodologies based on it require calibration. It seems that the most reliable calibration approach would be to subject standard gaseous mixtures of precisely and accurately known analyte concentration to the complete analytical procedure (starting from sampling to final analysis) identical to the procedure for a real sample.

Standard gascous mixtures used for calibration as well as for studies on isolation and enrichment of trace analytes from gases in the above approach should satisfy the following requirements [11–13]:

- concentration of an analyte of interest should be constant for a required period of time;
- concentration should be known with an accuracy much better than the accuracy of a calibrated instrument or method;
- mixtures should be available in quantities sufficient to perform planned studies;
- analyte concentration can preferably be calculated from such basic quantities as mass, temperature, pressure, etc.

For environmental analytics in general and for these studies in particular (mixtures of very low analyte concentration: ppm, ppb, ppt levels required), dynamic methods based on permeation of vapours of volatile organic compounds through membranes (mainly PTFE, polyethylene and silicone rubber) into a stream of diluting gas seem the most adequate. In such methods very low analyte concentrations can be obtained. These concentrations can be varied within a wide range by changing such parameters as membrane thickness and area, flow rate of diluting gas and temperature of a permeation vessel. The dynamic permeation methods has been extensively studied and used, among them the apparatus designed in our laboratory [1,14,15].

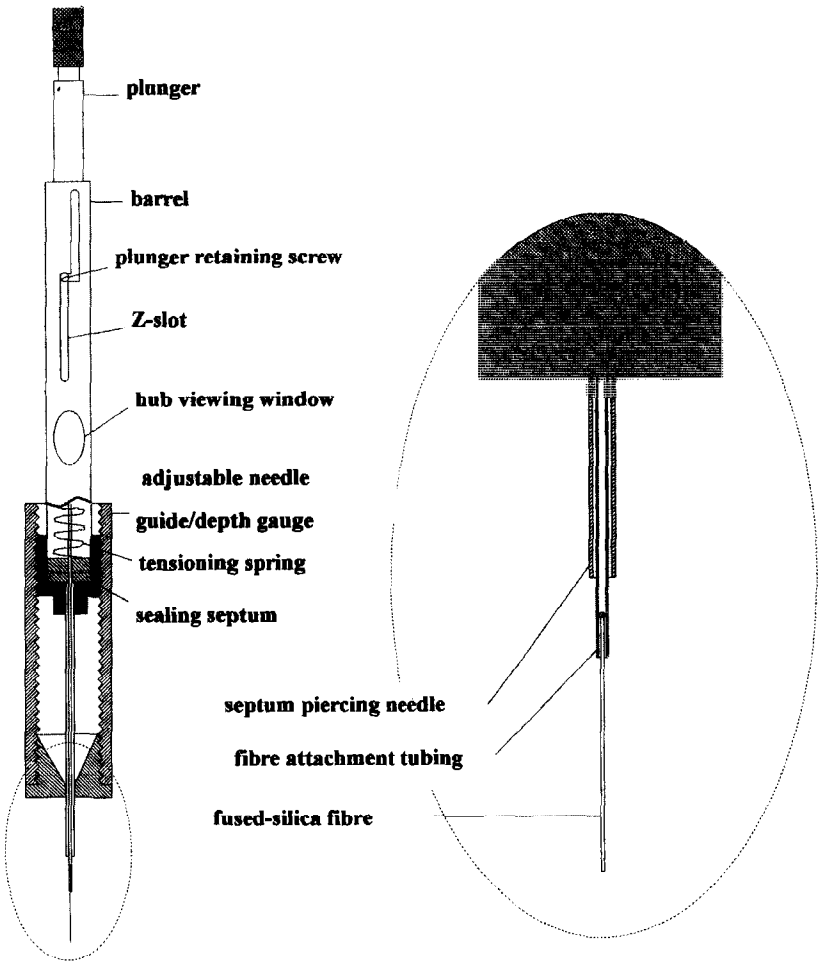

Fig. 2. SPME apparatus for manual sorption and injection [20].

The aim of this work was to develop a reliable method of SPME-GC-MS system calibration (output signal as a function of analyte concentration in gaseous sample) which can be used in analysis of different air samples (atmospheric, indoor and workplace air) for organic vapours. For the purpose we used the apparatus for permeative generation of standard gaseous mixtures described elsewhere [1] and modified to enable reproducible sampling of organic vapours present in the gaseous mixtures on an SPME fibre.

2. Experimental

2.1. Reagents and materials

n-Decane (pure) were from Merck, Germany, and carbon tetrachloride, chlorobenzene, toluene and *p*-xylene (all reagent grade) were from Polskie Odczynniki Chemiczne, Gliwice, Poland. PTFE foils of 50, 120 and 220 μm thickness (from Du Pont, USA) were used for the preparation of permeation membranes.

Table 2
Concentrations of organic compounds of interest in gaseous standard mixtures (purified air as a diluting gas)

Compound analyzed	Analyte concentration (mg m^{-3}) for different flow rates of diluting gas			
	25 cm^3 min^{-1}	50 cm^3 min^{-1}	100 cm^3 min^{-1}	150 cm^3 min^{-1}
Carbon tetrachloride	23.45	11.73	5.86	3.91
Toluene	2.33	1.17	0.58	0.39
Chlorobenzene	16.84	8.42	4.21	2.81
p-Xylene	1.22	0.61	0.3	0.2
n-Decane	0.75	0.38	0.19	0.13

2.2. Apparatus

The apparatus for the dynamic generation of gaseous standard mixtures with stop flow facility for sampling is given in Fig. 1. It consists of three generators (3) [1]. In each generator two or three permeation vessels are placed [1,16–19]. They are filled with liquid analytes of interest (carbon tetrachloride, toluene, chlorobenzene, *p*-xylene, *n*-decane). Diluting gas (atmospheric air purified from organic compounds) (1) is sucked by a suction pump (10) through purifier (1), drier (2) and generators (3) containing permeation vessels kept at a temperature of 28 ± 0.1°C. The stream of the gaseous mixture formed was then passed through a preliminary mixing chamber (4), Teflon 3-way valve (5), thermostated mixing glass chamber (6), glass 3-way valve (7), flowmeter (8) used for an accurate measurement of gaseous mixture flow rate and rotameter (9) with which flow rate is controlled. Mixing chamber (6) is equipped with a septum through which a needle of a SPME device can be inserted. During exposition the mixture flow through chamber (6) is stopped (the gas mixture by-passes the chamber).

GC-MS analysis was carried out with a Fisons GC-8000 gas chromatograph coupled with a Fisons MD-800 quadrupole mass spectrometer.

For SPME extraction an SPME holder for manual injection (SUPELCO, Bellefonte, PA, USA) with a 100 μm polydimethylsiloxane-coated fused-silica fibre (SUPELCO, Bellefonte, PA, USA) was used (Fig. 2) [20].

2.3. Calibration of permeation vessels

Permeation rates were determined by measuring vessel mass decrease (weighing) in a given time (1–30 days). When permeation rates became constant, permeation vessels were ready to use, and the concentration of a given analyte in a gaseous mixture was calculated from the permeation rate and diluting gas flow rate [1,19]. The concentrations of analytes in standard mixtures used in the studies are given in Table 2.

2.4. Analyte extraction (a) and injection into a gas chromatographic column (b)

(a) The membrane of the mixing chamber (Fig. 1) is pierced with an SPME syringe needle, the fibre is pushed out from the needle and exposed to a standard mixture for a given time and then withdrawn into the needle, whose tip is immediately closed by piercing it into a silicone septum to prevent the analytes from desorption.

Table 3
Parameters of fibre exposition

Exposition parameters	
Stationary phase	Polydimethylsiloxane
Thickness of stationary phase film	100 μm
Exposition temperature	25 ± 0.2°C
Mixture relative humidity	Dry air
Exposition time	0.5, 1, 2, 3, 10, 20 min
Flow rate of diluting gas (purified and dried air)	25, 50, 100, 150 cm^3 min^{-1}
Analyte concentration	as given in Table 2

Table 4
GC-MS parameters

Injection port	Splitless, (liner 1.2 mm I.D.)
Injector temperature	250°C
Desorption time	60 s
Analytical column	DB 5 MS 30 m × 0.32 mm I.D. 0.25 μm d_f (RESTEC, Bellefonte, USA)
Temperature program	30°C–2 min–5°C min^{-1} 50°C–15°C min^{-1} 230°C–10 min
Type of MS	SCAN
Ions for quantitation	Carbon tetrachloride 117, toluene 91, chlorobenzene 112, *p*-xylene 91, *n*-decane TIC
Ionisation	electron impact (70 eV)

(b) The device needle is quickly introduced into a splitless injector of a gas chromatograph, the fibre extended from the syringe for 20 s. At this time the analytes are desorbed and transferred into a GC column by carrier gas (parameters given in Table 3 and Table 4).

2.5. GC and MS parameters

The parameters of GC-MS are given in Table 4.

3. Results and discussion

Constancy of analyte concentration (after preconditioning) in gaseous standard mixtures, which is a basic requirement of the calibration method proposed, has been confirmed earlier [1]. Application of a mixing chamber of a special design makes SPME fibre exposition to a standard mixture simple and easy. Development of a calibration method requires the determination of minimum time necessary for equilibrium partitioning of analytes between a gaseous mixture and a fibre. For this purpose, the fibre was exposed to standard mixtures for different periods (0.5; 1.0; 2.0; 3.0; 5.0; 10 and 20 min). The fibre was exposed in the gaseous mixture at a temperature of 25 ± 0.2°C. Sorbed analytes were injected into a GC column and peak areas measured. It was found earlier that the injection parameters used (Table 4) ensure complete desorption of analytes from the fibre. In Fig. 3 plots of peak areas versus exposition time for different analytes concentrations are given. Each point is an average of five parallel measurements. For carbon tetrachloride, toluene, chlorobenzene, *p*-xylene and *n*-decane equilibration time ranges from 1.0 to 5.0 min (Table 5). The equilibration is relatively fast, and this step would extend the total time of an analytical procedure only slightly. A 10 min extraction time was selected for further experiments. For sampling at lower temperatures, e.g., outdoor air sampling on cold days, slightly longer extraction can be needed.

In the successive step, the relationship between SPME-GC-MS response and analyte concentration in the gaseous mixture (calibration curves) was studied. For each concentration five independent measurements were made.

The relatively high correlation coefficients (r) for linear regression ranging from 0.988 to 0.999 (Table 6) show that, in the examined concentration range, calibration curves can be assumed linear with high reliability. An example of a calibration curve is given in Fig. 4. Linearity of calibration curves, i.e., independence of partition coefficients on concentration, simplifies the analytical procedure. This was found for a fibre exposition temperature of 25°C, but should also be valid for other temperatures normally used during air sampling for organics.

However, partition coefficients (Kg) between the fibre coating and the gaseous phase are temperature dependent, which was quantitatively described for a number of organic compounds by Arthur et al. [8]. Therefore, the temperature of fibre extraction from the standard mixture (for calibration purposes) should be every time adjusted to a temperature of real sample extraction. Such an approach seems simpler and more accurate than the correction based on previously determined temperature variability of Kg. With the apparatus proposed this is easily done simply by changing the temperature of mixing chamber (6).

Humidity can affect sorption of organic compounds on the fibre but to small extent. As shown by Chai and Pawliszyn [10], the relative humidity reduces the amounts extracted at room temperature by less than 10% at up to 75%. The small

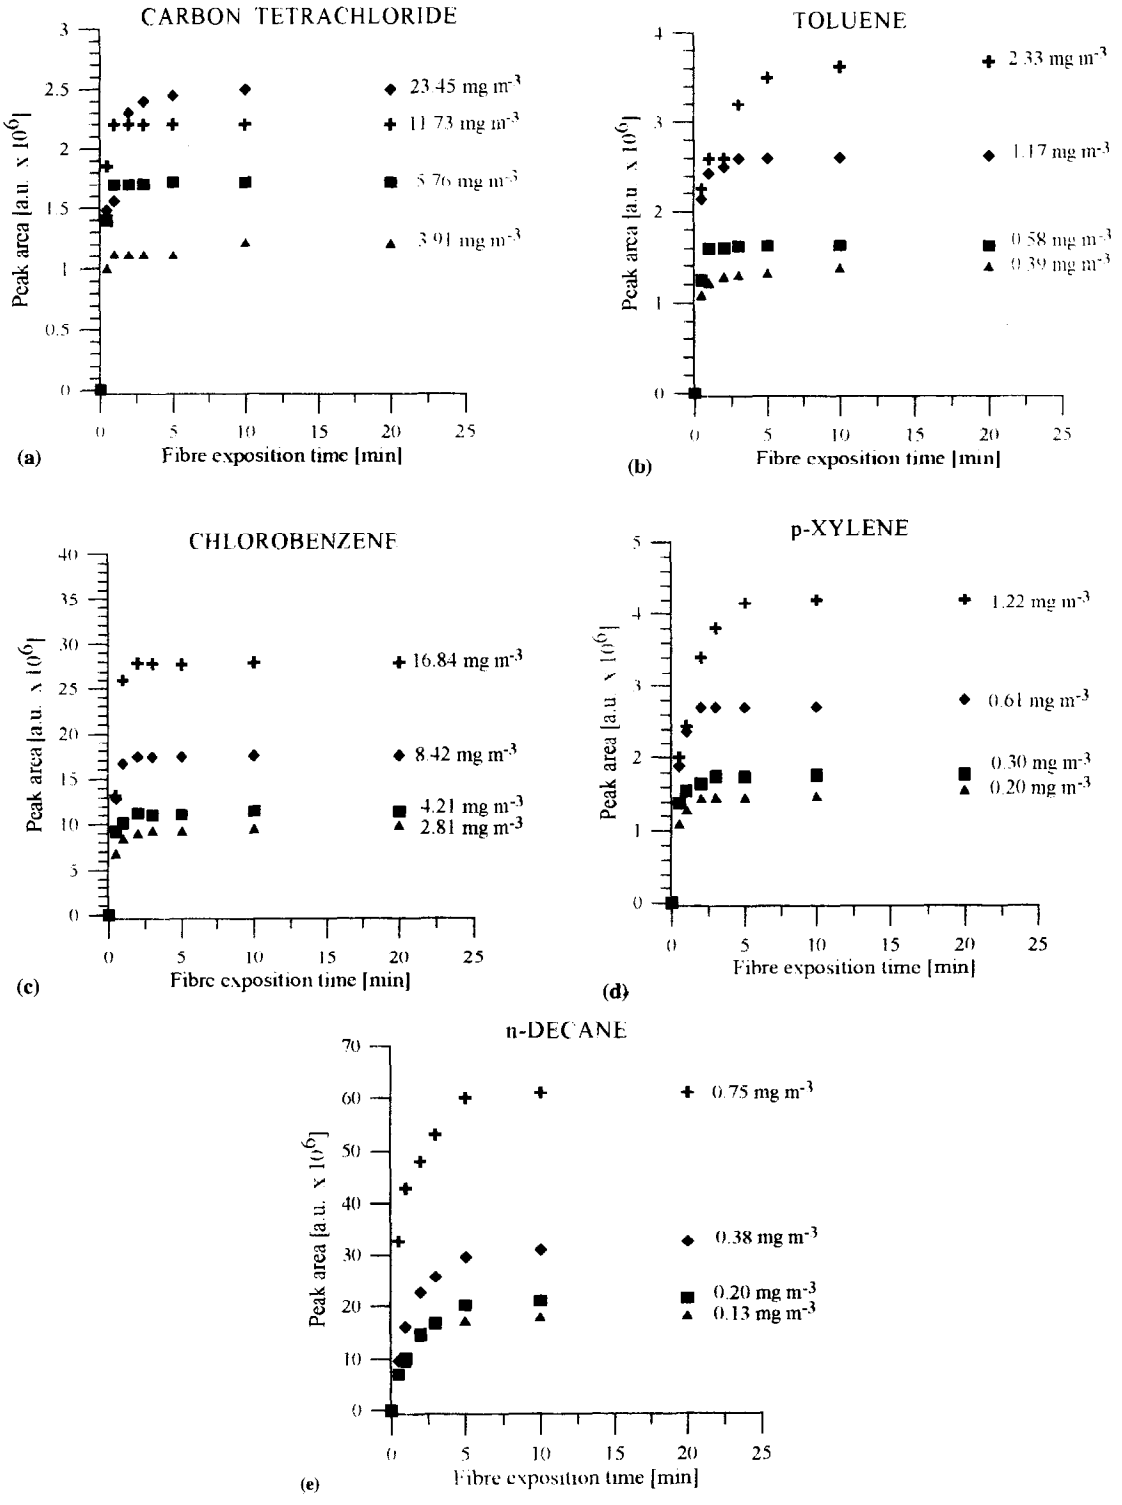

Fig. 3. Plots of GC-MS response (peak area in arbitrary units-a.u.) versus SPME fibre exposition time for different analyte concentrations in gaseous standard mixtures: (a) carbon tetrachloride; (b) toluene; (c) chlorobenzene; (d) *p*-xylene; and (e) *n*-decane.

Table 5
SPME equilibrium times for different organic compounds in gaseous mixture

Compound	Equilibration time [min] (concentration [mg m^{-3}])			
Carbon tetrachloride	1.0 (3.91)	1.0 (5.86)	1.0 (11.73)	2.5 (23.45)
Toluene	1.0 (0.39)	1.0 (0.58)	1.5 (1.17)	5.0 (2.33)
Chlorobenzene	1.5 (2.81)	1.5 (4.21)	1.5 (8.42)	1.5 (16.84)
p-Xylene	2.0 (0.20)	2.0 (0.30)	2.0 (0.61)	4.5 (1.22)
n-Decane	2.5 (0.13)	3.0 (0.20)	4.5 (0.38)	4.5 (0.75)

Table 6
Characteristies of calibration curves

Compound	*a* [a.u.]	S_a [a.u.]	*b* [a.u. mg^{-1} m^3]	S_b [a.u. mg^{-1} m^3]	Correlation coefficient *r*	Concentration range [mg m^{-3}]
Carbon tetrachloride	73×10^4	7.3×10^4	7.7×10^4	0.53×10^4	0.995	3.91 ÷ 23.45
Toluene	1.0×10^6	0.17×10^6	1.2×10^6	0.13×10^6	0.988	0.39 ÷ 2.33
Chlorobenzene	6.1×10^6	0.29×10^6	1.31×10^6	0.029×10^6	0.999	2.81 ÷ 16.84
p-Xylene	1.0×10^6	0.11×10^6	2.6×10^6	0.16×10^6	0.996	0.20 ÷ 1.22
n-Decane	0.3×10^7	5.2×10^7	8×10^7	1.2×10^7	0.980	0.13 ÷ 0.75

Each calibration curve consists of four calibration points and each point is an average of five measurements.
$y = bx + a$ (y—peak area in arbitrary unit (a.u.), x—analyte concentration in mg m^{-3}).

difference in humidity between a gaseous calibration mixture and an air sample analysed would influence the results but only slightly. The effect of humidity is nearly constant for the relative humidity range of 25–75%, which covers majority of indoor, outdoor and workplace air cases. Maintaining the humidity of standard gaseous mixtures within this range is relatively easy with the apparatus proposed.

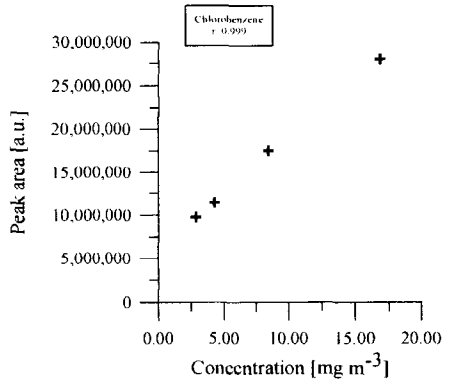

Fig. 4. The plot of SPME-GC-MS response versus concentration of chlorobenzene in a gaseous standard mixture.

4. Conclusions

The apparatus for the generation of standard gaseous mixtures with mixing and sampling chambers gives a mixture of uniform concentration and enables easy exposition of an SPME fibre to the mixture. Since the concentration can be easily controlled and calculated the easy and reliable calibration of SPME-GC system versus analyte concentration in gaseous sample is feasible.

The described calibration procedure should make the SPME technique a versatile, convenient and reliable tool for the determination of organic pollutants in various types of gaseous samples, such as indoor, atmospheric and workplace air. The determination would consist of two series of SPME-GC measurements: one for the sample studied and one for the standard mixture.

The analysis of the above types of samples using the SPME combined with the proposed method of calibration is relatively short and of

relatively low costs, since use of very pure solvents is eliminated, which is also important from environmental protection viewpoint.

Received 16 August 1996; received in revised form 21 October 1996; accepted 21 October 1996

Abstract

The utilization of a multicomponent gaseous standard mixture, containing CO and CO_2 and obtained by thermal decomposition of a so-called immobilized compound, for a single point calibration of a GC/FID system are described. The generation of such a mixture takes place as a result of thermal decomposition of a sample of chemically modified silica gel placed in a heated chamber of thermal desorber coupled with the device being calibrated via a catalytic methanizer. The mean amount of the analyte librated from unit mass of the gel was 0.71 mg g^{-1} (RSD = 3%) for carbon monoxide and 0.86 mg g^{-1} (RSD = 3%) for carbon dioxide. © 1997 Elsevier Science B.V.

1. Introduction

Outdoor and indoor air, water, soil, food and the workplace atmosphere are polluted by an enormous number of toxic chemicals. In some cases, these hazardous chemicals cannot be detected by our senses, such as smell or sight. So far, Chemical Abstracts list about 13 million anthropogenic compounds. Of those, at least 100 000 are commonly used in various areas of life and technology, over 10 000 are considered to be especially hazardous, and about 200 are considered to be carcinogenic [1]. Separation, identification and determination of such a large number of compounds constitutes a difficult analytical problem, particularly if the analytes are volatile, unstable, toxic or malodorous.

Every analytical process consists of a number of steps, including sampling, sample storage and workup, calibration and final determination. Each of these steps is prone to errors, whose main sources are [2–4]:

- sample contamination,
- losses of analytes resulting from analyte evaporation or adsorption on the surface of a container,
- chemical reactions taking place in a sample,

- interference among trace components or with a matrix,
- erroneous measurements (biased), improper calibration associated with unacceptable extrapolation and/or improper or unstable standards.

In order to reduce or eliminate these errors, new reliable analytical procedures with an increasingly greater accuracy and precision are being sought. One vital step of these procedures is calibration of measuring devices, i.e., determination of the relationship between the output signal and the quantity being determined. The method of calibration depends on a number of factors, including [5,6]:

- type of a measuring device,
- number of samples to be analyzed,
- possibility of preparation of a wide range of concentrations of standards to check an entire measurement range,
- required accuracy of determination,
- degree of matrix complexity of the analyzed sample.

In the analysis of gaseous environmental pollutants, gaseous standard mixtures play a very important role in the calibration of gas analyzers. A number of methods of generation of these mixtures have been described both in original papers [3,7–15] and in reviews [16–19].

Calibration of analytical measuring devices can be accomplished in practice in two ways:

- by checking the entire measuring range (including zero point) using a set of gaseous standard mixtures with varying concentrations of the analyte, including a so-called zero gas and, sometimes, also a pure analyte;
- by verifying the reliability of an analytical device through checking its response at only one point within the measuring range (a so-called single point calibration).

The use of thermal decomposition of so-called immobilized compounds, chemically bonded to the surface of silica gel, is a new approach to the problem of preparation of gaseous standard mixtures [20–25]. In order to change physico-chemical properties of the surface of silica gel, it can be modified through the reaction of active sites (the -OH groups on the gel surface) with modifiers. This procedure is commonly used for the preparation of silica gel for liquid chromatography applications [26]. The group bonded to the gel surface can in turn become a reactant

for subsequent reactions. Using suitable sequences of such reactions, almost any functional group can be immobilized on the surface of silica gel [27]. Silica gel can be modified with a variety of inorganic compounds. Such a modification results in the coverage of the gel surface with mono- or multimolecular layers of, e.g.: Al_2O_3, Fe_2O_3, Cr_2O_3, B_2O_3, TiO_2, etc., [28]. Among commonly used organic reagents, one should mention amines (resulting in the formation of the Si–NR bonds), alcohols (resulting in the formation of the Si–OR bonds), and alkyl derivatives (resulting in the formation of the Si–C bonds). The most stable of the above bonds are Si–C; consequently, this kind of modification of the silica gel surface is most commonly used as the first step in a series of reactions of immobilized groups. Alkyl- or arylchlorosilanes and alkoxyalkyl- or alkoxyarylsilanes are used most frequently to form the Si–C bonds. A specific chemical compound bonded to the silica gel surface (and called an immobilized compound) then undergoes chemical rearrangement at an appropriate temperature, yielding gaseous analytes which combine with a stream of carrier gas generating a gaseous standard mixture. The major factors influencing the composition of standard mixtures are the method of modification of the gel surface, the carrier (diluent) gas flow rate, the bed temperature, the mass of modified gel and the time of the decomposition process. Evident advantages of this method of preparation of gaseous standard mixtures include:

- high stability of modified gels at room temperature as a result of significantly higher temperatures of liberation of analytes, which facilitates the storage of batches of modified gels without the danger of slow decomposition of the immobilized compound resulting in an increased background;
- the possibility of preparation of a standard mixture immediately before calibration of an analytical instrument, thus reducing memory effects associated with adsorption of the analytes on the inside walls of an experimental setup;
- suitability for the generation of standard mixtures containing unstable, toxic or malodorous compounds.

In addition to the above advantages, this approach to generation of gaseous standard mixtures has some inconveniences, the most important of which is the variability of analyte concentration in the diluent gas at the outlet of the tube with the modified silica gel. However, similarly to the classical exponential dilution method, this concentration can be calculated at any moment since the beginning of thermal decomposition [19].

Table 1 lists the methods of preparation of gaseous standard mixtures by thermal decomposition of chemically modified silica gel that have been developed thus, far.

The present paper describes the results of investigations of the possibility of utilization of thermal decomposition of samples of chemically modified silica gel for the generation of a multicomponent gaseous standard mixture which can be used for the single point calibration of chromatographic detectors. Substituted alkoxyalkylsilanes were used for chemical modification of

Results of determinations of the amount of methane in the primary standard mixture after methanization of carbon dioxide, obtained during preliminary studies of the output of an FID

No.	Volume of gaseous mixture injected [μl]	Peak area for methane (arbitrary units)	Amount of CO_2 [mg]	Equivalent amount of CH_4 [mmol]
1	50	107175	8.20×10^{-4}	1.86×10^{-5}
2	100	214967	1.64×10^{-3}	3.73×10^{-5}
3	200	432167	3.28×10^{-3}	7.45×10^{-5}
4	400	856133	6.56×10^{-3}	1.49×10^{-4}
5	700	1494667	1.15×10^{-2}	2.61×10^{-4}
6	1000	2073000	1.64×10^{-2}	3.73×10^{-4}

silica gel. Samples of the modified gel were then placed in a sorption tube and inserted into a thermal desorber connected on-line with the analytical device being calibrated (the detector), and the calibration of the detector output at a certain point of its measuring range was carried out in this way. In this work, thermal decomposition of the immobilized compounds yielding carbon monoxide and carbon dioxide was used to generate a multicomponent gaseous mixture. Utilization of the process of methanization of the two components (following their separation on a gas chromatographic column) results in the formation of two different amounts of methane in one cycle, which can be used to calibrate a flame-ionization detector, a common measuring device in a number of analyzers and monitors of gaseous mixtures.

2. Experimental

2.1. Apparatus

An HP 5830 A gas chromatograph equipped with a cold on—column, splitless injector, an FID detector ($T = 150$°C), and a methanizer ($T = 400$°C, catalyst—Raney nickel supported on silica gel) were used in the investigations. The process of catalytic methanization was carried out in a stream of nitrogen (carrier gas) with an addition of hydrogen (10 ml min^{-1}). A batch of the nickel catalyst was prepared according to the literature [29]. Separations were performed in a 100 × 0.3 cm column packed with Porapak Q, 80–100 mesh, (Hewlett Packard). The column temperature was 25°C. The carrier gas (nitrogen) flow rate was 20 ml min^{-1}. The gas chromatograph was coupled with a purpose-designed tube furnace in which a tube with the modified silica gel was placed. The tube (100 × 3.5 mm) was previously silanized (to minimize the wall-analyte interactions) using the following conditions [30]: silanizing mixture—hexamethyldisilazane: trimethylchlorosilane (5:1); time of silanization: 48 h; silanization temperature: 150°C. The apparatus used in the investigations is shown in Fig. 1.

2.2. Reagents

Silica gel (MN-Kiesegel 60, 35–70 mesh; specific surface area 200 m^2 g^{-1}; Macherey, Nagel, Germany) was modified using the following procedure: a solution of 2 ml of γ-glycidoxypropyltriethoxysilane in 30 ml of dried toluene was added to 20 g of silica gel dried at 120°C. The obtained mixture was refluxed for 6 h. The product was filtered, washed successively with toluene, acetone, and diethyl ether, and then suspended in a solution of 1.8 g of oxalic acid in 25 ml of diethyl ether. After 24 h the obtained product was filtered, washed with water and methanol, and dried. Fig. 2 shows chemical reactions used in the modification of silica gel.

2.3. Calibration of the GC/FID system

Prior to the investigation proper, the measuring device to be standardized (FID) was cali-

Table 3

Analyte determined	Slope of the line a	Intercept of the line b	Standard deviation of the slope S_a	Standard deviation of the intercept S_b	Correlation coefficient R
CH_4 (following methanization of CO_2)	5.59×10^9	13975	1236	0.24	0.99

brated by using a so-called primary gas standard mixture which was prepared in the laboratory by a volumetric method. To a conical flask of an exactly known volume (608 ml), which was previously purged with pure nitrogen and closed tightly, 5.2 ml of pure carbon dioxide was added using a gas-tight syringe, followed by 15 ml of nitrogen (to obtain overpressure). The primary standard mixture prepared in this manner contained 623 ml of nitrogen and 5.2 ml of CO_2 (10.296 mg). Calibration of the detector was carried out by a direct injection of a volume of the primary standard onto a GC column. After the separation and methanization of CO_2, a GC detector signal originating from methane was acquired. The amount of methane is directly proportional and equimolar to the amount of carbon dioxide in the primary standard mixture. It is not necessary to prepare a primary standard mixture for carbon monoxide, because the FID signal resulting from methane can be converted to the amount of carbon monoxide considering the fact that 1 mol of CO is also equivalent to 1 mol of methane. The results of calibration of an FID detector are compiled in Table 2.

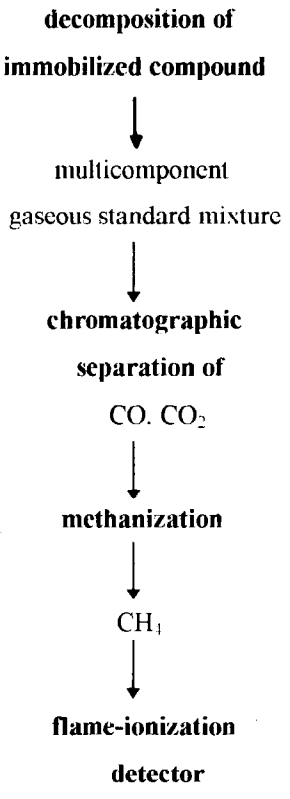

Fig. 3. Procedure used for the calibration of a flame-ionization detector employing two different amounts of methane in a single point calibration system.

Using the least-squares method, the relationship ($y = ax + b$) between a measured quantity y (the peak area) and the amount of methane x (mmol) was determined from the measurements carried out for a series of standards (Table 3).

2.4. Single point calibration of the GC/FID system utilizing the decomposition of immobilized compounds

A single point calibration of the GC/FID system was carried out by using methane formed from a standard mixture consisting of two volatile components: carbon monoxide and carbon dioxide generated in the process of thermal decomposition of the immobilized compound chemically bonded to the silica gel surface. The following procedure was used: a tube containing a weighed sample of chemically modified silica gel ($\pm$ 0.00001 g) was placed in desorber furnace (Fig. 1). Airtight connection was ensured by using PTFE washers. The tube was purged for 1

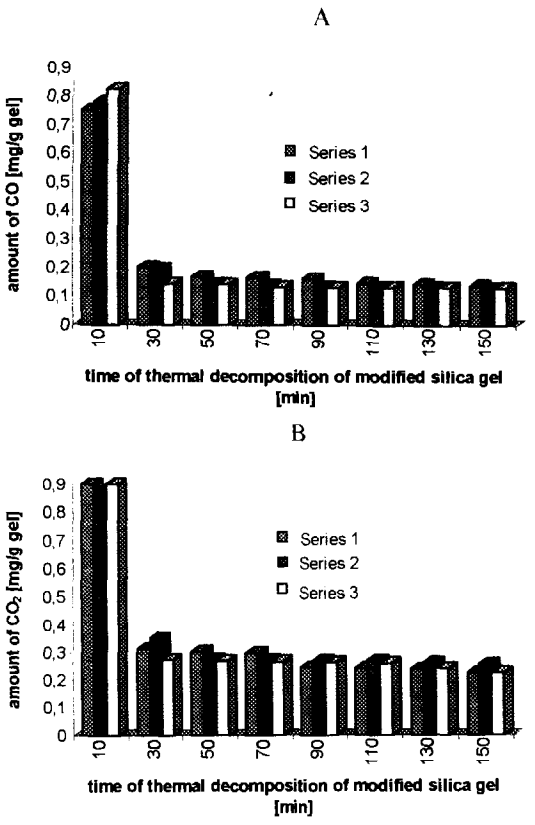

Fig. 4. Results of determination of the amounts of analytes liberated in the process of thermal decomposition of samples of modified silica gel (per unit mass of gel). Mass of silica gel: 1st series = 0.00797 g; 2nd series = 0.01302 g; 3rd series = 0.01247 g. A—determination of methane equivalent to the amount of liberated carbon monoxide. B—determination of methane equivalent to the amount of liberated carbon dioxide.

min at ambient temperature with a stream of carrier gas (nitrogen at 20 ml min^{-1}) to remove any air. Next, the furnace was heated electrically to a temperature of 300°C ($\pm$ 1°C), at which thermal decomposition of the silica gel sample was taking place. The conditions of thermal decomposition of the immobilized compound (temperature, time, and the diluent gas flow rate) have been previously determined using the same batch of chemically modified silica gel and were published elsewhere [22]. The time of thermal decomposition was measured from the moment of reaching by the bed the preset temperature. The measurements were performed by switching the position of a six-port valve, which caused the resulting standard mixture to be swept in a stream of carrier gas to the head of a GC column. Following the GC separation, the analytes (CO, CO_2) were passed in a stream of carrier gas (nitrogen) to a methanizer, where they were catalytically reduced in the presence of hydrogen to methane. After GC detection, a chromatogram was obtained which contained two peaks corresponding to methane, whose surface areas were directly proportional to the amounts of liberated analytes (1 mol of CO and 1 mol of CO_2 correspond to 1 mol of methane). A schematic diagram of the above procedure is shown in Fig. 3.

The described methodology of generation of more than one component, measured during thermal decomposition of a suitable immobilized compound followed by methanization of the analytes after their GC separation allows the use of single point calibration to check the readout of an analytical device simultaneously at two points within its measuring range.

Initially, the kinetics of thermal decomposition of chemically modified silica gel was examined, and the total amounts of the components generated as a result of this process (CO and CO_2) were determined. The total time of thermal decomposition of the immobilized compound at 300°C was 150 min; the first measurement was taken after 10 min from the initiation of the process, the next ones—every 20 min using the procedure described above. The measurements were carried out using three weighed samples of the same batch of chemically modified silica gel (with masses equal to 0.00797, 0.01302, and 0.01247 g, respectively). Fig. 4 (A, B, C) illustrates the course of thermal decomposition for each sample of the modified silica gel while the results of chromatographic determinations of total amounts of the liberated analytes (following their methanization) are listed in Table 4 and Table 5.

Subsequently, the amounts of analytes generated at a specific moment of thermal decomposition of the immobilized compound were determined. This will be of particular significance

Table 4
Results of determinations of total amounts of compounds liberated from the surface of chemically modified silica gel during its thermal decomposition ($T = 300°C$, $t = 150$ min)

Mass of gel sample [g]	0.0797		0.01302		0.01247

The compounds were determined in the form of equivalent amount of methane.

when using thermal decomposition of the immobilized compound the for single point calibration of an analytical system. Taking into consideration the fact that the largest amounts of the analytes are released in the initial phase of thermal decomposition (Fig. 4), the first 10 min of thermal decomposition were selected to generate sufficient quantities of CO and CO_2 (converted to methane) to accomplish a single point calibration of a GC/FID system. The objective of this investigation was to find the dependence of amounts of the analytes liberated from unit mass of the modified gel on the total mass of the gel used and thus, to determine the degree of homogeneity of coverage of the silica gel surface by the immobilized compound. At the same time, this is a test of the developed procedure for the preparation of modified silica gel. The determination of these properties is essential if chemically modified silica gels are to be used for the generation of standard mixtures employed in the calibration of measuring devices. The procedure followed was analogous to that used in the initial studies (kinetics of thermal decomposition of modified silica gel) and the amounts of the analytes liberated at 300°C during a 10 min decomposition were determined for 25 samples (of varying masses) of the same batch of chemically modified silica gel. The results of determinations of the amounts of liberated standards are listed in Table 6 and Table 7.

3. Discussion

On the basis of statistical analysis of the results of determination of methane formed in the process of methanization of carbon dioxide in the primary standard mixture (Table 3) it was established that the correlation coefficient ($R = 0.99$) obtained for a given number of samples ($n = 6$) is not significantly different from the critical value of the correlation coefficient (1.00 for $\alpha = 0.01$ which demonstrates a linear dependence of the detector output on the amount of the analyte.

The experimentally determined average total masses of the analytes liberated in thermal de-

23	0.01495	3.61×10^{-4}	0.67	3.09×10^{-4}	0.91
24	0.02808	7.46×10^{-4}	0.74	$5.86 - 10^{-4}$	0.92
25	0.00751	1.88×10^{-4}	0.70	1.67×10^{-4}	0.98

composition of the immobilized compound under the following conditions ($T = 300°C$, $t = 150$ min) per unit mass of the gel are 1.9 ± 0.2 and 2.7 ± 0.1 mg g^{-1} for carbon monoxide and carbon dioxide, respectively (Table 4). Relative standard deviations of the results for a given significance level ($\alpha = 0.05$) and $n = 3$ are about 10% and less than 5% for CO and CO_2, respectively (Table 5) which indicates a good precision. Based on the mole amounts of CO and CO_2 formed, which are equal to 0.07 ± 0.006 and 0.06 ± 0.003 mmol g^{-1} of gel, respectively, it can be concluded that in accordance with the reactions taking place on the silica gel surface, i.e., decarbonylation and decarboxylation (Fig. 2), equimolar quantities of the analytes are released (the experimental error is within 1%).

The process of thermal decomposition of the immobilized compound was found to have the highest yield during the first 10 min; afterwards, the amounts of the analytes released become progressively smaller which is understandable considering the finite amount of the immobilized compound on the surface of silica gel (Fig. 4). Relative standard deviations estimated from 25 determinations of the analytes liberated during the first 10 min of thermal decomposition of chemically modified silica gel at a given significance level ($\alpha = 0.05$) are within 3% (Table 7). The results obtained indicate that the amounts of the analytes liberated from unit mass of the gel do not depend on the mass of the gel used which means that the immobilized compound is bonded homogeneously to the surface of silica gel.

Table 7
Statistical analysis of the results of determinations of the amounts of carbon monoxide and carbon dioxide liberated during the first 10 min of thermal decomposition of samples of chemically modified silica gel expressed per unit mass of gel

Analyte (determined as methane)	Confidence limits for the average $n = 25$, $P = 95\%$ $\mu = \bar{x} \pm \frac{ts}{\sqrt{n}}$		Relative standard deviation [%]
	mg g^{-1} gel	mmol g^{-1} gel	
CO	0.71 ± 0.02	0.025 ± 0.0006	3
CO_2	0.86 ± 0.03	0.020 ± 0.0006	3

4. Conclusions

On the basis of experimental results one can draw the following conclusions:

- methanization of components following their chromatographic separation results in the formation of two different amounts of methane in one measurement cycle, thus yielding two data points in a single point calibration of a flame-ionization detector;
- a gaseous standard mixture generated through thermal decomposition of the immobilized compound can be used for the calibration of analytical devices in a very wide concentration range of the analyte (methane) because the amounts of the analytes liberated are directly proportional to the amount of silica gel used and,
- consequently, the amount of the analyte can be varied by changing the amount of modified silica gel;
- batches of chemically modified silica gel can be used not only as a source of analytes—components of gaseous standard mixtures but also as a source of small amounts of given analytes.

Sequential injection wetting film extraction applied to the spectrophotometric determination of chromium(VI) and chromium(III) in water

Yongyi Luo, Shigenori Nakano, David A. Holman, Jaromir Ruzicka, Gary D. Christian *

Center for Process Analytical Chemistry, Department of Chemistry, Box 351700, University of Washington, Seattle, WA 98195, USA

Received 16 August 1996; received in revised form 25 October 1996; accepted 4 November 1996

Abstract

The spectrophotometric determination of Cr(VI) and Cr(III) via sequential injection was used to demonstrate the sensitivity enhancement provided by a newly developed wetting film extraction system. The reaction product of Cr(VI) with 1,5-diphenylcarbazide was ion-paired with perchlorate and extracted into an organic wetting film consisting of octanol and 4-methyl-2-pentanone on the inner wall of a Teflon tube. The wetting film, with the extracted analyte, was then eluted with 100 μl acetonitrile and the analyte determined spectrophotometrically at 546 nm. Important optimized parameters were the selection of wetting film and elution solvents, the flow rate, the length and diameter of the extraction coil and the conditions for the formation of the ion paired chelate. Cr(III) was previously oxidized to Cr(VI) and calculated as the difference between total Cr and Cr(VI). An enrichment factor of 25 and a detection limit of 2.0 μg l^{-1} Cr(VI) were achieved with a sampling frequency of 17 h^{-1}. The calibration curve was linear up to 100 μg l^{-1} Cr(VI) ($r = 0.999$). The relative standard deviations were 2.8 and 2.0% at the 25 and 100 μg l^{-1} levels. © 1997 Elsevier Science B.V.

Keywords: Chromium; Extraction; Sequential injection; Spectrophotometry

1. Introduction

Recently, a flow injection extraction technique using replaceable organic wetting films on Teflon tubing was developed in our laboratory [1]. The value of this technique is that it has several key advantages over existing extraction methods, and it can be incorporated into many flow injection/sequential injection analyses to enhance sensitivity and selectivity. Compared with the long-standing segmented flow extraction methods, organic wetting film extraction is easier to apply because it does not involve phase segmentors, phase separators or discriminating on-tube detection of segmented flow streams [2]. Wetting film extraction furthermore consumes approximately ten times

PII S0039-9140(96)02180-7

less organic solvent. The extracting phase is injected and discarded during each analysis cycle so that regeneration or reuse are not necessary, unlike tube wall adsorption [3,4] or reversed permeation membranes [5].

Historically, the development of wetting film extraction grew out of Lucy's segmented method of flow injection extraction [6]. Lucy and Yeung emphasized the usefulness of stationary organic wetting films to delay the average flow rate of extracted species in an aqueous/organic segmented flow system. The delayed flow rate was due to the partitioning of extracted analytes between the flowing organic segments and the stationary film. The differing flow rates achieved a separation of the extracted and unextracted species. Previously, stationary films were usually regarded as a source of unwanted dispersion in segmented flow systems. A logical extension of Lucy and Yueng's approach was to dispense completely with the flowing organic segments and attain the full benefit of the stationary wetting film.

In this paper, we demonstrate the use of organic wetting film extraction to enhance the sensitivity and selectivity in the sequential injection analysis of Cr(VI) and Cr(III) in natural waters. The colorimetric determination of chromium(VI) and (III) in water using 1,5-diphenylcarbazide was selected partly because it has been used to demonstrate various flow injection configurations [7–17]. The enhancement of sensitivity also makes the chromium determination more useful for trace environmental analysis. Yoshimura enhanced the sensitivity of the Cr(VI) determination 10-fold by solid phase spectrophotometry using cation exchange beads [18]. A detection limit of 0.5 ng ml^{-1} was achieved. Unfortunately, electrolytes present in natural water interfered. The sample solution must be passed through a hydrogen-form cation-exchange column, or matrix matched standard solutions must be used [19]. In this work, electrolyte interference is avoided by extracting the colored complex quantitatively as an ion pair into an organic wetting film, resulting in a similar enhancement of sensitivity.

2. Experimental

2.1. Apparatus

Fig. 1 illustrates the sequential injection manifold for the preconcentration and spectrophotometric determination of chromium(VI). Solutions were driven by two peristaltic pumps (Alitea USA, Medina, WA) with Masterflex # 13, # 14 and # 16 Norprene pump tubes (Cole-Parmer Instrument Company, Chicago, IL) for different flow rates. A six-port rotary selection valve V_1 (Valco Instrument Co., Houston, TX) was used to select the solutions. A 5.0 ml holding coil was used as an injection loop on an injection valve, V_2. The holding coil consisted of 5.6 m of 18 gauge Teflon tubing, 1.07 mm i.d. (Small Parts, Miami Lake, FL). The sample and reagent were loaded into the coil by pump P_2. Another injection valve, V_3, was used to inject the eluting solution via a Teflon 100 µl injection loop. Both injection valves were six-port, two position valves (Valco). The eluting solution was loaded into the loop manually with a syringe. The extraction coil, EC, consisted of a 3.5 m length of thick-walled Teflon (PolyTetraFluoroEthylene, PTFE) tubing (Small Parts, Miami Lake, FL) with an inner diameter of 1.07 mm (18 gauge) coiled on a 20

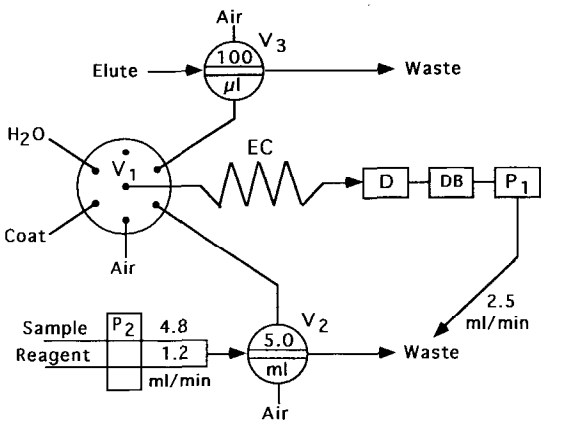

Fig. 1. Scheme of the sequential injection-wetting film extraction system. P_1, P_2 = peristaltic pumps, V_1 = selection valve, V_2, V_3 = injection valves, EC = extraction coil, D = detector, DB = displacement bottle, Coat = coating solvent, Elute = eluting solvent.

mm diameter rod. The extraction coil was connected to the common port of the selection valve, V_1. All other tubing connections were made with 0.8 mm i.d. Teflon tubing and Teflon nuts and ferrules (Upchurch, Oak Harbor, WA). A displacement bottle was placed between the detector and the pump P_1 to protect the pump tube from organic solvents. A Brinkmann colorimeter (PC-701, Brinkmann Analytical, Wesburg, NY) served as both the light source and detector. The transmittance cell was a sandwich cell with a 2.0 mm Teflon spacer [20]. The incident light passing through a 546 nm interference filter (Edmund Scientific) made two passes through 2.0 mm of solution for a total pathlength of 4 mm. Control of pump P_1 and valve V_1 and collection of data were performed with Atlantis software (Lakeshore Technologies, Chicago, IL).

2.2. Reagents and solutions.

All solutions were prepared in purified water (NANOpure II, Sybron Barnstead, Dubuque, IA). All chemicals were analytical reagent grade. Acetonitrile, acetone and methanol were used as received. All organic solvents that were immiscible with water were saturated with water before use.

Standard chromium(VI) solution (500 μg ml^{-1}) was prepared by dissolving potassium dichromate (Mallinchrodt) in water. Working solutions were made by step-wise dilution of the stock solution with water.

Standard chromium(III) solution was obtained by reducing 10.0 ml Cr(VI) stock solution with 25 mg Na_2SO_3 and 10 ml 6 M sulfuric acid. Excess sulfite was removed by boiling and then cooling the solution to room temperature. The solution was diluted to 100 ml with water. Working solutions were made by dilution of the obtained solution with water.

The colorimetric reagent was 1,5-diphenylcarbazide (DPC), also called 1,5-diphenylcarbohydrazide (Sigma). DPC solution was prepared by dissolving 0.1 g DPC in 10 ml acetone (J.T. Baker) and storing in a brown bottle at 4°C.

Sodium perchlorate solution was made by dissolving 61.2 g sodium perchlorate (Aldrich) and 1.0 ml of 6.0 mol l^{-1} sulfuric acid in water and diluting to 100 ml. Sodium perchlorate contains chromate impurities. The solution was purified by adding 1.0 ml of DPC solution and washing with aliquots of 4-methyl-2-pentanone (Aldrich) until the wash solution was colorless.

A color developing solution was prepared by mixing 2.5 ml DPC solution with 100 ml sodium perchlorate solution. This solution should be prepared daily.

A coating solution was made by mixing 10 ml octanol (J.T. Baker) with 20 ml 4-methyl-2-pentanone.

An ammonium cerium(IV) sulfate solution was made by dissolving 0.20 g ammonium cerium(IV) sulfate (Aldrich) in 2.5 mol l^{-1} sulfuric acid and diluting to 50 ml.

2.3. Sample preparation

For the determination of Cr(VI), the untreated, unfiltered water sample obtained just prior to analysis was loaded into the reaction coil. The same sample was then oxidized by Ce(IV) before aspirating into the reaction coil so that total Cr could be determined as Cr(VI). Samples were oxidized by adding 0.10 ml of the Ce(IV) solution to 9.9 ml sample then heating the mixture in a water bath for 5 min at 45°C. Samples were cooled to room temperature before loading. Lake, sea (Puget Sound) and drinking waters from Seattle were used as samples.

2.4. Procedure

The procedure, outlined in Table 1, is three chemical steps: (1) color development and ion pairing; (2) extraction into an organic wetting film; and (3) elution of the film to the detector. In the first step, the sample solution and reagent were merged in a T mixer and passed directly into a 5.0 ml reaction coil which was installed as an injection loop on valve V_2. The flow manifold and flow rates are given in Fig. 1. Before unloading the reaction coil into the extraction coil, the extraction coil, EC, had to be washed with water and coated with extraction solvent. A fresh film of organic solvent was formed on the extraction coil by switching valve V_1 to port 'Coat' and, aspirat-

Table 1

* Steps 1 and 6 were done concurrently to increase sampling efficiency.

ing with pump P_1. Next, a zone of air was aspirated from valve V_1 to separate the coating zone from the sample solution to follow. With a fresh extracting film on EC, the treated sample was aspirated from the reaction coil (on V_2) into the coil 'EC.' At this point, the complexed, ion-paired analyte was preconcentrated in the wetting film on EC. After the sample zone had passed, followed by a separating zone of air, the film was eluted to the detector by a zone of acetonitrile from the injection loop of valve V_3. Valve V_3 was switched manually, and pump P_1 was used to aspirate. Data was collected at 2 Hz.

3. Results and discussion

3.1. Coating solvent

Most critical to this work was the development of an organic thin film that could be formed and removed during each analysis cycle. The development of such a film required that we, firstly, identify solvents that extract our analyte well and, secondly, blend these solvents to optimize film characteristics. Extraction solvents were blended in order to satisfy the following necessary film characteristics: the film must be adequately insoluble in water, it must have a sufficiently high capacity for the analyte, it must be stable during extraction, and it must be eluted after sample perfusion.

Solvents containing hydroxyl and ketone functional groups were found to solvate the ion-paired chromium complex effectively. Other solvents tested were benzene, toluene, chloroform, carbon tetrachloride, dimethylsulfoxide, cyclohexane and hexadecane. All of these resulted in signals indistinguishable from those of blank solutions ($\sim$ 0.003 AU) when a 100 $\mu g\ l^{-1}$ Cr(VI) solution was used. Table 2 shows the absorbances resulting from various wetting film compositions.

The extraction solvents were blended to produce good wetting film characteristics according to some guiding principles. Operating properties were adjustable since ketone and alcohol extraction solvents have a range of physical properties. Film thickness was assumed to be the most critical film property. As a result, the strategy for finding the optimum mixture was straightforward. The solvent mixture was varied in order to vary the thickness of the film, while absorbance peak area was maximized. Film thickness was a guideline for optimization, but was not actually measured. Rather, the viscosity and surface tension of the solvent mixture were varied in the experiments since the film thickness is related to these, and their values are known for the pure solvents. Film thickness is directly proportional to viscosity and inversely proportional to surface tension [21]. The performance of the film was especially sensitive to viscosity.

There is a trade off between the capacity of the film for the analyte and the ease with which the

Table 2
Effect of coating solvent on the preconcentration of 100 $\mu g\ l^{-1}$ Cr(VI)

25% Octanol+75% MIBK	0.3337

film can be eluted to a detector. Both of these characteristics depend, predictably, on the thickness or viscosity of the film: thick films have high capacity but are more difficult to elute. As a lower limit, the film must be thick enough that it does not break up during sample perfusion. As an upper limit, it must be possible to remove the film quantitatively. Between these two limits, one should compromise between sensitivity and dynamic range. Lower capacity results in higher sensitivity because a smaller volume of extraction solvent yields higher enrichment factors. Higher capacity allows for a higher breakthrough concentration. A lower film thickness was chosen in this work. Although sensitivity was favored at the expense of dynamic range, the dynamic range was adequate for most water samples.

Film thickness and ease of elution were functions of the number of carbons for pure solvents. The solubility in water was a limiting factor for 2-propanol, 1-butanol and 4-methyl-2-pentanone. At five carbons or higher, alcohols were sufficiently insoluble in water, but they were too viscous so that the films were too thick. The perchlorate-Cr complex ion pair was completely extracted into the films, but the films could not be removed by satisfactory means. Excessive film thickness also decreased the sensitivity and enrichment factor by increasing the volume of the organic phase. Two selected extraction solvents, 1-octanol and 4-methyl-2-pentanone, had viscosities around the ideal value. These were blended to optimize film thickness. The highest sensitivity (peak area) was obtained with a mixture of 33% (volume) 1-octanol and 67% 4-methyl-2-pentanone.

The results shown in Table 2 verify that the perchlorate-paired complex did not adsorb onto the tubing wall. Without a wetting film, the absorbance of a 100 μg l^{-1} Cr(VI) standard solution was indistinguishable from that of a blank solution. Adsorption onto tubing walls has been used in the determination of ion-paired dye [3] and metal ion chelates [4].

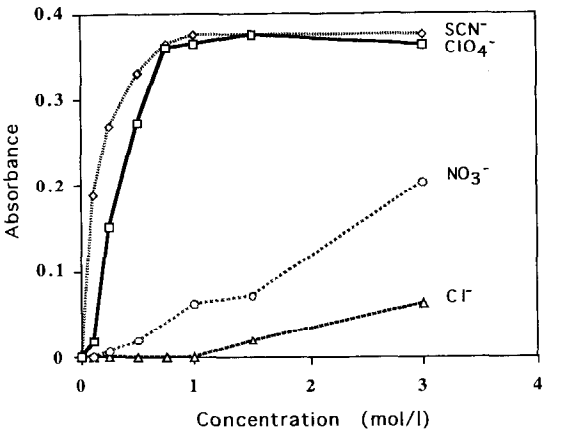

Fig. 2. Effect of pairing anion concentration on the extraction of Cr(VI).

3.2. Color development and ion-pairing conditions

Chromium(VI) forms an intensely colored complex with DPC in acidic solution. The reactions occurring were reported to be the simultaneously oxidation of DPC to diphenylcarbazone, the reduction of Cr(VI) to Cr(III), and the chelate formation of Cr(III) and diphenylcarbazone [22,23]. Although the structure of the chelate is still uncertain, it is evidently a cation [22]. The chelate can only be extracted into aqueous solution as a neutral ion pair in the presence of excess anions. Fig. 2 shows the performance of various counterions on the extraction of the colored chelate. The anion concentrations given are those of the extracting solution after flow manifold mixing. Thiocyanate and perchlorate were most efficient, but perchlorate was preferred based on interference studies (discussed later). The recommended perchlorate concentration, used for standards and samples, was 1 mol l^{-1}. Ion pairing did not alter λ max (540 nm) or the extinction coefficient.

The effect of sulfuric acid concentration was investigated by varying the concentration in the reagent solution. The peak heights were found to be highest and independent of sulfuric acid concentration over the range 0.005–0.1 mol l^{-1} (pH 0.7 ~ 2.0). It was also found that the acidity influenced the color development, but not the forma-

tion of ion paired complex. Sulfuric acid concentrations used for Cr(VI) and total Cr determinations in the proposed manifold were 0.012 mol l^{-1} (pH 1.6) and 0.032 mol l^{-1} (pH 1.2), respectively.

3.3. Elution solvent

Once the ion-paired chelate had been extracted into the 1-octanol 4-methyl-2-pentanone film, 100 μl of the elution solvent was injected into the extraction coil to disrupt the adhesion of the film to the Teflon and to elute it to the detector as one homogeneous segment. An ideal elution solvent is one which does not form a film or forms a very thin and unstable film. Such a solvent would be expected to have a low viscosity and a high surface tension [24]. The elution efficiencies of methanol, acetone and acetonitrile were investigated with 100 μg l^{-1} Cr(VI) standard solution. A small and adequate volume of elution solvent, 100 μl, was used throughout.

The efficiency of film elution after extraction was examined by measuring the peak areas of three sequential aliquots (100 μl each) of the elution solvent. Complete elution of the Cr(VI)-DPC complex was assumed for three aliquots. The percent recovered in the first aliquot is reported in Table 3 as the elution efficiency. With the smallest ratio of viscosity to surface tension, a single segment of 100 μl acetonitrile can elute 92% of the extracted analyte. The second and third aliquots, used for cleaning, eluted 7.4 and 1.3%, respectively.

3.4. Optimization of the manifold

Parameters of the manifold that were optimized were the flow rate, the sample volume and the length and diameter of the extraction coil. The oxidation of Cr(III) was also investigated.

Thickness of the wetting film is directly proportional to the inner diameter of the extraction coil. As a result, the extraction capacity (volume of the wetting film) is larger for wider and longer extraction coils. However, excessive coating solvent adsorbed on the coil requires excessive elution steps. The optimum extraction coil was PTFE tubing 3.5 m in length and 1.07 mm (18 gauge) inner diameter.

Wetting films formed much more readily on PTFE Teflon than on clear FEP Teflon. An equation predicting film thickness [21] that has long been cited in segmented flow extraction publications [24] neglects any consideration of the tubing material. Nevertheless, this equation was a useful guideline for predicting the effects of flow rate, viscosity and surface tension on film thickness.

Generally, a faster flow rate (pump P_1) results in a thicker film. In the range of 1.0–3.5 ml min^{-1} (1.8–6.5 cm s^{-1}), the peak areas were independent of the flow rate. Flow rates lower than 1.0 ml min^{-1} resulted in analyte breakthrough due to insufficient capacity because the film was too thin. Flow rates higher than 3.5 ml min^{-1} resulted in thick films with high capacity; however, analyte recovery was low partly because the contact time with the extraction solvent was shortened. Excessively high flow rates allowed even the elution solvent to form a film so that the elution of the analyte was incomplete.

To simplify the manifold, attempts were made to pump the aqueous sample and reagent directly into the extraction coil. The Cr(VI)-DPC reaction proved to be too slow [16]. The extraction efficiency was only 42% of that of the proposed system and conditions, as determined from relative peak areas. Having a separate reaction coil allowed as much time as needed for the ion paired chelate to form.

Different volumes of Cr(VI) standard solutions (100 μg l^{-1}) were injected into the extraction coil by changing the length of the reaction coil on valve V_2. The absorbances increased linearly with the injected sample volumes up to 6.0 ml (the total volume of sample plus reagent is 7.5 ml). Breakthrough occurred beyond 6.0 ml. A good compromise between sensitivity and sampling frequency was a sample volume of 4.0 ml.

The on-line oxidation of Cr(III) to Cr(VI) with Ce(IV) was reported to be incomplete [8,10]. The yield of Cr(VI) depended on the temperature, length of the reaction coil, flow rate, the concentrations of Ce(IV) and sulfuric acid, and the FIA manifold configuration. Coupling an oxidation system to the extraction system would make the manifold exceedingly complex. Therefore, water samples were pretreated. The oxidation was easily achieved by heating a mixture of 0.1 ml of Ce(IV) solution and 9.9 ml of water sample in a 45°C water bath for 5 min. Chromium(III) can be quantitatively oxidized to Cr(VI) and only one calibration curve is needed for the measurement of both Cr(VI) and total Cr.

3.5. System performance

Fig. 3A is a set of peaks observed for 25 and 100 μg l^{-1} Cr(VI) standard solutions as the eluted wetting film passed through the detector. The eluted film was preceded and followed by air. In contrast to most flow injection applications, the analyte signal was nearly constant as the zone passed through the detection cell. Extraction into a single homogeneous zone replaced the usual dispersion mixing. The irregular shoulders on the leading and following edges of the rectangular elution peak were due to light scattering at the solution/air interfaces. The light scattering was excluded by using only the absorbance measurements between 3.5 and 5 s, as in Fig. 3B. Fig. 3B shows absorbance versus time data of 27 runs of standard solutions ranging from 5 to 100 μg l^{-1} and two blanks.

The data shown in Fig. 3B was used to calculate a calibration curve. The average absorbance for each run was used. The data demonstrates a linear response to concentrations up to 100 μg l^{-1}. The y-intercept of the calibration line is indistinguishable from the blank absorbance value. The least squares line is absorbance =

$(3.913 \times 10^{-3})C—5.5 \times 10^{-3}$, $R^2 = 0.998$, where C is concentration in μg l^{-1}. The limit of detection, calculated on a 3σ basis, was 2.0 μg l^{-1} Cr(VI). The relative standard deviations of 25 μg l^{-1} and 100 μg l^{-1} Cr(VI) solutions were 2.8% ($n = 10$) and 2.0% ($n = 10$), respectively. The analysis can be performed at a rate of 17 h^{-1}.

3.6. Interference studies

Various ions were tested for interference in the determination of Cr(VI). No interference was observed for at least 1000 mg l^{-1} of Na(I), K(I), Ca(II), Mg(II), NH_4^+, Cl^-, NO_3^-, SO_4^{2-}, PO_4^{3-}, and 50 mg l^{-1} of Ni(II), Mn(II), Zn(II), Cd(II), Pb(II) on the determination of 100 μg l^{-1} Cr(VI). Analyses were performed using both thiocyanate and perchlorate as ion-pairing anions. However, thiocyanate resulted in positive interferences from Fe(III), Cu(II), Co(II) and Mo(VI). With perchlorate as the ion-pairing anion, all of the interferences were satisfactorily tolerated (Table 4) except V(V). Fortunately, V(V) is not likely to be encountered at such levels in most water samples.

3.7. Application

The method was applied to the determination of Cr(VI) and Cr(III) in tap water, lake water and Seattle area sea water samples. No interferences were found in three water samples tested by standard additions. The results of standard additions are given in Table 5.

4. Conclusion

The described wetting film extraction system is suitable for on-line preconcentration and separation. The method avoids the complications and performance limitations of segmented flow extraction which has been extensively studied for over two decades. With only μl scale organic solvent consumption, the sensitivity of an assay is enhanced in proportion to the enrichment factor. This extraction system can easily be coupled to detectors or subsequent analyzers because the analyte is uniformly distributed in a single segment of extraction solvent. Thus, it is possible to determine chromium at μg l^{-1} levels using simple spectrophotometric detection.

Received 30 July 1996; received in revised form 1 October 1996; accepted 2 October 1996

Abstract

The development of a glucose sensor suitable for use with whole blood is described. It is based on anodic oxidation at +700 mV of hydrogen peroxide with a platinum electrode covered with a gas permeable membrane. Glucose reacts with glucose oxidase immobilised on the external side of the membrane, and forms hydrogen peroxide which is able to cross the gas permeable membrane due to its high vapour tension, while other electroactive substances that are important interferents are completely blocked. This principle was discovered several years ago but no practical application was presented up to now. Therefore in this work a number of different commercial membranes were tested, in order to obtain a resistant, rapidly responding and interference free sensor to be used in conjunction with a blood gas measurement apparatus. Coimmobilisation of glucose oxidase and catalase was found to be useful for fast response and recovery of the electrode. Using some of the tested membranes, the linearity range is 1–15 mM, CV 5%, response time 90 s, recovery time for the next sample 120 s. The membrane's working life is 2–3 weeks. © 1997 Elsevier Science B.V.

Keywords: Biosensors; Glucose determination; Glucose oxidase; Gas permeable membranes

1. Introduction

Enzymes have been exploited for diagnostic purposes in several formats. In recent years enzymes have been coupled to electrochemical transducers, optical fibres, piezoelectric quartz and calorimetric devices in order to obtain biosensors for different chemical substances [1–3]. Great efforts have been made to find a glucose sensor for use in medical diagnosis. Most of the systems developed measure glucose by means of the anodic oxidation of hydrogen peroxide at +600 mV with a platinum electrode. However, several problems arise when the sample is whole blood. Glucose concentration can be up to 20 mM while the K_M of the glucose oxidase is around 1 mM, and the presence of other electrochemical active substances, like acetaminophen, ascorbic or uric acid are often important interferents in such samples [4–7]. Moreover, there is a pressing need in the medical community for an instrument which can measure glucose in whole blood at the same time as the blood gas parameters, like pH, pCO_2, pO_2 and electrolytes.

PII S0039-9140(96)02181-9

One recent approach proposed [8] a new version of glucose sensor exploiting the vapour tension of hydrogen peroxide. In this case a gas permeable membrane was placed in front of the platinum electrode where oxidation takes place. The principle is simple. Glucose reacts with glucose oxidase and forms hydrogen peroxide which, due to its high vapour tension, is able to cross a gas permeable membrane and is oxidised at the platinum electrode.

The interest in this approach arises because the electroactive compounds generally present in whole blood (or serum), like ascorbic acid, uric acid or acetaminophen, are thus completely blocked and the sensor is completely interference-free. However, the teflon membrane proposed in the original paper was very fragile and only a few measurements could be obtained by the experimental apparatus described [8]. More recently the same principle was exploited for hydrogen peroxide determinations [9].

This paper reports the results of research to find a composite membrane formed of three layers, the first a gas permeable membrane supported in order to be strong enough to last several days without loss of selectivity, the second contains the immobilised enzyme and the third is an external membrane which protects the enzyme from microbial attack. Therefore the purpose of this work was very practical: to try to find a suitable membrane working on the principle of interference-free hydrogen peroxide diffusion by exploiting membrane materials that are commercially available.

The assembly of the biosensor was designed to be used in conjunction with blood gas measurement and the experiments were carried out in order to obtain reliable results within the analysis time of such parameters (120 s). This requirement was essential because the medical request was to measure glucose in whole blood during blood gas measurements. Therefore we tried to optimise the glucose sensor using the same cell and procedure of a well known commercial clinical chemistry analyzer.

It is reported that the immobilised enzyme layer should be formed with glucose oxidase and catalase directly coupled on the gas permeable membrane. The catalase catalyses the oxidation of hydrogen peroxide. The enzymatic decomposition of H_2O_2 is then a mean to consume less oxygen during the glucose oxidation (which is a limiting factor) and to decrease the response time.

2. Experimental

2.1. Reagents

Glucose oxidase (GOD, EC 1.1.3.4) from *Aspergillus Niger* (grade VII-s, 100 U mg^{-1}) and catalase (EC 1.11.1.6) from bovine liver (2800 U mg^{-1}) were from Sigma (Italy). Polycarbonate membranes (pore size 0.03 μm) were obtained from Nuclepore (Costar, Milan, Italy). Polycarbonate membranes (pore size 0.015 μm) were a gift from Poretics (PBI International, Milan, Italy). Polytetrafluoroethylene membranes (pore size 0.5 μm) with and without a polyethylene backing (Fluoropore), polyvinilydene difluoride membranes (Durapore hydrophobic, pore size 0.45 μm) and polypropylene membranes (AN hydrophobic prefilters, pore size 0.6 μm) were from Millipore (Vimodrone, Italy). Polytetrafluoroethylene membranes, backed with polypropylene (0.5 μm) were from Whatman (Springfield Mill, UK). Polypropylene membranes (Metricel, pore size 0.1 μm) were from Dasit (Milan, Italy). Nylon membranes (Magna SH, pore size 0.45 μm) were from MSI (Micron Separation, Inc., Bologna, Italy). Urethane/fluoropolymer membranes, backed with polyester (Repel 100, pore size 0.1 μm; these membranes are no longer commercially available), modified acrylic copolymer membranes backed with nylon (Versapor-200R, pore size 0.2 μm) and with polyester (Versapor-200TR, pore size 0.2 μm) were obtained from Gelman Sciences (Milan, Italy). All other reagents used were of analytical reagent grade.

2.2. Enzyme membranes

2.2.1. GOD membrane

1 mg of lyophilised glucose oxidase (GOD) was dissolved in 100 μl Dulbecco buffer (pH 7.04, with

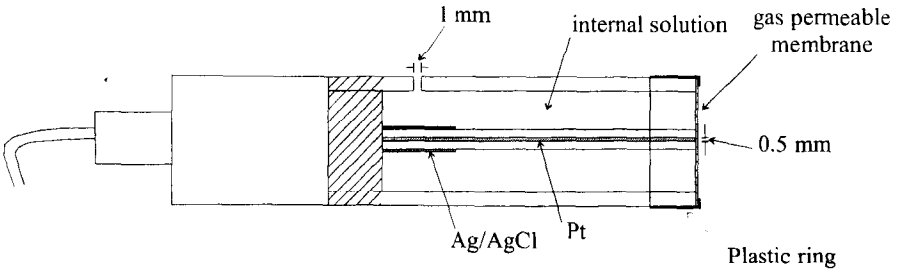

Fig. 1. A schematic representation of the I.L. modified oxygen electrode used as a glucose sensor.

composition 10 mM Na_2HPO_4, 1 mM KH_2PO_4, 2.7 mM KCl, 0.13 M NaCl). 5 μl of this solution were spread over a disk, 0.7 cm diameter, of gas permeable membrane. Immediately after, a solution of glutaraldehyde 2.5% in Dulbecco buffer was mixed over the same membrane. The membrane was left to dry at room temperature, then stored at 5°C.

2.2.2. God/catalase membrane

The membrane with coimmobilized GOD and catalase was prepared by spreading together over the disk 5 μl of GOD solution as described above, and 5 μl of a catalase solution in Dulbecco buffer, with an enzymatic activity equal to (or five times) the activity of the GOD solution. The same procedure as for the GOD membrane was followed.

2.3. Apparatus

The base sensor was an I.L. (Instrumentation Laboratory) modified oxygen sensor (P/N 70961-00), with the working electrode (platinum, diameter 0.5 mm) and the reference (Ag–AgCl) contained in the same jacket which was filled with Dulbecco buffer (Fig. 1). The electrode was used in the cell of a BGElectrolytes System, that is an automatic, microprocessor controlled, blood gas, electrolytes and hematocrit analyzer. Usually it is possible to measure pH, pO_2, pCO_2, Na^+, K^+,Cl^+, Ca^{2+} and hematocrit. The system has a constant temperature of 37°C. When a sampling cycle is initiated, the system aspires, preheats and analyses the blood sample. In our experimental work the glucose electrode replaced the calcium electrode, (Fig. 2) and was connected to an EG and G Electrochemical detector model 400. It was used for constant potential studies performed anodically at +700 mV.

2.3.1. Electrode assembly

The electrode jacket was closed by a plastic ring. The ring was used to keep the composite membrane in tight contact with the platinum surface. The composite membrane was formed of three layers, the inner layer was the gas permeable membrane, the second layer was the im-

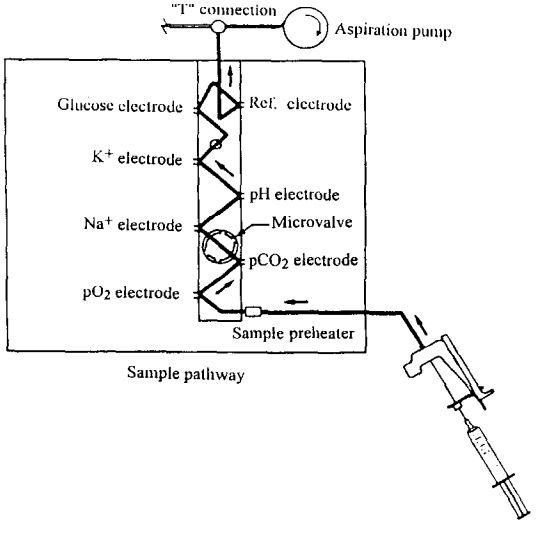

Fig. 2. Representation of the sample pathway. The glucose electrode substitutes for the calcium electrode of the original cell.

mobilised enzyme, and the outer layer was a polycarbonate membrane (pore size 0.03 μm). The side of the gas membrane on which the enzyme was layered and immobilised was mounted facing the outside of the electrode, in contact with the polycarbonate.

2.4. Measuring procedure

The apparatus had an automatic sampling cycle and it was started by the operator. About 240 μl of sample were aspirated into the cell (Fig. 2). Then the flow stopped and the sample remained in contact with the electrodes until the measurement was completed. The signals of the various electrodes were analysed by internal software. The glucose electrode in our system replaced the original calcium electrode and it was connected with the EG & G Electrochemical detector.

After 120 s, or before if all the standard electrodes reached an end point value or a peak value, the software started the washing cycle. The original washing solution, which contained a proteolytic enzyme, was substituted with Dulbecco buffer to protect the enzyme on the glucose sensor. The longest measurement, pCO_2, required about 2 min, and during this period the performance of the glucose sensor was evaluated. During this time the output current was recorded and the current values after 60, 90 and 120 s from the introduction of the sample into the cell were evaluated.

After washing a calibrating solution was aspirated into the cell and it was ready for a new sampling cycle. The time for washing and calibration is about 2 min. Therefore the glucose electrode had to revert to the base line during this time. The sensor was calibrated with 2–25 mM glucose concentration in Dulbecco buffer. The solutions were prepared daily from a 1 M stock solution. To check the integrity of the membrane we used a solution of 1 mM ascorbic acid in Dulbecco buffer. If the membrane was broken or impaired a high current value was obtained. An unimpaired membrane did not show any current increase with this ascorbic acid solution.

3. Results and discussion

3.1. Membranes

The aim of our research was to find commercial membranes with some ideal characteristics: a high permeability to H_2O_2 in order to give a high and quick response; good mechanical resistance, particularly required by the use of the electrode in the cell; and a surface on which the enzyme layer can link strongly (e.g. a certain roughness was found to be useful). For these reasons we tested various membranes, immobilising the enzyme glucose oxidase layer on them. The chosen membranes were all described as hydrophobic, water impermeable and only gas permeable.

For this kind of measurement it is essential to obtain a rapid return to base line during the washing step. To improve the behaviour of the tested membranes, we added catalase to the enzyme layer. The experiments were carried out with three types of membranes: Repel, Versapor-R and Versapor-TR.

Membranes with different GOD:catalase ratios were prepared, but we did not notice any significant difference, either in the signal intensity or in the response speed. In the experiments described we only used a 1:1 ratio.

3.1.1. Polytetrafluoroethylene membrane (Fluoropore, pore size 0.5 μm)

These membranes had a low mechanical resistance. They broke during assembly on the electrode, so they had a high response to ascorbic acid, and could not be used to measure glucose. (These membranes were the ones used in the original work [8].)

3.1.2. Polytetrafluoroethylene with polypropylene backing (Whatman, pore size 0.5 μm)

These membranes, too, had a low mechanical resistance. Generally the response to ascorbic acid rose after a few hours. None of these membranes could be used for more than a day. The response to glucose was high (5 mM of glucose gave, after 120 s, a current of 7.5 nA) but it rapidly reduced after a few hours. They gave a linear response over a 2–10 mM range. The return to base line after washing was rather poor (more than 5 min).

3.1.3. Polytetrafluoroethylene with polyethylene backing (Fluoropore, pore size 0.5 μm)

These membranes were very similar to the ones backed with polypropylene. Only few membranes were tested because of their low mechanical resistance.

3.1.4. Polypropylene membranes (AN hydrophobic prefilters, pore size 0.6 μm)

These membranes were not permeable to hydrogen peroxide so we were unable to take any measurement.

3.1.5. Nylon (Magna SH, pore size 0.45 μm)

Only a few membranes were tested. The response to glucose was good for intensity and reproducibility (the medium response to 5 mM glucose after 120 s was 1.99 nA, CV 1%) but the response was slow and the return to base line was very poor (more than 5 min, and longer times for high glucose concentrations). After only one day of use the membrane became sensitive to ascorbic acid.

3.1.6. Polyvinilydene difluoride membranes (Durapore hydrophobic, 0.45 μm)

These membranes had a good mechanical resistance so they did not have problems with interferences. They had good linearity in the range 2–10 mM. The response, however, decreases rapidly through the day resulting in very low reproducibility. On the second day of use there was no response to glucose.

3.1.7. Polypropylene membranes (Metricel, pore size 0.1 μm)

These membranes had a rather good mechanical resistance, and could be used for 2–4 days. The intensity of the response was quite variable between different membranes, going from 5 to 10 nA for a 5 mM glucose solution after 120 s. The CV was about 8%, but on the first day it could be under 1%. On the following days the response was reduced and the reproducibility got worse. The sensors were linear in the range 2–10 mM. The current did not reach a stable value in 120 s (Fig. 3) and the return to base line after washing was quite slow (more than 5 min).

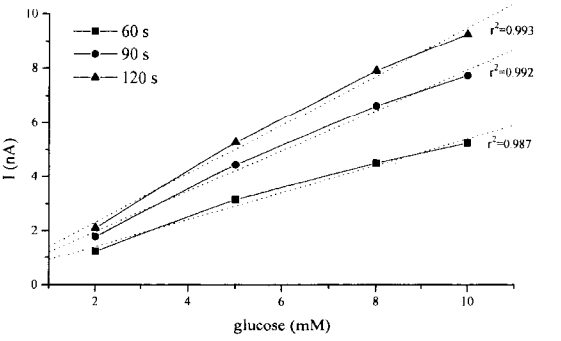

Fig. 3. Calibration curves after 60 (■), 90 (●) and 120 s (▲) from the introduction of the sample into the cell. The curves were obtained from a Metricel membrane with a GOD layer.

3.1.8. Urethane/fluoropolymer membranes, backed with polyester (Repel 100, pore size 0.1 μm)

This membrane was composed of two layers. The polyester had a backing function and it consisted of a felt adherent to the gas permeable part. This assured better mechanical stability. The enzyme solution was applied to the polyester side during immobilisation, and the roughness of the surface favoured the adsorption of the protein. Care was needed in mounting the membrane on the jacket. If the membrane was excessively drawn we got a small but measurable response to ascorbic acid (about a tenth for the same concentration of glucose). If the assembly was correct the membrane could usually be used for several days (7–15).

3.1.9. Experiments with GOD layer

The intensity of the current was variable from membrane to membrane (about 1 nA for a solution of 5 mM glucose after 120 s). The currents on the same day had good reproducibility with a CV of about 1.5%. The response rate was quite high, (Fig. 4a) and at low concentrations a plateau current was rapidly reached. The return to base line was rather quick (less than 5 min) but worse at higher concentrations (Fig. 4a). The current was linear up to 15 mM glucose.

3.1.10. Experiments with GOD/catalase layer

The membrane performance was improved using this layer. In Fig. 5 it is possible to see how

the response after 90 s was about the same as the one at 120 s, thus indicating reaching a plateau. The washing step was also quick at high concentration (return to base line was during the calibration step, i.e. about 2 min) while the sensitivity was similar to those for the corresponding GOD membrane. Fig. 4 compares a typical signal shape without (a) and with (b) the addition of catalase. As regards as the membrane working life, it ranged between 2–3 weeks. After some days we noticed a loss in linearity at concentrations over 10 mM, but return to the baseline remained good.

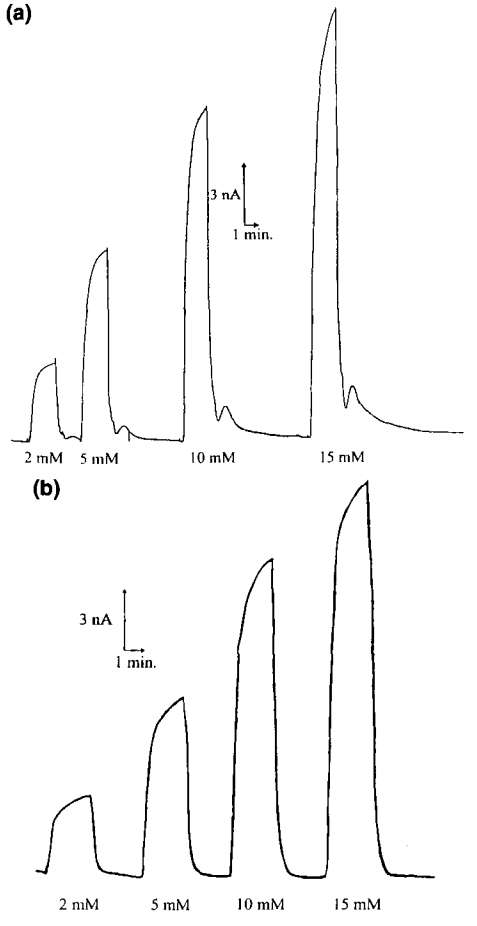

Fig. 4. Typical chart recordings obtained from a Repel membrane with: a, a GOD enzyme layer; b, a GOD/catalase enzyme layer.

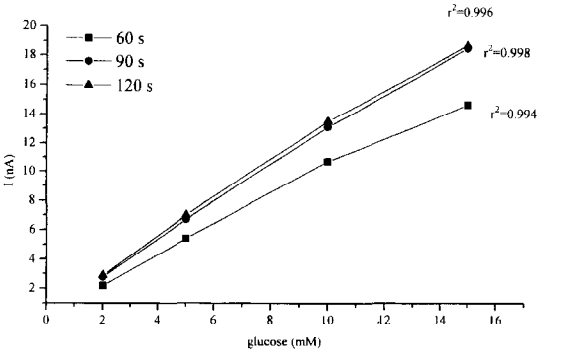

Fig. 5. Calibration curves after 60 (■), 90 (●) and 120 s (▲) from the introduction of the sample into the cell. The curves were obtained from a Repel membrane with a GOD/catalase enzyme layer.

3.1.11. Modified acrylic copolymer backed with nylon (Versapor-200R, pore size 0.2 μm) and with polyester (Versapor-200TR, pore size 0.2 μm)

We discuss the results for these two membranes together as they did not show any difference in behaviour. The structure was similar to the Repel membrane, with a hydrophobic polymer supported by polyester or nylon, but in this case, the hydrophobic layer was polymerised on both sides of the support, i.e. not separable. Both sides were treated to be hydrophobic. These results were with the enzyme layer composed of GOD/cata-

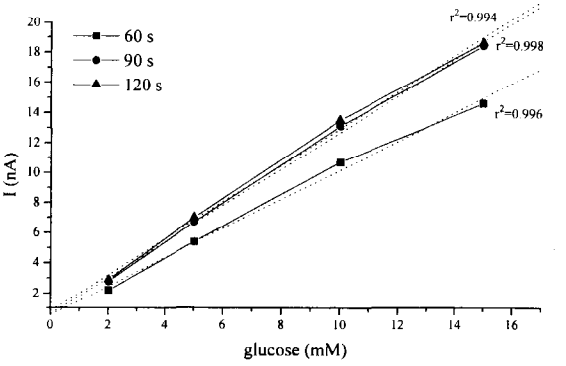

Fig. 6. Calibration curves after 60 (■), 90 (●) and 120 s (▲) from the introduction of the sample into the cell. The curves were obtained from a Versapor membrane with a GOD/catalase enzyme layer.

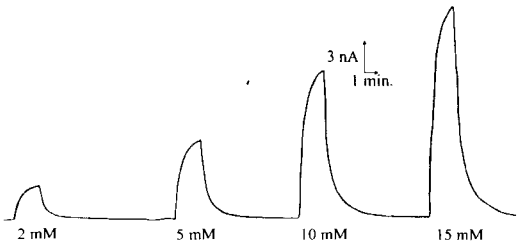

Fig. 7. Typical chart recording obtained from a Versapor membrane with a GOD/catalase enzyme layer.

lase. The signal was linear up to 15 mM (Fig. 6). The response rate was quite good, but return to baseline was worse than the Repel (compare Fig. 4b with Fig. 7). The medium intensity of the response was 10 nA for a solution 5 mM of glucose after 120 s, with a CV of about 5%. The calibration curve was constant for at least 2 weeks.

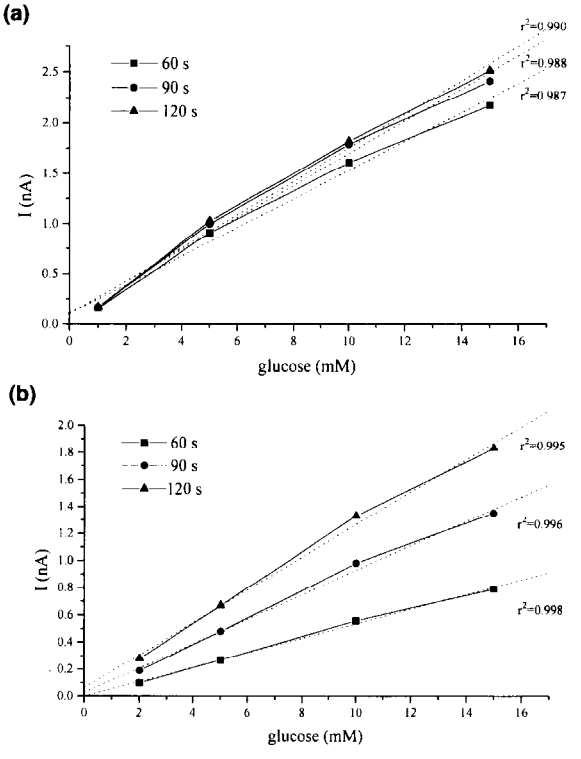

Fig. 8. Calibration curves after 60 (■), 90 (●) and 120 s (▲) from the introduction of the sample into the cell. The curves were obtained from a Repel membrane with a GOD enzyme layer. a, The external membrane was polycarbonate with a pore size of 0.03 μm; b, it was polycarbonate with a pore size of 0.015 μm.

4. Use of different polycarbonate membranes

Fig. 8 shows the results obtained with polycarbonate external membranes with pore size 0.03 μm and 0.015 μm. Using the 0.015 μm we noticed an increase in linearity (Fig. 8a) but at the same time the response rate and the washing rate greatly increased. Attention is drawn to the difference between the recorded current at 60, 90 and 120 s in Fig. 8a and b. With a 0.03 μm polycarbonate membrane, the current measured after 90 or 120 s were also very similar for the highest concentration, i.e. a plateau was reached. With the 0.015 μm, on the other hand, there was a large current variation during all the measuring intervals (Fig. 8a).

5. Conclusions

This research has shown that it is possible to obtain reliable results using the vapour tension of hydrogen peroxide and then completely eliminating interferences by any electrochemically active compound, namely ascorbic acid or acetoaminophen. However commercial membranes, generally used for separation purposes, are not completely suited for such a purpose. Thickness, pore size and hydrophobic treatment are very important features of the final membrane. In the composite membrane the presence of catalase mixed with glucose oxidase is of great importance for a practical glucose biosensor. The presence of it accelerates the response and return to base line. The results reported show it is possible to use this electrode in conjunction with and according to the measuring cycle of a well known commercial instrument developed for blood gas and electrolyte contents measurement of whole blood. Thus it is possible to answer the pressing medical need to develop an unique instrument measuring both blood gas parameters and glucose with a single

sample. It is our hope that in the near future such a sensor could be integrated into the same cell and exploited for glucose measurements in whole blood.

Analytical methodology for speciation of arsenic in environmental and biological samples

Marcela Burguera *, José Luis Burguera

IVAIQUIM (Venezuelan Andean Institute for Chemical Research), Faculty of Sciences, University of Los Andes, P.O. Box 542, Mérida 5101-A, Venezuela

Received 16 August 1996; received in revised form 18 February 1997; accepted 20 February 1997

Abstract

A literature search on the speciation of arsenic in environmental and biological samples shows an increasing interest of many researchers in the subject. Because of the low level of arsenic species in real samples, many problems related with its speciation remain unresolved: species instability during sampling, storage and sample treatment, incomplete recovery of all species, matrix interferences, lack of appropriate certified reference materials and of sensitive analytical methods, etc. These aspects are underlined in this paper. The continued development of new analytical procedures pretending to solve some of these problems claim for an up-to-date knowledge of the recent publications. Therefore, this paper pretends to review the latest publications on the chemical speciation of arsenic, emphasizing the increasing activity in the development of accurate and precise analytical methods. In most of the cases, separation and preconcentration is necessary, followed by element-specific detection for sensitivity improvement. Hydride generation following separation procedures (e.g., ion-exchange or high performance liquid chromatography) coupled to atomic absorption or atomic emission detectors proved to have sufficient sensitivity to monitor arsenic exposure, although restricts the analysis to hydride-forming species. Modified procedures including some kind of heating in the presence of highly oxidizing agents have proved successful to completely decompose the arsenic containing compounds to arsenate and so to extend the range of compounds which can be determined by these methods. On-line arrangements have the additional advantage of avoiding excessive sample handling, although some of them involve numerous steps and others are too costly to be recommended for routine use. The analytical figures of merits, specially detection limits are given for most of the methods in order to afford comparison and judge possible applicability. These studies, which have been approached in many different ways, would lead to knowledge that are determinant in the understanding of the cycle of this element in environment and of its physiological and toxicological behavior in the living organisms. © 1997 Elsevier Science B.V.

Keywords: Arsenic speciation; Environmental and biological samples; Analytical methodology

1. Introduction

The term 'speciation' in analytical chemistry, refers to the determination of different oxidation

* Corresponding author.

PII S0039-9140(97)00064-7

states of an element that prevail in a certain specimen or to the identification and quantification of the biologically active compounds to which the element is bound. Sparingly, in the investigation of toxic effects, the speciation of small molecules (organometallic compounds) is of concern, while for the study of the biological functions, the determination of large molecules has priority. This knowledge could help to explain the mobility, storage, retention and toxicity of the different species in different environments including the human body. The planning of the entire work, from sampling to the interpretation of data claim for an interdisciplinary research. Such studies require knowledge in the field of trace element analysis combined with experience in environmental and/or biochemical analysis [1].

Previously, the determination of total element concentrations was considered to be sufficient for clinical and environmental considerations. Although the total concentration of an element is still useful to know, and indeed is essential in many analytical schemes, the determination of species is an important task. The concentration of a toxic species is more relevant in the setting of environmental and biological standards than is the total elemental concentration. The collection, treatment and preservation of samples for quantitative analysis of species require careful consideration and planning. The nature of this task is very different from procedures for 'total' element determination, therefore analytical chemists are faced with very difficult problems in the acquisition of accurate data. Obviously, any procedure and apparatus adopted for sampling and the preservation of samples between the time of collection and the opportunity for analysis, should not disturb the equilibrium established among the species [2–4]. The introduction of biological contamination is equally undesirable, specially if the samples have to be stored for long periods; the presence of microorganisms and traces of oxygen might accelerate the deterioration of the sample, producing changes between species [4]. A holistic approach, which takes into consideration the various factors that influence the distribution of species of a given element before, during and after sampling is very much required. This is indeed essential if the results of experiments are to provide meaningful information that is indispensable for various studies. Speciation analysis involves a complex scheme of operations designed to simplify the analytical procedures to be implemented, but all, consist, in a way or another, in a separation step followed by the determination of the element in the different fractions. Despite the fact that the topic on speciation has been extensively documented in recent years in numerous publications, so far, there is no ideal method for any element speciation that unequivocally ensure high accuracy of the results. A closed look to the available literature on this subject shows the need for the availability of reference materials for quality control of particular species. Until now, most of the reference materials available for trace element determination in biological and environmental samples are only certified for the total element content [5,6].

A very tempting case to study for speciation is arsenic, which has an interesting behavior since: (1) it has different valence states, [As(III)/As(V)], interchangeable under certain conditions; (2) form small organometallic molecules which are biomarkers of exposure because, it is well known that in the mechanism of detoxification, inorganic arsenic is metabolized to monomethylarsonic acid (MMAA) and dimethylarsinic acid (DMAA); (3) is part of other organic compounds which remain unchanged in the body, like arsenobetaine (AsB), arsenocholine (AsC), arseno-sugars (AsS), arseno-lipids (AsL), etc.; (4) form macromolecular biomolecules, like those of arsenate bound to transferrin and hemoglobin [7]. The increasing interest in this topic is reflected in more than 500 papers, exhaustive reviews [8,9] and comprehensive monographs [3,10–12] published in recent years.

2. Concentration of arsenic species in biological and environmental samples

Arsenic is widely distributed in biosphere, thus the mobilization of the element by human activities (mining, smelting, glass making, refineries or pesticide manufacture) is estimated to exceed the

natural rate (from marine sedimentary rocks, weathering volcanic rocks or fossil fuels) by threefold; hence it might be anticipated that the distribution of the element in aquatic ecosystems and body fluids and tissues would be closely related to antropogenic activities [13,14]. As a result of the extensive use of the numerous arsenic compounds (Table 1), the element is found in a large variety of samples (fresh and sea waters, sediments, soils, plants, marine organisms, body fluids and tissues, etc.), in variable amounts and in a great variety of species.

In ground water, for instance, the levels of arsenic could exceed 20 mg l^{-1}, while in drinking water the concentrations may vary from 0.05 to over 60 mg l^{-1}. In some cases, these levels are two and even three orders of magnitude higher than those of most natural waters consumed by man [15,22]. Contamination of water and air near copper smelters in Argentina [15], Chile [16], USA [17] and Sweden [18] as well as the contamination of drinking water in Taiwan [19] and India [20–23] have been reported in numerous papers. In such samples, As(III) concentrations are normally only a small proportion of the total dissolved arsenic [24]. In an attempt to protect aquatic life as well as to establish a control over the implications of arsenic concentrations for public health, several international organizations [25–27], have prescribed a permissible dissolved, total arsenic

concentration in potable water between 0.008 and 0.05 mg l^{-1}. Despite the fact that it was known that different arsenicals exhibit very distinct toxicological properties, all regulations and reports related only to total arsenic and none differentiates between the toxic impacts of the various chemical species of arsenic [13]. Ingestion of contaminated ground water (containing arsenic of geological origin well above the maximum permissible limit), by people from several districts of West Bengal, India, resulted in excretion of inorganic arsenic and its metabolites in a proportion of more than 90%. It was reported that a daily intake of 1500 μg of inorganic arsenic (equivalent to drinking 1.5 l of water with an inorganic arsenic concentration of 1 mg l^{-1}) could produce signs of overt chronic arsenicism in some individuals [22]. Many of the affected people from India, usually drink more than 5 l per day and they showed serious signs of long-term arsenic exposure [20–23].

The concentration of arsenic in sea water is generally around 2 μg l^{-1} with the trivalent species being less than 10% of this level, while in normal soils the total arsenic concentration usually ranges from 1 to 40 μg g^{-1}, with higher levels in places where arsenicals are used for insect control or on disused mines tips. Certain plants growing on arsenic-enriched soils accumulate extremely high amounts of the element. Most human foods contain less than 0.5 μg g^{-1} arsenic, except those of marine origin which are more richer in arsenic than others. In marine animals and algae, because of biotransformation and accumulation, arsenic is present in organic forms and its concentration typically ranges from 1 to 100 μg g^{-1}. So, the total amount of arsenic ingested daily would be influenced by the amount and type of food included in the diet [28]. For instance, in rivers and soils it is present as arsenate, As(V), and arsenite, As(III); both inorganic species might be subjected to chemically and/or microbiologically mediated oxidation/reduction and methylation reactions, resulting in the transformation of inorganic arsenic in organic derivatives; simple methylated species (MMAA and DMAA) or more complex compounds (AsB, AsC, AsS, AsL, etc.) [29]. It is now certain that phytoplankton take up arsenate from aquatic environments, reduce it to arsenite and methylate the arsenite to produce MMAA and DMAA which are then excreted. This represents a mechanism of detoxification. Arsenobetaine, first reported as a major constituent of total arsenic in the tail muscle of the western rock lobster [30], the most frequently encountered water-soluble form of arsenic in higher aquatic organisms, is generally highly stable and is heavily bioaccumulated. This compound is believed not to be metabolized; after ingestion it is rapidly excreted unchanged in the urine [31]. Some studies, have however, demonstrated that arsenobetaine is unstable when irradiated with ultraviolet light alone [32] or in combination with an oxidizing agent [33]. Higher organisms also contain trimethylarsine oxide [29,34] and tetramethylarsonium ion [35,36]. There are also evidences of the presence of arsenocholine in seafood from polluted areas [37] and in dogfish reference material [38], although in lower concentrations than arsenobetaine. While some authors believe that this compound is also absorbed from the diet and it is partially transformed in arsenobetaine and trimethylarsine oxide [39], Shibata and Morita [36] demonstrated that trimethylarsonium ion and not arsenocholine was present in dogfish reference material. Undoubtedly, more work is necessary to solve these controversies. Arseno-sugars are others arsenic compounds in edible seaweed; there are evidences that the ingestion of seaweed may increase the urinary concentration of arsenic metabolites, one of which is DMAA [40]. Also the existence of arseno-lipids in marine and estuarine biota may be explained by the esterification of arseno-sugars. Although there is lack of evidence that the arsenicals present in foodstuff of marine origin do not cause any hazard to human health, the transformation among species might be taken into account and for reasons of toxicological reassurance should be determined by methods which can be routinely applied. From these statements, it seems clear that consumption of different kinds of food, water or beverages, as well as the amounts ingested, will affect differently the concentration of the different arsenic species in urine [34].

Arsenic is also present in the air at trace amounts, specially in the areas where its compounds are industrially used or where coal is burned. Its atmospheric concentration ranges from about 0.01 to 0.1 ng m^{-3} in clean areas such as Antarctica [41] and up to 500 ng m^{-3} near certain industrial environments such as copper smelters [42]. Particular attention must be paid to the measurement of these species while maintaining the initial As(III)/As(V) ratio during the sample collection, preparation and analysis steps. The average atmospheric concentrations of As(III) and As(V) were about 1.6 ± 1.4 and 5.4 ± 3.3 ng m^{-3}, respectively, in urban area of Los Angeles. Size-fractionated samples of atmospheric particulate matter were obtained employing a high-volume dichotomous virtual impactor as a sampler which allowed for the collection of a sufficient amount of sample so that both species could be routinely detected by HGAAS technique. Fine (< 2.5 μm aerodynamic diameter) and coarse ($>$ 2.5 μm) particles were collected employing different size filters with emphasis on the first fraction which is most efficiently collected in the lungs. This would help assess the impact of the potentially toxic species on human health. The data obtained indicate that both As(III) and As(V) species are present in ambient aerosol and that most of both species (about 75%) were found in the fine particle fraction. The primary source of arsenic in air is assumed to be As_4O_6, formed by the sublimation of As_2O_3 emitted from stationary high-temperature combustion processes (e.g., glass furnaces, primary metallurgical processes and fuel oil combustion) [43,44].

There are only limited studies on the arsenic distribution among different organs and body fluids. For example, the concentration of arsenic in urine of subjects without known exposure to arsenic is generally in the order of 10–20 μg l^{-1} while in the blood averages 0–12 μg l^{-1}, but intake of a meal of fish or shellfish may increase the total arsenic concentration to more than 50-fold, with no [45] or only two-fold [46] increase in excretion of methylated arsenic species. This invalidates the use of total urinary arsenic as an indicator of exposure to inorganic arsenic. In these cases it is advantageous to supplement the analysis with a more selective speciation. The results obtained by the application of such a method might be of interest if a person is suspected of being unable to methylate inorganic arsenic or of having a reduced ability to do so. One of the first studies of this kind determined the arsenic species (As(III), As(V), MMAA and DMAA) in urine of volunteers after ingestion of arsenite-rich wine (50 μg As), arsenate-rich drinking water (200 μg As) and crab meat (340 g) containing organo-arsenic compounds (about 2000 μg) [47]. Resulted that 10% of the arsenite was excreted as As(III), but the majority was methylated and excreted as MMAA and DMAA, 5 h after ingestion. Most of the arsenate was rapidly excreted without noticeable changes and only a small proportion was methylated, while the organic arsenic from the crab meat was quickly excreted without any change. Exposure to As_2O_3 in different industrial situations, results in increased urine arsenic concentrations, being inorganic arsenic, MMAA and DMAA the only relevant chemical forms; DMAA represented 60–70% of the total urinary arsenic elimination when comparing with the results from a reference population [45]. However, ingestion of seafood, even in such low amounts as 100 g, brings about a sharp increase in the total arsenic excretion; this is only confined to organic forms others than MMAA and DMAA. The time course of elimination of this dietary arsenic from the organism varies according to the load, but does not take more than 35–48 h. These results provide a simple tool to differentiate increases in urinary arsenic due to occupational or environmental exposure to inorganic arsenic from increases due to dietary intake of organic arsenic.

Some organic arsenicals have been extensively used as herbicides; it is likely to be present, together with inorganic arsenic species in soil samples. Extraction methods followed by spectroscopic detection have been applied with certain degree of success [48,49]. However, the differences between the soil types as well as the tedious clean-up of the arsenic residues are responsible for the low recoveries obtained.

The major problems in speciation studies are the immense hazards that exist due to contamina-

tion and losses of the element in the preparative steps of the sample for analysis. As these procedures require the use of various materials and reagents, highly pure materials and chemicals have to be made commercially available in order to exclude errors due to contamination. Large discrepancies are noted when comparing the data reported in the literature by different workers. The variations among workers may be due to two reasons: differences among the populations studied or inadequacy of the analytical methodology applied to the preparation of the samples for analysis. Although the first cause must be seriously taken into account, the latter seems more convincing; many researchers have experienced difficulties in the quantitative extraction of arsenic from the samples [13] while others claimed losses of volatile arsenic compounds during dry-ashing or heating with mineral acids [50]. To avoid these difficulties, investigators have also used nitric/sulfuric acids, both without catalysts [49] or in the presence of strong oxidizing agents like V_2O_5 [51,52], $K_2Cr_2O_7$ [51], $K_2S_2O_8$, H_2O_2, $K_2Cr_2O_7$, $KMnO_4$, V_2O_5, alone or in a mixture [53], claiming full recovery for all the species. Ultraviolet [33,39,53–56] or microwave [57–59] radiation and base hydrolysis [60] of the sample in highly oxidizing solutions have proved successful to completely decompose the arsenic containing compounds to arsenate. As photo-oxidation could result in the loss of potentially significant speciation information, less severe photolysis must be applied so that the presence of methylated arsenic compounds in marine waters could be detected in aqueous artificial samples [33,54], serum of uremic patients [55] or marine waters [56]. Also, to avoid the use of strongly reactive media resulted from digestion procedures, investigators developed methods for rapid solid-phase extraction of the non-toxic arsenic compounds from the matrix and the determination of the other arsenic species in the remaining portion [40,47].

Unless convincing evidence is given on the accuracy tests, the data obtained by any procedure could be dubious. Also it will be possible to reach solid conclusions only when sufficiently sensitive and selective analytical methods are developed. These methods must be capable to accurately distinguish between several forms of arsenic in different samples.

3. Analytical methodology for arsenic speciation

The numerous arsenic forms (Table 2) present in the environment and living organisms show large differences in their metabolism and toxicity [61]. Therefore, speciation studies are of critical importance. Also the arsenic species occur at very low concentrations so that reliable results are achieved only by means of very sensitive methods of analysis.

Table 2
Arsenicals of environmental and biological importance

Compound	Formula
Arsenious acid; arsenites; As(III)[a]	$HAsO_2$
Arsenic acid; arsenates; As(V)[a]	H_3AsO_4
Monomethylarsonic acid; (MMAA)[a]	$H_2(CH_3)AsO_3$
Dimethylarsinic acid; (DMAA)[a]	$H(CH_3)_2AsO_2$
Trimethilarsineoxide; (TMAO)[a]	$(CH_3)_3As^+O^-$
Tetramethylarsonium ion	$(CH_3)_4As^+$
Arsenobetaine; (AsB)	$(CH_3)_3As^+CH_2COOH$
Arsenobetaine; (AsC)	$(CH_3)_3As^+CH_2CH_2OH$
Arsenolipids; (AsL)	$(CH_3)_3As^+CH_2CHOHCOOH$ (trimethylarsoniumlactate)
Arsenosugars, (AsS)[b]	
[a] Compounds forming gaseous species: As(III) and As(V) form AsH_3 (B.P. = −55°C); MMAA forms monomethylarsine (CH_3AsH_2 with B.P. = 2°C); DMAA forms dimethylarsine ($(CH_3)_2AsH$ with B.P. = 36°C); TMAO form trimethylarsine ($(CH_3)_3As$).

[b] R_1 = OH, R_2 = OH (Giant clams and algae); R_1 = OH, R_2 = SO_3H (Macroalgae); R_1 = NH_2, R_2 = SO_3H (Brown algae).

Arsenic (III) and (V) are the most often determined species in environmental waters, soils and sediments, while organic arsenic species are common constituents of biological tissues and fluids. Usually the concentration of these species is at low ranges and necessitates a preconcentration step because most of the available detectors still lack the sensitivity for direct determination. Moreover, these detectors are also deficient in selectivity, thus a separation step is required prior to determination. The most popular analytical methods used for arsenic speciation are based on a combination of a powerful separation process with an adequate element-specific detector. The methods frequently used for separation and preconcentration are solvent extraction, precipitation and coprecipitation, ion-exchange chromatography (IEC), gas chromatography (GC) and high performance liquid chromatography (HPLC).

Numerous instrumental methods have been developed either for the determination of total arsenic or its methylated and inorganic forms in soils and sediments, water, air and biological fluids and tissues. Among them, the most commonly used include ultraviolet spectrometry [62–67], electrochemical methods (EQ) [68–74], atomic absorption spectrometry (AAS) mainly coupled to hydride generation (HG-AAS) [75–111], in continuous flows or flow injection systems (FI), atomic emission spectrometry (AES), generally with inductively coupled plasma (ICP-AES) [111–130], ICP-mass spectrometry (ICP-MS) [111–114,124–130]], electrothermal-AAS in graphite furnace (ETAAS) [131–146], X-ray spectrometry [149,150], neutron activation analysis (NAA) [150,151], atomic fluorescence spectrometry (AFS) [152,153], capillary electrophoresis [155–157], etc. On-line combinations of some separation techniques (e.g., HPLC or IEC) with the most sensitive detection methods (AAS or ICP-AES) seem to be highly successful and lower detection limits are obtained, specially if HG is performed before detection.

3.1. Spectrophotometric and electroanalytical methods

The spectrophotometric methods used for the selective determination of arsenic, are usually applicable only to inorganic arsenic. They are based on the formation of colored complexes with certain ligands. For example, arsenic(III) forms a colored complex with silver diethylditiocarbamate [62–64] while As(V) forms arseno-molybdenum blue complex [65,66]. Based on the pH control and on the reduction characteristics of the borohydride ion, the former method was modified so that arsine was generated at pH 4.5 [63] or 6 [64] from As(III) and at lower pH from As(V) [63,64]. The resultant gaseous compound was quantitatively absorbed in silver diethylditiocarbamate solution and the molecular absorbance of the red complex was measured at 525 nm. This procedure is appropriate to determine 0.1 mg l^{-1} of arsenic, but it is susceptible to interferences from both, trace elements and methylated species. The latter method consists in the use of an oxidizing agent like permanganate [65] or iodate [66] to convert all arsenic present in the sample to As(V) used to form the blue compound and then measure the absorbance at 865 nm. As little as 0.005 mg l^{-1} of each species can be detected. Selectivity is achieved by on-line separation of the main interference phosphate, arsenate and silicate using a strong anion-exchange microcolumn located in the aspiration line of the FI system [65].

Also As(III) reacts quantitatively with potassium iodate in the presence of sulfuric acid releasing an equivalent amount of iodine which imparts a pink color to a carbon tetrachloride extract [67]. The absorbance is measured at 520 nm. The last procedure is more sensitive than the previously two already mentioned above; the amount of arsenic detected is 0.002 mg l^{-1}. Besides that the spectrophotometric procedures are less sensitive than other alternatives, they only apply to inorganic species, require long reaction times, and the procedures involve reduction, oxidation, chelation and sometimes extraction and evaporation steps which might disturb the equilibrium between species in the original sample leading to erroneous results and interpretations.

Among the electrochemical methods, differential pulse polarography seems to offer possibilities for quantifying arsenic in both oxidation states.

The procedure is based on the fact that only As(III) is electroactive and directly determined in perchloric or hydrochloric acids as supporting electrolytes [68,69], while total inorganic arsenic was determined after reduction with aqueous sulfur dioxide. As(V) was evaluated by difference. Sulfur dioxide was selected as reducing agent because it reduces As(V) rapidly and quantitatively and the excess reagent is readily removed from the reaction mixture. At low arsenic concentrations, which is really the case for environmental and clinical samples, the procedure is subjected to interferences from some elements present in the matrix {Fe(II) and Cu(II)}, therefore a separation step might be necessary; distillation of As(III) as $AsCl_3$ in concentrated HCl has proved appropriate [70]. Determination of methylated species is also possible by voltametric methods after separation by ion-exchange chromatography [68]. The detection limits of 18 and 8 $\mu g\ l^{-1}$ obtained for MMAA and DMAA, respectively, are far from being sufficiently low so that the procedure be applied for the direct determination of the arsenicals in natural waters. Additionally, before obtaining the analytical signal and after the separation of the species, there are other steps like digestion of each fraction in hot, concentrated perchloric acid, reduction with sulfur dioxide and removal of the excess reagent, each being a powerful source of errors. As As(V) is the stable oxidation state in natural waters and in biological digests, its reduction, at very low concentrations to the trivalent state is difficult and the use of reducing agents like iodide, hydrazine, Cu(I), etc., interfere with the stripping process. Therefore, oxidation of As(III) which takes place spontaneously in the presence of dissolved oxygen is preferred since some investigations on gold-coated platinum-fiber electrodes have shown that As(V) can also be reduced to elemental arsenic provided that extremely low reduction potentials are used (-1.60 V versus Ag/AgCl electrode) [71]. So, as As(III) is easily reduced at a gold electrode, it ought to be possible to determine As(III) in the presence of As(V) by suitable choice of the electrolysis potential. Some voltametric procedures for the determination of As(III) and As(V) have been considered in an expert system developed using KES (knowledge engineering system) [72].

However, given all the difficulties mentioned above, specially those concerning interferences due to complex matrixes or to the presence of certain reagents, the electrochemical methods are not used for routine analysis in the speciation and determination of arsenic in complex matrices samples.

A combination of electrochemical and spectrophotometrical detection for As(III) and As(V) following ion chromatographic separation, respectively, permitted the sequential determination of arsenite and arsenate in water samples [73]. The detection limits were found to be 2.9 and 13 $\mu g\ l^{-1}$ while the recoveries for spiked waste water samples were in the ranges 97.5–104% and 93.5–103% for As(III) and As(V), respectively. In a recent work, Boucher et al. [74] succeeded to differentiate six arsenic species (As(III), As(V), MMAA, DMAA, AsB and AsC) by ion-pair reversed-phase liquid chromatography coupled with amperometric and ultraviolet detection. Arsenobetaine and As(III) were not separated and only As(III) is amperometrically active. The limits of detection ranged from 0.1 μM for As(III) to 1.0 μM for As(V), the method being adequate for the detection of typical arsenical concentrations of 20–50 $\mu g\ l^{-1}$ in normal urine.

3.2. Hydride generation-atomic absorption spectrometry.

The most widely accepted procedures for the analysis of arsenic at $\mu g\ l^{-1}$ level exploit the reduction of some arsenic compounds to gaseous arsines (Table 2). The gas is then thermally decomposed to give elemental arsenic for atomic detectors like AAS, or ICP-AES. Early methods for arsine generation involved the dissolution of metals (Zn, Mg, Al) in mineral acids to form nascent hydrogen which reacts with As(III) to form AsH_3. Other hydride ion precursors that have found use in generating hydrides are $TiCl_3$ [75], $SnCl_2$ in concentrated HCl [76] or Al in basic medium known as Fleitmann reaction [77,78]. The effective reaction with $NaBH_4$ gained acceptance and is now almost universally used for the generation of hydrides ever since its introduced into analytical chemistry [79]. It is well known that

trivalent and pentavalent arsenic show different behavior in the generation process, although it was claimed that some procedures only measure the total content of As in the sample. However, it was demonstrated that even at high concentrations of borohydride and at optimized acid concentrations, the response obtained from As(V) is 10% lower than that of As(III) [80]. The process of formation of arsine from As(V) suggests that there are two steps in the reaction: the reduction of As(V) to As(III) and the subsequent formation of AsH_3. The rates of the redox reaction that involve electrons transfer are rather slow and pH dependent, therefore it appeared that it might be possible to differentiate between the two species provided that the first stage of the reaction is slower than the second at high pH values. Therefore, differentiation is made possible using pH-selective arsine generation technique, in which, for As(V) strongly acidic solutions are required ($pH \leq 1$), while for As(III) hydride formation occurs in solutions up to pH 5 [81–87]. MMAA and DMAA are also reduced to the corresponding hydrides at pH 1. Furthermore, it is not only the pH that affects the speciation, but other factors such as kinetics and complexation are also involved [88,89]. Several researchers, each using their own procedure, came to different conclusions concerning the redox stability of aqueous solutions containing arsenic species and the time scale on which spontaneous changes in species distribution occurred [83,88].

There are two major operation modes of hydride generation systems, batch and continuous modes; both involve reduction of an acidic sample followed by the transport of the hydride to the atomizer. In the batch mode, acidified sample and reducing reagent are injected into a reaction vessel and any hydride produced is purged and carried by a stream of an inert gas, while in continuous systems, acidified sample solution and reductant are continuously delivered for the production of hydride and the gas is separated from the liquid waste in a gas-liquid separator (GPS) also with the aid of a carrier gas. The last mode has two versions: continuous flow and FI.

The hydrides generated in batch systems are either directly delivered to the detector or collected either in a container under pressure together with the hydrogen gas produced in the reaction or in a cold trap for preconcentration when high sensitivity is required. Then, are directly swept into the atomizer or are released via a chromatographic column which separates the products [81–85]. In such systems, peak height and shape are critically dependent on some factors which are difficult to control. However, each instrumental setup can be optimized either to yield a high hydride concentration to attain a high sensitivity or to provide the appropriate conditions to eliminate or at least to suppress the effect of varying matrix components. A strict control of the experimental conditions permits the volatilization of hydrides from As(III) and from the methylated species in a single sample aliquot due to the differences in their boiling points (Table 2). The arsines, together with water vapors, carbon dioxide and any other vapor generated during the reduction reaction are freezed-trapped and sequentially volatilized for elemental determination by AAS. These features have been described by several researchers [81–87]. The use of liquid nitrogen traps has greatly improved the sensitivity of the technique since the volatile arsines are preconcentrated over a period of 5–10 min from a large volume of sample and ultimately passed as a 'plug' of analyte to the detector. Temperature-controlled selective volatilization from the trap makes it possible to differentiate between the different arsenic species, but the other frozen gasses are also released. To prevent freezing of the water vapors in the cold trap, some hygroscopic materials are used to dry the gases. Calcium chloride was mostly used but after several determinations become wet and thus impermeable to argon. This often causes a back-pressure which can blew off the system [90]. Frequent replacement is therefore necessary and loss of arsines is reported. Van Elteren et al. [82] interfaced a novel drying system composed by a commercially available hygroscopic ion exchange membrane and separates the organic compounds without losses of the arsines. The separation of the trapped compounds is carried out under non-isothermic conditions and the low-boiling gases volatilize out of the trap in 10–30 s. A slow heating rate is optimum since at

high heating rates the separation can become poorer and thermal decomposition might take place with subsequent loss in sensitivity [91]. However, the heating rate is greater than 100°C min^{-1} in any case, since the trap is heated from −195 to approximately 60°C in 1–2 min. Apart from being less precise than the selective reduction procedures, these approaches have other problems associated, like the molecular rearrangement during HG and incomplete collection of the hydrides. Insufficient selectivity during the reduction step is another drawback; at pH 5 only As(III) is reduced but MMAA and DMAA to a certain degree as well [82]. The complexity of the system makes on site speciation impossible which implies storage of sample prior to analysis; speciation alteration has to be faced then, in particular for As(III). The generally applied cold trap is U-shaped and made of glass; the relatively high thermal resistance of glass makes cooling and especially heating a slow process at room temperature. In order to achieve better trapping, the tube was half-filled with glass beads, although it was reported that arsines are irreversibly captured by this material [83,92]. Better, more efficient and more reproducible arsines separation was achieved when using the U-tube packed with a gas chromatographic support. The use of a Teflon-lined stainless steel U-tube with a gas chromatographic solid phase permits faster cooling and heating [82–85]. Some kind of electrical heating was also applied to volatilize the species. These systems are also subjected to interference effects and their precision and recovery are strongly dependent on the experimental conditions such as flow of carrier gas, rate of thermal desorption, type of absorbing phase and size of column. Most of these difficulties have been overcome by using an automated and on-line HG-cryogenic trapping followed by MW irradiation to release the hydrides for AAS detection [93].

The use of continuous systems allow minimum sample handling, being less likely to suffer from the problems of contamination or alteration of arsenic speciation. Also continuous flow methods, mainly flow injection, appear to be more tolerant to the presence of nitric acid and to be less prone to transition elements interferences. This effect, at least in part, is due to kinetic discrimination; the reduction of the element to its hydride is completed before reduction of the transition metal ion. The kinetic discrimination in flow systems is responsible for the pronounced difference in sensitivity between the two oxidation states (at least one order of magnitude), so that a pre-reduction step is mandatory. In some procedures, As(V) is reduced to As(III) prior to HG by the use of reducing reagents like: KI [94], thiosulphate [95], or mixtures of KI-ascorbic acid [95] and L-Cysteine [96–99] to achieve pre-reduction for the determination of total arsenic. L-Cysteine was found to be clearly superior as reductant and releaser since provides greater freedom from interference and much better stability of solutions with low concentrations of analyte. The reagent consumption and particularly the acid concentration are significantly lower, which permits the change from use of highly corrosive solutions to solutions of low acidity and low toxicity. This is of advantage for the operator and for the instrumentation, it reduces the cost per determination and produces less hazardous waste. However, controlling the acid nature and concentration, no prereduction is necessary to improve the kinetics of hydride from As(V) [93,100,101]. Such procedures were used to determine As(III), As(V), MMAA and DMAA [93,100], as well as total arsenic and inorganic As(III) and As(V) by either FI or continuous flow HG-AAS in water samples [101]. Although simpler to operate and easier to automate, these systems are limited in their ability to obtain a correct speciation of As. In the presence of MMAA and/or DMAA, As(III) or As(V) will be overestimated. The error will be function of the pH values chosen for the selective volatilization of the inorganic arsenic species and of the amount of organic arsenicals present.

Brannon and Patrick [102] inserted a H_2SO_4 trap between the hydride generator and the AAS to separate alkylarsines from inorganic arsines. While AsH_3 passed through, the alkylarsines were trapped. However efficient, this system does not allow for the identification of the organic arsenicals present. Improved sensitivity was obtained for all the arsine forming species after IEC separation [33,103–105]. The fractions containing ar-

senic species were submitted to hydride generation in batch [33], in a FI system [102,103] or in an on-line arrangement [104]. Although the detection limits, in all cases, are in the range of the ng levels, the methods are only applicable to studies related to arsenic exposure and its monitoring.

Determination of ultra-trace amounts of As(III) (detection limit = 0.003 μg l^{-1})was recently achieved by FI-HGAAS prior on-line preconcentration by coprecipitation with lanthanum hydroxide or hafnium hydroxide [106].

During the last decade HPLC methods have been reported to be capable of separating the most commonly found arsenic species in samples of different types. They offer the advantage of minimizing chemical interferences and rearrangement reactions. However, the time required for the overall analysis is in the range 10–300 min, limiting their usefulness for routine applications. Furthermore, due to the high dilution factors always associated with conventional chromatographic separations, the most sensitive and specific detection techniques such as HG coupled to Flame-AAS, ICP-AES or ETAAS are needed to compensate for dilution. Also the eluents typically contain high concentration of salts which quickly build up on the nebulizer, ICP torch and/or sampling cones of the ICP-MS interface, leading to instrumental drift. HG following HPLC separation, eliminates this problem because the arsenic is converted to its gaseous hydride which is separated without the associated dissolved solids. In the application of coupled techniques care must be taken in the design of the interface, so that the flow rate of a gas or liquid through the chromatographic column must be matched or adjusted in some manner to the gas or liquid uptake rate of a particular detector [2].

Several systems have been developed, based on post-column HG for the determination of the four arsine-forming species in natural waters [107], brawn algae [108], urine [109,110], etc. Hakala and Pyy [109] used an HPLC coupled to a continuous flow system for HG and tetrabuthylammonium ion in phosphate buffer as the ion-pairing agent in the C18 reversed-phase column to determine arsenic metabolites in urine. Matrix interferences from urine samples with different salt content occurring in the separation of arsenic species can be reduced by matching the samples with the mobile phase and by using a relatively low injection volume. The detection limits were 1.0, 1.6, 1.2 and 4.7 μg l^{-1} for As(III), As(V), MMAA and DMAA, respectively. An automated and direct HPLC-FI-HG-AAS method was developed and statistically validated for the assessment of inorganic arsenic and its metabolites in urine [110]. The detection limits of this procedure were compared with those obtained by directly coupling the HPLC column to an ICP spectrometer. The limit of detection of the FI-AAS system is approximately 35 times lower than that of the ICP-AES system, but still not low enough to be able to detect arsenic compounds in urine from non-exposed persons. Therefore, these methods are not applicable to the analysis of urine from normal persons, but could be useful in analysis for arsenic species in urine from highly exposed persons, or persons suspected of being unable to, or having a reduced ability to methylate inorganic arsenic compounds. The major limitation in using HG as a part of the HPLC separation-element specific detector is that many environmentally and biologically important organoarsenic compounds such as AsB, AsC, tetramethylarsonium ion, AsS, etc., do not form volatile arsines and would not be detected. To solve this problem, an appropriate decomposition procedure is required.

An on-line HPLC-microwave-oven (MWO) oxidation with persulphate and HGAAS detection has been successfully applied for the determination of arsenite, arsenate, MMAA, DMAA, AsB and AsC in environmental samples [55]. An anionic cartridge located before the HPLC anionic column, quantitatively retained arsenite, arsenate, MMAA and DMAA. The AsB and AsC which passed through, were separated in the HPLC column, eluted and, each fraction, microwave irradiated after mixing with persulfate for their oxidation to arsenate. The conversion efficiency was reported to be closed to 100%. The solution from the MWO was cooled in an ice bath and mixed downstream with acid and borohydride to form the arsine which was swept into an AAS atomization cell. To determine the anionic species, the same procedure was followed, except that the

anionic cartridge was removed, and water was introduced instead of persulfate. The detection limits were between 0.3 and 0.9 ng (for 100 μl sample). A similar procedure was developed by Le et al. [111] except that they used a dual system to avoid removal of the cartridge during the procedure. Comparable resolution was obtained by using HPLC-separation-MW-digestion with HGAAS or ICP-MS detection. Complete separation of five arsenicals was achieved on a reversed phase C18 column by using sodium heptanesulfonate as ion pair reagent and the detection limits were for example 10 μg l^{-1} for arsenite, DMAA and AsB, 15 μg l^{-1} for MMAA and 20 μg l^{-1} for arsenate.

3.3. Inductively coupled plasma-atomic emission spectrometry

The detection limits achieved in an ICP-AES system are far too high to allow detection of the low concentration of arsenic species present in urine of normal persons. Additionally, when ICP-AES is used for detection, a severe interference by background ions strongly degrades the detection limits. The single ^{75}As isotope has an interference from $^{40}Ar^{35}Cl$ species which has the same mass-to-charge ratio as that of monoisotopic arsenic [112–114]. The extent of this interference is such that the direct determination of the analyte is impossible. In the determination of total arsenic this interference has been eliminated by the addition of nitrogen to the argon carrier gas [115]. Nitrogen addition was found to reduce analyte sensitivity, which made the technique unsuitable for analysis at the required levels. A substantial increase in sensitivity has been reported when using HPLC in combination with HG-ICP-AES [112,116,117]. In the HG step, the concentration of the HCl used is relatively high; as a result, the conventional GLS produces a 'residual aerosol' which is transported to the torch and converted into the interferent. Therefore, HCl should be replaced by mild HNO_3 and L-Cysteine be used as reductant and releasing agent. In that way, the interference from Ar^+Cl^- is avoided and, based on the kinetical reduction, simultaneous determination of As(III) and As(V) in waters was possible without interferences from transition elements [99]. The detection limit for As(V) was 3.4 μg l^{-1} and for As(III) 0.7 μg l^{-1}. Also the effect of the 'residual aerosol' can be eliminated by using microporous membranes as GLS [118,119]. Some workers suggested that selectivity could be improved by an initial separation of the analyte from the matrix (e.g., solvent extraction) followed by the generation of the hydride directly from non-aqueous media and the detection of the analyte by ICP-AES [120,121]. There are some advantages of these applications: (i) a straightforward combination of liquid–liquid extraction with HG to overcome matrix interferences and (ii) the opportunity to determine hydride forming elements in organic samples and solvents directly, without resorting to lengthy re-extraction procedures. The introduction of organic solvents into ICP presents particular difficulties and therefore, the use of miscelles and other organized media with a hybrid aqueous/organic character, could prove advantageous. Arsine can be generated with sodium borohydride from a didodecyldimethylammonium bromide (DDBA) vesicular medium [122]. It was found that the analytical performance of this vesicles-enhanced method is superior to the HG from aqueous media. No speciation studies have been reported, although the detection limits were improved by a factor of two compared with those observed when arsine was generated from aqueous medium, and greater tolerance to interferences was observed [121,122].

However, the most direct method for dealing with this interference is to use a high resolution mass spectrometer. Since the advent of the combination of ICP with MS, exceptionally low detection limits have been achieved [99,111–114,124–127]. Coupling HPLC to ICP-MS, the simultaneous determination of up to six compounds was possible in about 10 min with detection limits in the range few picograms. These values are sufficiently low to study the chemical species at their naturally occurring concentration levels. Also the speciation of arsenosugars in marine reference materials by HPLC-ICP-MS has been recently reported [127].

The cost of an existing commercial ICP-MS instrument makes it one of the most expensive HPLC detector and it may not be realistic to use it in routine analysis or for environmental monitoring. Unless a previous separation technique is used prior to the detection by ICP-AES, the use of HG is mandatory, limiting the method, as in the case of HGAAS, to the speciation of arsine-forming compounds, thus leaving valuable information behind. So, coupling IEC with ICP-AES simplified the process and overcame the interference of Ar^+Cl^-, as it does when coupled to ICP-MS [128]. Optimizing the two systems and using an ultrasonic nebulizer, it was possible to reach detection limits in the range of ng l^{-1} for As(V) and MMAA [129]. The procedure was completely automated for sample retention, elution and regeneration of the resin.

3.4. Atomic absorption spectrometry with electrothermal atomization (ETAAS)

Although the detection of the separated species using on-line techniques, like those described above is ideal, ETAAS is still advantageous because of its sensitivity (two orders of magnitude higher when compared with flame-AAS) and ease of operation. Furthermore, the instrumentation is available in many laboratories. However, this technique has proved limited potential for speciation, apart from being prone to errors owing to pre-atomization losses and to the fact that different arsenic compounds produce different ETAAS responses. Larsen found that using conventional STPF furnace program, calibration for all species was possible with standards prepared from only one calibrant, e.g., arsenate, but the operation of the instrument is relatively slow [131]. He studied the conditions under which ETAAS gives equal and optimum sensitivities for all the arsenic species under study. To improve sample throughput, a fast furnace program that includes the use of a chemical modifier, shorten the time needed for analysis and makes calibration of all species possible using two arsenic species as calibrants, i.e., one for the quaternary arsonium compounds and one for the other species. However, systematic investigations on the behavior of arsenic species in graphite furnace are lacking. Krivan and Arpadjan [132] studied the influence of different matrices (HCl, NaCl, HNO_3 and urine) and of various chemical modifiers (W, Pd and a mixture of W + Pd + citric acid) on the behavior of As(III) and As(V) in the graphite furnace by means of an ^{75}As radiotracer. Different treatments of the pyrocoated tubes showed to thermally stabilize the arsenic species. Such is the case of Ce(IV) [133] and tungsten-carbide coated tubes [134] which improved the responses from arsenite, arsenate, MMAA, DMAA. No pronounced stabilizing effect was observed for AsB and AsC without the addition of palladium chloride to the treated tubes [134]. Aqueous and methanolic solutions of these species were studied because they are the main components of the various extraction systems and HPLC effluents. Attention was directed to a detailed investigation of the pyrolisis stage, which is the most critical step for the analysis of highly volatile species. An attempt to separate in situ As(III) from AsB in W-treated tubes failed because, the authors claim, of the presence of significant amounts of AsB under the conditions used for As(III) determination.

Nevertheless some of the arsenic species occur in some samples at such low concentrations that even ETAAS cannot provide sufficient sensitivity, so that preconcentration procedures have to be combined in order to achieve the required detection power. Attempts to preconcentrate water samples by evaporation before injection onto the furnace have resulted in losses of arsenic and in redox reactions affecting the ratio of species. Many separation-preconcentration schemes, followed by ETAAS detection, include thin-layer chromatography [135,136], or coordination of the species to organic molecules and extraction in organic solvents [137–141], precipitation or co-precipitation [142], adsorption on surfaces like those of ion-exchange resins [143,144] or HPLC columns [145,146].

Extraction as a means of separation and preconcentration of species has been applied most often to solids such as soils, sediments, particulate matter filtered from water and air or biological tissues. A number of extractants have been used by many researchers as a means of selectively

removing the species from the bulk of the sample and also as a means of preconcentration prior to the quantification by ETAAS. Since As(V) cannot be extracted from acidic media, only As(III) could form the ammonium tetramethylenedithiocarbamate complex which is extracted into chloroform and then, is selectively quantified. Prior to the extraction, however, As(V) can be reduced with potassium iodide, thiosulfate, L-Cysteine, or mixtures of hydrogensulfite–thiosulfate and iodide–ascorbic acid. In this case, both oxidation states are determined simultaneously and the As(V) concentration is quantified by difference. Ammonium pyrrolidinedithiocarbamate (APDC) and *o,o*-diethylditiophosphate have been also used as chelating agents for the extraction of As(III) into chloroform followed by back-extraction into an aqueous phase [137].

As(III) is also separated by solid–liquid extraction with sodium diethylditiocarbamate (NaDDC) into methyl isobuthyl ketone (MIBK). Aliquots of the organic phase are determined by ETAAS using palladium in MIBK as chemical modifier. Total arsenic is determined using slurry sampling and Pd-$Mg(NO_3)_2$ to stabilize the arsenic [138]. Extraction of arsenite with sec-butyl dithiophosphate followed by the determination of arsenic in the extract by ETAAS [139] is another mean of inorganic arsenic speciation. These procedures are time consuming because they involve multi-step procedures and usually permit only a moderate preconcentration because there is a limited ratio of organic to aqueous phase that can be reliably handled. The on-line combination of liquid–liquid extraction principles with sorption on a solid phase column material permits the use of a wide selection of functional groups. Rapid and complete elution prevents extensive dispersion of the sample, such as in chromatographic systems. The use of a flow injection on-line separation of As(III)-diethylditiocarbamate complex sorbed on a C18 reversed phase packing (bonded silica with octadecyl functional groups), reduction of As(V) with a sulfite-thiosulfate-iodide solution and preconcentration for ETAAS allows the determination of As(III) and total arsenic in a short time [89]. The fast complexation and sorption (approx. 100 ms) maintain the natural equilibrium between species and prevents their shift during the analysis. One of the main advantages of the on-line technique is that preconcentration takes place in a closed system, avoiding any exposure of the sample to atmosphere. Because of this greatly reduced risk of contamination, very low and reproducible blank values can be obtained. Sample loading, column washing, elution and sample transfer are operations on-line which leads to enhanced precision and accuracy compared with manual batch procedures for sample treatment. Equilibrium needs not be attained because of the exact timing of all process. The strict reproducibility of the process excludes interferences due to kinetic effects. The total time for sample treatment fits well into the running time of a standard graphite furnace program.

A reliable analytical procedure aimed to separate arsenic species in waste and potable waters: it involves a separation step on an extraction chromatographic column filled with a support modified with dioctyltin dichloride [140]. This arrangement selectively extracts As(V) which is eluted from the column with HCl. The effluate containing As(III) and the eluate containing As(V) are then determined by ETAAS in the presence of a mixed modifier of Pd, W and citric acid.

It can be concluded that the extraction procedures mentioned above apply only to inorganic arsenic species. A recent work [141], however, confirmed the suitability of the application of an extractive procedure to the methylated arsenic species. Only inorganic arsenic, MMAA and DMAA were quantitatively extracted in toluene from acidified urine samples, then were stripped from the organic solvent with diluted nitric acid and detected by ETAAS in the range 10–50 μg l^{-1}. None of the other known organic arsenicals were extracted. The results were in good agreement when compared with those obtained by HPLC-ICP-MS and the extractive procedure was recommended for the evaluation of occupational exposure to inorganic arsenic.

Chen et al. [142] determined As(V) and As(III) species in environmental samples by ETAAS after coprecipitation with zirconium hydroxide and were able to differentiate between As(III) and

As(V) by using different temperature programs in the graphite furnace.

Pacey and Ford [143] and Grabinski [144] used the strong affinity of arsenic species for certain ion-exchange resins to completely separate four arsenic species and measure the analyte content in each fraction by ETAAS. These systems gave better detection limits and/or shorter analysis times than the extraction procedures.

The fairly long time required for the analysis of a series of collected fractions may be inconvenient for practical analytical work. More work is needed in this direction to fully exploit the potentiality of ETAAS for speciation. Probably coupling ETAAS directly with HPLC might be the answer; interfacing a stepwise operational procedure (ETAAS) with a continuously flowing effluent from the HPLC column is a real analytical challenge. Although the work reported until now [145,146], do not give experimental details on the instrumental arrangement, making this type of coupling it is not impossible [147,148].

3.5. Other methods

Apart from the procedures described above, and which are massively studied, there are scarce data in the literature about other potential techniques, like neutron activation analysis, mass spectrometry, X-ray crystallography, NMR and IR spectroscopy, etc., which can be used in arsenic speciation. This is probably because the amount of sample per analysis for some of them, as well as the availability of sophisticated and costly instruments in many laboratories are the limiting factors.

Coprecipitation with dibenzildithiocarbamate(DBDTC) and hydrated iron(III) oxide for As(III) and As(V), respectively, followed by the determination of arsenic by X-ray spectrometry was reported [149,150]. Detection limits as low as 0.02 $\mu g\ l^{-1}$ have been obtained. These procedures are also limited to the inorganic species only, although investigations on the behavior of some other arsenic species, e.g., MMAA and DMAA, showed that MMAA is coprecipitated quantitatively with DBDTC when a strong reducing mixture of iodide and thiosulfate was used to reduce As(V) to As(III), while DMAA is not coprecipitated at all. This implies that MMAA interferes in the determination of As(V) [150]. The precipitates were collected successively on membrane filters and arsenic determined by NAA of the filters and subsequent γ-spectrometry.

Extraction and preconcentration of arsenic species prior to irradiation were deemed necessary in NAA methodology, because firstly, the oxidation states of arsenic in the original samples irradiated cannot be distinguished after radiochemical separation and secondly the use of large volumes of samples for irradiation without preconcentration is unsuitable due to the small concentration factor involved. The separation step is also ideal to create an interference-free environment in the matrix during the activation period. The selective extraction of the ammonium tetramethylenedithiocarbamate complex of As(III) into chloroform and the detection of arsenic by NAA after back-extraction was reported by Yusuf et al. [151]. Reduction of As(V) to As(III) was achieved with thiosulfate. Marine samples were subjected to microwave radiation choosing a suitable program to prevent the change in oxidation states of arsenic species during the heating process.

Contrary to AAS, AFS has not been widely used in speciation studies because of its low sensitivity when HG is coupled to introduce the analyte in the diffusion flames normally employed as atom cells for this technique. However, the detection limits have been recently improved, because high-intensity excitation sources e.g., boosted-discharge hollow cathode lamps, have become commercially available [152]. When coupled with HPLC, the fractions could be efficiently nebulized into the flame, and so, AFS becomes a powerful tool for arsenic speciation, achieving detection limits as low as 35, 50, 20 and 20 ng for As(III), As(V), DMAA and MMAA, respectively, in 250 μl of volume injected [153]. The analytical potential of such hybrid techniques has been recently illustrated on coupling vesicle-mediated HPLC to low-power argon microwave-induced plasma (MIP) for mercury and arsenic speciation. A HG technique was used as interface between the exit of the HPLC column and the MIP held in a

Table 3
Analytical details of arsenic speciation in different samples

As species (samples)	Matrix	Measurement technique	Some details of the procedure	D.L. ($\mu g\ l^{-1}$)*	Ref.
As(III), AsT	Waters, sediments, synthetic mixtures	UV-vis	Red complex with diethyldithiocarbamate ($\lambda = 525$ nm) Also arsine absorbed on ligand solution	100	[62–64]
As(V), AsT	Waters	UV-vis	Molybdenum blue complex ($\lambda = 865$ nm) Use of oxidizing agents.	5	[65,66,70]
As(III)	Polluted water	UV-vis	Indirect determination. Reaction with iodate in H_2SO_4-I_2 give a pink color to a CCl_4 extract. ($\lambda = 520$ nm)	2	[67]
As(III), AsT	Synthetic mixtures, SRM	EQ	In voltametric methods only As(III) is electroactive using $HClO_4$ or HCl as supporting electrolytes (As(V) is reduced with SO_2).	N.I.	[68,69]
MMAA, DMAA	Synthetic mixtures	EQ	Differential pulse polarography applied after separation by IEC	18, 8	[68]
As(III), AsT	Seawater, urine	EQ stripping	In the presence of As(V) by suitable choice of the electrolysis potential. (60 s electrolysis)	0.1	[71,72]
As(III), As(V)	Waters	EQ+UV-vis	Following IEC	2.9, 13	[73]
As(III), As(V), MMAA, DMAA, AsB, AsC	Urine	EQ+UV-vis	Coupled to ion-pair reversed phase liquid chromatography	0.1–1 μM	[74]
Soluble As	Soils	HG-AAS	Continuous flow HG-AAS. Selectivity based on pH selective reduction	0.90 all	[64]
As(III), As(V)	Sediment interstitial waters	HG-AAS	As(III) coprecipitated with dibenzyldithiocarbamate in methanol and As(V) with sodium molybdate and tetraphenylphosphonium chloride. (The filters were digested)	N.I.	[82]
As(III), As(V)	Waters	FI-HG-AAS with CT (Fleitmann reaction)	An electrically heated Al column was used to generate arsine in alkaline medium.	0.25	[77]

Table 3 (continued)

As species (samples)	Matrix	Measurement technique	Some details of the procedure	D.L. ($\mu g\ l^{-1}$)*	Ref.
MMAA, DMAA	Sediment interstitial waters	HG-AAS with CT	AsH_3 generated in continuous flow (released on progressive worming at room temperature)	0.05–0.13	[82]
As(III), As(V), MMAA, DMAA,	Interstitial water	HG-AAS with CT	AsH_3 generated in continuous flow using pH selective procedure, trapped in liquid nitrogen (released on progressive worming at room temperature)	0.019–0.061	[86]
As(III), As(V), MMAA, DMAA,	Waters	HG-AAS with CT	Arsines generated 'in batch' by pH selective procedure and trapped in liquid nitrogen (released on electric heating)	1 ng each (up to 70 ml sample)	[91]
Inorganic As, MMAA, DMAA	Waters	HG-AAS with CT, GC separation	Arsines generated 'in batch' by pH selective procedure and trapped in a GC column in liquid nitrogen (released on progressive heating up to 150°C)	0.01 each	[85]
As(III), As(V), MMAA, DMAA,	Soil extract, water	HG-AAS with CT and GC separation	Arsines generated 'in batch' by pH selective procedure and trapped in a GC column in liquid nitrogen (released on electric heating) (Flame-in-tube burner for AAS)	0.026	[84]
As(III), As(V), MMAA, DMAA	Urine	HG-AAS with CT and GC separation	Arsines generated by FIA, cryogenically trapped in a GC column and released on heating in water bath)	N.I.	[98]
As(III), As(V), MMAA, DMAA	Urine	IEC-FIA-HG-AAS	Separation on a GC column. Determination of As in the fractions by FIA-HG-AAS	2 each	[103,104]
As(III), As(V), MMAA, DMAA, AsB and AsC	Urine, waters, synthetic fish and sediment extracts	HPLC-HG-AAS	On-line HPLC, microwave oxidation of all species to As(V), HG-AAS detection. The column retains the anionic species, while AsB and AsC are determined after MW-$K_2S_2O_8$ decomposition.	4–6	[57,58]
As(III), As(V), MMAA, DMAA, AsB and AsC, o- and p-arsanilate, phenylarsonate, tetramethylarsonium	Synthetic mixtures	HPLC-HG-AAS	HPLC-persulfate-mediated photo oxidation with a low power UV-irradiation stage prior to HG-AAS	0.3	[54]

Table 3 (continued)

As species (samples)	Matrix	Measurement technique	Some details of the procedure	D.L. ($\mu g\ l^{-1}$)*	Ref.

* Unless otherwise stated. λ = wavelength; D.L. = detection Limit; N.I. = not indicated; AsT = total arsenic; MMAA = monomethylarsonic acid; DMAA = dimethylarsinic acid; AsB = arsenobetaine; AsC = arsenocholine; and other abbreviation as in Fig. 1.

surfatron at reduced pressure. Enhancements in the emission signals of about 100% were found in miscelles of cetyltrimethylammonium bromide and the detection limits for the arsenic species investigated (arseneous, arsenic, monomethylarsonic and dimethylarsinic acids) were in the range 1–6 ng l^{-1}. This novel methodology has been successfully applied for arsenic speciation in tap and sea waters and in human urine [154].

Also direct current plasma (DCP) atomic emission spectrometry coupled to a modified HG system proved successful for the determination of As(III) and As(V) [90]. Both species could be determined as total arsenic without the need for any prereduction step.

Mohan et al. [59] evaluated the capability of HG-DC helium emission spectrometry as an analytical tool in the speciation of arsenic in soils treated with arsenical herbicides. Due to differences in soil type and samples pore size, the method only permitted semicuantitative speciation.

The separation power of capillary electrophoresis has been widely demonstrated, most of the studies being focused on the optimization of separation parameters for complex mixtures of compounds of biochemical interest. Little effort has been devoted to quantitative studies and less to arsenic speciation. López-Sánchez et al. [155] separate arsenite, arsenate, MMAA, DMAA and phenilarsonic acid in a fused silica capillary filled with a phosphate buffer and detected the signals with an on-column UV detector operated at 190 nm. Capillary electrophoresis with conductivity [156] or AAS [157] detection was also used to speciate arsenic and selenium compounds in water. The samples were injected electrokinetically at 25 mbar for 12 s on to a pretreated fused silica column. The separation was carried out at 25 KV with triton X-100 and cyclohexil-amine-ethanesulfonic acid at pH = 9.4. The detection limit was 40 μg l^{-1} for As(V).

4. Conclusion

From this survey it can be concluded that the analytical techniques available for the detection and speciation of arsenic are diverse. A schematic diagram summarizing the different techniques and some of the most relevant information, such as samples type, procedure and detection limits, are given in Fig. 1 and Table 3, respectively. Each approach possesses both advantages and disadvantages that must be considered with respect to the scope of the study and also the laboratory facilities available. Adequate quantitative determination of complex matrices require the establishment of efficient separation and preconcentration processes, good recovery in clean-up procedures and precision and accuracy controls. All these problems can be partly solved by performing speciation studies with in vivo and in vitro labeled radioactive compounds followed by gamma or beta measurements. This would greatly eliminate the hazard of distorted results due to exogenous amounts of the element; which are not radioactive and will escape detection.

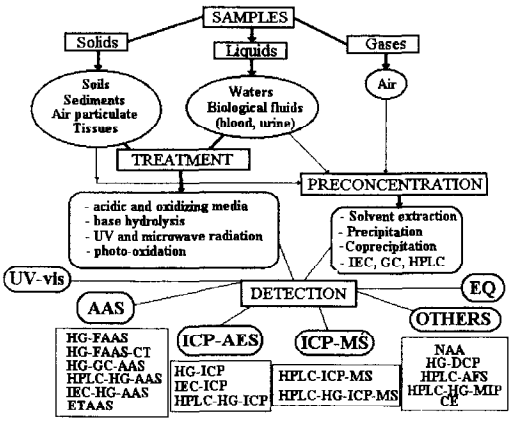

Fig. 1. Procedures for arsenic speciation in different matrixes. When environmental monitoring is used to asses the exposure to toxic compounds, it is important to be able to distinguish between the toxic species (arsenite, arsenate and the metabolites) and the non-toxic species (AsB and AsC). However, most of the methods outlined in this paper are unsuitable for routine analysis of real samples, although HPLC-HG-AAS, HPLC-ICP and HPLC-ICP-MS would appear to be a good choice in terms of sensitivity, selectivity and ease of operation. Their only disadvantage is that the instruments are expensive and not available in many laboratories.

Much work has to be conducted in order to understand first the natural distribution cycle of the element (the dynamics of its mobility through ecosystems) and to compare it with documented perturbations stemming from man's technological inputs and their impact on the public health. A balanced interdisciplinary approach is necessary, formed by analytical chemists, specialists in life sciences, statisticians, ecologists, etc. These multifaceted efforts would be able to respond questions regarding the biotransformation and redox reactions occurring in biological media as well as the interactions that could take place in the environment between arsenic compounds and other natural products to produce new organoarsenicals of perhaps totally different toxicity.

Received 20 September 1996; received in revised form 4 February 1997; accepted 4 February 1997

Abstract

An electrothermal vaporization (ETV) sample introduction device tantalum filament was combined with microwave plasma torch atomic emission spectrometry (MPT-AES) for determination of several trace elements. Some operating parameters of the system were optimized. The effects of easily ionized elements (EIEs) on the emission intensities of the tested elements were studied in detail. It was revealed that there was no interference resulting from small amount of sample matrix; while with the existence of large amount of sample matrix, the method of standard addition could be used to determine trace elements in samples. So, no modifier was required in this method. The results indicated that ETV-MPT-AES not only has the advantage of micro sample consumption (a volume of 3 μl for each injection), but also offers high sensitivities for the determination of Ag, Au, Ge, Pb, Sn and Te as compared with those obtained with pneumatic nebulization (PN) MPT-AES. © 1997 Elsevier Science B.V.

Keywords: Atomic emission spectrometry; Electrothermal vaporization; Microwave plasma torch

1. Introduction

Because electrothermal vaporization (ETV) has some distinct advantages over solution nebulization as a means of sample introduction in plasma atomic spectrometry the ETV method has been investigated extensively. The ETV sample introduction systems have been applied to inductively coupled plasma atomic emission spectrometry (ICP-AES) [1–3], ICP-mass spectrometry (ICP-MS) [3], direct current plasma-AES (DCP-AES) [3], microwave induced plasma-AES (MIP-AES) [1,3,4] and MIP-MS [5,6]. Due to the inability of the low-powered microwave plasma (MWP) to readily tolerate the introduction of large amount of foreign materials, one of the most common and nearly optimal techniques for converting liquid samples into dry aerosols and introducing them into MWPs is the ETV. Graphite [7–14] and metals (tungsten, tantalum, platinum) [15–27] have been used as furnace materials for ETV devices in MIP-AES. Compared with graphite furnace manufactured for graphite furnace atomic absorption spectrometry, metal vaporizers are of

PII S0039-9140(97)00065-9

low-cost and can work at low-power. Though in the development of ETV-MWP-AES, platinum filament was firstly used as a vaporizer [15], tungsten and tantalum were most often employed in latter studies [16–25]. The metal vaporizers used include tungsten loop [16,17], tungsten filament [18], tungsten boat [19,20], tantalum loop [21], tantalum filament [22], tantalum boat [23], and tantalum strip [24,15]. Brooks and Timmins [26,27] described a miniature device based on a heated tantalum filament which eliminated the dead volume and turbulence of the plasma gas was kept to minimum. Evans et al. [6] utilized a tantalum-tip electrothermal vaporizer. The vaporizer is such that the analyte is vaporized in the MIP, there by eliminating the dead volume.

Microwave plasma torch (MPT) was first developed by Jin et al. [28] as a new, attractive excitation source. The tolerance of it to the wet aerosols and molecular species is significantly improved as compared with conventional MWPs for the plasma formed with MPT is flame-like and has a central channel. Since the analyte is forced to pass through the central channel of the discharge, it is efficiently vaporized, atomized, excited and ionized, and causes minimal perturbation to the plasma [29]. MPT has been used as an excitation source for AES coupled with ultrasonic [30] or pneumatic [31] nebulization sample introduction system. Although these sample introduction systems are efficient, they consume relatively large amount of sample solution. In this work, a miniature ETV unit, based on a heated tantalum filament, has been designed to introduce micro aqueous samples into an MPT-AES system. The design of ETV was similar to that of Brooks et al. [26]. A desolvation system similar to that of Que et al. [32] was also set between the ETV unit and the MPT. The tantalum filament was surrounded by Ar carrier gas to avoid its exposure to the air. In addition, the drying time and drying temperature of the sample were strictly controlled to reduce or eliminate interferences caused by the matrix (it is especially important to remove water in samples at drying stage, because during vaporization stage the water can oxidize the tantalum filament at high temperature) and to minimize the vaporization of the tantalum. By doing so, no interference resulting from small amount of sample matrix was observed and no matrix modifier was needed. However, very large amount of the matrix did affect the emission intensities of the elements tested. In this case, the method of standard addition was necessary to be adapted.

Results obtained from our ETV-MPT-AES system proved that the method is not only sensitive, but also of low matrix effect, as well as less time and sample consuming. What is more, the whole instrumentation is compact and inexpensive.

2. Experimental

2.1. Apparatus

The MPT-AES system used is the same as described in our previous work [33]. The ETV system consists of a d.c. voltage stabilizer (maximum output voltage 10 V, laboratory built), a rheochord (maximum resistance 100 ohms) and an ETV atomizer (laboratory built, as shown in Fig. 1). Table 1 lists the operating conditions of the ETV-MPT-AES system used in this study.

2.2. Procedures

After ignition and stabilization of the plasma, 3 μl sample solution was injected onto the tantalum filament loop by using a micro-syringe through the sample inlet on the ETV introduction system. By applying different d.c. voltages across the terminals of tantalum filament, the sample was first dried for a while, and then vaporized and transported into the plasma by an Ar carrier gas. The emission intensity of the analyte was measured with a PMT (1P28) by the recorded peak height.

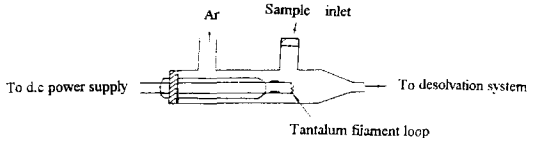

Fig. 1. Schematic diagram of ETV sample introduction system.

Table 1
Operating parameters of the ETV-MPT-AES system

MPT	Carrier and support gas	Ar
	Microwave frequency, MHz	2450
	Forward power, W	60
	Support gas flow rate, mL/min	400
	Carrier gas flow rate, mL/min	650
	Plasma viewing mode	Side-on
	Plasma viewing position	6–8 mm above the top of the torch
Monochromator	Slit-width, μm	25
	Slit height, mm	2
ETV system	Drying time, s	35–80
	Drying voltage, V	0.21–0.63
	Vaporizing time, s	3
	Vaporizing voltage, V	2.28–3.00

2.3. Sample preparation

Sediment sample, 0.5 g, was placed into a polytetrafluorethylene crucible. HF, 15 ml, and 8 ml of concentrated HBO_3 were slowly added in the crucible while it was being heated. When the sample was dissolved completely, 2 ml of $HClO_4$ was added into the crucible to get rid of the retained HF. Heated the solution till it was almost dry, then transported it to a 10 ml volumetric flask and diluted with de-ionized water to the mark.

3. Results and discussion

3.1. Solution medium

HCl, H_2SO_4, HNO_3, H_3PO_4 at various concentrations were used separately as the solution medium. It was observed that when the concentration of H_2SO_4, HNO_3 or H_3PO_4 exceeded 0.1 mol l^{-1} all emission intensities measured decreased, while the addition of HCl could increase the emission intensities of analytes.

The effects of HCl concentration on the emission intensities of different analytes are shown in Fig. 2. It seems that the enhancement effects of HCl are different for different elements. It was found that when the HCl concentration was in the range of 0.01 ~ 0.2 mol l^{-1}, the relative intensities reached a plateau. However, when the HCl concentration exceeded 0.2 mol l^{-1}, the enhancement effect began to reduce. It was also found experimentally that the background emission did not depend on the concentration of HCl. Thus, 0.1 mol l^{-1} HCl was selected as the solution medium in this work.

3.2. Flow rate of carrier gas

Fig. 3 shows the effects of flow rate of carrier gas on the emission intensities, which involves three aspects: (1) the carrier gas flow rate affects the residence times of the analytes in the plasma. The lower the carrier gas flow rate, the longer the residence time. As far as this aspect is concerned, low flow rate of carrier gas is better; (2) the process of the sample transportation to the plasma is also a process of sample diffusing in the carrier gas and depositing to the walls of vaporizer and transportation tube. The carrier gas flow rate affects the sample transportation and hence

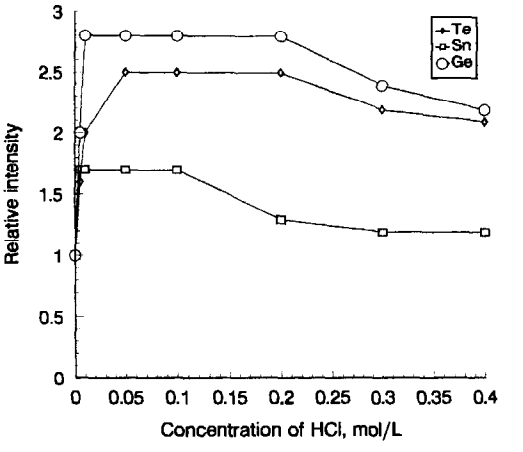

Fig. 2. Effect of HCl concentration on the emission intensities of different elements.

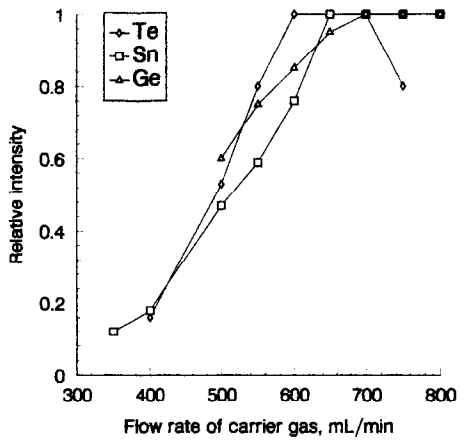

Fig. 3. Effect of carrier gas flow rate on the emission intensities.

the sample diffusion and deposition; (3) the change of the carrier gas flow rate results in a change of the plasma discharge status. It was observed that when the flow rate was relative low ($< 500 \sim 600$ ml min^{-1}), the emission intensities increased with the flow rate; when the flow rate went up to $600 \sim 700$ ml min^{-1}, the emission intensities reached maxima; however, with the further increase of the flow rate (> 700 ml min^{-1}), the emission intensities decreased or unchanged. Therefore, in this study a 650 ml min^{-1} carrier gas flow rate was chosen.

3.3. Flow rate of support gas

The effect of the flow rate of the support gas on the emission is shown in Fig. 4. For all elements tested the emission intensities reached maxima when the support gas flow rate goes up to about 400 ml min^{-1}.

3.4. Drying time and drying voltage

Water vapour can significantly absorb microwave at 2450 MHz, so if water in a sample is not removed, the excitation capability of the plasma will be affected. In addition, oxygen in water can oxidize tantalum filament under high temperature during the vaporization stage and hence reduce the lifetime of the ETV device. So it is necessary to remove water in samples as completely as possible during the drying stage.

Drying time and drying temperature are two correlative factors (the drying temperature was controlled by drying voltage). It was noticed that with the increase of the drying voltage, the optimum drying time became shorter. If drying voltage used is too high or drying time is too low, it will take longer time to remove water and takes longer time to complete the analysis.

For the determination of Te, a certain amount of reductant $SnCl_2$ was added into the sample solution (0.1% $SnCl_2$), thus Te will exist in Te^0 form. Since the boiling points of $TeCl_4$ and Te^0 are 390 and 990°C, respectively, the addition of $SnCl_2$ can minimize the loss of Te during drying stage. Fig. 5 shows the effect of drying time on the emission intensities of Te at different drying voltages.

Drying times and drying voltages of Sn, Ge, Ag, Au were also investigated and the optimum values are listed in Table 2.

3.5. Vaporization time and voltage

The sensitivities of ETV system for elements studied are better than that of PN system for the reason of higher solute transportation efficiency of the former. With the ETV system samples can

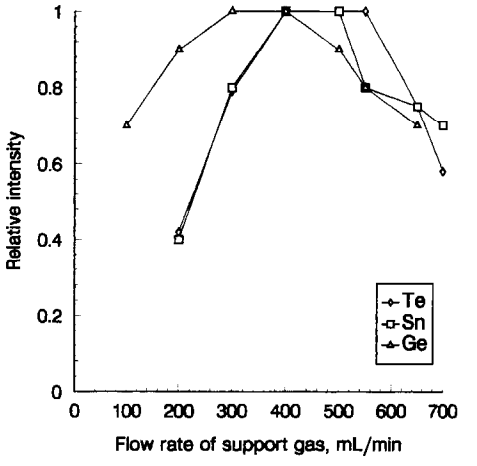

Fig. 4. Effect of support gas flow rate on the emission intensities.

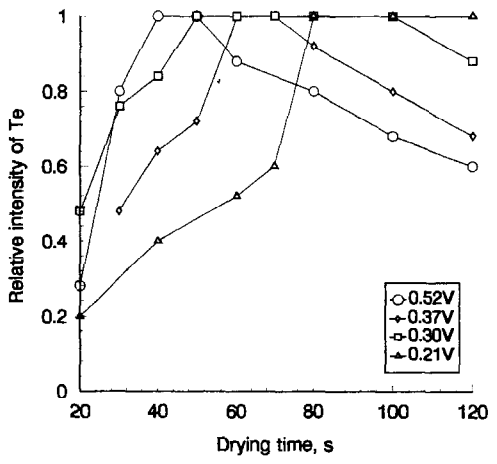

Fig. 5. Effect of drying time on the emission intensities of Te at different drying voltages.

be almost completely vaporized in a short time and transported into the excitation source by the carrier gas. In this study, to guarantee a complete vaporization of the element studied and an enough long lifetime of the tantalum filament, $3 \sim 4$ s was generally selected as the vaporization time. Fig. 6 presents the effect of vaporization voltages on the emission intensities. It is observed experimentally that the emission intensities increase with the mounting of the vaporization voltages when the vaporization voltages are low, while the vaporization temperatures (corresponding to the vaporization voltages) reach or exceed the boiling points of tested elements (their compounds), the emission intensities reach the maxima, and no more increase with the further increase of vaporization voltages will be observed because the analytes have been vaporized completely. What is more, too high vaporizing temperature can also shorten the lifetime of the tantalum filament. Therefore, to meet both requirements of vaporizing efficiency and lifetime of the tantalum filament, the vaporization voltages of different elements were optimized and shown in Table 2.

3.6. Effects of concomitant elements

3.6.1. Easily ionized element (EIE)

Since alkali metal elements, which are easily ionized elements (EIEs), especially Na and K are present in a wide variety of natural materials, the influence of EIEs upon the emission of analytes in the ETV-MPT-AES technique is of significant practical relevance. Fig. 7 illustrates the effects of some EIEs on the emission behaviour of the elements studied. Though the influences of the same EIE on the elements studied are not quite the same, they follow such general trends: (1) no obvious changes of emission intensities of the tested element occur with relatively low quantities of EIE (20 mg l^{-1} and less). (2) EIEs can cause either an emission enhancements (or suppressions) depending on EIE and element tested. The maximal emission enhancements (or suppressions) occur at EIE concentrations reaching around 500 mg l^{-1}. (3) When EIE concentrations go over about 500 mg l^{-1} the emission enhancements (or suppressions) reach plateaus. (4) The effects of EIEs on the emission intensities decrease when the concentrations of EIEs increase further to over about 1000 mg l^{-1}. (5) It is also observed that the extent of either suppression or enhancement correlates with the ionization potential(IP) of the EIE, i.e., Li > Na > K > Rb > Cs. This order is contrary to that reported by Matousek et al. [19] while is the same as that showed by our previous work (with PN introduction system) [17]. This phenomenon indicates that the mechanism of the effects of the same EIE on different line emission intensities may be similar. The mechanism involving enhanced collisional excitation was the most plausible explanation of the enhancement effect, and that the addition of EIEs may shrink the plasma and thus decrease the efficiency with which microwave energy is coupled to the plasma was said to be the reason for the suppression in the former work [30].

Effects of Na and K on the emission intensities of Sn with different sample introduction systems are shown in Fig. 8. It is observed that on the contrary to results obtained with ETV, the introduction of alkali metals will suppress rather than enhance the emission signals of Pb when a PN

Table 2
Drying time and voltage as well as vaporizing voltage for different analytes

Analyte	Ag	Au	Ge	Pb	Sn	Te
Drying time (s)	50–60	35–45	35–45	80–90	40–50	40–50
Drying voltage (V)	0.42	0.63	0.60	0.21	0.52	0.52
Vaporising voltage (V)	2.82	2.82	2.82	2.28	2.82	2.82

system is employed. The possible explanation for this may be that in the case of ETV the analyte is not transported into the plasma at the time while K and Na is vaporizing, and thus the effect caused by Na or K is reduced.

Some workers have investigated the mechanisms of EIE effect in an MIP with ETV sample introduction device [34,35]. In this work two experiments were performed to investigate the mechanism. Firstly, two different vaporization modes were employed. In the first mode, a 1.5 μl analyte solution and 1.5 μl of EIE (K) solution (both with 0.1 mol l^{-1} HCl) were injected onto two different sites of the tantalum filament loop, respectively. By this way the volatilization processes of the analyte and EIE were independent on each other. In the second mode, a 1.5 μl analyte solution containing EIE and a 1.5 μl HCl solution (0.1 mol l^{-1}) were injected onto the tantalum filament loop at the two sites the same as those in the former mode, respectively. Thus

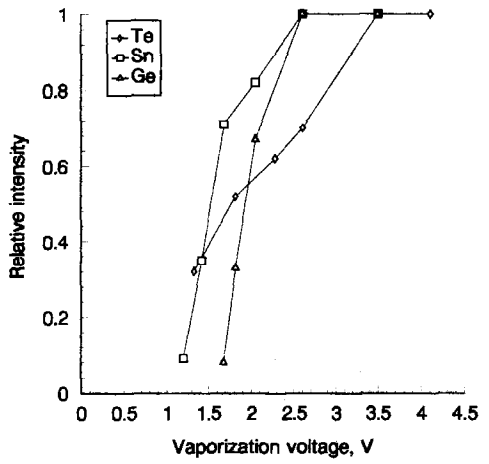

Fig. 6. Effect of vaporization voltage on the emission intensities.

the only difference between the two modes was that the analyte was vaporized separately from the EIE in the former while were vaporized together in the latter. The experimental results are shown in Fig. 9 and can be narrated as follows:

Generally speaking, EIEs can affect not only the vaporization behaviour but also the transportation process and the excitation behaviour of the analyte. When the concentration of EIEs are low, the results obtained from different vaporization modes are quite different. This indicated that, in this case, the EIE effects depends mainly on the vaporization process while the interference of EIE in excitation process in plasma is minor; with the increase of the concentration of EIEs, the two groups of results began to approach with each other (especially when the concentration of EIEs goes over 1000 mg l^{-1}). This reveals that when a large amount of EIEs is introduced into the system, their effects on transportation process and excitation process of the analytes will contribute more to the total EIE effect.

To understand the effect of EIE on vaporization, the time-resolved profiles of emissions for analyte and EIE were investigated. Curve 1 in Fig. 10 is the time-resolved profile of K obtained with KCl. Curves 2 and 3 in Fig. 10 are the time-resolved profiles of analyte Te obtained with a mixture solution of analyte $TeCl_4$ and KCl, and analyte ($TeCl_4$) alone, respectively. It is indicated from Fig. 10 that the addition of KCl shortened the time needed for the vaporization of analyte and the introduction of a certain amount of EIE can affect the vaporization of the element tested.

Over all, the EIE effect is a negative effect on the analyte determination and extremely complicated. It is related with many factors such as kind and amount of the analyte and EIEs themselves. However, EIE effect can also be making use of in

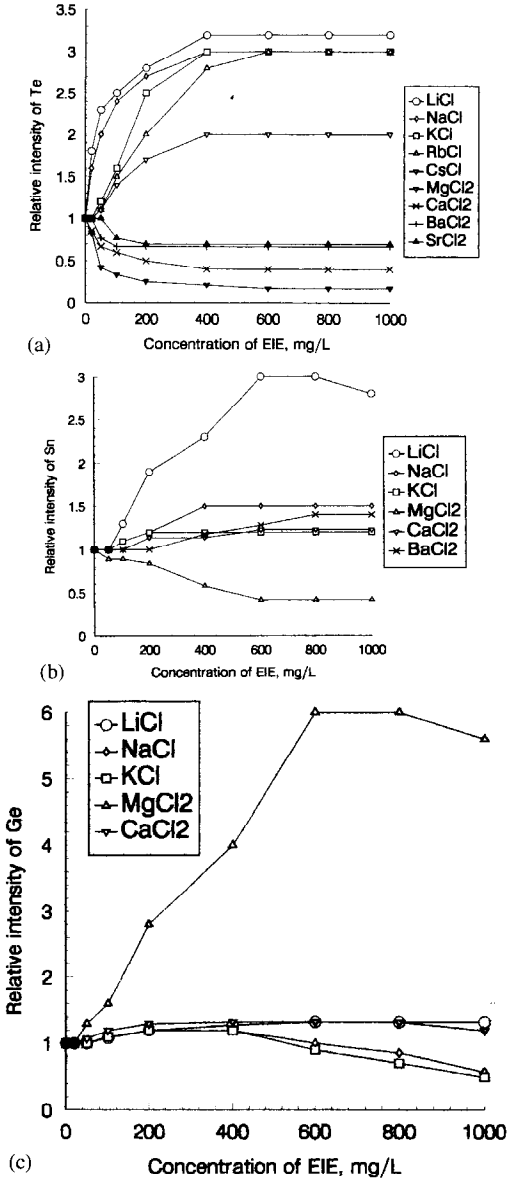

Fig. 7. Effect of EIEs on the emission intensities of (a)Te; (b)Sn; (c)Ge.

overcoming the matrix effects (including EIE effects themselves). For example, those EIEs with enhancement effects in a relatively wide concentration range can be used as matrix modifiers.

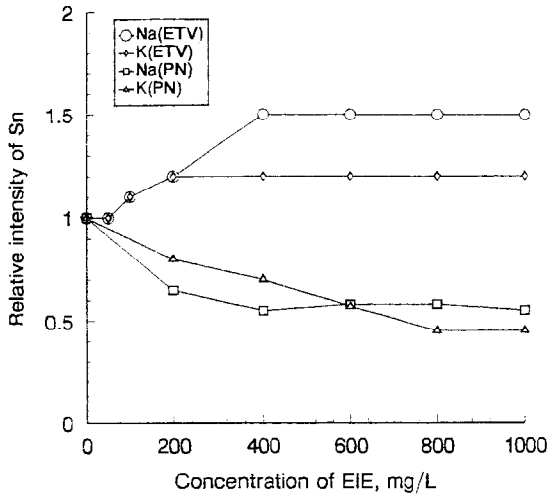

Fig. 8. Effect of Na and K on the emission intensity of Sn with two different sample introduction systems.

3.6.2. Alkaline earth metal element

For comparison, the effect of the alkaline earth metal element on the emission of analyte was also studied in the same manner as the above-mentioned method used in the studies for the effect of alkali metal elements. The effect of Mg, Ca, Sr and Ba on emission of Te, Mg, Ca and Ba on Sn as well as Mg and Ca on Ge are shown in Fig.

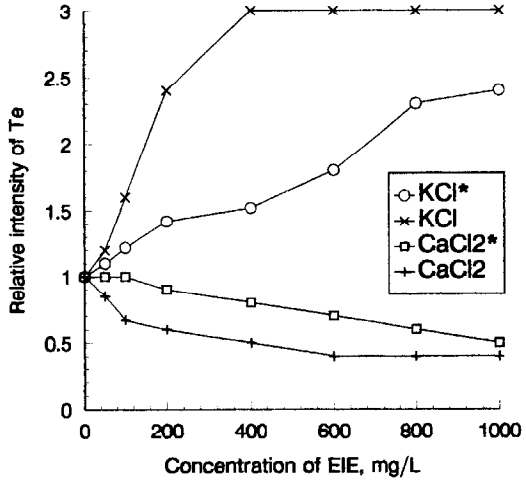

Fig. 9. Effects of Ca and K on the emission intensity of Te with different vaporization modes. *EIE and Te vaporized separately; the others, EIE and Te vaporized together.

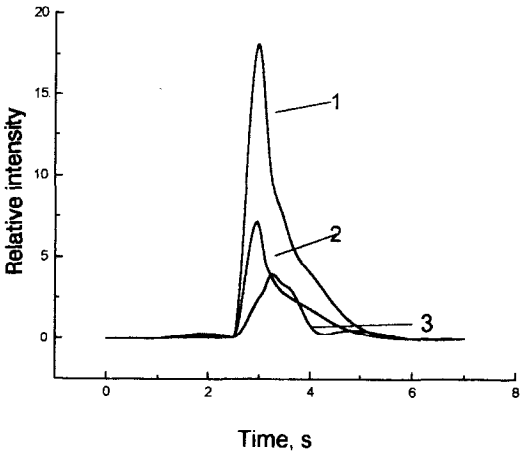

Fig. 10. Time-resolved profiles for K and Te. 1, 500 mg l^{-1} K, at K 404.72 nm; 2, 2 mg l^{-1} Te + 500 mg l^{-1} K, at Te 214.28 nm; 3, 1 mg l^{-1} Te, at Te 214.28 nm.

7(a, b and c), respectively. When two different vaporization modes were empolyed the effect of Ca on emission of Te was shown in Fig. 9. It was obvious from Fig. 7 and Fig. 9 that the effect of alkaline earth metal element on the same analyte is similar to that of alkali metal element.

3.6.3. Effect caused by other concomitant elements

Some concomitant element effects were observed. Table 3 shows some maximum concentrations values of coexistent elements including aluminum and iron allowed. Less than these concentration values the coexistant elements will not cause matrix effects on the determination of the analytes studied. For comparison, potassium and magnesium were also included in Table 3.

3.7. Analytical figures of merit

The detection limits, the linear dynamic ranges and relative standard deviations ($n = 11$) for elements studied by using the proposed technique were shown in Table 4. The standard deviation of the blank was used to calculate the detection limits (3σ). To make comparison the detection limits obtained with MPT-AES system with PN sample introduction are also included. It is obvious that the detection limits for easily volatile elements (Te, Ge, Sn, Pb) studied obtained with ETV-MPT-AES are lower than those obtained with PN-MPT-AES by 1–2 orders of magnitude, while detection limits for non-easily volatile elements (such as Ag and Au) are about the same as those obtained with PN-MPT-AES. The linear dynamic ranges are shown to be approximately three orders of magnitude. At the same time, a comparison of detection limits obtained in this work with those obtained in the literature is shown in Table 5.

3.8. Practical sample analysis

Several geochemical standard reference materials of China (GSD) were analyzed for the detection of Te, Sn, Ag with the proposed method and the results obtained were satisfactory, as shown in Table 6.

4. Conclusion

An ETV sample introduction device made of tantalum device has been coupled with an Ar MPT to determine several trace elements in environmental samples by AES without addition of any matrix modifier. The ETV-MPT-AES system has such advantages as high sensitivity, micro sample consumption, low matrix effect and low running cost. The studies reveal that EIE effects rely on not only the kind and amount of analytes and EIEs but also depend greatly on the sample introduction system (PN or ETV) and the sample introduction mode (whether EIE and analytes are vaporized together or separately). The analytical figures of merit show that the ETV-MPT-AES system is applicable to determination of trace elements in samples with low matrix. To those samples with relatively large amount of matrix, the method of standard addition can be employed. And also, suitable addition of large amount of certain EIE may be helpful because it was found experimentally that some EIE compounds (such as alkali chlorides) have constant enhancement effects in a fairly wide concentration range on most of the elements studied. The work in this direction is now in process.

On-line preconcentration with activated carbon for microwave plasma torch atomic emission spectrometry

Hanqi Zhang, Xianglin Yuan, Xiaojun Zhao, Qinhan Jin *

Department of Chemistry, Jilin University, Changchun 130023, People's Republic of China

Received 12 September 1996; accepted 4 February 1997

Abstract

This paper presents a method whereby trace elements are adsorbed in NH_4Cl–NH_3 medium on activated carbon and then determined by microwave plasma torch atomic emission spectrometry (MPT-AES). The working conditions (including microwave forward power, gas flow rate, NH_3–NH_4Cl concentration in the sample solution, HCl concentration in the eluant, sample introduction rate and preconcentration time) were investigated in detail. The effects of concomitant ions were studied. The experimental results for such analytes as Pb, Mn, Cd, Cu and Fe indicate that the procedure can eliminate fundamentally the interferences caused by alkali and alkaline earth metal elements and the application of it to the determination of iron in industrial silicon and tap water samples is successful.

Keywords: MPT; Activated carbon; FI; Preconcentration

1. Introduction

Although inductively coupled plasma atomic emission spectrometry (ICP-AES) has been widely applied to the determination of trace elements, the purchasing and operating costs are relatively high. Microwave induced plasma (MIP) has been receiving wide attention since it was used for spectrometric analysis in 1952 by Broida and Moyer [1] because it can provide high sensitivity for a large variety of elements with low operating costs. But traditional MIP sources have the disadvantages of low tolerance to the introduction of aqueous samples and significant interferences caused by easily ionized elements (EIEs), which limit its application to the practical sample analysis. In 1985, new microwave plasma supporting structure, microwave plasma torch (MPT) [2], was developed in the laboratory. It has been shown to have many attractive features such as the unique central channel which offers an easy way for sample introduction and enhances the interaction between the sample and plasma, the powerful excitation ability, and the less expensive running cost. Studies on the analytical performance of MPT in atomic emission spectrometry (AES) [3,4] have shown that the MPT discharge is a promising excitation source. However, the matrix effect is still a major factor that limits the MPT to be applied to the practical samples.

Activated carbon has been used as a trace collector for element preconcentration [5–24]. The mechanism involved in the adsorption of ions as trace compounds by the activated carbon is not completely known. Piperaki et al. [7] confirmed that sorption is quantitative when the chelate used contains systems of π-electrons in the molecule and when its centres for binding on carbon and those for the methyl ions are spatially separated so that their orbitals do not have a substantial influence with each other. Hutchinson and Schilt [8] considered there are two types of sites on activated carbon for adsorption, which are interpreted in terms of Langmuir parameters and ionic charge types of the adsorbates. Because activated carbon is a type of hydrophobic adsorbent which adsorbs nonpolar or little polar substances in aqueous solution, metal ions to be preconcentrated need to be transformed corresponding metal chelates [5–20], metal elements [21] or metal hydroxides [22–24] which could be adsorbed on activated carbon. Metal chelates could provide higher selectivity and high enrichment factors for such a preconcentration and separation. However, a strong acid is usually needed for elution and plasmas exhibit low tolerance to the introduction of strong acid. In addition, some noble metals can be reduced to elements being able to be adsorbed on activated carbon. In the literature [22,24], the pH of the solution was adjusted with NaOH, HCl or buffer solution $NaHCO_3$–Na_2CO_3, CH_3COONa–CH_3COOH, $Na_2B_4O_7$–(HCl or NaOH)–$NaClO_4$, and in general, higher pH value was adjusted with NaOH. It is obvious that the control and adjustment of pH are more difficult with NaOH than with buffer solution. In this work, the pH of solution was adjusted with buffer solution NH_4Cl–NH_3. Some trace elements are preconcentrated onto activated carbon in a NH_4Cl–NH_3 medium and then determined by flow injection (FI)-MPT-AES. It is evident from the experimental results that by using this ap-

proach the effects of alkali and alkaline earth elements on the determination of metal elements are eliminated efficiently.

2. Experimental

2.1. Apparatus

The block diagram of the experimental instrumentation used in this work is the same as that reported previously [25]. It consists of simple introduction system, desolvation system and MPT-AES system. The block diagram of sample introduction system is shown in Fig. 1. The desolvation system used in this work is the same as that used previously [3]. The components of the setup are listed in Table 1.

2.1.1. On-line preconcentration and elution

As shown in Fig. 1, the sampling loop in a regular FI set was replaced by an online preconcentration column, which was 4 mm i.d. and 40 mm long, filled with activated carbon and made of glass pipette. The activated carbon was limited in the column by two small plugs of plastic foam at either end. During the preconcentration step,

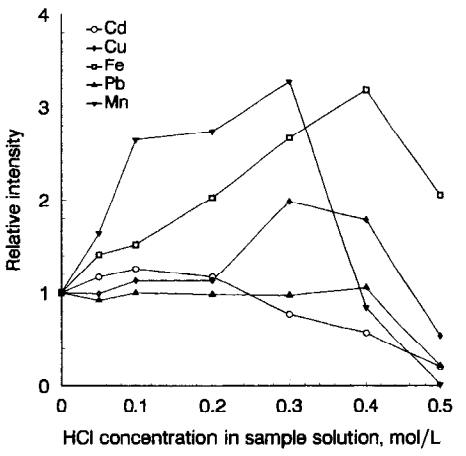

Fig. 2. Effect of HCl concentration in sample solution on emission intensity.

the eluant flowed from a peristaltic pump directly through the concentric pneumatic nebulizer to the plasma while the sample solution and reaction solution (certain concentration aqueous ammonia) were simultaneously pumped at the same rate separately into chemifold where they were mixed to form hydroxides. After the mixed solution passes through the activated carbon column, water was introduced to wash the activated carbon for a while, and then, the valve was rotated and

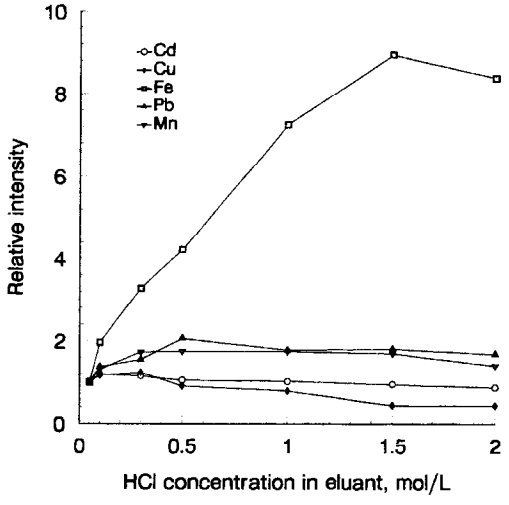

Fig. 3. Effect of HCl concentration in eluant on emission intensity.

the path of the eluant was redirected to flow through the preconcentration column, thereby the sample plug was carried into the MPT.

In addition, to make comparison, the system was also tested with regular flow injection (FI) and continuous pneumatic nebulization (CPN) sample introduction modes. In the FI mode, reaction solution was replaced by water and the preconcentration column was equivalent to a sample loop so there was no preconcentration. In the CPN mode, the FI on-line preconcentration setup was in the load position of the actuated injection valve and the sample was introduced into the MPT through the path of eluant.

2.1.2. Desolvation system

The desolvation system is similar to that of Ref. [3]. After the eluate was passed through the pneumatic nebulizer, it was desolvated by passing through a heating spray chamber, a tap-water cooled condenser and a concentrated sulfuric acid desiccator.

2.1.3. MPT

The MPT torch is similar to that of Ref. [26]. Its structure is like that of ICP torch, which consists of three concentric tubes. The central and intermediate tubes are made of copper and the outer tube is made of brass. The sample aerosol is introduced into the plasma through the central tube by a carrier gas. The plasma supporting gas is introduced through the intermediate tube. The plasma, a flame-like discharge, is formed between the central and intermediate tubes near the top of the torch and extended into the surrounding air.

2.2. Reagents

Activated carbon (Dalian Hongguang Chem. Eng. Factory, China) was soaked in 2 mol l^{-1} HCl for at least 24 h so as to remove the metal ions and other impurities sorbed on it.

Argon (99.99%) (Fushum Biousi., China) was used as both carrier gas and support gas. All reagents used were of superpure grade or analytical-reagent grade. De-ionized water was used in all experiments.

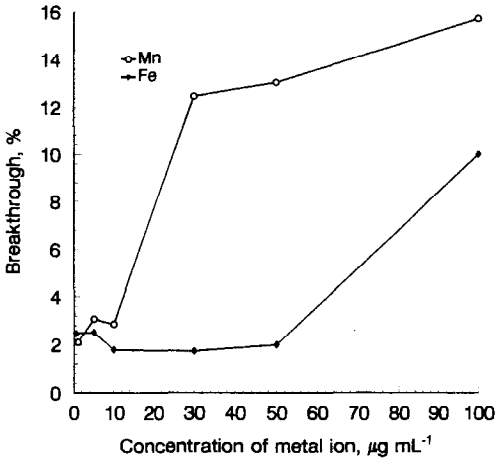

Fig. 4. Curves of breakthrough for Mn and Fe. The percentage of breakthrough is defined as the response of the element with the use of activated carbon column relative to the response without the column.

3. Results and discussion

3.1. Working conditions of MPT

The optimized operating conditions are given in Table 2.

3.2. Conditions for preconcentration and elution

The main experimental parameters influencing the process of preconcentration-elution for such analytes as Pb, Mn, Cd, Cu and Fe were investigated in detail.

3.2.1. Preconcentration time

The emission intensities of analytes increase with the increase of preconcentration loading time. The loading time selected in the experiment is 60 s.

3.2.2. HCl concentration in the sample solution and NH_3 concentration in reaction solution

To examine the effect of HCl concentration in sample solution, NH_3 concentration (0.5 mol l^{-1}) in reaction solution keeps constant. As shown in Fig. 2, the emission intensities increase or keep constant at first and then decrease with the increase of HCl concentration in sample solution.

Table 3
Analytical figures of merit of some elements obtained by this method

Element	Wavelength (nm)	Detection limit (ng ml^{-1})		Linear range (μg ml^{-1})	RSD (%)	EF
		a	b

a This work, ArMPT-AES, 60 W, FI on-line preconcentration with activated carbon.
b This laboratory, Ar-MPT-AES, 60 W, FI.

To examine the effect of NH_3 concentration in reaction solution, the HCl concentration (0.05 mol l^{-1}) in sample solution keeps constant.

In the present work, the pH value of the mixture solution (acidified sample + ammonia solution) was adjusted by concentration ration of HCl and NH_3. It is evident from above-mentioned experiments that the most intensive emission intensity was obtained when the NH_3 and NH_4^+ concentration in the mixture solution is approximately equal, and the corresponding pH value is about 9. The selected concentration of HCl in sample and NH_3 in reaction solution are 0.05 and 0.1 mol l^{-1}, respectively. The results are similar to that obtained in the absence of NH_3 [24]. In the present work, the mixture solution has an excess of ammonia (0.025 mol l^{-1}), Mn, Cd and Cu, especially Cd and Cu, are not precipitated under the conditions and mainly exist as the form of ammo complexes. Because the ammo complexes have positive charge and ammonia is a polar substance, it is difficult for them to be adsorbed on the activated carbon. However, because the hydroxides are preferably sorbed on activated carbon surface, the equilibrium is shifted, thus, hydroxides are sorbed on the surface anyway even if they are not present in solution.

3.2.3. HCl concentration in the eluant

To examine if the HCl concentration in eluant affected mainly on the process of elution of metal hydroxides on the surface of activated carbon or the process of emission of metal atoms in the plasma, the effect of HCl concentration in sample solution on emission intensities was investigated with CPN sample introduction mode. It was shown that there was no significant effect of HCl concentration on emission intensities of analytes directly introduced into the plasma. However, the effect of HCl concentration in the eluant on the emission intensities was obvious (see in Fig. 3). It is well known that $Fe(OH_3)$ precipitation can be formed at lower pH value than hydroxide precipitations of Pb, Mn, Cd, Cu when the metal ion concentrations are the same. So for most analytical lines studied, when the HCl concentration goes over 0.5 mol l^{-1}, the emission intensities are keeping constant or decreased slightly. But for iron, the emission intensity exhibits a maximum when HCl concentration in eluant is up to 1.5 mol l^{-1} because of the uneasy elution or iron hydroxide, thus 0.5 mol l^{-1} HCl for Pb, Mn, Cd and 1.5 mol l^{-1} HCl for Fe were selected as the eluant.

3.2.4. Breakthrough

The activated carbon in the column will be approaching a state of saturated adsorption little by little with the increase of the concentration of metal ions in the sample solution being studied. Fig. 4 shows a curve of breakthrough of the activated carbon column. It is obvious from the curves that the breakthrough volumes are basically constant when the concentrations of determined ions are low, and then increase sharply when the concentration of iron is higher than 50 μg ml^{-1} or the concentration of manganese is higher than 10 μg ml^{-1}. These experimental results are in agreement with the following results of

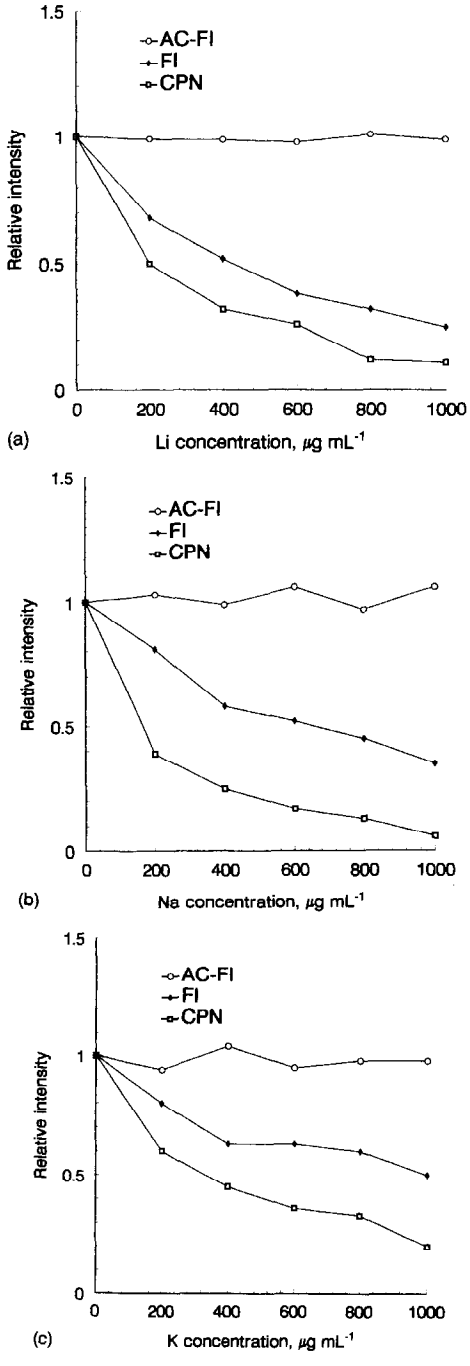

Fig. 5. Effect of EIEs (a, Li; b, Na; c, K) on emission intensity of Pb (405.8 nm)

dynamic linear range experiments (the dynamic liner range for Fe is 0.02–50 μg ml^{-1} and for Mn is 0.01–10 μg ml^{-1}).

3.3. Analytical figures of merit

The detection limits (3σ), dynamic linear ranges, precision and enrichment factors (EF) for elements studied obtained by this method are listed in Table 3. For comparison, Table 3 lists also detection limits obtained by FI-MPT-AES.

For all elements tested, the dynamic linear ranges are over 3 orders of magnitude and the relative standard deviations are in the range of 1.7–2.7%.

EF is a criterion used most often for evaluating preconcentration system. However, the precise meaning of the term is often not definite. Here EF [27] is defined as the ratio between the peak height with preconcentration and the peak height without preconcentration, a regular FI set-up was used.

3.4. Matrix effects

It has been shown that the interference caused by some concomitant ions is one of the major factors that limits the further development of MWP-AES [3,26]. Alkali and alkaline earth, Fe and Al exist in the nature in wide varieties, so the effects resulting from the elements were investigated in detail in this study.

3.4.1. Effect of easily ionized elements

It is clear from previous studies [28–30] that for traditional microwave induced plasmas the effect of EIEs on emission intensities is relatively significant. Additionally, the extent of interference depends on the sample introduction method adopted. To study the EIE effect, for this flow injection on-line preconcentration system with activated carbon (AC-FI), either FI or CPN sample introduction method was used. Fig. 5 shows that flow injection on-line preconcentration with activated carbon can eliminate fundamentally the interferences caused by EIEs. The reason is that EIEs are in existence of ions even in the basic solutions and can not be adsorbed by activated carbon. Flow injection alleviated the interferences

Table 4
Effects caused by EIEs

EIE[a]	EIE concentration ($\mu g\ ml^{-1}$)	Recovery (%)[b]				
		Cd (0.2 $\mu g\ ml^{-1}$)	Cu (0.3 $\mu g\ ml^{-1}$)	Fe (0.5 $\mu g\ ml^{-1}$)	Pb (4.0 $\mu g\ ml^{-1}$)	Mn (0.2 $\mu g\ ml^{-1}$)
Li	200	106	101	92	99	98
	400	106	104	96	99	97
	600	108	98	92	98	100
	800	102	72	102	101	98

[a] EIEs were added in the form of chloride.
[b] The emission intensity of each element is taken as 100 when no EIEs are added.

compared with continuous pneumatic nebulization as a result of sample dilution in the FI system [31].

Table 4 lists the effect of a series of concentration changes of EIEs on emission intensities of elements studied. It is evident from Table 4 that the effect of EIEs is minimized because of the use of FI on-line preconcentration technique, and Cl^- does not affect the determination.

Table 5
Effect of alkaline earth metal elements, Fe and Al

Element	Concentration ($\mu g\ ml^{-1}$)	Fold of concomitant element of not causing interference
Cd	0.2	Mg(1000), Ca(1000), Ba(1000), Fe(100), Al(100)
Cu	0.3	Mg(1000), Ca(1000), Ba(1000), Fe(50), Al(50)
Fe	0.5	Mg(1000), Ca(1000), Ba(1000), Al(20)
Pb	4.0	Mg(500), Ca(500), Ba(500), Fe(20), Al(20)
Mn	0.2	Mg(1000), Ca(1000), Ba(1000), Fe(100), Al(100)

3.4.2. Effect of other concomitant ions

Table 5 lists the effect of alkaline earth elements, Fe and Al on the emission intensities of elements studied. The experimental results are explained under these experimental conditions that the hydroxides of alkaline earth elements are not formed and, therefore, they can not be adsorbed on activated carbon. Although the hydroxides of Fe^{3+} and Al^{3+} can be formed and adsorbed on the activated carbon, they do not affect the determination of these elements within the concentration ranges studied. Some anions, such as Cl^-, SO_4^{2-}, NO_3^-, exist in many natural

Table 6
Results of determination of iron in industrial silicon samples

Sample	RSD (%)	Content (%)	
		Certified	Determined
1	3.7	0.39	0.38
2	4.1	1.15	1.12
3	3.0	2.92	2.95
4	3.1	1.51	1.49

Table 7
Results of determination of iron in tap water samples

Sample	Determined concentration (μg ml^{-1})	RSD (%)	Recovery (%)
1	0.05	3.5	100
2	0.33	4.0	105

samples or can be introduced into sample solution in sample digestion. It is indicated from the experimental results that these anions do not affect the determination.

3.5. Practical sample analysis

To investigate the applicability of this method developed, the contents of iron in industrial silicon (Table 6) and tap water samples were determined. The obtained values are in good agreement with the certified values. The recoveries of iron in tap water are in the range of 100–109% (Table 7). The RSDs in all cases are less than 4.1%.

4. Conclusion

This work demonstrates that flow injection online preconcentration and preseparation with activated carbon not only improves the detection limits but also eliminates fundamentally the interferences caused by alkali, alkaline earth elements. The proposed procedure is beneficial to improving the analytical performance of MPT and applying MPT to the analysis of practical samples. However, in some specific cases for determination of Pb in iron or aluminium alloy, some further improvements to eliminate the interferences caused by excess iron and aluminium are necessary.

Received 6 September 1996; received in revised form 26 November 1996; accepted 14 January 1997

Abstract

An amperometric diamine sensor is developed for clinical applications in diagnosis of bacterial vaginosis (BV). The sensor is based on crosslinked putrescine oxidase (PUO) which catalyzes the conversion of diamines (mainly putrescine and cadaverine) to products including hydrogen peroxide. The hydrogen peroxide is detected anodically at platinum electrode polarized at 0.5 V versus Ag/AgCl. Platinum-plated gold electrodes used as a substrate for the sensor construction, are batch-fabricated on a flexible polyimide foil (Kapton®, DuPont). A three-electrode cell configuration is used in all amperometric measurements. The sensor construction is based on three layers: an inner layer to reject the interference effect of oxidizable molecules, an outer diffusion controlling layer, and in addition, an enzyme middle layer. The enzyme layer was immobilized by crosslinking PUO with bovine serum albumin (BSA) using glutaraldehyde (GA). An optimization study of the enzyme solution composition was carried out. With the optimized enzyme layer, the biosensor showed a very high sensitivity and fast response time of ca. 20 s. The sensor has a linear dynamic range from (0.5–300 μM) for putrescine that covers the expected biological levels of the analyte. Details on sensor fabrication and characterization are given in the present work. © 1997 Elsevier Science B.V.

Keywords: Diamines; Biosensor; Bacterial vaginosis; Putrescine oxidase

1. Introduction

The three most common vaginal infections are: bacterial vaginosis (BV), candidiasis (yeast infection) and trichomoniasis (trich). BV, the most common type of vaginal infection, affects 35% of women visiting sexually transmitted disease clinics, 15–20% of pregnant women, and 5–15% of women visiting gynecologic clinics [1–3]. Women with symptoms usually have an increased, milk-like vaginal discharge with an unpleasant foul odor. However, about half of all patients may have no symptoms at all.

BV has become linked with increasing confidence to idiopathic premature labor which is the predominant cause of premature delivery in USA [4,5]. Despite the fact, BV is often unrecognized and diagnostically unsought in women without specific vaginal complaint. It is ordinarily not a screening target in women classically at risk for

* Corresponding author.

PII S0039-9140(97)00067-2

premature labor and in pregnant women generally. In the absence of typical BV symptoms, health providers may consider the current screening diagnostic options inadequate, neither sensitive enough nor specific enough to be reliable. Those procedures include examination of the vaginal odor, discharge character, density of clue cells (*bacillus* covered cells) microscopically, and nitrazine-paper pH measurement. The screening may not provide conclusive evidence and could unprofitably prolongs office visits. If a quick, reliable and low cost office-diagnostic test will be available, then BV screening would enter routine clinical practice, so a common complaint would be more cost-effectively managed.

The exact cause of BV is unknown, but is believed due to change of the natural balance of organisms found in the vagina. The more acidic *Lactobacillus* is replaced by high concentrations of *G. vaginalis*, anaerobes and *M. hominis*. The fishy odor of vaginal fluid with BV was reported mainly caused by putrescine (1,4-diaminobutane) and cadaverine (1,5-diaminopentane) [6,7], which are the decarboxylation products of arginine and lysine metabolism. These diamines are present in salt forms in the vagina. They become volatile and emit a fishy odor in alkaline pH. They are not detectable in women without a clinical diagnosis of BV. Although the exact cause of diamine production in vaginal fluid is not clear, its presence and association with BV have been widely confirmed. According to reported diamine screening test with TLC on population of more than 500 women, 88% of women with BV gave positive results while 92% of normal women gave negative results [7]. This convincing result predicts that diamine levels could be an effective marker in BV diagnosis. Trimethylamine has also been found only to be associated with BV patients, and not associated with normal women [8].

Detection of diamines in clinical samples currently requires time-consuming and relatively expensive electrophoretic [6], and chromatographic methods [7–10]. Enzymatic spectrophotometry has been used to study blood and urine samples where polyamines were served as cancer markers [11–17]. They provide good research tools, but are impractical to apply for routine clinical screening. An attractive alternative to these complicated analyses would be the miniature biosensors with electrochemical detection. In the last two decades, electrochemical biosensors have demonstrated their attractiveness in solving chemical and clinical problems [18–20]. Electrochemical polyamine biosensors have been reported [21–24]. They are mainly targeted at monitoring meat freshness [25–28] and plant growth-regulating activity [29,30]. No study has been reported with application of this sensor for BV diagnosis.

Until recently, pure and highly active polyamine oxidases were not readily available. Time-consuming protein purification procedures had to be taken to produce an analytically useful enzyme for amperometric sensors. However, putrescine oxidase [E.C. 1.4.3.10] from microorganisms is a pure active enzyme, and is also much more specific to putrescine and cadaverine than other polyamine oxidases (e.g., polyamine oxidase, E.C. 1.5.3.3; and diamine oxidase, E.C. 1.4.3.6).

Putrescine oxidase catalyzes the oxidation of diamines according to the following reaction:

$$H_2N(CH_2)_nNH_2 + O_2 + H_2O \rightarrow H_2N(CH_2)_{n-1}CHO + NH_3 + H_2O_2 \quad (1)$$

The generated H_2O_2 is detected amperometrically on the surface of the platinum-plated gold electrode.

Recent reports of amperometric sensors with PUO in homogeneous catalysis [25], and in immobilized form on substrates of graphite [30], thin layer gold [27], and thick layer graphite/TTF [28] showed that this enzyme is a promising one for the proposed work.

Growing interest have been shown to the flatform flexible biosensors. Some of the biomedical applications include monitoring pH, glucose, creatine, creatinine, and lactate levels [31–34]. The objective of this study is to develop a highly sensitive and selective, mass producible, and clinically acceptable diamine biosensor which will provide a screening device that meets the requirements for clinical diagnosis of BV. We present here a novel miniature diamine biosensor, based on crosslinked PUO, developed on a flexible sub-

strate. Its unique design is aimed at providing a sensor with high sensitivity and great selectivity against the potential interferences in vaginal fluid.

2. Experimental

2.1. Reagents

Putrescine oxidase [E.C. 1.4.3.10], 51.5 U mg^{-1} from *Micrococcus roseus* was received as a gift from Amano Pharmaceutical (Nagoya, Japan). Bovine serum albumin (fraction V), glutaraldehyde (25% aqueous solution), putrescine dihydrochloride (PUT), cadaverine dihydrochloride (CAD), spermine (SPM), tyramine (TYR), trimethylamine (TMA), L-lactic acid (sodium salt), fumaric acid, succinic acid, and pyruvic acid were purchased from Sigma (St. Louis, MO). The medical grade aliphatic polyurethane (Tecoflex SG 85A) was received as gift from Thermedics, (Woburn, MA). All other chemicals were of analytical reagent grade.

2.2. Apparatus and measurement procedure

2.2.1. Batch system

A computer controlled electrochemical measurement system was used throughout the experiments. The system contains an EG&G PARC M273A Potentiostat/Galvanostat, IBM PC-AT compatible computer, and M270 (v4.0) software for remote experimental control and data acquisition. All potentials were applied against a miniature Ag/AgCl reference electrode with flexible barrel (Cypress System, Lawrence, KS). The sensor was allowed to stabilize, and steady-state current values were obtained in all experiments. Data were collected at frequency of 1 Hz while a constant polarization potential of +0.5 V was applied on the putrescine sensor. All experiments were performed at room temperature (22 ± 1°C).

2.2.2. FIA system

The miniature diamine sensor was used in a single channel wall-jet flow system containing a manual sample injection valve (Rheodyne, Model 7125) fitted with a 20 μl injection loop. A carrier solution consisting of 0.1 M phosphate buffer (PB) of pH 7.2 was propelled by means of a Rabbit peristaltic pump (Rainin Instrument) through PTFE tubing (0.8 mm i.d.) at the desired flow rate. The tubing ended with a horizontally mounted 5 cm glass capillary tube (6.6 mm o.d. and 1 mm i.d.). The length of the tubing from the injection valve to the capillary was ~30 cm. The free end of the capillary was cut at 90° and polished with a fine emery paper. This end of the tube was brought into direct contact with the sensor surface. The sensor was mounted in a vertical position with connection wire directed upward. A Pt wire sealed to the glass capillary tube, 10 mm from the sensor, was used as a counter electrode. The reference electrode described above was inserted on the flowing stream, ca. 5 mm from the sensor, and sealed with epoxy. A schematic diagram for FIA is shown in Fig. 1. Sensor signals were recorded on a Yokogawa 3025 X-Y recorder.

2.3. Micro biosensor fabrication

2.3.1. Micro sensor substrate

Photolithographic technique has been used to fabricate the sensor substrate and details can be found in a recent publication [35]. Single-site planar gold electrodes (area = 0.06 cm^2) were batch-fabricated on flexible polyimide (Kapton®, DuPont) substrates (125 mm thickness). Two thin layers, chromium and gold, were sputtered onto the substrate. A layer of photodefinable polyimide

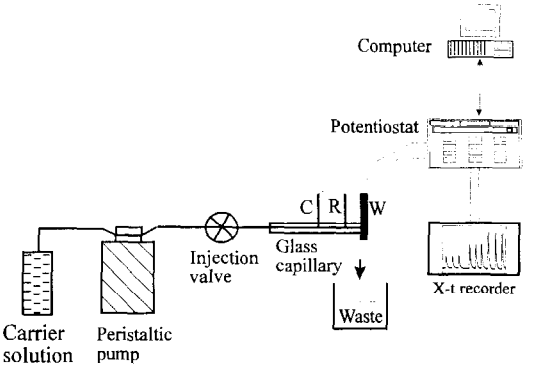

Fig. 1. Schematic diagram of single channel FIA setup.

was used to define both the electrode site and bonding pads. Each completed electrode substrate was cut from the wafer and connected through bonding pads to wires using silver epoxy (Epoxy Technology). Electrical contacts were insulated using silicone rubber (Dow Corning 3140 RTV). The gold substrate was further electroplated with a layer of platinum before the enzyme was immobilized. The platinization solution was prepared according to an early described method [36]. The surface was cleaned at $+500$ μA cm^{-2} for 30 s in the solution before a galvanostatic platinization current (~ 10 mA cm^{-2}) was applied for 5 min with a 5 cm diameter platinum mesh as counter electrode.

2.3.2. Modification of the sensor substrate

A thin film of poly *m*-phenylenediamine (*m*-PDA) was formed from 0.01 M *m*-PDA solution in PB by electrochemical polymerization using cyclic voltammetry. The potential was scanned between $+0.2$ to $+0.8$ V versus Ag/AgCl. The film forming process lasted about 2 h with scan rate of 2 mV s^{-1}. Then, the modified Pt electrodes were individually tested for interferences and sensors showing signals greater than 5 nA for 0.2 mM ascorbic acid were rejected. Less than 5% of the sensors were rejected in this test.

2.3.3. Immobilization of putrescine oxidase

The enzyme layer was immobilized on the electrode surface by crosslinking putrescine oxidase with bovine serum albumin using glutaraldehyde. To obtain an enzyme layer with high catalytic activity and good adhesion to the Pt and surrounding substrate, many sensors were prepared and tested with variable ratios of PUO, BSA, and GA. 1–3 μl aliquot of a freshly prepared enzyme mixture with specified composition in PB of pH 7.2 was quickly delivered onto the electrode surface with a micro syringe. The mixture was allowed to reticulate for an hour at room temperature.

2.3.4. Outer membrane layer

An outer layer was applied on the sensor by adding 2 μl of 1% polyurethane in pure THF solution. The sensor was allowed to dry in air for 10 min, washed with PB, and then stored at 4°C in phosphate buffer (pH = 7.2).

3. Results and discussion

3.1. Sensor calibration

A multilayer sensor is schematically represented in Fig. 2. Our results showed that membranes prepared with crosslinking 0.75 U PUO only gives a high quality sensor in comparison with ~ 15 U used for previous work reported by others. 1 μl aliquot of an enzyme mixture with final composition of 3% PUO-5% BSA-5% GA in phosphate buffer was used for all sensor preparations. The response of a typical putrescine sensor in phosphate buffer is illustrated in Fig. 3. The sensor has a detection limit of 0.5 μM for putrescine (S/N = 2), with linear response range up to 300 μM ($R^2 = 0.9997$). The sensor response to putrescine is very fast. An average response time of ca. 20 s ($t_{95\%}$) was obtained. The sensitivity of the sensor is 2.2 nA μM^{-1} within the linear concentration range. Sensors with enzyme layer only showed a narrower linear dynamic range (0.5–50 μM).

3.2. Sensor stability

Although they contain a small amount of enzyme, the sensors demonstrated very good stability. Fig. 4 showed the drifts of the sensor slope (S) relative to the initial slope (S_0), which was measured only a few hours after the sensor preparation. Approximately 200 measurements have been made for each sensor; they were kept in PB at 4°C when not in use. Sensors kept nearly 90% of the initial sensitivities in the first 10 days after a short period of conditioning. This period is long enough for disposable sensors in clinical applications.

3.3. The pH dependence of the sensor

The optimum catalytic activity of putrescine oxidase is known to be around pH 8.5 for homogeneous solution catalysis [37]. For diamine sensors with immobilized putrescine oxidase the

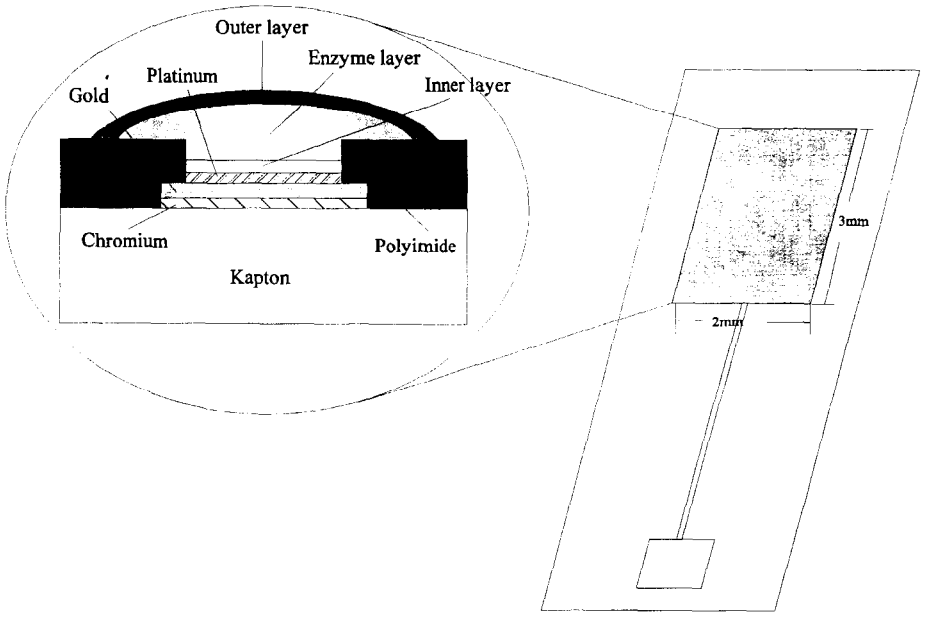

Fig. 2. Schematic diagram of a multilayer diamine sensor.

effects of pH of sample solution on sensor responses were studied with different buffers. Previous reports [27,28,30] have shown different pH profiles with maximum response in the range of pH 7–8.5. This is caused by different enzyme substrates and immobilization techniques used. In this study, three different buffers (0.1 M potassium phosphate, 0.1 M Tris–HCl + 0.1 M KCl, and 0.1 M H_3BO_3 + 0.1 M KCl + 0.1 M NaOH) were selected with pH ranging 6.5–9.5 to evaluate the sensor responses. In borate buffer the sensor gave the highest signal, and the maximum response of the enzyme sensor was observed at pH 8.5 with this buffer (Fig. 5). This agrees with the previous reported results [28]; however, we found that the sensor had the lowest background current and the fastest response time in phosphate buffer. In Tris–HCl buffer the sensor had the highest

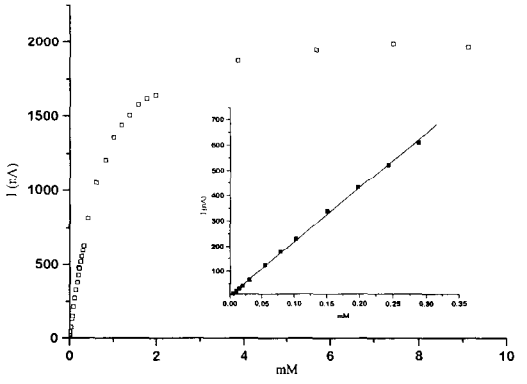

Fig. 3. Amperometric response of the diamine sensor to putrescine.

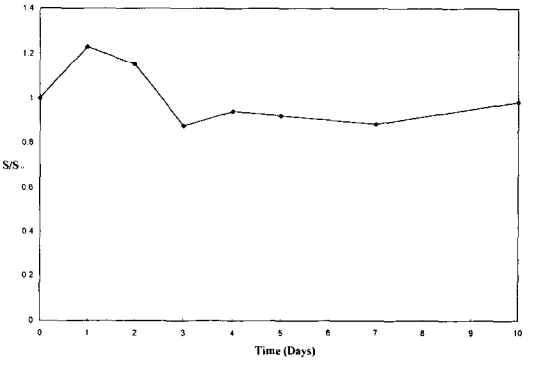

Fig. 4. Stability of diamine sensor (drift of the sensitivity).

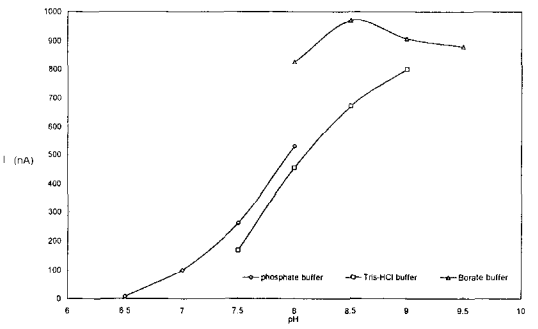

Fig. 5. Dependence of the response of the diamine sensor on sample pH in 0.1 M buffers (putrescine concentration = 100 μM).

background current and longest response time. In the following study, pH 8.5 borate buffer was used for all the subsequent work, but phosphate buffer of pH 7.4 was used for flow injection technique because of the fast response time of the sensors in this buffer.

3.4. Selectivity

3.4.1. Interference of other amines

The selectivity of the sensor toward other diamines (cadaverine), polyamine (spermine), monoamine (trimethylamine), and aromatic amine (tyramine) was investigated because most of these compounds are potential interferences in detection of putrescine in vaginal fluid for BV patients. Fig. 6 shows sensor responses to PUT, CAD and SPM. The sensor is more specific toward putrescine than CAD and SPE. For 10 μM

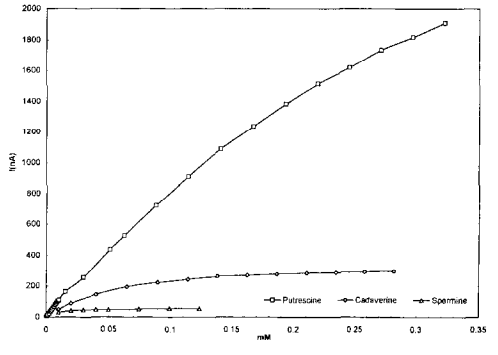

Fig. 6. Response of diamine biosensor to different amines.

substrate concentrations, sensor showed ~40 and ~20% response to CAD and SPM, respectively. However, those interference signals shown in Fig. 6 had very narrow dynamic range and the sensor responses became saturated (flat) at very low concentrations. The sensor did not respond to TMA up to 250 μM. The sensor showed response to TYR which is oxidized directly at the electrode surface under the applied potential.

To compare the enzymatic catalytic effect on those amines, their responses were studied at a bare Pt electrode without any modifications. Except TMA, all other amines showed slight signals at concentrations of 250 μM; however, these signals were negligible after coating a thin film of *m*-PDA on the Pt surface which rejected these interferences. To study the recovery of putrescine signal in the presence of various interferences, 10 μM of putrescine, interferences and mixture of putrescine with interferences were tested with the sensor, respectively. Additive signals were observed. Although this sensor also respond to cadaverine, it still could be used as a diamine indicator sensor, where total amount of diamines can be detected. It has been known that for normal women, both putrescine and cadaverine levels are undetectable in vaginal fluid, while significant amount of both diamines were found in sub-mM level with BV patients.

3.4.2. Interference of short chain organic acids existing in BV fluid

It has been well documented that normal women have a predominance of lactic acid in vaginal discharge produced by *Lactobacillus* [2], while BV patients lack lactic acid but have other short chain organic acids produced by anaerobes in the vaginal discharge. Further study showed that BV patients have high levels of succinate [6,38]. Later research, to directly measure the vaginal redox potential of the vaginal epithelial surface at the posterior fornix, showed that BV patients have an average E_h of −92 mV (on Pt electrode versus SHE), 78 mV lower than normal woman [39]. But the E_h were increased to normal level after the BV were successfully treated with metronidazole. They concluded the more reduced state of vaginal E_h for BV patients are caused by

the metabolism of anaerobic microbes, which in turn shifted the equilibrium of redox pairs such as lactate/pyruvate and succinate/fumarate (short chain organic acid produced by microbial metabolism).

To study the effects of these acids on the response of diamine sensor, 250 μM putrescine solution in the presence of 250 μM of L-lactic acid, fumaric acid, pyruvic acid and succinic acid, respectively were tested. The sensor did not respond to those acid and the putrescine signal were fully recovered.

3.5. FIA

The sensor was used as a detector in a single channel flow system. A flow rate of 2 ml min^{-1} was used throughout. With this flow rate, a good compromise between sensitivity and sample throughout was achieved. This system had a residence time of 16 s (time elapsed between sample injection to current peak maximum observed) with sampling rate of 60–80 h^{-1}. The system had very low background current, good peak reproducibility ($\pm$ 1.5%), and fast recovery time. A typical flow injection trace is presented in Fig. 7(a) along with a calibration curve in Fig. 7(b). The linear response range is up to 1 mM with sensitivity of 0.69 μA μM^{-1}. The detection limit for putrescine is below 25 μM.

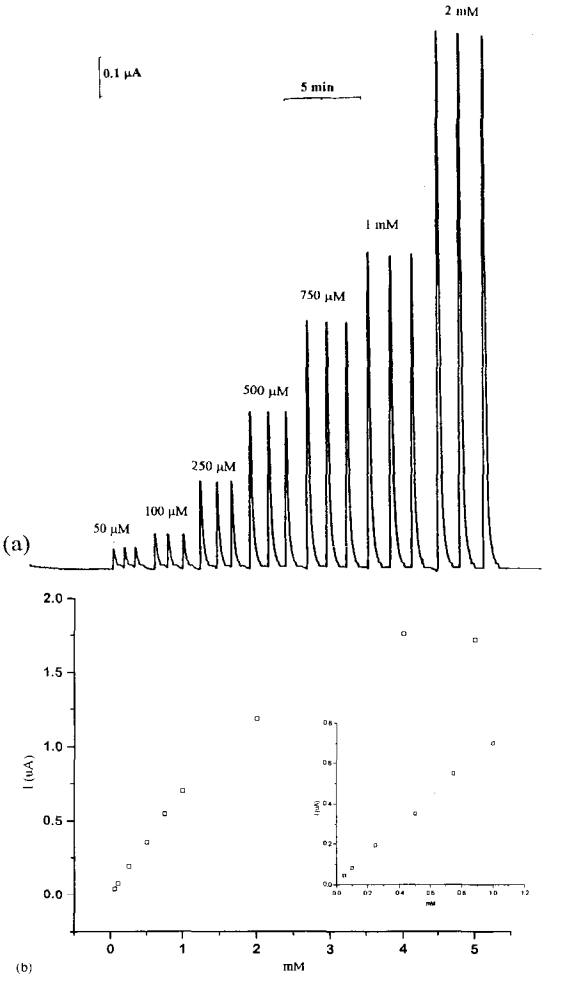

Fig. 7. Sensor response to putrescine with the flow injection technique (a) a typical FIA trace and (b) a calibration curve.

4. Conclusions

A miniature putrescine biosensor has been constructed with PUO on a flexible substrate. Besides its high analytical quality, each sensor contains only a minimum amount of enzyme and the substrates are batch fabricated. The system could eventually give any health provider a low cost, disposable sensor for routine clinic screening. Studies to detect the diamine levels in real samples by diamine sensors from normal and BV patients are scheduled. Further experiments, to study the reliability of the sensor acting as a clinical diagnosis tool for BV, are also under way. This test will be done by correlating the diamine (putrescine) levels detected by the sensors with diagnosis results obtained by current clinical screening procedures.

Received 27 August 1996; received in revised form 28 October 1996; accepted 21 November 1996

Abstract

A HPLC-DAD method is described for the analysis of the rodenticides warfarin, diphenadione and chlorophacinone, together with the phenylurea herbicides isoproturon and diuron, in soil samples. The HPLC parameters have been optimised to provide baseline separation with symmetrical peakshapes in short analysis times. The sample preparation consists of Soxhlet extraction followed by SPE clean-up on cyanopropyl silica. © 1997 Elsevier Science B.V.

Keywords: Rodenticides; HPLC optimisation; Soil samples; Sample preparation

1. Introduction

Rodenticides act in animal organisms as depressors of prothombin formation and supressors of capillary fragility, leading to hemorrhages [1,2]. Rodenticides are widely used in agriculture, often together with pre- and post- emergence phenylurea herbicides, which explains the occurrence of residues of those formulations in water and soil samples.

The complex structure of warfarin (3α-phenyl-β-acetylethyl-4-hydroxycoumarin), containing an acidic enol group and a ketonic moiety led to extensive chromatographic studies concerning the relation between peakshape and mobile phase composition or injection volumes and matrix effects [3,4]. Because of the antitumoral action of warfarin [5], the chromatographic analysis in biological fluids and organ extracts is well documented [6,7]. Moreover, due to the fact that the S(−) enantiomer of warfarin is more active than the R(+) enantiomer, different enantioselective separations by LC [8–16] and SFC [17] have been reported. The analysis of warfarin, coumatetralyl, bromadiolone, difenacoum and brodifacoum in liver extracts has been described [18,19].

Diphenadione [(2-diphenylacetyl)-1H-indene-1,3(2H)-dione] also named diphacinone and chlorophacinone [2[(4-chlorophenyl)phenylacetyl]-1H-Indene-1,3-[2H]-dione] are rodenticidal agents which have not been intensively studied.

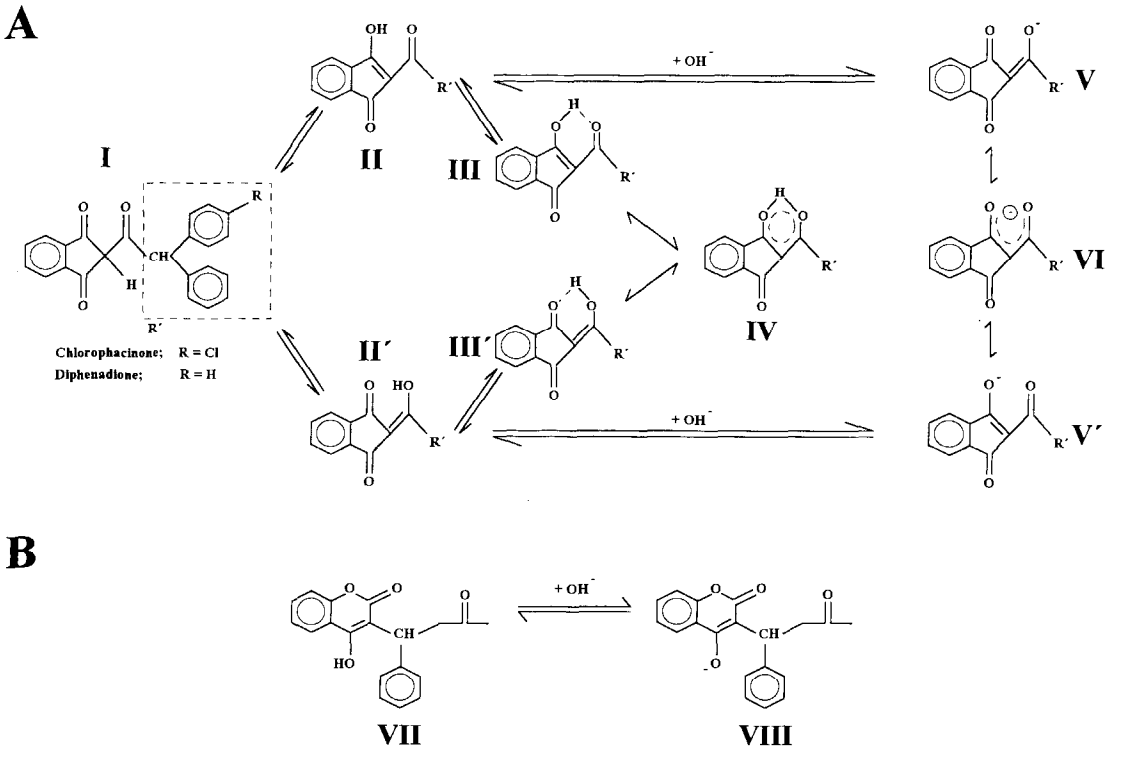

Fig. 1. Structure of W, DP and CP in relation with solvent polarity and/or pH.

Diphenadione and chlorophacinone analysis were determined in human serum and liver extracts, alone [20] or together with pindone and valone [21] or with warfarin [22]. Fluorescence detection of the diphenadione–Eu(III) complex was also reported [23].

The analysis of the rodenticides warfarin, diphenadione and chlorophacinone together with the phenylurea herbicides isoproturon and diuron in soil was the aim of the present work. The LC optimisation and the sample preparation steps are discussed.

2. Experimental

2.1. Chromatographic analysis

A Hewlett-Packard 1090 Model Liquid Chromatograph with automatic injector and Diode Array Detector was used. The chromatographic column was 20 cm L. × 4.6 mm i.d. packed with Hypersil ODS 5 mm (Hewlett-Packard). Injected sample volumes ranged from 5 to 250 ml. Detection was made at 310 nm for the rodenticides and at 247 nm for the phenylurea herbicides.

2.2. Materials

Warfarin (98%) was purchased from Aldrich. Diphenadione (99.9%), chlorophacinone (98.5%), isoproturon (99.9%) and diuron (99.9%) were obtained from Labor Dr. Ehrenstorfer GmbH, Germany. All solvents (water, acetonitrile, methanol) were HPLC grade from Lab Scan, Ireland. The other reagents were p.a. grade. SPE cartridges (ODS and CN, volume 3 ml, 500 mg adsorbent), were purchased from Analytichem International, UK.

Table 1
Solvents and gradient conditions applied in HPLC

Solvent System	A	B	C
Solvent (1)	Water	Aqueous 2 mM acetate buffer pH 4.2	Aqueous 0.5% phosphoric acid
Solvent (2)	Acetonitrile	Acetonitrile	0.5% phosphoric acid in acetonitrile
Gradient program	I	II	
Program	Solvent (2) programmed from 40% (5 min) to 60% at 4%/min, then to 100% in 0.1 min; flow rate 1 ml/min	Solvent (2) programmed from 40% (5 min) to 60% at 4%/min, then to 100% at 1%/min; flow rate increment from 1 to 2 ml/min between min 10 and 30.	

The soil sample was received for analysis and kept in the refrigerator at 4°C before analysis.

3. Results and discussions

3.1. Chromatographic optimisation

Diphenadione (DP) and chlorophacinone (CP) contain a β-tricarbonyl system, which results in ketoenolic tautomerism (Fig. 1A). The enolic structures are stabilised through an intramolecular hydrogen bond followed by delocalisation of the π electrons over the six atoms ring (structure IV). The enolic hydroxyl group can dissociate giving enolate formation (structures V,V'). Because of π electron conjugation in the enolate form, the negative charge is equally distributed over the two oxygen atoms resulting in structure VI. The global equilibrium can be summarised by:

keto form⇔enol form⇔enolate form

The rate of interconversion is pH dependent and is often catalysed by free silanols or metal ions residually present in HPLC column materials. The chemistry involved in β-carbonylic systems is very complex. For DP and CP some analogy can be found with α- and β-acids in hops and iso-α-acids in beer. The chemical transitions in those solutes has been studied [24] and the consequences for HPLC analysis have been described [25,26]. Good understanding of the equilibria between the different forms of DP and CP would require NMR experiments but this was not the aim of the present work. Nevertheless it is clear that the mobile phase composition will be of utmost importance for successful HPLC analysis. Dynamic interconversion between the different forms strongly affects the chromatographic partitioning process and peak distortion and retention irreproducibility can be anticipated. The mobile phase must inhibit chelating properties of the solutes in order to eliminate interactions with residual active centers in the column.

The same factors will influence the dissociation processes on the enolic group of warfarin (W), as shown in Fig. 1B.

Different mobile phase compositions and elution conditions have been evaluated (Table 1).

The chromatograms for a standard mixture containing the solutes of interest are presented in Fig. 2.

Warfarin and the phenylurea herbicides elute with good peak shape under all conditions. When the proton concentration in the mobile phase is, however, not controlled (gradient program I, solvent system A) the common anionic form may be present to a large extent giving rise to broad peaks with tailing (Fig. 2D). By lowering the pH to 4.2 (gradient program I, solvent system B) a slow equilibrium between the neutral keto and enol forms is probably established resulting in the observation of two distinct chromatographic peaks for each solute (Fig. 2C). At the low pH of

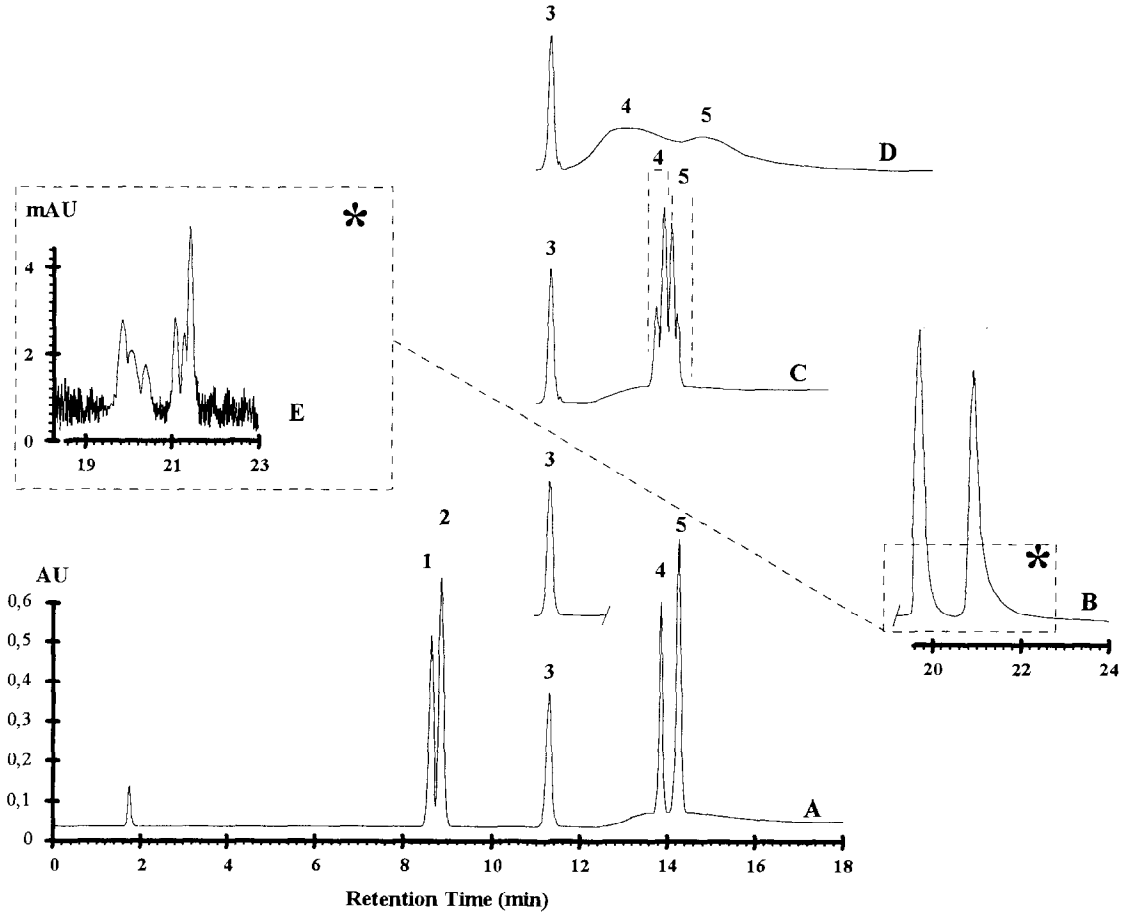

Fig. 2. Separation of isoproturon (1), diuron (2), W (3), DP (4) and CP (5) using different gradient elution profiles and solvent systems (conditions as described in text and Table 1).

the phosphoric acid solution (gradient program I, solvent system C), the rate of interconversion is fast relative to retention and only one single peak for each solute is observed (Fig. 2A). Increasing retention in the column by using gradient program II with solvent system C generates a better selectivity but peaks are slightly tailing (Fig. 2B). Moreover when the concentration of the solutes in the mobile phase is low, e.g., less than 10 ng, peak splitting is observed (Fig. 2E). This phenomenon must be related to the influence of residual silanolic groups or metal ion activity in the chromatographic system. Chromatogram 2E also suggests that the keto-enolic equilibrium constant K_T is pH independent, but the rate of interconversion obviously is pH dependent.

$$K_T = [\text{enol}]/[\text{keto}] = K_a^{\text{keto form}}/K_a^{\text{enol form}}$$

Under optimal elution conditions (gradient program *I*, solvent system *C*) the solute concentration no more influences the peak shape The minimal detectable amount corresponds to 1 ng of each solute injected onto the column. The sample loadability on the column depends on the solvent used. In pure acetonitrile containing 0.5% phosphoric acid, the loadability is restricted to 10 μl. Dilution in water/acetonitrile/phosphoric acid (49.75/49.75/0.5) allows injections up to 250 μl. For highly selective detection of W, DP and CP 310 nm is preferred for real samples, while 247 nm is the best wavelength for the detection of the phenylurea herbicides.

Table 2
Recoveries of isoproturon, diuron, W, DP and CP with Soxhlet extraction in function of time

Solvent	Extraction time (h)	Recovery (%)[a]									
		Isoproturon	RSD%	Diuron	RSD	Warfarin	RSD%	Diphenadione	RSD%	Chlorophacinone	RSD%
Methanol	1	78.8	1.5	116.1	2.5	54.9	2.9	45.4	2.3	16.4	4.9
Methanol	2	89.6	1.1	113.8	4.9	58.1	3.3	63.8	2.5	66.2	3.2
Methanol	16	24.8[b]	15.0	48.7[b]	13.3	56.8	4.0	66.4	1.0	89.1	2.6

[a] Values given are resulting by averaging data for three experiments.
[b] For longer periods at higher temperatures (Soxhlet extraction), isoproturon and diuron are decomposing.

3.2. Analysis of soil samples

Analysis of the rodenticides and phenylurea herbicides in soil samples requires a solid–liquid extraction step. Two procedures were evaluated: (a) ultrasonic extraction at room temperature; and (b) Soxhlet extraction. In order to study the extraction yields, 10 g of pure sea sand were spiked at the 10 ppm level with diuron, isoproturon, warfarin, diphenadione and chlorophacinone.

For ultrasonic extraction, 20 ml of solvent (acetone, methanol, acetonitrile, dichloromethane, as such and with 1% phosphoric acid) were added to the sea sand followed by ultrasonication during 15 min at 25°C. After filtration, the solvent was removed by evaporation and the residue taken up in 10 ml water/acetonitrile/phosphoric acid (49.75/49.75/0.5). Of this solution, 100 μl, were injected. Best recoveries were obtained with pure methanol: isoproturon 78%, diuron 104%, warfarin 69%, diphenadione 70% and chlorophacinone 68%. Repeating ultrasonic extraction with methanol on spiked blank soil, however, revealed that the recoveries for the phenylurea herbicides remained constant but dropped for the rodenticides to 44% for warfarin, 9.5% for diphenadione and 6.6% for chlorophacinone. All recoveries given are averaged values for five experiments and %RSDs were less than 5. This illustrates that specific solute-matrix interactions are extremely important and that extraction conditions have to be related with the characteristics of real samples. Ultrasonication at room temperature is definitely not efficient towards the extraction of the rodenticidal agents in real soil samples.

Soxhlet extraction was therefore carried out using the same spiked soil sample and 200 ml methanol as extracting solvent. The solvent selection was based on the recoveries obtained with the spiked sea sand samples. After extraction, the solvent was removed and replaced as described for the ultrasonic procedure. Recoveries in function of the extraction time for 10 ppm concentrations together with %RSD values for three experiments are enlisted in Table 2.

For the phenylurea herbicides, high recoveries are obtained for 1 and 2 h extraction time while longer extraction time results in decomposition of

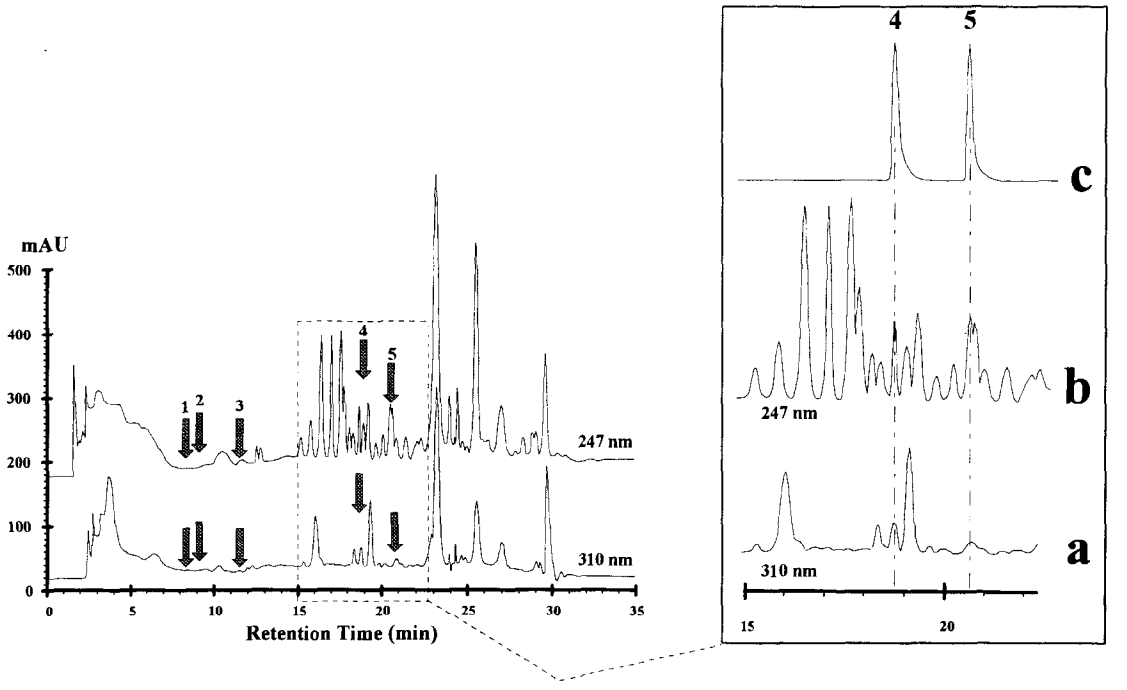

Fig. 3. Separation of rodenticides in extract of soil sample without clean-up.

these herbicides and thus low recoveries. For warfarin and diphenadione recoveries are constant over the 2–16 h extraction duration while for chlorophacinone extraction yields continuously increases with extraction time. As compromise 2 h were selected. Soxhlet extraction performed over 2 h at the 100 ppb level for each solute produced similar results i.e., 56.2% for W, 60.7% for DP and 65.2% for CP with RSD values in the order of 5% for three experiments.

Determination of the herbicides and rodenticides at low ppb level in real soil samples was, however, hindered by matrix interferences. Fig. 3 shows the analysis of a real sample analyzed with solvent C and program II and recorded at 247 nm for the phenylurea herbicides and at 310 nm for the rodenticides. As can be deduced from the Fig. 3, the phenylurea herbicides are absent but the presence of DP and CP can be elucidated. The strong background, however, did not allowed to confirm the presence of the rodenticides by means of their UV spectra and quantitation based on these data could be erratic.

Table 3
Recoveries of W, DP and CP on SPE-cyanopropyl silicagel as function of the composition of the washing solvent

	Recovery (%) on cyanopropyl silica[a]							
Washing solution ⇒ Compound ⇓	H_2O	RSD%	H_2O/ACN 9/1	RSD%	H_2O/ACN 3/1	RSD%	H_2O/ACN 3/2	RSD%
Warfarin	99.9	1.4	82.1	1.3	13.1	8.0	2.4	33.0
Diphenadione	90.5	1.8	89.2	1.3	88.0	1.1	18.1	13.8
Chlorophacinone	84.4	2.6	85.4	1.1	80.9	2.0	35.6	4.0

[a] Averaged results for three experiments.

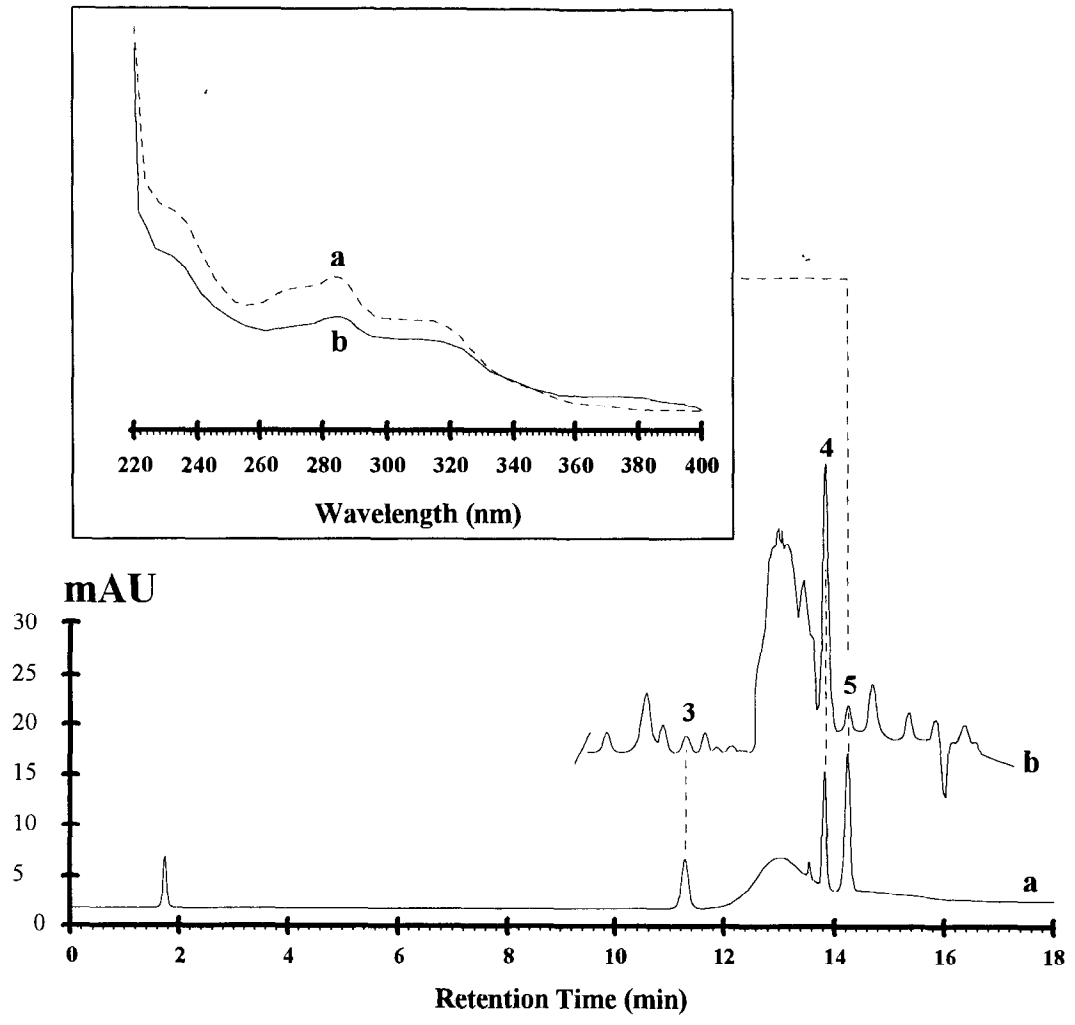

Fig. 4. Separation of rodenticides in extract of soil sample, after clean-up on cyanopropyl silicagel: (a) standard sample at the same concentration level; (b) real sample. Insert—a, recorded UV spectra of (5); b, reference spectra of CP.

To remove matrix interferences a clean-up procedure was therefore imposed to quantify the rodenticides. It is important to note that clean-up is not required for the analysis of the phenylurea at the 10 ppb level. In fact practical analysis is split in two parts. The first analysis consists of the injection of the sample as such at 247 nm for the determination of the phenylurea herbicides and analysis of the same extract but after clean-up at 310 nm for the determination of the rodenticides. Several SPE cartridges were evaluated but best results were obtained on cyanopropyl silicagel operated in the reversed phase mode. Preliminary experiments showed that washing conditions are extremely important, as outlined in Table 3.

There are no significant differences concerning recoveries of CP and DP when using water or water:acetonitrile 9:1 washing solutions. For W, recovery decreases with 20%, but results are still acceptable. Washing the adsorbent after sample loading with water:acetonitrile 9:1 results in a strong decrease of matrix interferences and those conditions were therefore considered optimal for the sample preparation procedure. The cartridge

was conditioned with 5 ml acetonitrile and dried during 4 min under vacuum. The dried residue from the Soxhlet extraction was retaken in 0.5 ml dichloromethane. An aliquot of 0.1 ml was loaded to the cartridge and the solvent was allowed to evaporate slowly. The adsorbent was then washed with 5 ml water/acetronitrile—9:1 containing 1% phosphoric acid. The adsorbent was dried under vacuum for 20 min and the rodenticides were desorbed with 4 ml acetone. The solvent was evaporated and the residue taken up in 0.5 ml water/acetonitrile/phosphoric acid—49.75: 49.75: 0.5. 250 μl were injected and the resulting chromatogram applying solvent C and gradient elution A is shown in Fig. 4.

The rodenticides can now easily be qualified through their UV spectra and quantified. The insert in Fig. 4 compares the UV spectra of chlorophacinone detected in the real sample (Fig. 4b) and in a standard solution (Fig. 4a). Measured concentrations of W, DP and CP were 3, 67 and 2 ppb, respectively. Reproducibility of the entire sample preparation process was satisfactory. Relative standard deviations for calculated concentration values are 1.2% for W, 4.6% for DP and 1.7% for CP, for a set of five experiments, carried out on a real sample over a 3 day period.

Received 16 August 1996; received in revised form 23 November 1996; accepted 23 November 1996

Abstract

Properties of six derivatives of 1-trifluoroacetylbenzene: [4-(*n*-butyl)- (1), 4-(*n*-hexadecyl)- (2), 4-dodecyloxy- (3), 4-(*n*-dodecylsulfonyl)- (4), *N,N*-dioctyl-4-trifluoroacetylbenzamide (5), octyl-*p*-trifluoroacetylbenzoate (6)] as neutral carriers for carbonate ion were examined and compared. The sensitivity towards carbonate ion was for (3) pH dependent. This eliminates (3) from practical applications in clinical analysis. When measuring CO_3^{2-} within the physiological range of human blood using as carriers compounds 1 and 2 the interference of chloride must be taken into account. In the case of carriers 4, 5, 6 this effect is negligible. Electrodes with membranes containing as carriers 2, 4, 5 and 6 were tested in an automatic potentiometric clinical analyser Microlyte 6, KONE. To avoid contamination by atmospheric CO_2 of three aqueous standards (TES, NaCl, $NaHCO_3$), pH was adjusted by coulomeric generation of H^+ or OH^- in a system devoid of carbon dioxide. Recovery of HCO_3^- calculated from measured CO_3^{2-} and pH, was investigated in a series of aqueous solutions and spiked bovine serum samples. The correlation between added and recovered concentration of HCO_3^- was linear with the intercept close to 0 and slope equal to 1 in aqueous solutions for all ligands and in bovine serum samples only in the case of ligand (2). © 1997 Elsevier Science B.V.

Keywords: Carbonate; Trifluoroacetophenone derivatives; Ion-selective electrode; Serum analysis

1. Introduction

For many years there is an interest in determining carbon dioxide species in biological samples. In blood at pH 7.4 the dominating form is hydrogencarbonate ranging from 0.010 to 0.050 mol l^{-1}. These conditions define the concentration of carbonate ions in the range from 2×10^{-5} to 1×10^{-4} mol l^{-1}. Until now an ionophore for hydrogencarbonate useful in ion selective electrodes has not been described. However one can determine carbonate ions despite of their rela-

* Corresponding author.

PII S0039-9140(97)00069-6

tively small concentration. The group of possible ionophores are trifluoroacetophenone derivatives [1–11]. Their selectivity is related to electrophilicity of substituents, which is correlated to Hammett constant (σ) [8,10]. The lipophilicity of the compound plays also an important role mainly in respect of the detection limit of the ion selective electrode.

Until now, another potentiometric indirect method was used in clinical analysis for measuring hydrogen carbonate in blood. This method used pCO_2 and pH measurements with respective electrodes. The use of the carbonate electrode is an alternative method. The technology of carbonate electrode manufacturing is easier and simpler in respect to pCO_2 electrode. This makes possible miniaturisation and the use in a line of electrodes in an analyser using the same sample of blood.

In this paper the analytical characteristics of six trifluoroacetophenone derivatives in solvent-polymeric membranes containing bis(2-ethylhexyl)-sebacate (DOS) as plasticiser are reported as well as their application in a potentiometric clinical analyser. A new method of carbonate standards preparation is also proposed.

2. Experimental

2.1. Reagents

Doubly distilled water was used for preparing all solutions, additionally water for measurements of CO_3^{2-} and pH was freshly boiled and devoid of CO_2 by bubbling the purified argon. Salts used were pure for analysis or pure (POCh, Gliwice, Poland). Tetrahydrofuran (THF) was obtained from Merck (Darmstadt, Germany), poly(vinyl chloride) (PVC), bis(2-ethylhexyl) sebacate (DOS), tetradodecylammonium tetrakis(4-chlorophenyl)borate (ETH 500), 4-(*n*-dodecylsulfonyl)-1-trifluoroacetylbenzene (4) from Fluka (Buchs, Switzerland), methyltridodecylammonium chloride (MTDDACl) from Polysciences, (Niles, IL) and *N*-tris[hydroxymethyl]methyl-2-aminoethanesulfonic acid (TES) from Sigma (St. Louis, MO), 4-(*n*-butyl)-1-trifluoroacetylbenzene (1) from Orion (Espoo, Finland), Quality Serum Sample (LOT38001B) obtained from KONE Diagnostics (Espoo, Finland).

Ionophores 4-(*n*-hexadecyl)-1-trifluoroacetylbenzene (2) and 4-dodecyloxy-1-trifluoroacetylbenzene (3) were synthesised according to [11]. The synthesis of ionophores *N,N*-*n*-dioctyl-4-trifluoroacetylbenzamide (5), octyl-*p*-trifluoroacetylbenzoate (6) is given below. Each membrane contained 0.076 g PVC as matrix, 0.10 g of DOS as plasticizer, neutral ionophore (5.0×10^{-5} mole of 4-(*n*-butyl)-1-trifluoroacetylbenzene (1), 1.6×10^{-5} mole of 4-(*n*-hexadecyl)-1-trifluoroacetylbenzene (2), 1.6×10^{-5} mole of *p*-dodecyloxytrifluoroacetylbenzene (3), 1.6×10^{-5} mole of 4-(*n*-dodecylsulfonyl)-1-trifluoroacetylbenzene (4), 1.6×10^{-5} mole of *N,N*-dioctyl-4trifluoroacetylbenzamide (5), 1.6×10^{-5} mole of *n*-octyl-*p*-trifluoroacetylbenzoate (6)) and MTDDACl (40 molar percent versus ionophore).

After dissolution in 3 ml of THF the mixture of components was poured into a 28 mm diameter glass ring placed on a glass plate and the solvent was allowed to evaporate. After 48 h round pieces of the membrane were cut out and fixed in the Philips IS 561 electrode body. Alternatively the THF solution was poured into the KONE electrode body and left for the solvent to evaporate.

2.2. Methods and equipment

Measurements were made at 25 ± 1°C in cell set as follows:Ag;AgCl,$KCl_{(Sat)}$‖1 mol l^{-1} KCl‖sample solution|membrane|internal solution|AgCl,Ag or in Microlyte 6 clinical analyser (KONE, Espoo, Finland). The internal filling solution was: 0.1 mol l^{-1} NaH_2PO_4, 0.1 mol l^{-1} Na_2HPO_4, 0.01 mol l^{-1} NaCl.

Electrodes were stored in the conditioning solution: 0.1 mol l^{-1} $NaHCO_3$.

The external reference electrode was a double-junction Ingold 9811 electrode. For monitoring of pH glass electrodes Ingold 104711 or Hydromet ERH 11 (Warsaw, Poland) were used. In measurements with the clinical analyser all electrodes except carbonate electrode were commercially available from KONE.

Single-ion activities were calculated according to Debye-Hückel theory [12]. For carbonate solutions the concentration of each species was calculated from protonation equilibria at measured pH.

The emf measurements with electrodes using Philips IS 561 bodies were performed using a digital voltmeter Solartron LM 1604 DC (Farnborough, Hampshire, UK) with multi-electrode sampler. Each reading was carried out 20 min after change of sample solution, when no further significant emf drift (0.2 mV min^{-1}) was observed. The measurements were made in the unstirred solutions.

For determination of selectivity coefficients by the separate solution method 0.1 mol l^{-1} NaCl and 0.1 mol l^{-1} $NaHCO_3$ solutions were used [8]. The selectivity coefficient for chloride ions was always taken into account for recalculation of potential values. The Henderson equation [12] provided corrections for the liquid-junction potential.

Potential response characteristics of electrodes was determined by stepwise addition of weighed amounts of $NaHCO_3$ (to obtain lowest concentrations dilution was used instead) to 0.01 mol l^{-1} solution of TES. The pH was kept constant by the addition of dilute sulphuric acid.

The effect of pH change was investigated by addition of diluted sulphuric acid to 0.025 mol l^{-1} solution of $NaHCO_3$.

Analytical recovery investigation of hydrogencarbonate concentration in aqueous solutions and in spiked bovine serum (KONE Diagnostic Control Serum Sample LOT38001B) was made by Microlyte 6 clinical analyser in which the carbonate electrode was inserted.

Vacuum test tubes (Becton Dickinson Vacutainer Systems, England) were used for storing hydrogencarbonate solutions.

Hydrogencarbonate aqueous standard solutions were prepared using coulometric titrations to generate OH^- ions. In coulometric titration a potentiostat OH-404/A (Radelkis, Budapest, Hungary) and two-compartment coulometric cell equipped with the magnetic stirrer were used. The solutions were deaerated and kept under argon. The anode and cathode compartments were separated by two G-4 sintered-glass disks and the space between them was filled with 2% aqueous NaCl solutions in 2% agar–agar. The titrations were performed in constant current conditions ($I = 40$ mA). Nickel anode was immersed in 0.1 mol l^{-1} Na_2SO_4 acidified to pH 2 with 0.1 mol l^{-1} HCl (anodic reaction: $Ni \rightarrow Ni^{2+} + 2e$). Platinum cathode was immersed in the solution being titrated (cathodic reaction: $2H_2O + 2e \rightarrow H_2 + 2OH^-$). The pH of titrated solution was controlled using pH glass electrode Ingold 104 711 with external reference electrode double-junction Ingold 9811 (Ingold, Switzerland) and the PHM-64 pH-meter (Radiometer, Copenhagen, Denmark).

Hydrogencarbonate standards of the composition given in Table 1. were prepared in the following way: pH of the solution of NaCl, KCl and TES was adjusted to the value of about 7 then appropriate amount of sodium hydrogencarbonate was added and pH adjusted further to the required value. To avoid contamination of hydroxide solution by CO_2 from air, the standard was titrated coulometrically. Other aqueous hydrogencarbonate solutions were prepared in the same way.

Standard solutions prepared in the way described above were stored in vacuum test tubes in the refrigerator. The composition of standards remained stable over 1 year, within experimental error of carbonate determination, i.e., $\pm 3\%$.

2.3. Synthesis

2.3.1. General

IR spectra were recorded on a UR-20 spectrophotometer (Zeiss, Jena, Germany). ^{1}H-NMR

Table 1
Composition of the hydogencarbonate standards

	Low (mmol l^{-1})	Normal (mmol l^{-1})	High (mmol l^{-1})
NaCl	98	95	70
KCl	6	4.5	3
TES	30	50	50
$NaHCO_3$	10	25	50
pH	7.0	7.4	7.8

spectra were recorded on Bruker (Karlsruhe, Germany) AM 500 (at 500 MHz) and Varian 200 (at 200 MHz) spectrometers. ^{13}C-NMR spectra were performed on Bruker AM 500 (at 127 MHz) and Jeol (Tokyo, Japan) FX 90Q (at 22.5 MHz). In all cases TMS was used as an internal standard. Melting points were measured on Boetius hot-plate microscope and were uncorrected.

2.3.2. Trifluoroacetylbenzoic acid hydrate

This compound was synthesised according to the modified procedure for 4-trifluoroacetylbenzoic acid [8]. To a solution of 7.80 g (33.1 mmol) of 1,4-dibromobenzene in 75 ml of dry THF cooled to −78°C, a solution of 1.6 mol l^{-1} *n*-butyllithium in hexane (20.7 ml, 33.1 mmol) was added during 20 min. After 30 min of stirring a solution of 3.4 ml (33.7 mmol) of methyl trifluoroacetate in 20 ml of THF was added during 15 min. The resulted solution was treated again with 20.7 ml (33.1 mmol) of 1.6 mol l^{-1} *n*-butyllithium at −78°C. After additional 20 min of stirring the solution was poured on a slurry of 50 g of crushed dry ice in 100 ml of THF and allowed to stand overnight. Organic solvents were then removed in vacuo and the residue was quenched with 50 ml of water. The water layer was extracted twice with 25 ml portions of toluene and was made strongly acidic by addition of 20 ml of conc. hydrochloric acid. The resulted solution was evaporated under reduced pressure to approximately one-third of the volume and was left to stand in a refrigerator for 12 h. The product (4-trifluoroacetylbenzoic acid hydrate) was collected as white crystals in the yield of 6.33 g (88%).

M.p. 175–177°C; ^{13}C-NMR (22.5 MHz, DMSO-d_6, δ): 90.0 (q, J = 31 Hz), 123.4 (q, J = 289 Hz), 127.8, 128.8, 167.2.

2.3.3. N,N-dioctyl-4-trifluoroacetylbenzamide

A sample of 4-trifluoroacetylbenzoyl chloride, prepared from 4-trifluoroacetylbenzoic acid hydrate using the method of Behringer et al. [8], (1.25 g, 5.28 mmol) was added to a solution of 1.53 g (6.33 mmol) of dioctylamine in 25 ml of dry pyridine at 0°C and was left to stand overnight in a refrigerator. Pyridine was then evaporated and the residue was quenched with 25 ml of toluene. The organic layer was washed successively with brine, 0.1 mol l^{-1} hydrochloric acid, 0.1 mol l^{-1} sodium hydrogencarbonate and brine. After drying over anh. magnesium sulphate and evaporation, the residue was chromatographed on 230–400 mesh silica gel using chloroform as eluent. Evaporation of the solvent and drying for 24 h under vacuum (0.01 Torr) afforded compound (*N,N*-dioctyl-4-trifluoroacetylbenzamide) as colourless oil (1.84 g, 67.2%)

^{13}C-NMR (127 MHz, $CDCl_3$, δ, stable conformers present): 13.95, 22.53, 26.41, 26.99, 27.42, 28.58, 28.94, 29.17, 29.29, 31.62, 31.74,,44.83, 48.87, 116.51 (q, J = 289 Hz), 127.10, 130.03, 130.12, 130.24, 130.28, 144.09, 169.63, 179.85 (q, J = 35 Hz).

Other analytical data were the same as described by Behringer et al. [8].

2.3.4. Octyl-4-trifluoroacetylbenzoate

A sample of 4-trifluoroacetyl chloride [8] (1.25 g, 5.28 mmol) was added in one portion to 4 ml of freshly distilled 1-octanol and the mixture was stirred at room temperature for 12 h. The excess of 1-octanol was removed under reduced pressure and the residue was chromatographed on 230–400 mesh silica gel using benzene–hexane (1:1, v/v) as eluent. Evaporation of the solvents afforded octyl-4-trifluoroacetylbenzoate as a colourless oil (0.85 g, 41.5%).

IR ($CHCl_3$, cm^{-1}): 1720, 1280, 940.

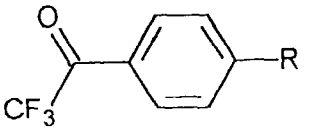
^{1}H-NMR (200 MHz, $CDCl_3$, δ): 0.91 (t, 3H, J = 7.6 Hz), 1.25–1.52 (m, 10H), 1.76–1.84 (m, 2H), 8.11–8.21 (m, 4H).

^{13}C-NMR (22.5 MHz, $CDCl_3$, δ):14.1, 22.7, 26.1, 28.7, 29.3, 31.9, 66.1, 116.5 (q, J = 293 Hz), 130.1, 132.9, 136.4, 165.2, 180.2 (q, J = 37 Hz).

3. Results and discussion

3.1. Properties of compounds

Properties of six derivatives of 1-trifluoroacetylbenzene were investigated. The structure of the compounds is shown on Fig. 1. The summary of their properties is given in Table 2. Ligands with



1. R=C_4H_9
2. R=$C_{16}H_{33}$
3. R=$OC_{12}H_{25}$
4. R=$SO_2C_{12}H_{25}$
5. R=$CON(C_8H_{17})_2$
6. R=$COOC_8H_{17}$

Fig. 1. Formulae of studied ionophores

strong electron acceptors as substituents improve carbonate selectivity [8]. The electrophilicity properties are reflected by Hammett constant (σ). The investigated ligands can be divided into two groups. The first one comprising ligands 1, 2, 3 having negative σ values and the second comprising ligands 4, 5, 6 having positive σ values. The first group of ligands is more sensitive towards chlorides. When measuring CO_3^{2-} within the physiological range of human blood for ligands 1, 2 and 3 one must take into account the chloride interference whereas for 4, 5, 6 this effect is negligible. Physiological chloride range in blood is from 0.08 to 0.13 mol l^{-1}. Lipophilicity measured as logarithm of partition coefficient between octanol and water gives us some indication about the value of the detection limit. Ligands 2 and 5 have the lowest detection limit in their respective groups which is consistent with their highest lipophilicity values, 11.1 and 8.0, respectively.

The sensitivity towards carbonates was for (3) pH dependent. The dependence of the electrode potential on pH changes were measured at total carbonate concentration of 25 mmol l^{-1} [11]. The slope of pH characteristic of an electrode containing ligand 3 was increasing with increasing pH.

Table 2

Table 3
Parameters of linear regression equations for selected electrodes

Ligand	Equation	
	Aqueous solutions	Serum samples
2	$Y = 1.00(\pm 0.07)X - 0.39(\pm 2.26)$ $r = 0.97$	$Y = 1.05(\pm 0.11)X - 0.65(\pm 2.02)$ $r = 0.96$
4	$Y = 1.09(\pm 0.07)X - 2.84(\pm 2.53)$ $r = 0.97$	$Y = 0.99(\pm 0.10)X + 13.25(\pm 3.27)$ $r = 0.97$
5	$Y = 0.97(\pm 0.07)X - 0.31(\pm 2.44)$ $r = 0.96$	$Y = 1.39(\pm 0.13)X + 0.68(\pm 3.49)$ $r = 0.97$
6	$Y = 1.00(\pm 0.07)X + 0.03(\pm 2.38)$ $r = 0.96$	$Y = 1.24(\pm 0.13)X + 0.48(\pm 3.43)$ $r = 0.96$

Y = Slope$X$ + intercept; (Y = recovery, X = added HCO_3^- in mmol l^{-1}).

This eliminates (3) from practical applications in clinical analysis.

3.2. Investigation of compounds in the clinical analyser

To estimate the possibility of application of carbonate electrode for biological samples, pH, Cl^- and CO_3^{2-} concentration were determined in clinical analyser. Carbonate concentrations were determined for the series of aqueous solutions, having: (i) ionic composition close to human serum; and (ii) bovine serum (Quality Serum Sample, KONE) spiked with $NaHCO_3$. The results are presented in Table 3. The graphical example of this correlation for ligand 2 is given in Fig. 2. The correlation of added and determined HCO_3^- both in aqueous solutions and in serum is satisfactory. In bovine control serum samples the slope of the recovery curve for some compounds (5, 6) is greater than 1 and for ligand 4 the intercept is not close to 0. This indicates additional unknown influences in serum samples. The only one electrode showing the same behaviour in aqueous solutions and in serum samples is that containing ligand 2.

4. Conclusions

Properties of six derivatives of trifluoacetophenone as neutral carriers for carbonate were examined.

Preliminary determination of carbonates in bovine serum was made using electrodes with investigated compounds (1, 2, 4, 5, 6) in potentiometric KONE Microlyte 6 clinical analyser. These results indicate that, at least, the sensor N° 2 can be used for rapid and simple potentiometric determination of HCO_3^- in blood. The response of this

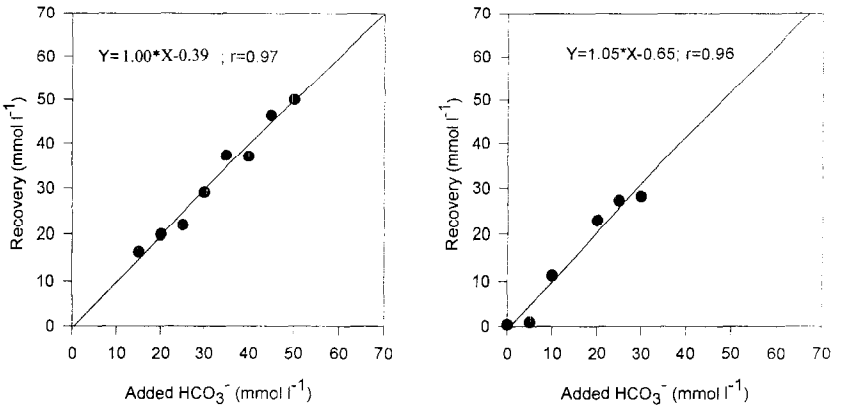

Fig. 2. Example of correlation between added and recovered HCO_3^- in aqueous solutions and in quality control serum for electrode with ligand 2.

sensor is not influenced by serum components. The poor selectivity against chloride ion can easily be compensated by simultaneous Cl^- concentration measurement.

Size fractionation of metals in wine using ultrafiltration[1]

Anthony J. McKinnon, Geoffrey R. Scollary *

School of Chemistry, The University of Melbourne, Parkville, 3052, Australia

Received 13 August 1996; received in revised form 4 December 1996; accepted 6 December 1996

Abstract

Ultrafiltration has been used to examine the size fractionation of lead, copper, iron, aluminium, calcium, potassium and sodium in white and red wines. Fractionation patterns demonstrated that the behaviour of lead is significantly different to the other metals considered. In red wine, there was a sudden decrease for lead between 100 000 and 30 000 nominal molecular weight cut off (NMWCO) and in white wine, a gradual decrease in the lead concentration was observed from 100 000 NMWCO. Iron was the only other metal which showed, for red wine, a size distribution pattern with a reduction in the iron concentration between 30 and 50% from 100 000 to 1000 NMWCO. Potential binding agents for lead and iron are discussed. The absence of any fractionation pattern for the other metals examined has been interpreted in terms of the metals existing as aquated cations (potassium and sodium), metal tartrate complexes (aluminium, copper and calcium) and either tartrate or phosphate for iron in white wine. The possibility of ultrafiltration disturbing kinetically facile processes, particularly for copper and calcium, is identified.

Keywords: Size speciation; Ultrafiltration; Wine; Wine instability; Lead; Copper; Aluminium; Calcium; Iron; Potassium

1. Introduction

Various metals can induce spoilage reactions in wine. These spoilage processes include precipitation of hydrogen tartrate (potassium) or tartrate salts (calcium), enhanced rate of oxidation (copper, iron) and haze formation (copper, iron and aluminium). In attempting to understand these spoilage processes, most studies have adopted the approach of measuring the total metal concentration and developing a 'rule-of-thumb' to minimise the onset of the spoilage process [1]. Metal speciation studies are relatively few [2], although a detailed investigation of calcium speciation has recently been described [3]. The presence of toxic metals in foods and beverages is always of concern and this is particularly the case with lead in wine [4]. However, toxicity of a metal is related to its bioavailability which in turn is related to its speciation.

It is well-established that, for water bodies, knowledge of the physico-chemical forms is essential for a proper understanding of the bio-geo-

chemical cycling of metals and it can be argued that this knowledge is also required to understand the spoilage processes and potential toxicity associated with metals in wine. A range of experimental techniques have been used to examine the physical and chemical speciation of metals in aqueous systems [5] and ultrafiltration is one technique that frequently yields useful information on the physical (size) speciation of metals as well as organic species. Recent work on the size fractionation of metals in river water [6] and rain water [7] as well as humic substances and their metal complexes [8,9] has clearly demonstrated the usefulness of ultrafiltration for metal speciation. Ultrafiltration has long been used in the food industry as a process tool. For wine, it has been used for examining factors affecting stability [10] and peptide distribution [11] but not for metal speciation.

This work was undertaken to determine the suitability of ultrafiltration for examining the distribution of metals in different particle size fractions. The metals of interest were those which are associated with wine spoilage processes or are regarded as potentially toxic. The results of the size fractionation patterns are interpreted in terms of the compounds with which the metals may interact. Some preliminary observations on the suitability of ultrafiltration for one particular wine have been reported previously [12].

2. Experimental

2.1. Containers and wine samples

All containers were pre-conditioned in 10% (v/v) nitric acid and washed with copious amounts of Grade 1 water (resistivity greater than 18 Mohm cm^{-1}) prior to use. Grade 1 water was used for solution preparation and dilutions.

Wine samples were either obtained commercially or were provided by wineries supporting this project in standard 750 ml glass bottles. A non-commercial wine was collected in 1 l plastic bottles. A complete description of this wine is given elsewhere [12]. After opening the bottle and removal of part of the wine, the headspace was flushed with nitrogen, the bottle re-corked and stored at 4°C until subsequent use.

2.2. Ultrafiltration procedure

The bottled wines were shaken by hand for 5–10 min prior to opening to ensure that any solid material was dispersed prior to the initial filtration stage. An aliquot (500 ml) was taken from the bottle and filtered through a Sartorius 0.45 μm cellulose acetate membrane filter. Portions (60 ml) of this filtrate were then ultrafiltered in parallel using an Amicon (W.R. Grace, Danvers, Ma) model 8050 stirred cell with positive nitrogen pressure. Amicon disc membrane ultrafilters of nominal molecular weight cut-off (NMWCO) values of 100 000 (YM100), 30 000 (YM30) 10 000 (YM10), 5000 (YM5) or 3000 (YM3) and 1000 (YM1) were used. The first 5–8 ml of the ultrafilter permeate was discarded and approximately 5 ml of the sample was retained in the stirred cell to avoid large concentration gradients. The ultrafilter permeate (about 50 ml) was collected and stored in acid-washed plastic bottles at 4°C under nitrogen until required for analysis. Each ultrafilter was used for one wine sample only.

2.3. Procedure for metal determination in ultrafiltrates

Aluminium was determined by graphite furnace atomic absorption spectrophotometry using an Hitachi (Tokyo, Japan) Z7000 system with polarised Zeeman background correction [13]. Iron and copper were determined using an Hitachi (Tokyo, Japan) Z6000 flame atomic absorption spectrophotometer using in-house validated methods. Stripping potentiometry using a Radiometer Analytical SA (Lyon, France) TraceLab 20 system was applied to the measurement of lead [14]. Sodium and potassium were determined by flame photometry on a Beckman Klina flame photometer [15]. Metal determinations were performed on the unfiltered wine, the 0.45 μm membrane filtered wine and each ultrafiltrate fraction.

Absorbance measurements at 420 and 520 nm were made on an Hitachi (Tokyo, Japan) U2000

UV/Vis spectrophotometer using 2, 5 or 10 mm cells, as appropriate, and corrected to standard 10 mm path length. These wavelengths have been used for some time to describe red wine colour [16]. Manipulation of these absorbance values allows red wine colour density and colour hue to be calculated [17].

3. Results

The initial ultrafiltration procedure included an ultrafilter with a NMWCO value of 500 and, with some wines, a significant cut off with this ultrafilter was observed for aluminium, calcium and iron. However, analysis of a spiked model wine (12% v/v aqueous ethanol saturated with potassium hydrogen tartrate and adjusted to pH 3.2 with tartaric acid) and spiked aqueous samples showed up to 50% removal of the metal spike suggesting that the cut off may well be a conse-

quence of metal retention by the ultrafilter rather than a size fractionation property of the wine. This differs from the observation of Cheng et al. [7] who found that, in their rain water analysis, a 500 NMWCO ultrafilter could be used. The reasons for this difference are not clear, but it was determined that the 500 NMWCO ultrafilter should not included in this wine metal profile study. The other ultrafilters used did not retain metals from spiked aqueous samples.

Apart from the sweet white wine, a botrytised Riesling, there was no difficulty in the ultrafiltration stage with the stirred cell arrangement, although some red wines proved to be a little difficult to pass through the 1000 NMWCO ultrafilter. *Botrytis*-infected wines generally contain a high concentration of glucans which would interfere with the filtration process, even in a stirred cell.

Table 1 and Table 2 present the metal distribution patterns for the first two studies. A change in the availability of the Amicon filters caused the use of 3000 NMWCO ultrafilter, in place of the 5000 NMWCO ultrafilter, for the data reported in Table 2. Copper and lead were included in the second study and sodium and potassium were excluded.

It is apparent from Table 2 that the distribution pattern for lead is significantly different from that of the other metals studied. This is clearly demonstrated in Fig. 1 where it is obvious that $\approx 80\%$ of the lead is cut off by the 10 000 NMWCO ultrafilter. As a consequence of these observations for lead (Table 2 and Fig. 1), the ultrafiltration proto-

col was modified to include ultrafilters with NMWCO values of 100 000 and 30 000. The values in Table 3 and Fig. 2 show that, for red wines, the cut off point for lead is between the NMWCO values of 100 000 and 30 000. For the white wines studied, there is a more gradual decrease in the lead concentration from 100 000 to 10 000 NMWCO.

Ultrafiltration also has a significant impact on the colour of red wine as is shown by the data in Fig. 3 and Table 4. Colour density ($A_{420} + A_{520}$) and colour hue (A_{420}/A_{520}) can be taken as two measures of red wine colour [16]. It is apparent from Table 4 that the colour density is affected markedly by ultrafiltration, but there is little effect on colour hue.

4. Discussion

4.1. Sodium and potassium

Within experimental error, there was no size fractionation observed for potassium for the six wines examined (Table 1) confirming earlier theoretical calculations that, at most, 1% of the potassium may be complexed with the hydrogen tartrate anion at wine pH [2]. The six wines used had been previously stabilised with respect to potassium hydrogen tartrate precipitation and this was verified by the similarity of the values obtained for the 0.45 μm membrane filtered wine compared with the unfiltered wine. Sodium complexes in wine have not been reported and it was not expected to see any size fractionation.

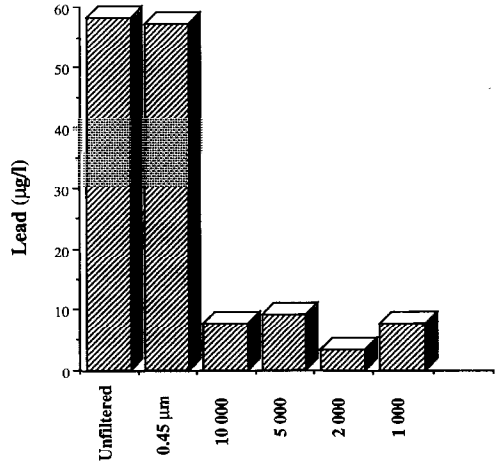

Fig. 1. Size fractionation of lead in Cabernet Sauvignon using 10 000, 5000, 2000 and 1000 ultrafilters. The unfiltered wine and 0.45 μm membrane filtered wine are included for comparison.

4.2. Aluminium

There was no noticeable size fractionation with the exception of Dry White # 5 where the reduction in the aluminium concentration between the unfiltered wine and the 0.45 μm membrane filtered wine is indicative of an aluminium haze. The high concentration of aluminium in this wine suggests that it has the potential for haze formation [17] and the cut-off between the unfiltered and 0.45 μm membrane filtered fraction is not surprising.

The absence of size fractionation is indicative of aluminium complexation with small molecules. In previous work on the speciation of aluminium in wine, there was tentative evidence [18,19] that aluminium is bound very strongly to tartaric acid and other related carboxylic acids found in wine such as malic and gallic acids and this correlates with the observed fractionation pattern.

4.3. Calcium

Similar to aluminium, there is essentially no variation in the calcium concentration with molecular size. For some red wines, there is an implication of a slow decrease in the calcium concentration with decreasing NMWCO value, although the change is not significant with respect to the experimental error.

These observations for calcium are surprising, as previous work has demonstrated that approximately 50% of the calcium in wine is complexed [20]. The possible complexing agents include the wine dicarboxylic acids, particularly tartaric and malic acids [21], as well as polyuronic acids [22]. As it is generally assumed that the polymer chain length of the uronic acid must be at least 10 units for significant interaction with calcium to occur [23], it is surprising that some size fractionation

was not observed in the wines examined here. However, an alternative explanation is that the calcium interactions with its binding agents are weak (a ten-fold dilution of wine significantly decreases the proportion of complexed calcium [20]) and the physical agitation associated with the stirred cell ultrafiltration system used in this study may have been sufficient to disturb the calcium/complexing agent interactions. Less mechanical methods of size fractionation are presently being considered to solve this dilemma.

The *Botrytis*-affected Riesling (Sweet White # 1, Table 1) showed some loss of calcium between the unfiltered wine and the 0.45 μm membrane filtered wine. This wine did contain a haze which, on analysis, was shown to contain a significant amount of calcium. There is significant anecdotal evidence in the wine industry to suggest that calcium is involved in instability processes of *Botrytis*-affected wines and this point is the subject of an on-going study.

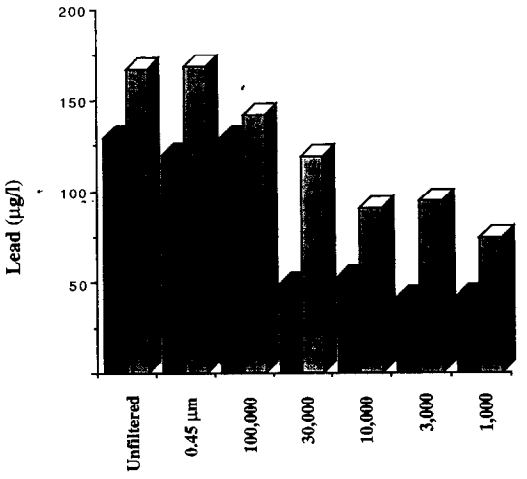

Fig. 2. Comparison of size fractionation patterns for lead in red (■) and white (▨) wine using 100 000, 30 000, 10 000, 3000 and 1000 ultrafilters together with the unfiltered wine and the 0.45 µm membrane filtered wine.

4.4. Copper

The distribution of copper is essentially independent of molecular size (Table 2 and Table 3), except for Dry Red # 4 where most of the copper is in the suspended phase. The chemistry of copper in wine is complex, but critical because of its role in enhancing the rate of oxidation. It is well established that copper can interact with catechin and caffeic acid [24–26] and, of course, with tartaric acid at wine pH [our unpublished observations]. In a non-wine system, Weber [24] has demonstrated that a copper/catechin complex is formed within a short time after mixing, but that this complex appears to breaks down as the mixture is allowed to age. Our work on copper-induced oxidation of catechin in a model wine has shown that there is a loss of ASV labile copper as the catechin oxidises and polymerises [26]. However, we have recently observed that the interaction of copper with the polymerised catechin is weak, as polyvinylpolypyrrolidone (PVPP) is capable of adsorbing the polymerised catechin which in turn releases all copper into solution in an ASV labile form [27].

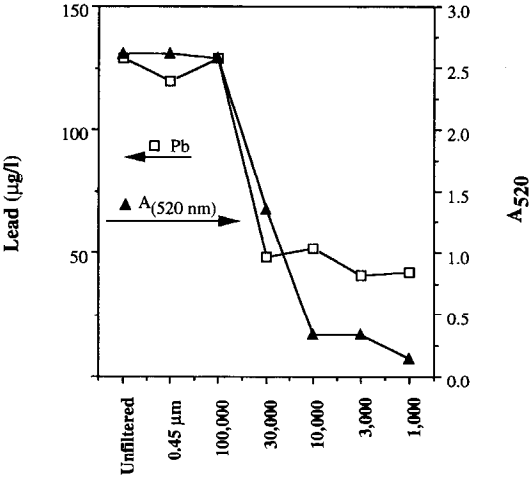

Fig. 3. Comparison of the size fractionation of lead and wine colour (A_{520}) for a red wine. Filtration pattern is the same as in Fig. 2.

These observations on the absence of any significant size distribution of copper may also be reflection of this weak interaction between copper and wine components such as catechin. That is, as proposed above for calcium, ultrafiltration may disturb the copper/organic polymer aggregates in solution.

4.5. Iron

The concentration of iron in white wine is independent of ultrafilter size, but there is a gradual decrease (a 30% reduction, on average) in concentration for red wine (Tables 1–3). The only exception is Dry White # 5, where most of the iron is in the insoluble phase (trapped by 0.45 µm membrane). The high iron concentration of the unfiltered wine would have induced the formation of a haze [28].

It is well recognised that iron binds strongly with humic substances (HS) and the tannin component of red wine has a distinct chemical resemblance to HS. In a study of aqueous HS by ultrafiltration, Burba et al. [8] noted that only iron showed a size distribution pattern similar to that of the HS itself. This observation was made at pH 3.7, approximate to the pH common for red wine. Thus, it is reasonable to assume that there is a some interaction between iron and the tannin component, but it must be also be recog-

nised that a significant proportion of the iron is still present at less than 1000 NMWCO. Obviously, iron can interact strongly with other wine components. Tartaric acid and phosphate must be considered to be potential binding agents: one form of iron-induced instability, especially in white wine, is thought to be iron phosphate precipitation [29].

4.6. Lead

Lead was determined by stripping potentiometry as this electrochemical stripping method has been shown to give results comparable with those obtained by graphite furnace AAS [14]. The particular advantages of stripping potentiometry for the measurement of lead in wine, especially with respect to alternative techniques such as anodic stripping voltammetry and graphite furnace AAS, have been described elsewhere [30,31].

The size fractionation of lead is markedly different to that observed for the other metals considered in this work (Tables 2 and 3 and Figs. 1 and 2). Even wines which are severely contaminated with lead (Dry Red # 5 and Dry White # 5; Table 2) show a very obvious cut off. Potential binding agents for lead in white wine include residual protein and procyanidins. Several wine proteins have sulfur groups in the active site which, of course, is a classic soft base ligand for the soft acid, Pb^{2+}. The gradual decrease in white wines is a reflection of the variation in molecular size of the proteins and procyanidins.

The marked cut off in the lead distribution in red wines indicates that a polymeric species, most probably tannin, is the binding species. It is already well established that lead binds with tannins and other polyphenols, for example, wattle tannin [32]. Addition of 'red tannin', a commercial wine making material, to a model wine has been shown to bind a significant proportion of the lead in the model wine [33].

The relationship between wine colour (A_{520}) and the lead size distribution (Fig. 3) is additional evidence for wine tannin being the binding agent. Further, the marked decrease in wine colour and colour density between 100 000 and 10 000 NMWCO (Fig. 3, Table 4) precludes any possibility of using ultrafiltration (for example, 10 000) as a method for removing lead from highly contaminated wines [12].

5. Conclusions

An obvious size fractionation pattern for lead in red and white wines is clearly discernible using ultrafiltration. However, with the exception of iron in red wine, ultrafiltration is limited in its ability to establish fractionation patterns for aluminium, calcium, copper and iron (in white wine). It is proposed that this limitation is a consequence of the mechanical action of ultrafiltration disturbing kinetically facile reactions, particularly for calcium and copper, where there is evidence that these metals exist in weakly associated complexes in solution. The effect of ultrafiltration on wine colour and colour density of red wine negates the application of ultrafiltration as a method of removing lead from contaminated wines.

Abstract

5-methylphenazonium methylsulphate, (commonly named phenazine methosulphate, PMS) mediated electroxidation of β-nicotinamide adenine dinucleotide (phosphate), reduced form, (NAD(P)H), on platinum, gold and carbon electrodes has been studied by electropolymerization of 1,2-, 1,3-, 1,4-diaminobenzene (DAB), pyrrole-2-carboxylic acid (PY-2-COOH) and 4,4′-dihydroxybenzophenone (DHB) in presence of PMS using cyclic voltammetry. The electroxidation of ascorbic acid has been evaluated on the electrodes elctropolymerized in absence and in presence of PMS. The same experiments have been carried out with NAD(P)H in solution. Results showed that the NAD(P)H is oxidized by PMS coimmobilized with the polymer film on the electrode surface. NAD(P)H has been measured in the range 10^{-6}–10^{-2} mol l^{-1} with a detection limit of 5×10^{-7} mol l^{-1}. Amperometric measurements of NAD(P)H have been carried out at -0.10 V and the efficiency of different electrodes based on different materials has been studied. The electropolymerization has been also carried out in presence of PMS and selected dehydrogenase enzymes. The activity of these enzymes has been tested amperometrically at -0.1 V. Enzyme substrates such as glucose, lactate and glutamate have been measured in the range 5×10^{-6}–1×10^{-2} mol l^{-1} with a detection limit 1×10^{-6} mol l^{-1}. Also the stability of these probes during time has been evaluated. © 1997 Published by Elsevier Science B.V.

Keywords: Electropolymerization; Dehydrogenase enzymes; Electrochemical biosensors; Interferences

1. Introduction

The use of NAD(P)$^+$ dependent dehydrogenase enzymes in amperometric biosensors has been studied in the past decade [1–5].

The oxidation of NAD(P)H on several electrodic materials has received great attention and strong interest by the scientific community during these years. The main reason is the possibility to use more than 200 redox NAD(P)$^+$ dependent enzymes for assembling a novel class of biosensors.

In fact a reversible and efficient oxidation of enzimatically active NAD(P)H to NAD(P)$^+$ is the key to use any NAD(P)$^+$ dependent dehydrogenase enzymes electrodes probe.

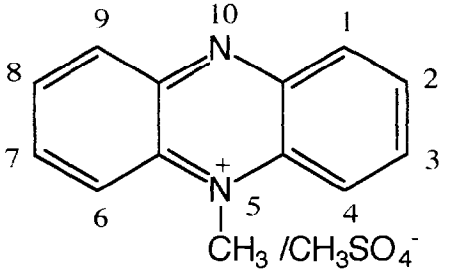
It is well known that the electrochemical oxidation of NAD(P)H involves a multi step (ECE) mechanism [6–8]. The electrochemical regeneration of $NAD(P)^+$ is affected by a degradation of the cofactor due to irreversible redox processes and overpotential constrains [9]. Moreover, the direct electron transfer between NAD(P)H and the electrode surface requires a relatively high overvoltage. Often electrode fouling and interfering background currents [10–12]: finally, the overvoltage leads to not enzimatically active $NAD(P)^+$ [13].

A way to overcome these problems has been the use of electron mediators which lower the working voltage to the formal potential of the mediator [4].

Mediators used for NADH oxidation are quinones [14], quinoid structures as phenoxazines [15], phenazines [16] or phenothiazines [17], polymetal lophthalocianines [18], ruthenium complexes [19] and quinoid redox dyes [20].

Mediators have been immobilized in many different ways, for example, by chemisorption [14], thus limiting the long-term stability of the biosensors due to the leaking of the catalyst from the electrode surface, by covalent attachment to the electrode or to functionalized conducting polymers [21], or to a polymer film deposited electrochemically onto the electrodic surface [22,23], mixed into carbon paste [24] or coupled with a polymer backbone mixed in a carbon paste, by electropolymerization of the mediator on the electrode surface [25–29]. One of these mediators is PMS, which acts as cofactor to mediate the electron transfer for many dehydrogenase enzymes.



The electrochemical behaviour of PMS has been studied by our group in aprotic solvents and in aqueous buffered solutions [30].

Recently, a bioreactor [31] was constructed using the immobilized glucose-6-phosphate dehydrogenase (G6PDH) on graphite electrodes surface where PMS was previously absorbed.

Amperometric sensors were assembled with $NAD(P)^+$-dependent dehydrogenases and PMS or other quinoid redox dyes [32]. The ionic redox mediators could be immobilized as Reineckates salts in graphite-epoxy composite electrodes.

In the literature, to our best knowledge, there is only one example of immobilization of PMS and glutamate dehydrogenase in a conducting polymer [33], but this probe suffered in low term stability by the leaking of the mediator and the enzyme.

An example of methylphenazonium-zeolite-modified enzyme sensor is reported for subnanomolar detection of phenols, consisting of tyrosinase, immobilized on a novel poly-urethane hydrogel [34].

Our work consists in the immobilization of PMS in a polymeric matrix during the electrosynthesis of different non conducting polymers on platinum, gold and carbon electrodes.

These sensors have been evaluated for PMS mediated reoxidation of NAD(P)H.

The advantage of this system is that the resulting probes covered with non conducting polymers are interference-free. In fact the possible interferences such as ascorbic acid, uric acid and paracetamol have been minimized.

The biosensors based on the immobilization of enzymes in non-conducting polymers have some advantages over conducting films: the film thickness of the non-conducting polymer is self-controlled during electropolymerization and leads to very thin and uniform films.

These biosensors generally have the advantage of fast response time and high sensitivity because of relatively high enzyme loading [35].

Moreover, the non-conducting polymer films are generally found to be more effective in both preventing the biosensors from fouling and eliminating the interferences from electroactive species.

These electrodes assembled as dehydrogenase enzyme electrode probes by electropolymerization of monomers with PMS and selected dehydrogenase enzymes, allowed the measurements of glucose, lactate and glutamate.

Response time, stability, linear range, detection limits and interferences have been evaluated.

2. Experimental

2.1. Materials

β-Nicotinamide adenine dinucleotide, reduced form (NADH), β-Nicotinamide adenine dinucleotide (NAD^+), β-Nicotinamide adenine dinucleotide phosphate, reduced form (NAD(P)H) and β-Nicotinamide adenine dinucleotide phosphate ($NAD(P)^+$) from Sigma, St. Louis, MO, were used without further purification. 1,2-1,3-1,4-Diamminobenzene (1.2-, 1.3-, 1.4-DAB, FLUKA), pyrrole-2-carboxilic acid, 4,4′-dihydroxybenzophenone and PMS from FLUKA Buchs, Switzerland were used as received.

β-D-(+)-glucose, glutamic acid, lactic acid (as lithium salt), ascorbic acid (AA), uric acid, paracetamol were purchased from Sigma.

Glucose solutions were allowed to mutarotate overnight at room temperature before use.

All other chemicals were of analytical grade. Phosphate buffers (0.1 mol l^{-1}) were prepared with distilled-deionized water using sodium dihydrogen phosphate dihydrate (FLUKA Biochemica Microselect for molecular biology). The pH was adjusted to the suitable value with pellets of sodium hydroxide.

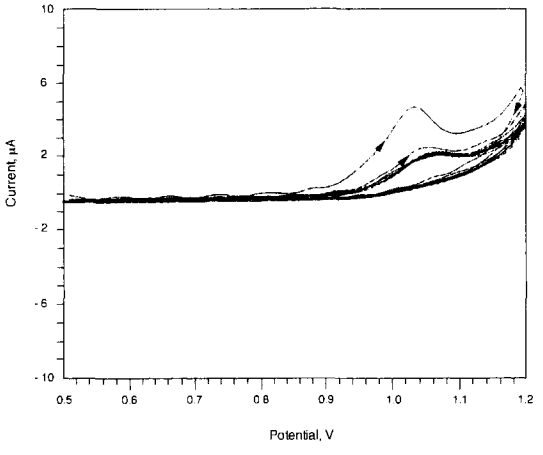


Fig. 1. Cyclic voltammograms for the oxidation of PPY-2-COOH 5 mmol l^{-1} at a gold electrode in a deoxygenated phosphate buffer (pH 8.1, I = 0.1). Scan rate 2 mV s^{-1}.

L-Lactic dehydrogenase type XI (EC 1.1.1.27; 700 units/mg) from rabbit muscle (LDH), glucose dehydrogenase (EC 1.1.1.47; 50–150 U mg^{-1}) from *Bacillus Megaterium* (GDH) and L-glutamic dehydrogenase type III (EC 1.4.1.3; 40 U mg^{-1}) from bovine liver (GlDH) were purchased from Sigma.

2.2. Apparatus

An AMEL polarographic system model 433A (AMEL, Milan, Italy) was used for voltammetric studies. The electrochemical cell consisted in a solid working electrode, a SCE reference electrode, and a Pt counter electrode. The gold (Au), platinum (Pt), glassy carbon (GC) working electrodes (surface nominal area 0.071 cm^2) were from AMEL.

Amperometric measurements were carried out with a 559 HPLC Detector from AMEL. Currents were recorded using a LKB 2210 strip chart recorder from Delft, Nederland.

All the measurements were carried out at 25 ± 1°C.

2.3. Procedure

The bare electrode used for the preparation of the sensors consisted of a Pt or Au or GC disks (2 mm diameter) sealed in a tygon tube.

The working electrode surface was polished with alumina (Al_2O_3, Buehler from Evanston, Illinois) powder of 1, 0.3 and 0.05 μm particle sizes just before use. After carefully rinsing with distilled water, electrodes were sonicated for almost 10 min. Moreover, the Pt and Au electrodes were pre-treated in 0.5 mol l^{-1} H_2SO_4 by potential cycling from −0.2 to +1.2V (vs. SCE) at a scan rate of 20 mV s^{-1}, until no changes in current were observed [36].

2.4. Electropolymerization with PMS in absence of enzyme

For the electropolymerization studies the following monomers have been used: 1,2-DAB, 1,3-

Table 1
Voltammetric data relative to polymers/electrodes in presence NAD(P)H and ascorbic acid

	ip_a (μA) at bare electrode	ip_a (μA) at covered electrodes	
		PPY-2-COOH	PDHB
Ascorbic acid (4 mM)			
(Pt)	7.14	1.04 (−86%)	0.91 (−87%)
(Au)	8.02	0.97 (−88%)	0.87 (−93%)
(GC)	7.51	0.92 (−87%)	0.98 (−88%)
NADPH (3 mM)			
(Pt)	3.98	0.38 (−95%)	0.44 (−88%)
(Au)	4.97	0.48 (−90%)	0.38 (−92%)
(GC)	4.23	0.42 (−90%)	0.41 (−90%)
NADH (3 mM)			
(Pt)	4.03	0.35 (−91%)	0.34 (−92%)
(Au)	5.01	0.43 (−91%)	0.41 (−95%)
(GC)	4.28	0.45 (−88%)	0.46 (−88%)

DAB, 1,4-DAB, PY-2-COOH and DHB. Each monomer was electropolymerized using a solution of sodium phosphate buffer 0.1 mol l^{-1}, which was deaerated for 30 min with Argon 99% (Air Liquide, France), in the presence of PMS.

Monomer and mediator concentrations have been varied from 5 to 9 mmol l^{-1} and from 0.8 to 4.0 mmol l^{-1} respectively. The electropolymerization has been carried out using cyclic voltammetry at pH values from 5.6 to 8.1. The scan rate has been varied from 20 to 2 mV s^{-1} and the potential has been continuously cycled from 0 to +0.8 V for 1.2-, 1.3-, 1.4-DAB, from +0.4 to +1.2 V for DHB and from +0.4 to +1.4 V for PY-2-COOH, until the current reached a value which remained constant after further cycling.

2.5. Voltammetric PMS and NAD(P)H measurements

To test the electrocatalytic behaviour of the entrapped PMS we used the following procedure: at the end of the electropolymerization the electrode was rinsed with the working buffer, then dipped in the same deaerated buffer solution and the potential scanned from +0.5 to −0.5 V.

Ascorbic acid, paracetamol at a concentration of 0.4 mmol l^{-1} and uric acid (saturated solution)

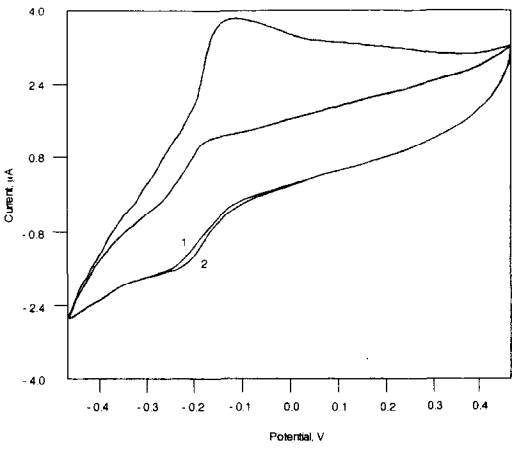

Fig. 2. Cyclic voltammograms at a PPY-2-COOH/PMS/gold electrode: (1) in a deoxygenated phosphate buffer (pH 8.1, $I = 0.1$); (2) in the presence of 0.5 mmol l^{-1} NADH. Scan rate 5 mV s^{-1},

were also tested in phosphate buffer pH 8.1, in the absence and presence of the polymer with the entrapped mediator. The same experiment was also carried out with solutions of NAD(P)H, ranging from 0.1 to 10 mmol l^{-1}.

Table 2
Catalytic efficiency of PMS for NAD(P)H oxidation from ratio of catalytic peak current I_{cat} to peak current I_{ox}, recorded in the same solution without NAD(P)H, in a buffer solution pH 8.1 $v = 10$ mV s^{-1}

Electrode	I_{cat} (μA)	I_{ox}(μA)	I_{cat}/I_{ox}
NADH 1 mmol l^{-1}			
(a) at a PMS/PPY-2-COOH/electrode			
Au	2.81	0.38	7.4
GC	0.88	0.35	2.5
Pt	2.64	0.36	7.3
(b) at a PMS/PDBH/electrode			
Au	3.12	0.37	8.4
GC	0.94	0.36	2.6
Pt	2.81	0.36	7.8
NADPH 1 mmol l^{-1}			
(a) at a PMS/PPY-2-COOH/electrode			
Au	3.24	0.38	8.5
GC	0.84	0.37	2.3
Pt	3.08	0.34	9.1
(b) at a PMS/PDHB/electrode			
Au	3.28	0.41	8.0
GC	0.83	0.32	2.5
Pt	3.13	0.41	7.6

2.6. Amperometric measurements

Interferences and NAD(P)H were also measured amperometrically at −0.1 V vs. SCE, using Au, Pt, GC electrodes, as follows: the polymer modified electrodes were dipped in a beaker containing 10 ml of phosphate buffer pH 8.1 and allowed to equilibrate at −0.1 V. After 10 min a stable current baseline was observed. Aliquots of NAD(P)H and/or interferences were added and changes in current recorded.

The response of the probe to the interferences and NAD(P)H has been measured weekly for 2 months and normalized to the initial response.

2.7. Electropolymerization with pms in presence of enzyme

The experimental conditions for the electropolymerization of the organic monomers in presence of the enzymes were the same of those carried out in absence of the enzyme.

We used gold and platinum electrodes. The electrodes were rinsed with the buffer solution to remove the non immobilized physically adsorbed PMS and stored in the same solution at 4°C.

The amount of enzyme used was 120 U ml^{-1}, for GDH, 160 U ml^{-1} for LDH and 80 U ml^{-1}, for GlDH.

Lower quantities of enzymes gave a signal current lower than that obtained with the amperometry reported above, higher quantities did not show any increase in current.

Amperometric measurements of glucose, lactate and glutamate were carried out using the procedure described for the NAD(P)H measurements, the difference being in $NAD(P)^+$ 1 mmol l^{-1} in the buffer solution and in the appropriate substrate injection aliquots.

3. Results and discussion

3.1. Electropolymerization studies

In previous works [37,38], we studied the electropolymerization of organic monomers together with oxidase and dehydrogenase enzymes on solid electrodes.

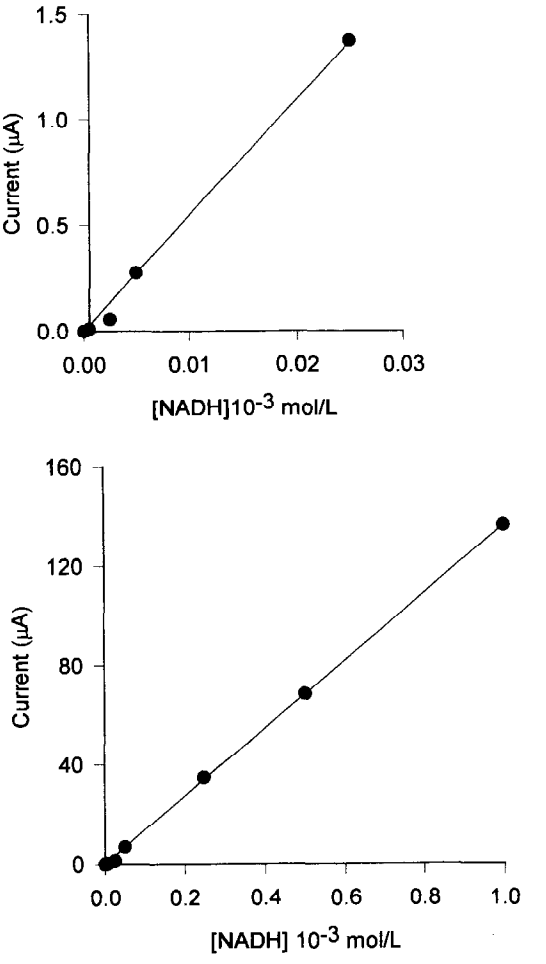

Fig. 3. Calibration curves of NADH at PMS/PPY-2-COOH/Au electrode: electrolyte: phosphate buffer 0.1 mol l^{-1}, pH 8.1; $E = -0.10$ V vs. SCE.

The generic reaction which involves the enzyme and PMS immobilized should have the following sequence:

$$\text{Substrate} + NAD(P)^+ + H^+ \rightarrow \text{Product} + NAD(P)H$$

$$NAD(P)H + PMS_{ox} \rightarrow NAD(P)^+ + PMS_{red} + H^+$$

$$PMS_{red} \rightarrow PMS_{ox} + 2e + 2H^+$$

All these reactions should occur at the electrode surface where the enzyme and PMS are immobilized and they make sense if the electrode surface is protected by the polymer film which should reject compounds electroactive at the potentials used to detect NAD(P)H/PMS mediated reaction.

3.2. Polymeric film formation

The first step of our study was the formation of the polymeric film on the electrode probes. Ascorbic acid was selected as interfering compound guide. Fig. 1 shows the effect of the electropolymerization of PY-2-COOH on a gold electrode. The potential was continuously cycled until a minimum current value was attained.

Results reported in Table 1 refer only to PPY-2-COOH and PDBH: data relative to the other polymers have been reported in previous works [37,38].

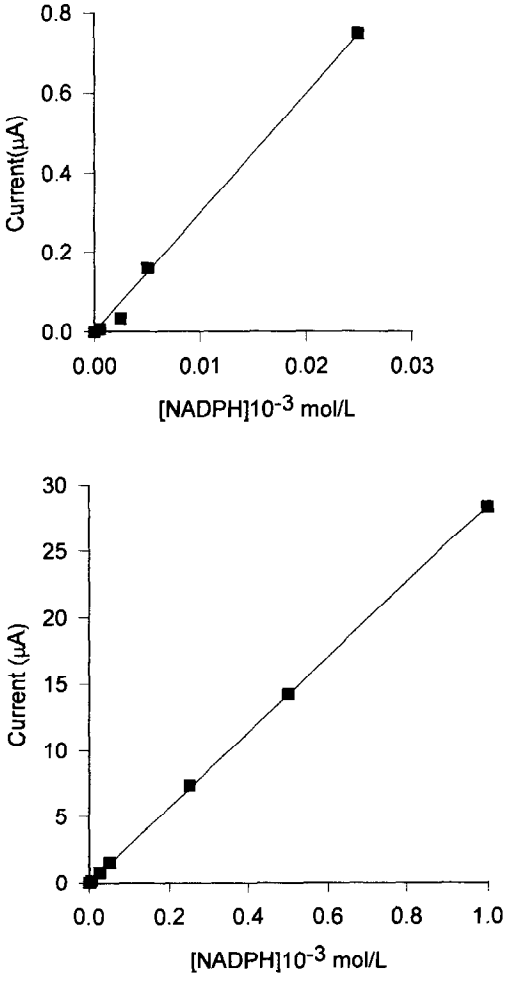

Fig. 4. Calibration curves of NADPH at PMS/PPY-2-COOH/Au electrode: electrolyte: phosphate buffer 0.1 mol l^{-1}, pH 8.1; $E = -0.10$ V vs. SCE.

3.3. Electropolymerization with PMS in absence of enzyme

In the second step the polymerization of the monomers in presence of PMS was carried out. In this case we evaluated the effects of the scan rate, pH and amount of PMS on the electropolymerization process. The optimum scan rate was 2 mV s^{-1}. Higher rates did not result in a mediator entrapment into the polymer [37,38], moreover we could hypothesize an unstable film formation because we observed that the response to ascorbic acid and to the other interferences increased after a week [39,40].

We investigated the ability of PY-2-COOH and DHB to form permselective films in aqueous buffered solution.

The permselectivity in these films can come from the deprotonated carboxylic groups for PPY-2-COOH [41] and from the carbonylic groups for DHB. Unlike the formation of overoxidized polypyrrole film, using these polymers, the overoxidation of the film and the introduction of the carbonyl groups by overoxidation is not needed.

3.4. pH study

The optimum pH value for the electropolymerization in presence of PMS was studied.

The pH value which gave a good result for the PMS electroactivity on the electrode surface was 8.1 and this value was used for further studies.

pH values from 5.6, reported as starting pH for electropolymerization study [42,43], to 7 did not show any entrapment of PMS on the surface of the electrodes. The minimum basic pH which gave a good result for the PMS electroactivity on the electrode surface was 8.1 and this value was used for further studies.

Table 3
Properties of PMS/PPY-2-COOH/enzyme electrodes probes

Enzyme	pH	Linearity range (mol l^{-1})	Slope (mA mmol $^{-1}$ l^{-1})	Response time (s)	Detection limit (mol l^{-1})	Reproducibility rsd% (4 measurements)
LDH	8.1	5×10^{-6}–1×10^{-2}	1.6	4–7	1×10^{-6}	3
GDH	8.1	5×10^{-6}–1×10^{-2}	1.1	5–9	1×10^{-6}	4
GlDH	8.1	5×10^{-6}–1×10^{-2}	1.9	6–10	1×10^{-6}	4

Moreover, this pH value was suitable for a good electropolymerization of PY-2-COOH because the monomer solubility at this pH is higher and the polymer itself shows the required permselectivity since the deprotonated carboxylic groups can repel, negatively charged compounds. Moreover, in the pH range from 5.6 to 7 the solubility of PY-2-COOH monomer is not sufficient to obtain a very compact film.

pH values higher than 8.1 were not used because the enzymes tested for the immobilization are less active at basic pH values (see Sigma Catalogue: pH 7.5 for GDH, pH 7.3 for GlDH and pH 7.5 for LDH).

The PMS amount was varied from 0.8 to 4.0 mmol l^{-1}. From the cyclic voltammetry we observed that the minimum concentration which gave an appreciable analytical signal was 0.8 mmol l^{-1}, then the current peak increased with the concentration of PMS and at a concentration higher than 3 mmol l^{-1} the current peak was constant. So we concluded that the amount of PMS entrapped was also constant.

Fig. 2 shows the voltammetric redox behaviour of PMS entrapped in PPY-2-COOH. Similar results were obtained with PDHB, while poly(1.2-DAB), poly(1.3-DAB) and poly(1.4-DAB) showed that the amount of PMS entrapped into the polymeric structure was not sufficient for the NAD(P)H catalytic oxidation.

The electrochemical behaviour of PMS at solid electrodes has been extensively studied and clarified in a previous paper [30].

In aprotic medium, the PMS reduction involves two quasi-reversible monoelectronic steps, in the potential range from $+0.5$ to -1.5 V.

In aqueous buffered solution, in the range of pH 4–10 a single reversible system is observed at -0.2 V vs. SCE, according to the following mechanism:

$$PMS_{ox} \underset{-2e^-,\ -H^+}{\overset{+2e^-,\ +H^+}{\rightleftarrows}} PMS_{red}$$

Unfortunately, the reduced form of PMS is strongly absorbed on the electrodic surface. Such an absorption disappears when a polymer modified electrode is used.

Table 4
Properties of PMS/PDHB/enzyme electrodes probes

Enzyme	pH	Linearity range (mol l^{-1})	Slope (mA $mmol^{-1}$ l^{-1})	Response time (s)	Detection limit (mol l^{-1})	Reproducibility rsd% (4 measurements)
GDH	8.1	1×10^{-5}–1×10^{-2}	1.4	4–8	5×10^{-6}	4
LDH	8.1	1×10^{-5}–1×10^{-2}	1.3	6–10	5×10^{-6}	3
GlDH	8.5	1×10^{-5}–1×10^{-2}	2.1	6–15	5×10^{-6}	3

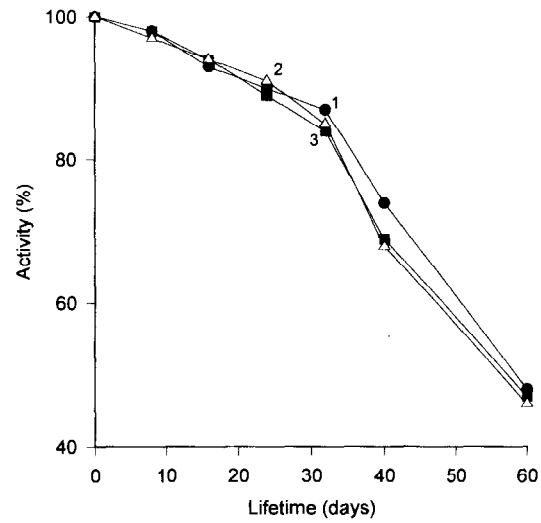

Fig. 5. response vs. time for (1) glucose at GDH/PMS/PPY-2-COOH/Au electrode; (2) lactate at LDH/PMS/PPY-2-COOH/Au electrode; (3) glutamate GLDH/PMS/PPY-2-COOH/Au electrode.

The voltammetric behaviour of PMS in a deaerated solution on a Au/PPY-2-COOH electrode in the range from $+0.5$ to -0.5 V vs. SCE shows a cathodic peak with the complementary anodic one.

The current is proportional to $v^{1/2}$ and to the PMS concentration.

The peak to peak separation (ΔE) is independent from the scan rate and its value of 30 mV is in reasonable agreement with the theoretical value of $56.6/n$ mV if $n=2$ for a two electron reaction.

The voltammetric results of PMS entrapped into the polymer film, showed that the peak to peak separation is similar than that obtained with PMS in solution. Moreover the difference (ΔE) between the anodic and cathodic peak potential is independent from v at low scan rates ($\Delta E \approx 29$ mV at $v = 10$ mV s^{-1}).

The peak current changed linearly with v, as expected for an entrapped redox species [44].

Similar results were obtained using Pt and GC electrodes.

The surface concentration of the electrochemically immobilized PMS on a gold electrode was evaluated by the integration of the peak (cathodic or anodic) and assuming a two electron mecha-

nism for the redox reaction [30]. The result was $(2.81 \pm 0.1) \times 10^{-7}$ mol cm^{-2} which is higher than those relative to PMS adsorbed on an electrode surface [15] or entrapped in a polypyrrole matrix [33].

3.5. NAD(P)H experiments

All the electrodes assembled with PPY-2-COOH or PDHB and PMS have been tested for NAD(P)H by cyclic voltammetry, then amperometrically.

The first step has been the voltammetric study of NAD(P)H with a modified electrode.

Voltammetric scans from -0.5 to $+0.5$ V have been carried out and the peak current was observed at -0.12 V for NADH and -0.14 V for NAD(P)H.

When the concentration of NAD(P)H was increased, the current peak increased linearly up to 1×10^{-2} mol l^{-1}. The peak current observed at -0.12 V for NADH and -0.14 V for NAD(P)H was a demonstration of the mediated reaction between PMS and NAD(P)H (Fig. 2). In fact the NADH oxidation at the naked electrode occurred at a potential around $+0.75$ V and the NADPH oxidation at $+0.77$ V [30] for all the electrodic materials tested.

So we can hypothesize the following mechanism:

$$NAD(P)H + PMS_{ox} \rightarrow NAD(P)^+ + PMS_{red} \quad (1)$$

$$PMS_{red} \rightarrow PMS_{ox} + 2e + 2H^+ \quad (2)$$

Table 2 reports the ratio I_{cat}/I_D of the anodic peak current of the mediator before (I_D) and after (I_{cat}) the injection of NAD(P)H 1 mmol l^{-1}. This was as a criterion for quantifying the electrocatalytic efficiency of NAD(P)H oxidation for different electrodic materials and for different polymeric films. This ratio was almost independent from the polymeric matrix, but strictly related to the electrodic materials, so we selected gold and Pt electrodes for further experiments. The differences observed are unclear and merit further investigation.

Probably, regarding the behaviour of GC, we have to consider different parameters such as the adsorption of PMS on the electrodic surface which lowers the catalytic activity of the mediator.

In fact, in a previous paper [30], we have studied and clarified, by CV, the electrochemical behaviour of PMS on solid electrodes and the trend of electrochemical parameters has indicated that the reduced form of PMS is strongly adsorbed on pyrolytic graphite and glassy carbon electrodes whereas no adsorption was observed on gold and platinum electrodes.

3.6. Amperometry of NAD(P)H

NAD(P)H has been detected in the range 10^{-6}–10^{-2} mol l^{-1} with a detection limit of 5×10^{-7} mol l^{-1}.

Figs. 3 and 4 report two calibration curves of NADH and NADH attained with a modified gold electrode. Same current changes were obtained when NAD(P)H was injected in a solution under Ar atmosphere or in a solution equilibrated with air.

The response time is about 10 s. After 10 h of repetitive measuring a decrease in response of 18% for NADH and of NADPH was observed. We have no direct information on how the mediator is entrapped by the polymer film but, from the data obtained, we can deduce that the mediator reacts rapidly with NAD(P)H so it should be entrapped in the external side of the polymer and the film layer should be sufficiently thin.

Injection of aliquots of paracetamol, uric and ascorbic acid, as reported in the Section 2, did not result in any currents change.

3.7. Electropolymerization in presence of enzyme

Only few examples are reported in the literature [45] of a dehydrogenase enzyme entrapment into a polymeric matrix.

In order to assemble electrochemical dehydrogenase enzyme electrode probes we polymerized the organic monomers (reported in the experimental) in presence of PMS and dehydrogenase enzymes. In this case, since NAD(P)$^+$ acts as cosubstrate for the enzymatic reaction, we used different concentrations of NAD(P)$^+$, to test the efficiency of the enzyme activity. The selected concentration of NAD$^+$ was 1 mmol l^{-1}: lower concentrations

resulted in a lower current output and higher concentrations did not show any increase in the current changes.

Tables 3 and 4 show the results obtained using different electrodes electropolymerized with two monomers together with different enzymes.

The analytical conditions of detection of glucose, lactate and glutamate are also reported in Tables 3 and 4. L-Lactic dehydrogenase type XI is NAD^+ dependent, but not $NADP^+$. In fact aliquots of lactate injected in a solution containing NADP+ did not result in any current change.

3.8. Stability

The probes were stored at 4°C when not in use. Every 10 days consecutive calibration curves were run to test the residual enzyme activity (Fig. 5). For all the probes used the enzyme activity showed a decrease of only 20% over 1 month period, then a more rapid decrease was observed, but a residual activity of about 40% over a period of 2 months was observed for all the three enzymes.

The main reason of the activity loss of the sensors during storage is due to the enzyme activity: this is because the lifetime of PMS/polymer/electrode was stable up to 3 months.

4. Conclusion

This work has shown for the first time the immobilization of dehydrogenase enzymes into non conducting films, together with PMS, thus resulted in the assembling of stable and interference free dehydrogenase enzyme electrode probes. Examples of detection of glucose, lactate and glutamate, showed a promising application for all dehydrogenase enzymes.

Metal-promoted shift of equilibrium between the two fluorescent forms of a synthetic macrocycloureide in view of designing chemical sensors

M. Dumaine-Bouaziz, D. Cordier *, P.R. Coulet

Laboratoire de Génie Enzymatique, UPRESA CNRS 5013, Université Claude Bernard Lyon 1, 43 Bd. du 11 Novembre 1918, 69622 Villeurbanne Cedex, France

Received 31 July 1996; received in revised form 24 February 1997; accepted 26 February 1997

Abstract

The emergence of the fiber-optic sensor era has stimulated investigations to create synthetic fluororeceptors capable of signaling the binding of metal ions. To fulfill this purpose, a new concept is presented: the metal-promoted shift of equilibrium between the two fluorescent forms of a synthetic receptor able to dimerize and to specifically recognize a metal ion by multiple non-covalent bonds. The thermodynamics of the dimerization itself and the dimer–zinc interactions are analyzed in terms of association constants. It is demonstrated that finely tuning the equilibrium between the monomeric and dimeric forms by controlling the pH, permits the alternate selective recognition and signaling of zinc or cadmium. © 1997 Elsevier Science B.V.

1. Introduction

For several years, there has been growing concern about heavy metals in the biosphere. Selenium, cadmium, mercury and lead are presently the most dangerous, owing to their increasing anthropogenic discharge in the environment and to their high toxicity. Although of less toxicity, copper, zinc and molybdenum are likely to pose a threat. The heavy metal pollution points out the need for reliable, fast and low-cost means for their aqueous detection.

Concerning zinc, the global excess burden on the environment due to mankind's activities is actually the result of smelting, refining and manufacturing processes, but domestic waste waters are also important sources and consequently high local concentrations are probable, especially in aquatic ecosystems [1]. According to its role as a cofactor of various enzymes, zinc is known as an important oligonutrient with strong physiological implications. Among others, including iron and manganese, the level of zinc is of importance in seawater [2,3] since this metal meets the needs of many species for survival, and for the productivity of plankton [4]. Therefore, it is not surprising that

PII S0039-9140(97)00072-6

several zinc measurement methods have been recently proposed, most of them combining, for instance, flow-injection analysis with an ion-exchange resin and fluorescence [3,5], or high-performance liquid chromatography (HPLC) and light absorption [6], or diffusive gradients in thin films and atomic absorption spectroscopy [7]. Besides, the function of zinc as a cofactor in enzymatic catalysis has been utilized in the design of enzyme-based zinc optical biosensors [2,8].

In parallel to the development of amperometric and optical biosensors [9], our group is now involved in the design and the study of stable artificial receptors for molecular recognition [10,11] with the purpose of elaborating new sensing layers usable in optodes (optical devices, by analogy with electrodes) for determining transition metal ions in water. A challenging goal is to get a signal, for instance fluorescent, when molecular recognition occurs. A previous work resulted in the synthesis of a promising water-soluble receptor, i.e., a macrocycloureide able to form a dimer at alkaline pH. Both the monomer and the dimer have distinctive fluorescence emission spectra. The dimer specifically complexes the zinc ion and the complexation induces a shift in the equilibrium between the monomer and dimer forms towards the dimer form. A fluorescence signal may thus be monitored which is the result of the (excited) dimer emission enhancement.

Basically, this is a metal-promoted shift of equilibrium between the two fluorescent forms of a receptor able to dimerize and specifically recognize a metal ion in water through a supramolecular process.

The emergence of the fiber-optic instrumentation, and the need for detection and quantification of heavy metals, in addition to the increasing interest of biologists for possible applications in their domain, have stimulated continuous investigations on artificial fluororeceptors able to complex metal ions with useful selectivity [12,13].

In the present article, an alternative to ion-promoted chelation-enhanced fluorescence (CHEF), at the origin of fluorescent chemosensors [13], is proposed for the detection of metal ion complexation.

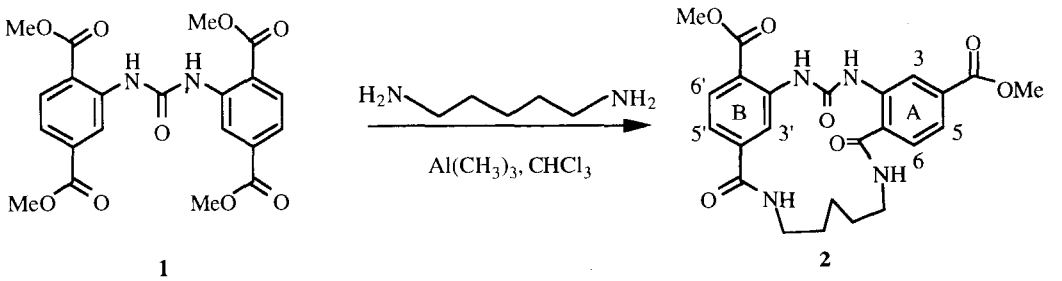
2. Experimental procedure

2.1. Synthesis of the receptor

The synthesis of the macrocycloureide has been described elsewhere [10]. Starting from this procedure, the protocol has been improved to lead to the following accelerated process: in a typical experiment, trimethyl aluminium (1.12 cm^3 of a 2 M solution in hexanes, i.e., 2.24 mmol) was added in a closed vessel under nitrogen to 10 cm^3 of dry chloroform. The mixture was cooled down to $-10°C$ with salt and ice and 134 μl (1.12 mmol) of 1,5-diaminopentane were slowly added with a syringe through a septum. The mixture was stirred for 20 min at $-10°C$ and then for 45 min at room temperature. After addition of 160 cm^3 of dry chloroform, the temperature of the mixture was increased to 0°C and a solution of tetramethyl 2,2′-ureylenediterephthalate (100 mg, 0.225 mmol, synthesized in a previous step [10]) in chloroform (30 cm^3) was rapidly added. The reaction mixture was stirred overnight in an ice bath under nitrogen and then for 4 h at 50°C. After reaction, the chloroform was evaporated under vacuum. The product was redissolved in methanol and by-products were filtered off. The filtrate was dried under vacuum and redissolved in 20 cm^3 of a 50 mM sodium phosphate buffer, pH 6. Insoluble by-products were filtered off and colored residues were removed by a charcoal treatment. After filtration and evaporation of the water, the product was dried under vacuum, enabling 39 mg (0.081 mmol, 36%) of a white solid to be obtained.

2.2. ^1H-NMR studies

For the 300-MHz ^1H-NMR (nuclear magnetic resonance) experiments, the conditions were the following: a concentrated solution of the macrocycloureide in water was diluted with a 50 mM buffer solution (with phosphate at pH 6, borate at pH 9 and carbonate at pH 10, 11 and 12) to obtain 0.6 ml of a macrocycle solution at 2 mM concentration. The solution was then evaporated and dissolved six times with D_2O, under nitrogen, taken again by 0.6 ml D_2O and transferred in an



1 2

Fig. 1. Building-up and structure of the fluororeceptor **2** (for details see Section 2).

NMR tube for the analysis. All proton signals were stable within the NMR time scale.

2.3. Fluorescence measurements

The macrocycle complexation was monitored in aqueous solution by recording the increase in fluorescence emission of either the dimer (at 432 nm for the zinc complexation with excitation at 356 nm) or the monomer (at 380 nm for the cadmium complexation with excitation at 332 nm). The complexation of metal ions occurred when aliquots (1 or 2 μl) of the zinc or cadmium chloride solution were added and mixed in the cuvette with the macrocycle solution (concentration: 0.1–1 mM), in 50 mM sodium phosphate buffer (PO_4^{3-}/HPO_4^{2-}), pH 12, for zinc, or 50 mM carbonate buffer, pH 9.5, for cadmium. The equilibria of dimerization and complexation of metal ions were stable, as verified by the steady state of the fluorescence signal when monitored for several minutes.

2.4. Potentiometric pH and conductometry titrations

The macrocycloureide obtained by the synthesis described above was flash-chromatographed on silica with dichloromethane 80/methanol 20 as the eluent. After careful calibration, pH and conductance were measured and monitored in 1 cm^3 of a 15-mM macrocycloureide aqueous solution in which aliquots (1 μl) of a carbonate-free 1 M NaOH aqueous solution were successively added and mixed with an automatic pipette. All samples were extemporaneously prepared. The solution temperature was maintained at 25.0 ± 0.1°C. The NaOH concentration was determined by automatic titration with phthalic acid. The cell constant of the conductometry cell was previously adjusted to 12.88 mS cm^{-1}, using a 0.1 M KCl solution. Data were corrected for the volume addition.

3. Results

3.1. Structure and ionization properties of the fluororeceptor

The structure of the receptor is asymmetrical, bearing no chiral center (Fig. 1). Such a type of molecule is known to potentially recognize chiral guests. This property is not imperative in the perspective of metal ions recognition but was retained for further building of structures with increased complexity from this molecule. To achieve this goal starting from a symmetrical bis-substituted urea, the synthetic plan revolved around the regioselectivity of the cyclization of the tetramethyl 2,2′-ureylenediterephthalate with the 1,5-diaminopentane: owing to the length of the five-membered arm of the diamine, the cyclization between an *o*-methyl and a *m*-methyl ester group could only occur after rotation about the Ar–NH bonds.

Another characteristic of the receptor is that it implies a macrocyclophane combining urea and benzamide units. Clearly the amide group is paramount in the natural recognition and folding

processes that involve proteins, and the urea group has proven to be a powerful ligating moiety, as demonstrated in spherands containing cyclic urea units [14] or as a substrate in supramolecular processes through hydrogen bonding interactions [15]. These two types of chemical groups have been chosen as metal-binding elements of the fluororeceptor. Their presence in the chemical structure is also at the base of the properties of the molecule concerning its solubility and dimerization.

The fluororeceptor dimerizes in aqueous solution [10] and is then able to complex zinc. Such a spontaneous self-assembling leading to a dimer in water is not surprising with a molecule bearing aryl rings since association constants of arenes in water are usually large, owing to the favored $\pi-\pi$ interactions [16]. An interesting characteristic concerning the phenomenon of dimerization of this receptor is its modulation by the pH [11] and, hence, the formation of the dimer of **2** in water was first investigated by monitoring the fluorescence emission of the molecule under various pH conditions. Its behavior is characteristic of the formation of an intermolecular excited dimer at alkaline pH [17]: red shifting (380 → 432 nm) of the emission maximum and decreasing of the emission intensity, finally lowered at pH 11 to 60% of the initial value at pH 6. The amplitude of the red shift is indicative of a tight dimer formation which is stabilized by $\pi-\pi$ (hydrophobic) and

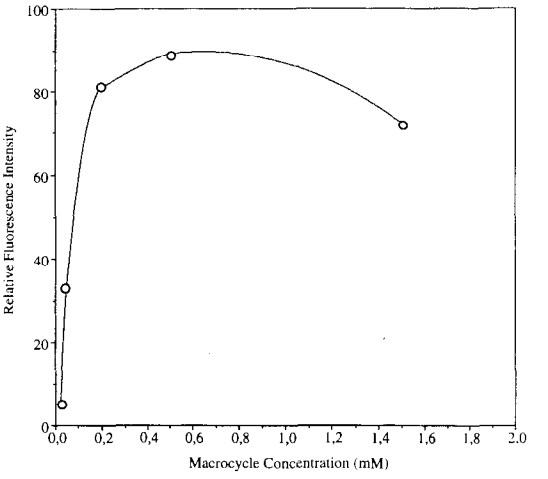


Fig. 2. Relative fluorescence intensity of an alkaline solution of the dimer as a function of its concentration ($\lambda_{ex} = 356$ nm, $\lambda_{em} = 432$ nm). Solvent: 50 mM aqueous sodium phosphate buffer (PO_4^{3-}/HPO_4^{2-}), pH 12.

polar interactions in alkaline medium. Fig. 2 illustrates the effect of the dimer concentration on the measure of the fluorescence intensity at pH 12. The curve exhibits the classical shape of the fluorescence versus concentration of any fluorophore solution: first increasing with a maximum steady level and then decreasing, owing to the concentration quenching which causes a fluorescence loss that is called the inner cell effect.

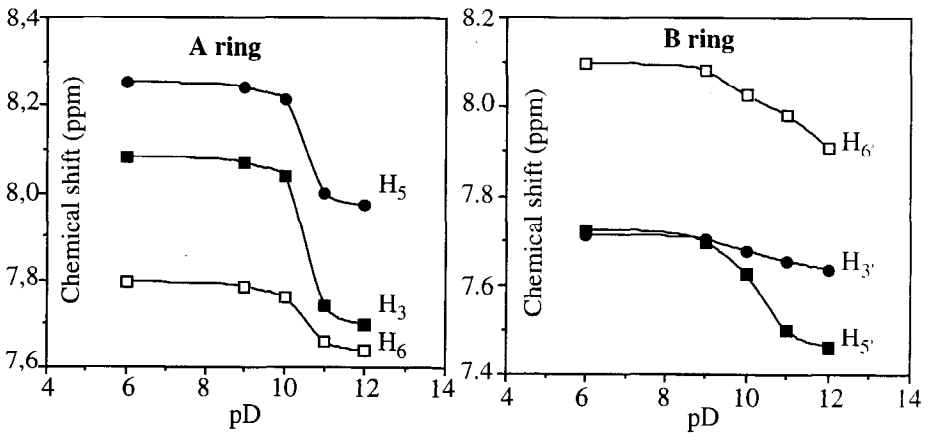

Fig. 3. Chemical shift of the aromatic protons of the two rings of **2** as a function of the pD; ([c] = 2 mM; 298 K).

Additional information required for a better comprehension of the dimerization process may be conveniently found by ^{1}H-NMR. Fig. 3, related to 300-MHz ^{1}H-NMR studies in parallel, shows the chemical shifts of the aromatic protons of the benzene rings A and B of fluororeceptor **2**, plotted as a function of the pD. All the signals are high-field shifted upon raising the pD of the medium. The well-defined discontinuity in the curves, approximately at the same pD value, characterizes the almost entire transformation of **2** into the dimer form. Below pD 9, the monomer form is predominant. Between pD 9 and 10, the monomer coexists with the dimer and the signals of the three protons of the A ring in the monomer are distinct from those of the dimer. All the signals of the A ring protons of the monomer coalesce with those of the dimer on and after pD 11. The simultaneous upfield shift of all the aromatic resonances upon alkalinization of the aqueous medium should be related to the dimerization of the receptor observed through the fluorescence change in the same conditions. The upfield shift of the resonances of the aromatic protons is usually the signature of a confinement of the nuclei in close proximity [18,19]. Hence these spectroscopic results indicate that the dimerization process occurs probably by a π-stacking process of the aromatic moieties of the molecules.

Taking into account the data of the NMR and fluorescence measurements, we inferred that a deprotonation of the molecule occurs at alkaline pH and thus we investigated the ionization behavior of the macrocycloureide, using a combination of potentiometry and conductometry techniques. With the macrocycloureide, the difficulty is increased by its insolubility above 20 mM in alkaline aqueous medium and, consequently, the pH measurements were made at 15 mM concentration. Furthermore, the weak acid–strong base titrations with a pH meter are highly inaccurate when the pK_a of the acid is high, especially when the solution is diluted, owing to the very gradual change of the pH around the equivalence point. Conductometry, under proper circumstances, can eliminate or at least minimize this problem. This is exemplified in Fig. 4, a typical titration curve of the macrocycle obtained by this method, in which

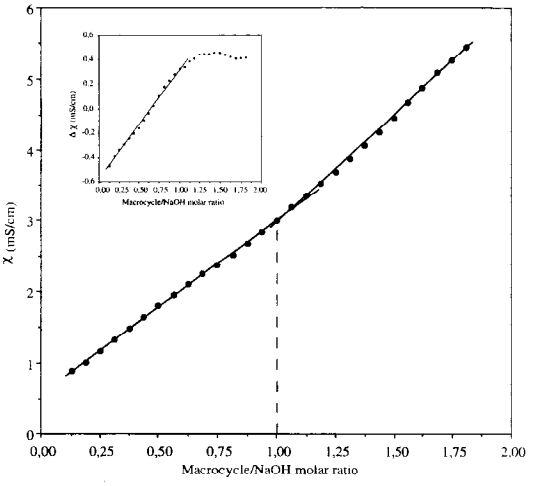

Fig. 4. Conductometric titration of a 15 mM solution of the macrocycloureide in water by a molar NaOH solution. Inset: differential conductivity between the 15 mM macrocycle solution and pure water as a function of the macrocycle/NaOH ratio.

the inset shown is obtained by subtraction of the values obtained with a 15 mM macrocycle solution to the values obtained with the water alone. It evidences the equivalence point obtained at 1 mole of sodium hydroxide per mole of macrocycle. Using the same experimental conditions with a pH meter, it was thus possible to measure the pH values at both the starting point and the semi-equivalence point of the titration. Computation led to an estimation of $pK_a = 12.4 \pm 0.7$. This value of the pK_a indicates that the macrocycloureide is a strong base, i.e., it is largely protonated in aqueous solution. Another point to be noted is the conductance of the 15 mM macrocycle solution which is significantly different from zero (0.72 ± 0.06 mS cm^{-1}) so that the solute should be a charged and very weak acid. These characteristics and data lead to the idea that the protonated macrocycle should be in a cationic form, MH^+. Among the chemical groups of the molecule which could act as an electron-donating group, the strongly basic carbonyl oxygen of the urea bridge is a good candidate (see Fig. 1). Its basicity is enhanced by the large dipole moment of the urea (4.6 D in unsubstituted urea) and the phenyl groups, which are directly connected to the

nitrogen atoms, could stabilize the cationic charge of the protonated molecule by a resonance effect through their π electrons. Another argument in favor of the implication of the urea group may be found in Fig. 3, which shows the largest high-field shift for the H_3 proton of the A ring of the molecule. This proton is in the closest vicinity of the urea group, pointing outside the molecule, and thus is not surrounded by other interacting chemical groups, like in the case of the H_3' proton. The largest pH-dependent chemical shift of the nuclei which is in proximity to the proton-binding site reflects undoubtedly its protonation state. A possible complementary intervening occurrence of the oxygen atom of one of the two amide bonds and of some water molecules, through a cluster involving hydrogen bonding, must also not be excluded.

3.2. Dimerization

Both NMR and fluorescence methods were used to determine the monomer (**2**) and dimer (**2·2**) concentrations at each pH value. At 298 K, the equilibrium of dimerization at the different pH values was almost instantaneously reached, as deduced from the monitoring of the fluorescence signal for several minutes. Therefore, association constants (K_{ass}, M^{-1}) and $-\Delta G^0$ values at 298 K for the equilibrium $\mathbf{2} + \mathbf{2} \rightleftarrows \mathbf{2 \cdot 2}$ were computed by employing the two methods. The monomer concentration at each pH value was calculated using limiting monomer peaks areas of both the Me protons and H_5 NMR signals and limiting fluorescence emission intensity of the monomer. Limiting values were estimated by extrapolation to pH 0 from the plots of the peaks areas or emission intensity of the monomer as a function of pH. K_{ass} values obtained by both methods were in good agreement and, hence, the mean values of K_{ass} and their corresponding errors could be computed.

The values vary with the pH, as summarized in Table 1, showing a large increase of K_{ass} at alkaline pH. On the other hand, it was observed that the dimer is thoroughly soluble in chloroform (though slightly soluble in alkaline aqueous medium where it forms aggregates above 20 mM [10]), whereas the monomer is especially soluble in water. This is the result of increased hydrophobic interactions between the molecules of **2** upon alkalinization of the medium. In water, these interactions shift $\mathbf{2} + \mathbf{2} \rightleftarrows \mathbf{2 \cdot 2}$ on right, increasing the dimer form, which is much less soluble in water. The dimer is soluble in chloroform because chloroform is a less polar solvent than water: its dielectric constant is only 4.806 against 78.5 for water. The monomer **2** has a structure which shows that two kinds of interactions may be expected: the ionic interactions, when the macrocycloureide is protonated, and the $\pi-\pi$ interactions, through the two aromatic rings. The large difference in the free binding energy ($\Delta\Delta G^0 = 4$ kcal mol^{-1}), observed in water upon raising the pH from 6 to 11, may be attributable to the enhancement of the strong aromatic interactions between two molecules of **2**, when the deprotonation of the macrocycloureide, decreasing the ionic interactions, turns the balance toward the $\pi-\pi$ interactions. The subsequent dimerization of **2** should also be largely favored by the desolvation, a consequence of the increased hydrophobicity of the molecule.

With the view to evaluating the effects of protonation (charge effect) and the effects of the van der Waals forces (hydrophobic effect) on the dimerization process, the solvent dependence of the binding strength in the dimerization was investigated at alkaline pH, using mixtures of 50 mM, pH 11 carbonate buffer and 1,4-dioxane. The latter was chosen owing to its miscibility with water and its very low dielectric constant (2.209). The polarity of such a mixed solvent may be easily modulated by changing the dioxane/buffer ratio. If the aromatic interactions are predomi-

nant in the homodimer formation at alkaline pH, $2 + 2 \rightleftarrows 2 \cdot 2$ should be shifted to the left when the dioxane content increases, owing to enhanced competition between the dimer formation and the solvation of the deprotonated monomers by the dioxane. This is indeed what is observed. The electronic absorption spectrum of the monomer exhibits a maximum et 334 ± 1 nm that does not vary, even at a high dioxane ratio, whereas upon raising the dioxane proportion, the dimer maximum at 356 ± 1 nm in aqueous medium is progressively shifted to the monomer maximum absorption: at 84% 1,4-dioxane, almost all the dimer is dissociated. These results lead to the assumption that upon decreasing the polarity of the mixture of solvents, the dimer progressively dissociates, shifting the equilibrium toward the monomer form, which at alkaline pH is better solvated by dioxane than by water, owing to the increasing hydrophobicity of the macrocycle at alkaline pH (a consequence of the deprotonation of the amide and urea moieties). In other words, the competition between solvation (association of the monomer with the solvent) and dimerization (association of two monomers) turns to the advantage of the former when water is replaced by dioxane as a solvent.

The study of the thermodynamics of the dimerization reaction was found to be a useful way to investigate the part of the solvent during the dimerization process. Using ^{1}H-NMR data, values of K_{ass} (M^{-1}) for **2** dimerization at pH 11 changed with temperature as follows: 222 590 (308 K); 174 520 (318 K); 130 690 (328 K); 108 270 (338 K). The van't Hoff plot least-squares line ($\ln K_{ass} = -\Delta H^0/RT + \Delta S^0/R$, $r = 0.99$) of the data provided $\Delta H^0 = -5 \pm 2$ kcal mol^{-1} and $\Delta S^0 = 9 \pm 6$ eu. This behavior is similar to that found for complexation of substituted benzene guests by cyclophanes in water [20]. Calculating the free energy change at pH 11 and 298 K employing the equation $\Delta G^0 = \Delta H^0 - T\,\Delta S^0$ with ΔH^0 and ΔS^0 obtained by the van't Hoff analysis, leads to a value (-8 kcal mol^{-1}) in good agreement with the value of ΔG^0 at pH 11 obtained from of the association constant (Table 1).

A comparison between the enthalpy and entropy changes, taking into account the errors, leads to the conclusion that this is a predominantly enthalpy-driven process, which is probably the result of many van der Waals contacts between the two monomer units (the hydrophobic effect). Nevertheless, the van't Hoff plot least-squares line shows that the entropy dimerization term is not negligible and this signifies that the free energy change of the reaction is enhanced by the decollection of many solvent molecules from the macrocycle (they return to a less ordered state, enhancing the global entropy of the system). This desolvation of the macrocycle largely pays the entropy cost of the association of monomers units. In other words, the entropy gain, owing to the difference between the water molecules that solvate the monomer and those that solvate the dimer, amply pays the entropy cost of the association of the monomer into an homodimer. This observation completes and confirms the results obtained by forcing the equilibria by means of mixture of solvents. The dimerization mainly appears to be the consequence of two phenomena: first the deprotonation of the macrocycle leads to increased π–π interactions which give rise to stacking between aromatic parts of two monomer units (this is supported by the ^{1}H-NMR data in Fig. 3) and secondly, in parallel, the solvation by water decreases, owing to the non-ionic character of the macrocycle.

3.3. Analysis of dimer–zinc(II) interactions

The complexation of the zinc ion with the macrocycloureide occurs through a two-step process: a first equilibrium (Eq. (1)) involves the monomer and the dimer, and a second equilibrium (Eq. (2)) leads to the complex between the dimer and the zinc ion, keeping in mind that one zinc ion is associated with one molecule of dimer [11]. The equilibria and equations are considered to take place in the buffer region and to be reached and stable before the measurement. For simplification, charges and associated water are omitted in the following equilibria:

$$\mathbf{2} + \mathbf{2} \rightleftarrows \mathbf{2 \cdot 2} \quad (1)$$

$$\mathbf{2 \cdot 2} + \mathbf{Zn} \rightleftarrows \mathbf{2 \cdot 2 \cdot Zn} \quad (2)$$

The association constant of Eq. (1) has been determined at pH 11 (Table 1). The shift of Eq. (2) to the right is favored at pH > 10. This property of the interactions between the metal ion and the dimer has been utilized to quantify zinc at pH 12. Thus, determination of the association constant K_{Zn} between zinc and the dimer should be of interest. Since the equilibrium (Eq. (2)) is dependent on Eq. (1), both the association constants must be determined in the same physico-chemical conditions. However, it was not possible to determine with enough accuracy the association constant of Eq. (1) at pH 12, owing to the very low NMR signals then obtained. This led us to calculate the association constant of the dimer with zinc at pH 11. As pointed out below, the other metal ions which were tested do not bind significantly with the dimer at pH 12.

At the equilibrium, the ratio of the concentration of the dimer–zinc complex [**2·2·Zn**] to the product of the concentrations of the free dimer [**2·2**] and free zinc [**Zn**] defines the association constant K_{Zn}

$$K_{Zn} = \frac{[\mathbf{2\cdot 2\cdot Zn}]}{[\mathbf{2\cdot 2}][\mathbf{Zn}]} \quad (3)$$

Similarly, the equilibrium constant of Eq. (1) is

$$K_{ass} = \frac{[\mathbf{2\cdot 2}]}{[\mathbf{2}]^2} \quad (4)$$

The zinc and macrocycle mass balance leads to the two following equations at equilibrium:

$$[\mathbf{Zn}] + [\mathbf{2\cdot 2\cdot Zn}] = [\mathbf{Zn}]_{Tot} \quad (5)$$

$$\frac{[\mathbf{2}]}{2} + [\mathbf{2\cdot 2}] + [\mathbf{2\cdot 2\cdot Zn}] = \frac{[\mathbf{2}]_{Tot}}{2} \quad (6)$$

where $[\mathbf{Zn}]_{Tot}$ and $[\mathbf{2}]_{Tot}$, are respectively the initial total zinc and macrocycloureide concentrations. At equilibrium and fixed pH, between 0 and 1 mol zinc added per mole of dimer, [**2·2**] and [**2·2·Zn**] depend solely on the amount of zinc. These two variables are related to the increase of the fluorescence emission of the dimer upon addition of zinc ions. Hence, it is possible, knowing the amount of dimer before the addition of zinc, to estimate the amount of total dimer at equilibrium. This leads to the following last equation:

$$\frac{[\mathbf{2\cdot 2\cdot Zn}] + [\mathbf{2\cdot 2}]}{[\mathbf{Zn}] + [\mathbf{2\cdot 2\cdot Zn}]} = \frac{[\mathbf{2\cdot 2}]_0 + [\mathbf{2\cdot 2}]_{Sh}}{[\mathbf{Zn}]_{Tot}} \quad (7)$$

where $[\mathbf{2\cdot 2}]_0$ is the dimer concentration before the addition of zinc (Eq. (1)) and $[\mathbf{2\cdot 2}]_{Sh}$ is the increase of the dimer concentration induced by the shift of Eq. (2) upon zinc addition. This last parameter may be deduced from the least-square straight line of the dimer emission increase as a function of the amount of zinc added at pH 11 ($y = 98.49 + 52.99x$: y is relative fluorescence intensity, x is mole zinc added per mole macrocycloureide, $r = 0.98$).

Accordingly, numerical values are ascribed to the known parameters: $K_{ass} = 2.7 \times 10^5$ M^{-1}, $[\mathbf{2}]_{Tot} = 1 \times 10^{-4}$ M, $[\mathbf{Zn}]_{Tot} = 0.25 \times 10^{-4}$ M, $[\mathbf{2\cdot 2}]_{Sh} = 5.86 \times 10^{-6}$ M. Solving the system of Eqs. (3)–(7) gives the following concentrations at equilibrium of the system: $[\mathbf{2\cdot 2}] = 3.8 \times 10^{-5}$ M, $[\mathbf{Zn}] = 1.91 \times 10^{-5}$ M, $[\mathbf{2}] = 1.19 \times 10^{-5}$ M and $[\mathbf{2\cdot 2\cdot Zn}] = 0.59 \times 10^{-5}$ M. The association constant of the dimer with zinc at pH 11 is $K_{Zn} = 8 \times 10^3$ M^{-1}. This value is in close agreement with those reported elsewhere for complexes of zinc with imidazole-containing peptides derivatives [21,22].

3.4. Quantitative signaling of the complexation of metal ions

The shift of equilibrium of dimerization depends on the complexation of a metal ion by either the monomer or the dimer species. This property may be utilized to finely tune the conditions of the specific measurement of a metal ion. The dimer is formed at alkaline pH with two molecules of the fluororeceptor which associate at a relatively large distance, and this ensemble offers coordination possibilities for three of the four bonds of a tetrahedral ion (ion B in Fig. 5), the last one involving an external anion like a chloride ion. For instance, the dimer has the ability to form a complex with an ion that may be Zn(II), which is a tetrahedral coordinated ion [10]. With the optimal conditions for a B ion complexation, no A ion recognition signal is delivered, partly because the complexation of the B ion makes the receptor unable to recognize the A ion. This is exemplified by the inability of the Cd(II) ion to

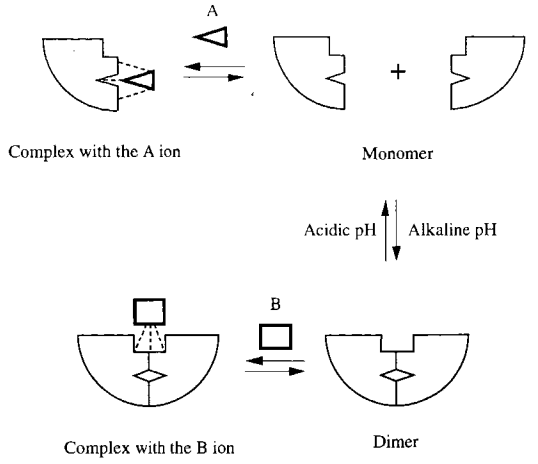

Fig. 5. Schematic representation of the selective complexation of the metal ions A and B with either the monomer or the dimer of the fluororeceptor whose equilibrium is first modulated by the pH. The A ion may be Cd(II) and the B ion may be Zn(II). Both the monomer and the dimer forms are fluorescent with different maximum emission wavelengths.

give a complexation signal with the fluororeceptor in the conditions of the recognition of the Zn(II) ion at pH 12. Cd(II) has the same coordination type as Zn(II) but has a larger ionic radius (0.92 Å instead of 0.74 Å). Conversely, there is no Zn(II) complexation with the monomer, which is able to recognize the Cd(II) ion in moderate alkaline pH conditions (pH 9.5).

Hence, in this example, for a signal of complexation to be delivered by the receptor, the amount of dimer must be significant, the ionic radius of the metal ion must fit with the available space between the two elements of the dimer and, finally, the coordination type of the metal ion should be recognized by the dimer. More generally, modifying the protonation of the molecule through the pH of the aqueous medium allows both the coordination geometry and the amount of receptor to be controlled, by the dimerization process. Since the coordination geometry together with the ionic radius is at the basis of the recognition process of the metal ion and since the fluorescence response is determined by the amount of the fluorescent species, one has the means to modulate both the receptor specificity for a given metal ion and the amplitude of the fluorescence signal.

3.5. Selectivity of the receptor

The specificity of the complexation governs the selectivity of the receptor. The specificity for zinc is illustrated by comparison with cadmium. No dimer emission enhancement can be obtained with this metal at pH 12. Further investigations on the protonation of the receptor have shown that a cadmium measurement was possible, using the monomer as the recognition element at pH 9.5, but the stoichiometry and equilibria of the complex receptor/cadmium are more complicated then in the case of zinc, probably owing to the intervention of water in multiple equilibria. Nevertheless determining the Cd(II) amount is possible upon the addition of the metal, by measurement of the slight increase of the fluorescence signal at the maximum emission wavelength of the monomer. The response is linear for the concentration range 75–375 μM. In the same conditions, no increase of the fluorescence of the monomer occurred with the Zn(II), Cu(II) and Hg(II) ions. An illustration of the differential response for cadmium and zinc is presented in Fig. 6. The slope of the straight line for zinc is much more important than for cadmium but the addition of

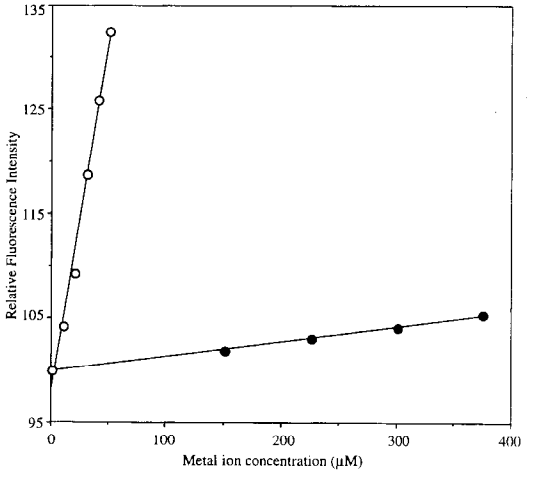

Fig. 6. Relative fluorescence intensity of the fluororeceptor as a function of metal ion concentration: (○) Zn(II), pH 12, $\lambda_{ex} = 356$ nm, $\lambda_{em} = 432$ nm, dimer emission); (●) Cd(II), pH 9.5, $\lambda_{ex} = 332$ nm, $\lambda_{em} = 380$ nm, monomer emission). Fluororeceptor concentration: 0.1 mM.

Table 2
Effect of interfering metal ions on the accuracy of the measure during the determination of 10, 20, 30, 40 and 50 μM zinc in phosphate buffer at pH 12 with the fluororeceptor concentration fixed at 0.2 mM

Interferent	Zinc conc. (μM)	Error (%) at 15 μM conc. of interferent	Error (%) at 100 μM conc. of interferent
Cd(II)	10	−1.8	0.9
Cu(II)	10	−2.5	−1.1
Hg(II)	10	0.0	0.9
Cd(II)	20	−1.5	0.6
Cu(II)	20	−2.4	−1.3
Hg(II)	20	0.3	0.4
Cd(II)	30	−3.8	−0.3
Cu(II)	30	−3.4	−2.2
Hg(II)	30	2.2	0.8
Cd(II)	40	−5.6	−1.1
Cu(II)	40	−3.9	−3.6
Hg(II)	40	2.3	−0.6
Cd(II)	50	−4.6	−0.6
Cu(II)	50	−2.8	−3.8
Hg(II)	50	4.9	0.8

the latter distinctly stresses the shift of the monomer/dimer equilibrium toward the monomer form. It is clear, however, that from an analytical point of view, the 5% amplitude variation observed in the range 75–375 μM, although reproducible, is not large enough. Fig. 6 exemplifies the utilization of the metal-promoted shift of equilibrium between the two fluorescent forms of a receptor and demonstrates that the conditions of the recognition may be adjusted to adapt to different ions. Preliminary results obtained in parallel with Cu(II) confirm this possibility (data not shown).

The selectivity of the zinc fluororeceptor (dimer at pH 12) was investigated by measuring the error on the determination of 10, 20, 30, 40 and 50 μM zinc ions mixed with 15 and 100 μM cadmium, copper or mercury ions. This panel of divalent metals was chosen with regard to their representativeness concerning their coordination type and size: cadmium displays predominantly the same geometry as zinc but is larger, copper has the same radius (0.71 Å) but is rather square coordinated and mercury, predominantly, has linear coordination with an ionic radius of 0.83 Å [23]. Mean results (six replicates in each case) are summarized in Table 2.

Since, for zinc measurement, the signal is correlated to the increase of the amount of dimer, a positive effect is the result of an interaction of the interfering ion with the receptor, thus shifting the dimer amount at a higher level. An opposite effect of the interferent species leads to a negative error. Cadmium, which forms a complex with the monomer, slightly decreases the signal then obtained. Copper has the same effect, while mercury causes an increase of the signal. Given the precision of the zinc measurement at 20 μM (1.5%, see below), the results point to no significant effect (e.g., $>3\%$) of the three interferents at 20 μM zinc concentration for both the interferent concentrations. With the other four zinc concentrations that were tested, the errors seem to be less important at 100 μM interferents concentration than at 15 μM. If this difference is significant, it might be explained by the effect of the interferents on the stability of the zinc–fluororeceptor complex, through a mechanism that remains to be determined.

Globally, the selectivity for zinc appears satisfying since at both 15 and 100 μM concentration of interferents, the errors are within 5%, except for the slightly higher value for 40 μM zinc in the presence of 15 μM cadmium. As pointed out

above, pH is the crucial variable that permits one to drive the specificity of the complexation for a given ion. Hence, defined conditions allow the metal-promoted shift of equilibrium to be initiated by the complexation of the ion, either with the monomer or with the dimer and this particular feature explains the performance in terms of selectivity of the fluororeceptor.

3.6. Detection limit and accuracy of the zinc measurement

Concerning these important parameters of a metal dosage, the zinc measurement at pH 12 with the fluororeceptor gave the following results: the fluorescence response was linear ($r = 0.99$, $n = 6$) from 5 to 50 μM added zinc, for a fluororeceptor concentration of 0.2 mM. The precision, based on the repeated analysis of samples containing 20 μM Zn, was 1.5% ($n = 6$). The detection limit, defined as the concentration of metal ions determined for three standard deviations above the mean of four replicate measurements of the zero standard, e.g., the control without any metal ion, was 5 μM.

4. Conclusion and trends

The metal-promoted shift of equilibrium between the two forms of a dimerizing fluororeceptor synthesized in our group was shown to be a promising tool for the aqueous detection and measurement of metal ions. By simply controlling, through the pH, the balance between the monomer and dimer forms, it is possible to turn on the complexation with zinc or with cadmium ions. Like in natural mechanisms, such supramolecular structures use the multiple noncovalent bonds for molecular recognition in aqueous solution. Recently, a system derived from a linear polyamine has been shown to self-assemble similarly upon metal complexation [13]. Such a strategy, exploiting the host–guest recognition in water by preorganized small molecules susceptible to large changes in their molecular conformation upon the binding event, is certainly of great promise. In our case, zinc measurement appears to be satisfying concerning both the selectivity and the detection limit. The specificity of the recognition process is the basis of the selectivity of the receptor. However, with the search for exquisite selectivity appearing more and more a costly task, the tendency is now toward sensor arrays combined with chemometrics which may provide the same results at a lower expense [24]. The two approaches are not exclusive and even may be complementary when a second-order instrumentation including an optode is designed around a fluororeceptor whose selectivity was proved to be satisfactory.

Opt(r)odes take a growing place in the development of chemical sensors. The utilization of optical fibers now allows a wide variety of chemical detection schemes to be proposed. These new perspectives should enlarge the means of quantification or detection of various molecules and ions [25].

Although chromogenic and fluorogenic devices are conceivable, the latter offers considerable advantage owing to the high sensitivity associated with fluorescence signal detection. The sensing element of the optode is mainly composed of the receptor which, in fluorogenic devices, will deliver a light emission signal upon recognition of the ion or molecule for which it has been designed.

The development of such an optode, based on the fluororeceptor properties, is under investigation, the first step consisting in the immobilization of the receptor on a waveguide. In parallel, the modification of the macrocycloureide by functionalizing the free methyl ester groups and the covalent bridging of the dimer, are underway. We also intend to design daughter molecules by refining the functionalization of this first-generation structure to achieve various chiral complexations. We are confident that this could open the way to new selective and promising sensing devices.

Abstract

A simple technique has been developed for preconcentration of gaseous trace organic compounds on solid sorbents, followed by gas chromatography. The sorbent is packed in a cartridge prepared from a syringe needle placed in the gas chromatographic injector and the analytes previously adsorbed are thermally desorbed at the injector temperature and then directly swept by the carrier gas into the column. The system has been tested for a charcoal-based adsorbent and silica gel, with pentane, methanol, ethanol and acetone as the model analytes. The procedure is rapid, the detection limits vary from a few nmol l^{-1} to values below 0.1 nmol l^{-1} (i.e., a few ppb), the linear dynamic range amounts to at least five concentration decades and a typical relative standard deviation is 10% at the nmol l^{-1} concentrations. It has been shown that the method is readily applicable to determination of instantaneous concentrations of the analytes in natural and industrial atmosphere and to their monitoring in human breath which is important for medical and hygienic practice. In general, the procedure is applicable to low-molecular volatile organic compounds. © 1997 Elsevier Science B.V.

1. Introduction

The increasing atmospheric pollution necessitates continuous improving of methods for monitoring of pollutants and checking the exposure of people to them. Gas chromatography belongs among the most common methods employed not only in industrial hygiene, but also in medicine in analysis of human breath [1–6].

The pollutant concentrations in the atmosphere and the contents of medically important organic compounds in exhaled air are usually too low for

direct determination and preconcentration techniques are required, the most common being absorption of analytes in liquids, their freezing out or adsorption on solids at a decreased or ambient temperature [7–15]. Absorption in liquids has advantages in possible use of chemical reactions of the analytes with the liquid leading to their conversion into stable compounds and thus, to an improvement in the trapping efficiency and in the possibility of collecting samples with a relatively high humidity. The drawbacks involve analyte losses through evaporation and/or stripping by the test gas passed through the absorption liquid and the necessity of using poorly volatile solvents that complicate the subsequent GC analysis. The freezing out with, e.g., liquid nitrogen or helium, is advantageous in its capability of collecting all the analytes (including highly volatile ones), in exclusion of side reactions of the analytes and in selectivity of collection at various temperatures; on the other hand, a possibility of aerosol formation and high contents of water in liquefied samples are disadvantageous.

Preconcentration on solid sorbents belongs among the most frequent techniques (including recommended EPA and ISO methods [16,17]). The subsequent desorption may employ liquids or heat. Among the advantages are the possibility of regulating the selectivity and sorption capacity and of using mixed sorbents [12]. Problems may be caused by incomplete adsorption of highly volatile compounds, desorption of substances with higher molecular masses, chemical reactions of analytes with the sorbent and limited carrier gas flow rates.

The present paper compares preconcentration of model volatile compounds (pentane, methanol, ethanol and acetone) on a charcoal-based adsorbent and silica gel, followed by thermal desorption and GC determination, for analyses of the ambient air and human breath. Charcoal-based adsorbents are still the predominant choice for organic vapour trapping [11,13,18–22]. They have superior sampling capacities, but their properties depend on their origin and the method of preparation [13]. Silica gel is a suitable sorbent for polar organic compounds, e.g., alcohols and aldehydes [23]. The adsorbent can be packed in a modified syringe needle and desorption carried out in the injection port [23–25]. The experimental arrangement described below is very simple.

2. Experimental

2.1. Materials

All the chemicals were analytical grade, from Lachema, Brno, Czech Republic.

The charcoal adsorbent (trade name CNH charcoal), with a specific surface area of ca. 1050 $m^2\ g^{-1}$ (Slovenské Závody, Hnúšta, Slovakia), was made from wood filings and activated with water vapour. The fraction with a grain size from 0.1 to 0.25 mm was obtained by sieving, decanted in cold water, thoroughly washed with boiling distilled water and then dried for 40 min at 105°C.

Silica gel L (Merck, Germany), with a grain size of 0.2–0.3 mm, was washed with 5% hydrochloric acid and with water to neutral reaction and then activated for 8 h at 200°C.

Table 1

2.2. Apparatus

Adsorption cartridges were made according to ref. [23] from a stainless steel syringe needle 110 mm long, with an outer and inner diameter of 2.5 and 2.0 mm, respectively (Fig. 1). The needle tip was formed by fusion into a symmetrical, sharp point and a 0.5 mm hole was made circa 4 mm above the point. The needle was pushed through the septum of the chromatograph injection port and its end was connected to the carrier gas source through a three-way valve. The needle was packed with a defined amount of a sorbent (ca. 50 mg) and closed at both the ends with quartz wool. The sorbent bed was then fixed in place with a little metallic spring. Prior to sample collection, the cartridges were activated by passage of nitrogen at a flow rate of 30 ml min^{-1} and temperature of 300°C for 90 min. After the sample collection, before the thermal desorption step, the cartridges were briefly purged with nitrogen at room temperature, to remove atmospheric oxygen.

A CHROM 5 gas chromatograph (Laboratorní Přístroje, Prague, Czech Republic) was used with a glass column, 1.5 m long, 3 mm i.d., packed with Porapak Q (80-100 mesh, Waters, USA) and nitrogen carrier gas with a flow rate of 23 ml min^{-1}. The specific retention volumes of the solutes on the CNH charcoal and silica gel and their temperature dependences were measured with a glass column 20 cm long, 1 mm i.d., which contained 0.3123 g of CNH charcoal or 0.4646 g of silica gel. A FID was used with flow rates of hydrogen and air of 25 and 300 ml min^{-1}, respectively. The temperatures of the column, injector port and the FID were 160, 300 and 160°C, respectively.

The injection port was adapted according to Fig. 1 to permit thermal desorption of analytes from the cartridge. The three-way valve allowed by-passing of the carrier gas directly into the port, or its passage through the cartridge; after the time required for desorption (10 s), the valve was switched and the analytes were swept to the analytical column. To prevent the analytes from escaping during the desorption stage, the injection port liner was replaced by a glass tube with an external diameter of 5 mm, sealed at the bottom end (Fig. 1). This means that the losses of the analyte by diffusion are negligible, as experimentally verified. On passage of the carrier gas through the cartridge, the analyte desorbed is forced out of the sealed tube through the gap between the cartridge and the tube orifice. This causes, of course, a somewhat greater dispersion of the analyte zone, but this is not critical. It was further experimentally confirmed that no appreciable decomposition of the analytes occurred during the 10 s desorption period used [23].

The atmospheric samples were collected by pumping the test air through the cartridges at a defined flow rate regulated by a needle valve and measuring the sample volume either by a gas-tight syringe or a gas burette.

The samples of human breath were collected at the 3rd Internal Clinic, the 1st Faculty of Medicine, Charles University, Prague, in a 40 l plexiglass chamber. The chamber was provided with five outlets. Two of them were used to connect a respiration mask, one for supplying the oxygen consumed by breathing, one for connection of an expansion vessel and one for the collection of samples. The two inlets for connection of the tubes of a respiration mask were provided with a single-way valves permitting only a one-

* Breath of a person 2 h after consumption of 1 l of beer; sample volumes, 250 ml. The confidence interval was calculated from five parallel measurements for a 0.05 significance level.

way air circulation. The volume of the air exhaled was measured by a respirometer. The pressure balancing vessel was made of a 2 l glass cylinder, immersed upside down in a vessel with water; on breathing out, the air from the chamber expanded into the cylinder and on breathing in it was drawn back into the chamber. The oxygen consumed was replenished from a pressure cylinder, maintaining the atmospheric pressure all the time. A person breathed through the respiration mask for 4 min, which represents circa 80 l of exhaled air; hence, the air in the chamber was circa two-fold preconcentrated in the analytes. An air sample of a defined volume was then taken from the chamber by suction through the cartridge using and air pump. A $CaCl_2$ vent (3 mm i.d., bed length 50 mm) was placed before the cartridge to remove humidity. The samples with volumes of 20–500 ml were collected at a flow rate of 30 ml min^{-1}. The GC experiments carried out with the sample cartridges packed with $CaCl_2$ and a standard mixture of analytes confirmed that the $CaCl_2$ vent caused no change in the analyte contents.

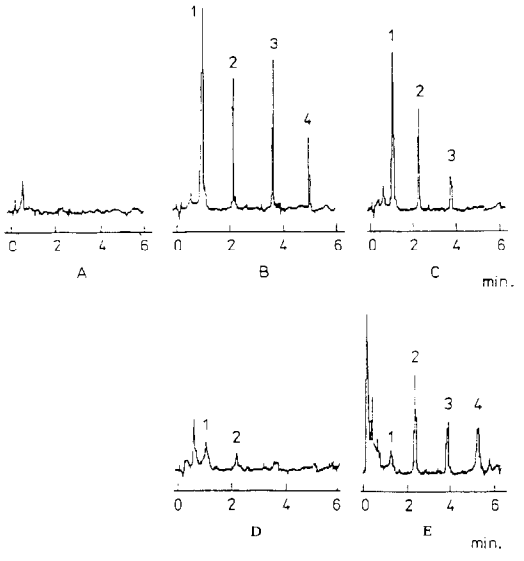

Fig. 2. Chromatogram of blank (A), standard mixture (B), air collected in the laboratory (C), air collected outside the building (D), human breath collected in the laboratory (E): 1, methanol; 2, ethanol; 3, acetone; and 4, pentane. The analyte concentrations determined (in nmol l^{-1}): Methanol: 17.0 (B), 13.0 (C), 1.9 (D), 1.6 (E); Ethanol: 8.7 (B), 6.7 (C), 1.2 (D), 6.5 (E); Acetone: 25.0 (B), 5.8 (C), 8.9 (E); Pentane: 6.4 (B), 4.2 (E). Sample volumes, 250 ml.

2.3. Procedures

Standard samples with defined analyte concentrations were prepared in two ways. For sampling of small volumes (up to 0.05 ml), a calculated amount of an analyte (max 10 μl of a liquid) was injected into a calibrated glass infusion bottle with a volume of 1200 ml. It was experimentally verified that gaseous samples prepared in this way retained a constant concentration for at least 6 h. For sampling of larger volumes (up to 0.5 l), a 50 l plexiglass chamber was used with a stirrer and a septum through which the cartridge was forced; the sample volumes collected were selected so that the maximum change in the analyte concentration did not exceed 0.2% and thus, the error could be neglected.

The breakthrough curves were measured with 800 mg of methanol per m^3 of air drawn from the 50 l plexiglass chamber through two cartridges connected in series. After passage of each 50 ml portion of the gas mixture, the methanol content in the downstream cartridge was determined and

oa new cartridge was connected; the measurement was continued until 50% breakthrough occurred whose relative value was obtained from the ratio of the inlet to the outlet concentration.

In the measuring procedure itself, a defined sample volume was passed through the precolumn, the precolumn was connected to the three-way valve in the bypass position, pushed through the septum of the injection port heated to 300°C and, after the desorption period (10 s), the three-way valve was switched for the carrier gas to sweep the desorbed analytes into the analytical column. The analytes were identified by comparing their retention times with those of standard substances. For quantitation, calibration plots were used obtained with standard mixtures of the analytes (see above).

3. Results and discussion

Pentane, methanol, ethanol and acetone have been selected as model analytes because they may occur in human breath. Pentane is formed by peroxidation of unsaturated fatty acids contained in tissues and its concentration in breath varies from 0.04 to 8 nmol l^{-1} [26–31], in dependence n different solubilities in fatty tissues and variations in the metabolism of individuals. Methanol and ethanol are contained in breath not only after intake of alcoholic beverages, but also as metabolic products and their concentrations vary between 1.3 and 8.5 nmol l^{-1} (without alcohol uptake), in dependence on the actual state of the organism [32–35]. The acetone concentration in breath of healthy individuals varies between 10 and 90 nmol l^{-1} and is several orders of magnitude higher for diabetics [32,36–38]. In view of these low concentrations, direct GC analysis is impossible.

When using solid sorbents for analyte preconcentration, a total recovery of at least 75% is required [1]. The sorption capacity is usually evaluated in terms of the breakthrough volume, which can either be calculated or determined experimentally (directly or indirectly) [39–42]. The direct experimental method is based on passage of a gas mixture of known concentration and its detection at the outlet, the indirect approach employs the specific retention volume V_g, related to 1 g of the sorbent, i.e., the gas volume from injection to the peak maximum, corresponding to a breakthrough of 50% of the analyte. The V_g value at a required sorption temperature is obtained by extrapolation of the log V_g dependence on the reciprocal of the temperature. An error of this method is caused by non-linearity of the log V_g versus 1/T dependence [42]. A disadvantage of indirect methods lies in their inability to describe the effect of the experimental conditions on the breakthrough volume. The real 'safe breakthrough volume' (usually given as a 1, 5 or 10% of the total breakthrough) must consider the atmospheric humidity, fluctuations in the solute flow through the sorbent, inhomogeneity of the gaseous solute sample, the mechanical properties of the sorbent (the grain size and the packing properties in the column) and the character of the sorption process [11]. Therefore, breakthrough volumes obtained indirectly are usually verified by direct methods.

The present paper compares the sorption properties of the CNH charcoal and silica gel. Carbopack C and Tenax GC were also tested, but the former was found unsuitable because of a generally poor sorption capacity due to a low specific surface area [43] (ca. 10 m^2 g^{-1}) and the latter exhibited a sufficient sorption only for pentane and acetone and not for the alcohols. The unsuitability of Tenax GC for volatile compounds has already been pointed out [4,23] (the breakthrough volume for methanol is only 0.4 l at 32°C). For the CNH charcoal and silica gel, the temperature dependences of the specific retention volumes were measured and extrapolated to 20, 35 and 300°C, corresponding to the temperatures of the atmosphere, of the human breath and of the desorption, respectively; for 35°C, the retention volumes were also extrapolated to the sorbent amount in the cartridge. The results are given in Table 1 for the CNH charcoal and in Table 2 for silica gel.

All the solutes tested are strongly adsorbed on the CNH charcoal. Silica gel does not adsorb pentane (the V_g value at 25°C is only 180 ml), while for methanol and ethanol are the breakthrough volumes at 35°C higher than those on the CNH charcoal, respectively.

Table 5
Concentrations of volatile compounds (nmol l^{-1}) in the air measured at different places and times (the CNH charcoal)

Solute	Chem. lab May, 17	Corridor May, 17	Chem. lab May, 21	Corridor May, 22
Methanol	690	240	21.5	22.5
Ethanol	500	111	10.9	66
Acetone	121	—	17	85
Pentane	—	—	4.2	2.8

Sample volume, 250 ml.

The reliability of the breakthrough volumes obtained from the retention volumes was verified by direct measurement for the CNH charcoal and methanol as the solute exhibiting the lowest adsorption; for the conditions Section 2. A breakthrough of 0.1, 10 and 50% occurred after passage of 850, 1000 and 1400 ml of a gas mixture containing methanol in the concentration of 800 mg m^{-3}, respectively, while a value of 1300 ml was obtained by the indirect measurement of V_g (50% breakthrough). This difference is caused by the different way of the CNH charcoal packing in the column and the cartridges and by the errors caused by extrapolation of the V_g values measured at higher temperatures to 20°C. The efficiency of the cartridge was approx. 20 theoretical plates.

The carrier gas flow rate and desorption temperature were optimized by the measurement of the analyte recovery (in %) for the CNH charcoal and silica gel, using a 10 s desorption time. The maximum recoveries were obtained at 25 ml min^{-1}, which was also the optimal flow rate for Porapak Q column. The desorption temperature was optimized in the same way, obtaining the highest recovery at 300°C; at higher temperatures, the injection septum was degraded. The recoveries for the CNH charcoal and silica gel are compared in Table 3. Higher values were obtained for silica gel.

Preconcentrations of analytes from human breath on active carbon and silica gel were compared and the results are given in Table 4. Two aliquots of the same sample were analyzed, one after adsorption on the CNH charcoal and the other after adsorption on silica gel; for illustration, an analysis of the breath of a person after intake of an alcoholic beverage is also given in Table 4. It follows from Table 4 that the values obtained after preconcentration on silica gel are $\approx 10\%$ higher than those obtained on the CNH charcoal, with the exception of pentane which is very little sorbed on silica gel (Table 1 and Table 2). The analysis of a human breath sample collected 2 h after consumption of 1 l of beer (containing ca. 36 g of pure ethanol) yielded a nine times higher value for ethanol compared with the other breath samples (see Table 4). A typical relative standard deviation of the determination was ca. 10% at a concentration level of units of nmol l^{-1}.

The detection limits for the volatile compounds studied (twice the absolute noise value) vary from a few nmol l^{-1} to well below 0.1 nmol l^{-1}.

Table 6
Analysis of human breath—comparison of effects of the surrounding environment (the CNH charcoal, nmol l^{-1})

Comparison of the measured concentrations of volatile compounds (nmol l^{-1}) in breath with published data (the CNH charcoal)

Solute	Our results	Published data	References
Methanol, ethanol	1.6–8.7	1.3–8.5	[32–35]
Acetone	2.9–8.9	10–90	[32,36–38]
Pentane	0–4.2	0.04–8	[26–31]

Chromatograms of the analytes at concentrations close to the detection limits can be seen in Fig. 2. The blank recording was obtained on passage of pure nitrogen through the cartridge under the conditions of determination.

3.1. Applications

The concentrations of volatile compounds in the atmosphere inside and outside a chemical laboratory were measured on various days. The values obtained are given in Table 5. The high concentrations of methanol and ethanol on the 1st and 4th day were caused by HPLC experiments performed in the laboratory.

At the same time, the breath of a person exposed to this atmosphere (inside and outside the laboratory) was analyzed (Table 6). It follows from Table 6 that the values obtained depend on the ambient atmosphere. Rather high levels were found in the person who spent most of his time in the laboratory working with methanol and ethanol during HPLC experiments. The concentrations of volatile compounds in the breath of a person who left the laboratory, collected at different times after departure (1–15 h), were found to be constant, independent of the previous exposure in the laboratory.

We compared our results on breath analysis with the published data. As can be seen from Table 7, our results fall in the concentration range published by other authors with the exception of acetone, where lower values were found in this work; however, the variability of the data on the acetone content in the breath of healthy individuals is very large.

The industrial atmosphere in a dye factory was analyzed using the described method. The results are given in Table 8. High concentrations of solvents were found both in the production hall and in the solvent dispensing unit.

Table 8
Analysis of industrial environment in the Colorlak factory (the CNH charcoal, μmol l^{-1})

Solute	Production hall	Solvent dispensing unit
Acetone	0.33 ± 0.03	0.85 ± 0.05
Toluene	1.85 ± 0.05	0.35 ± 0.04
Ethanol	—	0.61 ± 0.06

Sample volume, 100 ml.

4. Conclusion

The method described makes it possible to measure instantaneous concentrations of volatile compounds in the air and human breath. It is thus, possible to monitor fluctuations in the pollutant concentrations in industrial atmosphere or in human breath during operations hazardous to health. This paper was not intended as a clinical study and thus, only a few men and women provided the breath samples to be analyzed.

The detection limits vary from a few nmol l^{-1} to less than 0.1 nmol l^{-1}. The main advantages of the proposed method lie in the very simple methodology and easiness and rapidity of the analyses. Its drawbacks involve the fact that the samples collected are not particularly large, the desorption temperature is limited by that of the chromatograph injection port and the elution curves are slightly dispersed in the collection cartridges.

Acknowledgements

We are indebted to MUDr. J. Poòka, CSc of the 3rd Internal Clinic of the 1st Faculty of Medicine, Charles University, for valuable discussions and kind permission to use the plexiglass chamber for the obtaining samples of human breath.

Abstract

We have developed a low cost pH sensor based on an optical reflective device (ORD) coupled to a toughened, lightly crosslinked aminated polystyrene membrane. Protonation of the amine group causes the polymer to swell. This is accompanied by a decrease in the turbidity of the membrane. As a result, reflected intensity measured by the ORD is a function of pH. The resulting pH sensor is inexpensive and has modest power requirements. The sensor is stable, provided the membrane is not allowed to dry out and crack. Changing ionic strength affects response both by changing the turbidity of the membrane due to refractive index effects and also by reducing the extent to which the protonated polymer swells. Increasing temperature leads to a larger change in turbidity. © 1997 Elsevier Science B.V.

Keywords: Optical reflective device; pH sensor; Polystyrene

1. Introduction

We are interested in developing chemical sensors based on optical changes accompanying polymer swelling. The material that we have worked with is porous, lightly crosslinked polystyrene derivatized with a functional group that binds the analyte of interest. Analyte binding causes shrinking or swelling by changing the affinity of the polymer for the external solvent. In an earlier study we showed that porous derivatized polystyrene can undergo multiple swelling and shrinking cycles without cracking if it is toughened by adding Kraton G1652, a styrene–ethylene, butylene–styrene triblock copolymer [1]. In that study it was observed that aminated polystyrene beads became visibly clearer when protonation in acidic media caused them to swell. Based on this observation, we prepared a single fiber optical pH sensor based on reflectance changes accompanying polymer swelling [2] and pH sensitive membranes that could be coupled to multiple optical fiber measurements [3]. We also conducted an extensive study of the effects of formulation variables on polymer morphology and the rate and magnitude of its response to changes in pH [4]. More recently, we have proposed that the optical response of the membrane is due to reflection at the interface between the bulk polymer and water containing pores [5].

When the polymer is exposed to acidic aqueous solutions that protonate the amine, it swells because the positive charge that arises from protonation increases the affinity of the polymer for the solvent. This process effectively dilutes the bulk polymer with water causing its refractive index to decrease so that it is closer to the refractive index of the water in the pore space. This reduces the reflectance at the polymer-pore interface resulting in a decrease in reflected intensity that is the basis for sensing.

In this manuscript we report that the optically sensitive membranes that we have developed can be coupled to an 'optical reflective device' (ORD) to make a robust, low cost sensor. An ORD is simply a light emitting diode (LED) and a phototransistor combined in the same package and configured to respond to the presence of a reflecting surface at or near the surface of the device. The retail cost of a currently available ORD is less than $5.

The objective that inspired this study was the development of a sensor that would be suitable for remote unattended measurements of pH in seawater. The ORD provides compactness, low power requirements and low cost while the membrane based on polymer swelling is stable with time. Thus, the combination of these two promises to be a useful sensing technology for applications of this sort. Because of the intended application to seawater measurements, information is included on the effects of ionic strength and temperature on response because these are both important issues for measurements in the ocean.

2. Experimental

2.1. Reagents

Vinylbenzyl chloride (98%, 30% para/70% meta) was obtained from Dow. Divinylbenzene (55%) and benzoyl peroxide were purchased form Polysciences, Warrington, PA. Kraton G1652, a styrene–ethylene/butylene–styrene triblock copolymer (29% styrene, 71% ethylene/butylene) was donated by Shell Chemical. Vinylmethoxysiloxane oligomer was obtained from Huls America. Dodecane, octadecane, polystyrene (MW 2500), xylene, piperidine, 1,4-dioxane, diethanolamine were obtained from Aldrich. Trihydroxyaminomethane hydrochloride (Tris) was obtained from Sigma. Other buffer reagents were from Fisher.

Acetate and ammonium buffers were used to adjust pH 4.0 and 10.0, respectively. Tris buffer was used in the experiments to evaluate response versus pH. The concentration of the buffer components was 0.10 M. The ionic strength of the buffer was adjusted with sodium chloride.

2.2. Apparatus

Models 710 and 710F ORDS were purchased from Optek Technology. Both models have an LED that emits a band of light centered at 930 nm. The 710F model has a filter to exclude ambient light over both the LED and phototransistor while the 710 is unfiltered. Fig. 1 shows both the ORD and the battery powered circuit used to power the LED and collect the signal from the phototransistor. The ORD is 5.6 mm in diameter and 3.8 mm thick.

A plastic light tight cell was constructed for optical measurements. The ORD was mounted in the cap of the cell such that the optically sensitive membrane was located ca. 1 cm below the bottom of the cap. The bottom of the cell was filled with sufficient solution to contact the membrane but not the leads from the ORD.

A Cary 5 uv-vis-nir spectrophotometer was used for direct membrane turbidity measurements using a membrane mounted in a cuvet in contact with buffer of the desired pH. A Brookfield viscometer was used to measure the viscosity during prepolymerization.

2.3. Membrane preparation

Membrane formulations were taken from earlier work [3]. The monomer for all experiments was vinylbenzyl chloride (VBC). The divinylbenzene level was 2 mol.% (moles DVB/moles monomer), and the Kraton level was 2 weight.% (g Kraton/g monomer). The formulation included

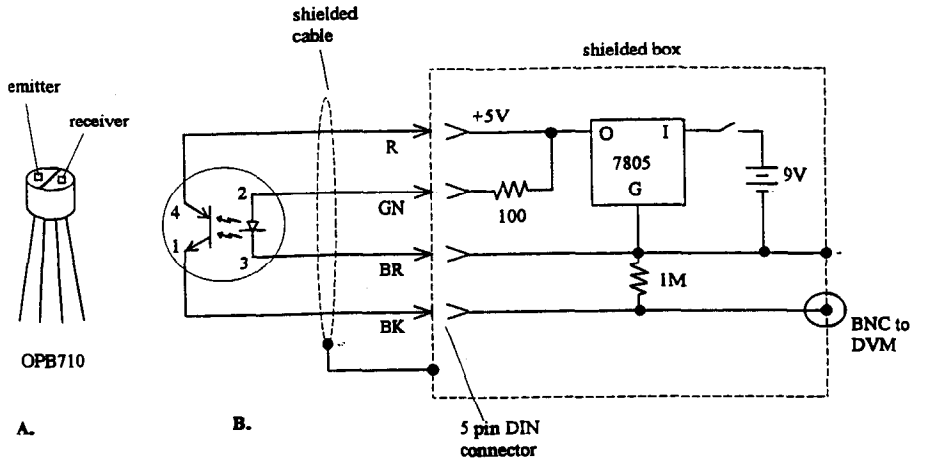

Fig. 1. Measurement apparatus including (A) Optek Technology 710 optical refective device and (B) schematic diagram of battery powered circuit for evaluation of sensors prepared by coupling the ORD and the polymer. Connections 1 and 4 are to the collector and emitter of the phototransistor. Connections 2 and 3 are to the LED.

2:1 xylene:dodecane as a porogenic solvent. In a few experiments, 2:1 polystyrene:octadecane was evaluated as the porogenic solvent. In all experiments, the level of porogenic solvent was 40 vol.% (volume porogenic solvent/volume monomer × 100). The initiator was benzoyl peroxide.

Membranes were prepared using a viscous partially polymerized solution, or prepolymer, as described previously [3]. The polymerization is initiated by heating a stirred solution of polymer and allowing the reaction to proceed to the point where there is a significant increase in viscosity. The reaction is then stopped by lowering the temperature of the solution. Membranes were formed by curing a small volume of prepolymer between two 1″ × 3″ glass microscope slides separated by a spacer. Prior to membrane formation, one of the slides was pretreated with vinylmethoxysiloxane oligomer to introduce vinyl groups onto the surface of the glass. The surface was first treated with 2.0 M HCl for 4 h. It was then silanized by refluxing the glass slides in a solution of 10 ml of vinylmethoxysiloxane oligomer and 30 ml of distilled toluene for 6 h. The other surface was sprayed with TFE release agent dry lubricant (Miller-Stephenson) to facilitate release of the membrane after polymerization. Membrane thickness was controlled using 25, 76 and 127 μm Teflon spacers (Berghof, Concord, CA). The two glass slides were held together by a spring clip and cured in an 85°C water bath for 6 h. After polymerization, the membrane adheres to the surface that was reacted with vinylmethoxysiloxane oligomer.

Diluents and unreacted monomer and crosslinker were removed by soaking in acetone for several hours, decanting, and then repeating the cycle. After air drying, the glass bound membrane was cut into smaller pieces that were just large enough to completely cover the ORD surface. Membranes were then derivatized by reacting them with 1:1 acetone:diethanolamine for 2 days at room temperature. The membranes were then washed with 0.1 M HCl three times to remove any unreacted diethanolamine and rinsed with deionized water. The membranes were preconditioned by soaking in pH 4 buffer (acetic acid/sodium acetate) for 24 h and cycled between pH 10 (ammonium/ammonia) and 4 at least three times prior to making any measurements on the membrane. The membranes were stored in distilled water when not in use.

The glass microscope slides with the membrane were attached to the ORD surface with transparent silicone RTV cement. The RTV cement was also used to pot the ORD connections to protect

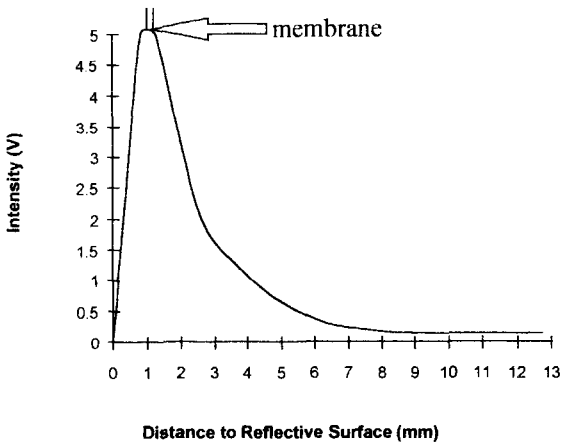

Fig. 2. The intensity measured by phototransistor of the ORD versus the distance between the ORD surface and a reflecting surface. This location of the polymer membrane on this curve is indicated by the arrow.

them from water during testing. The microscopy slide serves not only as a support for the membrane but also as a spacer to locate the membrane in the region where ORD is most sensitive. Fig. 2 illustrates this by showing where the membrane is located on a curve showing ORD signal versus distance between the ORD surface and a reflecting metal surface.

Unless otherwise specified all measurements were made at room temperature. In the experiment to evaluate the effect of temperature on response, the sensor temperature was raised above room temperature by placing it in a water bath at the desired temperature. To lower the temperature below room temperature, the sensor was placed in an ice bath. Response was measured when the sensor reached the desired temperature.

3. Results and discussion

3.1. General observations

All of our prepared membranes appear cloudy and reflect light. From previous work, we know that this is because the membranes contain pores with dimensions sufficiently large to reflect light [5]. In an aqueous environment, the pores are filled with water with dissolved solutes, which has a lower refractive index than the bulk polymer. The degree of cloudiness varies from batch to batch. One source of variability is the degree of prepolymerization. During prepolymerization, the solution becomes cloudy. As the polymer forms, the aliphatic component of the porogenic solvent separates into a distinct phase that eventually becomes pore space after polymerization is complete and the porogenic solvent is removed. Because the polymer components are stirred during the prepolymerization step, this may facilitate separation of the dodecane into smaller domains. Table 1 shows data from an experiment undertaken to assess the effect of the degree of prepolymerization on membrane cloudiness. The data show that a higher degree of prepolymerization is accompanied by a higher degree of cloudiness and smaller response.

When polymerization begins, it is very rapid as evidenced by an extremely rapid increase in viscosity with time. As a result, using our simplistic approach, it is difficult to stop the prepolymerization process at the same viscosity each time.

While membranes tend to be cloudy throughout, the degree of cloudiness is not uniform. This suggests that there may have been some large scale phase separation arising because the polymer is more dense than the monomer and the porogenic solvents. A relative standard deviation

Table 1
Effect of viscosity after prepolymerization on response

Viscosity (cp)	Signal at pH 4.0 (mV)	Signal at pH 10.0 (mV)	Change in signal (mV)
14.0	1300	2710	1410
35.5	4330	4780	450
100	4910	4920	10

of 11% has been observed for turbidance measurements at different locations in membranes from the same batch [6]. The relative standard deviation increases to 18% when membranes with the same formulation from different batches are compared [6]. These data emphasize the need to hold the membrane in a fixed position when it used for sensing. Sensor-to-sensor reproducibility is limited by membrane heterogeneity.

The results shown in this paper are for polyVBC derivatized with diethanolamine. The aminated polymer swells at low pH because protonation of the amine introduces a positive charge onto the polymer and increases its affinity for water. Previous work has shown that diethanolamine modified polymer beads are useful for sensing pH from 6.8–7.8 [1]. Because this is below the range of interest for seawater, attempts were make made to derivatize polyVBC with more strongly basic amines, e.g., piperidine, in the hopes that they would respond to higher pHs. However, the more strongly basic amines tended to attack the bond between the membrane and glass substrate causing the membrane to delaminate during the derivatization step.

A limited number of membranes were prepared using 2:1 styrene (M.W. 2500): ocatadecane as the porogenic solvent. This porogenic solvent has a lower affinity for the polymer than 2:1 xylene:dodecane. As a result phase separation occurs earlier in the polymerization process. These membranes responded more rapidly than membranes prepared using xylene: dodecane but were more 'brittle' and tended to flake.

3.2. Response to pH

Fig. 3 shows turbidity versus pH at four different ionic strengths measured in a spectrophotometer at 930 nm. As observed in previous work [2,3], there is a larger decrease in turbidity with decreasing pH. The polymer swells with water as it is protonated this dilutes the polymer chains with water, reducing its refractive index. As the refractive index of the bulk polymer gets closer to the refractive index of the water-filled pores, the turbidity of the membrane decreases.

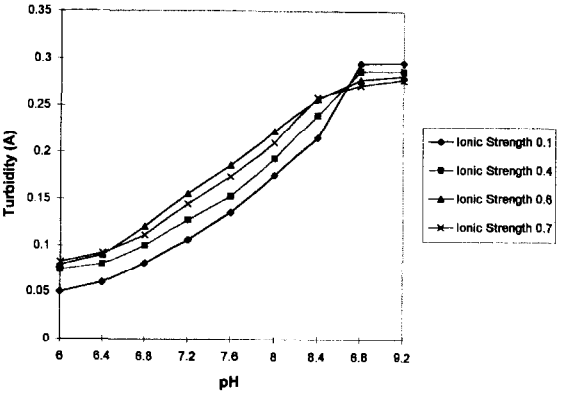

Fig. 3. Turbidity versus pH (in absorbance units) for a 75 μm thick membrane at four different ionic strengths measured at 930 nm with a spectrophotometer.

The magnitude of the change decreases with increasing ionic strength. Two effects contribute to this. First, the refractive index of the aqueous solution that occupies the pore space in the membrane is larger at the higher concentrations of sodium chloride that are used to adjust ionic strength. This in turn reduces the amount of light reflected at the interface between the bulk polymer and the aqueous solution in the pores. This explains why the turbidity decreases at high pH where the amine group is completely deprotonated.

The second effect of ionic strength is to reduce the extent of swelling of the protonated membrane. The swelling of charged crosslinked polymer networks can be viewed as an electrostatic repulsion effect or an osmotic pressure effect [7]. If it is viewed as arising from electrostatic repulsion, the effect of increased ionic strength is to shield adjacent positive charges such that the repulsive effect is reduced. Viewed as an osmotic pressure effect, swelling arises from the difference between the charge density on the polymer and the ionic strength in solution. Increasing ionic strength in solution reduces this difference and thus leads to less swelling.

In addition to affecting the degree of swelling and the membrane optical properties, increasing ionic strength also shifts the amine pK_a. Normally, increasing ionic strength favors the protonated form of the amine but the data in Fig. 3

show that the highest pK_a is observed at the lowest ionic strength. We suspect that this effect is related to the activity of water. At high ionic strength, there is less water in the polymer. This means the activity of water in the polymer is lower and the tendence of water to solvate a charged site on the polymer diminishes.

The data in Fig. 3 confirm earlier work showing that the diameter of aminated polyVBC beads depends on ionic strength [1]. If these materials are to be used for sensing in seawater or other high ionic strength media, provisions will have to be made for calibrating in media of equivalent ionic strength and correcting for any fluctuations in ion strength.

Fig. 4 shows reflected intensity versus pH measured with the ORD sensor. As expected it parallels the change in turbidity with pH measured in the spectrophotometer. Fig. 5 shows both the rate and range of response as a function of membrane thickness. The response rates shown are for a membrane exposed to a pH 4.0 buffer after it has equilibrated with a pH 10.0 buffer. As expected, the reflected intensity and response time both increase with membrane thickness. The 90% response times are 20, 180, 330 and 600 s for membranes that are 25, 75, 127 and 254 μm thick, respectively. As the membrane thickness is increased from 25–75 μm, the response time increases with the square of the membrane

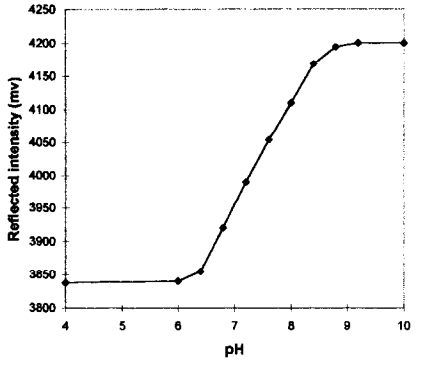

Fig. 4. Reflected intensity versus pH measured with the ORD coupled to a 75 μm thick aminated polystyrene membrane. The ionic strength is 0.1 M.

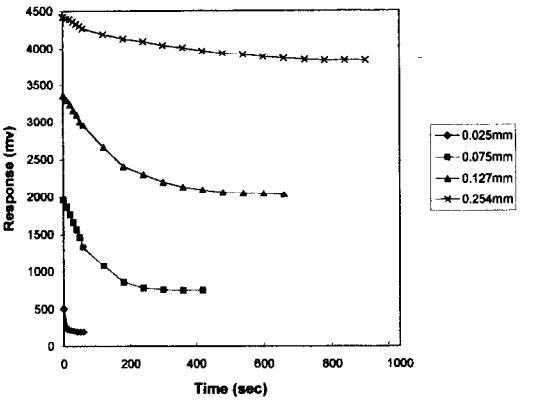

Fig. 5. Reflected intensity versus time for membranes of varying thicknesses initially equilibrated at pH 10.0 and then exposed to a pH 4.0 buffer. This curve shows not only the rate of response but also the magnitude of the intensity change. The ionic strength is 0.1 M.

thickness. This is expected if response is limited by the rate of diffusion into the membrane. This relationship does not extend to the thicker membranes, probably because these membranes have not completely equilibrated within the measured period.

The signal for the 25 micrometer thick membrane decreases by a factor of 2.74 from 0.52 to 0.19 volts. the signal for the 75 micrometer thick membrane decreases by a factor of 2.61 from 1.96–0.75 volts. Although the relative change is slightly smaller, the absolute change is larger so this thickness was used for the other measurements presented in this manuscripts. At membrane thicknesses greater than 75 μm, both the swollen and unswollen membranes are sufficiently turbid to reflect a large percentage of the incident light. As a results, the difference in signals for the swollen and unswollen membrane decreases at high membrane thickness.

Fig. 6 shows that reflected intensity decreases with increasing temperature. The largest effect is for the swollen polymer at pH 4.0. This is consistent with earlier data showing that the degree of swelling increases with temperature [1]. If the swelling is viewed as an osmotic pressure effect, then the explanation for the increase in swelling is that osmotic pressure is proportional to absolute

temperature. There is a smaller effect at pH 10.0. We do not have a ready explanation for this since previous work has shown that unprotonated aminated polyVBC shrinks slightly with increasing temperature. This should lead to a small increase in turbidity. Increasing temperature will also cause the refractive indices of both the solution in the pores and the polymer to change. Since the refractive index of liquids normally varies more strongly with temperature than the refractive index of solids, it is likely that the refractive index difference between the two phases is temperature dependent. However, this effect is expected to be smaller than the effect of temperature on swelling.

3.3. Membrane stability

Membrane stability is an important issue since one of our goals was to improve upon the stability of optical sensors based on indicator dyes. Consistent with previous work, we found that membranes that remain moist will respond for multiple swelling and shrinking cycles. One membrane was cycled between pH 4.0, 7.0 and 10.0 over 30 days with less than 2% drift. However, dried membranes tended to crack and then would degrade mechanically when rehydrated. When used for practical applications, we envision that each sensor would be individually calibrated and would have to be recalibrated at intervals. However, the low degree of drift indicates that recalibration intervals could be as long as a month, provided that the membrane is not allowed to dry out.

When the membrane was repeatedly cycled between pH 4 and 10, the relative standard deviation of intensity measurements at each pH was less than 1%.

If the membrane accumulates compounds that absorb at 930 nm, then this will interfere with sensor response. Fortunately, few compounds absorb at this wavelength so this is not expected to seriously limit sensor applicability.

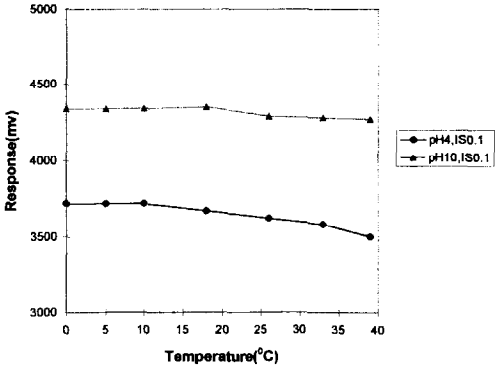

Fig. 6. Reflected intensity versus temperature for both the swollen (pH 4.0) and unswollen (pH 10.0) forms of a 75 μm thick membrane. The ionic strength is 0.1 M.

4. Conclusions

This study shows that turbidity changes accompanying the swelling of derivatized membranes may be coupled to optical reflective devices to make a chemical sensor that is inexpensive, has low power requirements and is stable with time if the membrane is not allowed to dry out. It also shows that response is affected by both ionic strength and temperature. These parameters must be accounted for when calibrating the sensor and a correction must be applied if there are variations in either ionic strength or temperature.

Hexaacetato calix(6)arene as the novel extractant for palladium

V.J. Mathew, S.M. Khopkar *

Department of Chemical Technology, University of Bombay, Bombay 400 019, India

Received 15 July 1996; received in revised form 10 December 1996; accepted 23 December 1996

Abstract

A novel method is proposed for the solvent extraction of palladium. A superamolecular compound, hexaacetato calix(6)arene in low concentration in toluene quantitatively extracts microgram concentration of palladium at pH 7.5. It can be stripped from the organic phase with 2 M nitric acid and determined spectrophotometrically as its stannous chloride complex at 635 nm. The probable composition of the extracted species is $Pd(HR)_2Cl$. As low as 1×10^{-3} M of extractant is adequate for quantitative extraction. Toluene was the best diluent. With nitric and perchloric acid (1.5–3 M) the stripping was complete. Palladium was separated in large ratios from alkali and alkaline earths (1:50). The main group elements were tolerated in higher ratios (1:25), but ions like zinc, cadmium, iron, nickel, platinium, thorium, vanadium and molydenum were tolerated at low concentrations (1:1). The ions showing strong interference were copper, chromium. The relative standard deviation is $\pm 1.1\%$. © 1997 Elsevier Science B.V.

1. Introduction

Calix(*n*)arenes [1] are superamolecular compounds which have a three dimensional network of 4–8 bridged phenolic units with varying annular space in which metals can be trapped due to the ionic interaction [2,3]. As the properties of calixarenes can be varied by chemical modification or effective substitution it was facinating to investigate the solvent extraction behaviour of metals. Calixarene form stable metal complexes [4]. The planar structures were obtained for complexes of crown ethers with alkali and alkaline earths [5], however, cryptands formed three dimensional structure with transition metals improving their selectivity [5]. The varying annular size ranging from 1.4–2.4 Å in calixarenes facilitated separation of metals with varying atomic sizes.

Calixarenes was used for solvent extraction of alkali and alkaline earths [6]. Calix(4)arene amides were also used for extracting and studying solution thermodynamics of complexation of s-block metals [7]. The ketone derivative of calix(4)arene was used for extraction of palladium and silver [8] from highly acidic nitrate media. A new calixarene, diphenylphosphino calix(4)arene methyl ether, was also used for extraction of alkali metals and few transition elements [9]. The carboxylate derivatives of calixarenes were used for the extraction of trivalent lanthanides [10–12]. *N*-Dimethyldithiocarbomoylethoxy-substituted calix(4)arene was used for extraction of the chlorocomplexes of divalent pal-

ladium and platinum [13]. The thia crownether [14,15] and azacrown analogues [16] of dibenzo18crown6 were used for the separation of palladium from platinum, gold and iron. Some crownethers were also used in stripping voltametric studies of palladium [17]. The *p*-tertbutyl calix(6)arene was used for first time for extraction of palladium from ammonical alkaline solutions to ascertain nature of the extracted species [18] as 1:1.

Calix(6)arene occupies intermediate position between calix(4)arene and calix(8)arene in relation to conformational mobility. The orthosubstituted derivatives were effective in complexation, extraction and transport of metal ion. Our work on extraction of cobalt with hexaacetato calix(6)arene [19] promoted us to investigate similar method for extraction of palladium. Such method is described in this paper.

2. Experimental

The hexaacetato *p*-tertiary butyl calix(6)arene derivative (Fig. 1) was prepared by similar procedure as described earlier [19].

The product was characterised with IR, 1H NMR, 13C NMR spectroscopy. The m.p. and elemental analysis also furnished useful information. The solubility of the extractant in organic phase was reasonable at room temperature to facilitate solvent extraction studies.

A stock solution of palladium was prepared by dissolving 1.66 g of palladium chloride (Johnson Mathey, England) in 1 l of distilled water containing 5 ml of 11.5 M hydrochloric acid. The solution was standardised gravimetrically with dimethylglyoxine [20]. It contained 100 μg/ml of palladium. The solution containing 5 μg/ml of palladium was prepared by 20-fold dilution.

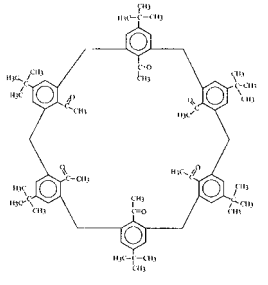

Fig. 1. Structure of calix(6)arene and acetyl derivative.

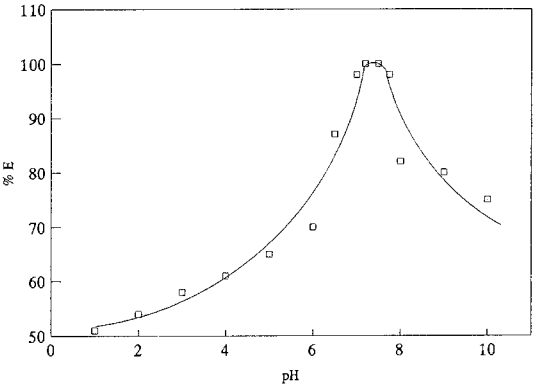

Fig. 2. Extraction as a function of pH.

3. General procedure

An aliquot of solution containg palladium was taken and its pH adjusted to 7.5 with diluted ammonia or hydrochloric acid. Then, the solution was made to 10 ml. It was transferred into a separating funnel; 10 ml 1×10^{-3} M of hexaacetato calix(6)arene in toluene was added to it. The resulting solution was equilibrated for about 10 min. The two phases were allowed to settle and separate. Palladium from organic phase was stripped with 2 M nitric acid. Palladium from the aqueous phase was determined spectrometrically [21] as its complex with stannous chloride at 635 nm. The amount of palladium was computed from the calibration curve.

4. Results and discussion

4.1. Extraction as the function of pH

The extraction of palladium was carried out at varying pH from 1.0–10.0 (Fig. 2). The extraction commenced at pH 1.0 (52.4%) and at pH 4.0 it was (60%). The extraction was quantitative between pH 7.0–7.4. shows the equilibrium in

Table 1
Extraction as the function of calix(6)arene concentration

Hexaacetato calix(6)arene (1×10^{-4} M)	*E* (% Extraction)	*D* (Distribution ratio)
0.1	2.5	0.30
0.5	35.0	0.50
1.0	46.3	0.86
2.0	62.2	1.64
5.0	89.0	8.11
8.0	95.1	19.54
10.0	99.9	999.00
50.0	99.1	110.10

pH range 7.0–7.4 is favourable for the formation of the complex. At higher pH of extraction there is the possibility of hydrolysis. This indirectly promotes competing equilibria with the formation of complex, resulting in a decrease in extraction.

The probable mechanism of extraction can be summarised as:-

1. $(HR)_{aq} = (HR)_{org}$, where HR = hexaacetato calix(6)arene
2. $Pd + 2HR = Pd(HR)_2 + 2H^+$ (in aqueous phase)
3. $Pd(HR)_2 + Cl^- = Pd(HR)_2Cl$ (Ion pair formation in aqueous phase)
4. $(Pd(HR)_2Cl)_{aq} = (Pd(HR)_2Cl)_{org}$ (Transformation to organic phase)

5. Extraction as a function of calix(6)arene concentration

Palladium was extracted at pH 7.2 with varying concentrations of hexaacetato calix(6)arene. The concentration was varied from 0.1×10^{-4} to 50×10^{-4} M. The extraction was 46.3% with 1×10^{-4} M of extractant. However, the extraction was quantitative with 10×10^{-4} M of extractant (Table 1). With increased concentration of extractant the phase separation is rendered difficult. We used 10×10^{-4} M of the extractant for routine work.

6. Extraction with various diluents

The different diluents with varying dielectric constant were used. The 0.001 M of calix(6)arene in various diluents was equilibrated at pH 7.2 with equal volumes of aqueous phase containing palladium (Table 2). Only with toluene as the diluent, the extraction was complete. The extraction never exceeded 80% with all other diluents. With cyclohexane and nitrobenzene the extraction was $< 40\%$. This showed non-polar diluents were best. This is because in polar solvents the association of cationic species with extraction is minimum, while in nonpolar solvents in absence of repulsive process the extraction is maximum. Toluene was preferred as the diluent as it has minimum toxicity and offers better phase separation.

Table 2
Extraction with various diluents

Solvent	Dielectric constant	*E* (% Extraction)	*D* (Distribution ratio)
Dichloromethane	9.08	78.0	3.55
Dichloroethane	10.50	74.4	2.90
Chloroform	4.80	78.0	3.55
Carbon tetrachloride	2.24	74.4	2.90
Benzene	2.28	90.2	9.24
Toluene	2.30	99.9	
Xylene	2.38	68.3	2.15
Cyclohexane	2.0	39.0	0.64
Nitrobenzene	34.8	36.6	0.68

Table 3
Effect of stripping agent

M	HCl		HNO_3		H_2SO_4		$HClO_4$	
	%E	D	%E	D	%E	D	%E	D
0.5	–	–	87.8	7.20	65.4	1.8	93.9	15.40
1.0	78.0	3.55	89.6	6.45	70.7	2.4	95.1	22.54
1.5	78.0	3.55	99.9	999.0	73.2	2.7	96.3	26.32
2.0	79.3	3.82	99.9	999.0	75.0	3.0	93.9	15.40
3.0	95.1	22.52	99.1	110.1	75.8	3.1	92.5	12.30

7. Effect of stripping agents

After extraction of palladium at pH 7.2 with 1×10^{-3} M of extractant it was stripped with various mineral acids as the stripping agents (Table 3). With 3 M hydrochloric the stripping was more than 95.1%, with 0.5 M sulphuric acid it was 85.36%, or 1.5 M perchloric acid it was 96.34%. With 2 M nitric acid the stripping was quantitative because at this molarity the optimum conditions of extraction were reversed. Hence 2 M nitric acid was used as the stripping agent.

8. Nature of extracted species

The nature of extracted species was ascertained by plotting graphs of Log D against Log (HR) at fixed pH 7.2. The slope was 1.9 (Fig. 3). Therefore the probable composition of the extracted species is 1:2, i.e. $Pd(HR)_2$. It may be assumed that the calix(6)arene derivative exists in the 'winged' conformation, i.e. '1,4-alternate' conformer. This situation gives rise to a conformation in which the aryl groups in the 1- and 4-positions project outward like a pair of wings perpendicular to the aryl groups in the 2-, 3-, 5- and 6-positions which are colinear, forming a channel into which other molecules might comfortably fit. The metal ion is probably held between two calixarene moieties by ionic attraction to the substituted oxygens. It is presumed that no true covalent bond formation exists, but an ion-dipole electrostatic attraction between the metal ion and oxygen atoms is possible.

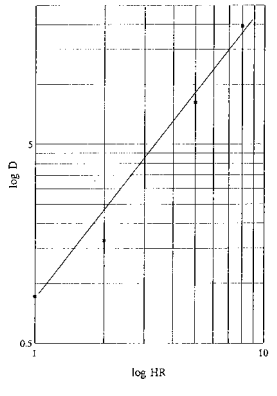

Fig. 3. Log D versus log calixarene concentration.

Table 4
Effect of diverse ions

Foreign ion	Amount tolerateed (μg)	Ratio
Li^+, Na^+, K^+, Cs^+	1500	1:50
Ca^{2+}, Sr^{2+}, Ba^{2+}	1500	1:50
Mg^{2+}, Al^{3+}, In^{3+}, Se^{4+}, Mn^{2+}	750	1:25
Zn^{2+}, Cd^{2+}	300	1:10
Mo^{6+}, V^{3+}, Th^{4+}	150	1:5

Pd, 30 μg; pH 7.2; 0.001 M in toluene.

9. Effect of diverse ions

Palladium was extracted in the presence of large number of diverse ions (Table 4). The tolerance limit was set as the amount of foreign ion causing $\pm 2\%$ error in recovery of palladium. All the anions (excepting thiocyanate which in fact is strong complexing ligand for palladium) were tolerated in the ratio exceeding 1:100. The alkali and alkaline earths were tolerated in the ratio of 1:50 while most of the main group elements were tolerated in the ratio of 1:25. Some transition metals were tolerated in ratios less than 1:10. While iron, cobalt, nickel, platinum were tolerated in ratios of 1:1, however, copper, chromium, rhodium, uranium showed strong interference.

The proposed method is compared with the existing methods of separations. The solvating solvents [22] like tributylphosphate did not permit extraction from nitric acid but it extracted it from thiocyanate media. The extraction with B-diketones was incomplete. The extraction with oxine and oxime offered weakly coloured complexes facilitating direct spectrophotometry. Thus, extraction with hexaacetato calix(6)arene was possible at very low concentration of reagent. The period of equilibrium was minimum. The use of non-toxic solvents like toluene was favourable. The method permitted separation of palladium from iron, cobalt, nickel and platinum which were commonly associated. The calixarene can be synthesised at low cost, with high yield and best purity. The proposed method is simple, rapid and selective. It permits separation and determination of palladium within 30 min. The relative standard deviation is $\pm 1.1\%$.

Received 13 September 1996; received in revised form 26 December 1996; accepted 29 December 1996

Abstract

The ability of cysteine to form complexes with cadmium(II) in aqueous solutions has been investigated at 25°C and in constant ionic medium NaCl at two different concentrations, 1.00 and 3.00 mol l^{-1}. The presence of chloride ions was necessary to avoid the precipitation of cadmium(II). Two kinds of measurements were carried out. The electromotive force of galvanic cells containing glass and cadmium amalgam electrodes was measured as a function of cadmium and hydrogen ion concentrations in acid or moderately alkaline solutions in order to obtain the free concentration of cadmium(II) and hydrogen ions. The experimental data obtained in 1.00 mol l^{-1} NaCl were explained by assuming the presence of CdHL and CdH_2L_2, while those obtained in 3.00 mol l^{-1} NaCl were accounted for with the formation of CdHL, CdH_2L_2, CdH_3L_3 and CdH_2L_3. Moreover, polarographic measurements were carried out under the same experimental conditions but in alkaline solutions, and the formation of CdL_2 and CdL_3 was assumed from the shift of E(1/2) of cadmium(II) with an excess of cysteine. The stability constants of the assumed species were determined. Protonation constants of cysteine in 1.00 and 3.00 mol l^{-1} NaCl have been also determined. A comparison with the behaviour of serine and α-aminopropanoate towards cadmium(II) is proposed.

Keywords: Cadmium(II) complexes; Cysteine complexes; Sulfur containing amino acids complexes

1. Introduction

Among aminoacids, the sulfur-containing aminoacids have raised interest in many respects. Hughes [1] showed that the sulfhydryl group of serum albumin combines with mercury(II) and Benesch et al. [2] that it forms complexes with silver. Klotz et al. [3], from absorption spectra studies, found that the order of affinity for the sulfhydryl group of bovine albumin is lead(II) > cadmium(II) > zinc(II) > copper(II).

The total concentrations for blood plasma models [4] show that among the amino acid components, cysteine (2-amino-3-mercaptopropanoic acid) is present at the highest concentration, reaching a value ≥ 100 μmol l^{-1}. The ratio between cysteine and cation concentration is higher than 2/1.

As it seems of interest to study quantitatively the equilibria between cysteine ($H_2NCH(CH_2SH)COOH = H_2L$) and cations, the main and more recent surveys of literature on this subject [5–7] report only few papers. In particular the behaviour of cysteine as ligand of cadmium(II) was studied very little.

According to Li et al. [8], the formation of a precipitate prevents the determination of the stability constants of cadmium(II) cysteinate complexes at an ionic strength of 0.15 mol l^{-1} (KNO_3). Also Walker et al. [9] confirmed that the cadmium(II)—cysteinate system precipitated at 25°C and in 3.00 mol l^{-1} $NaClO_4$ even at very low concentration ($\sim 10^{-3}$ mol l^{-1}). They explained their potentiometric measurements with the formation of two species CdL and CdL_2 with $\log \beta = 12.88$ and 19.63, respectively. More recently, Cole et al. [10] asserted again that cadmium(II) forms an insoluble complex with cysteinate, but only in the range $5.0 \leq pH \leq 7.5$, thus, a large proportion of the formation curve could be obtained. They explain their potentiometric measurements at 37°C and 0.150 mol l^{-1} NaCl by assuming the presence of the species: CdL ($\log \beta_{1,1,0} = 10.3$), CdL(OH) ($\log \beta_{1,1,-1} = 2.42$), CdL_2 ($\log \beta_{1,2,0} = 16{,}92$), CdL_2H ($\log \beta_{1,2,1} = 24.97$), CdL_2H_2 ($\log \beta_{1,2,2} = 30.93$), CdL_3 ($\log \beta_{1,3,0} = 19.78$), CdL_3H ($\log \beta_{1,3,1} = 29.21$). The same authors determined the protonation constants of the ligand ($\log k_1 = 10.10$, $\log k_1k_2 = 18.03$ and $\log k_1k_2k_3 = 19.99$) by using potentiometric titrations carried out by means of a glass electrode. Most of the complexes found by Walker et al. [9] and Cole et al. [10] are different from one another. The latter authors propose the formation of complexes also with the participation of OH or H. These differences are probably due to the narrow pH range investigated because of the precipitation and the different experimental conditions.

More recently Berthon [11], by commenting upon the results obtained by the above researchers for investigating Cd(II)-cysteine, has proposed the constants of Cole et al. [10] as tentative.

Since cadmium(II) is one of the more toxic metals in the environment, the cases of cadmium poisoning are increasing and the assimilation of cadmium from man depends on the form under which the metal is present. It seems therefore very important to know the behaviour of aminoacids (in this case cysteine) present at high level in food and in blood towards cadmium(II). As cadmium(II) behaves similarly to zinc(II) its block of the normal process of zinc metabolism and its accumulation for the kidneys, liver and blood vessels can be supposed. On the other hand, as we have studied the complex formation between many amino acids (glycine, serine, histidine, ornithine, aspartate, glutamate) and cadmium(II) [12–15], we intend to investigate the behaviour of sulfur-containing aminoacids towards cations.

As the aim of this work was to study cysteine as ligand of cadmium(II) in a wide range of concentrations of the reagents, it was necessary to prepare all the solutions in a constant ionic medium. Use of an ionic medium of high concentration with respect to the reagents, allowed to assume as negligible the activity coefficients variations in spite of the change of the concentrations of the reagents [16].

By taking into account the results of earlier researchers [8–10] and looking for a suitable ionic medium, we found that, at high chloride concentration, it was possible to obtain clear solutions of cadmium(II) in the presence of cysteine. With 1.00 mol l^{-1} NaCl as an ionic medium, clear solutions were obtained in a limited range of hydrogen ion concentrations, but in 3.00 mol l^{-1} NaCl no precipitation occurred in the whole range of hydrogen ion concentrations, even after a day and at different ratios. It is reasonable to suppose that the high Cl^- concentration partially complexes cadmium(II) and avoids its precipitation.

For the above reasons we studied the behaviour of cysteine towards cadmium(II) at 25°C and in both 1.00 and 3.00 mol l^{-1} NaCl. The protonation constants of cysteine (L^{2-}) were also determined under the same experimental conditions.

2. Experimental

2.1. Method

Complexation between cadmium(II) and cysteine was studied assuming that the reagents Cd^{++}, H^+ and L^{2-} react according to the following equilibrium:

$$qCd + pH + rL \Leftrightarrow Cd_qH_pL_r \quad \beta_{q,p,r}$$

where charges are omitted, $q \geq 1$, $p \geq \leq 0$, $r \geq 1$ and the constant $\beta_{q,p,r}$ is defined according to the following relationship: $c_{Cd_qH_pL_r} = \beta_{q,p,r}\ c_{Cd}^{q}\ c_h^{p}\ c_L^{r}$. Here and in the following, small c_x and capital C_x stand for free and total concentration of the generic species x, respectively. C_H represents the analytical excess of hydrogen ion with respect to the ionic medium. Negative values of C_H correspond to hydroxyde ions concentrations and negative p values denote the presence of OH in the species formed.

To find the prevailing q, p and r values and the values of $\beta_{q,p,r}$, 2 kinds of approaches were performed. In the first one, electromotive force (e.m.f.) measurements of the following galvanic cells were performed:

$(-)$Cd(Hg)/SolutionS/R.E.$(+)$ (I)

$(-)$R.E./SolutionS/G.E.$(+)$ (II)

R.E. and G.E. are reference and glass electrodes, respectively, and Cd(Hg) the amalgam electrode. Solution *S*, prepared in the constant ionic medium, alternatively 1.00 or 3.00 mol l^{-1} NaCl, had the following general composition:

C_{Cd} mol l^{-1} in Cd^{2+}, C_H mol l^{-1} in H^+, C_L mol l^{-1} in cysteine, (Y-2C_{Cd}-C_H) mol l^{-1} in Na^+ and Y mol l^{-1} in Cl^-. Y is the concentration of the ionic medium, 1.00 or 3.00 mol l^{-1} NaCl.

The e.m.f. of the cells Eq. (I) and Eq. (II), at 25°C and in mV units, can be expressed, respectively, as follows:

$$E_I = E_I^\circ - 29.58 \log c_{Cd} - Ej;$$

$$E_{II} = E_{II}^\circ + 59.16 \log c_h + Ej$$

where E_I° and E_{II}°, 2 constants and Ej (the liquid junction potential) were determined in the first part of each e.m.f. measurement series, in the absence of the ligand, when $C_{Cd} = c_{Cd}$ and $C_H = c_h$. The liquid junction potential, which depends only on c_h [16], under these experimental conditions was found to be $Ej = -61c_h$ and $-16c_h$ in 1.00 mol l^{-1} and 3.00 mol l^{-1} NaCl, respectively. After the determination of E_I°, E_{II}° and Ej, the concentration of the ligand was increased gradually, whereas C_{Cd} and C_H were kept constant for each series of measurements. From the measurement of E_I and E_{II}, the values of c_{Cd} and c_h could be obtained for each point.

The analytical values of C_{Cd}, C_L and C_H and those measured c_{Cd} and c_h, are the experimental data provided by this approach.

In the investigation carried out at Y = 1.00 mol l^{-1}, titrations were interrupted at $-\log c_h \leq 5$, because precipitation occurred beyond this limit. E.m.f. measurements carried out in Y = 3.00 mol l^{-1} could be continued further but only until $-\log c_h \sim 8$, because of two different difficulties. The first was the response of the glass electrode which, in 3.00 mol l^{-1} of Na^+ agrees with that of the H_2 electrode only until $-\log c_h \leq 9$ as explained below. The second was the wrong response of the cadmium amalgam electrode, which does not reach stable e.m.f. values at high cysteine concentration and at $-\log c_h \geq 8$.

At very high $-\log c_h$ values, the polarographic approach was used. The shift of the $E_{(1/2)}$ of cadmium(II) induced by the addition of an excess of cysteine was measured at selected and constant $-\log c_h$ values. The $E_{(1/2)}$ value of a solution of the following general composition was determined in the absence of the ligand and at $-\log c_h \leq 3$:C_{Cd} mol l^{-1} in Cd^{2+}, C_H mol l^{-1} in H^+, (3-2C_{Cd}-C_H) mol l^{-1} in Na^+ and 3.00 mol l^{-1} in Cl^- = solution P.An excess of NaOH and ligand was added to solution P to reach the selected value of C_H in the same ionic medium. Keeping C_{Cd} and C_H constant, the concentration of the ligand was gradually increased.

Based on the protonation constants determined below, it was assumed that at $-\log c_h \geq 12$, $C_H = c_h$ or $C_{OH} = c_{OH}$ and $C_L = c_L$. Several series of measurements were carried out at different C_H and C_{Cd}. The experimental data $\Delta E_{(1/2)}$, C_{Cd}, C_H and C_L were elaborated according to De Ford and Hume [17,18] and Rossotti and Rossotti [19] to obtain the value of q, p and r and the relative stability constants in these experimental conditions.

Measurements of the e.m.f. of the cell:

$(-)$Pt,H_2/Solution T/R.E.$(+)$ (III)

were performed to obtain k_n, i.e., the protonation constants of L^{2-}, defined as follows: $c_{H_nL} = k_n\ c_h\ c_{H_{n-1}L}$. For cell (III), the liquid junction potential due to OH^- was calculated to be negligible in 3.00 mol l^{-1} NaCl, in 1.00 mol l^{-1} NaCl it was

determined as $E'j = -8c_{OH}$. Solutions T were prepared in 1.00 or 3.00 mol l^{-1} NaCl, respectively, so that protonation constants K_n could be determined at 25°C and in both ionic media. E.m.f. values of cell (III) reached equilibrium within 1 h after each addition and their value remained constant for several hours also in the presence of cysteine.

2.2. Reagents

Cadmium(II) chloride was prepared and analysed as described previously [14]. Hydrochloric acid, sodium hydroxyde and sodium chloride were prepared and analysed as described in ref. [20]. Preparation and behaviour of cadmium amalgam (0.01% weight of cadmium) have been described earlier [21]. Particular care had to be taken for the purification and conservation of cysteine in order to avoid its possible oxidation. A Sigma (DL-cysteine product) was twice recrystallized from bidistilled water. A DL-cysteine product was used because preliminary tests carried out with D-, L-, and DL-cysteine did not give significant differences and other D-, L, and DL-ligands (for example aspartate [22]) did not exhibit stereoselectivity. The purified product was dried by keeping it in a vacuum desiccator in the presence of P_2O_5 and under N_2 atmosphere. Its stoichiometric composition was checked by iodometric and thermometric analysis. The results of several determinations agreed within $\pm 0.1\%$ with the theoretical composition $H_2N\text{-}CH(CH_2\text{-}SH)COOH = H_2L$. However, from periodical check, it could be deduced that, in spite of the care paid to keep cysteine, it deteriorated after about 10 weeks of the purification. It was necessary to recrystallize again the product and to treat it as described above. Test solutions were prepared by checking cysteine the day before the use. The contact with air was minimized by using N_2 atmosphere during the preparation of the solutions and the measurements.

2.3. Apparatus

E.m.f. measurements of cells (I), (II) and (III) were carried out by using a Keithley mod. 199 or a Leeds and Northrup mod K5 and Radiometrer pHM64 or Metrohm mod. 654, respectively. The potentiometric salt bridge and the reference electrode (R.E. = Ag, AgCl/ Y mol l^{-1} NaCl, saturated with AgCl) were similar to those previously described [16]. The values of $E_I\text{-}E_I^\circ$ and $E_{III}\text{-}E_{III}^\circ$ were reproducible within ± 0.1 mV, while those of $E_{II}\text{-}E_{II}^\circ$ within ± 0.2 mV. The values of E_{III} were constant 30–45 min after each addition and remain constant within ± 0.1 mV overnight.

Voltammetric measurements (DP50) were carried out with a VA processor Metrohm mod. 646 connected with a Metrohm VA stand mod. 647. As the polarographic reference electrode was the same, $\Delta E_{(1/2)}$ could be calculated by subtracting the value of $E_{(1/2)}$ measured after the addition of the alkaline solution of the ligand, from that of the solution P. The $\Delta E_{(1/2)}$ values were reproducible within ± 3 mV. All measurements were performed at 25°C. Nitrogen and hydrogen used for the H_2 electrode for the determination of the protonation constants of cysteine (L^{2-}) were ultrapure gas 99.999%.

The response of the glass electrode was checked against that of the H_2 electrode assumed to be correct. Both measurements agreed within ± 0.1 mV until $-\log c_h \leq 9$, but beyond this limit the glass electrode value started to deviate from H_2 electrode markedly and consequently related e.m.f. measurements could not be considered reliable.

3. Results and calculations

Two kinds of experimental data have been obtained in this investigation: e.m.f. measurements at two ionic medium concentrations and polarographic data.

3.1. E.m.f. measurements

3.1.1. Protonation constants of cysteine

According to Berthon [11], the relatively high value of $\log k_1$ of cysteine, makes its accurate determination difficult since a pH range where the GE response becomes less reliable is investigated. Furthermore, value of $\log k_3$ must be deter-

mined at high C_H, with possible variation in the ionic strength. By using 3.00 mol l^{-1} NaCl as an ionic medium and the H_2 electrode we overcame both difficulties.

Measurements of e.m.f. of cell (III) were performed at 1.00 and 3.00 mol l^{-1} NaCl, respectively. From the knowledge of C_H, C_L and $-\log c_h$ obtained from the e.m.f. measurements, the protonation function Z was obtained for $C_L = 0.010$, 0.025 and 0.050 mol l^{-1}, in the range $1 \leq -\log c_h \leq 11$ and $0.3 \geq C_H \geq 0$. Since Z was independent of C_L for both ionic medium concentrations, polymeric species were not present in appreciable amount and then, from the dependence of Z *versus* $-\log c_h$, the values of protonation constants of cysteine were obtained. Refined k_n and k'_n values and their limits of error, obtained by using a computer program BSTAC [23], are collected in Table 1.

3.1.2. Complex formation in ionic medium 1.00 mol l^{-1} NaCl

Measurements were performed at different C_H (0.100, 0.070, 0.050, 0.035 and 0.025 mol l^{-1}) and different C_{Cd} (2.00, 1.00, 0.50 and 0.25) $\times 10^{-3}$ mol l^{-1}. Unfortunately, it was not possible to carry out measurements at higher C_{Cd} concentrations and even for $C_{Cd} = 2.00$ and 1.00×10^{-3} mol l^{-1}, e.m.f. values were not stable at $-\log c_h \geq 4.5$. The slow formation of precipitate precludes the increase in the ligand concentration.

Table 1
Protonation constants of cysteine in both ionic media studied at 25°C

NaCl	$\log k_1$	$\log k_1k_2$	$\log k_3$
1.00 mol l^{-1}	10.26 ± 0.02	18.48 ± 0.04	2.04 ± 0.10
3.00 mol l^{-1}	10.56 ± 0.02	19.09 ± 0.03	2.26 ± 0.10
Literature values			
KCl 0.2 mol l^{-1}	10.16	18.26	1.86 [29,30]
$NaClO_4$ 0.5 mol l^{-1}	10.37	19.14	2.50 [31]
$NaClO_4$ 1.0 mol l^{-1}	10.35	19.02	1.96 [31]
$NaClO_4$ 3.0 mol l^{-1}	10.69	19.40	2.40 [32]

For cadmium(II), the mass balance equation can be written as follows:

$$C_{Cd} = c_{Cd} + \Sigma\Sigma\Sigma q\beta'_{q,p,r} c_{Cd}^q c_h^p c_L^r \quad (1)$$

where q, p, r and $\beta'_{q,p,r}$ in this case are referred to 1.00 mol l^{-1} NaCl as an ionic medium. In Eq. (1) hydrolytic species of cadmium(II) were neglected based on the studies of Biedermann and Ciavatta [24].

The $\eta[=\log(C_{Cd}/c_{Cd})]$ function, calculated for each experimental point from Eq. (1), is plotted *versus* $-\log c_h$ in Fig. 1.

Fig. 1 shows that points obtained at the same C_H but at C_{Cd} 0.50 and 0.25×10^{-3} mol l^{-1} fall on the same curve. By increasing C_{Cd} small deviations could be observed. Based on the results obtained in 3.00 mol l^{-1} NaCl where precipitation does not occur, we supposed that these deviations can be attributed to e.m.f. measurements relative to solutions which do not attain real equilibrium.

To verify the presence of mixed species with protons, the free concentration of ligand, c_L, was calculated from the mass balance equation of C_H, which can be written as follows:

$$C_H = c_h + \Sigma n k'_n c_h^n c_L + \Sigma\Sigma\Sigma p\beta'_{q,p,r} c_{Cd}^q c_h^p c_L^r \quad (2)$$

where k'_n are the protonation constants of the ligand of Table 1, hydrolytic species of cadmium(II) are neglected and the constants refer to 1.00 mol l^{-1} NaCl, as an ionic medium. As only $C_{Cd} = 0.50$ and 0.25×10^{-3} mol l^{-1} points are considered, first approximation values of c_L for each point can be calculated by means of Eq. (2) by considering the last term as negligible.

By plotting η *versus* $-\log c_L$, points fall on different curves at different values of C_H. Since η is an increasing function of C_H, complexes containing protons ($p > 0$) are also formed. From the k'_n values and the $-\log c_h$ range investigated, it can be inferred that most of the cysteine is in the HL form. Thus, it can be supposed that cadmium(II) is bound to the form HL of cysteine. To verify this hypothesis, η is plotted *versus* $-\log(c_L c_h)$ in Fig. 2, where all the points fall on the same curve, independently of C_{Cd} and C_H.

The values of the constants obtained by applying the method of the normalized curves of Sillén

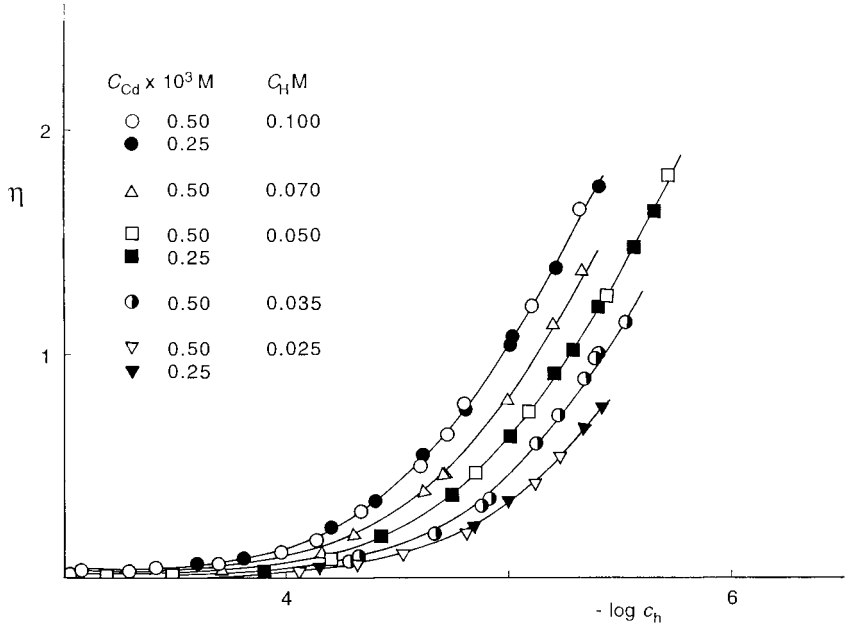

Fig. 1. Experimental data obtained in 1.00 mol l^{-1} NaCl, as ionic medium. Points at $C_{Cd} \geq 0.50 \times 10^{-3}$ mol l^{-1} are not plotted. Curves are calculated using constants in Table 2.

[25] and by using a computer program BSTAC [23] and practically coincident, are collected in Table 2.

3.1.3. Complex formation in ionic medium 3.00 mol l^{-1} NaCl

The high concentration of ionic medium was employed to study a wider range of concentration of the reagents and avoid the precipitation.

Measurements of e.m.f. of the cells (I) and (II) were performed in the range $1 \leq -\log c_h \leq 8$, at $C_H = 0.300$, 0.175, 0.100, 0.050 and 0.025 mol l^{-1} and at $C_{Cd} = (5.00,\ 2.50,\ 1.00,\ 0.50) \times 10^{-3}$ mol l^{-1} so that the formation of polynuclear or mixed complexes with a high ratio p/r could be favoured.

By applying the above explained procedure, the function η could be calculated. Fig. 3, where η is plotted *versus* $-\log c_h$, shows that points at the same C_H and different C_{Cd} fall on the same curve. Therefore, polynuclear complexes in cadmium(II) are not present in appreciable concentration and then $q = 1$. Since points obtained in the range $0.005 \geq C_{Cd} \geq 0.0005$ mol l^{-1} lie on the same curve, the deviations observed at 1.00 mol l^{-1} NaCl were to be attributed to starting precipitation. Thus the absence of polynuclear complexes even at ionic medium 1.00 mol l^{-1} NaCl is confirmed.

To find the prevailing values of p and r and the values of $\beta_{1,p,r}$, the free concentration of the ligand c_L, was calculated for each point by means of Eq. (2), by neglecting the last term and by using the k_n values determined in 3.00 mol l^{-1} NaCl. The c_L values obtained from Eq. (2) can be considered only as a first approximation. Although all the test solutions were prepared so that $C_{Cd} \leq 0.02\ C_H$, at the highest C_{Cd} values (i.e., 0.005 mol l^{-1}) refined $-\log c_L$ are different with respect to the first approximation $-\log c_L$. The difference never exceeds 0.02 units, but, the high number of protons participating to the complex formation implies significant differences in the calculation of the theoretical curves.

Fig. 4, where η is plotted as a function of $-\log c_L$, shows that points obtained at different C_H fall on different curves so that η is an increasing function of C_H. Therefore, protonated com-

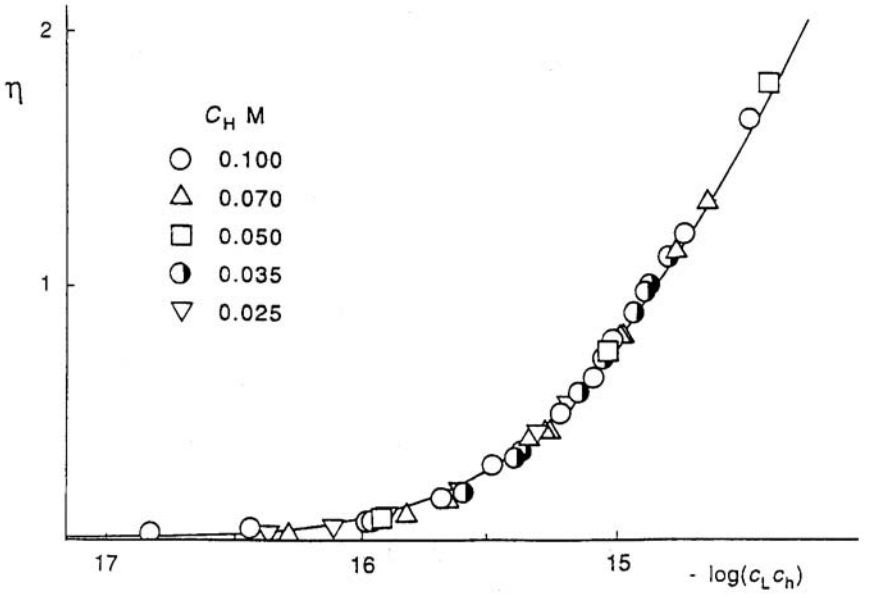

Fig. 2. Most of the experimental data plotted in the form $\eta[=\log(C_{Cd}/c_{Cd})]$ *versus* $-\log(c_L c_h)$. All the points fall on the same curve. The curve is calculated by means of the constants in Table 2.

plexes are formed and $p \geq 0$. The experimental data, treated as previously described [15], could be interpreted by assuming the presence of the species CdHL, CdH_2L_2, CdH_3L_3 and CdH_2L_3, with the relative stability constants.

Taking into account the complexity of the system, the $\beta_{1,1,1}$, $\beta_{1,2,2}$, $\beta_{1,3,3}$ and $\beta_{1,2,3}$ values obtained as first approximations and the values of $-\log c_L$ had to be refined. A computing procedure was applied. The BSTAC program was used in which the analytical and measured data were introduced. After a lot of different trials, such as the introduction of new species or the elimination of some the program interpreted the experimental data by assuming the species found with the graphic method. The differences between first approximation and refined constants are not very large and the proposed values are collected in Table 3. The error limits reported next to the β values are those given by the computer, because they are higher in the graphic treatment. Among a total of 310 points, 106 show a positive deviation with $[\eta_{ex}\text{-}\eta_{cal}]$ never bigger than 0.008, whereas the negative residual never exceeds 0.007.

The values of the constants in Table 3 are used to calculate the theoretical curves, which are drawn through the points on Fig. 3 and Fig. 4. The good agreement between points and curves supports the validity of our procedures and conclusions.

3.2. Results of the polarographic measurements

Since we were not able to obtain stable and reproducible e.m.f. measurements in cells (I) and (II) at high free concentration of cysteine and high $-\log c_h \geq 8$, it was not possible to collect information on the complex formation by means of potentiometric measurements.

From preliminary approaches, it was observed that by applying differential pulse polarography (DP50) a peak relative to cadmium was obtained, as expected, at -660 ± 2 mV versus R.E. By adding to a cadmium(II) solution an excess of cysteine and at $-\log c_h \sim 12$, a peak relative to the complex formation between cadmium(II) and cysteine was obtained. The response the polarographic measurements was very satisfactory, because the reduction of the complex took place at

a more negative and very different potential with respect to the cysteine peak.

It could be calculated that both the reduction of cadmium(II) in acid solution ($-\log c_h \leq 3$) and the reduction of the complex cadmium(II)—cysteine with ligand in excess and in alkaline solution ($-\log c_h \geq 12$) were relative to reversible processes. For the former the slope of 30 ± 1 mV and for the latter the slope 29 ± 1 mV could be calculated. Fig. 5 as an example, shows a polarogram of a solution of the composition:

$C_{Cd} = 10^{-3}$ mol l^{-1}, $C_H = -0.010$ mol l^{-1}, $C_L = 0.003$ mol l^{-1} in ionic medium 3.00 mol l^{-1} NaCl. The first peak is due to the presence of cysteine, while the second one is relative to the reduction of the complex.

As it was not possible to measure accurately $-\log c_h$ in our solutions, we selected high values of $C_{OH} = -C_H \geq 0.01$ mol l^{-1}. On the basis of the k_1 value, cysteine could be considered completely deprotonated (i.e., in the form L) and the equality $C_H = c_h$ was assumed for each series of measurements.

Several measurements were carried out at increasing concentration of cysteine and at different C_{Cd} and C_H values. Polarograms at $C_H = -0.010$, -0.020, -0.035, -0.070 and -0.100 mol l^{-1} were obtained.

For each C_H and C_{Cd} value, the total concentration of cysteine was increased to about 0.050 mol l^{-1}. By applying the method proposed by De Ford [17,18] and Rossotti [19], the composition of the complexes and their stability constants can be obtained. From the $\Delta E_{(1/2)}$ and the excess of cysteine with respect to cadmium(II), it can be calculated that the complex formation is independent of C_{Cd} and C_H (i.e., $q = 1$ and $p = 0$), but no evidence is found for the 1:1 complex. The formation of CdL_2 is assumed and a first approximation value $\delta_{1,0,2}$ is calculated, where it is supposed that:

$$\delta_{1,0,2} = \beta_{1,0,2} + \beta_{1,0,3} c_L \quad (3)$$

By increasing the concentration of cysteine could be observed an increase of $\delta_{1,0,2}$ and then the formation of CdL_3 had to be considered. By plotting $\delta_{1,0,2}$ *versus* C_L (Fig. 6), points fall all together independently of the C_H concentration, but a linear dependence of $\delta_{1,0,2}$ on C_L must be considered. All the points can be approximated with a straight line, thus the hypothesis of Eq. (3) is verified. The intercept on the ordinate and the slope give the $\beta_{1,0,2}$ and $\beta_{1,0,3}$ values, respectively. The values of $\log \beta_{1,0,2} = 14.40 \pm 0.08$ and $\log \beta_{1,0,3} = 16.0 \pm 0.1$ have been determined which are reported with others in Table 3. On the points of Fig. 6 the full line is calculated with the values proposed for the constants, while dashed lines are calculated by taking into account the proposed limits of error. It can be deduced that CdL is not present at appreciable concentration and polynuclear complexes or complexes with loss of protons are not present.

Table 2
Values of the stability constants ($\log \beta_{1,p,r}$) of the complexes assumed to explain the experimental data obtained in 1.00 mol l^{-1} NaCl

Species	Graphical	BSTAC	Proposed
$CdHL$ ($\log \beta_{1,1,1}$)	15.23 ± 0.1	15.20 ± 0.04	15.2 ± 0.07
CdH_2L_2 ($\log \beta_{1,2,2}$)	30.50 ± 0.1	30.47 ± 0.03	30.47 ± 0.05
Literature values			
	25°C and 3.00 mol l^{-1} $NaClO_4$		[9]
CdL ($\log \beta_{1,0,1}$)	12.88		
CdL_2 ($\log \beta_{1,0,2}$)	19.63		
	37°C and 0.15 mol l^{-1} NaCl		[10]
CdL ($\log \beta_{1,0,1}$)	10.3		
CdL_2 ($\log \beta_{1,0,2}$)	16.92		
$CdLH_{-1}$ ($\log \beta_{1,-1,1}$)	2.42		
$CdHL_2$ ($\log \beta_{1,1,2}$)	24.97		
CdH_2L_2 ($\log \beta_{1,2,2}$)	30.93		
CdL_3 ($\log \beta_{1,0,3}$)	19.78		
$CdHL_3$ ($\log \beta_{1,1,3}$)	29.21		

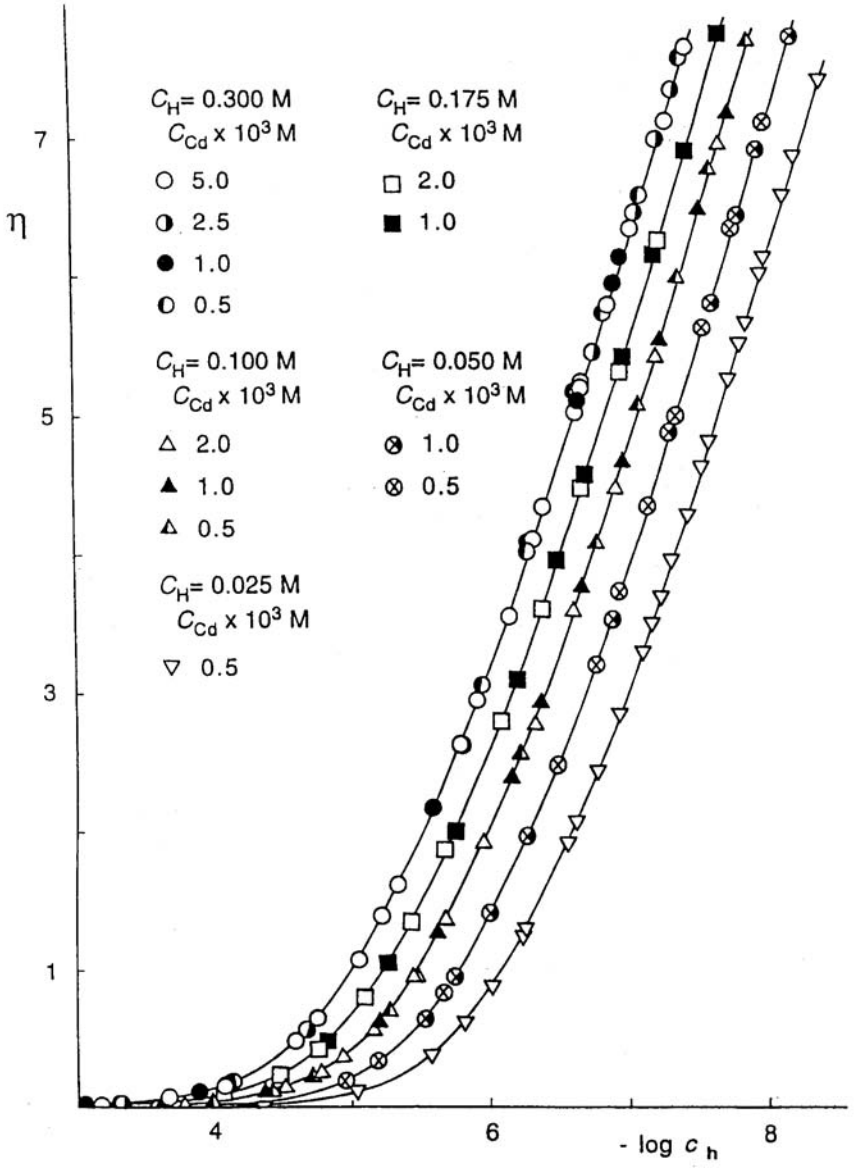

Fig. 3. Experimental data obtained in 3.00 mol l^{-1} NaCl as ionic medium. Curves are calculated using constants in Table 3.

4. Discussion

Complex formation of cysteine and cadmium(II) has been studied at 25°C and at two different concentrations of ionic medium NaCl. The use of 3.00 mol l^{-1} of NaCl was necessary to investigate a wide range of concentration of the reagents in clear solutions, i.e., without precipitation.

The Cl^- -complexing does not introduce, however, any significant complication but only the general limitations of a constant ionic medium [16], i.e., no distinction between species containing a different number of solvent salt ions and molecules. Thus the concentration of CdH_3L_3 really represents: $\Sigma_x\Sigma_y\Sigma_w\ c_{CdH3L3\ (Na+)x(Cl-)y(H2O)w}$ with $x \geq 0$, $y \geq 0$ and $w \geq 0$, unknown.

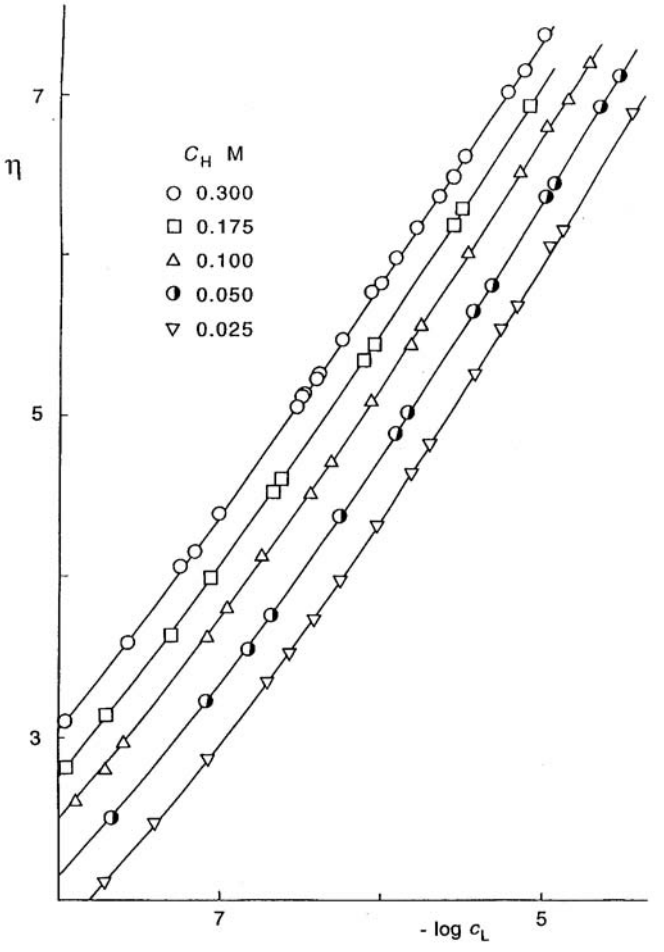

Fig. 4. Most of the experimental data plotted in the form $\eta(-\log c_L)$. The presence of protonated species is evident. The constants in Table 3 are used to calculate the curves.

Protonation constants of the ligand were determined in both ionic media. Their values increase by increasing the concentration of the ionic medium, according to the trend found by Ellilä [26] for the constant of acetic acid in NaCl at different concentrations.

Species and constants proposed here to explain the experimental data agree little with those of literature. This is to be attributed to the very different experimental conditions (temperature and ionic medium) and to the narrow range of concentrations previously investigated. The presence of the species CdH_2L_2 found by Cole et al. [10] is here confirmed. Its stability constant ($\log \beta_{1,2,2} = 30.62$) is not too far from that of Cole et al. ($\log \beta_{1,2,2} = 30.93$) by considering the very different experimental conditions.

Walker et al. [9] and Cole et al. [10] found the presence of CdL and CdL_2, even if with different stability constants. Both groups performed their experiments near the range of precipitation. Our data do not give appreciable evidence of CdL and the formation of CdL_2 takes place in alkaline solution where solutions with a high ratio cysteine/cadmium(II) (for instance 50:1) were investigated. The stability constant of CdL_2 is very different that found by Walker et al. [9] and Cole et al. [10] because they performed only e.m.f.

Table 3
Values of the stability constants ($\log \beta_{1,p,r}$) of the complexes assumed to explain the experimental data obtained in 3.00 mol l^{-1} NaCl

Species	Graphical	BSTAC	Proposed	Method
CdHL($\log \beta_{1,1,1}$)	15.46 ± 0.1	15.40 ± 0.08	15.40 ± 0.08	E.m.f.
CdH_2L_2 ($\log \beta_{1,2,2}$)	30.6 ± 0.1	30.62 ± 0.06	30.62 ± 0.06	E.m.f.
CdH_3L_3 ($\log \beta_{1,3,3}$)	44.72 ± 0.08	44.65 ± 0.05	44.65 ± 0.05	E.m.f.
CdH_2L_3 ($\log \beta_{1,2,3}$)	37.0 ± 0.2	36.80 ± 0.04	36.80 ± 0.05	E.m.f.
CdL_2 ($\log \beta_{1,0,2}$)	14.40 ± 0.06	—	14.40 ± 0.06	$\Delta E_{(1/2)}$
CdL_3 ($\log \beta_{1,0,3}$)	16.0 ± 0.12	—	16.0 ± 0.12	$\Delta E_{(1/2)}$

measurements and in alkaline solutions where the response of the glass electrode deviates with respect to that of hydrogen electrode. Moreover, the experimental conditions were very different.

The presence of other species is not found here in appreciable amount. The assumed complexes explain very well the experimental data, as it can be seen from the agreement between curves and experimental points. The species CdL(OH) can be excluded by considering the results obtained at $-\log c_h \geq 12$ polarographically, as proved also by the plot of Fig. 6.

It can be interesting to compare the results obtained in 1.00 and 3.00 mol l^{-1} NaCl. The latter ionic medium allows a complete investigation. The comparison of the results is limited to the constants of CdHL and CdH_2L_2. These constants of CdHL and CdH_2L_2 are higher in 3.00 mol l^{-1} than in 1.00 mol l^{-1} NaCl. The k'_n and k_n values provide an explanation for this surprising evidence. Cysteine behaves as a stronger base in 3.00 mol l^{-1} than in 1.00 mol l^{-1} NaCl. If the constants of the following equilibria are calculated at both concentrations of NaCl:

Table 4
Comparison among stability constants of the 1:1 and 1:2 complexes formed by α-aminopropanoate, serine, and cysteine with cadmium(II)

Species	CdL	CdL_2
Ligand		
α-Aminopropanoate (1.00 mol l^{-1} $NaClO_4$)	4.05	7.33
Serine (3.00 mol l^{-1} $NaClO_4$)	4.33	8.19
Cysteine (1.00 mol l^{-1} NaCl)	4.97	9.92
Cysteine (3.00 mol l^{-1} NaCl)	4.84	9.50

For cysteine and only in this table, L denotes HL.

$$Cd^{2+} + HL \Leftrightarrow CdHL \quad \beta_1$$

$$Cd^{2+} + 2HL \Leftrightarrow CdH_2L_2 \quad \beta_2 2$$

it is found that:

in 1.00 mol l^{-1} NaCl $\log \beta_1 = 4.97$ and $\log \beta_2 = 9.92$

in 3.00 mol l^{-1} NaCl $\log \beta_1 = 4.84$ and $\log \beta_2 = 9.50$.

The stability constants $\log \beta_1$ and $\log \beta_2$ in 1.00 mol l^{-1} are higher than in 3.00 mol $^{-1}$ NaCl because chloride forms complexes with cadmium(II) according to Biedermann et al. [27].

By using the constants of Table 3, distribution curves of the species found can be calculated as a function of $-\log c_h$ for $C_L = 0.100$ and 0.050 mol l^{-1} (Fig. 7(a) and (b), respectively). In the figures the percentage of each species corresponds to the

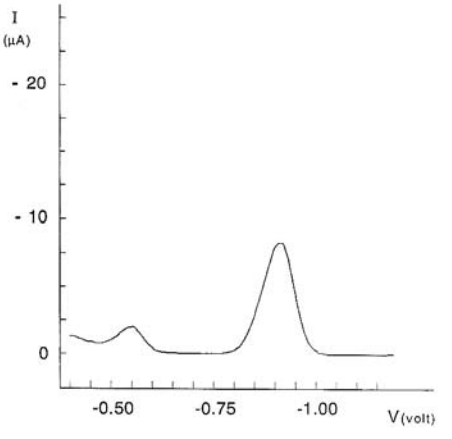

Fig. 5. A polarogram, as an example, of cadmium(II) with an excess of cysteine at $C_{OH} = 0.010$ mol l^{-1} and in 3.00 mol l^{-1} NaCl. I(μA) and V(volt) stand for current intensity and cathodic potential (*versus* R.E.), respectively.

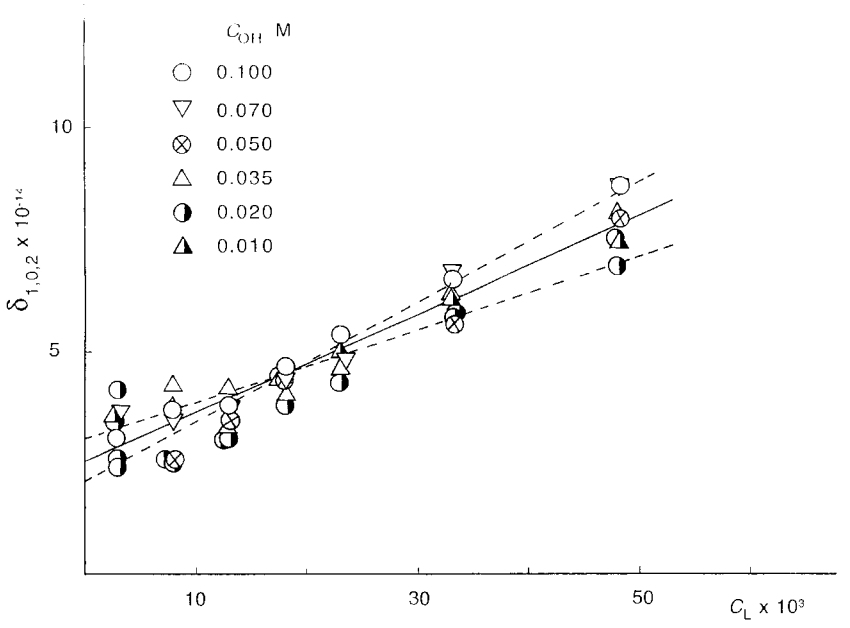

Fig. 6. The dependence of the value of $\delta_{1,0,2}$ on the concentration of cysteine. The full line corresponds to the values assumed for $\beta_{1,0,2}$ and $\beta_{1,0,3}$. Dashed lines correspond to error limits.

distance between the two curves which define the existence range of the species.

In both cases only the species CdHL, CdH_2L_2, CdH_3L_3, CdH_2L_3 are present, because even at $-\log c_h = 8$ and $C_L = 0.100$ mol l^{-1}, the contribution of CdL_2 is equal to or less than 1% of C_{Cd}. For both C_L values, the formation of complexes between cadmium(II) and cysteine starts at $-\log c_h \sim 4$ and the percentage of CdHL does not exceed 20%. The percentages of CdH_2L_2 and CdH_3L_3 are higher and CdH_3L_3 reaches at $-\log c_h \sim 7$ the percentage of 70%. At this value of $-\log c_h$, the species CdH_2L_3 represents 10% of the total cadmium(II), but at $-\log c_h \sim 8$ it becomes more than 50%.

Till $-\log c_h \sim 6.5$, cysteine bonds cadmium(II) in the HL form, i.e., by means of its monoprotonated form. The HL form can correspond to the protonation of NH_2 or S-. If it is supposed that the sulfhydrylic group is protonated first, CdHL, CdH_2L_2 and CdH_3L_3, could be five-membered chelate rings formed between aminic nitrogen and carboxylic group. At $-\log c_h \geq 7$, the contributions of sulfur and nitrogen must be considered. Thus, in CdL_2 and CdL_3 the bond between cadmium(II) and sulfur is also involved.

It becomes interesting to compare the behaviour of cysteine, serine, and α-aminopropanoate towards cadmium(II). Complex formation for the system cadmium(II) serine [12] and α-aminopropanoate [28] was previously investigated and the stability constants are collected in Table 4. The species CdL and CdL_2 of the other ligands correspond to CdHL and CdH_2L_2 for cysteine, respectively.

Although the constants for Cd(II)-cysteine have been obtained in NaCl as ionic medium, the order of stability is α-amino -propanoate < serine < cysteine. The presence of both oxygen and sulfur atoms give more stability to the complexes, and sulfur contributes more than oxygen. The values collected in Table 4 are relative to complexes formed by serine and cysteine with alcoholic sulfhydryl groups, respectively protonated. The stability constants of CdL_2 and

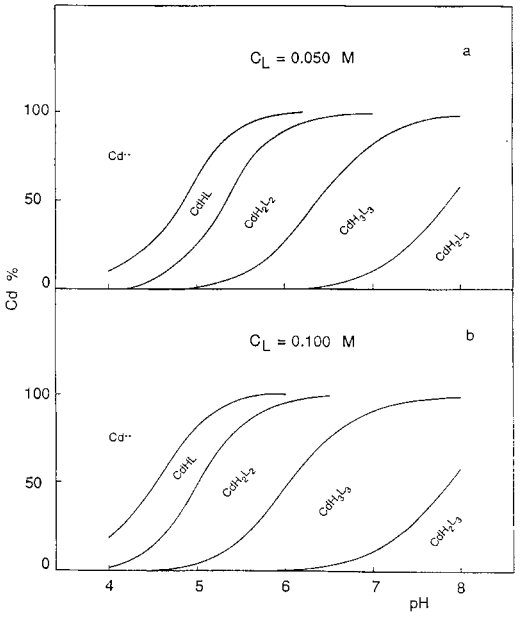

Fig. 7. Distribution curves of assumed species as a function of pH at two different C_L: (a) 0.050 and (b) 0.100 mol l^{-1}.

CdL_3 of cysteine (deprotonated), found at $-\log c_h \geq 12$ are of another order of magnitude.

In conclusion cysteine forms complexes with cadmium(II) in aqueous solutions. The ligand is mainly present as HL till $-\log c_h \sim 6$, but the ligand in its deprotonated form L, bonds cadmium(II) in alkaline solution. The stability of the complexes is high because it is reasonable to believe that the formation of stable chelate rings between cysteine and cadmium(II) takes place.

Liquid–liquid extraction of some lanthanide metal ions by polyoxyalkylene systems

A.M.Y. Jaber *, Abdul-Elah Al-Naser

King Fahd University of Petroleum and Minerals, Chemistry Department, Dhahran, 31261, Saudi Arabia

Received 11 September 1996; received in revised form 22 January 1997; accepted 23 January 1997

Abstract

Polyoxyalkylene systems, namely, polypropylene glycol (PPG-1025), polyethylene glycol (PEG-600) and polybutadieneoxide (PBDO-700) dissolved in either nitrobenzene or 1,2-dichloroethane have been tested as prospective extractants for some lanthanide metal ions (Eu^{3+}, Pr^{3+} and Er^{3+}) from their aqueous solutions in the presence of picrate anions. The metal ions were quantified before and after extraction using the inductively coupled plasma emission spectrophotometry technique. The percent extraction and the distribution coefficients have indicated that pH of the aqueous phase, picrate concentration and the organic solvent are the major parameters that affect the extraction efficiency of the metal ions. The optimum pH range was found to be 3.5–5.5 and the picrate concentration should be as high as possible; however, a picrate concentration of about 0.05 M proved to be adequate for a near quantitative extraction. In all cases, nitrobenzene enhanced a higher percent extraction compared to 1,2-dichloroethane. The efficiency of the polyoxyalkylene systems to extract certain lanthanide metal ions was in the order PBDO-700 > PPG-1025 > PEG-600 when nitrobenzene was the organic solvent and in the order PPG-1025 > PBDO-700 ≈ PEG-600 when 1,2-dichloroethane used as the solvent in the organic phase. The extractability of PPG-1025 towards the lanthanide metal ions was in the order $Pr^{3+} > Eu^{3+} > Er^{3+}$ irrespective of the organic solvent used. The stoichiometry of the extracted polyoxyalkylene ion-pairs with the lanthanide metal ions has been estimated. Each mole of metal ions is associated with three moles of picrate anions and 13 to 14 moles of propyleneoxide units in the case of PPG-1025, and about 9 to 10 moles of ethyleneoxide units in the case of PEG-600 and 10 moles of butadieneoxide units in the case of PBDO-700. © 1997 Elsevier Science B.V.

Keywords: Polyoxyalkylene; Lanthanides; Extraction; Picric acid

1. Introduction

Macrocyclic polyethers (crown ethers) have been given extensive attention in terms of their uses as selective and efficient extractants for some metal ions from their aqueous solutions and as active sensors in ion-selective membrane electrodes. The acyclic polyethers, for example, polyethylene and polypropylene glycols have proved to compete with the crown ethers for their use as metal ion extractants and active sensors in many instances.

* Corresponding author.

PII S00 9-9140(97)00033-7

Tetraphenylborate salts of polyoxyalkylene complexes with some metal ions gave successful electrodes for the respective metal ions like, for example, Ba [1,2], Ca [3], and Li [4], ion selective membrane electrodes.

Polyoxyalkylene nonionic surfactants having the poly(oxyethylene) chain have been tested as extractants for alkali and alkaline earth metal ions. Solvent extraction studies allowed also the assessment of the nature of the complex formed between the ligands and the metal ions in terms of complex stability and stoichiometry. The complexation equilibrium constant and the extraction efficiency of alkali and alkaline earth metal ions have been studied with high molar mass noncyclic poly(oxyethylene) ligands and their derivatives in either nitrobenzene [5,6] or chlorinated organic solvents such as dichloromethane, chloroform and carbon tetrachloride [7–13]. These studies proved that the extractability of polyoxyalkylene systems towards the metal ions is almost similar to the crown ethers and it is dependent on the nature of polyoxyalkylene and its organic solvent, size and charge of the metal ion, pH of the aqueous phase and nature of the anion associated with the ion pair extracted to the organic phase. The tendency for extraction was found to be more effective with bulkier anions like picrates and thiocyanates since they are less hydrophilic compared to small anions like chloride.

The rare earth metal ions have been mainly separated by solvent extraction methods using various extractants, for example, di-(2-ethylhexyl)phosphoric acid [14] and long-chain alkyl substituents of *N*-phenylhydroxylamine [15,16] which showed large separation factors among lanthanides(III). Ion-associate extraction systems [17], namely, 2,3-naphthalenediol as a diprotic chelating reagent and benzyldimethyltetradecylammonium chloride as ion-associate reagent have shown large separation factors for Pr^{3+}, Eu^{3+}, and Yb^{3+} ions at low pH values. Crown ethers, namely, 15-crown-5, 12-crown-4, and dibenzo-18-crown-6 in nitrobenzene phase have been tested as extractants for individual rare earth ions from aqueous solutions containing picrate anoins. Tb^{3+}, Eu^{3+}, Gd^{3+}, Nd^{3+} and Yb^{3+} have been extracted by 15-crown-5 [18]. Lanthanides have been also extracted from an aqueous phase containing trichloroacetate as a counter ion by 18-crown-6 in 1,2-dichloroethane [19]. The extraction selectivity towards lanthanides was enhanced when EDTA has been added to the aqueous phase.

Some lanthanide complexes with several polyethylene glycols and glymes were isolated and their properties were investigated by Hirashima et al. [20]. Stability constants and some other properties of lanthanide nitrate complexes with tri, tetra, and pentaethylene glycols have also been investigated [21]. It was found that stability of the complexes decreases with an increase in the atomic number of lanthanides. Further more, high molar masses polyethylene glycols in dichloromethane phase have been tested [22] as extractants in the liquid–liquid extraction of some actinides (U, Np and Pa). It has been reported that the extraction efficiency of the three actinides from acidic thiocyanate solution increases in the order U(VI) > Pa > Np.

It is obvious from the literature reports that the studies concerning application of the polyoxyalkylene nonionic surfactants as extractants for the rare earth metal ions are limited. The extraction facilitates preconcentration of these metal ions from their matrices and it may be imperative when these metal ions are to be determined by many experimental methods. Polyethylene glycols, polypropylene glycols of various ranges of molar masses and polybutadieneoxide in either 1,2-dichloroethane or nitrobenzene phase have been tested as extractants for three lanthanide metal ions, namely, praseodymium, Pr^{3+}, europium, Eu^{3+}, and erbium, Er^{3+}, from aqueous phases containing picrate anions.

1.1. Extraction equilibria and stoichiometry of extracted complex

Equilibria proposed in the literature for metal ion extractions by either crown ethers or acyclic polyethers were treated in different ways depending on the nature of the system since many parameters should be considered in such systems. The most possible equilibrium may be suggested for this study is

$$M^{z+} + b/nL^* + zX^- \rightleftharpoons ML_{b/n}X_z^* \quad (1)$$

where M^{z+} is the metal ion of charge z, L^* is the polyoxyalkylene ligand in the organic phase (the asterisk refers to the organic phase), b/n, is the number of moles of polyoxyalkylene ligand associated with one mole of metal ions, where b refers to the number of moles of alkylene oxide units (AOU) associated with a mole of metal ions and n is the average number of AOUs per mole of polyoxyalkylene. X^-, is the picrate anion associated with the ion-pair extracted to the organic phase. Assuming that dissociation of the ion-pair, $ML_{b/n}\,X_z^*$, in the organic phase is negligible, then the extraction equilibrium could be expressed as follows,

$$K_{ex} = \frac{[ML_{b/n}X_z^*]}{[M^{z+}][L^*]^{b/n}[X^-]^z} \quad (2)$$

The distribution ratio, D, is expressed by the ratio of the organic metal ion concentration, $C_{M^{z+}}{}^*$, to the aqueous metal ion concentration, $C_{M^{z+}}$, in all chemical forms, that is, $D = C_{M^{z+}}{}^*/C_{M^{z+}}$. Thus, D may be expressed as follows,

$$D = \frac{[ML_{b/n}X_z^*]}{[M^{z+}] + [ML_{b/n}^{z+}]}$$

Assuming that partitioning of the polyoxyalkylene into the aqueous phase is negligible, consequently, $[M^{z+}] > > [ML_{b/n}^{z+}]$. Hence, the distribution ratio will be expressed by the following equation,

$$D = \frac{[ML_{b/n}X_z^*]}{[M^{z+}]} \quad (3)$$

Introducing the term D into the K_{ex} expression in Eq. (2) gives,

$$K_{ex} = \frac{D}{[L^*]^{b/n}[X^-]^z} \quad (4)$$

Rearranging Eq. (4) and taking log of both sides gives,

$$\log K_{ex} + b/n \log [L^*] = \log \frac{D}{[X^-]^z} \quad (5)$$

Taking into consideration the dissociation of picric acid, HX, in the aqueous phase into H^+ and X^- ions and under the condition that $[HX] > > [M^{3+}]$, the concentration of picrate anion X^- in Eq. (5) may be expressed as follows,

$$[X^-] = (K_a[HX])^{1/2}$$

Inserting the value of $[X^-]$ into Eq. (5) gives,

$$\text{Log } K_{ex} + b/n \log [L^*] = \log \frac{D}{k_a^{z/2}\,[HX]^{z/2}} \quad (6)$$

Rearrangement of Eq. (6) gives,

$$\text{Log } D = \log K_a^{z/2} + \log K_{ex} + b/n \log [L^*] + z/2 \log [HX] \quad (7)$$

The terms, k_a and k_{ex} are expected to be constants under the extraction conditions, hence when $\log D$ is plotted against $\log [L^*]$ a straight line with a slope of b/n and intercept of, $\log K_a^{z/2} + \log K_{ex} + z/2 \log [HX]$, will be obtained. On the other hand, when the polyoxyalkylene concentration, [L*], is kept constant while the picric acid concentration, [HX], is varied and $\log D$ is plotted against $\log [HX]$, a straight line with a slope of $z/2$ is expected, where z is the number of moles of picrate anions associated with one mole of metal-picrate species. From the two plots, stoichiometry of the complex $ML_{b/n}\,X_z^*$ and $\log K_{ex}$ may be estimated.

2. Experimental

2.1. Materials

Polyethylene glycol (PEG-600), polypropylene glycol (PPG-1025 and PPG-2000) and polybutadiene oxide (PBDO-700) were all of reagent grade from Polyscience. Picric acid was of purum grade from Fluka. Praseodymium, europium, erbium and lanthanum stock solutions were obtained either from a spectroscopic grade (1000 ppm) stock solutions provided by Alfa products or prepared from high metal oxides provided by Fluke. Nitrobenzene and 1,2-dichloroethane were of purum grade provided by

Fluka. All other reagents used were of analytical grade and all standard solutions were prepared in distilled deionized water.

2.2. Instrumentation

A Perkin Elmer Plasma (400 ICP) spectrometer was utilized for the metal ion analysis after extraction. The spectra were measured at an observation height of 11 mm with an integration time of 100 ms and a photomultiplier voltage of 600 V. For all lines the built-in auto-background correction was applied. An Orion 720A pH meter in conjunction with a Corning combination pH glass electrode were used to measure the pH of the solutions. A mechanical shaker (Burrell, Model 75) was used to homogenize the samples during the extraction process.

2.3. Extraction procedure and measurements

The aqueous phase was prepared by mixing appropriate volumes of certain concentrations of both, picric acid and the metal ion solutions. The organic phase was prepared by dissolving the required amount ($<0.01-0.3$ M) of the polyoxyalkylenes (PEG, PPG or PBO) in either nitrobenzene or 1,2-dichloroethane solvents. Equal volumes (10 ml) of both phases were transferred to a separatory funnel and shaken mechanically for 30 min; a time found to be enough to get complete separation. The mixture was then left to stand for 30 min after which the aqueous phase was separated and analyzed for the metal ion concentration left using the ICP technique. Lanthanum, La^{3+}, at a level of 10 ppm was added as an internal standard into both, the sample and the calibration solutions. The correlation coefficients for all calibration curves were better than 0.9999. As a check experiment, the organic phase was separated and the metal ion was stripped to the aqueous phase by either 0.1 M HNO_3 or HCl. Results obtained indicated that the amount extracted into the organic phase is same as that lost from the aqueous phase, thus further analysis of the organic phase was not needed.

3. Results and discussion

3.1. Effect of picric acid concentration on extraction

The lanthanide metal ion extraction studies have been initiated by fixing the metal ion and the polyoxyalkylene concentrations at levels of about 100 ppm and 0.1 M, respectively. However, the picrate anion concentration was varied in the range of 0.01 M to about 0.055 M; the maximum picrate concentration was limited by its water solubility. The studies indicated that extraction is enhanced with the increase in the picrate anion concentration irrespective of the type of metal ion, polyoxyalkylene system or organic solvent. When picric acid concentration was increased from 0.017 to 0.052 M, the percent extraction of Eu^{3+}, for example, has increased from 9 to 52%, 6 to 45% and 2 to 20% when the polyoxyalkylene was PPG-1025, PEG-600 and PBDO-700, respectively, with nitrobenzene as the organic solvent. However, when 1,2-dichloroethane replaced nitrobenzene in the organic phase, the percent extraction of Eu^{3+} has increased from 3 to 31%, 7 to 38% and 1 to 5% in the case of PPG-1025, PEG-600 and PBDO-700 extractants, respectively.

3.2. Effect of pH on extraction

The optimum pH for a maxim percent extraction was determined by carrying out the extraction with fixed concentrations of polyoxyalkylenes (0.3 M), picric acid (0.055 M) and the metal ion to be extracted (100 ppm). However, the pH of the aqueous phase was varied by incremental additions of 0.1 M sodium hydroxide solution. It was not possible to raise the pH to values higher than 5.5 due to hydrolysis of the metal ions in the aqueous phase. In fact, the aqueous solutions became turbid at pH values higher than 5.5 and a decline in the percent extraction was observed.

Fig. 1 shows the extraction of Pr^{3+}, Eu^{3+} and Er^{3+} by PPG-1025 in nitrobenzene (curves 1, 2 and 4, respectively) under the conditions

mentioned above. Curve 3 of Fig. 1 shows the pH effect on the extraction of Eu^{3+}, for example, by PPG-1025 in 1,2-dichloroethane. It is obvious from all curves that the percent extraction increases by increasing the pH until it levels off at pH > 3.5 for all metal ions studied. This behavior has been noticed irrespective of the polyoxyalkylene system or the organic diluent used. Thus, the optimum pH for an efficient extraction lies within the range of 3.5–5.5. The low extractability at low pH values may be attributed to the proton extraction to the organic phase rather than the metal ion itself. However, the increase in pH facilitates the dissociation of picric acid and more picrate will be available for extraction.

3.3. Effect of polyoxyalkylene and the organic diluent on extraction

Extraction of metal ions has been caried out from aqueous solutions containing about 100 ppm of the metal ion, 0.055 M picric acid at pH 4.5, a value within the optimum pH range, using varying concentrations (from < 0.01 to ~ 0.3 M) of polyoxyalkylene. The percent extractions of Eu^{3+}, for example, by PPG-1025 and PEG-600 in

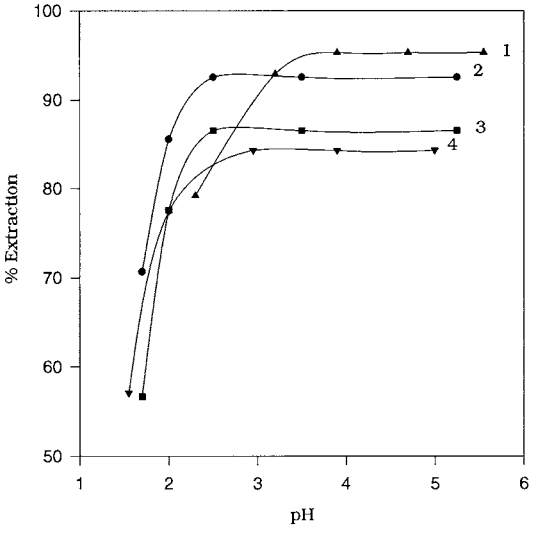

Fig. 1. Extraction of lanthanide metal ions from aqueous medium containing 100 ppm M^{3+}, 0.055 M picric acid at various pH values by 0.3 M PPG-1025. (1) Pr^{3+} into nitrobenzene, (2) Eu^{3+} into nitrobenzene, (3) Eu^{3+} into 1,2-dichloroethane, (4) Er^{3+} into nitrobenzene.

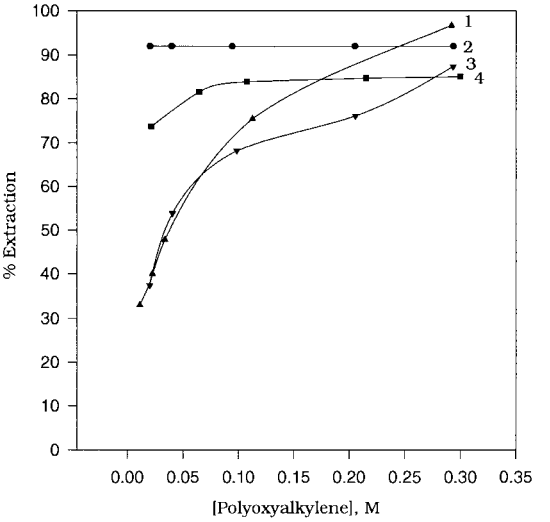

Fig. 2. Extraction of europium from aqueous medium containing 100 ppm Eu^{3+}, 0.055 M picric acid at pH 4.5 into organic phase containing various concentrations of polyoxyalkylenes in nitrobenzene or 1,2-dichloroethane. (1) PBDO-700 in nitrobenzene, (2) PPG-1025 in nitrobenzene, (3) PPG- 1025 in 1,2-dichloroethane, (4) PEG-600 in nitrobenzene.

nitrobenzene have reached their maximum values at polyoxyalkylene concentrations as low as $<$ 0.05 M (Fig. 2, curves 2 and 4). Same behavior has also been observed for Pr^{3+} extraction by PPG-1025 and PEG-600 under same conditions. However, the effect of polyoxyalkylene concentration on extraction efficiency was more significant in cases such as PBDO-700 in nitrobenzene (Fig. 2, curve 1) and all polyoxyalkylene systems in 1,2-dichloroethane (Fig. 2, curve 3 as an example). The percent extraction for these systems has increased as a function of concentration and became almost quantitative when its concentration in nitrobenzene became 0.3 M indicating the insignificance of a further increase in polyoxyalkylene concentration.

Table 1 shows the maximum percent extractions obtained at 0.3 M polyoxyalkylenes in the presence of 0.055 M picric acid in the aqueous phase at pH 4.5. The table indicates that the trend for extraction efficiency of Eu^{3+} by polyoxyalkylene in nitrobenzene organic phase was in the order PBDO-700 > PPG-1025 > PEG-600. This behavior may be attributed to the relative hydrophobic shielding of the alkyleneoxide units to the dehydrated metal ion when the ion-pair is

formed in the organic phase. The hydrophobicity may increase in the order of PEG (with the ethyleneoxide units, $-CH_2-CH_2-O$) < PPG (with propyleneoxide units, $-CH(CH_3)CH_2-O$) < PBDO (with butadieneoxide units $-CH_2-CH=CH-CH_2O$). However, the extraction of Eu^{3+} under same conditions but with 1,2-dichloroethane as the organic phase was in the order PPG-1025 > PBDO-700 ≈ PEG-600. Thus, the extraction selectivity with respect to PPG-1025 and PBDO-700 is reversed when a relatively low dielectric constant organic solvent is used.

The extraction efficiency has been found to be dependent, also, on the molar mass of the polyoxyalkylene system, that is, the number of alkylene oxide units surrounding the metal ion. The percent extractions of Pr^{3+}, Eu^{3+}, and Er^{3+}, from 0.055 M picric acid at pH 4.5 using 0.15 M of PPG have been found as 80.0, 82 and 75.0%, respectively, when PPG-1025 was used, meanwhile they have been increased to about 93, 94 and 84%, respectively, when PPG-2000 was introduced into the nitrobenzene organic phase. Same trend but with a higher relative increase has been observed when 1,2-dichloroethane was the diluent in the organic phase; for example, the percent extraction of Eu^{3+} has been increased from 40.0% in the case of PPG-1025 to 59% in the case of PPG-2000. A similar trend has been reported previously [7,13,24,25] for some transition metal ions, alkali and alkaline earth metal ions using various polyethylene glycols, polypropylene glycols, poly(oxyethylene) and poly(oxyethylene) derivatives of different molar masses. The enhancement of extraction has been ascribed [7] to the increase of hydrophobic property by the increase of the number of alkyleneoxide units.

Table 1
Percent extractions of Eu^{3+}, Pr^{3+} and Er^{3+} with various polyoxyalkylenes at the optimum conditions

Poly-oxyalkylene	M^{3+}	Organic phase	
		Nitrobenzene	1,2-Dichloroethane
PPG-1025	Eu^{3+}	92.7	87.4
	Pr^{3+}	95.8	91.2
	Er^{3+}	80.3	61.4
PEG-600	Eu^{3+}	85.0	60.0
PBDO-700	Eu^{3+}	96.7	61.1

[M^{3+}] 100 ppm, pH 4.5, $[\text{Picric acid}]_{\text{initial}}$ 0.055 M, [polyoxyalkylene] 0.3 M in nitrobenzene or 1,2-dichloroethane organic phase.

Table 1 also shows that percent extractions of the three metal ions by PPG-1025 in either nitrobenzene or 1,2-dichloroethane is in the order $Pr^{3+} > Eu^{3+} > Er^{3+}$. This trend is consistent with the ionic radii of the metal ions studied (ionic radii for Pr^{3+}, Eu^{3+} and Er^{3+} are: 1.013, 0.950 and 0.881 Å, respectively). A similar trend has been reported for the extraction of some lanthanide metal ions with crown ethers [18]. Since the ion-pair formation in the organic phase should be preceded by dehydration of the metal ions, Pr^{3+} with the relatively larger ionic size and the smallest relative hydration energy is expected to show the highest relative extractability.

All extractions studied were carried out using nitrobenzene and 1,2-dichloroethane as diluents in the organic phase. The percent extraction in the case of nitrobenzene was always higher than that of 1,2-dichloroethane regardless of pH of the aqueous phase, the polyoxyalkylene system or the metal ion. This behavior may be attributed to the configuration of the ion-pair formed in the organic solvent as suggested earlier [26]. The polyoxyalkylene molecule coordinates to the metal ion through the ether oxygen atoms and it wraps around the cation in a helical configuration which is stabilized in an organic solvent of high dielectric constant. Further more, the energy of solvation of picrate lipophilic anion by nitrobenzene is greater than that by 1,2-dichloroethane [26].

3.4. Effect of metal ion concentration on extraction

Europium has been extracted from aqueous solutions containing various concentrations of Eu^{3+}, 0.033 M picric acid at pH 4.5 into nitrobenzene or 1,2-dichloroethane containing 0.3 M PPG-1025. The percent extraction of Eu^{3+} was constant (about 92%) up to about 100 ppm Eu^{3+} (Fig. 3) then it showed a significant drop in either nitrobenzene or 1,2-dichloroethane; in fact, the percent extraction has dropped down to about 25% when the initial concentration of Eu^{3+} has reached 357 ppm (Fig. 3).

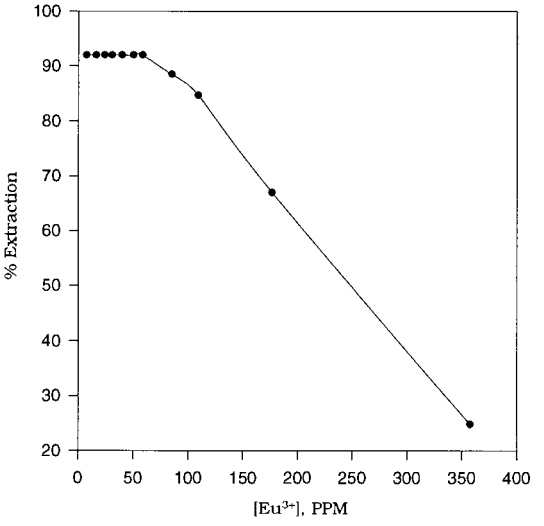

Fig. 3. Extraction of europium from aqueous medium containing various concentrations of Eu^{3+}, 0.033 M picric acid at pH 4.5 by 0.3 M PPG-1025 in nitrobenzene.

This behavior may be attributed to the depletion of picrate anion in the aqueous phase which is necessary to form the species, $M^{3+}.Pic^-$ which is readily extracted to the organic phase. Repetitive extraction experiments were carried out in which Eu^{3+} has been extracted from aqueous phases containing >100 ppm Eu^{3+} in the presence of 0.033 M picric acid at pH 4.5 into either nitrobenzene or 1,2-dichlorethane phase containing 0.3 M PPG-1025. In each experiment, a fresh organic phase has been added in the second extraction step; almost nothing has been extracted in the second step. This indicates the vital role of picrate which has been almost depleted in the first step. At high picric acid concentrations, some picrate may be transferred to the organic phase in the form of molecular picric acid [23] decreasing the chance for ion-pair formation with the metal ion M^{3+}.

3.5. Evaluation of ion-pair stoichiometry and extraction efficiency

In a series of experiments the initial concentration of polyoxyalkylene, $[L^*]_{initial}$ in 1,2-dichloroethane, was varied in the range of 0.01 to 0.3 M fixing the concentration of the metal ion, $[M^{3+}]$, at a level of 100 ppm (6.7×10^{-4} M), that of picric acid at 0.055 M and the pH at a value of 4.5 (a value within the optimum pH range for extraction). Thus, the conditions for Eq. (7) are met. Since $[L^*]_{initial} >> [M^{3+}]$ even with the lowest polyoxyalkylene concentration (~ 0.01 M), the equilibrium concentration of poloxyalkylene, [L*] in Eq. (7) may be replaced by the initial concentration, $[L^*]_{initial}$. Consequently, the number of moles of AOUs, required to combine with one mole of metal ions has been estimated from plots of log D against log $[L^*]_{initial}$. Plots for the ion-pairs of PPG-1025 ($n = 17.4$ propyleneoxide units, POU) with the M^{3+}-picrate species are shown in Fig. 4, curves 1, 2 and 3. The correlation coefficients for these curves were better than 0.99 in most cases. From the slopes of these curves it was possible to find that each mole of metal ions studied (Pr^{3+}, Eu^{3+} or Er^{3+}) is bound to about 13 to 14 moles of POUs (Table 2). However, when the data were plotted for extraction of Eu^{3+} with PEG-600 or PBDO-700 (Fig. 4, curves 4 and 5, respectively) it is found that number of ethyleneoxide units, EOU, estimated per a mole of

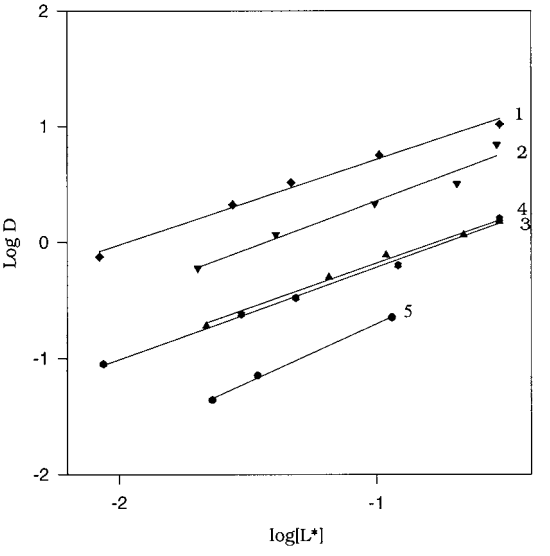

Fig. 4. Log D versus log [L*] for lanthanide metal ions extracted by PPG-1025, PEG-600 and PBDO-700 in 1,2-dichloroethane. [Picric acid] 0.055 M, $[M^{3+}]$ 100 ppm, pH 4.5. (1) Pr^{3+} by PPG-1025, (2) Eu^{3+} by PPG-1025, (3) Er^{3+} by PPG-1025, (4) Eu^{3+} by PEG-600, (5) Eu^{3+} by PBDO-700.

Table 2
Number of moles of alkyleneoxide units (AOU)[a] associated with a mole of M^{3+} extracted from an aqueous phase containing 0.055 M picric acid and 100 ppm of metal ion, into 1,2-dichloroethane containing varied concentrations of polyoxyalkylene

Polyoxyalkylene	M^{3+}	No. AOUs/metal ion[a]	Log K_{ex}
PPG-1025	Eu^{3+}	14.4	3.50
PPG-1025	Pr^{3+}	12.8	3.78
PPG-1025	Er^{3+}	13.8	2.91
PEG-600	Eu^{3+}	10.2	2.94
PBDO-700	Eu^{3+}	10.0	2.63

Log K^{a}_{ex} values for the ion-pairs $POA.M^{3+}.pic^{-}$ are also given.
[a] Number of AOUs and Log K_{ex} values for the ion-pairs are calculated, respectively, from the slopes and the intercepts of the curves in Fig. 4.

Eu^{3+} in the ion-pairs of PEG-600 ($n = 13.2$ EOU) is about 10 and number of moles of butadieneoxide units, BDOU, per a mole of Eu^{3+} for the ion-pairs of PBDO-700 ($n = 10$ PDOU) is also about 10 (Table 2). The curves for BBDO-700 were not linear thus only the linear portion of the curve was considered for the stoichiometry estimation as shown in Fig. 4, curve 5. Thus, the stoichiometry of the ion-pairs in the case of PBDO-700 is almost 1:1, PBDO:Eu^{3+}. These results are consistent with what has been reported earlier, where about 12 moles of EOUs or POUs are associated with a mole of alkaline earth metal ions [27].

On the other hand, another set of experiments have been carried out in which the concentration of the metal ion, M^{3+}, was fixed at 100 ppm (6.7×10^{-4} M), the picric acid concentration, [HX], was varied in the range of 0.01 to 0.055 M and the polyoxyalkylene concentration was fixed at 0.1 M in either nitrobenzene or 1,2-dichloroethane organic solvent. Since $[\text{picric acid}]_{initial}$ was $>> [M^{3+}]_{initial}$, hence the conditions for Eq. (7) are fulfilled. Thus log D was plotted against log $[\text{picric acid}]_{initial}$ according to Eq. (7). Typical plots are shown in Fig. 5 for the extraction of Eu^{3+} (curves 2 and 4) and Er^{3+} (curves 1 and 3) into PPG-1025 in nitrobenzene or 1,2-dichloroethane. All curves plotted indicate a linear relationship with a correlation coefficient better than 0.99 and a slope of about 3 (ranging from 2.7 to 3.2) regardless of the polyoxyalkylene system, the type of metal ion or the solvent in the organic phase. Consequently, M^{3+}-picrate species stoichiometry is consistent with what is expected for a trivalent metal ion with a univalent anion. This finding confirms the validity of the model assumed for extraction according to Eqs. (1)–(7) mentioned above.

Further more, Log K_{ex} values for the various metal ions with the polyoxyalkylenes studied have been estimated from Eq. (7) assuming that $z = 3$ and k_a of picric acid = 0.513; these values are shown in Table 2. It is obvious from Table 2 that Log K_{ex} values estimated under same conditions of pH indicate that the trend for extraction efficiency of Eu^{3+} into the 1,2-dichloroethane phase was in the order PPG-1025 > PEG-600 > PBDO-700. However, the extraction efficiency for the metal ions by PPG-1025 was in the order $Pr^{3+} > Eu^{3+} > Er^{3+}$.

The separation factors (K^{I}_{ex}/K^{II}_{ex}) for Pr^{3+}/Eu^{3+}, Pr^{3+}/Er^{3+} and Eu^{3+}/Er^{3+} were calculated from log K_{ex} values given in Table 2 and found to be 1.9, 7.4 and 4.0, respectively.

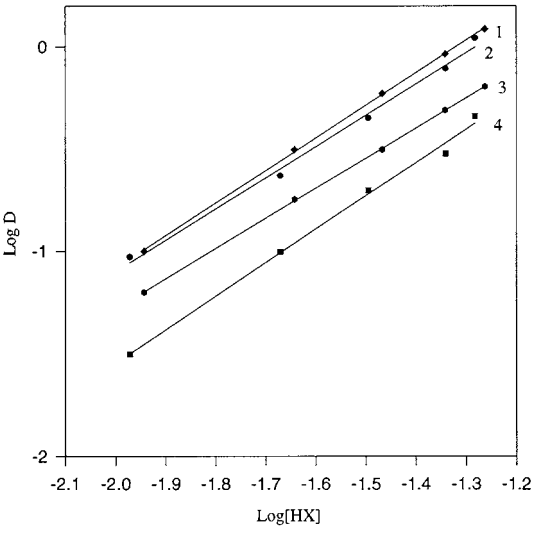

Fig. 5. Log D versus log [HX] for lanthanide metal ions extracted by PPG-1025. (1) Er^{3+} into nitrobenzene, (2) Eu^{3+} into nitrobenzene, (3) Er^{3+} into 1,2-dichloroethane, (4) Eu^{3+} into 1,2-dichloroethane. [Picric acid] 0.055 $[M^{3+}]$ 100 ppm, [Polyoxyalkylene] 0.1 M.

Attempts were made to apply similar extraction studies for the same systems under same conditions but in the presence of nitrobenzene as the organic diluent. Since the extraction has been carried out at the optimum pH (4.5), the percent extraction has reached its maximum values for most systems at the lowest polyoxyalkylene concentrations used. Thus, plots of $\log D$ against $\log [L^*]_{initial}$ were leveled off at very low polyoxyalkylene concentrations. Consequently, extraction experiments were carried out under same conditions but without pH adjustment. In fact, the pH measured was 2 or below where the extraction efficiency for all systems is very low. plots of $\log D$ against $\log [L^*]_{initial}$ under these conditions were in a similar fashion as those for 1,2-dichloroethane mentioned above. The slopes of the curves showed that each mole of metal ions (Pr^{3+}, Eu^{3+}, Er^{3+}) studied is bound to about 14 moles of POUs, 9 EOUs and 10 BDOUs. Log K_{ex} values estimated from Eq. (7) indicated that the efficiency of extraction for the metal ions studied by the polyoxyalkylene systems was in the same order as that in the case of 1,2-dichlorotethane organic phase diluent.

4. Conclusion

Lanthanide metal ions represented by europium, praseodymium and erbium can be extracted near quantitatively from their aqueous solutions in the presence of a lipophilic anion, namely, picrate anion, which forms an extractable species with the lanthanide metal ions. the extraction is facilitated by ion-pair formation with a polyoxyalkylene system in an organic solvent which should possess a fairly high dielectric constant. The optimum conditions for a maximum percent extraction are: [Picric acid] 0.05 M, pH 3.5–5.5, [Polyoxyalkylene] 0.3 M, as well as nitrobenzene as the organic phase. The extraction efficiency was in the order $Pr^{3+} > Eu^{3+} > Er^{3+}$. A larger number of alkyleneoxide units for the same type of polyoxyalkylene (higher molar mass) provides better extraction efficiency for these metal ions. The extraction efficiency under the optimum conditions mentioned above for the same metal ion by different polyoxyalkylenes was in the order PBDO > PPG > PEG in the case of nitrobenzene organic solvent, but when 1,2-dichloroethane was the organic solvent the extraction efficiency was in the order PPG > PBDO ≈ PEG. It has been found that 13 to 14 propyleneoxide units are associated with a metal ion in each ion-pair with PPG-1025 molecule. In the case of PEG-600, about 9 to 10 ethyleneoxide units were associated with a metal ion per an ion-pair. However, for the ion-pairs with PBDO-700 the stoichiometry was 1:1, M^{3+}:PBDO. In all cases the species extracted from the aqueous phase was M^{3+}:3 picrate confirming the validity of the proposed extraction equilibria.

The reproducibility of the extraction experiments has been checked for extraction of Eu^{3+} at the optimum conditions by PBDO-700 in nitrobenzene and found excellent; the relative standard deviation for 10 replicates was 0.27%.

Effect of interfering ions on hexamethyldisiloxane microdiffusion method

R.W. Kahama *, D.N. Kariuki, L.W. Njenga

Received 21 June 1996; received in revised form 16 December 1996; accepted 3 February 1997

Abstract

Acid diffusion in the presence of hexamethyldisiloxane (HMDS) enables complete recovery of ionic fluoride from standards containing varying concentrations of aluminium as one of the main interfering ions. Acid diffusion without HMDS shows a decrease in fluoride recovery as aluminium ion concentration increases. The fluoride concentration in the trapping solution is determined directly on the diffusion cover with a combination fluoride electrode after neutralising and buffering. The same procedure was used for the analysis of fluoride in soil and plant materials containing high concentrations of aluminium ions. For the same samples, the concentrations of aluminium, iron and silicon were determined using atomic absorption spectrophotometer (AAS). © 1997 Elsevier Science B.V.

Keywords: HMDS microdiffusion; Interfering ions; GLC

1. Introduction

The determination of fluoride has been greatly facilitated by the increased adoption of diffusion procedures for the separation of fluoride from interfering substances and the introduction of suitable buffers. Severe problems still arise in separation methods for trace fluoride analysis in biological specimens due to interfering ions [1]. These ions have been removed by precipitation at pH 8–9 [2] and by the use of complexing agents such as Tiron, CDTA and EDTA [3].

In diffusion procedures, few authors have considered the effect of interfering ions, which form strong complexes with fluoride, on the rate of diffusion [4]. Some authors [5] have used sulphuric and perchloric acids for diffusion at 60°C for 20 h to find the effect of aluminium and silicon on fluoride recovery from standards. Both ions showed higher interference in sulphuric acid.

The use of HMDS in diffusion experiments have provided a more rapid method for fluoride separation at room temperature [6]. Its use has become widespread due to its simplicity and adaptability to fluoride determination in large number of samples. Several authors [7–9] have used and modified the method in the analysis of different biological samples. However, the effect of interfering ions on the rate of HMDS-aided

PII S00 9-9140(97)00041-6

diffusion is not well documented. Aluminium levels in vegetables and plants have been reported to be in the range of 180–1350 μg g^{-1} [2] and this work addresses itself to whether such aluminium values would interfere with fluoride separation while using HMDS in standards, soils and plant materials. The effects of the presence of iron and silicon on fluoride recovery have also been considered.

2. Experimental

2.1. Apparatus

Combination fluoride ion-selective electrode (Orion, Cambridge, MA, USA, model 96-09), ion analyzer (Orion Model 407A and 920A), polystyrene Petri dishes 60 × 15 mm, Finn pippettes, polystyrene tips, shaker (GFL model 315), AAS Perkin Elmer model 2380, gas chromatograph (Chrompack model CP9001), and centrifuge.

2.2. Reagents

All chemicals were of analytical grade. Double distilled deionised water was used throughout the work. Reagents and solutions were freshly prepared and stored in plastic bottles except perchloric acid. Diffusion acid was prepared as reported by Kimarua et al. [10].

2.3. Aluminium standard solution

Aluminium standard solution was prepared by dissolving 13.90 g of hydrated aluminium nitrate $[Al(NO_3)_3 \cdot 9H_2O]$ in 250 cm^3 of water then made up to 1 l to make 1000 mg l^{-1}. It was stored in a plastic bottle.

2.4. Standard fluoride solution

First, 2.210 g of sodium fluoride (initially dried for 2 h at 120°C) was dissolved in 250 cm^3 of water, then made up to 1 l to give 1000 mg l^{-1}. This was stored in a plastic bottle.

2.5. Silicon standard solution

A solution containing 10 mg l^{-1} (500 mg l^{-1} for soil samples) was prepared by mixing 1.30 g of hydrated silicic acid powder ($SiO_2 \cdot nH_2O$) with 5 cm^3 of water. Then, 1.52 g of sodium hydroxide pellets were added to the mixture and shaken gently. After complete dissolution 30 cm^3 of water was added and allowed to cool. The solution was then diluted to 50 cm^3 with water and stored in a plastic bottle.

2.6. Iron standard solution

First, 1000 mg l^{-1} iron solution was made by dissolving 8.63 g of hydrated ammonium iron(III) sulphate $[NH_4Fe(SO_4)_2 \cdot 12H_2O]$ in water and diluted to 1 l. The solution was stored in a 1 l plastic bottle.

2.7. Procedure with ion-selective electrode

For fluoride analysis, polystyrene Petri dishes whose lids had been edged with acetone then rinsed with water were used. On each lid, a hole was made about 1.5 cm from the edge, using a soldering iron. The hole was for adding acid and sample using a Finn pipette. Then, 50 μl of 0.5 M sodium hydroxide was applied on the lid in form of eight drops. After replacing the lid, the Petri dish was sealed all round with a strip of parafilm. A 2.0-cm^3 aliquot of fluoride standard solution with a known amount of aluminium was put through the hole at the bottom of the Petri dish which contained 0.2 cm^3 of 1.0 M silver nitrate. Then, 2.0 cm^3 of 4.0 M perchloric acid was added and the hole quickly covered with a piece of parafilm. The dishes were placed on a shaker for 6 h at room temperature (20–23°C). After 6 h the lids were kept in a dessicator for the drops to dry. The dried up drops were dissolved in 50 μl of 0.5 M HCl and 50 μl TISAB II (pH 5.2) and the fluoride measured with a combination fluoride electrode. The same procedure was repeated using 0.1 g of plant materials and g of soil samples. Calibration standards and blanks were also subjected to the same diffusion procedures.

Table 1
Fluoride recovery from 1.0 and 2.0 μg ml^{-1} fluoride standard solution in the presence of 0.0–1000 μg ml^{-1} aluminium ions at room temperature with and without HMDS

Aluminium added (μg ml^{-1})	Mean percentage recovery			
	With HMDS		Without HMDS	
	A	B	A	B
0.0	100.0	99.0	6.2	6.0
100.0	103.0	102.0	1.8	1.6
200.0	102.0	98.0	1.4	1.2
500.0	102.0	99.0	—	0.7
800.0	100.0	100.0	—	—
1000.0	103.0	102.0	—	—

A, 1.0 μg ml^{-1} F.
B, 2.0 μg ml^{-1} F.
All concentrations are in μg ml^{-1}.
A dash (—) indicates that the fluoride concentration was below the detection limit.

2.8. Electrode calibration

NaF standards containing 0.1, 0.5, 1.0, 5.0, 10.0 and 20.0 μg ml^{-1} were prepared and treated the same way as the samples. Calibration of the electrode was done with two standards at a time on the 420A ion analyser (used for measurements in Table 1). At least five standards were used on the 920A concentration mode which then calculated the blank and the slope (used for measurements in Table 2). The measurement of the samples were carried out in a volume of 0.1 cm^3 and between measurements, the electrode was cleaned with water. The electrode was stored in 10 μg ml^{-1} NaF solution without any buffer. All the fluoride in the samples were concentrated above the detection limit of the electrode which was 0.02 μg ml^{-1}.

2.9. Procedure for gas liquid chromatography

Fluoride was determined on a CP9001 (Chrompack) gas chromatograph with a back flush system. It consists of a wide bore injection system, two wide bore columns of 10 and 25 m (WCOT Fused Silica with a coating of CP-SIL 5CB) and a flame ionisation detector [11]. The samples were weighed into 4 cm^3 borosilicate glass vials. Then, 0.5 cm^3 of water was added followed by 1 cm^3 of 8.0 M perchloric acid. The reagent solution was added which consists of 1 cm^3 toluene, 0.5% (v/v) trimethylchlorosilane (TMCS) and 0.0025% (v/v) iso-pentane (internal standard). The vial was closed immediately with a cap and septum. The reaction mixture was rotated overnight at 4°C then centrifuged for 2 min at 4000 rpm. A 1-μl sample was injected from the toluene layer to the column in duplicates and peak heights were determined and correlated to standard injections of known amounts of fluoride. Calibration curves were made with fluoride standards of 0.1–100 μg ml^{-1} from a stock solution of 1000 μg ml^{-1}. Straight lines were obtained with $r^2 = 0.999$.

Table 2
Concentration of fluoride in the sample

Sample	$[F^-]_1$	$[F^-]_2$	$[F^-]_3$	% Rec.	% CV
Tea bags	81.80	216.13	316.80	100.5	2.7
Green tea leaves	310.66	2280.00	2390.00	110.0	0.4
Terere Amaranthus	0.00	2.04	102.45	100.41	2.6
Spinach	0.00	4.64	105.09	100.45	5.7
Soil 113	15.56	100.00	200.33	100.33	2.2
Soil 118	22.17	229.75	338.00	108.25	1.2

$[F^-]_1$, fluoride levels in the absence of HMDS.
$[F^-]_2$, fluoride levels in the presence of HMDS.
$[F^-]_3$, fluoride levels in spiked samples (with 100 μg g^{-1} F) in the presence of HMDS.
CV, coefficient of variation for the recovery of spiked samples: S.D./Mean × 100.
All concentrations are in μg g^{-1}.

2.10. Aluminium, silicon and iron

Two procedures were follows:

1. Using hydrochloric acid and hydrofluoric acid for soil samples and concentrated nitric acid and perchloric acid for plant samples in the hot digestion method as reported in the AAS manual [12].
2. Using 4.0 M perchloric acid under the same conditions of the diffusion process. Then, 1.2 g of the samples were placed in plastic containers and 50.0 cm^3 of 4.0 M perchloric acid was added. The contents were placed on a shaker for 6 h. After filtering, the contents were analyzed for aluminium, iron and silicon using the AAS.

3. Results and discussions

In direct potentiometric analysis of fluoride, the tolerance limit of aluminium is 27 ppm at pH 6 and 2.7 ppm at pH 5.5 in the presence of Tiron as the masking agent [3], while in the indirect spectrophotometric method, the critical concentration is 22 ppm [13]. It is also indicated that the release of fluoride ion from aluminium varies with the masking reagent used, pH and the concentration of fluoride and aluminium ions. At the diffusion temperature of 60°C silicon forms a viscous gel in the presence of acids and thus reduces the rate of diffusion due to the trapping of the HF in the micellar spaces [5]. However, at room temperature, no gel is formed and the residue does not hinder the diffusion of trimethylflurosilane (TMFS). The documented interference during HF diffusion by Gustafsson and Njenga [5] indicates a decrease in fluoride recovery in standards as aluminium and silicon concentrations are increased. However, the literature on the effect of interfering ions on HMDS diffusion is scarce.

In the present study, the HMDS method was first tested with sodium fluoride standard solutions in the range 0.5–1.0 μg ml^{-1} with a recovery of 99.5–100.3% ($n = 4$) indicating high accuracy and precision of the method.

In the absence of aluminium and HMDS, acid diffusion at room temperature gave recoveries of about 5% added fluoride. This value does not change significantly for aluminium concentrations below 100 μg ml^{-1}. However, above 100 μg ml^{-1} aluminium, recoveries decreases and at 500 μg ml^{-1} no fluoride is recovered as shown in Table 1. It is stipulated that in the absence of HMDS, HF reacts with other HF molecules and with water to form higher molecular weight complexes which do not diffuse due to their high boiling points.

Table 1 also gives the recoveries of fluoride from 1.0 and 2.0 μg ml^{-1} fluoride standard solutions in the presence of 100–1000 μg ml^{-1} aluminium at room temperature in the presence of HMDS. Recoveries between 99.0–103.0% were realised indicating little or no interference from aluminium ions when HMDS is used.

The study was extended to four plant samples and two soil samples whose fluoride, aluminium, iron and silicon contents were determined. Table 2 shows the fluoride levels, recovery from spiked samples and analytical variations expressed as a coefficient of variation for the recovery of the added fluoride. Fluoride concentration ranges from as low as 2.0 μg g^{-1} in Terere (*Amaranthus*) to 2280 μg g^{-1} in green tea leaves. Regardless of the very high aluminium concentrations (Table 3), different levels of fluoride are obtained whose comparison with spiked samples gives acceptable recoveries with coefficient of variation between 0.4–5%. In the absence of HDMS, 10–15% fluoride was available for measurement except in tea bags which had 37%.

Table 3 gives the levels of aluminium, iron and silicon. Except for tea leaf samples, the aluminium levels during diffusion are lower than the total but high enough to have an effect during diffusion. The total levels of the ions are those obtained by extractions with acids different from the actual diffusion acids. To evaluate the actual concentrations of the ions during diffusion, perchloric acid was used for extraction and the levels determined by AAS.

The concentrations obtained are an indication of what is extracted by perchloric acid during diffusion. Such levels have been shown to fere with diffusion at 60°C but from the fluoride levels and recoveries, there is no interference in

the presence of HMDS. The study clearly indicates that HMDS can be used for samples with high levels of interfering ions without any interference in the diffusion and the procedure can be applied to biological materials having high levels of aluminium, silicon and iron.

In order to validate the results, the fluoride concentrations of similar samples were also measured with a GLC. Table 4 gives the percentages of fluoride in the samples while using both GLC and HMDS microdiffusion. The data indicate that the two methods are comparable. The principle behind the extraction of fluoride is similar in both methods based on acid-promoted reaction trimethylchlorosilane (TMCS) in GLC and HMDS in microdiffusion with fluoride.

Received 18 June 1996; received in revised form 7 January 1997; accepted 3 February 1997

Abstract

Using the model of ideally associated solution, the effect of ion association of the ion exchanger sites with main and foreign counterions on the selectivity of ISEs based on liquid ion exchangers has been considered. Equations which describe the potentiometric selectivity coefficient as a function of ion association constants in the membrane phase and of standard free energies of transfer of the determined and foreign ions from water to the membrane are obtained for the following main cases: (a) the determined and foreign ions are single-charged; (b) the determined ion is double-charged and the foreign ion is single-charged. It is shown that in the case of single-charged main and foreign ions, the ratio of the ion association constants has a great effect on the potentiometric selectivity of membranes, only if the ion exchanger sites produce less strong associates with the determined counterion as compared with the foreign one. Otherwise, this effect is insignificant. The selectivity for double-charged ions should increase, other things being equal, as the first constant of association of these ions with the ion exchanger sites increases. The effect of producing ion triplets of the type $I_2R^{(\pm)}$ on the selectivity of ISEs is also considered. Experimental data are presented which illustrate the effect of the nature of the ion exchanger on the potentiometric selectivity. Some procedures employing the factor of ion association for increasing the potentiometric selectivity of liquid ion exchange membranes are considered. © 1997 Elsevier Science B.V.

Keywords: Electrodes; Ion association; Potentiometric selectivity

1. Introduction

The presence of relationship between the potentiometric selectivity of ISEs and the relative strength of binding main and foreign ions with the ion exchanger site follows directly from Sandblom, Eisenman and Walker's theory [1] and is one of the most important conclusions of Nikolsky-Schultz's general theory of glass electrodes [2], whose main statements are applicable to some extent to membanes based on liquid ion exchangers. Stover and Buck [3,4] have shown that apart from forming ion pairs, the ratio of mobilities of ion exchanger sites and counterions in the membrane phase can also have an important effect on the selectivity coefficient. It should be noted that this effect increases with ion association. Armstrong and co-workers [5–7] have shown that

PII S00 9-9140(97)00042-8

mobilities of ion exchanger sites and counterions in plasticized polyvinylchloride membranes can differ by more than an order of magnitude. Thus, the possibility of exhibition of the mentioned effect seems quite realistic. On the other hand, experiments have shown that the nature of the ion exchanger usually does not have an important effect on ISE selectivity [8–11]. It is interesting to note that similar data were obtained both for fully dissociated nitrobenzene-containing membranes and for membranes with a relatively low dielectric constant. In general, this situation is consistent with results of the works on ion association [12,13], from which it follows that ion exchanger site-counterion association constants are almost independent of the ion nature. Moreover, Morf has shown [14] that even in those cases when charged ionophore tends to selective interaction with one of the ions, this property of the charged ionophore cannot be transformed completely into potentiometric selectivity. Therefore, for some time the concept prevailed that use of charged ionophores was not so promising as compared with neutral carriers as concerns achievement of high potentiometric selectivity.

However, for the recent 10–15 years the various anion-selective electrodes based on charged ionophores (derivatives of vitamin B_{12} [15–18], porphyrins [19–28], phthalocyanins [29], tin-organic, palladium-organic compounds [30–34] etc.) were described which were able to form sufficiently strong complexes with the determined ion. Selectivity of such electrodes differed substantially from selectivity of the Hofmeister series, which could not be explained reasonably within the formalism developed in [14]. Egorov and co-workers [35,36] have shown that the theoretical prohibition of the transformation of the selective ion exchanger affinity to the determined ion into potentiometric selectivity could be overcome, if the concentration of free ions of selective ion exchanger is stabilized in the membrane so that it could not change greatly in the course of the ion exchange reaction with the interfering ion. To do this, it was suggested to introduce into the membrane a lipophilic ionic additive having charge opposite to that of the ion exchanger sites and forming a rather well dissociating salt with the latter. It was shown experimentally that this procedure could, for example, increase substantially the selectivity to the cations of primary-tertiary amines as compared with quaternary ammonium cations which, according to [37], form less strong ion associates. The mechanism of functioning of the membranes based on highly selective ion exchangers (or charged carriers, according to the classification [38]) was thoroughly considered by Schaller and co-workers [39–41]. In particular, they showed that introduction of a lipophilic ion additive into the membrane was very important in the case of cation-selective electrodes but not so important in the case of anion-selective electrodes, since PVC membranes always contain anion admixtures that actually function as a lipophilic additive and provide selectivity close to optimal. Those authors obtained quantitative expressions for the electrode response and selectivity coefficients as a function of the membrane composition, solvation and complex formation parameters, which is important both for understanding of the functioning mechanism of such ISEs and for optimization of membrane compositions and measurements conditions.

In the present contribution the influence of the features of ion exchanger site-counterion interaction on the potentiometric selectivity of the membranes being in contact with sample solution containing both primary and interfering ions is discussed. New experimental data are presented which illustrate the effect of the ion exchanger nature on ISE selectivity.

2. Experimental

2.1. Reagents

2.1.1. Ion exchangers

Quaternary ammonium salts, namely, trinonyloctadecyl-ammonium (TNODA), dimethyldioctadecylammonium (DMDODA) and *N*,*N*,*N*-tridecyl-2-hydroxyethylammonium (TDHEA) were synthesized by stepwise alkylation of octadecylamine (the first two salts) and monoethanolamine, respectively, by halogen alkyls following the method of Veigand-Hilgetag [42].

The produced compounds were isolated and purified by extraction in the octane–dimethylformamide system [43]. For all compounds produced the contents of the main substance determined by nonaqueous potentiometric titration with respect to halogen ion was at least 99%. The contents of amine impurities in these compounds determined spectrophotometrically in the form of ion associates with picric acid following Lestchev et al. [44] did not exceed 0.01%. Trinonyloxybenzenesulphonic acid (TNBS) was produced by alkylation of pyrogallol by nonyl bromide followed by sulphonation [45]. The product was isolated and purified by extraction in the hexane–dimethylsulphoxide system. Di(2-decyloxyphenyl)phosphate (D(2DP)P) and di(3-nonyloxyphenyl)phosphate (D(3NP)P) were produced in the reaction of phosphorus chloroxide with the appropriate alkoxyphenol. These compounds were synthesized and purified following the procedure used for these kind of compounds [46]. For the last three compounds, the contents of the main substance determined by nonaqueous potentiometric titration amounted to at least 97%.

2.1.2. Plasticizers and solvents

Dibuthylphthalate (DBP), 1-bromnaphthalene (BN), *o*-nitrophenyloctyl ester (NPOE) and organic solvents toluene, nitrobenzene and cyclohexanone of reagent grade were purified by distillation. Dioctylphenylphosphonate (DOPP) was synthesized in the reaction of phenylphosphonedichloride with octanol following Cosolapoff [47]. Then, the product was isolated from the reaction mixture by extraction in the hexane and water/dimethylsulphoxide mixture (1:4). The isolated plasticizer was purified in the chromatographic column filled with S40/100 silicagel; the mobile phase was a chloroform/methanol mixture (9:1) [48]. Trihexylphosphate (THP) was purified from acid admixtures by treatment of hexane solution of the reagent with sodium hydroxide solution in the water/dimethylformamide mixture following [49]. 3-Nonyloxyphenol (NOP) was produced by alkylation of resorcinol by nonyl bromide. The product was distilled after extraction from the reaction mixture.

2.1.3. Polymer matrices and aqueous electrolytic solutions

Polyvinylchloride PZh-S70 was used as a polymer matrix of ISE membranes. Aqueous electrolytic solutions were prepared using distilled water. Dry salts used for these purposes were of at least analytical reagent grade.

2.2. Preparation of samples

Membranes of ISEs were prepared following the standard method [50]. The membrane compositions are presented in Table 1. Various interesting series of compounds of quaternary ammonium were obtained by ion exchange.

2.3. Measurements of ion exchange constants

Exchange of chloride for sulphate was studied at the constant temperature $T = 293 \pm 1$ K in the toluene-water system at an ion exchanger concentration of $1.7 \cdot 10^{-2}$ M. The contents of sulphate ions in the water phase varied in the range 0.005–1 M. After the system attained equilibrium the chloride ion concentration in the aqueous and organic phases was found by potentiometric titration by silver nitrate solution, and the sulphate ion concentration was found from the difference using the material balance equation. It was observed that the anion exchange constant depended substantially on the sulphate ion concentration, which is consistent with the available literature information [51] and can be ascribed to formation of the complex anion $NaSO_4^-$. Estimated concentration constants of anion exchange are given in Table 2.

2.4. Measurements of ion association constants

Ion association was studied at $T = 293 \pm 1$ K in the toluene–nitrobenzene system containing 10% v/v of nitrobenzene at constant current. Electric conductivities of a series solutions of quaternary amonium salts (QAS) were determined at concentrations of 10^{-2}–10^{-7} M. Then, the constants of ion association were calculated from the formula:

$$k_{ass} = (1 - \alpha)/(\alpha^2 \cdot C)$$

Table 1
The composition of produced ISE membranes

Membrane	PVC (%, w/w)	Plasticizer (%, w/w)				Ion exchanger (M)					NOP (w/w, %)
		DBP	THP	1-BN	NPOE	DOPP	TNODA	TDHEA	TNBS	D(3NP)P	D(2DP)P	DM-DODA	
I	33.3	66.6					$1.2\cdot10^{-1}$						
II	33.3		66.6				$1.2\cdot10^{-1}$						
III	33.3			66.6			$1.2\cdot10^{-1}$

XIII	33.3					66.6					$2.5\cdot10^{-2}$		

where α is the dissociation degree of QAS found with Stokes' method [52], C is the concentration of QAS in the solution.

2.5. Potentiometric measurements

Potentiometric measurements were taken at $T = 293 \pm 1$ K with an I-130 digital ionometer with an EVL-1M.3 silver–silver chloride reference electrode. Selectivity coefficients were determined with the method of mixed solutions for SO_4^{2-} ion selective electrode with a constant sulphate-ion background of 10^{-3} M and against the background of main ion of 0.1 M for the other ISEs. K_{ij}^{pot} was calculated from the equation:

$$K_{ij}^{pot} = \frac{a_i}{(a_j)^{z_i/z_j}} (10^{(E_2 - E_1)/\theta} - 1)$$

where a_i and a_j are the activities of the main and foreign ions; z_i and z_j are the charges of the main and foreign ions; E_1 and E_2 are the potentials of ISE in the background and mixed solutions; θ is the slope of the electrode function.

3. Results and discussion

3.1. The model of ideally associated solution. Single-charged ions

In media with low and moderate dielectric constants such as ISEs membranes (except those based on nitrobenzene or nitrogroup-containing plasticizers), liquid ion exchangers are present mainly in the form of ion associates with appropriate counterions, when the relative amount of free ions in the membrane is negligible. In these systems, the ion exchange constant determined experimentally is described by the equation:

$$K_{ij}^{(2)} = K_{ij}^{(1)} \cdot K_{jR}/K_{iR} \quad (1)$$

where $K_{ij}^{(2)}$ is the equilibrium constant of the ion exchange process, e.g., for cation-exchanger:

$$J_{aq}^{+} + \overline{RI} \xrightarrow{K_{ij}^{(2)}} I_{aq}^{+} + \overline{RJ} \quad (2)$$

$K_{ij}^{(1)}$ is the ion exchange constant only determined by standard free energies of transfer of ions I and J and is independent of the nature of the ion exchanger:

Table 2
The effect of the ion exchanger nature on the ion association, ion exchange and potentiometric parameters

Ion exchanger	Ion	Ion association constant	$K_{SO_4^{2-},Cl^-}$* for $C_{SO_4^{2-}}$		$K^{pot}_{SO_4^{2-},Cl}$
			$5\cdot10^{-2}$ M	1.0 M	
TNODA	SO_4^{2-}	$4.6\cdot10^{8}$	$4.8\cdot10^{1}$	$5.0\cdot10^{2}$	$1.5\cdot10^{3}$ (IX)
	Cl^-	$4.9\cdot10^{9}$			
	Pic^-	$3.1\cdot10^{8}$			
	$TPhB^-$	$4.1\cdot10^{7}$			
DMDODA	SO_4^{2-}	$4.8\cdot10^{8}$	$7.2\cdot10^{-1}$	5.0	$6.5\cdot10^{1}$ (X)
	Cl^-	$8.0\cdot10^{9}$			
	Pic^-	$5.9\cdot10^{8}$			
	$TPhB^-$	$2.7\cdot10^{7}$			

* $K_{SO_4^{2-},Cl^-}$ is the equilibrium constant of the process: $.2\ Cl^- + \overline{SO_4^{2-}\cdots(R^+)_2} \rightarrow 2\ \overline{Cl^-\cdots R^+} + SO_4^{2-}$

$$K_{ij}^{(1)} = \exp[(\Delta G_i^0 - \Delta G_j^0)/RT], \quad (3)$$

K_{iR} and K_{jR} are the constants of ion association of I^+ and J^+ counterions with the ion exchanger sites R^-. Thus, as it was shown by Eisenman [1], in highly associated systems, the ion exchange selectivity depends directly on the ratio of the constants of association of the ion exchanger sites with the corresponding counterions.

While considering the potentiometric selectivity, we restrict ourselves to the model including only the effect of the foreign ion J^+ on the interphase potential at the membrane–solution interface, assuming that for membranes based on liquid ion exchangers, the diffusion potential inside the membrane is unimportant. If the differences of the activities of ions I^+ and J^+ in the near-boundary layer and in the bulk of the sample solution are neglected, the effect of the foreign ion J^+ consists in changing the activity of the main ion I^+ in the membrane phase. In the first approximation this change may be described in terms of the concentration constants of ion exchange and of ion association. In the case of associated systems, concentrations of free (solvated by the solvent but not bound to the associates) ions is described by the equation:

$$\bar{C}_i = \frac{\bar{C}_{iR}}{K_{iR}\cdot\bar{C}_R} \quad (4)$$

where $\bar{C}_R$ is the concentration of the free ion exchanger site R^-. In the approximation of the model of ideally associated solution, this concentration is described by the equation

$$\bar{C}_R = \sqrt{\frac{\bar{C}_{iR}}{K_{iR}} + \frac{\bar{C}_{jR}}{K_{jR}}} \quad (5)$$

where $\bar{C}_{iR}$ and $\bar{C}_{jR}$ are the equilibrium concentrations of the corresponding ion associates described by the equations

$$\bar{C}_{iR} = \frac{\bar{C}_R^{tot}\cdot C_i}{C_i + K_{ij}^{(2)}\cdot C_j} \quad (6)$$

$$\bar{C}_{jR} = \frac{\bar{C}_R^{tot}\cdot K_{ij}^{(2)}\cdot C_j}{C_i + K_{ij}^{(2)} C_j} \quad (7)$$

where $\bar{C}_R^{tot}$ is the total concentration of the ion exchanger in the membrane.

It follows from Eqs. (4) and (5) that the change in the concentration of free counterions I^+ in the membrane that characterizes the interfering effect of the foreign ion J^+ is determined not only by completeness of the ion exchange process but also by the ratio of the ion association constants. Let the condition $K_{iR} > K_{jR}$ be satisfied. According to Eqs. (1) and (2) this should lead to a decrease in the concentration of the associate JR in the membrane. However, decrease in the portion of the less strong ion associate JR is compensated for, to a great extent, by its greater ability to generate free site R^-, which, according to Eq. (4), is accompanied by decrease in the concentration of the free counterion I^+ in the membrane. As a result, use of a selective ion exchanger producing stronger associates with the ion I^+ should not lead to appropriate increase in the potentiometric selectivity.

In this case the equation that expresses explicitly the experimentally determined potentiometric selectivity coefficient in terms of exchange parameters of the system can be easily obtained from the theory of ISEs based on liquid ion exchangers developed by Morf. According to [14], for an electrode immersed into the solution studied that contains simultaneously the determined and interfering ions the membrane potential is described by the equation:

$$E = E_i^0 + (1-\tau) \cdot RT/F \ln(a_i + K_{ij}^{(1)} a_j) + \tau \cdot RT/F \ln(a_i + K_{ij}^{(2)}) \quad (8)$$

where τ is the electric transport number of the ion exchanger site R^-, and $K_{ij}^{(1)}$ and $K_{ij}^{(2)}$ are physically the same as was defined above.

Assuming the diffusion potential to be zero, which is valid at $\tau = 0.5$ and combining Eq. (8) with Nikolsky's equation:

$$E = E_i^0 + RT/F \ln(a_i + K_{ij}^{pot} \cdot a_j) \quad (9)$$

we obtain

$$K_{ij}^{pot} = [(a_i + K_{ij}^{(1)} a_j)^{1/2} \cdot (a_i + K_{ij}^{(1)} \cdot K_{jR}/K_{iR})^{1/2} - a_i]/a_j \quad (10)$$

As follows from [3–7], neglect of the diffusion potential could hardly be considered quite reasonable. Nevertheless, to simplify the formalism, the assumption is ordinarily used in consideration of the effect of ion association on the potentiometric selectivity of the membrane [39–41,53].

If only foreign ions J^+ are presented in the solution analysed, Eq. (10) is reduced to the equation obtained in [39] for the separate solution method:

$$K_{ij}^{pot} = K_{ij}^{(1)} (K_{jR}/K_{iR})^{1/2} \quad (11)$$

When the association constants are equal ($K_{jR} = K_{iR}$), Eq. (10) is reduced to Nikolsky's ordinary equation.

In the general form analysis of Eq. (10) is rather difficult. Meanwhile, since this equation express explicitly the dependence of K_{ij}^{pot} on the constants of ion exchange and ion association, the effect of these parameters on K_{ij}^{pot} can be investigated in a simple way by mathematical modelling. The obtained results are presented in Fig. 1. It can be seen that $K_{ij}^{pot} \ll 1$ is the necessary condition for attainment of high selectivity for the ion I^+. In this case the ratio of ion association constants K_{iR}/K_{jR} is important only at $K_{iR} < K_{jR}$. On the contrary, at $K_{iR} \geq 10K_{jR}$ further increase in the constant of association of the ion exchanger site R^- with the main ion I^+ has actually no effect on K_{ij}^{pot} which tends to $(1/2)K_{ij}^{l}$. In the case when $K_{ij}^{l} \gg 1$, changes in the ratio K_{iR}/K_{jR} has some effect on K_{ij}^{pot} at $K_{iR} > K_{jR}$ as well. However, this case has no practical interest, since K_{ij}^{pot} is always larger than 1, tending to $(K_{ij}^{(1)})^{1/2}$.

Of course, by virtue of the assumptions made, the above scheme does not reflect the real situation quite rigorously. Nevertheless, it seems useful since it allows us to follow, at least qualitatively, the effect of ion association on K_{ij}^{pot}.

The present conclusions agree well with experimental data on the effect of the nature of the quaternary ammonium cation on K_{ij}^{pot}. The data are summarized in Table 3. It can be seen that an ISE based on salts of TDHEA containing a solvation-active OH group in the direct vicinity to the ion exchange centre, exhibit higher selectivity to sulphonate- and carboxylate-containing anions in the presence of perchlorate and picrate ions as compared with ISEs based on salts of TNODA. The observed effect can reasonably be explained

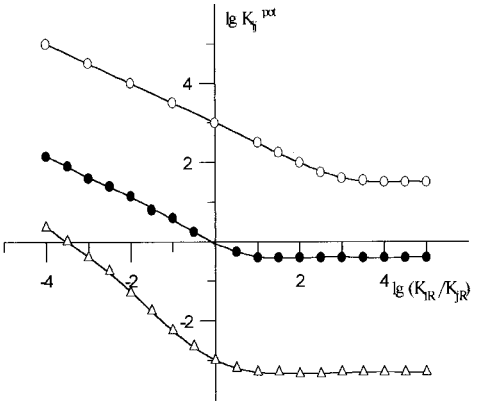

Fig. 1. Calculated selectivity coefficients for $I^{(\pm)}$ over $J^{(\pm)}$ for ion exchanger based membranes. To calculate the selectivity coefficients according to Eq. (10), the following assumptions were made: $a_i = a_j = 1 \cdot 10^{-2}$ M; $K_{ij}^{(1)}$ equals $1 \cdot 10^3$ (hollow circle); (filled circle); $1 \cdot 10^{-3}$ (hollow triangle).

Table 3
The effect of membrane components on the values of ISE selectivity coefficients in the presence of foreign ions

Determined ion	Plasticizer	Selectivity coefficients		$\frac{K_{ij}^{pot}(TNODA)}{K_{ij}^{pot}(TDHEA)}$
		Ion exchanger TNODA	Ion exchanger TDHEA

* The membranes contain 14% w/w 3-nonyloxyphenol.

by increase in the strength of ion associates produced by anions with TDHEA cations as a result of formation of a hydrogen bond additional to electrostatic interaction. It is natural that the strength of this bond should depend on polarity of the anion, increasing from picrate and perchlorate to sulphonate- and carboxylate-containing anions. This effect results in a 10–20-fold increase in the ion exchange constants for exchange of benzoic acid derivatives for perchlorate and 2,4-dinitrophenolate ions [54]. However, K_{ij}^{pot} values change only by a factor of 1.5 to 3. It is noteworthy that the observed change in K_{ij}^{pot} is almost independent of the nature of the plasticizer and persists in the presence of the specific solvating additive resorcinol monononyl ester.

Selectivity of such ISEs can be increased somewhat, if the membrane is manufactured so that it functions as an indirect electrode, when only a small part of the selective ion exchanger (5–10%) is in the form of the determined ion I and the other part is in the form of more lipophilic ion A which is slightly capable of being displaced by the main ion to the near-electrode layer of the sample solution ($K_{iA}^{(2)} \geq 10^4$). If this electrode is immersed in solution of the determined ion I, the concentrations of the ion associates IR and AR in the membrane remain almost invariant. Thus, the concentration of the lipophilic ion A, that appears in the near-electrode layer as a result of ion exchange, is proportional to the concentration of the main ion I in the sample solution and the potential is a linear function of C_i. In this case the effect of the foreign ion J should be exhibited to the extent at which it leads to changes in the concentration of the ion associate IR in the boundary layer of the membrane, i.e. in accordance with the experimental ion exchange constant $K_{ij}^{(2)}$. We tested this method for a toluenesulphonate selective electrode based on TDHEA (picrate was used as a lipophilic anion) and found that in the presence of perchlorate as a foreign ion the electrode selectivity was two times higher as compared to ISE based on individual salt form of this ion exchanger. The electrode works effectively at least 6 month and its main analytical characteristics (the detection limit, the slope of the emf response, stability of the potential) are not inferior to ISEs based on individual salt form, because of which the suggested method can be recommended for practice.

If the ion to be determined produces less strong associates with the ion exchanger site as compared with the interfering one, as it follows from the results discussed, the potentiometric selectivity always can be improved by decreasing the ratio of ion association constants K_{jR}/K_{iR}. In the case of quaternary ammonium cations ions) and primary–tertiary ammonium cations or alkaline metal cations (foreign ions) the required effect can

be easily achieved by using plasticizers with high dielectric constant, that according to [55], results in leveling of ion association constants. The efficiency of this procedure is confirmed experimentally as when *o*-nitrophenyloctyl ester or nonyl ester of *o*-nitrobenzoic acid is substituted for dibutylphthalate or dioctylphthalate, selectivity to quaternary ammonium cations becomes 3–10 times higher [35].

3.2. The model of ideally associated solution. Double-charged ions

If the membrane contains liquid ion exchanger, which is the salt of single-charged site R^- with double-charged counterion I^{2+}, according to [14], the membrane potential in the solution containing both the main ion I^{2+}, and the foreign single-charged ion J^+ is described by the equation:

$$E = E_i^0 + (1-\tau) \cdot RT/F \ln\left[\sqrt{a_i + \frac{1}{4}K_{ij}^{(2)}a_j^2} - \sqrt{\frac{1}{4}K_{ij}^{(2)}a_j^2} + \sqrt{K_{ij}^{(1)}a_j^2}\right] + \tau \cdot RT/F \ln\left[\sqrt{a_i + \frac{1}{4}K_{ij}^{(2)}a_j^2} + \sqrt{\frac{1}{4}K_{ij}^{(2)}a_j^2}\right] \quad (12)$$

where

$$K_{ij}^{(1)} = (2K_{iRR}/K_{jR})^2 \cdot K_{ij}^{(2)} \quad (13)$$

$$K_{ij}^{(2)} = (K_{jR} \cdot k_j)^2/(2\bar{C}_R^{tot} \cdot K_{iR} \cdot K_{iRR} \cdot k_i) \quad (14)$$

K_{iR} and K_{jR} are the ion association constants characterizing the ion pairing of ion exchanger site R^- with counterions I^{2+} and J^+ respectively, K_{iRR} is the ion association constant characterizing the ion pairing of ion exchanger site R^- with single-charged complex IR^+, k_i and k_j are so-called individual distribution coefficients proposed by Eisenman [1], $\bar{C}_R^{tot}$ is the total concentration of ion exchanger sites in the membrane.

Neglecting the diffusion potential and assuming $\tau = 0.5$, we obtain

$$E = E_i^0 + RT/2F \ln\left[a_i + \sqrt{K_{ij}^{(1)}a_j^2}\left(\sqrt{a_i + \frac{1}{4}K_{ij}^{(2)}a_j^2} + \sqrt{\frac{1}{4}K_{ij}^{(2)}a_j^2}\right)\right] \quad (15)$$

Combining Eq. (15) with Nikolsky's expanded equation for single- and double-charged ions:

$$E_i = E_i^0 + RT/2F \ln(a_i + K_{ij}^{pot} \cdot a_j^2) \quad (16)$$

we find:

$$K_{ij}^{pot} = \sqrt{\frac{K_{ij}^{(1)}K_{ij}^{(2)}}{4}} + \sqrt{\frac{K_{ij}^{(1)}K_{ij}^{(2)}}{4} + \frac{K_{ij}^{(1)}a_i}{a_j^2}} \quad (17)$$

With account of Eqs. (13) and (14), Eq. (17) can be transformed to the following form convenient for analysis:

$$K_{ij}^{pot} = \frac{1}{2} \cdot \frac{K_{ij}^{(3)}K_{jR}}{\bar{C}_R^{tot}K_{iR}} + \sqrt{\left(\frac{1}{2} \cdot \frac{K_{ij}^{(3)}K_{jR}}{\bar{C}_R^{tot}K_{iR}}\right)^2 + 2\frac{a_iK_{ij}^{(3)}K_{iRR}}{a_j^2\bar{C}_R^{tot}K_{iR}}} \quad (18)$$

where $K_{ij}^{(3)}$, a hypothetic ion exchange constant in a fully dissociated system, is described by the equation:

$$K_{ij}^{(3)} = k_j^2/k_i \equiv \exp[(\Delta G_i^0 - 2\,\Delta G_j^0)/RT] \quad (19)$$

ΔG_i^0 and ΔG_j^0 are standard free energies of transfer of ions I^{2+} and J^+ from aqueous phase into membrane. Eq. (18) is equally valid for anion exchange membranes too.

It follows from Eq. (18) that increase in K_{iR} as well as increase in $\bar{C}_R^{tot}$ should always be accompanied by increase in the potentiometric selectivity for double-charged ions in the presence of single-charged ones. On the contrary, increase in $K_{ij}^{(3)}$ and increase in K_{jR} should always lead to increase in the interfering effect of single-charged ions. This situation seems quite reasonable. At first glance, it is surprising that increase in the second constant of ion association of the primary ion with the ion exchanger site (K_{iRR}) is accompanied by deterioration of the selectivity. Two oppositely directed factors act in this situation. On the one hand, in accordance with ion exchange equilibrium, increase in K_{iRR} should lead to decrease in the concentration of ion associate JR in the membrane. On the other hand, as K_{iRR} increases

the role of the ion associate JR in the production of free ion exchanger sites R^- becomes more important, so that even small concentration of ion associate JR is able to lead to an essential change in the concentration of free sites R^-, and, as a result, of free ions I^{2+} in the membrane. Eventually, the net action of these factors leads to a weak dependence of K_{ij}^{pot} on K_{iRR}.

If in the analysed solution foreign ions J^+ are only present, Eq. (18) is simplified to:

$$K_{ij}^{pot} = (K_{ij}^{(3)} \cdot K_{jR})/(\bar{C}_R^{tot} \cdot K_{iR}) \quad (20)$$

It can be easily shown that Eq. (20) fully agrees with the expression of K_{ij}^{pot} obtained in [39] for ions of different charges when it is determined by the separate solution method:

$$K_{ij}^{pot} = \frac{\bar{C}_i}{k_i}\left(\frac{k_j}{\bar{C}_j}\right)^{z_i/z_j} \quad (21)$$

where $\bar{C}_i$ and $\bar{C}_j$ are the concentrations of free ions I^{z_i} and J^{z_j} in the boundary layer of the membrane, which is in contact with the sample solution containing the only ions I^{z_i} or J^{z_j}, respectively. Since, as follows from the Eigen-Denison-Ramsey-Fuoss' theory [56], $K_{iR} \gg K_{iRR}$, the dissociation of single-charged associate IR^+ makes a negligible contribution to the concentration of free sites R^-. Therefore, according to the equation of electroneutrality, in the absence of ion J^+ $\bar{C}_R \cong \bar{C}_{Ri}$. As a result, the concentration of free ions I^{2+} in the membrane is described by the equation

$$\bar{C}_i = \frac{\bar{C}_{iR}}{K_{iR} \cdot \bar{C}_R} \cong \frac{1}{K_{iR}} \quad (22)$$

If the membrane is in contact with solution containing only the foreign ion J^+, the concentration of free ions J^+ in the membrane phase is described by the equation:

$$\bar{C}_j = \bar{C}_R = \sqrt{\frac{\bar{C}_R^{tot}}{K_{jR}}} \quad (23)$$

Bearing in mind that $k_j^2/k_i = K_{ij}^{(3)}$ and substituting Eqs. (22) and (23) into Eq. (21), we obtain Eq. (20).

The present theoretical conclusions agree qualitatively with experimental data. It can be seen from the data summarised in Table 2 that ion exchange affinity to sulphate-ion depends substantially on the nature of the ion exchanger: the sulphate–chloride exchange constant becomes 70–100 times lower in the case of substitution of DMDODA for TNODA. Meanwhile, the ratio of the second constants of association of sulphate-ion and of single-charged ions with cations of these ion exchangers changes slightly. It suggests a strong dependence of the first constant of association of sulphate-ion on the nature of the ion exchanger. This suggestion seems quite reasonable in view of the fact that the sulphate-ion whose charge is distributed uniformly among four oxygen atoms is able to interact specifically with positively charged hydrogen atoms nearest to the cation centre provided their steric accessibility. It is evident that the interaction in the case of atoms carrying negative and positive charges, oriented in an optimal way and located at the closest distance from one another, should be more effective in comparison with 'indifferent' electrostatic attraction of ions when this interaction is impossible because of steric hindrances. This should lead to increase in the sulphate-ion association constant and manifest itself in potentiometric selectivity, which agrees qualitatively with experimental results (see Table 2).

It is interesting that in the case of indirect electrode, when 10% of DMDODA is in the sulphate form, and 90% is in the form of lypophilic borohydride $B_{10}H_{10}^{2-}$, the value $K_{SO_4^{2-},Cl^-}^{pot}$ is 3.5 times lower as compared with ISE based on $(DMDODA^+)_2SO_4^{2-}$ [57].

3.3. Violation of the model of ideally associated solution. The effect of forming ion triplets on ISE selectivity

If the ion exchanger interacts with the determined ion not only following the electrostatic interaction mechanism, but is also able to form coordination bonds with them and this ability is partly preserved after forming an ion-pair, favourable conditions are provided for formation of ion triplets of the type $I_2R^{(\pm)}$:

$$IR + I^{(\pm)} \overset{K_s}{\rightarrow} I_2R^{(\pm)} \quad (24)$$

In this case the ion associate IR is a kind of neutral carrier for $I^{(\pm)}$ and the equilibrium constant of this process is formally similar to the complex formation constant.

The equation which expresses the experimentally determined potentiometric selectivity coefficient in terms of ion exchange, ion association and complex formation constants can be obtained as follows. In the solution of determined ion the membrane potential is described by the equation:

$$E_1 = E_i^0 \pm \theta \lg[(a_i)_1/\bar{C}_i^0] = E_i^{0'} \pm \theta \lg(a_i)_1 \quad (25)$$

where $\bar{C}_i^0$ is the initial concentration of the ion $I^{(\pm)}$ in the membrane.

In the presence of the foreign ion $J^{(\pm)}$ in the solution studied, the equation is valid:

$$E_2 = E_i^0 \pm \theta \lg[(a_i)/\bar{C}_i] = E^{0'} \pm \theta \lg(a_i + K_{ij}^{pot} \cdot a_j) \quad (26)$$

where $\bar{C}_i$ is the concentration of the free ion $I^{(\pm)}$ in the membrane being in contact with the mixed solution. Subtracting Eq. (25) from Eq. (26) and performing simple manipulations, we obtained:

$$K_{ij}^{pot} = a_i/a_j \cdot (\bar{C}_i^0/\bar{C}_i - 1) \quad (27)$$

If the total portion of ions in membrane is relatively small, i.e. the ion exchanger primarily occurs in the form of ion-pairs, without foreign ions the concentration of ion triplets is described by the equation

$$\bar{C}_{i_2R}^0 = \bar{C}_i^0 \cdot C_R^{tot} \cdot K_S \quad (28)$$

With account of the equation of electroneutrality we obtain

$$\bar{C}_R^0 = \bar{C}_i^0 + \bar{C}_{i_2R}^0) = \bar{C}_i^0 \cdot (1 + \bar{C}_R^{tot} \cdot K_S) \quad (29)$$

Finally, expressing the value of $\bar{C}_i^0$ in terms of the constant of ion association and substituting $\bar{C}_R^0$ from Eq. (29), we have

$$\bar{C}_i^0 = \frac{\bar{C}_R^{tot}}{K_{iR} \cdot \bar{C}_R^0} = \sqrt{\frac{\bar{C}_R^{tot}}{K_{iR} \cdot (1 + \bar{C}_R^{tot} \cdot K_S)}} \quad (30)$$

In the presence of the foreign ion J not tending to formation of ion triplets, the condition of electroneutrality becomes

$$\bar{C}_R = \bar{C}_i(1 + \bar{C}_R^{tot} \cdot K_S) + \bar{C}_j \quad (31)$$

In this case it is assumed that the addition of I to the ion associate RJ is characterized by the same equilibrium constant K_S. Otherwise, more bulky expressions are obtained but the essence of the conclusions remains basically the same.

Expressing the free ion concentrations $\bar{C}_i$ and $\bar{C}_j$ in terms of ion association constants, we obtain

$$\bar{C}_R = (1 + \bar{C}_R^{tot} \cdot K_S) \cdot \frac{\bar{C}_{iR}}{K_{iR} \cdot \bar{C}_R} + \frac{\bar{C}_{jR}}{K_{jR} \cdot \bar{C}_R} \quad (32)$$

Solving the above equation for $\bar{C}_R$ and substituting the obtained value in Eq. (4), we obtain:

$$\bar{C}_i = \frac{\bar{C}_{iR}}{\sqrt{K_{iR}}} \cdot \frac{1}{\sqrt{(1 + \bar{C}_R^{tot} \cdot K_S) \cdot \bar{C}_{iR} + \frac{K_{iR}}{K_{jR}} \cdot \bar{C}_{Rj}}} \quad (33)$$

Substituting Eqs. (30) and (33) into Eq. (27) and expressing equilibrium concentrations $\bar{C}_{iR}$ and $\bar{C}_{jR}$ by Eqs. (6) and (7), one can evaluate K_{ij}^{pot}.

The qualitative effect of forming ion triplets on K_{ij}^{pot} can be traced by comparison of the ratios $\bar{C}_i^0/\bar{C}_i$ for the case considered and for ideally associated solution, when there are no ion triplets. It follows from Eqs. (30) and (33) that

$$\frac{\bar{C}_i^0}{\bar{C}_i} = \frac{\sqrt{\bar{C}_R^{tot}}}{\bar{C}_{Ri}} \cdot \sqrt{\bar{C}_{Ri} + \bar{C}_{Rj} \cdot \frac{k_i}{k_j} \cdot \frac{1}{1 + \bar{C}_R^{tot} \cdot K_S}} \quad (34)$$

If ion triplets are absent, then

$$\bar{C}_i^0 = \sqrt{\frac{\bar{C}_R^{tot}}{K_{iR}}} \quad (35)$$

And according to Eqs. (4) and (5) we obtain:

$$\frac{\bar{C}_i^0}{\bar{C}_i} = \frac{\sqrt{\bar{C}_R^{tot}}}{\bar{C}_{Ri}} \cdot \sqrt{\bar{C}_{Ri} + \bar{C}_{Rj} \cdot \frac{k_i}{k_j}} \quad (36)$$

Comparison of Eqs. (34) and (36) shows that in the case of forming ion triplets the contribution of the second term in the expression under the radical sign decreases proportionally to the factor $(1 + \bar{C}_R^{tot} \sim \cdot \sim K_S)$, which should be exhibited in the appropriate increase in the potentiometric selectivity for I. To summarize, it can be stated that forming ion triplets leads to increase in the concentration of free ion exchanger sites in the membrane. As a result, the concentration of the free

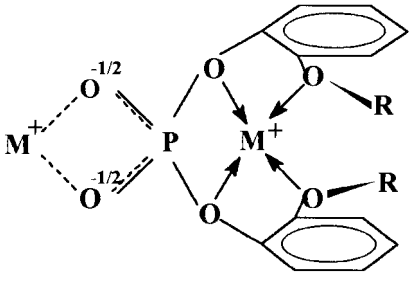
Table 4
The effect of the nature of the ion exchanger on cation exchange membrane selectivity reversible to calcium cation

Membrane	Selectivity coefficients relative to cations							
	Li^+	Na^+	NH_4^+	K^+	Mg^{2+}	Fe^{2+}	Cu^{2+}	Zn^{2+}
XI	10^{-2}	$2\cdot10^{-2}$	10^{-1}	$7\cdot10^{-3}$	$2.5\cdot10^{-2}$	$2\cdot10^{-2}$	$1.6\cdot10^{-2}$	$1.3\cdot10^{-2}$
XII	$2\cdot10^{-1}$	$1.6\cdot10^{-2}$	$6\cdot10^{-2}$	$4\cdot10^{-3}$	$5\cdot10^{-3}$	10^{-2}	$1.3\cdot10^{-2}$	$1.3\cdot10^{-2}$
XIII	$5\cdot10^{4}$	$1.6\cdot10^{2}$	$8\cdot10^{2}$	6	10^{-1}	$4\cdot10^{-1}$	$1.6\cdot10^{-1}$	$2.5\cdot10^{-1}$

ions I is also stabilized and not subjected to strong changes when rather small numbers of low-strength associates RJ penetrate into the membrane. This mechanism is likely to be realized in some anion-selective electrodes based on charged carriers capable of forming coordination bonds with appropriate anions.

We have found a very strong effect of the nature of the ion exchanger on the ISE selectivity in the study of Ca^{2+}–ISEs based on derivatives or orthophosphoric acid (see Table 4). For membranes based on TNBS and D(3NP)P the selectivity series typical of membranes based on dialkyl(aryl) phosphoric acids is observed. On the contrary, for membranes based on D(2DP)P the selectivity for single-charged ions, especially, for Li^+, increases substantially (by 4 and more orders of magnitude).

At present, we have no experimental data that could give inequivocal and complete explanation of the mechanism of the observed phenomenon. However, a most probable reason seems to be exhibition of a kind of the crown effect by D(2DP)P molecules containing alkoxysubstitutents in the ortho-position, which provide favourable conditions for coordination of single-charged ions that results in forming ion triplets:



For double-charged cations solvated effectively by strong base dioctyl-phenylphosphonate, formation of such complexes should be less beneficial.

4. Conclusion

The present experimental and theoretical results indicate that feasibilities of transforming ion exchange selectivity into potentiometric one are substantially different for single- and double-charged ions. In ideally associated ion exchange membranes, that do not contain ionic admixtures, increase in the efficiency of interaction of the ion exchanger with determined single-charged ions has an important effect on the value of K_{ij}^{pot} only when $K_{iR} < K_{jR}$, which agrees with theoretical results [14]. However, if $K_{iR} > K_{jR}$, then without special procedures intended to stabilize the ion exchanger sites $R^{(\pm)}$ concentration in the membrane phase, which are described in [35,39–41], the gain in K_{ij}^{pot} is not high, as a rule. The case, when the ion exchanger sites form ion triplets of type $I_2R^{(\pm)}$ with the determined ion can be exception. In this case ion associate IR functions as a kind of a neutral carrier for determined ion $I^{(\pm)}$.

In the case of double-charged ions, increase in the first constant of ion association of the main ion with the ion exchanger sites (K_{iR}), all other things being equal, should always lead to benefit in potentiometric selectivity.

Spectrophotometric study of the charge transfer complexes of some pharmaceutical butyrophenones

Hassan F. Askal

Pharmaceutical Analytical Chemistry Department, Faculty of Pharmacy, Assiut University, 71 526-Assiut, Egypt

Received 13 September 1996; received in revised form 5 November 1996; accepted 4 February 1997

Abstract

The molecular interactions between haloperidol and droperidol as electron donors and each of iodine; 7,7,8,8-tetracyanoquinodimethane (TCNQ); 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ); tetracyanoethylene (TCNE); 2,4,7-trinitro-9-fluorenon (TNF); and 2-3-5-6-tetrabromo-1,4-benzoquinone (Bromanil) as acceptors have been investigated spectrophotometrically. Different variables affecting the reaction were studies and optimized. Beer's law was obeyed in a concentration limit of 2.5–2500 μg ml^{-1} for the studied drugs with various acceptors used. Electron affinities (E_A) of the acceptors were found to correlate with both the time required for maximum colour formation and the molar absorptivities of haloperidol and droperidol. A Job's plot of the absorbance versus the molar ratio of the drugs to iodine indicated 1:1 ratio. The proposed methods were found to be rapid and sensitive and may be applied for estimation of named drugs in pharmaceutical dosage forms without interferences from the common additives encountered. Percentage recoveries ranged from 99.1–102.2%. © 1997 Elsevier Science B.V.

Keywords: Charge transfer complexes; Droperidol; Haloperidol; Spectrophotometry

1. Introduction

Different reported methods for the determination of haloperidol (I) and droperidol (II) butyrophenone neuroleptics have been reviewed [1,2]. The methods reported involve the following techniques: uv spectrophotometry [3], fluorometry [4,5], extraction photometry [6], condensation reaction with phenylhydrazine [7,8], reaction with 1,2-naphthoquinone-4-sulphonic acid [9], polarography [10,11], proton magnetic resonance spectroscopy [12] and high performance liquid chromatography [13–22]. USP XXII and NF XVII specify a non aqueous titrimetric method for the analysis of pure drugs and a uv spectrophotometric one for their dosage forms [23].

The molecular interactions between electron donors and acceptors are generally associated with the formation of intensely coloured charge transfer complexes, which absorb radiation in the visible region [24]. The photometric methods based on these interactions are usually simple and convenient because of the rapid formation of the complexes. Haloperidol and droperidol are good *n*-electron donors and will form charge transfer complexes with σ- or π-acceptors.

π-Acceptors such as TCNE, TCNQ, DDQ and *p*-Bromanil are known to yield charge-transfer

PII S00 9-9140(97)00043-X

complexes and radical anions with a variety of electron donors [24–26]. This donor-acceptor interaction has been investigated with two butyrophenones as electron donors (Scheme 1).

The reported spectrophotometric methods are either non specific, time consuming, indirect, or suffering from the disadvantage of low sensitivity. In addition, most of the published assay methods for butyrophenones were suggested for their determination in biological fluids rather than in pharmaceutical preparations.

This study describes simple, direct, sensitive and precise spectrophotometric methods for the determination of haloperidol and droperidol via complexation with σ and π-acceptors in their common dosage forms and irrespective of the presence of contaminants and additives.

2. Experimental apparatus

A Perkin-Elmer Lambda 3 B UV/VIS (Norwalk, CT, USA) and a Uvidec-320 (Tokyo, Japan) Spectrophotometers with 10 mm matched silica cells were used for all spectral measurements.

2.1. Chemicals and reagents

Haloperidol and droperidol were obtained from Gedeon Richter, Budapest, Hungary. Iodine resublimed, Riedel De-Haen AG, Germany, 8.5 mg ml^{-1} in 1,2-dichloroethane, the solution was stable for at least 1 week at 4°C.

7,7,8,8-tetracyanoquinodimethane (TCNQ), Aldrich Chem Co., Milwaukee, USA, 1 mg ml^{-1} in acetonitrile, the solution was stable for at least 1 week at 4°C.

2,3-Dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), Merck-Schuchardt, Munich, Germany, 2 mg ml^{-1} in methanol, the solution was prepared fresh daily.

Tetracyanoethylene (TCNE), Nacalai Tesque, Kyoto, Japan, 1 mg ml^{-1} in acetonitrile, was prepared fresh daily.

2,4,7-trinitro-9-fluorenon (TNF), Fluka, Switzerland), 2 mg ml^{-1} in acetonitrile, was prepared fresh daily.

2,3,5,6-tetrabromo-1,4-benzoquinone (*p*-Bromanil), Hopkin and William, Essex, England, 5 mg ml^{-1} in methanol, was prepared fresh daily.

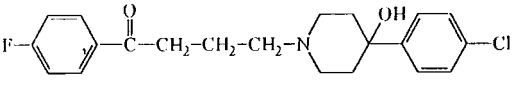
All solvents used are of analytical grade.

2.2. Pharmaceutical formulations

The following commercial formulations were subjected to the analytical procedures: Halodol® decanoas ampoules labelled to contain 70.52 mg decanoas ester of haloperidol equivalent to 50 mg haloperidol ml^{-1}, benzyl alcohol and sesame oil; Halodol® drops, labelled to contain 2 mg haloperidol ml^{-1} (Janssen Pharmaceutica I Beerse I, Belgium); Safinace® tablets; labelled to contain 5 mg haloperidol/tablet (Kahira Pharm. and Chem., Cairo, Egypt, under license of G.D. Searle, High Wycombe, England); Droperidol self prepared tablets, obtained by addition of 5 mg of droperidol to 50 mg each of starch and sucrose and 10 mg each of gum acacia, lactose, magnesium stearate and talc.

2.3. Standard solutions

Weigh accurately 1.25 g of either haloperidol or droperidol into a 50 ml calibrated flask. Dissolve the drug in methanol. Dissolve (DDQ or bromanil) in methanol, (TCNQ or TCNE) in acetonitrile and (iodine or TNF) in 1,2-dichloroethane give a final volume of 50 ml. Dilute quantitatively to obtain the suitable final concentration, Table 1.



Haloperidol (I)

[b] For droperidol.

2.4. Procedure

2.4.1. General procedure for colour development

In 10 ml calibrated flasks, place aliquots volumes containing 25–15 000 and 25–25 000 μg for haloperidol and droperidol, respectively. Add 1 ml of the reagent and dilute to the mark with the corresponding solvent, Table 1. Measure the absorbance of the solution at the wavelength of maximum charge transfer bands after the appropriate time at 25°C ± 5 against reagent blank treated similarly.

2.4.2. Tablets

Tablets, 20, of the drug were weighed and powdered. A quantity of the powdered tablets equivalent to about 50 mg drug was transferred into a 50 ml calibrated flask. Then, the procedure is followed as under for standard solutions.

2.4.3. Drops

Dilute an appropriate volume of the solution in a volumetric flask so as to represent 1 mg ml^{-1}. Proceed as directed under tablets.

2.4.4. Injection solutions

A volume of the solution containing about 50 mg drug was transferred into a 50 ml calibrated flask. then the procedure is followed as directed under tablets.

2.4.5. Molecular ratio of reactants in complex

The Job's method of continuous variation [27] with 2×10^{-3} M iodine solution with either 4.24×10^{-4} M haloperidol or 2.12×10^{-4} M droperidol bases were prepared in 1,2-dichloroethane.

3. Results and discussion

The immediate change of the violet colour of iodine in 1,2-dichloroethane (520 nm) to a lemon yellow upon reaction with the investigated compounds was taken as suggestive of charge transfer complex formation which justified scanning in the uv range for the new bands (Fig. 1). The complex formation is distinguished from other slow oxidation or substitution reactions of the halogens with butyrophenones, by being practically instantaneous, in analogy to ionic reactions. Further confirmation of the charge transfer nature of the reaction was obtained on extracting the drugs from the complex by shaking with aqueous mineral acid, whereby the violet colour of iodine in 1,2-dichloroethane was restored.

All measurements with iodine were performed at 295 and 365 nm for haloperidol and only at 368 nm for droperidol due to interference from its native uv absorption (Fig. 1).

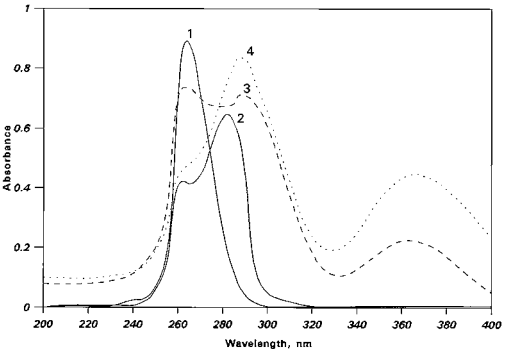

Fig. 1. Absorption spectra of: 1, haloperidol (15.2 μg ml^{-1}); 2, droperidol (10.3 μg ml^{-1}); and 3, 4 their reaction products with iodine respectively, all in 1,2-dichloroethane.

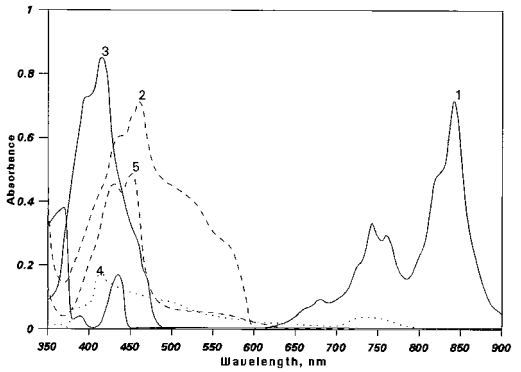

Fig. 2. Absorption spectra of the reaction products of haloperidol 125, 127, 25.5, 1500 and 216.5 μg ml^{-1} with each of TCNQ (1), DDQ (2), TCNE (3), TNF (4), and bromanil (5), respectively.

The interaction of haloperidol and droperidol with selective polyhaloquinones and polycyanoquinones π-acceptors was found to yield intensely coloured radical anions (Fig. 2). Butyrophenones interaction with TCNQ in acetonitrile solution was found to yield a deep colour causing characteristic long wavelength absorption bands. The predominant chromogen with TCNQ is the blue coloured radical anion which probably resulted through the dissociation of an original donor-acceptor complex with the drugs. The dissociation of the complex was promoted by the high ionizing power of acetonitrile solvent. Further support to this assignment was provided by the identity of the absorption maxima with those of TCNQ radical anion produced by the iodide reduction method in acetonitrile [28].

The resulting maxima of the investigated drugs with DDQ, bromanil and TNF are similar to that of radical anions of these acceptors obtained by the reduction method and coincide with the values reported in the literature [25,29].

With butyrophenones and TCNE, the characteristic shaped absorption band of TCNE radical anion with reported maximum in acetonitrile at 432 nm was not formed. Instead doplet at 394 and 414 in acetonitrile was formed which corresponds to the 1,1,2,3,3-pentacyanopropenide (PCNP) anion. From the quantitative point of view, PCNP anion is preferable to TCNE anion on grounds of its higher molar absorptivity [28]. The weak and small molar absorptivity in case of the reaction between TNF or bromanil and investigated drugs may be explained or due to the insufficient ionization of these relatively week π-acceptors which possess lower electron affinity than DDQ, TCNQ and TCNE [24].

The results for variation of reagent concentration, Table 1, indicated that 1.0 ml of either 0.05% iodine, 0.1% TCNQ, TCNE, 0.4% DDQ or 1.0% bromanil are suitable. The higher concentrations of the reagents may, on the other hand, be useful for rapidly reaching equilibrium, thus minimizing the time required to attain the maximum absorbance at the corresponding wavelength of charge transfer complex. Neither the studied drugs nor the reagents have a significant absorbances at the corresponding wavelengths of maximum absorbance except in case of droperidol.

3.1. Choice of solvent

Although, charge transfer complex as probably been formed in many solvents, the high cut-off points of some solvents obscured the scanning of the shorter wavelengths and therefore clear-cut spectroscopic evidence for charge-transfer formation could not be ascertained. Also the low solubility of the drugs in some other solvent restricted their use.

1,2-Dichloroethane may be used directly as an assay solvent in case of iodine and TNF. With iodine, haloperidol showed a major charge-transfer bands at 295 and 365 nm and for droperidol at 368 nm.

The formation of TCNQ radical was possible in methanol; however, response between absorbance and concentration was not linear. Furthermore, the molar absorptivity of the obtained chromogen was relatively lower compared with that in acetonitrile. The latter was considered as an ideal solvent because it offered excellent solvating power for TCNQ reagent and gave high absorbance.

Table 2
Quantitative parameters for the complexation of haloperidol (I) and droperidol (II) with different acceptors

(1.37)	II	300–2500	120	0.00028	0.0328	0.9998	3.200

[a] Electron affinity of different acceptors (Ref. [24]).
[b] Measured at 295 nm.
[c] Measured at 368 nm.

In case of TCNQ and TCNE, as an assay solvent acetonitrile afforded maximum sensitivity owing to its high dielectric constant which promotes maximum yield of TCNQ radical anion. Methanol afforded maximum sensitivity in cases of DDQ and Bromanil, in spite, chloroform can also be used.

3.2. Reaction time

The reaction time was determined by following the absorbances of the developed colour at different time intervals. The development of colour was highest and immediate with iodine. Development time with other acceptors increase up to 90 min (in case of TNF). The developed colour for all cases remained stable thereafter 2 h at room temperature, Table 1.

3.3. Quantification

At fixed experimental conditions, the intensity of absorption at the specified wavelength was found a function of the concentration of the investigated drugs. In all cases studied, Beer's law plots were linear with very small intercept, in the general concentration range of 2.5–2500 μg ml^{-1}, Table 2.

3.4. Stoichiometric relationship

The application of the Job's method of continuous variation indicated 1:1 ratio for the two drugs with iodine. This indicates that only one nitrogen is responsible for the formation of the complex although droperidol has three nitrogen atoms, Scheme 1. This can be explained on the basis that a univalent, partially positively charged droperidol species may be formed initially during the charge-transfer process, which may not be easily engaged in additional complex formation. Both the two nitrogen atoms in the bezimidazolinone part are acidic. This suggestion is supported by the behaviour of this compound in non-aqueous medium where it was found to be titrated as a monobase (pK_a 7.64). In case of haloperidol (pK_a 8.30), [30] the ratio was found to be also 1:1.

3.5. Correlation between electron affinity of the acceptors with each of development time and sensitivity

The electron affinity (E_A) of the different acceptors varied with the sensitivity of the assay, expressed as (ϵ) values as well as development time (t), in a regular pattern.

Regression analysis of the above correlations by the method of least squares afforded:

Table 3

[a] Average of five determinations.
[b] Self prepared tablets. Theoretical values at 95% confidence limit, *t*: 2.78 and *F*: 6.39.

$E_A = 2.42 - 0.0145\ t$ $(r = -0.9380)$
$E_A = 1.40 + 0.000072\ \epsilon$ $(r = 0.9203)$, for haloperidol
$E_A = 1.42 + 000066\ \epsilon$ $(r = 0.8998)$, for droperidol

3.6. Interference study

The presence of the fluoride atom acting as an electron withdrawing group does not affect the formation of the charge-transfer complex owing to the existence of tertiary basic electron donating group in the butyrophenone molecule. The energy of charge-transfer depends on the ionization potential of the donor and the electron affinity of the acceptor, hence the λ_{max} values of the other π-donors mostly differ of that of the investigated compounds if they are able to form charge-transfer complexes.

3.7. Analysis of dosage forms

The proposed charge-transfer spectrophotometric methods were applied to the determination of haloperidol in tablets, drops and injection solution in addition to droperidol in self prepared tablets. The results were compared statistically with those obtained by applying the official USP XXII and NF XVII methods for safinace tablets and halodol injection. These methods are based on measuring the absorbances of the solution from tablets or injections and standard solution after certain treatments at 245 nm. The results for halodol drops and droperidol prepared tables were compared with their respective uv-absorption. In the *t*: and *F*: tests, no significant differences were found between the calculated and theoretical values (95% confidence) of the proposed and reported methods. This indicates similar precision and accuracy. Data of Table 3 suggested that the present procedures could be applied to the assay of these drugs in their single dosage forms without interference. Frequently countered common ingredients of formulations were found not to interfere. Percentage recoveries ranged from 99.1–102.2%.

4. Conclusions

From the aforementioned results, the suggested procedures using σ and π-acceptors confirm their suitability for spectrophotometric analysis of named compounds in the micro range. The strongly red shifted bands combined with the intensity of absorption and very low reagent background obviously recommended these procedures for routine analysis of haloperidol and droperidol in bulk drugs and dosage forms with minimum interference.

Amplified potentiometric determination of pK_{00}, pK_0, pK_1, and pK_2 of hydrogen sulfides with Ag_2S ISE

Y.S. Su, K.L. Cheng *, Y.C. Jean

Department of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110, USA

Received 28 June 1996; received in revised form 3 February 1997; accepted 4 February 1997

Abstract

The chemical capacitor theory has been applied to accurately determine dissociation constants of H_2S with the Ag_2S ion-selective electrode (ISE). The theory's principle is based on the measurement of the change in electrode charge density as a result of protonated or unprotonated sulfide adsorbed on the electrode surface. This charge density is related to the potential. Connection of each individual capacitor in series amplifies the potential according to the equation, $E_{total} = E_1 + E_2 + E_3 + \cdots E_n$. As the charges of individual capacitors are concentrated to one capacitor area, the charge density rises, and the potential increases. The pK_{00}, pK_0, pK_1, and pK_2 are reported as 1.8, 2.12, 7.05, and 12.0, respectively. The pK_{00} and pK_0 are reported here for the first time. The pK_1 agrees well with the literature values; however, the pK_2 differs from those reported recently under extreme conditions. Reasons for disproving the unreasonably high $pK_2 \gg 17$–19 values are given based on calculations. Mainly, when $pK_2 \gg 17$–19, the experimental results do not fit the equilibrium equations, $pH = (pK_1 + pK_2)/2$, $pK_1 = (pK_0 + pK_2)/2$, and $pH = pK_2 + \log(HS^-)/(S^{2-})$. © 1997 Elsevier Science B.V.

1. Introduction

Electrode potential amplification has been explained by several authors [17,18] as the potential amplification of a cell. Cheng, Song, and Yang [15], however, have reported the theory of potential amplification of a chemical capacitor, emphasizing the difference between cells and capacitors [16]. The principle of the capacitor technique is to measure the potential change of protonated and unprotonated adsorbates on the electrode surface, which serves as a zwitterionic capacitor. The electrode net charge density varies with changes in the protonation and deprotonation, complexation, or dissociation: the dissociation constants are determined from these changes in charge density. At a certain pH, one may determine the species ratio in the solution based on the reversible equilibrium reaction. If two species of equal concentration are involved in the equilibrium, pH equals pK_a at the intersection. The dissociation constants, therefore, are easily determined. Amplification makes the technique more sensitive and accurate for the determination of dissociation constants of weak

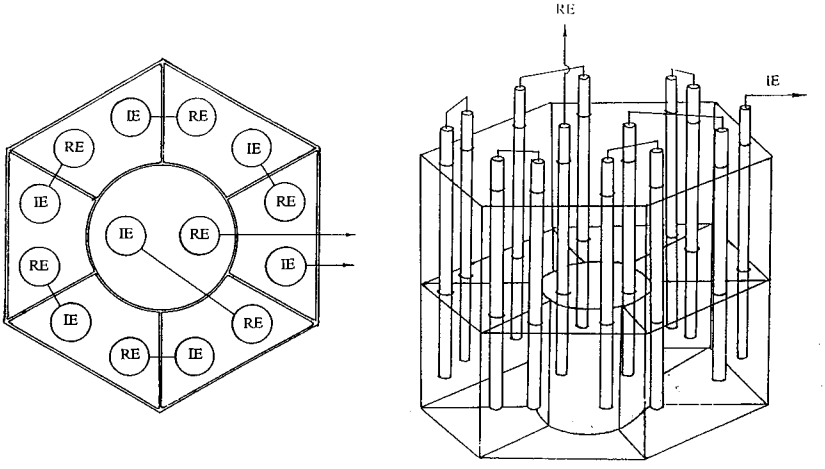

Fig. 1. Electrode assembly; (a) seven electrode connection; (b) measurement device.

acids, because it produces higher curve slopes than does unamplified potential.

In this paper, we report the application of the solid state Ag_2S ion selective electrode (ISE) as a capacitor to the amplified potentiometric determination of dissociation constants of H_2S. With appropriate ISEs, there may be applications for the determination of constants of other weak acids, complex reactions, and structural confirmation.

2. Experimental

The solid state Ag_2S ISE was prepared from Ag_2S precipitate pressed (under 12 tons cm^{-2} pressure) to produce a 1.0 mm × 10.0 mm disc. It was fixed atop a polymer electrode stem. Instead of an internal solution, the inner membrane surface was joined with liquid silver epoxy resin and silver wire. The potential was measured with a Fisher Model 825P pH meter and the pH was measured with a Chemtrix Model 430 pH meter. The experimental set-up is shown in Fig. 1. It should be stated that the test solution must be placed in each separate dish. Each indicator ISE and the Ag/AgCl reference electrode in each solution served as a capacitor unit. All capacitor units were connected in series (Fig. 1).

The 1×10^{-2} mol of Na_2S was dissolved in 100 ml of SAOB solution (salicylic acid–ascorbic acid oxygen buffer) and diluted to 1 l. A series of standard Na_2S solutions (10^{-2}–10^{-6} M) were prepared through dilution of the above standard solution containing 10 ml of SAOB 100 ml^{-1}. The SAOB solution contained 40 g of NaOH, 80 g of acetyl salicylic acid, and 35 g of ascorbic acid l^{-1}. Addition of SAOB solution prevents the oxidation of Na_2S. The Na_2S solution should be stored in a tightly stoppered plastic bottle with a shelf life of about 2 weeks. Discard it if it turns brown or dark.

For the determination of dissociation constants, 80 ml of water and 5 ml of 1.0×10^{-2} M Na_2S solution were mixed in a 150 ml beaker; the solution was adjusted to pH 13.5 or pOH 0.5 by adding 0.5 M NaOH solution. After each addition of 2 M HNO_3 through a burette, the pH and potential were recorded. The measuring interval is preferred to be about 0.2–0.4 pH unit difference. In the strong basic range the preferred interval would be kept about 0.1–0.15 pH unit. In order to avoid the loss of H_2S gas in an acid medium, the measurements were done quickly and the beaker was covered with a plastic paper. After addition of a base or acid, the solution was mixed; however, the solution was not stirred during pH and potential measurements.

3. Results and discussion

We have indicated that a membrane electrode acting as a parallel capacitor should follow the capacitance law. Therefore, the E_{total} resulting from connecting the capacitors in series with multimembrane electrodes is the sum of each capacitor potential (not cell potential) [15].

$$E_{total} = E_1 + E_2 + E_3 + \cdots E_n \quad (1)$$

When each capacitor is the same ISE in a same sample solution, the above equation becomes

$$E_{total} = \sum_{i=1}^{n} E_i \quad (2)$$

In the present experiment, $n = 4$. The amplification is illustrated in Fig. 2 and in acid and base with the pH glass electrode [15]. This capacitor potential amplification may find many applications, such as a simple portable voltameter without any electronic amplification, a device for surface charge measurement, etc. Here, we apply it to the accurate determination of dissociation constants of a dibasic acid, H_2S.

For titration of a Na_2S solution (already basic) with a HNO_3 solution, the potential versus pH relationship is shown in Fig. 3. The relationship indicates the distribution of each sulfide species on the Ag_2S electrode surface. The electrode surface charge density changes due to the protonation or deprotonation of electrode surface, resulting in the potential change.

At the beginning, the S^{2-} predominates; during the protonation, (S^{2-}) gradually decreases with

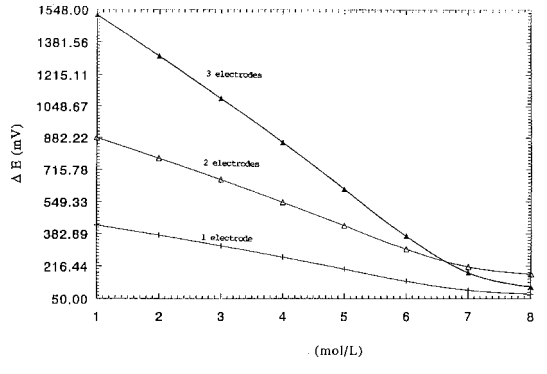

Fig. 2. Ampified calibration curves.

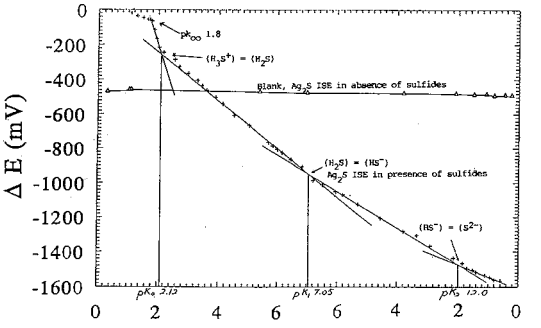

Fig. 3. Determination of pK_a with amplified Ag_2S ISE (four electrodes).

increasing (HS^-). There is a slope. At a point where one-half of the S^{2-} is protonated, further addition of H^+ starts to form $HS^- + H^+ \rightarrow H_2S$ with a different slope. An intersection is produced from the two slopes. At the intersection, $(S^{2-}) = (HS^-)$, $pH = pK_2$ or $pOH = pK_2$. Similarly, pK_1 and pK_2 are obtained from other intersections in Fig. 3. The results are shown in Table 1. When a single ISE was used, the pK_1 and pK_2 were found to be 6.98 and 12.3–12.5, respectively. When four ISEs were used, the pK_1 and pK_2 were found to be 7.05 and 12.0, respectively. Obviously, this is an electrode reaction resulting in changes of the electrode charge density and the electrode surface potential.

Cheng derived the capacitor electrode potential [16],

$$E = k\left(\sum q^+ - \sum q^-\right) \quad (3)$$

where q^+ and q^- are the charge density of positive charges and negative charges at the electrode surface. That is, only the net charge density is counted, even though both positive and negative charges are present, zwitterionic. The potential amplification is the addition of all charges together from each individual electrode (capacitor) to one electrode surface area. As a result, the charge density rises, and the potential also increases.

Our pK_1 of H_2S agrees well with most of the values in the literature. The pK_2 of H_2S has been widely in the literature (Table 1). In the

Table 1

Reaction	Present work		Reference												
			[1]	[2]	[3]	[4]	[5]	[6]	[7]	[8]	[9]	[10]	[11]	[12]	[13]	[14]
$H_4S^{2+} \rightleftharpoons H^+ + H_3S^+$	pK_{00}	1.8														
$H_3S^+ \rightleftharpoons H^+ + H_2S$	pK_0	2.12														
$H_2S \rightleftharpoons H^+ + HS^-$	pK_1	7.05	7.04	7.02	7.00	7.24	7.00	8.00	6.99	7.04	7.00				7.0	7.05
$HS^- \rightleftharpoons H^+ + S^{2-}$	pK_2	12.0	11.94	13.9	12.92	14.92	15.00	13.92	12.89	14.92	14.00	19 ± 2	17.2	16	17	12.4

recent literature, there seems to be an increasing tendency to believe the $pK_2 \gg 12$ is a better value [2,10–13]. Our $pK_2 = 12.0$ agrees well with the early reported values (Table 1). After carefully studying recently reported results ($pK_2 \gg 17$–19), we reached the following conclusions.

One of the reasons for obtaining the high pK_2 of H_2S may be attributed to the high concentrations of NaOH and/or Na_2S used. Experimental results might be misinterpreted. The equilibrium

$$HS^- \leftrightharpoons H^+ + S^{2-} \tag{4}$$

is not intended for the presence of highly-concentrated electrolytes which may form other side complexes or different equilibria. Indirect measurements and extrapolation are sometimes not reliable. Introduction of the term acidity function (H_-) instead of pH made their calculations and conclusions questionable [10,13]. It is also improper to use the terms activity and activity coefficient with high concentrations [10,12]. Our simple and sensitive measurements from a dilute solution are based on the direct measurement of the variation of $(HS^-)/(S^{2-})$ and charge density on the ISE electrode surface, which is the mirror of the test solution. When $(HS^-) = (S^{2-})$, $pOH = pK_b$ or $pH = pK_2 = pK_a$. The $pK_2 = 12.0$ obtained at the intersection in Fig. 3 is believed to be accurate.

Unlike other techniques, such as acid–base titration which requires a high purity sample for determining the 50% titration, the amplified potentiometric technique does not require a 100% pure sample, as it only measures the $(HS^-)/(S^{2-})$ ratio change.

Several means are available for testing the reliablilty of pK_2 values of H_2S.

1. Test with the equation

$$pk_2 = (pk_1 + pk_3)/2 \qquad \text{or}$$
$$pk_1 = (pk_0 + pk_2)/2 \tag{5}$$

(See Table 2)

$$pk_1 = (pk_0 + pk_2)/2 = (2.12 + 12.0)/2 = 7.06$$

$$pk_1 = (pk_0 + pk_2)/2 = (2.12 + 19)/2 = 10.6$$

Table 2
Calculated second dissociation constants from equation $pK_2 = (pK_1 + pK_3)/2$ or $pK_1 = (pK_0 + pK_2)/2$ (no protonated amine acids involved)

Acid	pK_1	pK_2 (experimental)	pK_3	pK_2 (calculated)
H_3BO_3	9.24	12.24	13.80	11.52
H_3AsO_4	2.24	6.96	11.50	6.87
H_3PO_4	2.14	7.20	12.35	7.20
Benzene-1,2,3,-tricarboxylic acid	2.88	4.75	7.13	5.0
H_3S^+	2.12	7.05	12.0[a]	7.06
	(pK_0)	(pK_1)	(pK_2)	
		13.0[a]	7.6	
		14.0[a]	8.1	
		17.0[a]	9.6	
		19.0[a]	10.6	

[a] These are pK_2 values of H_2S reported in the literature Table 1.

Calculation of pK_1 with $pK_2 = 19$ leads to an answer of 10.6, which does not agree with any known value.

Table 3
pH values of NaHS solution at different concentrations (T = 21.5°C)

Concentration (mol/l)	E (mV)	pH
0.008	−130.3	9.25
0.009	−131.6	9.27
0.01	−134.6	9.32
0.011	−135.8	9.37
0.0823	−152.2	9.76[a]
0.0927	−153.4	9.78
0.103	−156.3	9.83
0.113	−157.4	9.85
0.117	−158.6	9.87
0.123	−158.6	9.87
0.8	−195.8	10.34
0.9	−197.0	10.36
1.0	−200.0	10.41
1.1	−201.2	10.43
1.2	−203.6	10.47
2.9	−221.0	10.76
3.0	−224.0	10.81
3.1	−225.2	10.83
3.2	−227.0	10.86
3.3	−228.2	10.88

The *o*-phthalic acid is a dibasic acid with pK_1 2.95 and pK_2 5.41. Its KHP solution gives a pH of approximately 4.2 that is in good agreement with the equation $pH = (pK_1 + pK_2)/2$.
[a] This group of data was determined at 21.5°C.

2. Test with the equation

$$pH = (pk_1 + pk_2)/2$$

$$pH = (7.05 + 12.0)/2 = 9.5$$

$$pH = (7.05 + 19)/2 = 13.0$$

By using $pK_2 = 12.0$, the pH = 9.5 is in good agreement with the experimental value pH = 9.5 (NaHS solution), not pH = 13.0 with $pK_2 = 19$ (Table 3).

3. In the titration of Na_2S solution with an acid at the right part of Fig. 3,

$$S^{2+} + H_2O \rightleftharpoons HS^- + OH^- \quad (6)$$

$$pOH = pk_b - \log(S^{2-})/(HS^-) \quad (7)$$

When

$$(S^{2-}) = (HS^-),\ pOH = pk_b = pk_2 \quad (8)$$

The titration yields an intersection at pH 12 or pOH 2.0, not $pK_2 = 17$ or 19. This experiment shows that when Na_2S is dissolved in water it does not produce all OH^- in Eq. (6), as assumed by some of the authors [10].

4. The presence of O_2 in the solution, which interferes with the dissociation constant measurements, was overemphasized [10,13]. Kubli found no O_2 effect in his pK_2 determination [14]. Our experiment was done in the presence of SAOB to prevent oxidation of Na_2S. Meyers also misquoted (or misinterpreted) the titration of 0.04942

Table 4
Calculation of sulfide distribution ratio

NaOH estimated	pOH =	pK_b −	$\log(S^{2-})/(HS^-)$	$(HS^-)/(S^{2-})$	$(S^{2-})/(HS^-)$
10^5 M	3	2	(−1)	10	0.1
	2	2	(0)	1	1
	1	2	(1)	0.1	10
	0.1	2	(1.9)	1/80	80
	0	2	(2)	1/100	100
	−1	2	(3)	1/1000	1000
	−1.3	2	(3.3)	1/2000	2000
	−1.3	−3	(−1.7)	50	1/50
	−3 (calculated)	−3	(0)	1	1
	−1.3	−5	(−3.7)	5000	1/5000
	−5 (calculated)	−5	(0)	1	1

pOH = −1.3 18 M NaOH, pH 19 or pOH−5 would be equivalent to 10^5 M NaOH.

M NaOH solution in Kubli's pK_2 values of 12. Meyers' objection to Kubli's experiment was not justified, as Kubli titrated a solution of 0.04942 M Na_2S solution instead of 0.04942 M NaOH solution. As we know, Na_2S is not completely hydrolyzed in water all the way to produce OH^- (see Eq. (6)) even assuming $pK_2 > 14$ (See Table 4). Kubli just dissolved the Na_2S in water without adding any NaOH. Titration of OH^- as shown in Eq. (6) with 0.5223 N HCl by Kubli is an indication of how much OH^- is produced under the equilibrium.

The sulfide distribution ratio has been calculated according to Eq. (7) (Table 4). It is evident that the $(S^{2-})/(HS^-)$ ratio depends on the pH of the solution and pK_a or pK_b. For instance, at pOH 1 or pH 13, and $pK_2 = 12.0$ or $pK_b = 2.0$, the $(S^{2-}):(HS^-) = 10:1$. The Na_2S is far from the complete dissociation at pH 13. At pOH 0 or pH 14, and $pK_2 = 12.0$ or $pK_b = 2.0$, the $(S^{2-}):(HS^-) = 100:1$. If the $pK_2 = 17$, $(S^{2-}) = (HS^-)$, or $(S^{2-}):(HS^-) = 1:1$; this would require pOH-3 or 10^3 M NaOH. This calculation based on Eq. (7) disproves the possibility that $pK_2 \gg 12$. The figures in Table 3 also confirm that $pK_2 = 12.0$ is a reasonable value. Any questionable constant should be scrutinized by other techniques and calculations.

4. Conclusion

The dissociation constants of hydrogen sulfides have been determined by the sensitive amplified potentiometric Ag_2S ISE method: pK_{00}, pK_0, pK_1, and pK_2 are 1.8, 2.12, 7.05, and 12.0, respectively. The pK_1 agrees with the literature values. The pK_{00} and pK_0 from different acid media are reported here for the first time; the pK_{00} should be further studied. The pK_2 value has always been subject to considerable debate. Most textbooks have used values of $pK_2 \sim 12$–14, in general agreement with ours. However, some authors believe $pK_2 > 17$ or even 19, the value which has been accepted by the modern text. A few means have been applied to test the reliability of pK_2 values, and reasons for unreasonably higher pK_2 values are presented. One reason may be the high concentrations of NaOH or Na_2S used. The amplified potentiometric method to measure variation of sulfides adsorbates at the electrode surface due to protonation and deprotonation. The

present amplified potentiometric method may find applications for other weak acids and complexes with appropriate ISEs.

Polarographic determination of diffusion coefficient values of In(III) in potassium chloride and nitrate supporting electrolytes

Stephen Kariuki, Howard D. Dewald *

Department of Chemistry, Clippinger Laboratories, Ohio University, Athens, OH 45 701-2979, USA

Received 11 July 1996; received in revised form 9 September 1996; accepted 2 October 1996

Abstract

The diffusion coefficient values of In(III) in potassium chloride and potassium nitrate supporting electrolytes have been determined by polarography. Also, the half-wave potential, $E_{1/2}$, and the $|E_{3/4} - E_{1/4}|$ values have been calculated. The results show ionic strength and chloride concentration effects on electrode kinetics in the reduction of In(III). © 1997 Elsevier Science B.V.

Keywords: Adsorption; Complex formation; Diffusion coefficient; Dropping mercury electrode; Indium; Reversibility

1. Introduction

Under the influence of a chemical potential gradient, diffusion of an electroactive species involves the interdiffusion of the redox species, solvent molecules, and supporting electrolyte ions [1]. The diffusion velocity of a species in a given supporting electrolyte will be greatly influenced by the solution composition resulting from molecular and ionic interactions involved in the whole diffusion process. In spite of the complexities involved in the diffusion process, several methods for obtaining diffusion coefficient values for various species have been devised. Our recent review presents the diffusion coefficient values for a variety of metallic ions [2]. We pointed out that even when different studies have used the same techniques and supporting electrolytes for the diffusion coefficient measurement, the values may turn out to be different, sometimes quite substantially.

The electrochemical behavior of indium has been of interest to many. In recent years Doyle, et al. [3] developed a voltammetric immunoassay for proteins based on the anodic stripping voltammetric detection of an In(III) ion label. An aluminum alloy containing indium has been used as a sacrificial anode for the cathodic protection of steel structures in marine environments [4]. Indium has also been used to alter the electrochemical properties favorable for battery applications [5]. Liquid In/Ga alloy has been found useful by Sinclair, et al. when applied to the surfaces of glasses and ceramics for use as electrodes [6]. The electrocatalytic activity of an indium electrode for the reduction of CO_2 has also been demonstrated [7,8]. The diffusion coefficient of indium metal in mercury

* Corresponding author.

PII S00 9-9140(97)00046-5

was determined by means of the dropping mercury electrode by Stackelberg and Toome [9]. Turnham [10] has reported the In(III) diffusion coefficient values determined polarographically in several supporting electrolytes over the concentration range of 0.008–0.1 M. The diffusion coefficient values reported presently are for 0.5 mM In(III) in concentrations of 0.024–3 M KNO_3 and KCl and are compared with those obtained by Turnham [10]. Besides the determination of the diffusion coefficient values, we report the $E_{1/2}$ and $|E_{3/4} - E_{1/4}|$ values for In(III). These results present aspects of the reduction process of In(III) such as reversibility, complexation with chloride, and adsorption of chloride on the dropping mercury electrode.

2. Experimental

2.1. Equipment

The polarograms were obtained using an EG and G Princeton Applied Research Corporation (PARC) Model 264A Polarographic Analyzer/Stripping Voltammeter connected to an EG and G PARC Model RE 0089 X-Y Recorder. The dropping mercury electrode (DME) had an average drop time (t) in KNO_3 electrolytes of 2.29 s and an average mercury flow rate (m) of 3.44 mg s^{-1} with an applied potential of -0.75 V. At -1.20 V, the average t and m values were 2.06 s and 3.45 mg s^{-1}, respectively. At -0.75 V, the average values of t and m in KCl electrolytes were 2.23 s and 3.42 mg/s, respectively, while at -1.2 V the average values of t and m were 1.97 s and 3.43 mg/s, respectively. At each potential, the drop time was determined by measuring the time required for 20 drops of mercury to form and fall while the mass flow rate was determined by collecting mercury for not less than 10 min. The height of the mercury column above the capillary (EG and G PARC MCC0001) tip was 85 cm. The depth of the capillary immersion into the electrolyte was about 0.5 cm. The capillary had a length of about 25 cm while the radius of its lumen was about 0.16 mm. Besides the DME, the electrochemical cell (EG and G PARC K0066/K0060) was also equipped with a platinum wire auxiliary electrode and an aqueous saturated calomel electrode (SCE, EG and G PARC K0077). A resin cartridge (Barnstead D8902) connected to a glass still (Barnstead Fi streem2) was used to obtain doubly distilled deionized water. The pH of the solutions was measured using an Orion Research Digital Analyzer M501 and pH glass electrode (Orion Model 91-04).

2.2. Reagents and chemicals

The hydrated indium(III) nitrate (Alfa, Puratronic grade—99.999%), potassium chloride (Fisher Scientific, A.C.S. grade), potassium nitrate (Lab Chemicals, 99.99%), and Triton X-100 (Z.D. Gilman) were used as received. Mercury (Bethlehem Instrument, A.C.S. grade) was also used as received. High purity nitrogen gas was used for purging the In(III) solutions. The buffers of pH 4.00 and 7.00 used for calibrating the pH electrode had been obtained from Fisher Scientific.

2.3. In(III) reduction

0.5 mM $In(NO_3)_3 \cdot xH_2O$ in a given concentration of the supporting electrolyte was polarographed by scanning the potential from -0.1 V to about -1.8 V versus SCE. The baseline for each polarogram was extrapolated from which diffusion current measurements were made. To confirm that the plateau currents used for measurements were diffusion-limited, maximum current values for In(III) reductions at particular nitrate and chloride concentrations were plotted against the square root of the Hg-column height. The plots were linear with a correlation coefficient better than 0.99. The maximum diffusion current was measured either at -0.75 V or at -1.2 V. Reduction of In(III) in each supporting electrolyte containing 0.0002% Triton X-100 (w/v) was repeated four times from which the mean was taken. During the polarographic measurements, the temperature was maintained at 25 ± 0.1°C with the help of a water bath. $|E_{3/4} - E_{1/4}|$ values were determined directly from the polarogram. The $E_{1/2}$ were determined by using the Heyrovsky and Ilkovic equation [11].

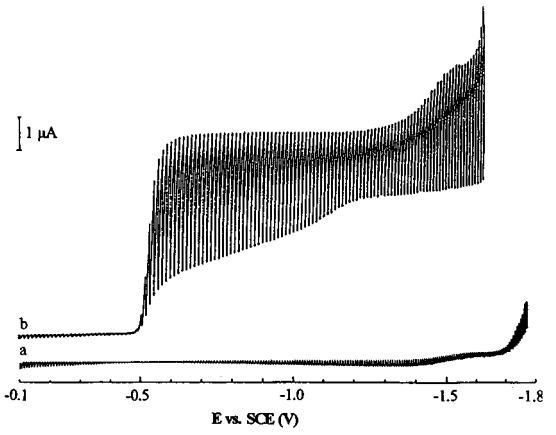

Fig. 1. Polarograms for (a) background and (b) 0.5 mM In(III) in 0.04 M KNO_3; scan rate = 5 m V s^{-1}; $E_i = -0.1$ V; Temp. = 25°C; 0.0002% (w/v) Triton X-100; At −1.2 V, m = 3.45 mg s^{-1} and $t = 2.06$ s.

3. Results and discussion

3.1. In(III) in presence of nitrate supporting electrolytes

3.1.1. Diffusion coefficients in KNO_3 supporting electrolytes

Solutions of In(III) in KNO_3 supporting electrolytes had a pH of 3.36 ± 0.10. The reduction of In(III) in KNO_3 supporting electrolytes gave waves, which at low supporting electrolyte concentrations, were characterized by large maxima of the first kind [12]. A concentration of 0.0002% (v/v) of Triton X-100 was used as a maxima suppressor. This concentration compares with the one Turnham [10] had previously used. Fig. 1 shows a typical polarogram of 0.5 mM In(III) in 0.04 M KNO_3. As seen from the polarogram, two reduction waves were obtained, the first one being for In(III). The second plateau arises from the reduction of hydrogen ions present in the solutions as indicated by their pH values. Any formation of In(Hg) at the electrode surface might also have catalyzed discharge of H_2 by the reduction of H_2O. This possibility was not explored further. The hydrogen reduction wave for solutions containing In(III) was observed at a less negative potential than without In(III).

The Ilkovic equation [13]

$$i_d = 708nD^{1/2}Ct^{1/6}m^{2/3} \quad (1)$$

was used to evaluate the diffusion coeffcient values. The symbol i_d is the diffusion limited current in μA, n is the number of electrons involved in the electrode reaction, D is the diffusion coefficient of the electroactive species in cm^2 s^{-1}, C is the concentration of the electroactive species in mM, t is the drop time of mercury in seconds, and m is the mass flow rate of mercury in mg s^{-1}.

The diffusion coefficient values of In(III) in KNO_3 are listed in Table 1 and Table 2. The diffusion current measurements in Table 1 were made at −1.2 V while those in Table 2 were made at −0.75 V. Changing of the potential for the current measurements was found necessary since at higher concentrations of the supporting electrolyte (0.2 M–3 M KNO_3), the hydrogen ion reduction appeared shifted to potentials less negative than −1.2 V. The choice of −0.75 V as the

potential at which all the diffusion coefficient current measurements would have been made would have been an ideal one. However, large maxima were observed at lower concentrations of supporting electrolyte and at 0.0002% Triton X−100. The maxima found in In(III) in 0.024 M KNO_3 required 0.0013% Triton X-100 to eliminate them, but this lowered considerably the diffusion currents at −0.75 V. A few of the diffusion coefficient values obtained are similar to the ones reported in the literature [10], while most vary from the reported values. All the values obtained are smaller. The diffusion coefficient values as seen in Table 1 and Table 2 tend to decrease with the increasing concentration of the supporting electrolyte.

The diffusion coefficient is related to the viscosity of solution [14]. However, any changes in viscosity for the concentrations of supporting electrolyte and maxima suppressor we used, are not expected to be large enough to cause a significant change in the diffusion coefficient values that we observed. The change in ionic strength for the concentrations of supporting electrolyte we used is however, major, and is therefore expected to significantly contribute to the diffusion coefficient values [15]. This effect of the ionic strength is particularly notable in 3 M $KN0_3$, where diffusion coefficient value at that concentration is much lower than at other concentrations of supporting electrolyte.

3.1.2. Half-wave potentials and $|E_{3/4}-E_{1/4}|$ values

The expression for the determination of the half-wave potential, $E_{1/2}$, was derived by Heyrovsky and Ilkovic [11]. It takes the form:

$$E = E_{1/2} - \frac{0.05915}{n}\log\frac{I}{I_d - I} \quad (2)$$

where E is the potential of the working electrode and I is the current at a given potential. By plotting E versus $\log[I/(I_d-I)]$, a straight line was obtained whose intercept gave the $E_{1/2}$ values. The $E_{1/2}$ values found in Table 1 and Table 2 appear shifted to more negative values with increasing ionic strength. An increase in the ionic strength of solution results in a decrease in the activity coefficient of the reducible ion. However, since it is the logarithm of the inverse of the activity coefficient of the reducible ion that is related to $E_{1/2}$ values [16], a considerable change in the activity coefficient should have only a small effect on the $E_{1/2}$ value. Our results qualitatively fit well with this theory since no significant changes are observed in the values of $E_{1/2}$ with the increasing concentration of the supporting electrolyte.

The $|E_{3/4}-E_{1/4}|$ values that were obtained are listed in Table 1 and 2. They seem higher than the predicted value of 18.8 mV [17,18] for a 3-electron reversible reduction process. These findings support that the reduction of In(III) in KNO_3 occurs in an irreversible manner.

3.2. Indium in presence of chloride supporting electrolytes

3.2.1. Diffusion coefficients in the KCl supporting electrolytes

Solutions of In(III) in KCl supporting electrolyte were found to have a pH of 4.15 ± 0.16. Polarograms of In(III) had two reduction waves as observed in KNO_3 solutions. Further, the reduction waves of In(III) in low concentrations of KCl supporting electrolytes had big maxima of the first kind [12]. However, the maxima were not as big as the ones found in KNO_3. The maxima found in In(III) in 0.024 M KCl required 0.0002% (w/v) Triton X-100 to eliminate them. Further, it was noted that the maxima found in In(III) diminished very rapidly with the increasing concen-

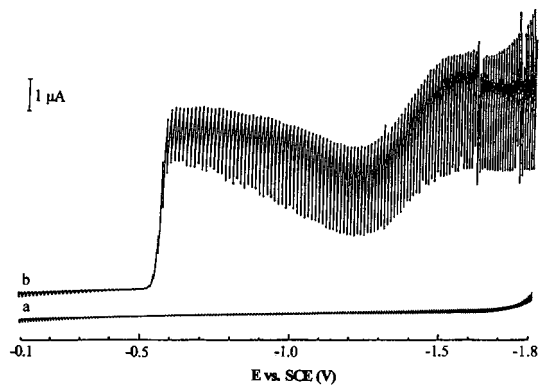

Fig. 2. Polarograms for (a) background and (b) 0.5 mM In(III) in 0.4 M KCl; scan rate = 5 mV s^{-1}; $E_i = -0.1$ V; Temp. = 25°C; 0.0002% (w/v) Triton X-100; at -1.2 V, $m = 3.42$ mg s^{-1} and $t = 2.23$ s. The polarogram exhibits a minimum at -1.25 V.

tration of the KCl supporting electrolytes. This was not so for In(III) in KNO_3 supporting electrolytes. A concentration of 0.0002% Triton X-100 was used to reduce the maxima found in In(III) in KCl supporting electrolyte to make easy measurements of the currents. However at higher concentrations of the KCl supporting electrolyte (from 0.2 to 3 M), a minimum (vice infra) could be observed (Fig. 2). Thus the maximum currents were made from the current measurements at -0.75 V.

The diffusion coefficient values of In(III) in the supporting electrolyte (Table 3) have an overall trend of decreasing with the increasing concentration of KCl up to 0.1 M. Just like the case of KNO_3 supporting electrolyte, the diffusion coefficient values in the KCl supporting electrolyte appear smaller than the literature values [10].

From 0.2 to 3 M KCl, the currents were found to appreciably increase with the increasing supporting electrolyte concentration, an effect that may be attributed to changes in electrode kinetics with the increasing concentration of the chloride [19–23]. Several groups have explained the increased currents of reducible species that form complexes that adsorb on the electrode [24–28]. These groups found that in solutions containing complex-forming molecules or ions adsorbable at the electrode surface, the metal cations can accumulate at the electrode-solution interface by entering into complexes with the adsorbed ligands. This accumulation of the metal cations leads to an enhancement of current or sensitivity, a feature that some groups [29,30] have taken advantage of in electroanalytical determinations. A plot of the current measured at -0.75 V of 0.5 mM In(III) versus the concentration of KCl supporting electrolytes from 0.2 to 3 M KCl suggests that as the concentration of the KCl is increased, some species whose reduction gives enhanced currents are formed each time. The observed currents for the reduction of In(III) in 0.2 to 3 M KCl appeared influenced by adsorption phenomena and were therefore not used to evaluate the diffusion coefficient values.

Engel, et al. [23] have also observed minima in the oxidation of indium amalgams polarographically in perchloric acid, sodium thiocyanate, hydrochloric acid, and sodium bromide solutions. They attributed the minima to the oxidation of

In(Hg) through the adsorbed halide. Moorhead, et al. [31] also reported observing minima in the reduction of the In(III) species in the presence of the 0.1 and 1 M KCl supporting electrolytes. Visco [32] described a minimum as a region of negative resistance in the reduction of the In(III) in the acidic solution of halides or pseudohalides. A further discussion about the minimum observed in the polarographic wave of In(III) in aqueous electrolyte solutions may be obtained from de Levie and Husovsky [33]. The minima we obtained increase in size with the increasing concentration of the potassium chloride showing that they are associated with the chloride concentration. The adsorption of the anion at the dropping mercury electrode also appears associated with the potential of the electrode.

3.2.2. Half-wave potentials, n and $|E_{3/4} - E_{1/4}|$ values

The $E_{1/2}$ values obtained for In(III) in KCl supporting electrolyte show definite shifts toward more negative values with the increasing concentration of the KCl. This contrasts with the pattern of $E_{1/2}$ values with the increasing concentration of the KNO_3 supporting electrolyte. Pines [34] earlier made observations that $E_{1/2}$ values of the metal ions shift to more negative values by complex formation.

The n values were also determined from the slope of the straight line obtained by plotting the potential of the dropping mercury electrode against the values of $\log[I/(I_d - I)]$. $|E_{3/4} - E_{1/4}|$ values were determined directly from the polarogram recorded. Lingane [35] obtained n values of three for the In(III) species reduction in 0.1 and 1 M KCl, respectively. Our values agree well with his. The $|E_{3/4} - E_{1/4}|$ values that we obtained are also close to the predicted one [17,21] of 18.8 mV for a 3-electron reversible system.

4. Conclusion

We were able to obtain the diffusion coefficient values for the polarographic reduction of In(III) in KNO_3 and KCl supporting electrolytes. The values are smaller than the reported ones [10] obtained under similar conditions. The calculated value of the diffusion coefficient using the Nernst–Einstein relation [36] is 5.94×10^{-6} cm^2 s^{-1}. This calculation, which is based on the molar conductivity of an ion, assumes that at infinite dilution intermolecular or interionic interactions do not exist. In real solutions this can never be the case. The values $|E_{3/4} - E_{1/4}|$ predicted reversibility of reduction of the In(III) in KCl supporting electrolyte. An irreversible behavior is observed for In(III) in KNO_3. Finally, we note that due to minima that occur in the reduction of the In(III) species in high concentrations of KCl, polarographic analysis of mixtures with other ions, such as gallium(III), would be more difficult.

Potentiometric study of reaction between tetrabutylammonium periodate and phenothiazine in chloroform; application to the analysis of phenothiazine derivatives

M.H. Pournaghi-Azar *, Kh. Farhadi

Department of Analytical Chemistry, Faculty of Chemistry, University of Tabriz, Tabriz, Iran

Received 29 July 1996; received in revised form 8 January 1997; accepted 15 January 1997

Abstract

The reaction between tetrabutylammonium periodate and phenothiazine in the presence of the strong acids in chloroform was studied by potentiometry and the reaction pathways were determined. The oxidimetric titration conditions of phenothiazine derivatives using a standardized chloroform solution of tetrabutylammonium periodate were optimized and a potentiometric detection of end points was utilized. The relative standard deviation for the determination of 5 mg phenothiazines was obtained about 1–1.5%. The method was applied for the determination of phenothiazines in various pharmaceutical preparations after extraction into chloroform. © 1997 Elsevier Science B.V.

Keywords: Non-aqueous solvent; Phenothiazines; Potentiometry; Chloroform

1. Introduction

Several electroanalytical methods have been developed for the determination of phenothiazine derivatives in pharmaceutical preparations [1–10]. Usually, the potentiometric method can be simple and fast for pharmaceutical analysis. Ion selective membrane electrodes have been used for the potentiometric determination of some phenothiazine drugs [11]. Two-phase potentiometric titration was also reported [12]. Most of the employed methods for the determination of phenotiazine drugs in pharmaceutical preparations follow a preliminary separation by solvent extraction into an organic solvent, therefore direct application of potentiometric titration method in extracts is fast and sensitive when a suitable reagent and indicator electrode is available [9,13,14]. Golabi et al. [13] have applied the potentiometric titration for the determination of phenothiazine drugs using a chloroform solution of bromine. Since the bromine solution in chloroform suffer from a lack of stability and oxidizing strength, the use of a suitable oxidizing agent in chloroform seem to be interesting.

The aim of the present work is to study the reaction between tetrabutylammonium periodate and phenothiazines in chloroform in order to develop a potentiometric method of analysis on the basis of the oxidimetric titration for the deter-

mination of phenothiazine derivatives. The investigated phenothiazines are given in Table 1.

2. Experimental

2.1. Apparatus

A Video titrator Vit 90 (Radiometer) coupled with a Toshiba P321SL printer or an E 536 potentiograph equipped with an E 578 titration stand (Metrohm) were used to plot the normal and inflection forms of the titration curves.

2.2. Reagents

The solvent used was chloroform G.R. from E. Merck, tetrabutylammonium periodate (AIO_4), perchlorate ($ACIO_4$), chloride (ACl) and iodide (AI) were from Janssen. A 0.001 M solution of AIO_4 in chloroform was used. This solution was stable in refrigerator during the weeks. Concentrated perchloric acid 70% and *p*-toluenesulfonic acid (TSO_3H) from E. Merck was used as a suitable strong acid for acidifying the test solutions up to 0.1 M. A 0.005 M phenothiazine solution was prepared by dissolving the pure substance (Aldrich). Chloroform solutions of *N*-substituted phenothiazines such as promethazine, chlorpromazine, perphenazine, trifluoperazine and thioridazine were prepared from their pure hydrochlorides (purchased from local sources).

2.3. Electrodes

The reference electrode Ag/AgCl (sat'd), 0.05 M ACl and 0.5 M $ACIO_4$ in chloroform prepared in a separated compartment with a dense ceramic plug in the bottom was used. The indicator electrode was Pt wire or Pt disk.

2.4. Procedures

2.4.1. Extraction and separation of phenothiazines from pharmaceutical preparations

The pharmaceutical preparations were obtained from local sources in various forms (tablet, syrup and injection) and phenothiazines were extracted into chloroform as follows: An accurately measured volume of syrup and injection solutions or weighed portion of finely powdered tablets equivalent to about 50 mg of phenothiazine drugs (as their hydrochlorides)were transfered to a 125-ml separating funnel, 10 ml of 1 M NaOH, was added and extracted with three 20-ml portions of chloroform, shaking gently for 3 min to avoid emulsion formation. The extracts were combined in a 100-ml volumetric flask.

2.4.2. Standardization of AIO_4

A 10-ml portion of 0.01 M AIO_4 solution in chloroform was pipetted into a 125-ml separating funnel and the required amount of AI and a suitable strong acid such as *p*-toluenesulfonic or perchloric acid was added up to 0.1 M. The solution was shaken two times

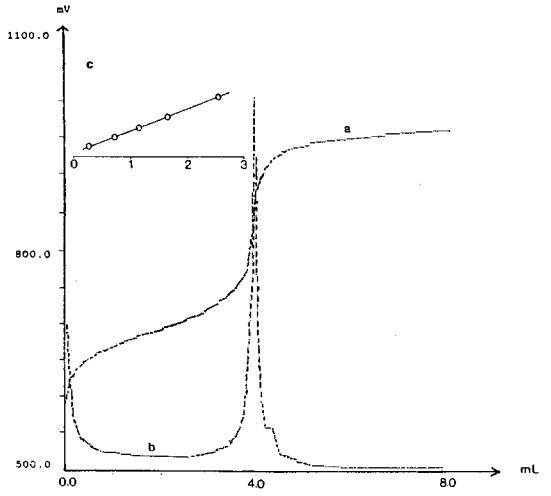

Fig. 1. Potentiometric titration of 5 ml 0.005 M phenothiazine + 5 ml 0.2 M *p*-toluenesulfonic acid with 0.0009 M AIO_4 solution (a) plots of E vs. V_{AIO_4}, (b) $\Delta E/\Delta V$ vs. V_{AIO_4} and (c) E vs. $\log[x/F(1-x)^2]$, delivery rate: 0.5 ml min^{-1}.

with a 10-ml portion of 1 M aqueous solution of KI for 2 min. The aqueous phases were separated and combined in a conical flask. The yielded I_2 according to the following reaction [14]:

$$7AI + AIO_4 + 8TSO_3H \rightleftharpoons 4I_2 + 8ATSO_3 + 4H_2O$$

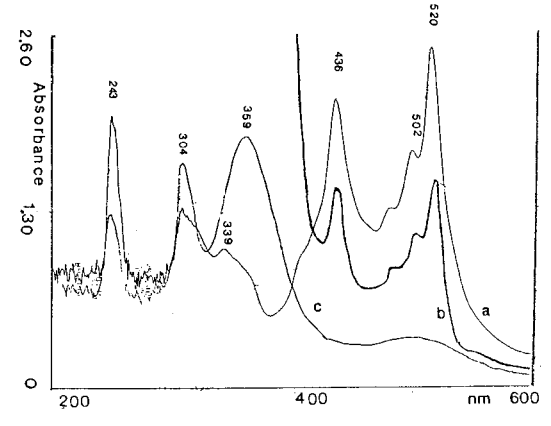

Fig. 2. Absorption spectra of (a) titrated solution of Ph with AIO_4 at the equivalence point, (b) partially oxidized Ph solution in chloroform with molecular oxygen and (c) acidified iodine chloroform solution.

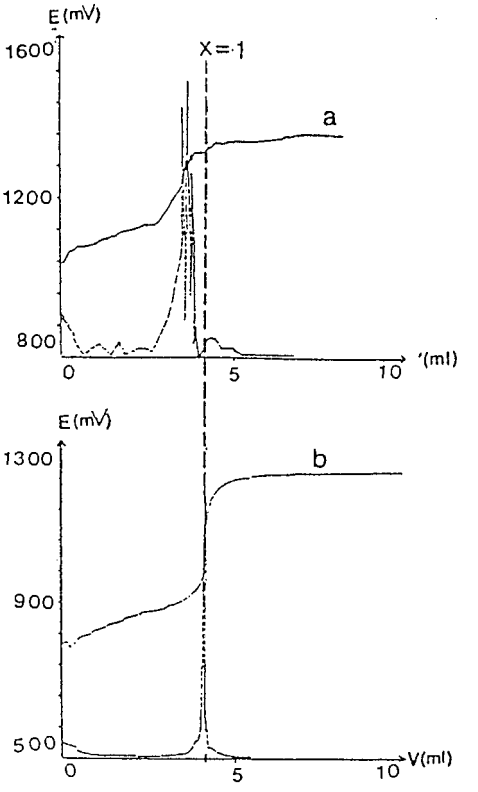

Fig. 3. Potentiometric titration of 5 ml 0.005 M phenothiazine with 0.0009 M AIO_4 solution in the presence of (a) 0.1 M sulfuric acid and (b) 0.1 M *p*-toluenesulfonic acid, delivery rate 0.5 ml min^{-1}.

which extracted in aqueous phase, was titrated with a 0.01 M standard solution of thiosulfate.

2.4.3. Titration of phenothiazine drugs

A 10-ml portion of chloroform extracts, obtained from the extraction of pharmaceutical preparation samples was pipetted into the reaction vessel and a required amount of strong acid such as *p*-toluenesulfonic acid or perchloric acid was added up to 0.1 M. The solution was titrated with AIO_4 solution (about 0.001 M) at a delivery rate of 0.5 ml min^{-1} using the autotitrator and the titration curve was plotted.The quantitative determination of phenothiazine drugs in the extracts is achieved in one of the following ways:

1. A standardized solution of AIO_4 is used in titration.

2. Another titration is carried out with a second 10-ml aliquot of pure *N*-substituted phenothiazine. The quantity of phenothiazine is calculated by comparison of the volumes of titrant used in 2 titrations.

2.4.4. Reaction pathways and stoichiometry

The results obtained from our previous works reveal that: (a) the potentiostatic oxidation of phenothiazines in chloroform occurs in two one-electron steps by forming the cation radical and dication respectively [9] and (b) the reaction between AIO_4 and AI gives rise to the formation of AI_3 and I_2, respectively [14]. Therefore on the basis of results mentioned above (a,b) the titration reaction may be proceeded according to one of the following schemes:

1. Oxidation of phenothiazines to cation radical involving a 3-step process.
   (a) $8Ph + AIO_4 + 8TSO_3H \rightleftharpoons AI + 8PhTSO_3 + 4H_2O$
   (b) $11AI + AIO_4 + 8TSO_3H \rightleftharpoons 4AI_3 + 8ATSO_3 + 4H_2O$
   (c) $7AI_3 + AIO_4 + 8TSO_3H \rightleftharpoons 11I_2 + 8ATSO_3 + 4H_2O$
2. Oxidation of phenothiazines to cation radical involving a one step process only.
   $14Ph + 2AIO_4 + 16TSO_3H \rightleftharpoons I_2 + 14PhTSO_3 + 2ATSO_3 + 8H_2O$
3. Oxidation of phenothiazines to dication involving a 2-step process.
   (a) $14Ph + 2AIO_4 + 16TSO_3H \rightleftharpoons I_2 + 14PhTSO_3 + 2ATSO_3 + 8H_2O$
   (b) $14PhTSO_3 + 2AIO_4 + 16TSO_3H \rightleftharpoons I_2 + 14Ph(TSO_3)_2 + 2ATSO_3 + 8H_2O$

   where Ph and A show phenothiazine and tetrabutylammonium cation, respectively.

Considering $x = (\text{added } AIO_4)/(C_o/8)$ (where C_o is the initial concentration of phenothiazine), according of scheme 1 the titration plots E vs. V_{AIO4} must show three inflection points at

$$x = 1\left(\frac{C_o/8}{C_o/8}\right),\ 1.09\left(\frac{3C_o/44}{C_o/8}\right)$$

and

$$1.14\left(\frac{C_o/7}{C_o/8}\right)$$

respectively. While on the basis of Scheme 2 only one potential rise is expected to appear at $x = 1$ where

$$x = \frac{\text{added } AIO_4}{C_o/7}$$

At least considering the Scheme 3, two equivalence points at $x = 1$ and $x = 2$ are expected to appear, where

$$x = \frac{\text{added } AIO_4}{C_o/7}$$

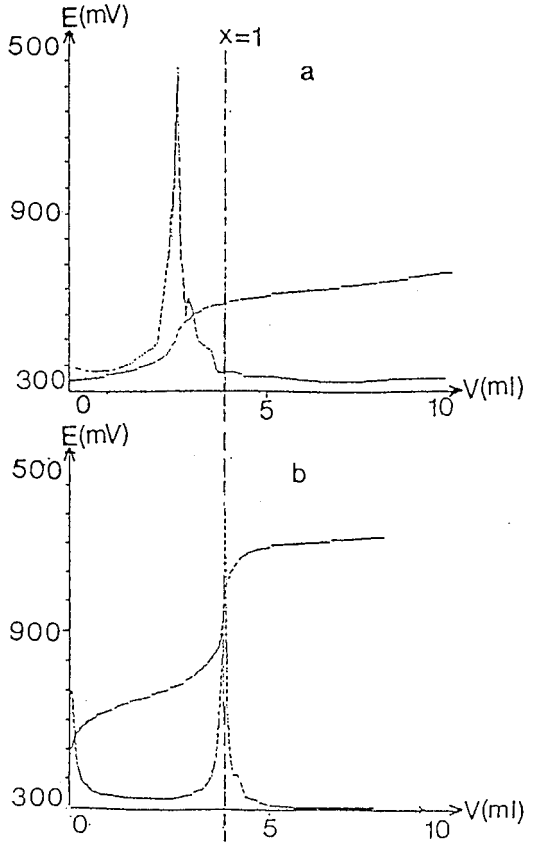

Fig. 4. Potentiometric titration of 5 ml 0.005 M phenothiazine with 0.0009 M AIO_4 solution in the presence of 0.1 M perchloric acid with delivery rate of (a) 1 ml min^{-1} and (b) 0.5 ml min^{-1}.

3. Results and discussion

The potentiometric plot for the titration of 5 ml 0.005 M phenothiazine in chloroform with a standardized chloroform solution of AIO_4 (0.0009 M) in the presence of 0.1 M *p*-toluenesulfonic acid was shown in Fig. 1. As seen in this figure the potential ranges from 600 to 1000 mV vs reference electrode and only one inflection point appears at $x = 1$. On the other hand the plot of E vs. V_{I_2} during the addition of 0.001 M chloroform solution of I_2 to 10 ml 0.005 M phenothiazine shows that the potential remains unchanged. These observations lead us to conclud that the reduction product of AIO_4 by phenothiazine is I_2 and the titration reaction pathway corresponds to the Scheme 2. Alternatively, this can be tested by an analysis of the experimental titration curve. The electrode potential on the two sides of the equivalence point can be expressed as follows at 25°C.

Before the equivalence point:

$$Ph^+ + e \rightleftharpoons Ph$$

$$E = E^{o_{Ph}} + 0.059 \log \frac{[Ph^+]}{[Ph]} \quad (1)$$

because of the ion-pair formation, a dissociation equilibrium must also be considered for $PhTSO_3$ and $ATSO_3$ as follows:

$$PhTSO_3 \rightleftharpoons Ph^+ + TSO_3^-,$$

$$K_1 = \frac{[Ph^+][TSO_3^-]}{[PhTSO_3]} \quad (2)$$

$$ATSO_3 \rightleftharpoons A^+ + TSO_3^-, \qquad K_2 = \frac{[A^2][TSO_3^-]}{[ATSO_3]} \quad (3)$$

According to Eqs. (2) and (3) we can write:

$$[TSO_3^-] = [Ph^+] + [A^+] = \frac{K_1\,[PhTSO_3]}{[TSO_3^-]} + \frac{K_2[ATSO_3]}{[TSO_3^-]}$$

$$[TSO_3^-]^2 = K_1[PhTSO_3] + K_2[ATSO_3] \quad (4)$$

and from Eqs. (2) and (4) we have

$$[Ph^+] = \frac{K_1^2\,[PhTSO_3]^2}{K_1[PhTSO_3] + K_2[ATSO_3]} \quad (5)$$

$$E = E^{o_{Ph}} + \frac{0.059}{2} \log \frac{K_1^2[PhTSO_3]^2}{[Ph]^2(K_1[PhTSO_3] + K_2[ATSO_3])} \quad (6)$$

Considering

$$x = \frac{\text{added } AIO_4}{C_o/7}$$

on the basis of the reaction of Scheme 2, at any point of the titration we can write:

$[Ph] = F(C_o - xC_o)$, $[PhTSO_3] = FxC_o$

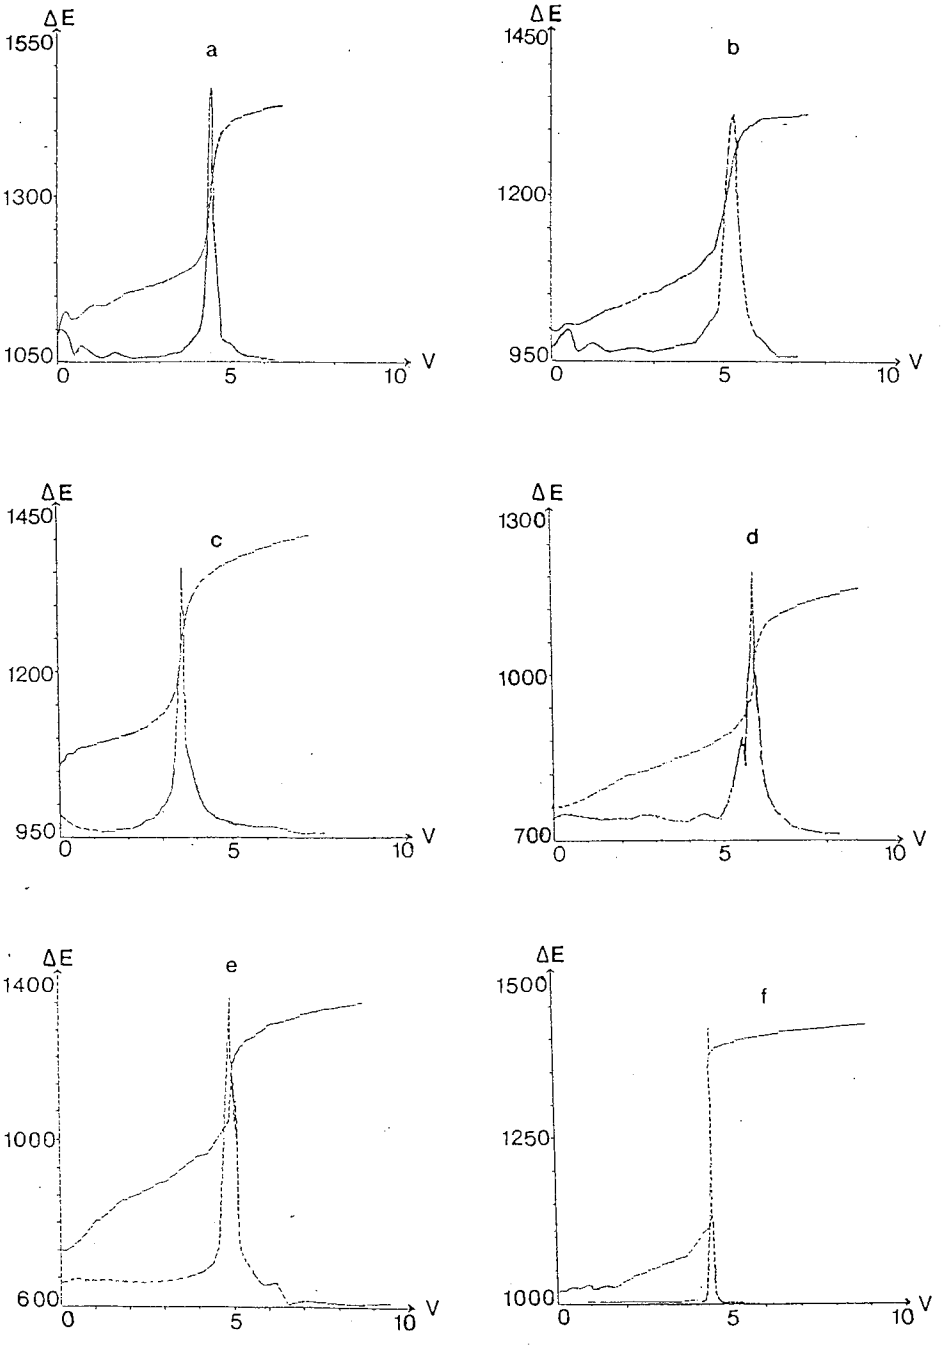

Fig. 5. Potentiometric titration curves of 10-ml portion of chloroform extracts containing about 5 mg of phenothiazine drugs with a 0.00085 M solution of AIO_4 in the presence of 0.1 M $HClO_4$. The extracts correspond to the extraction of about 25 mg of phenothiazine derivatives from (a) chlorpromazine 25 mg tablet^{-1}, (b) promethazine 25 mg tablet^{-1}, (c) thioridazine 10 mg tablet^{-1}, (d) chlorpromazine 50 mg 2 ml^{-1}, (e) promethazine 5 mg 5 ml^{-1}, and (f) perphenazine 5 mg 1 ml^{-1} into 25 ml (10, 10 and 5 ml) of chloroform.

Table 3
Determination of phenothiazinic drugs by potentiometric and USP methods

	Nominal content	Found[a]	
		Proposed method	USP method
Promethazine tablet	25 mg tablet^{-1}	26 ± 1	26.0 ± 0.6
Perphenazine ampoule	5 mg ml^{-1}	5.3 ± 0.2	5.5 ± 0.3
Trifluoperazine tablet	5 mg tablet^{-1}	5.5 ± 0.3	5.3 ± 0.2
Thioridazine tablet	25 mg tablet^{-1}	25 ± 1	25 ± 1

[a] Mean of three determinations and 90% confidence interval of the mean.

$[ATSO_3] = FxC_o/7$, $F = V/V + v$, where V is the initial volume of test solution, v is the volume of added AIO_4

$$E = a_1 + \frac{0.059}{2}\log\left(\frac{x}{F(1-x)^2}\right) \quad (7)$$

With:

$$a_1 = E^{oPh} + \frac{0.059}{2}\log\frac{7k_1}{C_o(k_1 + 7k_2)} \quad (8)$$

After the equivalence point

$2AIO_4 + 14e + 16TSO_3H \sim$

$\rightleftharpoons I_2 + 2ATSO_3 + 14TSO_3^-$

$$E = E^{oIO_4} + \frac{0.059}{14}\log\frac{[AIO_4]^2[TSO_3H]^{16}}{[I_2][ATSO_3]^2[TSO_3^-]^{14}} \quad (9)$$

Considering Eq. (4) and the concentration balance:

$[I_2] = FC_o/14$, $[ATSO_3] = FC_o/7$, $[PhTSO_3] = FC_o$

$[AIO_4] = FC_o(x-1)/7$, $[TSO_3H] = 0.2F$we can rewrite Eq. (9) as follows:

$$E = a_2 + \frac{0.059}{14}\log F^8(x-1)^2 \quad (10)$$

With: $a_2 = E^{oIO_4} + 0.067\log[TSO_3H]/C_o - 0.029\log(7k_1 + k_2) + 0.004$

The plot of E vs. $\log[x/F(1-x)^2]$ for $0 < x < 1$ and E vs. $\log[F^8(x-1)^2]$ for $x > 1$ gave straigth lines with slopes of 0.059/2 and 0.059/14 respectively (see Fig. 1C). This agree with the proposed stoichiometry for the titration reaction according to Scheme 2. The three replicate potentiometric titration plots of the phenothiazine solutions of various concentrations were analysed and the titration reaction pathway of Scheme 2 was confirmed. The same stoichiometry were observed for the titration reactions of the *N*-substituted phenothiazines investigated.

3.1. Spectrophotometric investigation

The absorption spectra of (a) diluted (10 times) of titrated solution of Ph (0.0025 M) with AIO_4 in the presence of 0.1 M TSO_3H at the equivalence point, (b) partially oxidized Ph solution by molecular oxygen ($Ph^+ + Ph$) and (c) violet coloured solution of 0.001 M iodine + 0.1 M TSO_3H in chloroform are given in Fig. 2. The absorption maxima appeared at visible region 600–400 nm (a and b) confirmed that the oxidation product of Ph with AIO_4 was Ph^+ (cation radical). On the other hand looking to spectrum (c) clears that the iodine solution in acidified chloroform has three absorption maxima at 502,359 and 3043 nm. In titrated solution of Ph by AIO_4 these absorption maxima of I_2 also appeared,while the first is overlapped by some absorptive maxima of Ph. Note that the absorptive maxima for yellow-red coloured AI_3 in chloroform appeared at 509 and 288 which differs from the spectrum of I_2. These findings shows that the reduction product of AIO_4 by Ph I_2 and the reaction pathway of Scheme 2 is confirmed.

4. Analytical aspects

4.1. Optimization of the titration conditions

In order to optimize the proposed potentiometric method the effect of some experimental variables were studied. Of the various acids tested, *p*-toluenesulfonic acid and perchloric acid were found to be the most suitable for phenothiazine (Fig. 3). But for *N*-substituted phenothiazines the titration reactions proceed according to scheme 2, only in the presence of 0.1 M perchloric acid. On the other hand the most reproducible and accurate result was obtained with a delivery rate of 0.5 ml min^{-1} (Fig. 4)

4.2. Performence characteristics

The precision and accuracy of the proposed method was evaluated by analysis of three pure samples of each phenothiazine investigated and comparing the results with those obtained by the official USP method [15] based on acidimetric titration in anhydrous acetic acid (Table 1). As shown by the recoveries and standard deviations ranging from 0.9 to 1.8% a satisfactory agreement between the results was obtained (except thioridazine). This was confirmed by statistical analysis, based on the variance ratio test (*F* test) and Student's *t*-test (see Table 1). The detection limit of the method depends on the oxidation ability of phenothiazine via molecular oxygen. On the other hand the reproducibility and accuracy of the determination at low concentration level, suffered from a lack of stability of the test solutions via molecular oxygen. However we have demonstrated that the satisfactory results with the relative S.D. of 0.8–2.5% for the determination of 0.0008–0.05 M of some phenothiazine derivatives such as chlorpromazine and trifluoroperazine ($n = 3$) can be obtained and a concentration range 0.001–0.02 M may be suitable for the titration of studied phenothiazines.

4.3. Application to dosage forms

Several phenothiazine drugs obtained from the local sourses were analysed by the present method. The results shown in Table 2 indicate that the phenothiazines in dosage forms of various claimed amount ranging from 5–25 mg per tablet and 1–25 mg ml^{-1} of injection can be conveniently determined by the proposed potentiometric method with good precision. Fig. 5 illustrates the potentiometric titration of some phenothiazines extracted from the dosage forms (tablet, ampoule or syrup) into chloroform (see experimental procedure).

We have evaluated the accuracy of the proposed method by performing experiments on the samples prepared from dosage forms and pure drugs. A mean recovery of 101% (ranging from 99.8 to 102.2%) was found (Table 2). Furthermore the results obtained for some typical pharmaceutical preparations by the present method were compared with those obtained by the time consumming official USP methods [15]. The results are given in Table 3. As can be seen, there is reasonable fair agreement between the present and official methods.

5. Conclusion

The proposed potentiometric titration method in chloroform is fast, precise, accurate and general. This method is suitable for the routine analysis of commonly used phenothiazine drugs in various commercial formulations (tablet, ampoule and syrup) of various amount of drugs ranging from 5 to 25 and 1 to 25 mg ml^{-1} for injections, instead of the tedious time consumming official methods. Interferences from common excipients are prevented by the selective extraction of phenothiazines into chloroform.

Determination of abscisic acid by cathodic stripping square wave voltammetry

P. Hernández, M. Dabrio-Ramos, F. Patón, Y. Ballesteros, L. Hernández *

Departamento de Química Analítica, Universidad Autónoma de Madrid, Madrid, Spain

Received 10 October 1996; received in revised form 15 January 1997; accepted 12 February 1997

Abstract

In this paper a study is accomplished on behavior in a mercury electrode, of the phytohormone abscisic acid and of the conditions of accumulation in a HMDE. A mechanism is proposed of reduction based on its electrochemical behavior and proving the product of the reduction through mass spectrometry of bulks. A method is proposed for the determination of Abscisic acid (ABA) with a quantification limit of 58 ng ml^{-1}. The procedure is applied wing determination of ABA in pears through the combination of high performance liquid chromatography (HPLC) with electrochemical quantification. © 1997 Elsevier Science B.V.

Keywords: Abscisic acid; Phytohormone; Mercury electrode

1. Introduction

Plant hormones or phytohormones are regulators that are produced by the plant itself. In low concentrations, they control the physiological processes. Phytohormones are classified into four groups: auxines, gibberellines, cytoquinines and inhibitors. Abscisic acid (ABA) belongs to the latter, which is quite different from the other groups of plant growth substances, as it inhibits or delays the physiological or biochemical process of plants [1].

Abscisic acid was isolated from young cotton fruit (*Gossypium hirsutum*) by a research group led initially by Corns and subsequently by Addicot [2]. Its structure, shown in Fig. 1, was determined by Ohkuma and associates [2].

The levels of concentration of this inhibitor vary considerably from one plant species to another and depend on environmental conditions [1]. Philips and Waring [2] studied this variation in *Acer pseudoplatanus* buds and leaves, finding

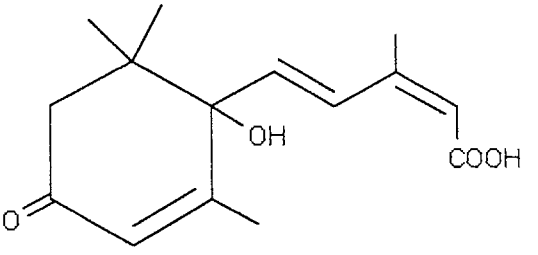

Fig. 1. Molecular structure of abscisic acid (ABA).

* Corresponding author.

PII S00 9-9140(97)00049-0

minimum levels of ABA in June in the terminal buds and maxima in winter, precisely the opposite of the leaves. This suggests that the inhibitor formed in the leaves in summer shifts to the terminal buds at the start of autumn.

Hormonal action depends on the hormone concentration, the presence and characteristics of the receptor and the elements involved in the signal transduction chain. The hormone-receiver complex, i.e., the activated receiver, is the first link in the signal transduction chain, which provokes a primary response. This in turn begins a series of changes which, as a whole, make up the complex physiological response.

In the case of abscisic acid, there is no single biological activity, which instead is manifested in several types of physiological response. The ABA has a great inhibiting effect on the growth of many types of plants. It is not the only growth-inhibiting substance, but it is the only one that is non-toxic. A seed treated with ABA, for example, can germinate once it is placed in another medium. With another inhibitor, this seed does not germinate [2].

Seed germination is regulated by the level of ABA and gibberellins (phytohormones that stimulate cell division or prolongation, or both). Gibberellins induce the synthesis of α-amylase, while the ABA inhibits this action, stopping cell division and hence growth [3].

Abscisic acid accelerates the abscission process in flowers and fruit, as well as in the reproductive organs of a wide variety of plant species [4], and ABA is also responsible for the closure of the stomas in the leaves of some plants such as *Triticum vulgare*, thus producing a reduction in transpiration [5].

In addition to plant activity, it has been suggested that abscisic acid inhibits reproduction in insects and the growth of tumours in some types of mice [2].

Given its importance, abscisic acid has been studied widely from an analytic perspective ever since its discovery. The first technique used to identify this acid, at the start of the 1960s, was paper chromatography (PC), which was soon replaced by thin layer chromatography (TLC). Detection was by means of UV spectroscopy because abscisic acid has an intense, well defined band [2]. As other techniques spread, however, TLC and PC was left as a mere technique for sample pre-purification. Gas chromatography (GC) and high performance liquid chromatography (HPLC) began to be used in the 1970s to study abscisic acid, and coupled to mass spectroscopy (MS) are an excellent method of identification [6,7]. The problem in HPLC analysis is the low specificity of the UV detector. GC-MS is a powerful method for identification, but the samples must be cleaned up. The lower limit of detection of ABA is 50 ng in HPLC. Before the analysis, crude samples should be purified by solvent partitioning and preparative TLC or by a short column such as the C_{18} Sep-pak cartridge [2]. Bioassay and immunoassay has been also used for determination and quantification of abscisic acid, and does not require pre-purification, although the experimental period tends to be very long due to the preparation of the antigen and the antiserum [8].

In recent times, the same techniques used in previous years have continued to be used for the determination and quantification of ABA, although additional techniques such as ELISA have arisen. We have not, however, found any literature on the electrochemical study of this phytohormone. This analysis, discussed in the present paper, is approached using square wave voltammetry (SWV), given that the coupling of an accumulation step to an impulse technique would enable us to obtain detection thresholds in the order of ng ml^{-1}. The use of an electrochemical measurement provides an additional selectivity which allows one to avoid the needed pre-purification steps used on other methods, such as GC or HPLC-UV. Likewise, the limit of detection obtained in this proposed method for quantification of ABA is similar to those obtained by using other traditional methods.

2. Experimental

2.1. Reagents and equipment

- A 0.2 mg ml^{-1} solution of abscisic acid (ABA) in methanol prepared from the crystallized

form supplied by SERVA (New York, USA). The solutions must by refrigerated and not exposed to light.

- Analysis quality reagents.
- Deionised water using Milliro-MilliQ (Water System) equipment.
- PAR polarographic analyser model 384B, equipped with a Ag/AgCl/KCl (3M) reference electrode and a platinum counter electrode. This polarograph was used for the square wave and cyclical voltammetry analyses using a hanging drop mercury electrode (HDME).
- Bioanalytical System Potentiostat BAS 100, equipped with a mercury pool electrode, a saturated calomel electrode as the reference electrode and a platinum electrode as the counter electrode. These were used for a coulometric analysis of the abscisic acid.
- HEWLETT PACKARD model 5890 Series II gas chromatograph with a HEWLETT PACKARD model 5971A spectrometry detector used to identify the coulometric reaction products.
- High performance liquid chromatography composed of a GILSON 302 pump connected to a GILSON 802C manometric module, with a GILSON 116 UV detector attached to the unit. The HPLC was used a the preparative separation method in a plant extract for subsequent electrochemical detection.

2.2. Procedure

The polarographic cell contains a 10-ml buffer solution at a previously adjusted pH and a known concentration of abscisic acid. The O_2 was eliminated by means of a stream of N_2 for 5 min in the first measurement and 30 s in the subsequent potential scans. An accumulation time (t_{ac}) was applied at an accumulation potential (E_{ac}) with a stirring speed of 400 r.p.m. The polarogram was recorded between -0.4 and -1.1 V for a mercury drop electrode of 0.0278 cm^2 average area, replaced for each measurement, against an Ag/AgCl 3M electrode and a platinum counter electrode. The equilibrium time was 5 s.

In order to establish the measurement conditions, the corresponding variable was modified in each analysis to find the optimum response value, establishing initial conditions of: square wave frequency (f) at 50 Hz with increments in the step wave potential (E) of 2 mV in each cycle, producing a scan rate of 100 mV s^{-1}. The pulse amplitude (a) was 20 mV.

2.2.1. Extraction procedure

The procedure used was as follows: 51.35 g of pears was pulverised after prior freezing with liquid nitrogen. Methanol (200 ml) was added, ensuring contact by constant stirring at 4°C for 24 h. The extract was vacuum filtered on a G4 filter plate, and the resulting extract was evaporated at 40°C in a rotary evaporator to a minimum volume. The extract was centrifuged to remove pigments and lipid phases, dissolved in methanol and levelled to 10 ml.

2.2.2. Methylation of the ABA carboxyl group [14]

100 μl of a 50 μg ml^{-1} ABA solution in methanol was taken and the solvent was evaporated by means of a N_2 stream. The dry residue was dissolved in 100 μl of a mixture containing acetonitrile:water:methanol:pyridine (7:1:1:1), adding 5 μl of methylchloroformate (MCF), which acted as the methylating agent, 100 μl of chloroform and 100 μl of 1M sodium bicarbonate. The abscisic acid was methylated in this medium, and afterwards the methylated compound was extracted in the chloroform, which remained at the bottom. After separating the two phases, the chloroform was removed by evaporation using a N_2 stream, leaving a dry residue that was dissolved in 100 μl of hexane.

3. Results and discussion

3.1. Influence of pH and accumulation potential on the abscisic acid reduction

The purpose of this study was to ascertain the conditions that facilitate the greatest adsorption of abscisic acid on the surface of the mercury droplet.

The measurements were made in different solutions containing 1.6 μg ml^{-1} of ABA in $HClO_4$, 1

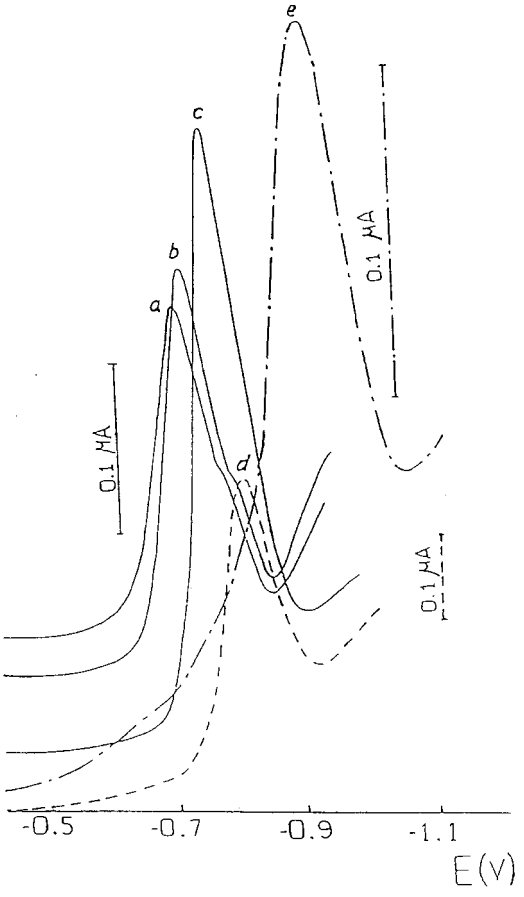

Fig. 2. Square wave voltammograms of abscisic acid reduction at different pH values: (a) pH 0; (b) pH 0.3; (c) pH 1; (d) pH 2 and (e) pH 3.

and 0.1 M, and H_3PO_4 0.04 M, obtaining the desired pH for the analysis in each case with KOH additions. An accumulation time of $t_{ac} = 30$ s was used, along with the rest of the conditions described in Section 2.2. The accumulation potential (E_{ac}) was varied for each pH value.

Fig. 2 shows the results for pH lower than 3. Beyond this pH, the width at half height grows considerably while the peak intensity diminishes, with a poor definition of the hormone reduction wave. In the concentrations at which it was found, the abscisic acid was not electroactive at basic medium.

Our results suggest that the pH is achieved at pH = 1, where the best wave definition and the highest peak intensity corresponding to the electroreduction of the phytohormone appear. We chose an accumulation potential of $E_{ac} = -0.4$ V and pH 1 for the subsequent analyses.

From the analysis of the variation in the pH, we obtain a shift in the peak potential towards more cathodic values, indicating an intervention of the protons in the reaction of the abscisic acid electroreduction. This shift shows two linear zones with differing slopes in the pH range under consideration. For pH levels between 0 and 2, the linear dependence fits the equation of the line:

$$E_p = -0.74 - 0.05 \text{ pH}; \quad r = 0.986$$

when the pH is between 2 and 4, the variation of the peak potential is linear, fitting the equation:

$$E_p = -0.64 - 0.1 \text{ pH}; \quad r = 0.993$$

in which peak potential is expressed in V.

The point of intersection between the two straight lines produces the value of pK corresponding to the abscisic acid system, obtaining a value of p$K = 1.9$.

A coulometric study was performed in a BAS-100 electrochemical analyser using a cell with a mercury pool electrode as the working electrode. A perchloric acid-sodium perchlorate solution at pH 1 containing 200 g of abscisic acid was placed in the cell. Applying a potential of -1.0 V, the ensuing number of electrons involved in the process was $n = 4$ [9].

To identify the product of the electrolysis, the solution was fed through a Sep-Pak C_{18} cartridge, after which the reduction product was eluted with methanol. The acid group of the molecule was methylated, and the product was injected into the GC-MS. The mass spectrum indicates the reduction of two double conjugated bonds (Fig. 3).

The proposed reduction mechanism for the ABA is in Fig. 4.

3.2. Influence of the scan rate

The scan rate was analysed in cyclic voltammetry over a 1.6 μg ml^{-1} solution of ABA in $HClO_4$ 0.1 M at pH 1. In all the measurements, the accumulation time was $t_{ac} = 30$ s, and accumulation potential was $E_{ac} = -0.4$ V.

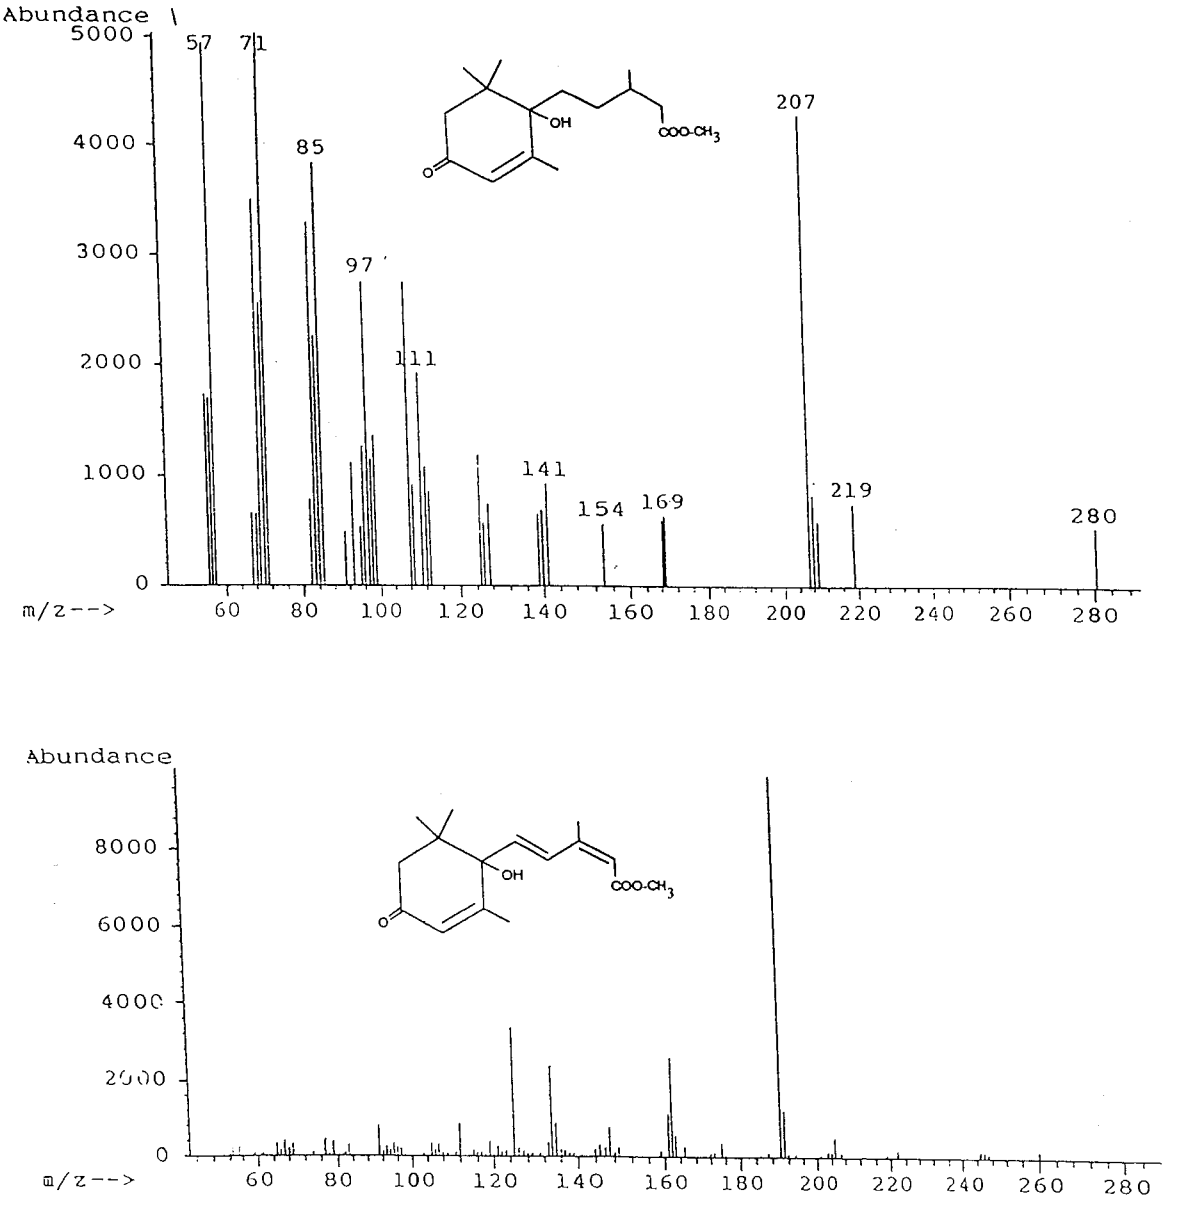

Fig. 3. Mass spectrum for the methylated ABA (down) and for the methylated product of the ABA electrolysis (up).

The data obtained with an increase in the scan rate indicate a shift in the peak potential towards more cathodic values. This variation of the peak potential in the abscisic acid reduction behaves linearly with the logarithm of the scan rate, following the equation

$$E_p = -0.7185 - 0.0422 \log v; \quad r = 0.996$$

where E_p is the peak potential expressed in V, and $\log v$ is the decimal logarithm the scan rate.

The intensity of the peak increases linearly with the scan rate, fitting the equation

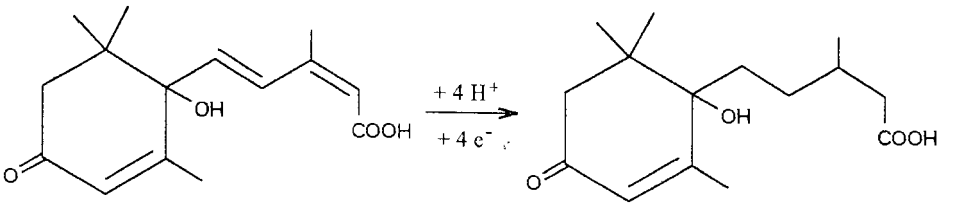

Fig. 4. The proposed reduction mechanism for the ABA.

$i_p = 0.0968 + 0.0021v; \quad r = 0.9994$

where the peak intensity is expressed in μA and the scan rate in mV s^{-1}.

This behaviour indicates that the abscisic acid reduction is produced by means of an adsorptive process controlled by diffusion [10] and is irreversible.

By representing the logarithm of the peak intensity at different scan rates against the peak potential, we obtain a linear relation that fits the equation

$\log i_p = -13.367 - 19.785E_p; \quad r = 0.995$

Using the value of the slope and knowing the number of electrons consumed in the electroreduction of the ABA, we can calculate the charge transfer coefficient, obtaining a value $\alpha = 0.31$ [11].

The influence of the square wave frequency was calculated under the conditions described in the Section 2.2, with the exception of the frequency variation. The results indicate that there is a linear dependency of the peak intensity on the frequency in accordance with the ratio:

$i_p = 3.059 \times 10^{-2} + 5.76 \times 10^{-3} f; \quad r = 0.9998$

expressing i_p in μA and where f is the square wave frequency expressed in Hz.

There is also a linear variation in the peak potential against the decimal logarithm of the frequency which fits the equation

$E_p = -0.72 - 0.044 \log f; \quad r = 0.997$

where E_p is the peak potential expressed in V and $\log f$ is the logarithm of the square wave frequency.

This analysis of the square wave frequency enables us to ascertain kinetic parameters of the electroreduction reaction of the abscisic acid in the mercury electrode. The value of the slope can be used to calculate the charge transfer coefficient (α), which can be calculated via the expression

$\Delta E_p / \Delta \log f = RT/Fn\alpha$

obtaining a value of $n = 1.58$. By means of coulometry, we found that the number of electrons exchanged by the molecule was $n = 4$. Hence, the value of the load transfer is $\alpha = 0.33$ [12].

Given that the peak intensity is linear with the square wave frequency, and that the peak potential is linear with the decimal logarithm of the square wave frequency, we can deduce that the electrochemical reduction process of the abscisic acid is of the adsorptive type controlled by diffusion. This concurs with the data obtained in the cyclic voltammetry analysis.

3.3. Influence of the square wave amplitude

From the variation in the square wave amplitude, we can obtain the degree of absorption of the ABA over the measurement electrode, i.e. the coating coefficient (Γ) of the mercury droplet used for measurement [12,13].

For this purpose we used an abscisic acid solution at 1.6 μg ml^{-1} concentration in $HClO_4$ at pH 1. We established an accumulation time of $t_{ac} =$ 30 s and the rest of the conditions as described in Section 2.2. The results are shown in Fig. 5.

In Fig. 5 we see an increase in the intensity of the peak with the amplitude of the square wave up to a value of $a = 40$ For higher values of the square wave amplitude, there is no significant increase in the peak intensity.

For square wave amplitude values lower than 20 mV, there is a linear increase in the value of the peak intensity that fits the equation:

$$i_p = 0.038 + 0.013a; \quad r = 0.992$$

where the peak potential is expressed in mV and the peak intensity in μA. On the basis of the slope of the line obtained for small square wave amplitudes, and knowing that the electrode has an surface area of 0.0278 cm^2, we can calculate a value for the coating coefficient of the mercury droplet of $1.9 \pm 0.7 \times 10^{-11}$ mol cm^{-2} [12,13].

3.4. Influence of the scan increment

Variations in the value of the scan increment produce changes in the intensity of the peak, which affect the sensitivity of the method. At the same time, however, the width at half height also varies, which affects its selectivity. A compromise must therefore be sought between the two factors.

In our measurements, we used a 1.6-μg ml^{-1} solution of ABA at pH 1 in $HClO_4$ 0.1 M, which acted as the supporting electrolyte. An accumulation time of $t_{ac} = 30$ s was set, using the rest of the initially established parameters.

Applying selectivity and sensitivity criteria, we took $E = 5$ mV as the optimum value for subsequent measurements as this combines a width at half height of $w_{1/2} = 95$ mV with a peak intensity of $i_p = 0.709$ μA.

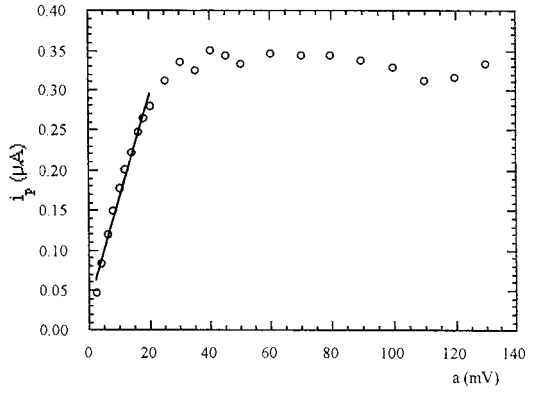

Fig. 5. Variation in peak intensity with square wave amplitude. Conditions in text.

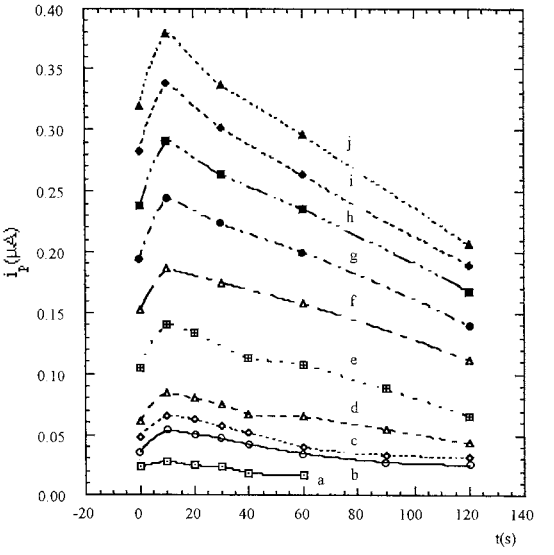

Fig. 6. Variation in peak intensity with accumulation time for different concentrations of ABA: (a) 0.1 μg ml^{-1}; (b) 0.2 μg ml^{-1}; (c) 0.3 μg ml^{-1}; (d) 0.4 μg ml^{-1}; (e) 0.6 μg ml^{-1}; (f) 0.8 μg ml^{-1}; (g) 1.0 μg ml^{-1}; (h) 1.2 μg ml^{-1}; (i) 1.4 μg ml^{-1} and (j) 1.6 μg ml^{-1}.

Fig. 6 graphs the results of varied accumulation times. In all cases, the adsorption of the hormone to the electrode reaches the highest peak intensity at an accumulation time of 10s. If this time is increased, the intensity of the peak diminishes. The optimum value is therefore $t_{ac} = 10$ s.

3.5. Influence of the buffer type

In the analysis of the influence of pH, the optimum working value was set at pH 1. On the basis of this condition, we tested different types of electrolytes: hydrochloric acid–sodium chloride, sulphuric acid–sodium sulphate, and finally perchloric acid–sodium perchlorate. Solutions of all these electrolytes at different concentrations were prepared to fix the ionic strength of the medium. Sulphuric acid–sodium sulphate solutions produce the highest peak intensities, the higher, the greater the concentration of electrolyte. This solution was thus used as a buffer medium and a support electrolyte at a 1 M concentration.

3.6. Influence of the ABA concentration

In the study of the effect of abscisic acid concentration on the peak intensity, the optimum conditions of the medium were set at those discussed in the previous sections.

The polarographic cell contained 10 ml of sulphuric acid-sodium sulphate solution at 1 M concentration, pH 1, which acted as a support electrolyte and different amounts of abscisic acid. An inert atmosphere was created by a stream of N_2 prior to each measurement. An accumulation potential $E_{ac} = -0.4$ V was applied for 10 s, with an equilibrium time of 5 s. The initial scan potential coincided with E_{ac}, and the final potential was set at -1.2 V to permit the full development of the wave.

Instrumental variables during the measurement stage were set at, pulse amplitude $a = 40$ mV, scan increment $E = 5$ mV, and square wave frequency $f = 120$ Hz, producing a scan rate of 600 mV s^{-1}.

There is an increase in the peak intensity with the concentration, shown in the superimposed voltammograms in Fig. 7.

This dependence of the peak intensity on concentration follows a linear relationship, which fits the expression

$$i_p = -1.76 \times 10^{-2} + 7.89 \times 10^{-4} C; \quad r = 0.999$$

The intensity of the peak is expressed in μA while the concentration is in ng ml^{-1}.

The relative error of the method ranges between 0.3 and 0.8% in absolute values and the relative standard deviation varies between 2.1 and 7.8%, producing a detection threshold of 30 ng ml^{-1} and a quantification threshold of 58 ng ml^{-1}.

4. Application

After optimising the abscisic acid determination method, it was applied to an extract of pears taken straight from the tree at the initial growth stage.

The extract obtained from little pears, like abscisic acid, contains many other compounds that interfere with voltammetric measurements, making purification necessary. For this purpose, HPLC was used as the preparatory technique in a 10-μm column of C_{18}, using a 0.01M mixture of methanol:phosphoric acid at pH 3 (1:2 v/v) as the eluent at a flow of 1.8 ml min^{-1}, and a UV detector at a wavelength of 270 nm. The retention time of the abscisic acid was 19.51 min. The corresponding fraction was collected at the column outlet.

For the purification process, we injected into the column a mixture containing 3 ml of extract and 6 ml of phosphoric acid with a 500 μl loop.

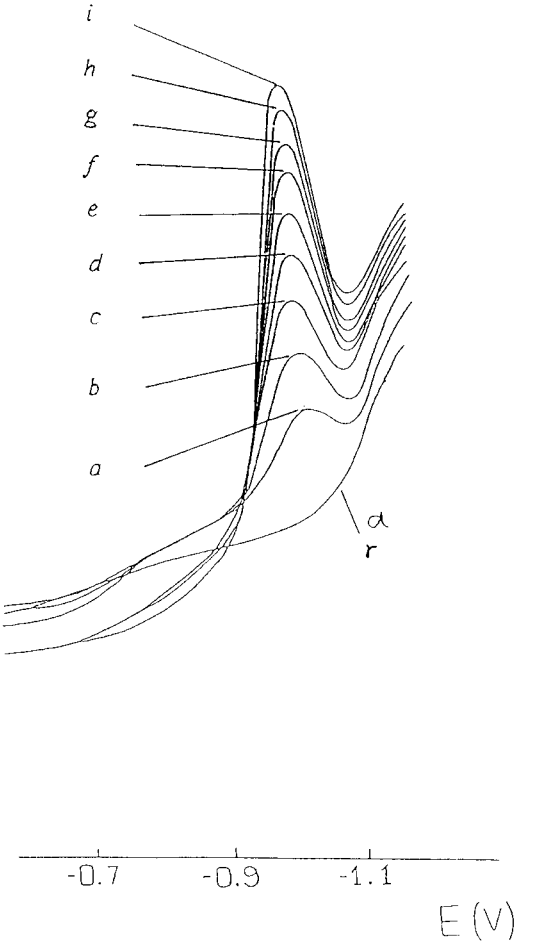

Fig. 7. Square wave voltammograms of abscisic acid reduction at different concentrations: r = residual current; (a) 75 ng ml^{-1}; (b) 125 ng ml^{-1}; (c) 150 ng ml^{-1}; (d) 250 ng ml^{-1}; (e) 300 ng ml^{-1}; (f) 350 ng ml^{-1}; (g) 400 ng ml^{-1}; (h) 450 ng ml^{-1} and (i) 500 ng ml^{-1}.

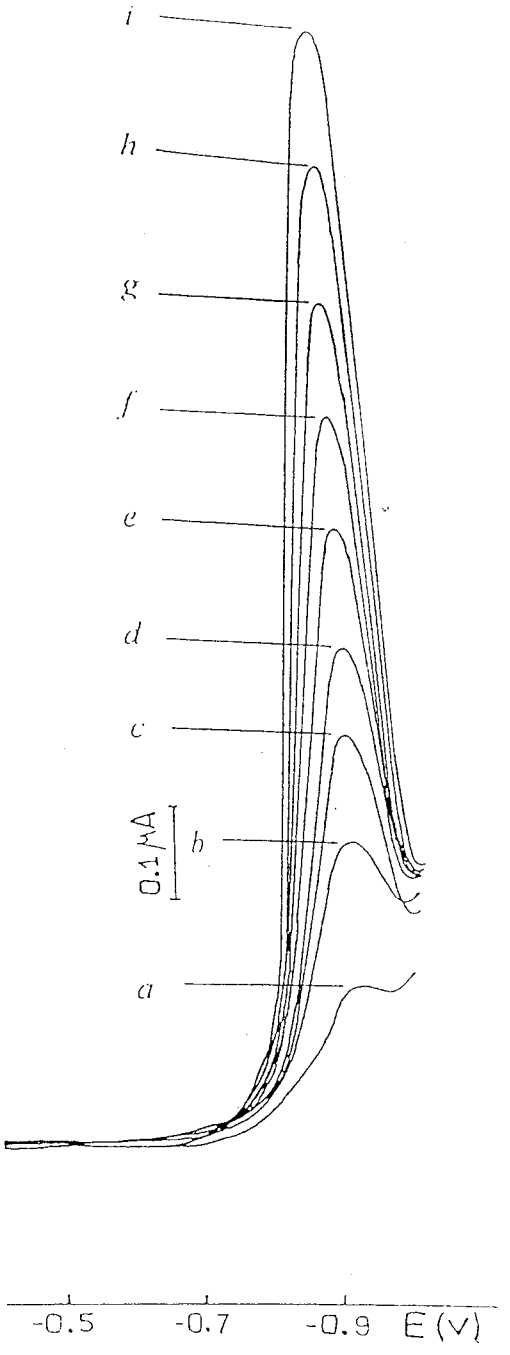

Fig. 8. Square wave voltammograms of real sample (a) and spiked samples with different concentrations: (b) 50 ng ml^{-1}; (c) 100 ng ml^{-1}; (d) 150 ng ml^{-1}; (e) 200 ng ml^{-1}; (f) 250 ng ml^{-1}; (g) 300 ng ml^{-1}; (h) 350 ng ml^{-1} and (i) 400 ng ml^{-1}.

This process was repeated four times, collecting a total volume of 20.3 ml at the outlet of the column.

Square wave voltammetry was used for the measurement under the same conditions as the calibration of the abscisic acid. In order to find the ABA concentration contained in the extract, we performed standard additions. The intensity of the peak increases linearly with the concentration of the added ABA, fitting the equation:

$$i_p = 0.0529 + 2.108C; \quad r = 0.999$$

where the peak intensity is expressed in μA and the concentration in μg ml^{-1} (Fig. 8).

Extrapolating from the straight line, we find a 0.025 μg ml^{-1} concentration of ABA in the measurement cell. Taking into account the successive dilutions of the sample, and the calculated extraction yield (78%), we can calculate that the amount of abscisic acid contained in the initial pear sample was 3.1 ± 0.1 μg per gram of pear. This is the average value obtained in 5 samples for which the same extraction process was carried out. This method has been used since the signal obtained for the ABA through HPLC determination with UV detection remains under its quantification limit. In the same way, with a direct electrochemical measure, the nature of the sample produces adsorptions in the electrode that make the signal of the ABA to disappear. So, in this work, a separation through HPLC is combined with a very sensitive electrochemical detection. Hence, in whatever the vegetal sample it was necessary to determine ABA, this proposed method can be applied.

Spectrophotometric determination of iron with ferrozine by flow-injection analysis

M.I. Pascual-Reguera *, I. Ortega-Carmona, A. Molina-Díaz

Department of Physical and Analytical Chemistry, Faculty of Experimental Sciences, University of Jaén, E-23071 Jaén, Spain

Received 14 August 1996; received in revised form 22 November 1996; accepted 10 February 1997

Abstract

Two methods for the determination of iron by normal FIA and reversed FIA were developed using sodium 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-4′,4″-disulphonate (ferrozine). The reagent formed a chelate with Fe(II) in hexamethylentetramine buffered medium at pH 5.5. In one previous reaction coil Fe(III) was reduced to Fe(II) by ascorbic acid and in the other reaction coil the complexation reaction was developed. The linear range of the determination was 0.5–6 and 0.1–5 μg ml^{-1} of iron for normal FIA and reversed FIA respectively. The proposed method was sensitive (detection limit 0.012 and 0.010 μg ml^{-1}), rapid and reproducible (RSD 0.3 and 0.28%). The method was satisfactorily applied to the determination of iron in waste water, toadstool tissue, potato leaves, human hair and bauxites at a sampling rate of 90 and 50 samples h^{-1} for normal FIA and reversed FIA respectively. © 1997 Elsevier Science B.V.

Keywords: Flow system; Spectrophotometry; Iron; Ferrozine

1. Introduction

The relative importance of iron for man can be assessed when compared with other common elements. So, accordind to Nelson [1], iron is seen to make up 1.5% of, and is the eighth most abundant element in, the lithosphere. A means of measuring the relative importance of different elements in pure chemistry is to compare the relative numbers of compounds they form. Such a comparison showed a few years ago that iron occurred in around 2.3% of all known compounds, the total number listed being around 8.5 millions [2]. The iron is one of the most important element involved in the living process, being indispensable to all members of the plants and animal kingdom.

Flow-injection analysis (FIA) is a well accepted analytical technique owing to its versatility, flexibility, ease of operation and high sample throughput [3].

The measurement of the absorbance of the complex formed between iron(II) and some typical chromogenic reagents is one of the methods most frequently used for the determination of iron in many kinds of samples. Before total iron can be determined, either oxidation of iron(II) to iron(III) or reduction of iron(III) to iron(II) is required [4–9].

PII S00 9-9140(97)00050-7

This paper describes the development of two flow injection systems (normal and reversed) for the determination of total iron based on the use of ferrozine (sodium 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-4′,4″-disulphonate)(Fz), as a chelating agent for iron (II) after reduction of Fe(III) with ascorbic acid. Fz is a very sensitive and selective reagent for iron(II) giving a 1:3 (Fe:Fz) magenta chelate with a sharp absorption peak at 562 nm and a molar absorptivity of 27 900 l. mol^{-1} cm^{-1} [10]. This is an important advantage with respect to the popular method based on the iron(II)-1,10-phenantroline complex. Nevertheless, Fz is a more expensive reagent. For this reason, as is usual in FIA techniques when the reagent constitutes the major cost of the determination, a second method based on reversed FIA [11] (where the reagents are injected into a continuous stream of the sample) is also proposed in this paper besides normal FIA method. Reversed FIA mode increases the sensitivity in many applications providing a lower range of concentrations to be reached [3]. This is a very important feature in trace analysis when the volume of sample is not a limiting factor. The reverse FIA mode is here adequate, compensating the drawback of the higher consumption of sample volume.

2. Experimental

2.1. Reagents

All reagents were of analytical-reagent grade and bidistilled water was used throughout.

Standard iron(III) solution. Prepared by dissolving 0.0860 g of iron(III) ammonium sulphate (Panreac R.A.) in 0.1 M sulphuric acid, which was standardized by EDTA titration, to give 100 mg l^{-1} stock solution of iron(III). The stock solution was diluted to an appropriate concentration as required after adding 0.05 M sulphuric acid.

Sodium 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-4′,4″-disulphonate (ferrozine, Fz) (Fluka, R.A.). Solutions of various concentrations were prepared by dissolving Fz in water. These solutions were stored under refrigeration. In these conditions they went stable for at least 30 days.

Buffer solutions (pH 5.5.) were made by dissolving 4 g of hexamethylentetramine (HMTA) and 2 ml of hydrochloride acid 1 M in 200 ml of water.

Ascorbic acid solution 1%.

2.2. Apparatus

Ultraviolet and visible spectra and real-time data acquisition of flow injection peaks were obtained using a Lambda 2-UV-VIS Spectrophotometer (Perkin Elmer). The instrument was interfaced to an IBM PS/2 mod. 30-286 running Perkin-Elmer computerized spectroscopy software (PECSS V 4.1). The flow cell used (Hellma 178.011-OS) had a 80-μl internal volume and a 10-mm light pathlength. The pump used was a GILSON MINIPULLS three peristaltic pump. The pH measurements were made with a Crison Model 2002 pH-meter fitted with a glass-saturated calomel electrode assembly and a temperature probe.

2.3. Manifolds

The two manifolds used are shown in Fig. 1.

2.4. Treatment of samples

2.4.1. Water

Waste water was filtered through a 0.45-μm membrane filter (Millipore) and collected in a polyethylene container carefully cleaned with nitric acid. The sample was stored at 4°C until analysis. Analyses were performed with the least possible delay. The usual general precautions were taken to avoid contamination.

2.4.2. Toadstood tissue (Amanita muscaria)

Firstly all foreign matter, especially adhering soil, was removed from the sample by means of successive washings with distilled water, 0.1 M HCl and doubly distilled water (we avoided an excessive washing in order to prevent leaching). The sample was rapidly dried into a forced draft oven for 24 h at 70°C prevent decomposition or weight loss by respiration and ground in a hand-mill. A suitable quantity was weighed

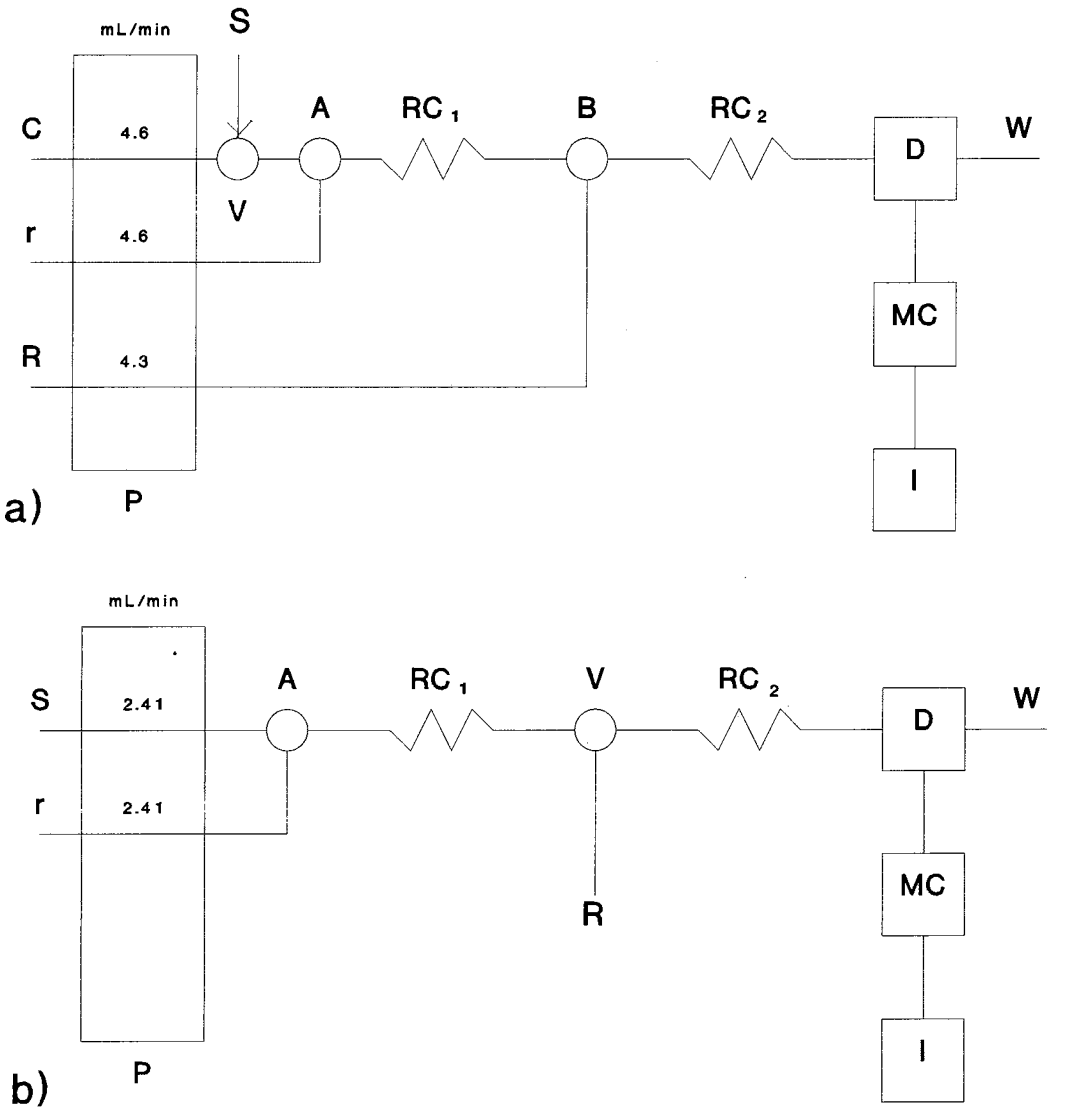

Fig. 1. Manifold configuration. (a) Normal FIA; (b) reversed FIA; S, sample; C, carrier solution (water); r, reducing agent solution (ascorbic acid 1%); R, buffered solution (pH = 5.5) of Fz (10^{-2} M); P, pump; V, 4-way rotary injection valve equipped with teflon tube loops of 600 μl (a) and 30 μl (b); A and B, confluence points; RC_1 reaction coil (0.8 mm i.d; 100 cm long); RC_2 reaction coil (0.8 mm i.d; 150 cm long); W, waste; D, detector equipped with flow cell; MC, microcomputer; I, impresor.

(1.0370 g dry material) into a quartz crucible and placed in a cool furnace; the mineralization was carried out as described by Pinta [12], heating slowly to 450°C for 2 h and holding at this temperature for 2 h. further. The sample was removed, cooled, the ashes were carefully wet with a fine stream doubly distilled water, and then 1 ml of 3 M HCl was added. The crucible was covered with a watch glass, cautiously heated on a hot plate until boiling point and finally let to stand for a few minutes. The solution was filtered through Whatman No. 42 paper over a 100-ml volumetric and diluted to volume. The iron content was determined on an aliquot, as described in the procedure.

2.4.3. Human hair

Firstly, the sample was washed with Mistol detergent and then, oven-dried with forced-draft for 24 h at 60°C. A suitable quantity was weighed (10 g) and treated successively with 30 ml of nitric acid and 3 ml of sulphuric acid until boiling. Finally, 25 ml of hydrogen peroxide were added little by little until the solution was colourless and then evaporated nearly to dryness. The final solution was transferred to a 25-ml volumetric flask, and diluted to volume.

2.4.4. Bauxites

The sample (≈ 0.1 g) was dissolved in a HF–HCl–H_2SO_4 mixture in a teflon crucible in the usual way and the solution obtained transferred to a 100-ml volumetric flask, and diluted to volume.

2.4.5. Potato leaves

The sample was oven-dried with forced-draft for 18 h at 65°C. Then, the sample was ground into fine pieces successively with a glass roller and a hand-mill and overnight dried at 70°C. A suitable quantity was weighed (5 g) into a quartz crucible and burned at 450°C as described above. The solution obtained was quantitatively transferred into a 25-ml volumetric flask.

3. Results and discussion

The iron reacts with Fz forming an only coloured (magenta) chelate compound whose absorption spectra measured against a reagent blank had a maximum absorption at 562 nm, as indicated in the literature [10].

4. Normal FIA

4.1. Flow injection procedure

The manifold of the normal flow injection system used is shown in Fig. 1a. A 3-line system was used for the determination of iron. The sample (600 μl) containing 0.5–6 μg Fe/ml at pH 2, is injected into the carrier (bidistilled water) stream by a 4-way injection valve Reodhyne to which a volume control loop is attached. In the first confluence point, the stream is mixed with the reductor (ascorbic acid) in the 100-cm reaction coil (RC_1). At this point the reduction of Fe(III) to Fe(II) is achieved. The 1×10^{-3} M ferrozine solution buffered at pH 5.5 with HMTA/HCl is pumped at 4.3 ml min^{-1} and mixed in the 150-cm reaction coil (RC_2) where the formation of coloured complex is carried out. The absorbance of the complex in the flow cell is measured at 562 mn. The PTFE tubing is of 0.8 mm i.d.

4.2. Optimization of flow system

4.2.1. Effect of pH on iron complex formation

The dependence on pH of the complex formation with ferrozine was studied in the range pH 1–11 (Fig. 2) using Fe(II) and without using buffer solution. The peak signals were maximum and constant between pH 4 and 8. These results agree with those found by other authors [10,13]. The manifold used was similar to the one described above but suppressing the line of the reducing agent and the raction-coil RC_1. The chosen value of pH was 5.5.

Buffer nature and concentration. Different buffer solutions (KH_2PO_4/NaOH, potassium phthalate/HCl, HOAc/NaOAc and HMTA/HCl) were tested. The latter buffer (pH 5.5) was found to yield the best results. The effect of the concentration of buffer solution was investigated from 0.07 to 0.25 M HMTA and no change in the absorbance values was found. As concentrations below 0.10 M are not recommended because the 'buffering capacity' is low, we propose a solution of 0.14 M HMTA. If we work with Fe(III), a previous step of reduction, which has to be made at low values of pH, is necessary. If the buffer is made to merge after mixing the reagent and the sample, the signal decreases owing to the dilution and dispersion. By buffered reagent merge with the reduced iron, the signal remains. This option was chosen for ulterior experiments.

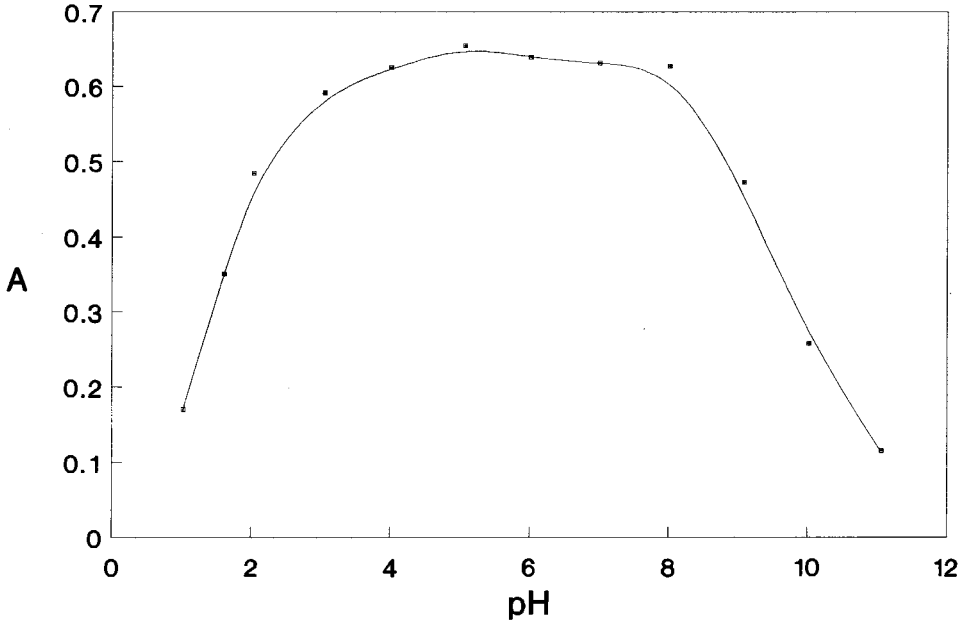

Fig. 2. Effect of pH on the iron complex formation. [Fe(II)] = 8.96×10^{-5} M; [Fz] = 3.60×10^{-4} M.

4.3. Sample volume

The influence of the sample volume on the absorbance was investigated by injecting volumes in the range 100–700 μl of 8.96×10^{-5} M iron standard solutions. A 600-μl volume was selected as optimun because the maximun signal of absorbance reached a constant value from 500 μl.

4.4. Reagent concentration

The influence of Fz concentration was studied in the range 1.0×10^{-4} to 1.0×10^{-2} M being the last selected.

4.5. Effect of reducing agent

For the determination of total iron, a reductant must be used. The effect of the nature of a few reducing agents was examined and the ascorbic acid (1%) was chosen.

4.6. Influence of pH of the sample

The influence of pH sample is shown in Fig. 3. The absorbance decreases drastically from pH 2.5 because the reduction of Fe(III) by ascorbic acid requires high acidity according to other authors [14].

The pH values above four give no detectable signals. A value pH 2 is recommended for the procedure. The decrease of the reducing efficiency of the ascorbic acid (AC) on Fe(III) has two reasons: (i) The reduction is due to the fully protonated form of the AC, that is why the shape of Fig. 3 resembles a titration curve. The dissociation constant of AC is $K_1 = 6.17 \times 10^{-5}$ and (ii) the formation of $Fe(OH)_3$ for pH$>$3 it is also possible by this concentration of Fe(III) in the working solutions, because the solubility of $Fe(OH)_3$ is very low ($K_{sp} = 6 \times 10^{-38}$).

4.7. Effect of the reaction coil lengths

The effect of the length of the reaction coils (RC_1 and RC_2 in Fig. 1) was examined. The results

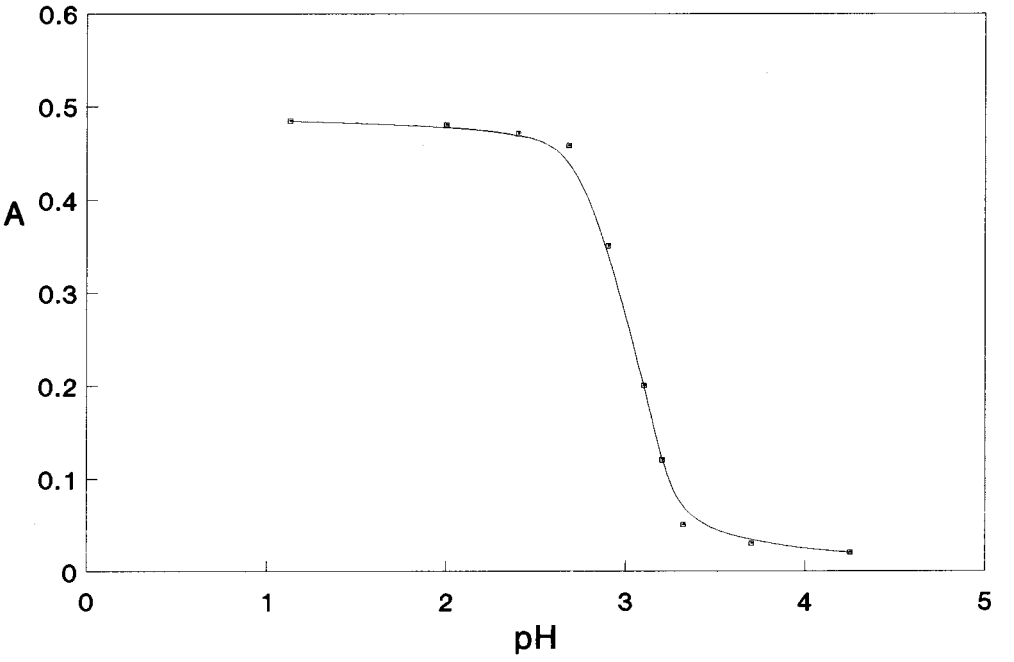

Fig. 3. Effect of sample acidity. [Fe(III)] = 8.96×10^{-5} M; [Fz] = 10^{-2} M; [Ascorbic acid] = 1%.

indicated that both reaction of reduction (RC_1) and formation of coloured chelate compound (RC_2) are fast because the influence of reaction coil lengths are not very significant. If the lenghts of both coils were shortened by 50%, the signal decreases only by 10%. The chosen values were 100 and 150 cm respectively.

4.8. Effect of flow-rate of the solutions

The effect of the flow-rate of the peristaltic pump was examined by varying the range from 2.63 to 5.25 ml min^{-1}. Since the absorbance value is constant from 30 rpm, the optimum value chosen was 4.6 ml min^{-1}.

4.9. Calibration graph

The calibration graph was linear in the range 0.5–6.0 μg ml^{-1} of iron(III). The analytical parameters are summarized in Table 1.

4.10. Interferences

The effect of various ions on the determination of 5 μg ml^{-1} of Fe(III) were investigated using the proposed manifold. The tolerance limit was taken as the amount which caused an error of ± 5% in each peak height. The tolerance limits for the ions studied are shown in Table 2. Of the ions tested, the only major interferences were from EDTA, PO_4^{3-} owing to the reaction with the

sample, and Cu(II) owing to the reaction with the reagent. 0.1 M semicarbazide removes the last interference. The method is very selective.

4.11. Applications

The method was applied successfully to the determination of total iron in waste water, toadstool tissue, potato leaves, human hair and bauxites.

4.12. Potato leaves

Two samples were analysed by the proposed procedure. The standard addition calibration graph method was applied owing to the matrix effect. This fact could be evaluated from the ratio of the slopes of the standard addition calibration graph to that of the standard calibration graphs. The ratios were 0.834 and 0.677 respectively. The results obtained (Table 3) by the proposed method were in good agreement with those obtained by atomic absorption spectrometry (AAS) because there was not significative difference ($P<0.05$) between the average values obtained by both methods (t-Student criterion).

4.13. Human hair, toadstool tissue ('Amanita Muscaria') and bauxites

The bauxites selected were *Bauxite (Dominican)* Ref. 697 and *Bauxite(Arkansas)* Ref. 69b provided by National Bureau of Standard. Since no matrix effect was found, the determination of iron in these samples was performed by applying the standard calibration graph method ($y = 0.011 + 0.158x$). As in the above samples, the results obtained were compared with those found by AAS or with the certified values and equally the concordance was excellent, by using the same criterion as above.

4.14. Waste water

The method was applied to the determination of iron in a waste water from 'Batán' (Jaén city), by standard calibration graph. The result obtained was 0.116 μg ml^{-1}. In order to check the accuracy of the proposed method, a recovery study was carried out. The results shown in Table 3 confirm the validity of the method proposed.

5. Reversed FIA

In this case, the manifold used is shown in Fig. 1(b). Now, the sample is used as carrier and it is reduced by ascorbic acid in reaction coil RC_1. Once this reduction takes place, buffered Fz is directly injected in the manifold, the colour being developed in the reaction coil RC_2. No significant influence on the signal was found when varying the length of RC_1 and RC_2. Therefore, the same length as for the manifold for normal FIA mode (Fig. 1(a)) was used. The flow-rate of the pump gave the highest signal at 2.41 ml min^{-1}. The influence of the concentration of the reagent and the acidity of the sample was also similar to that in normal FIA mode. The optimum sample injection volume was 30 μl.

Calibration graph was linear for the iron range 0.1–5 μg ml^{-1}, which means that reversed FIA allowed determinations over a wider range than normal FIA. Other figures of merit are shown in Table 1. As it is evident from the results the reversed FIA offers a some more high sensitivity and a lower detection limit than normal FIA mode. Nevertheless, the most remarkable advantage of reversed FIA versus normal FIA method is the lower consumption of a very expensive

Received 4 November 1996; received in revised form 22 January 1997; accepted 23 January 1997

Abstract

A new method using microemulsified samples is presented. It is for the determination of chromium naphthenate in gasoline by flame absorption spectroscopy. The method has the advantage of simplicity, speed and the use of aqueous standards for calibration instead of organic standards. Coexistent elements do not disturb the determination. Results obtained by this method were better than those obtained by other methods for the same samples. © 1997 Elsevier Science B.V.

Keywords: Chromium Naphthenate; Gasoline; Microemulsion; Flame atomic absorption spectroscopy

1. Introduction

In order to apply gasoline to various uses, certain amounts of organometallic additives are often added to gasoline to improve its property. The most commonly encountered additive elements in gasoline are lead, manganese, calcium, magnesium, copper, cobalt, chromium, nickel, and zinc. For examples, alkyl lead compounds and methylcyclopentadienyl manganese tricarbonyl are added to gasoline as anti-knock agents. Chromium naphthenate and cobalt naphthenate are added to gasoline as anti-static agents. The control of the additive concentrations is important in the control of the physical and chemical properties of gasoline. Atomic absorption spectroscopy is a technique of particular utility in the determination of the additive element concentrations in gasoline. It combines the virtues of simplicity, sensitivity and relatively low cost. In recent years the flame is still by far the most popular and convenient atomization source employed in atomic absorption spectroscopy. The flame provides sufficient sensitivity for most organometallic additives' analysis requirements met in the petroleum industry.

The gasoline sample must be prepared for analysis prior to its presentation to the atomic absorp-

tion spectrometer. The choice of sample preparation is varied, each method having its own particular advantages and limitations. The conventional methods to prepare gasoline samples are: dry ashing, wet digestion, extraction and dilution with solvent. A major disadvantage of dry ashing is the possible loss of volatile elements or compounds. The wet digestion method and the extraction method involve intricate steps, are time-consuming and prone to causing deviation. The method of dilution with solvent may cause low nebulization efficiency, fuming flame and unstable absorption measurements when the gasoline samples have especially great viscosity and interfacial tension values. In addition, this method is inconvenient because the standards must be prepared with organometallic standard substances that are difficult to purify and prepare. We have solved above problems by adding surfactant, cosurfactant and water into gasoline to form microemulsion systems, then directly introducing the microemulsions into the flame of an atomic absorption spectrometer. This principle has been applied to the determination of ferrocene and cobalt naphthenate in gasoline samples [1,2].

2. Experimental

2.1. Apparatus and reagents

A Model GFU-202 atomic absorption spectrometer made by Beijing Analytical Instrument Factory, equipped with an air–acetylene flame burner and hollow-cathode lamp for chromium were used. All glassware and polythene bottles were acid washed with a solution containing 2.0 mol l^{-1} HNO_3 and 1.5 mol l^{-1} HCl and rinsed with redistilled water (18.0 MΩ cm^{-1}).

Standard chromium stock solutions of 1000 μg ml^{-1} was prepared by dissolving chromic chloride ($CrCl_3$) in redistilled water and diluted to needed concentration when being used.

The reagents including sodium dodecyl sulfate (SDS), sodium dodecyl sulfonate (AS), butanol, *n*-hyptane, octane and nonane were of analytical reagent grade, and water was redistilled.

2.2. Operating parameters for determination

Wavelength: 357.9 nm; lamp current: 2.5 mA; slit width: 0.2 mm; air flow: 7.5 l min^{-1}; acetylene flow: 1.75 l min^{-1}; burner height: 19.0; measurement time: 5 s.

2.3. Procedure

In a 25 ml volumetric flask, 1.00 ml oil to be analyzed was added accurately. Then, 5.4 ml butanol, 1.8 g sodium dodecyl sulfate were added. Finally, water was added to adjust the volume to 25 ml. After being vibrated for 1 min, the microemulsion system of the oil sample was obtained. Absorbance was then measured at selected operating parameters of the apparatus.

2.4. Method for preparing standard solution

In a 25 ml volumetric flask, 1.00 ml *n*-heptane was added accurately; 5.4 ml butanol and 1.8 g sodium dodecyl sulfate were added also. Then standard solution of chromium in needed volume was added, and water was added to adjust the volume to 25 ml. After being vibrated for 1 min, the standard microemulsion system of chromium was obtained.

3. Results and discussions

3.1. Properties of microemulsions

Microemulsions are transparent or translucent, low viscosity and homogeneous stable systems consisting of water, oil, surfactant and cosurfactant, spontaneously formed at appropriate ratio. According to their different compositions, microemulsion systems can be divided into three types: the O/W (oil in water) type, the W/O (water in oil) type and the B.C. (bicontinuous) type. Particle diameters of the disperse phase in microemulsion systems are between 0.01 and 0.1 μm, and the oil–water interfacial tensions are less than 10^{-5} N m^{-1}. Microemulsion systems have great stability, are mixable with oil, water certain concentration ranges. They have strong solubilization power to organic and inorganic substances [3–5].

Table 1
Concentration ranges of water in the microemulsion systems

Systems	Gasoline (ml)	SDS (g)	AS (g)	Butanol (ml)	Water (ml)*
A	0.5	3.3		4.2	10.7–>50
B	1.0	1.8		5.4	7.8–35
C	6.0	2.6		5.4	8.4–19.8
D	8.0	2.2		7.2	6.4–15.2
E	0.5		3.4	4.2	7.3–>50
F	3.0		6.7	8.4	5.5–21.5

*The lower limits are clear points, the upper limits are cloud points.

3.2. Selection of the concentration ranges of water in microemulsion

In the experiments, the amounts of gasoline, SDS, AS and butanol were decided respectively at first. Then water was slowly added into the systems. Volumes of water added into the systems, were recorded respectively at clear points and cloud points. Thus the concentration ranges of water in the microemulsion systems at experimental conditions were decided. The results are given in Table 1.

Different compositions were chosen for the respective determination of the samples according to the concentrations of chromium naphthenate in gasoline to be analyzed. In our previous experiments [1,2], we found that SDS, one of the most typical anionic surfactants, acts not only to enhance absorption but also to suppress interferences. Using the slope of the working curve as a measure of sensitivity, the optimum the concentration ranges of water in the microemulsion systems is system B. In subsequent experiment, the system B was chosen as the concentration ranges of water in microemulsion. No difference of ralative standard deviation (RSD) was observed between the system B microemulsion system and a nonideal microemulsion system.

3.3. Effects of existing forms of chromium in microemulsion systems on absorbance

Experimental results showed that the absorbances of microemulsion systems only had connection with concentrations of chromium, and the existing forms of chromium are not relevant to it. That is to say, both organic standards and inorganic standards were good.

3.4. Effects of coexistent elements on absorbance

In a 25 ml microemulsion system containing chromium of 1.0 μg/ml, 50 μg Ca^{2+}, 50 μg Mg^{2+}, 50 μg Hg^{2+}, 50 μg Pb^{2+}, 50 μg Zn^{2+}, 40 μg Al^{3+}, 40 μg V^{5+}, 30 μg Cu^{2+}, 30 μg Cd^{2+}, 30 μg Mn^{2+}, 30 μg Co^{2+}, 20 μg Fe^{3+} and 20 μg Ni^{2+} were added respectively, and absorbances were obtained according to the method stated above. The results showed that, compared with the microemulsion systems having no coexistent elements, the variations of absorbances were all less than 5.0%. So it could be concluded that the coexistent elements stated above did not disturb the determination of chromium naphthenate in gasoline.

3.5. Effects of variety of alkanes on absorbance

Gasoline is a kind of alkane mixture system mostly consisting of 7–9 carbons. In the experiments, microemulsion systems containing 1.0 μg ml^{-1} of chromium were prepared using *n*-heptane, octane, nonane as oil phases respectively. The results showed that the variations of absorbance were less than 5.0%. So in our experiments, *n*-heptane was chosen as oil phase in place of gasoline to prepare the standard microemulsion systems.

Table 2
Analytical results of gasoline samples and standard addition recovery experiments

Samples	Cr Found (μg/ml)	RSD (%)	Cr added (μg/ml)	Cr Recovered (μg/ml)	Recovery (%)
1	18.71	2.04	10.00	10.24	102.4
2	17.54	2.77	10.00	9.73	97.3
3	17.15	3.41	10.00	9.65	96.5
4	19.67	2.20	10.00	10.39	103.9
5	17.17	1.55	10.00	9.66	96.6

3.6. Working curve

The standard microemulsion systems containing chromium of 1.00, 2.00, 3.00, 4.00 and 5.00 μg ml^{-1} were prepared and their absorbances were determined. The corresponding regression equation and coefficient of correlation were calculated. The results were as follows:

$A = 0.0034 + 0.0571C$ (μg ml^{-1})

$r = 0.9962$

The standard addition curve of gasoline samples was also determined and graphed at the same time, and the two curves have almost the same slope ratio. That also showed that coexistent elements in gasoline samples did not disturb determination.

3.7. Determination of the samples

According to the experimental method stated previously, concentrations of chromium naphthenate in five gasoline samples were determined respectively. At the same time, standard addition recovery experiments were conducted. The results were given in Table 2.

4. Conclusions

When the method is applied to analysis of gasoline, the dry ashing and wet digestion steps to prepare the samples can be avoided. The analytical time is shorten. At the same time, because of the small interfacial tensions of microemulsion systems, the nebulization efficiency of the samples is high, the average diameter of gasoloid particles is small, the combustion of the flame is stable. Another advantage is that in the analytical process there is no need to substitute aqueous standards of chromium for organic standards.

Analysis of 2-ethylhexyl-*p*-methoxycinnamate in sunscreen products by HPLC and Raman spectroscopy

Jingcai Cheng [a], Ying-Sing Li [a,*], Richard L. Roberts [b], George Walker [b]

[a] *Department of Chemistry, The University of Memphis, Memphis, TN 38152, USA*
[b] *Schering-Plough Healthcare Products, Memphis, TN 38151, USA*

Received 25 October 1996; received in revised form 3 February 1997; accepted 3 February 1997

Abstract

The analyses of 2-ethylhexyl-*p*-methoxycinnamate (EHMC) using HPLC and Raman spectroscopy have been undertaken and compared. EHMC, which is one of the most widely used sunscreen agents in suncare products in the US, exhibits a strong Raman signal. This signal clearly appears in both ethanol solutions of EHMC as well as in commercial sunscreen lotions containing this sun screen agent. A method for the direct detection and analysis of EHMC has been developed using Raman spectroscopy. This was accomplished by correlating the Raman intensities with the HPLC assays for a series of prototype suncare formulations. Based upon this information, it would be possible to employ Raman spectroscopy as an in-process control method in the commercial production of suncare products containing EHMC. The possibility of applying surface-enhanced Raman scattering for trace analysis was discussed. © 1997 Elsevier Science B.V.

Keywords: Sunscreen lotion; HPLC; Raman spectra; Surface-enhanced Raman scattering; Fiber optic probe

1. Introduction

Because skin cancer and photoaging appear to be related to excessive sunlight exposure, and the layer of ozone above us (providing protection from UV) is reported as decreasing, sun screen product use is becoming more popular than ever [1]. It is well-known that the most dangerous UV light is UVB (290–320 nm) which has short wavelengths and thus relatively higher energy. It is important to protect human skin from damage which can be caused by UVB. Among the various UVB sunscreen agents approved for use in sun screen products, 2-ethylhexyl-*p*-methoxycinnamate (EHMC) is the one most widely used [2]. It is effective in absorbing UVB, is insoluble in water, has a good safety record and is relatively inexpensive. Being considered as drug products, sunscreen products must be analyzed for their sunscreen content. Consequently, it is important to have a simple, fast analytical method for the product quality control. Like most drug and cosmetic products, EHMC in sunscreen lotions is usually analyzed by HPLC using UV detection [3]. Compared to infrared, ultraviolet, nuclear magnetic resonance and mass spectrometry,

* Corresponding author. Fax: +1 901 6783447.

PII S00 9-9140(97)00054-4

HPLC not only makes the isolation of the many components in sunscreen products possible, but also provides qualitative and quantitative information. While these benefits are significant, the method is also rather time-consuming, fails to supply definite qualitative information from a simple experiment, and can not be used as an on-line detection method.

Like infrared spectroscopy, Raman spectroscopy can provide 'finger prints' for molecules and is useful for quantitative analysis and structural determination. Applying multichannel detection techniques has significantly reduced the Raman data collection time. Additionally, an optical fiber probe can be employed in conjunction with a Raman spectrophotometer to collect Raman spectra of samples in remote sites [4]. These would make it possible to develop an on-line analytical process, which is useful for more rigorous production control of sunscreen products. If surface enhanced Raman scattering (SERS) [5] is applied, a very high sensitivity of detection can be achieved [6].

2. Experiment

2.1. Instrumentation

The Raman spectroscopic system used in the present study has been described previously [7]. An argon ion laser (Lexel Laser, Model Excel 3000) line at 514.5 nm was used with the laser power adjusted to 100 mW at the laser head unless mentioned otherwise. Glass capillary tubes filled with solution samples were positioned by using a Spex 1438 sample holder. The resulting Raman scattering signals were collected with a 6:1 off-axis ellipsoidal mirror. Silica/silica optical fiber (200 μm cone diameter, 230 μm cladding diameter, NA 0.22) was used for sample excitation and Raman signal collection. The excitation fiber and the collection fiber (3M company) were arranged in a 1×6-fiber bundle configuration, and oriented normal to the sample surface. The optical probe was fabricated by Nanjing Institute of Glass Technology, China. An Eppendorf Model 5414 centrifuge was employed in the sample preparation.

HPLC assays used an octadecyl silica (ODS) column which was a 250×4.6-mm Supelcosil LC-18 (5 μm) and kept at ambient temperature during analysis. The guard column was a 20×4.6-mm cartridge column filled with a 5-μm Supelosil packing and was held on a reusable column holder. UV detection was at 308 nm and absorbance unit full scale was at 0.50. The mobile phase was composed of 85% methanol, 14.5% water and 0.5% acetic acid with a constant flow speed of 1.5 ml min^{-1}.

2.2. Chemicals

EHMC, 2-ethylhexyl-2-hydroxybenzoate (EHHB) and 3,3,5-trimethylcyclohexyl-2-hydroxybenzoate (THHB) were provided by Schering-Plough Healthcare Products and used without further treatment. Glacial acetic acid was ACS grade while isopropanol and methanol were HPLC grade. Ethanol was obtained from Aaper Alcohol and Chemical Co. and used as received. Different concentrations of a prototype suncare formulation were provided by Schering-Plough Healthcare Products. Water used throughout this work was deionized with Milli-Q™ Water System and subsequently distilled.

2.3. Procedure

All sunscreen active ingredients used in this study are soluble in ethanol. For Raman measurements, samples of the pure ingredients or their alcohol solutions were directly injected into glass capillary tubes through the open end and these open ends were immediately sealed using Critoseal. Ethanol was also used as a solvent to extract the active ingredient from the sunscreen lotion prior to Raman measurements. After mixing a defined weight of lotion with ethanol, the mixture was mixed ultrasonically at 50–60°C for 30 min, stirred at room temperature for 5 min, and then again ultrasonically treated at 50–60°C for another 30 min. The liquid fraction of the mixture was separated by centrifuging the sample for 30 min. The resulting liquid was then used for Raman However, when an optical fiber probe was used for Raman detection, no extraction and isolation was conducted.

SER experiments were carried out by adsorbing samples onto the surfaces of silver particles or silver films. The SERS-active substrates were prepared following the methods described previously [8,9].

For HPLC analyses, both standard and sample solutions were prepared using isopropanol as the solvent. The stock solution was prepared by dissolving 0.5 g EHMC into 250 ml of isopropanol. The working standard solution was then prepared by diluting 8.0 ml of the stock solution to 100 ml with isopropanol. The sample solution was obtained through 1:10 dilution of the extraction solution.

3. Results and discussion

3.1. Raman spectroscopy of EHMC, EHHB and THHB

Fig. 1 shows the Raman spectra of pure EHMC, EHHB and THHB. For EHMC (Fig. 1A), there are three very strong peaks located at 1176, 1608 and 1640 cm^{-1}. The bands around 3000 cm^{-1} are relatively weak. Raman spectra of EHHB and THHB (Fig. 1B and Fig. 1C, respectively) are distinctly different from that of EHMC. Additionally, the relative intensities of Raman signals of both EHHB and THHB are quite low when compared with the three intense peaks of EHMC (about 1:15).

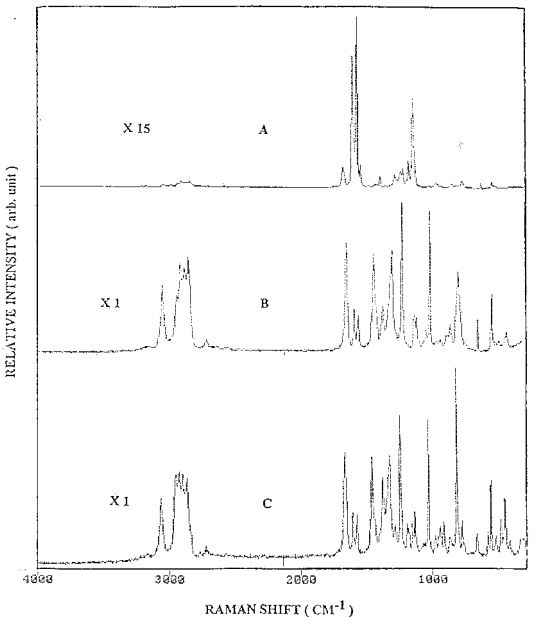

Fig. 1. Raman spectra of pure sun block agents: (A) EHMC; (B) EHHB; (C) THHB. The intensity of spectrum A has been reduced by a factor of 15.

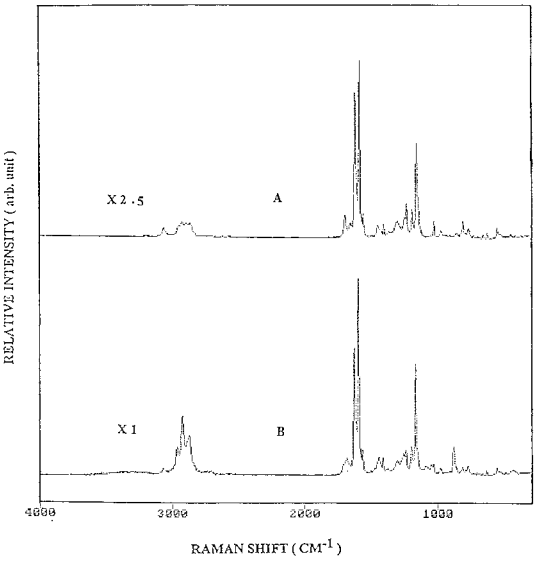

Fig. 2. Raman spectra of two different mixtures of EHMC, EHHB and THHB. Weight rates: (A) EHMC/EHHB/THHB = 1:1:1; (B) EHMC/EHHB/THHB = 7.5:5:8. The intensity of spectrum A has been reduced by a factor of 2.5.

3.2. Raman spectroscopy of mixtures of EHMC, EHHB and THHB

In this study, two different mixtures were prepared and their Raman spectra were recorded. The first one is composed of an equal proportions of each ingredient. The second mixture contained all these ingredients in the appropriate ratios similar to those employed in commercial sunscreen products. Fig. 2 displays the Raman spectra of the mixtures. Due to large Raman cross section of EHMC, the spectra of the mixtures primarily show EHMC features.

3.3. Calibration curve for EHMC

Because of the dominance of the EHMC Raman intensity in common mixtures, quantitative information of EHMC can be obtained from Raman spectroscopy without isolation or other pretreatment. In this study, the 1176-cm^{-1} band of EHMC was chosen for all measurements because of its high intensity, better resolution, and lack of interference from the other nearby bands. In the Raman spectral intensity measurements, two possible sources of deviation are the uneven background near the measured Raman peaks and the optical misalignment. One method to reduce the deviation and to improve the analytical precision is the use of an internal standard. In the Raman spectra of EHMC solutions, there are no overlapping major peaks between ethanol (solvent) and EHMC (see Fig. 3) that may reduce the accuracy of intensity measurements. Fig. 3 also clearly shows that the Raman spectral intensity of

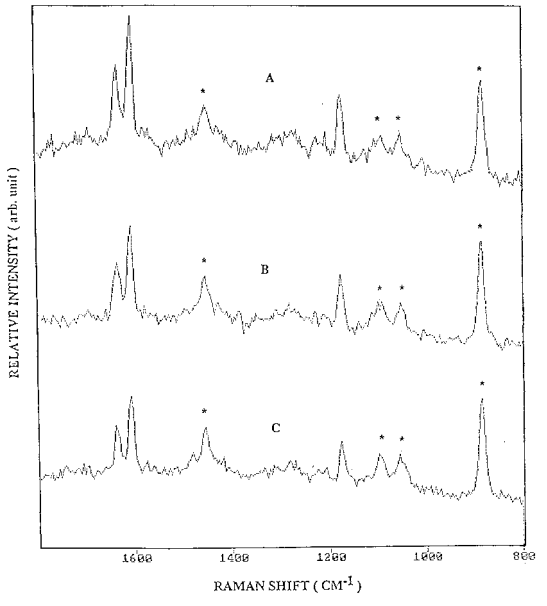

Fig. 3. Raman spectra of sun block lotions solutions obtained for ethanol extractions from different amounts of the lotion: (A) 30%; (B) 25%; (C) 20% by weight. Peaks marked with * are contributed by ethanol; unmarked peaks are due to EHMC. The composition of EHMC in the lotion is 7.5% by weight.

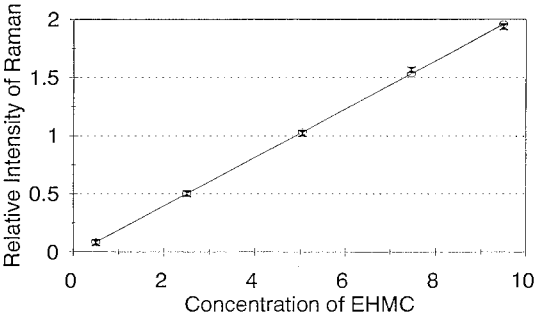

Fig. 4. Calibration curve of EHMC by Raman spectroscopic analysis. Linear regression equation: $Y = 0.2082X - 0.0202$.

EHMC increases with the weight percentage of EHMC in the ethanol extractions from the sunscreen lotion. It appeared that ethanol is a good internal reference because of the absence of overlapping of its 888-cm^{-1} band.

To reduce the effect of the uneven background of the Raman spectra, we measured the base-line at several different wavelengths and used them as background reference points for the intensity measurement of the 888 cm^{-1} band. Similarly, eight measurements of base-line were made as background reference points for correcting the measured intensity of the EHMC band at 1176 cm^{-1}. The final intensity was the average value of these measurements. Fig. 4 shows the calibration curve constructed for EHMC based on the intensity ratio of EHMC and ethanol in the concentration range of 0–10% by weight. This calibration curve demonstrates that a high degree of linearity exists between concentration and relative Raman intensity in the concentration range studied. A linear regression of the intensity data gave:

$$Y = 0.2082X - 0.0202$$

,where X is the concentration of EHMC in % (W/W), and Y is the relative Raman intensity. The correlation coefficient for the linear regression equation is 0.9993.

3.4. Analysis of EHMC in ethanol solution by Raman spectroscopy

Three different methods, Raman detection via capillary method, Raman detection via optical

Table 1
Measured concentrations[a] of EHMC in ethanol solution analyzed by Raman spectroscopy and HPLC methods

Concentration of EHMC	Raman capillary method		Raman optical fiber method		HPLC mean concentration[c]

[a] All concentrations are expressed as % (W/W).
[b] Each given value obtained by Raman spectroscopic method is an average of three measurements.
[c] HPLC concentrations are obtained from duplicate measurements.

fiber probe method, and HPLC, were used. In the capillary method, Raman scattering measurement was conducted for the sample filled into a capillary tube. In the fiber optical method, the optical fiber probe was either inserted into the sample solution or placed close to the solution/air or the solution/glass interface.

In the Raman spectroscopic analysis of sunscreen samples, the same conditions as those used in establishing the EHMC calibration curve were used. Seven different concentrations of solutions were prepared by mixing the weighed amounts of EHMC and ethanol. The concentrations of these samples were determined by measuring the relative Raman intensity of the solution along with the use of the calibration curve. For each sample, the spectral intensity measurement was repeated in triplicate with the use of an internal standard. The mean concentrations along with the standard deviations are listed in Table 1. No significant differences between the results obtained from these two Raman optical configurations are noticeable. The Raman signal-to-noise ratio obtained with the capillary method was better than that obtained by the fiber optical method. For this reason, the results obtained from the capillary method have smaller standard deviations than those obtained with the fiber optic probe.

3.5. Analysis of EHMC in ethanol solutions by HPLC

Also listed in Table 1 are the measured concentrations of EHMC using HPLC method. In each case, the listed concentration is an average of two HPLC measurements. It is seen from Table 1 that the accuracy of the results obtained by HPLC for the low concentration sample is better than that from the Raman spectroscopy methods. This probably arises from the low Raman spectral intensity resulting from the low concentration of sunscreen agent present in these sample solutions. However, there are no obvious differences among these three methods at higher concentrations.

3.6. Analysis of EHMC in sunscreen lotion

In the Raman spectroscopic analysis, only the capillary method was used to determine the concentration of EHMC in sunscreen lotion from the measured spectral intensity. In the experiments, each datum point was determined in triplicate. Listed in Table 2 are the measured concentration obtained by Raman spectroscopic method and by HPLC method. For the same reason given above, the experimental results obtained the low concentration of EHMC are more accurately determined by HPLC than by Raman spectroscopy.

Table 2
Measured concentrations[a] of EHMC in sunscreen lotion extracted with ethanol by Raman spectroscopy with capillary and HPLC methods

Concentration of EHMC	Raman capillary spectroscopy method		HPLC mean conc.[c]
	Mean conc.[b]	S.D.

3.7. Summary and prospects in the future development of Raman spectroscopy analysis

Results obtained from the present study idicate that the quantitative analysis of EHMC in commercial sunscreen products can be achieved using Raman spectroscopy. It has also demonstrated the possibility of measuring the Raman spectrum of EHMC in sunscreen lotion using an optical fiber probe. These results, combined with those of recent studies on the fiber optical pathway configuration, and its Raman signal background [10–12] show that the technique may be developed into a useful method as an in-process monitoring in the commercial preparation of suncare product.

Experimental data reveal that the normal Raman intensity of EHMC is one order of magnitude more intense than those of EHHB and THHB. This make it feasible to detect EHMC than to detect EHHB and THHB in mixtures by Raman spectroscopy. The intense EHMC bands can interfere and overshadow the weak Raman spectra of EHHB and THHB. One potential method to lower the Raman spectroscopic detection limit of EHMC and to detect EHHB and THHB in mixtures is to measure the SER spectra by using different silver sols and silver plates as SERS-active substrates [13]. A basic requirement for developing a Raman spectroscopic method for the trace analysis of the active ingredients of suncare products is to make these components SERS-active.

In the present study, attempts to obtain the SER spectrum for any of the sunscreen ingredients in the water-based silver substrates failed which is probably due to the hydrophobic character of esters. Earlier studies [8,14–16] have demonstrated that the surface Raman enhancement of organic acids are active because the carboxylate group can easily be adsorbed onto the surfaces of silver particles. For this reason, we carried out a hydrolysis for EHMC under an alkaline condition and collected the SER spectrum of the hydrolysis products adsorbed in hydrogen peroxide silver sols [8]. Fig. 5 shows the SER spectrum of 1.0×10^{-4} M EHMC hydrolysis solution along with the SER spectrum of *p*-methoxycinnamic acid in ethanol. *p*-Methoxycinnamic acid is expected to be a hydrolysis product of EHMC. A comparison of these two spectra in Fig. 5A and Fig. 5B indicates that *p*-methoxycinnamic acid is the major contributor to the SER spectrum of the hydrolysis solution. No normal Raman spectrum could be detected for the same hydrolysis solution (see Fig. 5C)—an indication of the high sensitivity of SERS detection. The present SER experiment has increased the spectral intensity of EHMC by at least a factor of 1000. Expectively, the sensitivity of the Raman spectroscopic analysis for EHMC can be improved by the same factor.

Abstract

The simultaneous determination of lanthanide family elements is one of the greatest problems in analytical chemistry, due to the close similarity of their chemical properties. Spectrophotometric methods are generally of limited use, due to the various mutual spectral interferences involved. By using multivariate calibration methods (partial least-squares regression, PLSR), it was possible to obtain a model that adjusts itself perfectly to the values of the mixture concentrations used in the calibration. The model used absorption spectra in the 290–800 nm range for a set of 20 different mixtures of Ce, Pr, Nd and Sm, and made possible the determination of Ce, Pr and Nd concentrations of a commercial rare-earth product, with significantly greater precision than the conventional univariate calibration method. Determination of the Sm concentrations was not possible, since its concentration was below the concentrations used in the model definition. © 1997 Elsevier Science B.V.

Keywords: Lanthanides; Spectrophotometric determination; Multivariate calibration

1. Introduction

The technological and industrial development of the last decades has promoted a pronounced increase in the demand for elements from the rare-earth family. Due to their various and interesting applications, they are required in many different fields, such as in the glass and ceramic industries, metallurgy, nuclear chemistry, electronics, etc. [1,2]. This large demand has promoted the development of many studies intending to find new methods for the quantification of these species, which is extremely difficult due to the close similarity of their chemical properties [1,2], making it difficult to use conventional analytical methods [3,4].

Analytical methodologies that are relatively specific and sensitive are found only within the group of modern instrumental techniques, among which are plasma atomic emission spectroscopy [5], fluorescence spectroscopy in the optical and X-ray regions [6,7], radiochemical [8,9] and chromatographic techniques [10], etc. Classical and universally used techniques such as atomic ab-

sorption and emission flame spectroscopy are of very limited use since the elements under study characteristically present a tendency to form refractory oxides and to ionisation, which implies complex absorption spectra [11,12]. The unavailability of selective chromogenic reactants means that spectrophotometric techniques are only useful for the determination of the total quantity of the elements of this family. The selectivity is restricted, in the best cases, to the determination of a single element, from a mixture with two or three components [13–16].

Banks and Kingman in 1956 [17], and Stewart and Kato in 1958 [18], presented their results of exhaustive studies intended to verify the feasibility of determining mixtures of rare-earths through spectrophotometry. These works showed the great complexity of the absorption spectra from a mixture of this kind, presented calculations of interference factors that allow to correct some of the various spectral interferences, and finally, proposed a procedure that would allow the determination of mixtures of rare-earth elements. As described, these methodologies are of little use for analytical determination, due to factors such as:

The use of interference correction factors will work correctly only when it is possible to estimate previously the concentration of the interfering component. The determination of different species in the presence of a large number of congeners is practically impossible, due to the various interferences.

This methodology allows for the determination of mixtures with two or three components, all of them with concentration of the same order of magnitude, typically 10–100 g l^{-1}.

The determination involves various precipitation, dissolution and transference operations, which makes the process lengthy, tedious and subjected to many possible error sources.

In this work the possibility of implementing an analytical methodology for mixtures of rare-earth elements (cerium, praseodymium, neodymium and samarium) is investigated, applying the spectrophotometric technique proposed by Banks and Klingman [17], and Stewart and Kato [18], but with the use of multivariate calibration techniques (partial least-squares regression, PLSR). The utilisation of this statistical method to the resolution of chemically related problems was initiated by Wold and colaborators in the early 1980s [19]. After this, the number of works using this method has increased significantly, mostly in working out data for spectral, spectrographic and electrochemical analyses [20].

2. Experimental

2.1. Reactants and standard solutions

The cerium standard solution was prepared from $CeCl_3$. $7H_2O$ (98.5%, Merck), the praseodymium standard solution from Pr_2O_3 (99.5%, Koch-Light), the neodymium standard solution from a $Nd_2(CO_3)_3$ (reactant supplied by the brazilian Federal Fiscal Service, without purity specifications) and the standard solution of samarium from Sm_2O_3 (99.9%, Aldrich). All these solutions were prepared by direct dissolution of the reactants in 2.0 mol l^{-1} $HClO_4$ (assisted by heating in a water bath), and complexometrically standardised by the use of EDTA and xylenol orange [21].

2.2. Working sample

The sample utilised is commercially distributed by NUCLEMON (Nuclebrás de Monazita e Associados Ltd., Brazil) as 'rare-earth chloride', corresponding to a concentrate obtained by chemical treatment of 'Brazilian monazite'. The monazite is submitted to various physical and chemical processes for the separation of thorium, uranium, lead and other radioactive species. The resulting rare-earth chloride is then concentrated and packed as a final product, containing approximately 250 g of rare-earth oxides per liter of solution. The distribution of rare-earth elements in this product is presented in Table 1. The solution for analysis was obtained by precipitation of the hydroxides with an aqueous solution of NH_3 from a volume of 100 mL of the sample, with later dissolution in 100 ml of 2.0 mol l^{-1} $HClO_4$.

2.3. Instruments

Spectrophotometric measurements were made with a Hitachi spectrophotometer, model U-2000, using 1 cm quartz cells. Standard solution volumes were taken in a Metrohm microburette, using 0.5000 ml taps.

2.4. Analytical procedure

Known amounts of the standard solutions or working sample were placed in a 5-mL volumetric flask and completed to the final volume with 2.0 mol l^{-1} $HClO_4$. The final concentration of these solutions varied between 1.0 and 4.0 g l^{-1} of cerium, and 2.0 and 8.0 g l^{-1} of praseodymium, neodymium and samarium. The absorption spectra were taken in the 290–800 nm range.

2.5. Experimental design

The Calibration of the methodology under study was made with the conventional univariate method and a PLSR [19], using the recorded adsorbance values between 290 and 800 nm as the dependent variables, with intervals of 2 nm. The experimental planning used for the multivariate calibration of the method is presented in Table 2. The mathematical program MATLAB 4.0 was used for the absorbance data processing. The PLSR was performed by using the PLS-toolbox 1.5 [22], based on NIPALS algorithm.

3. Results and discussion

3.1. Conventional calibration

The complexity of the spectra presented in Figs. 1 and 2 points to the difficulties that can been found in a determination of this kind, particularly due to the various spectral interferences that can be observed. Each of the studied elements, however, presents at least one absorption peak that is subjected to less interference and that can be used for analytical purposes. By the criterion of the lowest possible interference, the following spectral lines were chosen for the analysis:

Cerium: 295 nm; Neodymium: 793 nm; Praseodymi um: 442 nm; Samarium: 401 nm

Using these absorption lines and pure standard solutions, conventional calibration curves were made, whose equations and correlation indexes are presented in Table 3. By using these calibration curves, of excellent linearity, individual deter-

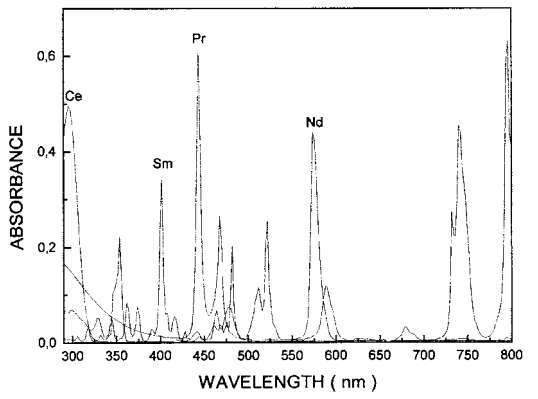

Fig. 1. UV-VIS spectrum of the lanthanides. Ce = 5.0 g l^{-1}; Nd = 10.0 g l^{-1}; Pr = 10.0 g l^{-1}; Sm = 20.0 g l^{-1}.

minations were performed for each of the species of interest, to which different quantities of the other elements were added. The results, presented in Table 4, confirm different degrees of interference in the determination of neodymium, cerium and samarium; this interference becomes more significant for increasing concentrations of the interfering elements, and becomes critical for cerium and samarium. In the case of praseodymium the interference is of little significance, not causing large errors in this case. These same curves were used for the determination of the elements of interest in the problem sample. Since this is a rare-earth concentrate, with larger concentrations cerium and neodymium and much smaller concentrations of praseodymium and samarium, different dilutions of the solution were analysed in such a way that the concentration of each of the monitored species would reach, is at least one of these solutions, the concentration range established for the calibration. The results obtained, as presented in Table 5, are useful to illustrate the difficulties of this determination. Even though the determination of synthetic mixtures indicated discrete interferences, the determination of the sample becomes much more difficult due to the diversity of species involved and the large differences in concentrations found. The percentile difference between the real and obtained values (20–40%) invalidates the determination of Pr, Sm and Ce by this classical univariate method.

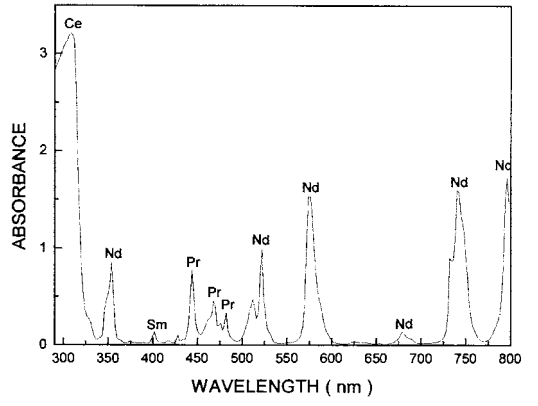

Fig. 2. UV-VIS spectrum of the working sample.

3.2. Multivariate calibration

By utilising the PLSR, and following the experimental design described in Table 2, a model for calibration was obtained that allowed determination of concentration of the components present in the calibration mixtures.To determine the optimal number of principal components to be used in the model, a full cross validation procedure can be used. In this procedure, the calibration is repeated N times, where N is the number of samples in calibration, each time treating one calibration sample as prediction object. At length all the calibration objects have been treated as prediction objects and the estimated prediction residual error sum of squares (PRESS) are used for determining the number of principal components necessary to establish the better model. Since full cross validation is based on repeated calibrations which may be some time-consuming for the computer, an important alternative is to perform cross validation by only splitting the calibration set into M ($M < N$) segments. In our case, the model was rebuilt and tested ten times, with 14 samples to build the model and six samples to validate it, in each time. The result of this cross validation procedure is presented in Fig. 3. Ideally, the predictive capacity of a model can only be assessed by testing on new objects. However, in many cases cross validation give sensible results with

[b] Reported by Banks and Klingman [17], and Stewart and Kato [18].

high information about the predicting ability of the model [19]. From Fig. 3 it is possible to verify that after the sixth principal component no significant improvement in PRESS is obtained. Then was chosen 6 principal components to perform the calculations.

By working out the model in terms of these six principal components, and by the elaboration of a graphic of the residuals as function of the leverage (relative position of the observations of the independent variables) as shown in Fig. 4, it was possible to verify the presence of two anomalous samples (outliers).In this figure, it was drawn the relative position of the observations for all 4 analytes being determined simultaneously (appearing four times the same number for each sample). The large value of the leverage (a criterion used for anomalous sample detection) of the standard solutions 14 and 17 in the calibration stage shows that both are outliers. Therefore, these standard solutions were removed from the calibration stage, and the PLSR methodology was applied again. As this system is more robust than other analogous statistical tools [19], it was seen that the parameters from the previously obtained model did not change very much due to the removal of the two samples from the calibration.

The concentrations predicted by the model are very close to the real concentrations, as shown in Table 6 (mean percentile difference around 2–3%), which indicates the validity of the calibration set. Using the linear PLSR model developed here, different dilutions of the problem sample were analysed, with the results presented in Table 7.It was performed determinations directly on the working sample without dilution, and determinations after dilution of 1.7, 2.5, 5 and 10 times. It is possible to verify from Table 7 that the determinations for neodymium and praseodymium could be carried out even without any dilution. The results for diluted sample or not were very similar. This ability for extrapolation outside of the concentration calibration range is very important, since samples with large difference in concentrations of neodymium and praseodymium can be analysed. For cerium it was necessary a dilution of ten times to be possible its determination.

It can be observed from this set of results that the neodymium determination is perfectly feasible, as it was by conventional calibration, since the interferences are of little significance. For praseodymium and cerium the multivariate calibration model allows the reduction of the error by approximately 100%, making the determination of these elements also feasible. For samarium, on the other the determination was not possible, since its concentration was below the values used in the model definition.

Table 4
Determination of synthetic mixtures of lanthanides using conventional univariate calibration

Element (λ, nm)	Real concentration (g l^{-1})	Interferents (Conc., g l^{-1})	Found concentration (g l^{-1})	Error (%)

	2.00	Pr,Nd,Sm(4.0)	3.47	+73.5
	4.00	Pr,Nd,Sm(2.0)	5.01	+25.1
	4.00	Pr,Nd,Sm(4.0)	5.49	+37.2

The error of about 10% on the praseodymium and cerium determination can be explain in terms of interferences by other species present in the working sample. On the other hand, the presence of impurities in various standard which contain significant amounts of each other is also a limiting factor for the analytical performance of the methodology. Neodymium oxide from Fluka, for example, contains about 0.1% of Pr_6O_{11} and Sm_2O_3, while praseodymium oxide contains 0.1% of CeO_2 and Nd_2O_3. Nevertheless, the reduction of the error in relation to determination by univariate ways is very significant, and demonstrate that the multivariate method is a powerful tool for difficult determinations like this.

The results obtained for neodymium and praseodymium in the working sample using univariate and multivariate methods (Tables 5 and 7)

can be statistically compared using Students' *t*-test. A significant difference between the average results for praseodymium, and no difference for neodymium, were found using a significance level of 5%. This results denote, one more time, the superior ability of the multivariate method in the praseodymium determination.

Table 7
Lanthanide determination on the working sample by multivariate calibration (PLS-linear)

Element	Certified[a] conc. (g l^{-1})	Found concentration[b] (g l^{-1})					Average (error, %)[c]
		D0	D1	D2	D3	D4	
Nd RSD (%)	39.65	39.19	39.79	40.87	41.06	39.67	40.12
		2.0	1.9	2.3	1.8	2.2	(+1.2)
Pr RSD (%)	11.38	10.66	10.00	9.66	9.87	11.16	10.27
		4.2	3.7	4.1	4.0	3.3	(−9.7)
Sm RSD (%)	5.40	ND	ND	ND	ND	ND	—
		—	—	—	—	—	—
Ce RSD (%)	96.68	[d]	[d]	[d]	[d]	88.50	88.50
		—	—	—	—	1.2	(−8.5)

D0 corresponds to determinations carried out directly on the working sample.
D1, D2, D3 and D4, correspond to determinations carried out on dilutions of 1.7, 2.5, 5.0 and 10.0 times.
ND = Concentration below the limits of the model.
[a] Concentration provide by NUCLEMON.
[b] Mean of two determinations.
[c] Error relative to the certified concentration.
[d] Absorbance above the limits of the model.

4. Conclusions

The spectrophotometric determination of Ce, Pr, Nd and Sm present many inconveniences, arising from the complexity of their absorption spectra. Using a conventional calibration and monitoring just the wavelengths of maximum absorption, the obtained results carry significant errors, arising from the multiple interferences mentioned above. By using a multivariate calibration, that allows to establish a calibration model through the use of the whole absorption spectrum, the results obtained have much smaller errors, basically because the monitoring of various wavelengths makes the contribution of the interference signals to significantly smaller.

Abstract

The classification of normal and cancer groups with four multivariate methods according to metal contents in serum and hair samples has been discussed in the present paper. Results show that the four multivariate methods, stepwise discrimination analysis, principal components analysis, hierarchical cluster analysis, and stepwise cluster analysis can distinguish the two groups correctly. The independent samples of both normal and cancer groups were tested and can be distinguished correctly by the four methods. Therefore, these methods can be used as an aid for diagnosis of lung cancer according to the metal contents in serum and hair samples. © 1997 Elsevier Science B.V.

1. Introduction

With the development of industry, our bodies as well as our environment have been polluted by numerous pollutants which have been proved as a cause of cancer. The relationship between trace metal contents and cancer has attracted many researchers for some years. The reason is of two-fold. First, some trace elements are nutrients for human health. These elements play an important role in the biochemical process of human body. On the other hand, these elements must be kept below certain levels, otherwise, they become toxic. The correlation between metal contents in human body and cancer has been proved to be existent. Some researchers declared that the metal contents of copper in serum can be used to diagnose liver cancer [1,2], ovary cancer [3] and alimentary channel cancer [4]. The contents of zinc and copper in serum have been used to diagnose liver cancer and lung cancer [5–7]. The contents of manganese, copper, zinc, arsenic, nickel, chromium, cadmium, and iron, etc., in serum and blood have been used to diagnose lung cancer and gastric cancer [8–10].

In recent years, metal contents in human body have been used as an aid for diagnosing various diseases including cancer in clinical medication. Wang et al. [11,12] have used chemometric methods to diagnose cancer patients according to metal contents obtained by inductively coupled plasma atomic emission spectrometry (ICP-AES). Even though the biochemical mechanism of these elements for the cause of cancer in human body is not very clear in the present stage, more research work has to be done to get a better understanding of the relationship and more clinical investigations should be given to make the correlation more useful and more reliable.

In the present paper, the metal contents in serum and hair samples obtained by inductively coupled plasma atomic emission spectrometry (ICP-AES) have been used for the classification of normal people and cancer patients. Four multivariate statistical methods, stepwise discrimination analysis, principal components analysis, hierarchical clustering, and stepwise clustering, were used for the classification. Independent prediction samples were tested and they were distinguished correctly by the four methods.

2. Experimental

2.1. Apparatus

A multichannel inductively coupled plasma atomic emission spectrometer (Mark-II type of Jarrell-Ash 800 series, manufactured by Fisher Scientific, Jarrell-Ash Division) was used for the present study. The operating conditions are given in Table 1.

Table 1
Operation conditions for the ICP spectrometer

Forward power	1.15 kW
Observation height	18 mm ALC
Plasma argon gas	17 l min^{-1}
Auxiliary argon gas	1.0 l min^{-1}
Carrier argon gas	0.5 l min^{-1}
Sample uptake rate	3.0 ml min^{-1}

An 80 486 personal computer was used for multivariate statistical computation. The program package for the multivariate analysis written with Quick BASIC was developed in the laboratory. The fundamentals and algorithms are not given here because they can be found elsewhere, for example, in [13,14].

2.2. Standards and reagents

The standard stock solutions of the elements studied in this work were prepared from high purity metals or oxides. High purity nitric acid, perchloric acid and distilled water were used for the sample digestion and the blank.

2.3. Sampling

Two groups of samples were used for the study, one for controlled (normal) group and the other for cancer group. The samples (serum and hair) of controlled group were taken from healthy persons. The samples of cancer group were taken from lung cancer patients in the clinical hospitals of Norman Bethune University of Medical Sciences, Changchun, People's Republic of China. The cancer patients were not committed by any radioactive or chemical treatment. The distributions of ages and sex were similar in the two groups.

2.4. Procedure

2.4.1. Serum

The blood samples of controlled and cancer groups were sampled from healthy people and lung cancer patients, respectively, between 5 and 8 am and were centrifugalized for 30 min by a $3500 \times g$ centrifugal machine. The serum were kept at -20°C for storage. The serum sample was digested with $HNO_3 - HClO_4$ (5.0:0.5 ml) mixture at the temperature of 120°C and then diluted to proper volume for determination.

2.4.2. Hair

The hair samples taken between 1–10 mm from root were washed by detergent first and then by distilled water until they were ensured being clean.

Table 2
Basic statistics for measurement of serum samples (μg ml^{-1})

Variable	Element	Normal group (n = 39)		Cancer group (n = 36)	
		Mean	S.D.	Mean	S.D.
x_1	Fe	1.988	0.913	2.168	0.938
x_2	Ca	93.78	6.851	75.62	11.14
x_3	Mg	24.58	2.655	20.16	3.77
x_4	Cu	0.929	0.232	1.392	0.278

x_6	P	116.1	32.76	103.7	17.60
x_7	Zn	0.033	0.014	0.029	0.012
x_8	Sr	0.762	0.253	0.753	0.209

The hair sample was digested with HNO_3-HClO_4 (5.0:0.5 ml) at the temperature of 120°C after pre-digestion with concentrated HNO_3 for over night.

3. Results and discussion

3.1. Basic statistics

The serum and hair samples of normal and cancer groups were analyzed by inductively coupled plasma atomic emission spectrometry (ICP-AES). The basic statistics for serum and hair samples are given in Table 2 and Table 3, respectively. For the serum, 39 samples for normal group and 36 samples for cancer group were used and eight elements were analyzed. For the hair, 21 samples were used for both normal and cancer groups and 19 elements were analyzed. It can be seen from the Table 2 and Table 3 that some significant differences of elemental concentrations exist between normal and cancer groups for both serum and hair samples. For example, the contents of aluminum are significantly different between the normal and cancer groups. It seems that the content of aluminum can be used as a simple criterion to discriminate the normal and cancer groups. However, to use this only one element may be dangerous for a diagnosis. In the results reported by Zhu et al. [12] for human hair samples, there was not a significant difference of aluminum content between normal and cancer groups, while the difference of zinc content between the two groups is quite big (266.7 μg g^{-1} for normal people and 179.7 μg g^{-1} for cancer patient). This means that except for the difference of metal contents from region to region, there may be some interactions between elements. To find out the relationship between cancer and elemental concentrations is not an easy task because the cancer is related with overall elemental concentrations rather than one by one, and there are also close relations between elements (variables). For this reason, conventional univariate approach for correlating the cancer and an elemental concentration failed to reach this goal. Multivariate statistical method is a good choice because it takes the overall elemental concentration and the interaction between elements into account to establish the relationship.

3.2. Stepwise discrimination

The stepwise discrimination analysis is a linear discrimination method based on F-test for the significance of the variables. In each step one variable will be selected on the basis of its significance. Nine samples were taken from the normal and cancer group, respectively, in a random manner, which were used as prediction set. Therefore, 57 samples, of which 30 are in normal group and 27 in cancer one, were used to get the discrimination functions. Five significant variables (elements) were extracted from the eight variables investigated after five steps for serum: x_2 (Ca),

Table 3
Basic statistics for measurement of hair samples (μg ml^{-1})

Variable	Element	Normal group ($n=21$)		Cancer group ($n=21$)

x_{19}	Zn	171.1	41.16	151.38	37.16

[a] Not detected.

x_4 (Cu), x_5 (Cr.), x_6 (P), and x_7 (Zn). The discrimination function is given below and the discrimination and prediction results are given in Table 4.

$$y_1 = -72.24 + 1.36x_2 + 3.57x_4 + 0.59x_5 + 0.084x_6 + 67.34x_7$$

$$y_2 = -58.69 + 1.08x_2 + 16.03x_4 + 3.86x_5 + 0.053x_6 - 44.97x_7$$

For the classification and prediction using hair samples, five samples in each group were utilized for prediction. Samples, 32, of which 16 in normal and cancer groups, respectively, were used to obtain the discrimination functions. In a similar way, five significant variables (elements) were obtained from the initial 19 elements for hair samples after five iterations: x_1 (Al), x_5 (B), x_{10} (Cr), x_{15} (P), and x_{17} (Sr). The discrimination function is given below and the results are given in Table 5.

$$y_1 = -48.86 + 1.66x_1 + 8.25x_5 + 15.43x_{10} + 0.19x_{15} + 1.80x_{17}$$

$$y_2 = -12.47 + 0.58x_1 + 1.98x_5 + 2.29x_{10} + 0.12x_{15} - 0.88x_{17}$$

From the scores given in Table 4 and Table 5 for serum and hair samples, respectively, it can be seen that the classification can be made by comparing Y_1 and Y_2 values: regarding as normal when $Y_1 > Y_2$; regarding as cancer when $Y_1 < Y_2$. Table 4 and Table 5 also show that all the independent prediction samples are distinguished correctly for both serum and hair samples using the discrimination functions. This means that this criterion is valid for the prediction of normal and cancer groups based on the elemental contents in serum and hair samples.

3.3. Principal components analysis (PCA)

Principal components analysis (PCA) is a projection method that reduces the dimensionality in a data matrix retaining most significant information. PCA has been used for processing the trace elemental contents to extract principal

components (significant variables) and to establish the classification of cancer patients and normal persons. Unlike the stepwise discrimination method discussed in the previous section, the PCA is an unsupervised classification method. For serum, eight variables (elements) are reduced to two new variables. These are vectors PC1 and PC2 (first and second principal components). The new variables are also referred to as Factor 1 and Factor 2. According to the loading values of the stated components, it can be deduced that the variables (elements) x_2 (Ca), x_3 (Mg), x_4 (Cu),

[a] 'n' refers to normal croup and 'c' refers to cancer group.
[b] Prediction sample.

x_5 (Cr), x_6 (P), x_7 (Zn), and x_8 (Sr) are the most significant factors in the classification. To display the points in two principal components dimensions, the first two principal components are chosen to represent the information. Firstly, 57 samples, the same as the training set used in the stepwise discrimination in last section, were processed by PCA and were presented in a two-dimensional graph. Then the 18 samples used as prediction set in the discussion of stepwise discrimination were added to the training set, and then all the samples were analyzed by PCA. The localization of 75 samples (39 for normal group and 36 for cancer group), according to their score values, on the plane defined by the new variables Factor 1 and Factor 2 are shown in Fig. 1. By comparing the two-dimensional presentation graphs of before and after adding the 18 prediction samples, it was found that the localization of the training set slightly changed and all the prediction samples fell into the right groups, respectively.

In a similar way, the 16 hair samples used as training set in the stepwise discrimination were analyzed by PCA first, then all the hair samples including training and prediction sets were processed by the method. The PCA reduces the initial 19 variables (elements) to two new variables. The localization of 42 samples (21 for normal and cancer groups, respectively) on the plane of Factor 1 and Factor 2 are shown in Fig. 2.

Most serum samples for normal people and cancer patients shown in Fig. 1 can be distinguished by a line, except for one for each group, resulting in the correct answers of over 97%. For the samples the normal and cancer groups can be clearly distinguished by a straight line (see Fig. 2).

3.4. Clustering analysis

Hierarchical clustering analysis (HCA) provides a visual means of estimating relationships among multidimensional points. Euclidean distance has been used to represent the similarity between samples. HCA is also an unsupervised recognition method and no a prior knowledge is needed. Prediction samples can be added to the samples with known classifications (working as training set) and then be analyzed by HCA. The classification of prediction samples can be distinguished from dendrograms or distances. The clustering diagram for serum and hair are given in Fig. 3 and Fig. 4, respectively. It can be seen that all the samples including training and prediction samples for both serum and hair have been correctly classified into normal and cancer groups.

Stepwise clustering analysis (SCA) is a dynamic clustering method. This method has also been used for the classification of normal and cancer groups for variables (elements) of serum and hair samples. The Euclidean distances from the centroids of two classes have been calculated for all

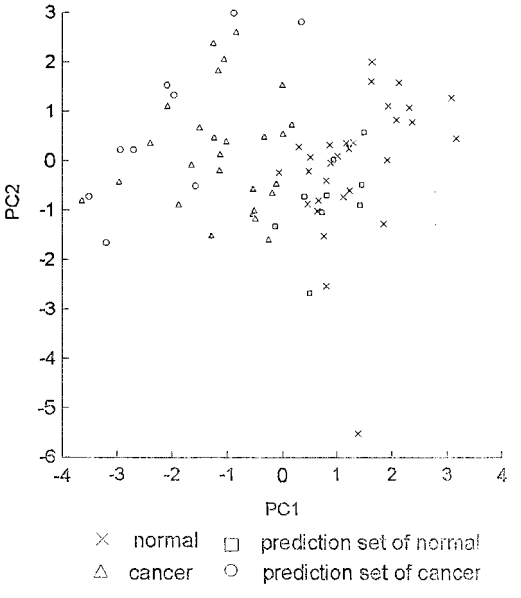

Fig. 1. Localization of 39 samples of group and 36 samples of cancer group for serum on the plane defined by two principal components.

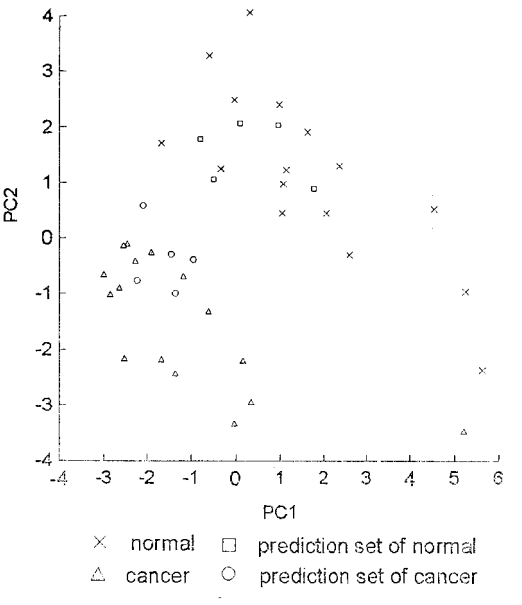

Fig. 2. Localization of 21 samples of both normal and cancer groups for hair on the plane defined by two principal components.

serum and hair samples, respectively. The stepwise clustering results for training and prediction samples based on the metal contents in serum and hair samples are given in Fig. 5 and Fig. 6, respectively. It can be seen that the normal and cancer groups for serum samples can be discriminated by a straight line. For the hair samples, the two groups can be classified correctly with an exception. One cancer sample was fallen in normal group. This sample needs further investigation.

4. Conclusions

1. The metal contents in serum and hair samples can be used to distinguish the normal people and cancer patients.
2. Multivariate statistical methods such as stepwise disaffirmation, principal components analysis, hierarchical clustering, and stepwise clustering analysis can be used as an aid for diagnosis of lung cancer according to the metal contents in serum and hair samples.

3. In some cases, exceptions may occur. However, the classification is statistically correct. The exception does not distort the significance of this method in aiding the diagnosis of lung cancer.

4. The main advantage of these multivariate methods is the fact that no a priori information on the classification is needed, and the significant information can be extracted during the statistical treatment.

5. The studies on diagnosis of cancer based on metal contents are now at the preliminary stage, so this kind of method is rather empirical at this stage. More work has to be done to establish the relationship between metal contents and cancer, even though the collection of samples is difficult and costly.

Abstract

The β-type complex formed between yttrium and *p*-carboxychlorophosphonazo (CPApK) has been studied. It was found that Y-CPApK complex can give a maximum absorptivity in a buffer media of HAc–NaAc ranging from pH 3.5–4.3 and at a wavelength of 732 nm. Under the conditions employed, the molar absorptivity was found to be 7.72×10^4 l mol^{-1} cm^{-1} and the molar ratio of Y-CPApK was 1:2. The linear range was within 2–16 μg of yttrium in 25 ml solution. One of the characteristics of the complex was its high tolerance for calcium and hence a method of separation and enrichment of microamounts of yttrium by using calcium oxalate precipitate was developed and applied to measure yttrium in nickel-base alloys. The parameters which were related to the formation of the β-type complex of Y-CPApK were discussed and a comparison of existing β-type complexes between yttrium and the chlorophosphonazo reagents of chromotropic acid was made. © 1997 Elsevier Science B.V.

Keywords: β-type complex; *p*-carboxychlorophosphonazo; Spectrophotometric

1. Introduction

Due to their excellent analytical behavior, the bisazo reagents of chromotropic acid have been widely studied and applied in the field of spectrophotometry [1]. Some of these reagents can react with yttrium to form β-type complexes, such as *p*-chloro-chlorophosphonazo (CPApC) [2], *p*-methyl-chlorophosphonazo (CPApM) [3,4], *p*-nitro-chlorophosphonazo (CPApN) [5], *p*-ethoxycarbony-chlorophosphonazo (CPApE) [6]. These methods can differentiate the absorption spectra of yttrium complexes from those of rare-earth-element complexes so that yttrium can be measured in the presence of rare earths.

p-Carboxychlorophosphonazo (CPApK), synthesized in our laboratory, has the same characteristics as the reagent mentioned above, i.e., it can react with yttrium to form a sensitive β-type complex. In this paper, the optimum conditions for color development of the Y-CPApK complex are reported in detail. It was found that Y-CPApK complexes can give the maximum absorption in the buffer media of HAc–NaAc

ranging from pH 3.5–4.3 and at the wavelength of 732 nm. Under the conditions employed, the molar absorptivity was found to be 7.72×10^4 l mol^{-1} cm^{-1}. One of the characteristics of the complex is its high tolerance for calcium, so a method of separation and enrichment of microamounts of yttrium by using calcium oxalate precipitate was developed and applied for the determination of yttrium in nickel-base alloys satisfactorily.

2. Experimental

2.1. Apparatus

Absorbances were measured on a Shimadzu UV-3000 dual-wavelength/double-beam recording spectrophotometer with 1.0 cm cells. A model PHS-2 pH meter (Shanghai Second Analytical Instruments Factory) was used for pH measurement.

2.2. Reagents

A standard stock solution of yttrium (1 mg ml^{-1}) was prepared by dissolving 0.1270 g of Y_2O_3 (Spectrum pure) with 5 ml of 6 M hydrochloric acid and transferring the solution to a 100 ml flask, diluted to volume. The working solution (10 μg ml^{-1}) was prepared by dilution with distilled water. HAc–NaAc buffer (pH 3.9) was prepared by mixing 26.54 g of $NaAc \cdot 3H_2O$ and 77.3 ml of HAc and diluting to 500 ml. The pH 5.0 HAc–NaAc buffer was prepared by mixing 26.54 g of $NaAc \cdot 3H_2O$ and 6.0 ml of HAc and diluting to 500 ml with distilled water. CPApK was synthesized by coupling the diazotized 4-aminobenzoic acid, which was run by dropwise adding sodium nitrite solution in 4 M HCl at 0°C, and chlorophosphonazo I in a pH 9–10 solution which was adjusted with 10% lithium hydroxide. The details were described in a previous paper [7]. Purification of CPApK follows the procedure used commonly for the chlorophosphonazo reagents of chromotropic acid as discussed in [8]. The CPApK working solution (0.02%) was prepared by dissolving 0.02 g of CPApK in 100 ml of water. All the reagents used were of analytical reagent grade.

2.3. Procedure for the determination of yttrium

To an aliquot containing 2–26 μg of yttrium in a 25 ml flask, add 1.5 ml of pH 3.9 HAc–NaAc buffer solution, 1 ml of 0.02% CPApK and ect, stand for 15 min. Dilute to volume with water and mix well. The absorbance was measured at 732 nm in a 1 cm cell against a reagent blank.

3. Results and discussion

3.1. Absorption spectra

The absorption spectra of CPApK and its β-type complex of Y-CPApK are shown in Fig. 1. The absorption maximum of CPApK was at 560 nm, while the yttrium complex had a characteristic absorption peak at 732 nm wavelength, where the absorption of CPApK was negligible. In fact, water can also be used as a reference solution for the determination of Y-CPApK complex at the chosen wavelength of 732 nm.

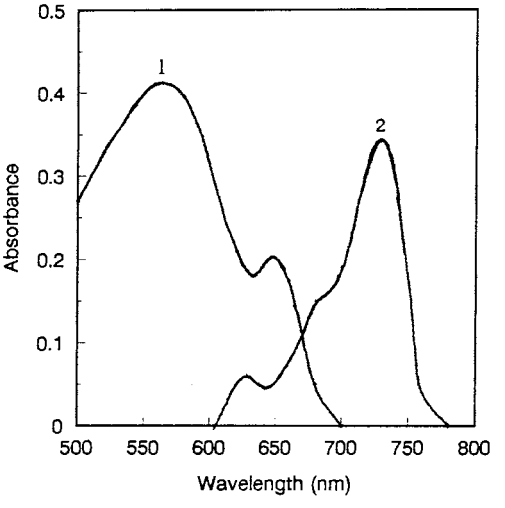

Fig. 1. Absorption spectra of CPApK and β-type complex of Y-CPApK. (1) CPApK against water blank. (2) Y-CPApK against blank reagent; Y, 10 μg; CPApK, 1.18×10^{-5} mol l^{-1}; pH 3.9 HAc–NaAc buffer, 1.5 ml; standing time in small volume, 15 min.

3.2. Effects of acidity and media

The pH value of the colored solution was adjusted by introducing HAc to the pH 5.0 HAc–NaAc buffer and the absorbance was recorded. The pH range of 3.5–4.3 is favorable to form the β-type complex of Y-CPApK and the absorbance is constant over this range. In the experiment, pH 3.9 is chosen. Various volumes of pH 3.9 HAc–NaAc buffer solution were introduced into the colored solution to test the effecting of amounts of HAc-NaAc. It was found that the complex can obtain its maximum and constant absorption within 1–2 ml of pH 3.9 buffer solution. So 1.5 ml of pH 3.9 HAc–NaAc solution was chosen. When the same pH value (pH 3.9) was buffered with hexamethylidine-tetramine(HMTA)–HCI or potassium hydrogen phthalate (KHP), the absorbances of the Y-CPApK complex at 732 nm were near to zero, i.e., the results suggested that no β-type complex formed in the two media.

3.3. Effect of amounts of CPApK

It was found that 0.8–1.5 ml of 0.02% CPApK was required to obtain the favorable absorbance for 10 μg of yttrium. Hence 1.0 ml of CPApK solution was used in all subsequent work.

3.4. Effect of surfactants

Generally speaking, introduction of surfactant can improve sensitivity and/or selectivity of the colored complexes between rare-earth elements and bisazo reagents of chromotropic acid by forming colloid bundles. Here, effect of surfactants was tested. An appropriate surfactant was not found to improve the analytical characteristics of the Y-CPApK complex. For instance, introducing animal glue can cause the solution turbid, adding cetylpyridy-bromide (CPB) resulted in precipitate and using Tween-80, TritonX-100 or ethylalcohol impeded the β-type complex to form.

3.5. Stability of the Y-CPApK complex

The prepared color solutions were kept in small volumes (not more than 10 ml) to stand for different time before dilution to 25 ml. Then dilute and record their absorbances (See Fig. 2). When the standing time was more than 10 min, full color was developed and kept constant at least 15 h. A standing time of 15 min was used in this work.

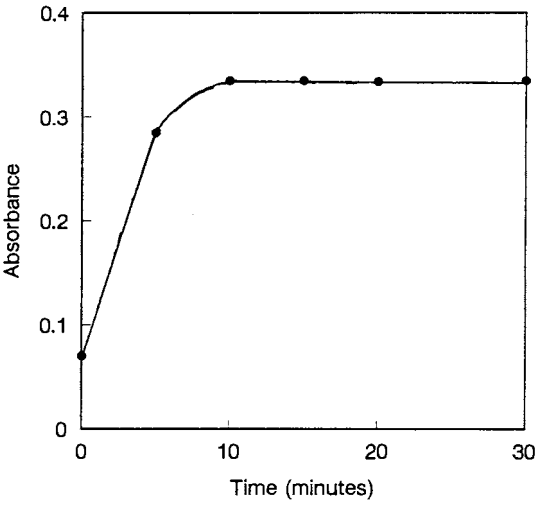

Fig. 2. Effect of standing time in small volume; Other conditions as in Fig. 1.

3.6. Calibration graph

Various amounts of yttrium were used to develop the color of the complex under the conditions employed and measure the absorbances. Plot the calibration graph of absorbance against amount of yttrium. The linear range was within 2–16 μg of yttrium in 25 ml solution and the molar absorptivity was found to be 7.72×10^4 l mol^{-1} cm^{-1}.

3.7. Effect of foreign ions

Colored solutions containing 10 μg of yttrium and various amounts of foreign ions were prepared and follow the determination procedure. If an error of 5% was considered tolerable, the tolerance limits of foreign ions were listed in Table 1. Among them, Bi^{3+}, Fe^{3+}, Ai^{3+}, Zn^{2+} and Cr^{3+} interfered, but Ca^{2+} had a higher tolerance limit. There were low tolerances (less

than 10 μg) for rare-earth elements. So a method of separation and enrichment of microamounts of yttrium was established by using the co-precipitate of yttrium and calcium oxalate.

4. Sample analysis

A sample of 0.5 g of nickel-base alloy was weighed into a 100 ml beaker, 16 ml of mixture of nitric acid and hydrochloric acid (1:3) was added to dissolve it and the mixture was heated to evaporate the solution to near dry. Distilled water, 20 ml, were added to the beaker and then 2 ml of 10% $H_2C_2O_4$. The pH value of the solution was adjusted to the range of 2.0–2.5 with 1:1 ammonia solution. After 2 ml of 10% calcium chloride was introduced, a small amount of calcium oxalate precipitate was formed. When the pH value of the solution continued to increase to 4, more precipitate formed in the solution. The solution was filtered and the precipitate washed with water. The precipitate was redissolved from the filter paper with 2 ml of 1:10 HCl and the filtrate collected in a 50 ml flask and diluted to the volume. Sample solution No.A-s-81, 2 ml, and 5 ml of No.A-s-82 sample solution were taken into 25 ml calibrated flask respectively, and follow the determination procedure. Yttrium in eight samples of A-s-81 and A-s-82 nickel-base alloys was determined, respectively. For A-s-81 sample, the percentage of mean yttrium content found in eight determinations was 0.0456, (standard value, 0.046) and relative standard deviation was 0.87. For A-s-82 sample, the percentage of mean yttrium content found was 0.0101, (standard value, 0.01) and relative standard deviation was 2.25. As the yttrium content in No.A-s-81 sample was beyond the linear range, less amounts of this sample had to be taken.

Table 1
Tolerance limits for foreign ions in the determination of 10 μg of yttium

Ion	Tolerance limit (μg)	Ion	Tolerance limit (μg)
K^+	10 000	Mn^{2+}	500
Na^+	10 000	Mg^{2+}	500
NH_4^+	10 000	Pb^{2+}	200
Cl^-	10 000	Cd^{2+}	100
NO_3^-	10 000	Ce^{2+}	100
SO_4^{2-}	10 000	Cr^{2+}	20
Ca^{2+}	2500	Zn^{2+}	13

Fe^{2+}	1000	Fe^{3+}	10
Co^{2+}	500	Bi^{3+}	8

5. Form change of Y-CPApK

H.C. Liu [9] has surveyed the β-type complexes formed between rare earth elements and bisazo reagents of chromotropic acid in detail. Generally speaking, the sort of reactions were closely related with such factors as medium, temperature, volume of color development, surfactant and organic reagent, etc. Here, the effects of the above factors were discussed on the formation of the β-type complex of Y-CPApK.

5.1. The change of absorption spectra of Y-CPApK from α-type to β-type

Usually, the change of the complexes (e.g., listed in Table 2) from α-type to β-type performed faster in a high-concentration solution than that in a dilute solution. The effect of standing times was tested. Absorption spectra were recorded at different standing times, (i.e., the newly prepared color solution was kept in a small volume and allowed to stand for different times before dilution), as shown in Fig. 3. Among them, curve 1 was recorded after the solution was prepared and diluted immediately (i.e., zero standing time), and curve 2 and curve 3 had a standing time of 5 and 10 min, respectively. Curve 1 had three peaks with the maximum absorption wavelength of 630, 680 and 732 nm. The two peaks with the wavelength less than 700 nm were called α-type and the third peak with the wavelength more than 700 nm was named β-type as defined in the references [10,11]. It was shown in Fig. 3 that the absorption of the peak at 732 nm increased and the peak at 680 nm decreased with the increase of standing time. When the standing

Table 2
Comparison of β-complex characteristics of yttrium

Reagent	Medium	λ (nm)	ϵ (1×10^4) (mol l^{-1} per cm)	Linear range (μg per 25 ml)	Molar ratio	Tolerance limit for Ca^{2+} (μg)	Ref.

CPApN	0.1 mol l^{-1} HCl	730	6.67	8–25	—	100	[5]
CPApE	pH 3.5 HAc–NaAc	726	4.48	6–14	—	300	[6]
CPApC	pH 4.5 HAc–NaAc	746	15.6	3–14	1:1	2000	[2]
CPApK	pH 3.9 HAc–NaAc	732	7.72	–16	1:2	2500	[a]

[a] This paper.

time was more than 10 min (curve 3), the β-type complex can reach its maximum absorption. Fig. 2 described that the maximum and constant absorbance of the β-type complex of Y-CPApK can be reached by employing standing time of 10–30 min. If the color solution was prepared and diluted to the mark immediately, the change of the complex from α-type to β-type needed more time to reach completion, i.e., needed much longer standing time in a normal solution volume.

5.2. Effect of medium

Conditions for the formation of β-type complexes were relatively rigid. For the complex of Y-CPApK, a complete change from α-type to β-type took place only in the medium of HAc–NaAc with the pH ranging from 3.5 to 4.3. When the pH value of the color solution was more than 4.3 or less than 3.5, the reaction did not go to completion. In the medium of hexamethylidine tetramine (HMTA)–HCl or potassium hydrogen phthalate (KHP) with the same pH value (pH 3.9), the absorption peak at 732 nm can not be observed. This result was coincident with those in Table 2, except that of CPApN. We can not conclude that the acetate system was critical, but at least favourable for the formation of the β-type complexes.

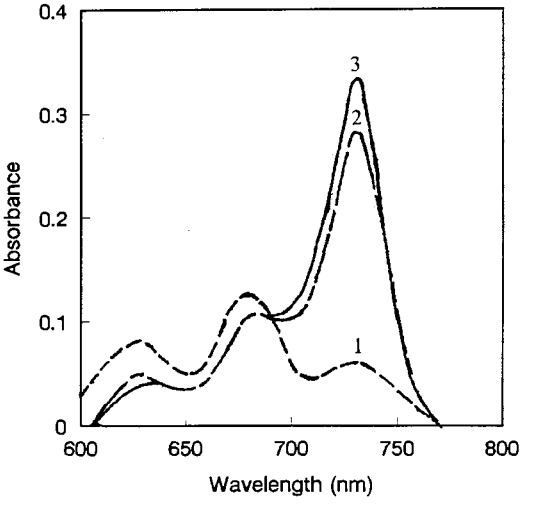

Fig. 3. Absorption spectra of Y-CPApK at different standing time in small volume. (1) 0 min, (2) 5 min, (3) 10 min; other conditions as in Fig. 1.

5.3. Effect of temperature

In the course of color development, the α-type complex of Y-CPApK formed first and then gradually changed to β-type. This reaction was affected greatly by temperature. Between 20–30°C, Y-CPApK reached its maximum absorption after 10 min. When a lower temperature was employed, the rate of reaction decreased. When temperature increased to 45°C, the reaction reached completion in not more than 10 min, but the absorbance at 732 nm was less than that at 25°C. Precipitation occurred in the solution when temperature was 60°C.

5.4. Composition of the complex

The molar composition of the Y-CPApK complex, formed under the condition employed, was ascertained by the molar-ratio method and Job's method of continuous variations. Both methods indicated that the ratio of metal to ligand was 1:2.

6. Comparison between the β-type complexes of yttrium

Several existing β-type complexes between yttrium and bisazo reagents of chromotropic acid presented in references were listed in Table 2. All the listed complexes had maximum absorption wavelength of more than 700 nm and most of them needed a weak HAc–NaAc buffer. On the other hand, the β-type complex of Y-CPApK had a much higher tolerance for calcium, which established the basis of separation and enrichment of microamounts of yttrium by using calcium oxalate precipitate.

Thermodynamic parameters for the formation of dimeric hydrolytic species of copper(II) in aqueous $NaClO_4$ solution at different ionic strengths

Alessandro De Robertis *, Concetta De Stefano, Claudia Foti, Grazia Signorino

Dipartimento di Chimica Inorganica, Chimica Analitica e Chimica Fisica dell'Università, Salita Sperone 31, I-98 166 Messina (Vill. S. Agata), Italy

Received 12 November 1996; accepted 26 February 1997

Abstract

The hydrolysis of copper(II) has been studied in experimental conditions for which polynuclear species are formed prevalently. The study has been carried out by the pH-metric technique at different temperatures and ionic strengths in $NaClO_4$ aqueous solution. As previously reported in literature, the most important hydrolytic species is $Cu_2(OH)_2^{2+}$. For copper(II) concentrations greater than 75 mmol dm^{-3}, also the species $Cu_2(OH)^{3+}$ is formed in appreciable amount. The formation constants of these species have been determined, together with their dependence on ionic strength. The temperature coefficients of equilibrium constants allowed to obtain the relative formation enthalpies. © 1997 Elsevier Science B.V.

Keywords: Aquatic chemistry; Dependence on ionic strength; Hydrolysis of copper(II); Polynuclear hydroxo species

1. Introduction

The hydrolysis of copper(II) has been studied by several researchers, using different techniques [1–13]. Nevertheless remarkable discrepancies can be found among the different works, both as concern the type of hydrolytic species, and the values of the thermodynamic parameters associated to the formation of such species. A series of objective difficulties gives account of these discrepancies. (a) The study of the hydrolysis of copper(II) is before all hindered by the formation of precipitate at relatively low pH, and the percentage of hydrolized copper in solution is always quite low [1]. (b) The precipitates that are formed are gelatinous and of different stoichiometry [$Cu(OH)_2$, CuO, $Cu(OH)_{1.5}X_{0.5}$ ($X = Cl^-$, NO_3^-), $Cu(OH)_{1.714}(ClO_4)_{0.286}$] [1,14]. (c) For copper(II) concentrations greater than 1 mmol dm^{-3}, different polynuclear species are formed. (d) The formation of the gelatinous $Cu(OH)_2$ has been often interpreted as formation of the bis-complex, and this has led to the calculation, for this species, of an unreliable hydrolysis constant. (e) The pH-metric measurements (that are the most suitable

* Corresponding author. Fax: +39 90 392827; e-mail: derobertis@chem.unime.it

PII S00 9-9140(97)00075-1

for this type of study) are limited from the fact that fairly high metal ion concentrations must be used (greater than 0.1 mmol dm^{-3}), while for the scarce solubility of the hydrolytic products it would be convenient to work with more diluted solutions; on the other hand solubility and ISE-Cu measurements are strongly limited by other factors (gelatinous, active solids with high surface energy precipitates; adsorption of copper within the apparatus; kinetic influences on the response of ISE-Cu).

In the literature there is generic agreement only on the formation of the dimeric species $Cu_2(OH)_2^{2+}$ (also the reported hydrolysis constants are generally in fairly good agreement). The formation of monomeric species $Cu(OH)_j^{(2-j)+}$ ($j = 1,\ldots, 4$) has been hypothesized, but the relative reported hydrolysis constants must be considered critically. Moreover, the formation of many other polynuclear species has been proposed [$Cu_2(OH)^{3+}$, $Cu_3(OH)_4^{2+}$, $Cu_3(OH)_2^{4+}$, and 'core plus link' species $Cu_{n+1}(OH)_{2n}^{2+}$], however without agreement among the different authors both on the type of species and on their hydrolysis constants. Finally, there are no systematic researches on the ionic strength dependence, and on medium effects of hydrolysis constants.

Recently, we have undertaken a work on the complexation of copper(II) with ligands of different nature, in different ionic media, in order to obtain a picture, as realistic as possible, on the speciation of this cation in the natural fluids, in presence of low molecular weight ligands (also in relation with our interest to the effect of the ionic medium on the complexation). Therefore it is necessary (particularly in the study of complexes of ligands not very stable, with protonation constants in the neutral-acidic range, such as polycarboxylic acids) the exact knowledge of the hydrolysis constants of the copper(II), at different analytical concentrations, at different temperatures, and at different ionic strengths and media.

In this first paper, we report an investigation on the copper(II) hydrolysis at fairly high analytical concentrations, where it is expected the formation of polynuclear species only, at different temperatures (10, 25, 37, 45°C) and ionic strengths ($0 \leq I \leq 1$ mol dm^{-3}) in $NaClO_4$. This medium was chosen assuming that it is fully dissociated, and that ClO_4^- does not form ion pairs with copper(II).

2. Experimental

2.1. Materials

Solutions of $Cu(ClO_4)_2$ were prepared from Fluka puriss. reagent and standardized complexometrically. For $NaClO_4$ solutions, Fluka puriss. reagent was used, after purification according to Grenthe [15], and drying under vacuum. Standard $HClO_4$ solutions were prepared from the concentrated reagent (C.Erba r.p.) and standardized against sodium carbonate (C.Erba r.p.); standard NaOH solutions were prepared by diluting concentrated ampoules Fluka, and standardized against potassium biphthalate. All the solutions were prepared with bidistillated water, and grade A glassware.

2.2. Apparatus

The concentration of the free hydrogen ions was measured by means of different potentiometric systems. (a) Potentiometer Metrohm mod. 654 connected to a combination Ross type electrode Orion mod. 8102; (b) potentiometer Metrohm E605 coupled with a Metrohm glass electrode and an Ingold saturated calomel electrode; (c) potentiometer Amel mod. 337, connected to a combination Ross type electrode Orion mod. 8102. All potentiometric systems had minimum reading 0.1 mV and reproducibility ± 0.2 mV. The three equipments were connected to a Metrohm motorized burette Dosimat mod. 665 (minimum reading 0.001 ml), and to a PC that, with appropriate software, allows the fully computerized titrations. The measurement cells (50 ml) were thermostatted at 25 ± 0.1°C and the solutions were stirred magnetically. In order to eliminate O_2 and CO_2, pre humidified N_2 was bubbled into solutions.

2.3. Procedure

The solution (30 ml) containing copper(II) (50–125 mmol dm^{-3}), $NaClO_4$ and an excess of $HClO_4$ (2–5 mmol dm^{-3}) was titrated with standard NaOH up to the precipitation (about 60–70 experimental points), i.e., 5.4 (diluted solutions) $\leq pH_{max} \leq 4.9$ (concentrated solutions). $NaClO_4$ was added to the same solution, in order to reach the prefixed ionic strength value (max $\sim$ 1 mol dm^{-3}). $HClO_4$ was added in order to calculate the internal E^0_{int} value. By separate titration (as a check), we calculate E^0_{ext}, at the same temperature and ionic strength value; if $|E^0_{int} - E^0_{ext}| > 1.5$ mV, the titration was rejected and repeated. From these data also the liquid junction potential ($E_j = j_a[H^+]$) was calculated.

2.4. Calculations

The nonlinear least squares computer program ESAB2M [16] was used for the refinement of all parameters of an acid–base titration (E^0, K_W, coefficient of junction potential, (j_a), analytical concentration of reagents). For the calculation of complex formation constants (β_{pq}), together with the parameters for the dependence on ionic strength, BSTAC [17] and STACO [18] computer programs were used. β_{pq} values are referred to the reaction $pCu^{2+} + qH_2O = Cu_p(OH)_q^{(2p-q)+} + qH^+$. Statistical methods were used for the selection of species, as proposed by Vacca and Sabatini [19]. ES4ECl [17] program was used to draw the distribution diagrams.

2.5. Ionic strength dependence of formation constants

The general Debye–Hückel type Eq. (2.1) can be used to take into account the dependence on ionic strength of formation constants (β = generic equilibrium constant; $^T\beta$ = constant at infinite dilution)

$$\log \beta = \log^T \beta - g(I) + CI + DI^{3/2} + EI^2 \qquad (2.1)$$

were

$$g(I) = z^* I^{1/2} \times (2 + 3I^{1/2})^{-1}$$

$$z^* = \Sigma\,(\text{charges})^2_{\text{reactants}} - \Sigma\,(\text{charges})^2_{\text{products}}$$

C, D and E are empirical parameters, which can be obtained by fitting experimental data. Results of a series of investigations [20–22], showed that, when all the interactions occurring in the solution are considered (or they are negligible, i.e., $K < 0.1$ dm^3 mol^{-1}), in the range $0 \leq I \leq 1$ mol dm^{-3}, the above empirical parameters are dependent only on stechiometry of the formation reaction:

$$C = 0.10p^* + 0.23z^*; \qquad D = -0.10z^*;$$

$$E = 0$$

with

$$p^* = \Sigma\,(\text{moles})_{\text{reactants}} - \Sigma\,(\text{moles})_{\text{products}}$$

(the parameter E becomes relevant for $I > 1$ mol dm^{-3}). When considering hydrolysis reactions, the activity of water must be taken into account, too. For the electrolytes here considered, the simple relationship $\log a_w = -0.015\ I$ (with a mean error $\epsilon \sim 0.002\ I$) can be used. Therefore

$$C = 0.085p^* + 0.23z^*$$

If refined C (for data at $I \leq 1$ mol dm^{-3}), Eq. (2.1) reduces to

$$\log \beta = \log^T \beta - z^*[I^{1/2} \times (2 + 3I^{1/2})^{-1} + 0.1I^{3/2}] + CI \qquad (2.2)$$

3. Analysis of literature data

Some literature data on the hydrolysis of copper(II) are reported in Table 1. In this Table only thermodynamic parameters for the species $Cu_2(OH)_2^{2+}$ and $Cu_2(OH)^{3+}$ are reported. Other proposed polynuclear species are not, in our opinion, to be taken into consideration (see also hereafter). The mononuclear $Cu(OH)^+$ species is formed in very low percentages, and a rough estimate of its formation constant is sufficient for the study of the other more important species. By considering $\log \beta_{11}$ reported (in $NaClO_4$) and some ΔH^0 values, we were able to estimate the first hydrolysis constant of copper(II) in the ranges $5 \leq T \leq 50$°C and $0 < I \leq 3$ mol dm^{-3}:

$$\log \beta_{11} = \log^{T} \beta_{11} - g(I) + CI - 0.09I^2 \quad (3.1)$$

$$\log^{T} \beta_{11} = -7.5 + 0.020(T-25) \quad (3.2)$$

$$C = 0.47 - 0.003(T-25) \quad (3.3)$$

with a mean error ± 0.15 ($>95\%$ confidence interval).

4. Results and discussion

4.1. Selection of the species and determination of hydrolysis constants

Several calculations were performed, with both BSTAC and STACO computer programs [17,18], in order to select the best set of species formed in our experimental conditions. The possible formation of following species was taken into account: $Cu_2(OH)^{3+}$, $Cu_2(OH)_2^{2+}$, $Cu_2(OH)_3^{+}$, $Cu_3(OH)_4^{2+}$, (the hydrolysis constant of monomeric species $Cu(OH)^{+}$ was kept constant in the calculations, using the values of Eqs. (3.1), (3.2) and (3.3)). As expected, for all temperatures and ionic strengths, calculations showed that the more important species is $Cu_2(OH)_2^{2+}$; for $C_{Cu} \geq 75$ mmol dm^{-3}, the species $Cu_2(OH)^{3+}$ is formed in appreciable amount and cannot be neglected. At 25°C the ratio (BSTAC calculations) $s_1^2/s_0^2 \cong 2$ [s_1^2 = variance in e.m.f., considering the formation of $Cu_2(OH)_2^{2+}$; s_0^2 = idem, considering the formation of $Cu_2(OH)_2^{2+}$ and $Cu_2(OH)^{3+}$], which is highly significant (for 495 experimental points). Analogous calculations, for the other temperatures with both computer programs, gave also significant statistical parameters for the formation of two dimeric species. In Table 2, the hydrolysis constants are reported at different temperatures and ionic strengths, in both molar and molal scales. The dependence of hydrolysis constants on ionic strength and on temperature is shown in Fig. 1 and Fig. 2.

4.2. Dependence on ionic strength of hydrolysis constants

The dependence on ionic strength of hydrolysis constants (Fig. 1) was taken into account by using Eq. (2.2). The refined value of C (see Table 2) is in accordance with the one found for systems when no significant interactions between components and background salt occur. In fact, for the species $Cu_2(OH)_2^{2+}$, at 25°C, we found $C = 0.361$, and in a preceding work on the hydrolysis of $(CH_3)_2Sn^{2+}$ [23] it was found $C = 0.365$ in $NaNO_3$ and/or $NaClO_4$ solutions [23]; both values of this parameter agree with $C = 0.375$ found in a general analysis of the dependence on ionic strength of formation constants [22]. These C values agree also with several other ones obtained in previous investigation [20–22,24]. Analogous considerations can be made for the dependence on ionic strength of the species $Cu_2(OH)^{3+}$. The above results allow to consider the hydrolysis constants of copper(II) in $NaClO_4$ as the baseline for other studies in different media. Moreover, the temperature gradient of C for both dimeric species, through affect by a quite large error, is in accordance with previous findings [17,21].

[b] Ionic strength in mol kg^{-1}
[c] ± 3 (std. dev.).
[d] Empirical parameter of Eq. (2.1).

4.3. Dependence on temperature of hydrolysis constants

The dependence on temperature (see Fig. 2) shows, as expected, that hydrolytic reactions are endothermic. We found for the reaction (ΔH^0 in kJ mol^{-1}, ΔS^0 in J K^{-1} mol^{-1}; $T = 25$°C, $I = 0$ mol dm^{-3}; obtained from $\log \beta_{pq}$ molal values)

$$2Cu^{2+} + 2H_2O = Cu_2(OH)_2^{2+} + 2H^+,$$

$$\Delta H^0_{22} = 68.1(\pm 1.8),$$

$$\Delta S^0_{22} = 27 \pm 1$$

and for the reaction

$$2Cu^{2+} + H_2O = Cu_2(OH)^{3+} + H^+,$$

$$\Delta H^0_{21} = 46.1(\pm 2.7),$$

$$\Delta S^0_{21} = 35 \pm 2$$

By considering Eq. (3.2) and Eq. (3.3), we have, for the reaction

$$Cu^{2+} + H_2O = Cu(OH)^+ + H^+,$$

$$\Delta H^0_{11} = 34(\pm 5),$$

$$\Delta S^0_{11} = 30 \pm 3$$

Finally, for the dimerization reaction, we have

$$2Cu(OH)^+ = Cu_2(OH)_2^{2+},$$

$$\Delta H^0_d = 0 \pm 5,$$

$$\Delta S^0_d = 86 \pm 4$$

4.4. Relevance of the hydrolysis of copper(II)

In Fig. 3 we report some distribution (% species versus pH) in different analytical conditions. The pH range for the hydrolysis of cop-

and Martell [3] give log $\beta_{22} = -10.6$ ($I = 0$ mol dm^{-3}, $T = 25$°C). Our value log $\beta_{22} = -10.54 \pm 0.06$ lies between the two above ones. Analogous considerations can be made for ΔH^0 values. As regards the species $Cu_2(OH)^{3+}$ only hydrolysis constants at $I = 3$ mol dm^{-3} can be found [3,4,11,12]. Smoothed values of log β_{11}, log β_{21} and log β_{22}, at different temperatures and ionic strengths (obtained using data from this work and from literature), are reported in Table 3.

4.6. Concluding remarks

Main conclusions of this work are as follows.

(i) Hydrolytic species of copper(II), in moderately concentrate solutions, are $Cu_2(OH)_2^{2+}$ and $Cu_2(OH)^{3+}$, with small amounts of $Cu(OH)^+$.

(ii) The dependence on ionic strength (in $NaClO_4$ solutions) (simply described by Eq. (2.2) with C values of Table 2) shows that reported log β_{pq} values can be used, in the ranges $0 < I \leq 1$ mol dm^{-3} and $10 \leq T$ (°C) ≤ 45, as baseline for further studies in other media (NaCl, synthetic sea water, etc.).

(iii) Smoothed values of Table 3, can be used as recommended values for the hydrolysis of copper(II).

Determination of ion-selective electrode characteristics by non-linear curve fitting

Paddy Kane, Dermot Diamond *

School of Chemical Sciences, Dublin City University, Dublin 9, Ireland

Received 11 September 1996; received in revised form 3 February 1997; accepted 7 February 1997

Abstract

A simple practical method of determining potentiometric selectivity coefficients of ion-selective electrodes (ISEs) is described in which electrode characteristics (slope, potentiometric selectivity coefficients and cell constant) can be determined by fitting the experimental data obtained using the fixed interference (FI) method to an appropriate model by non-linear least-squares regression. The proposed method is simple to implement practically, and data processing can be easily achieved through use of the optimisation add-on, Solver, bundled with Microsoft Excel. The flexibility of the method is demonstrated by modelling the response of a valinomycin potassium-selective electrode with the Nikolskii–Eisenman equation and a recently proposed alternative to the Nikolskii–Eisenman equation for cases where the ionic charges on the primary and interfering ions are unequal. © 1997 Elsevier Science B.V.

Keywords: Curve-fitting; Excel; Ion-selective electrode; Potassium; Potentiometric selectivity coefficients; Valinomycin

1. Introduction

The most widely used methods for determining potentiometric selectivity coefficients of ISEs have been the separate solution (SS) method [1], the fixed interference (FI) method [1] or what Umezawa et al. [2] refer to as the two-solution method. The fixed primary ion (FPI) method [1] has also been used but is less popular. The matched potential (MP) method, developed by Gadzekpo and Christian [3], has been recommended by Umezawa et al. [2] when the ionic charges of the primary and interfering ions are unequal or when the electrode response to either ion is non-Nernstian. In a variation of the SS method, Bakker [4] has described a method where the ISE is conditioned in a solution of interfering ion.

In practical terms, all of these methods involve the transfer of electrodes to different solutions and as such, are subject to 'carryover' error. The SS method and Bakker's variation on it [4], have the disadvantage that they are not realistic representations of the practical behaviour of the electrode since in practice, measurements are made in the presence of both primary and interfering ions, and competitive processes can have a significant effect on the electrode response. However, Bakker's approach is interesting in that the ISE, with a membrane containing the tetraphenylbo-

* Corresponding author.

rate salt of an interfering ion, is conditioned in an interfering ion solution. The difficulty that the interfering ion has in displacing the primary ion from the membrane when the ISE is conditioned in a primary ion solution and then transferred to an interfering solution, is thus avoided and a Nernstian response is expected from interfering ions, something which does not always occur when electrodes are conditioned in primary ion solutions. The potentiometric selectivity coefficients obtained are therefore more representative of the ion-exchange process. However, they are not representative of practical electrode behaviour, where the conditioning and calibration of the ISE in solutions of the primary ion, is standard practice.

The FI method, as traditionally used [1], involves the preparation of a range of solutions with different primary ion activities but with a constant activity of interfering ion and, as such, the method is tedious and open to operator error. Furthermore, analysis of the data obtained by this method usually involves manually finding the point of intersection of the extrapolated linear portions of a plot of the cell potential versus the log of the activity of the primary ion [1]. This has two disadvantages; firstly, a decision has to be made as to which points are part of the linear portions of the plot and this makes the method subjective. Secondly, as Moody and Thomas [5] point out, the potentials in the plateau region of this plot are subject to an unacceptable degree of irreproducibility and drift. Srinivasan and Rechnitz [6] derived two equations for high and low values of potentiometric selectivity coefficients, respectively, and these allow potentiometric selectivity coefficients to be determined from data relating to a range of activities. However, their methods require some a priori knowledge of selectivity before choosing the activities of the primary and interfering ions and the appropriate equation. Furthermore, their methods allow no 'at a glance idea' of selectivity, as provided by the traditional FI method.

In principle, the MP method requires just two experimental points to calculate the potentiometric selectivity coefficient (or the interference ratio since, as Maccà [7] points out, the quantity obtained by the MP method is by definition, different to the traditional potentiometric selectivity coefficient). In practice, however, this method requires measurements to be made in solutions of different concentrations of interfering ion and then sophisticated interpolation if it is to be accurate. As such, it is no less tedious or time consuming than the traditional FI method. Another disadvantage of the MP method is that for electrodes which are very selective, the level of interferent required to equalise the potentials may be so high as to make the method unrealistic since, in practice, such levels of interferents are unlikely to be encountered and extrapolation to lower interfering ion activity is not generally advisable. Furthermore, Maccà [7] claims that the interference ratio is more concentration dependent than the potentiometric selectivity coefficient.

Therefore, there is a need for an approach which is practically simple to implement, and which removes the subjectivity of the conventional FI method [1]. Previously, Yuliang et al. [8] used a non-linear regression approach with electrode measurements of halide ion mixtures. However, they have given no indication (either numerical or graphical) of the quality of the fit to Nikolskii–Eisenman equation. Furthermore, they give no details of how their approach was implemented, and therefore it is impossible to comment on the reliability of their results or how easy it is to process data with their method. In a variation on the FI method, Davey et al. [9] plotted the peak heights obtained using a flow-analysis approach versus the log of the primary ion activity at constant concentration of interfering ion. They then used values in the curved region of the plot to determine potentiometric selectivity coefficients using a data linearisation technique based on the Nikolskii–Eisenman equation. Unfortunately, their method did not yield a value for the Nernstian Slope Factor. Diamond and Forster [10,11] and Saez de Viteri and Diamond [12] have proposed very rigorous non-linear modelling approaches based on multivariate calibration and simplex optimisation which enabled potentiometric selectivity coefficients to be in mixed solutions containing up to four ions. However, these methods are not simple to implement, as

even with partial factorial design, 32 calibration solutions are required to characterise a four-electrode array.

There has been some discussion in the literature on alternatives to the Nikolskii–Eisenman equation. Morf et al. [13] proposed an equation for neutral carrier-based calcium-selective ISEs, relating to mixed-ion solutions where the interfering ion is singly-charged. Meyerhoff and coworkers [14] have developed a formalism for ISEs of three different carrier types, for mixed-ion solutions which is applicable to all combinations of primary and interfering ions of different charge.

In this paper, we describe a very simple procedure for obtaining experimental data, and subsequently fitting the data to a mathematical model in order to obtain estimations of the cell constant, the Nernstian Slope Factor and potentiometric selectivity coefficients. In the proposed method, the primary ion activity is varied by means of a series of small volume 'spikes', added to a single solution, with the electrodes continually in contact, and measuring the cell potential after each addition. Therefore, no transfer of electrodes between measurements is involved and the preparation of relatively few solutions is required. The entire response curve is then fitted to an appropriate model (for example, the Nikolskii–Eisenman equation or the Meyerhoff formalism [14]) to obtain the electrode parameters (Nernstian Slope Factor, cell constant and potentiometric selectivity coefficient for the interfering ion) which provide the best-fit to the experimental data through minimisation of the least-squares error. This non-linear analysis is carried out using the Solver optimisation add-on available in Microsoft Excel for Windows 95, version 7.0 which, with its graphical user interface, is very simple to use. As Excel is normally bundled with PCs these days, the user does not have to invest in any relatively expensive specialised mathematical or statistical packages to perform the calculations.

Despite the known limitations of the Nikolskii–Eisenman equation (the primary and interfering ions should have Nernstian slopes and the same ionic charge), we decided to use this model because of the large database of information on this model in existence in the literature. For the same reason, we chose a valinomycin-based potassium selective electrode because of the wealth of data available for this ISE to which we could compare our results.

2. Experimental

2.1. Materials

All metal chlorides used were of analytical reagent grade. High molecular weight poly(vinyl chloride) (PVC) lithium chloride, potassium chloride, valinomycin, tetrahydrofuran, bis(2-ethylhexyl)sebacate (DOS) and potassium tetrakis(4-chlorophenyl)borate (KTpClPB) were purchased from Fluka. Magnesium chloride, calcium chloride and barium chloride were purchased from BDH. Sodium chloride and ammonium chloride were purchased from Riedel de Haen. Milli-Q grade distilled water from Millipore was used throughout.

2.2. Apparatus

A potassium-selective electrode was prepared according to the procedure of Lu et al. [15] using valinomycin as the ionophore. The components and composition of the membrane used in the ion-selective electrode (ISE) are the same as that used by Knoll et al. [16] and are given in Table 1. Membrane resistance and potential measurements were made with a Hewlett Packard 34401 A multimeter and a standard calomel electrode (SCE) as a reference, obtained from EDT Instruments, Dover, Kent, UK.

2.3. Determination of potentiometric characteristics

The ISE and the SCE were placed in 25.0 cm^3 of a 0.1 mol dm^{-3} aqueous solution of an interfering chloride, for example, sodium chloride. Aliquots (2, 5, 20, 45, 70 and 100 μdm^3) of mixture 1 (0.01 mol dm^{-3} potassium chloride
0.1 mol dm^{-3} interfering chloride (aq.)) and

then mixture 2 (5, 15, 30, 100, 400 and 1000 μdm^3), (1.00 mol dm^{-3} potassium chloride (aq.), 0.1 mol dm^{-3} interfering chloride (aq.)) were added in the order given. These additions were made with micropipettes, keeping the tip of the micropipettes just above the surface of the solutions while making the addition. The solution was stirred magnetically throughout. After each addition, the potential of was recorded after 1 min. After all additions had been made, the entire procedure was repeated twice. In this manner, the primary ion (K^+) concentration was varied over a very wide range (8.0×10^{-7}–0.06 mol dm^{-3}) while the interfering ion concentration was kept constant without having to transfer the electrodes to new solutions.

This procedure was repeated for other interfering ions (Li^+, NH_4^+, Ca^{2+}, Mg^{2+} and Ba^{2+}).

Potentiometric selectivity coefficients were also determined by the SS method [1] (0.1 mol dm^{-3} solutions of metal chlorides) for comparison.

2.4. Treatment of results

The potential, E, of a potassium-selective electrode in the presence of both K^+ and an interfering ion, B^{z+}, is given by the Nikolskii–Eisenman equation:

$$E = E^0 + S \log(a_K + k_{KB}^{Pot} a_B^{1/z}) \quad (1)$$

where: E^0 is the cell constant; S is the Nernstian slope factor; k_{KB}^{Pot} is the potentiometric selectivity coefficient; a is the activity of the subscripted ion; z is the ionic charge on the interfering ion.

Single-ion activity coefficients, f, were calculated using the Davies equation:

$$\log f = -Az^2 \left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.2I \right) \quad (2)$$

where I is the ionic strength of the solution and A is the Debye–Hückel parameter which was determined using:

$$A = 1.82481 \times 10^{-6} (DT)^{-1.5} \text{ mol}^{1.5}\text{dm}^{-0.5} \quad (3)$$

where T is the absolute temperature and D is the dielectric constant of the solvent.

The values used for D for the solvent water were either the known value at 20°C [17] or calculated values based on the temperature of the experiment and empirical equations [18]. Corrections were made to experimental potentials using estimations of the liquid junction potentials, E_J, of the reference electrode, calculated according to the Henderson formula [19] using single-ion activities. A typical set of results are given in Table 2 for Na^+ as the interfering ion.

Non-linear curve fitting was carried out to fit the mean experimental values of the corrected cell potentials given in Table 2, to the Nikolskii–Eisenman model (Eq. (1)), using the optimisation add-in, Solver, available in Microsoft Excel for Windows 95 version 7.0 and the method of Walsh and Diamond [20]. The optimised model returned estimates for the model parameters k_{KB}^{Pot} (see Table 3, Study 1), E^0 and S (both given in Table 4). In the case of each interfering ion, the potential of the solution containing interfering chloride only was ignored in the analysis as the drift in this reading was far greater than that for any other reading (typically after 1 min, when the reading was taken, the drift was 0.1 mV s^{-1} for the solution containing interfering chloride only but for any other reading, it was approximately 0.2 mV min^{-1} after 1 min). It is worth noting that for a given set of measurements, optimisations with Solver produced the same set of values for E^0, S and k_{KB}^{Pot} regardless of the initial values of these parameters. Thus, we can be confident that the optimisations converged at the global minimum, and that the error space is relatively smooth. The experimental potentials and those obtained by Solver are plotted in Fig. 1(a)–(f).

The Na^+ activity remains relatively constant except for the most concentrated solution.
[a] S.D., standard deviation.
[b] This value was not used in the non-linear analysis as the drift in the reading was too great, as is explained in Section 2.4.
[c] The mean of these a_{Na} values were used to calculate the LOD (Eq. (7)).

An alternative to Eq. (1) for a mixture of a primary ion and an interfering ion with ionic charges of $+1$ and $+2$, respectively, has recently been proposed by Meyerhoff and co-workers [14]:

$$E = E^0 + \frac{RT}{F} \ln\left(\frac{a_K}{2} + \frac{\sqrt{{a_K}^2 + 4a_B(k_{KB}^{Pot})^2}}{2}\right) \quad (4)$$

Replacing the RT/F term with the Nernstian slope factor, S and using common logs, Eq. (4) becomes:

$$E = E^0 + S \log\left(\frac{a_K}{2} + \frac{\sqrt{{a_K}^2 + 4a_B(k_{KB}^{Pot})^2}}{2}\right) \quad (5)$$

Using the same experimental data, Eq. (5) was fitted to the mean values of the corrected cell potentials, in the cases of the doubly-charged interfering ions. See Fig. 2(a)–(c) for the response curves and Table 3, Study 2 and Table 4 for the electrode characteristics obtained using Eq. (5) as the model for the response curve.

The data obtained from calibration of the ISE (i.e., where measurements are made on solutions containing only the primary salt) can also be modeled with this Solver technique, simply by assuming that the sum of the $k_{KB}^{Pot}a_B^{1/z}$ terms in the extended version of Eq. (1) for several interfering ions is constant for each of the calibration solutions. However, Eq. (5) was not used to model the calibration results as it is applicable only for a mixture of a primary ion of charge $+1$ and one interfering ion of charge $+2$.

[g] 0.140 mol dm^{-3} solution of sodium chloride.
[h] Equal concentrations of primary and interfering ions.
[i] Unequal concentrations of primary and interfering ions.

The goodness of fit of the optimised model to the experimental data can be quantified by the standard deviation of the experimental values from best-fit curve, σ [21]:

$$\sigma = \sqrt{\frac{\Sigma (E^* - E)^2}{n - p}} \quad (6)$$

where: E^* is the predicted potential; E is the measured potential; n is number of measurements (12 in this case); p is the number of parameters to be varied to determine the curve of best fit (three in this case).

σ, unlike the correlation coefficient which can be used in linear regression only, is approximately equal to experimental error of the dependent variable and has the same unit of measurement.

For comparison, Table 3 also lists potentiometric selectivity coefficients, obtained using the SS method [1] (Study 1), and the FI method [1] (Study 3 and 4, in the case of the doubly charged interfering ions) using the same FI experimental data and Eq. (7) [22]. The limit of detection (LOD) used when applying Eq. (7) is estimated by determining the K^+ activity for which the linear and rising portion of the graph deviates by $2.303RT \log 2/F$ mV from the curved part as described the Nikolskii–Eisenman model (Study 3) or by Eq. (5) (Study 4). As the interfering ion

[a] The S and E^0 values quoted were obtained by linear analysis on the mean of the corrected potentials.
[b] The errors quoted are the standard deviation of the values obtained from non-linear analysis of three replicate data sets for the interfering ion studies. In the case of pure K^+ solutions (first row), the errors are the standard error of the slope and intercept of the regression line calculated over the activity range 10^{-4}–0.1 M.

activity varies slightly (for example, see Table 2), the mean value of a_B^{1/z_B} in the region of the LOD was used to calculate the potentiometric selectivity coefficient when using Eq. (7).

$$k_{KB}^{Pot} = \mathrm{LOD}/a_B^{1/z_B} \quad (7)$$

The estimated limits of detection are given in Table 4.

3. Results and discussion

Before testing newly fabricated electrodes, the membrane integrity was checked by measuring the d.c. resistance. These were found to lie in the range 1.0–1.1 MΩ, which is typical for PVC-membrane ISEs [23].

Table 3 shows that the $\log k_{KB}^{Pot}$ values obtained using the data analysis method based on Nikolskii–Eisenman model (Study 1) are very similar to those obtained for similar membrane compositions using both the conventional FI method (Study 3) and the SS method (Study 5). Given the variety of experimental conditions, methods and conditions under which the measurements were made, the degree of agreement between the results of the various studies illustrated in Table 3 is very encouraging. In almost every case, the general trend is the same ($Li^+ < Na^+ < NH_4^+$ and $Mg^{2+} < Ca^{2+}$), and the values are within an order of magnitude of each other. One exception is the value for the Li^+ potentiometric selectivity coefficient reported by Moody et al. (Study 15) [31] which is significantly lower than all other studies. Gadzekpo and Christian [3] obtained very different $\log k_{KB}^{Pot}$ values (by four different methods) for a valinomycin-based potassium ISE (see value for Na^+ potentiometric selectivity coefficient for example, Studies 19–22). In the case of Ca^{2+} and Ba^{2+}, good selectivity is obtained by all three methods used in this research, although there are some slight differences in the values of the coefficients. However, this is to be expected in these types of measurements, and is reflected in the variations reported by other researchers (see Table 3). Metzger et al. [24] and Gadzekpo et al. [25] have also demonstrated with a number of ionophores that different values for potentiometric selectivity coefficients are obtained depending on whether the FI method or the MP method is used. We believe that our new method is to be preferred as it involves minimising the sum of the squares of the errors over the entire data set (covering a wide range in primary ion activity) rather than using selected portions of the response curve in a very subjective way.

Of results quoted from other researchers in Table 3, those from Knoll et al. [16] (Study 6) are

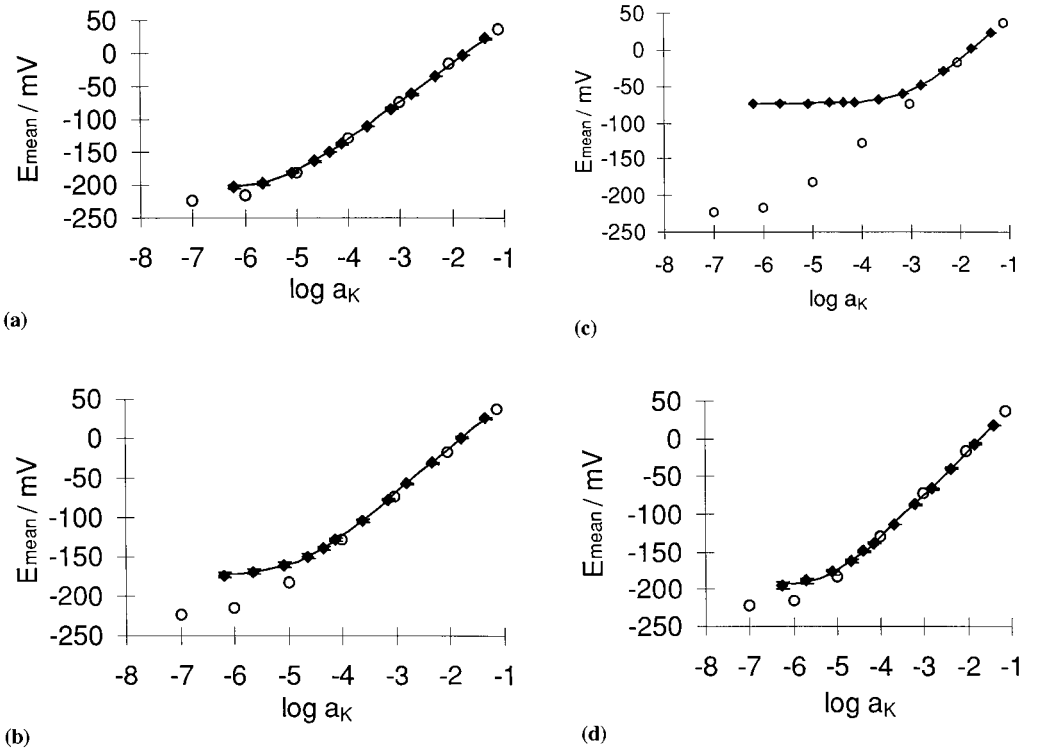

Fig. 1.

important as the membrane components and composition employed are identical to those used in this investigation, and they used the FI method [1] for determining potentiometric selectivity coefficients. Cosofret et al. [26] (with Membrane L in their paper) used membranes with similar components and composition to this investigation but estimated the potentiometric selectivity coefficients by means of the SS method (Study 7). In both cases, while the values are not an exact match with our data (Study 1), the variations are reasonable given the differences in experimental methods and design.

Table 3 also lists the $\log k_{KB}^{Pot}$ values obtained with the formalism (Eq. (5)) recently proposed by Meyerhoff and co-workers for situations where the primary ion charge is $+1$ and the interfering ion charge is $+2$ (Study 2). These values were calculated using the same experimental data used for the Nikolskii–Eisenman model (Study 1), but with the least squares error generated from Eq. (5). The trends in the $\log k_{KB}^{Pot}$ values using both models are the same ($Mg^{2+} < Ca^{2+} \approx Ba^{2+}$), but Eq. (5) generates slightly more negative values. With both models, the average relative standard deviation of the potentiometric selectivity coefficient for the three doubly charged interferents is 15–16% ($n = 3$). The trends in the $\log k_{KB}^{Pot}$ values obtained with the conventional FI method [1], using both the Nikolskii–Eisenman equation and Eq. (5) are also the same ($Mg^{2+} \approx Ca^{2+} < Ba^{2+}$, see the Study 3 and 4 results).

In the light of Bakker's work on ISEs conditioned in an interfering ion solution [4], it could be argued that the potentiometric selectivity coefficients obtained are merely an indication of the detection limit of the ISE. If our results were in fact a measure of the LOD of the electrode, then one expect that the effect of the interfering ion would be the same in each case. However, the

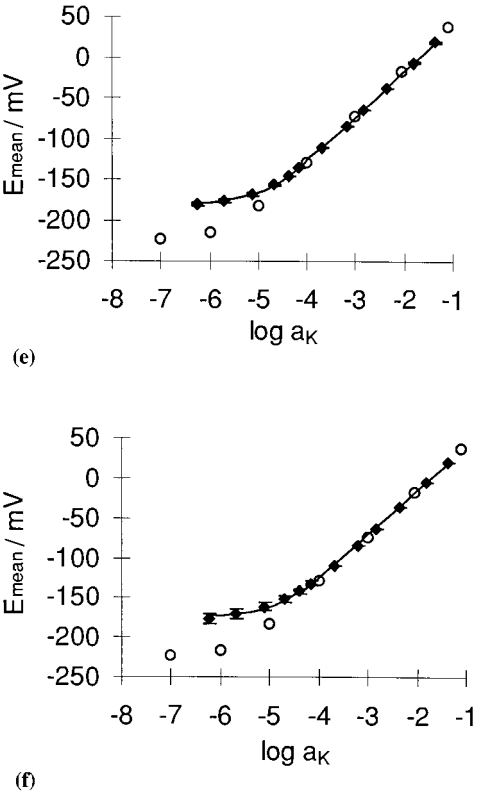

Fig. 1. (a)–(f) Plot of mean experimental potentials (◆) and predicted potentials (line) according to the optimised model based on Eq. (1), versus log a_K with standard deviations as error bars ($n = 3$). The interfering ions are Li^+ (a), Na^+ (b), NH_4^+ (c), Mg^{2+} (d), Ca^{2+} (e) and Ba^{2+} (f). The circular points are potentials obtained with pure potassium chloride solutions.

response curves in Fig. 1 invalidates this latter argument as the location of the plateau region of the graph is clearly dictated by the identity of the interfering ion. Clearly therefore, the log k_{KB}^{Pot} values obtained with our new method are a measure of practical selectivity.

The Nernstian Slope Factors, S, obtained using the Nikolskii–Eisenman model and Eq. (5) (given in Table 4), are all close to the ideal Nernstian values, as would be expected for a valinomycin ISE.

The cell constants, E^0, obtained with the Nikolskii–Eisenman model (Table 4), are similar for interfering ions of a given charge but are different for ions of different charge. One reason for this difference is that the E^0 values for the doubly-charged ions decreased by approximately 2 mV on correcting the experimental potentials for variation in the liquid junction potentials but this correction brought about negligible change in the E^0 values for the singly-charged ions (i.e., agreement was closer prior to correction). Similar values are obtained with Eq. (5) as the model as would be expected. Nernstian slope factors obtained in the presence of doubly-charged interfering ions are slightly higher (by ca. 0.6 mV) and the log (LOD) values are slightly more negative using Eq. (5) as the model. Overall, the differences in electrode parameters returned by the two models are small. Given the ease with which Excel can be set up to model either equation with the same data sets, it would be for other groups to compare electrode parameters obtained with both approaches. We have already obtained data show-

ing similar agreement for parameters calculated Meyerhoff's formalism and the Nikolskii-Eisenman equation from data obtained with the calcium selective electrode and several singly-charged interferents.

In any curve-fitting exercise, it is useful to compare the quality of the fits obtained with the experimental data. One approach is to use the standard deviations of the experimental values from the best-fit curves, σ (see Eq. (6)) [21].

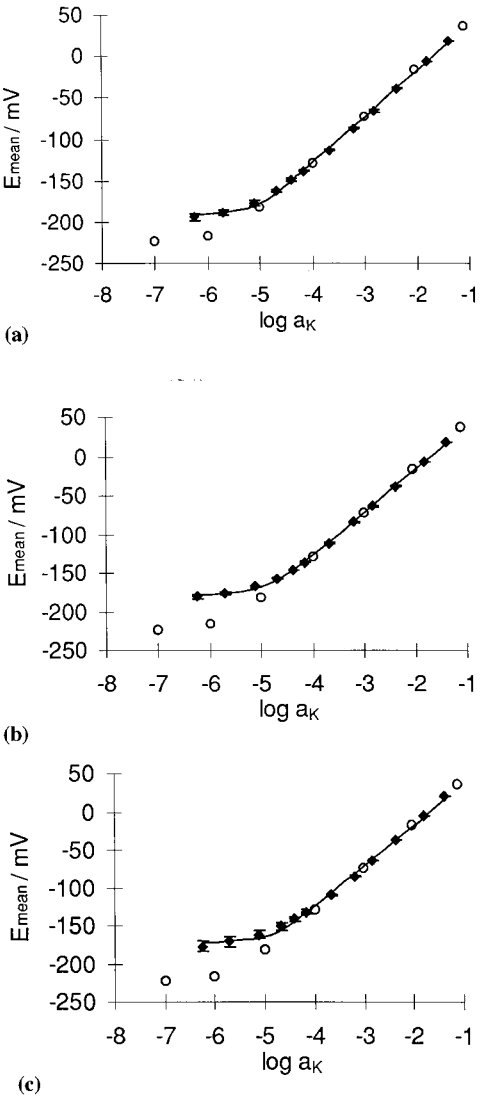

Fig. 2. (a)–(c) Plot of mean experimental potentials (◆) and predicted potentials (line) according to the optimised model based on Eq. (5), versus $\log a_K$ with standard deviations as error bars ($n = 3$). The interfering ions are Mg^{2+} (a), Ca^{2+} (b) and Ba^{2+} (c). The circular points are potentials obtained with pure potassium chloride solutions.

Table 5
Standard deviation of the experimental values from the curve of best fit, σ

Interfering ion	σ/mV$^{-1a,b}$	σ/mV$^{-1a,b}$
	Model: Eq. (1)	Model: Eq. (5)
Li^+	0.68 ± 0.02	
Na^+	0.86 ± 0.22	
NH_4^+	0.51 ± 0.04	
Mg^{2+}	0.96 ± 0.12	2.28 ± 0.18
Ca^{2+}	0.71 ± 0.02	2.03 ± 0.04
Ba^{2+}	2.07 ± 0.58	3.50 ± 0.35

[a] Obtained by non-linear analysis of the mean corrected potentials.
[b] The errors quoted are standard deviation of the values obtained from non-linear analysis of the individual potentials.

Table 5 lists the σ values obtained using Eq. (1) (and Eq. (5) for the doubly charged interfering ions) as the models. These values are low enough to suggest that the optimised model fits the experimental data very well for each interfering ion and that therefore, the values returned for the model parameters are accurate. For example, in the case of Na^+, the σ value of 0.86 mV is very low considering the large range in potentials covered (more than 200 mV), and the standard deviation in the experimental mean potentials which vary from 0.8 mV (at high K^+ activity) to 4.1 mV ($n = 3$). The utility of the σ parameter is well illustrated by comparing the values for the different ions. Clearly, Ba^{2+} gives by far the worst fit for both models, and this is confirmed by visually comparing the actual curves (see Fig. 1(f) in comparison with other curves in Fig. 1 and Fig. 2(c) in comparison to other curves in Fig. 2).

The σ values obtained when using Eq. (5) as the model for the doubly-charged interfering ions, are greater than that obtained when using the Nikolskii–Eisenman model. This would suggest, in the case of our data, that the –Eisenman model (Eq. (1)) gives a better overall fit to the experimental data than Eq. (5).

The residual plots resulting from the fits obtained by the two models are illustrated in Fig. 3(a)–(c). These plots confirm that the Nikolskii–Eisenman model gives better fits in all three cases to those obtained with Eq. (5). Our results therefore suggest that there is no major difference in the electrode parameters obtained with either model, but that the quality of the fit is superior with the Nikolskii–Eisenman model for these particular data.

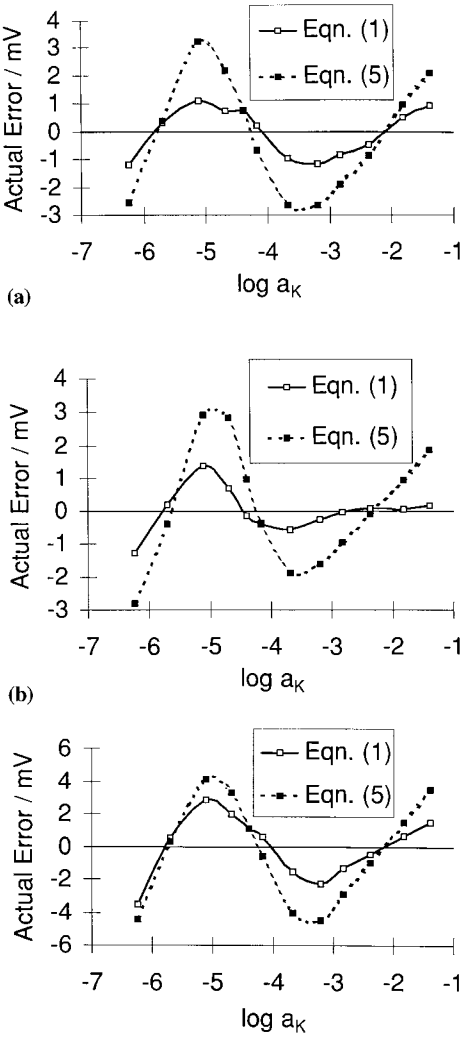

Fig. 3. Plot of residual error resulting from the fit of the Eq. (1) (solid line) and Eq. (5) (broken line) to the mean experimental potential versus log a_K. The interfering ions are Mg^{2+} (a), Ca^{2+} (b) and Ba^{2+} (c).

4. Summary

We believe that the method of determination of potentiometric selectivity coefficients described in this paper is superior to the conventional mixed solution and SS methods for the following reasons:

1. Conventional beaker-to-beaker measurements are prone to carry-over contamination between measurements; this cannot occur in the experimental procedure that we have developed as all measurements are performed in a single vessel.
2. Relatively few solutions need to be made up, and the experimental procedure is practically simple to implement. Hence it is easy to replicate data sets.
3. Transfer of electrodes between beakers results in the formation of an open circuit with associated large transient shifts in cell potential, which the cell may or may not fully recover from. This does not happen in the proposed method as the electrodes are in continuous contact with the sample, and no open circuit is generated at any time during an experimental run.
4. The use of a non-linear curve fitting approach means that all the experimental data are used to estimate the electrode parameters. Unlike the conventional FI method [1], there is no element of subjectivity, and the approach can easily cope with ions of differing charge.
5. The ease with which Excel spreadsheets can be modified allows the analyst to quickly investigate the usefulness of models other than the Nikolskii–Eisenman equation such as Eq. (5). A macro can be easily written (with the Record Macro option on the Tools menu) for modifying the Worksheet relating to one interfering ion and this macro is then executed for each of the other interfering ions.
6. The quality of the electrode parameters can be compared at a glance through the σ value in a single run. Furthermore, examination of the response curves in Fig. 1 and Fig. 2, or the residual error plots (Fig. 3) enable a very comprehensive picture of the data quality to be obtained.

7. Finally, Solver can change up to 200 parameters simultaneously and so, in principle, potentiometric selectivity coefficient measurements can be made for a primary ion in the presence of many interfering ions, should this be required.

In conclusion, we feel that this approach, if adopted by other investigators, would enable electrode parameters to be more rigorously measured, and would lead to much greater confidence in the applicability of these data.

Abstract

A simple, sensitive and rapid differential pulse polarographic method has been developed for the quantitative determination of organophosphorus pesticides such as dicrotophos, crotoxyphos and chlorfenvinphos in agricultural formulations in universal buffers of a pH range 2.0–12.0. The sample is treated with ethanol to facilitate the dissolution of these pesticides. Both standard addition and calibration methods can be used for the analyses. The lower detection limits are 1.25×10^{-9}, 1.05×10^{-9} and 1.0×10^{-9} M, respectively. The method can be applied successfully to determination of these pesticides in grains and soil. © 1997 Elsevier Science B.V.

Keywords: Chlorfenvinphos; Crotoxyphos; Dicrotophos; Differential pulse polarography

1. Introduction

One of the most important classes of insecticides is organophosphorus compounds. Dicrotophos [I], crotoxyphos [II] and chlorfenvinphos [III] are systemic and general insecticides [1,2]. These are effective against a wide range of insects on fruits, vegetables, and commercial crops. Today these are widely used because of their low persistence and high effectiveness. Reliable analytical procedures are therefore needed for their determination.

(III)

By reviewing literature of many studies [3–7] it is found that a number of organophosphorus pesticides have been determined by means of techniques such as gas chromatography, thin-layer chromatography, high performance liquid chromatography as well as spectrophotometry. A gas chromatographic method has been used for the determination of dicrotophos in foods [8], and fruits and vegetables [9]. Crotoxyphos has been determined by a gas chromatographic method [10] in industrial chemical residues and by HPLC [11]. Electrochemical techniques [12,13] have been widely used for the determination of $>C{=}C<$ containing pesticides. But no discussion has been given to understanding the differential pulse polarographic behavior of the title compounds and to the determination of these compounds by means of differential pulse polarography.

This article attempts to understand the pulse polarographic behavior of these pesticides and describes an electroanalytical procedure for the determination of these pesticides in formulations, grains and soil samples with the aid of differential pulse polarography.

2. Experimental

Differential pulse polarograms were obtained with a Metrohm E506 polarecord connected to a E616 VA Scanner. The three-electrode assembly consisted of a dropping mercury electrode (of area 0.0223 cm^2) as working electrode, a saturated Ag/AgCl(s), Cl^- reference electrode, and a platinum wire auxiliary electrode. All experiments were performed at 25 ± 1°C; pH measurements were carried out with a Elico digital pH meter. Dissolved air was removed from the solutions by degassing with oxygen-free nitrogen for 10 min.

The compounds were supplied by 'Promochem', West Germany. The purity of the compounds was tested by boiling point determination. Stock solutions were prepared by dissolution of the required amounts of compounds in ethanol. The Universal buffers of pH 2.0–12.0 are prepared from 0.2 M boric acid, 0.05 M citric acid and 0.1 M tri sodium orthophosphate [14]. All chemicals used were of AnalaR grade.

3. Results and discussions

The differential pulse polarographic behavior of dicrotophos, crotoxyphos and chlorfenvinphos was examined over the pH range 2.0–12.0. All these compounds were found to give a single well-defined peak in all the buffer systems studied. The single peak is attributed to reduction of the carbon-carbon double bond ($>C{=}C<$) in a two-electron process. Typical differential pulse polarograms for crotoxyphos and chlorfenvinphos are shown in Fig. 1.

The reduction process for these pesticides is diffusion controlled and adsorption free in all the buffer systems studied, as evidenced by the linear plots of i_m (i_m = maximum current observed in differential pulse polarography) versus $t^{2/3}$ (t = drop time) passing through the origin [15]. Variation of E_m (E_m = potential at maximum current in differential pulse polarography) values toward more negative potentials upon increasing the concentration of depolarizer [16,17] indicated the irreversibility of the electrode process. In the above compounds, E_m values depend on pH and shift towards more negative potentials with an increase in pH of the buffer solutions (Fig. 2).

It is observed from a comparison of the peak potentials of the three compounds that chlorfenvinphos is more easily reduced than dicrotophos and crotoxyphos. The presence of two electron-withdrawing chlorines in chlorfenvinphos makes reduction of the carbon-carbon bond easier in chlorfenvinphos than in dicrotophos and crotoxyphos. The order of reduction is as follows

(from the comparison of peak potentials): chlorfenvinphos > crotoxyphos > dicrotophos.

3.1. Analysis

In Fig. 2, the variation of peak current for reduction of dicrotophos as a function of pH is presented. It can be observed that the peak current shows a maximum at pH 4.0, since in this media proton involvement is high making > C=C < group protonated which in turn gets reduced more easily. But in basic media (pH 8.0–12.0), the reduction of > C=C < group is not easily facilitated owing to the less availability of protons. The polarographic peaks obtained at pH 4 and 6 for the title compounds were well-resolved and used for the analysis. For the quantitative estimation of the three compounds, both calibration and standard addition methods were used. Peak heights were found to be linear in the range 1.0×10^{-5}–1.9×10^{-9} M, 1.5×10^{-5}–4.0×10^{-9} M, and 1.25×10^{-5}–1.5×10^{-9} M for dicrotophos, crotoxyphos and chlorfenvinphos, respectively. The detection limits were found to be 1.25×10^{-9} M, 1.05×10^{-9} M, and 1.0×10^{-9} M for the respective compounds. The detection limit (dl) [18] was calculated using the expression dl = 3 S.D./m, where S.D. = standard deviation and m = slope of the calibration plot.

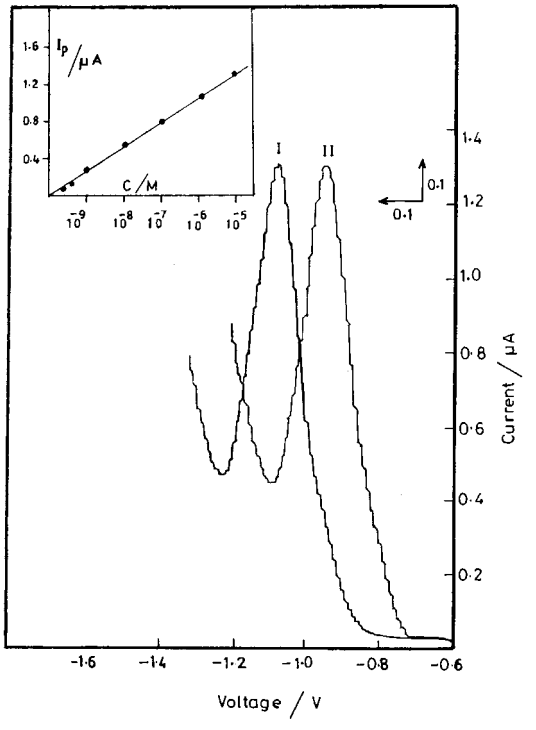

Fig. 1. Typical differential pulse polarograms of crotoxyphos (I) and chlorfenvinphos (II) in pH 4.0. Concentration = 1.0×10^{-5} M; Drop time = 2 s; Pulse amplitude = 50 mV. The linear plot of peak current versus concentration of crotoxyphos is shown in the inset.

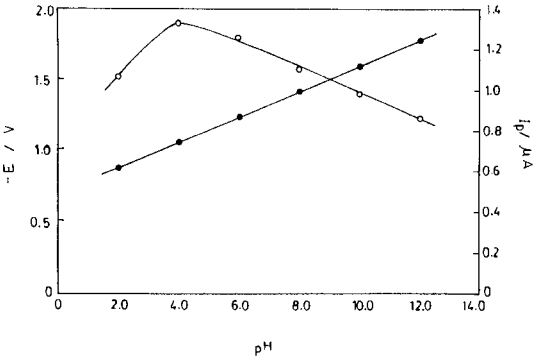

Fig. 2. Variation of peak current (○) and peak potential (●) for dicrotophos reduction as a function of pH. Concentration = 1.0×10^{-5} M; Drop time = 2 s; Pulse amplitude = 50 mV.

3.2. Recommended analytical procedure

A stock solution (1.0×10^{-5} M) is prepared by dissolution of the appropriate amount of the electroactive species in ethanol. Standard solution, 1 ml, is transferred into a polarographic cell and diluted with 9 ml of supporting electrolyte and then deoxygenated with nitrogen gas for 10 min. After the polarogram is recorded, small increments (0.2 ml) of standard solution are added and a polarogram is recorded after each addition under similar conditions. In present study, the best precision was obtained at pH 4.0, with a drop time of 2 s, a pulse amplitude of 50 mV, and an applied potential of −1.05 V, −1.12 V, and −0.95 V (vs. Ag/AgCl(s)), respectively, for the three compounds. The relative standard deviations and correlation coefficients were found to be 1.24 and 0.993%, 1.1 and 0.998%, and 1.29 and 0.996% for the respective compounds.

Table 1
Determination of dicrotophos, crotoxyphos and chlorfenvinphos in formulations by differential pulse polarography

Compound	pH of the supporting electrolyte	Labelled amount (mg)	Average amount found ± S.D. (mg)*	Average recovery (%)
Dicrotophos formulation

	6.0	5.0	4.89 ± 0.043	97.80

* Each value is an average of three determinations.

This procedure was successfully used for the determination of these compounds in their formulations at different pH values.

3.3. Analysis of formulations

The required quantity of formulation corresponding to a 1.0×10^{-3} M stock solution was accurately measured and transferred into a 100 ml volummetric flask containing 50 ml of ethanol. A solution of approximately 1.0×10^{-5} M was prepared by dilution of this stock solution with universal buffer. Assay results for dicrotophos, crotoxyphos, and chlorfenvinphos in formulations at pH 4.0 and 6.0 are given in Table 1.

3.4. Analysis of pesticides in grains or soil

Grain (rice or wheat) samples (50 g) or soil sample (25 g) were sprayed with known amounts of dicrotophos, crotoxyphos, or chlorfenvinphos and left for 2–4 h. The extracts were prepared by treatment of a crushed sample with 100 ml of acetone. The extract was evaporated to dryness. The residue of dicrotophos, crotoxyphos, or chlorfenvinphos was dissolved in ethanol and transferred to a 50 ml volummetric flask.

Results obtained for the determination of pesticides in grains and soil are presented in Table 2. Recoveries of dicrotophos, crotoxyphos, and chlorfenvinphos from 96.33 to 99.67%, which indicates the accuracy and reproducibility of the proposed differential pulse polarographic method.

Table 2
Recovery of dicrotophos, crotoxyphos and chlorfenvinphos added to grains and soil

Compound	Amount added (mg)	Average amount found* (mg)			Average recovery (%)		
		Wheat	Rice	Soil	Wheat	Rice	Soil
Dicrotophos	5.0	4.863	4.954	4.962	97.25	99.08	99.24
	10.0	9.895	9.845	9.825	98.95	98.45	98.25
	15.0	14.81	14.74	14.98	98.72	98.25	98.85
	20.0	19.84	19.89	19.81	99.18	99.45	99.05
Crotoxyphos	5.0	4.874	4.945	4.943	97.48	98.90	98.85
	10.0	9.810	9.915	9.855	98.00	98.65	98.55
	15.0	14.79	14.87	14.79	98.62	99.15	98.65
	20.0	19.42	19.86	19.79	97.08	99.32	98.95
Chlorfenvinphos	5.0	4.850	4.858	4.868	97.00	97.15	97.35
	10.0	9.850	9.890	9.780	98.50	98.90	97.80
	15.0	14.81	14.86	14.81	98.70	99.04	98.70
	20.0	19.52	19.65	19.78	97.60	98.25	98.90

* Each value is an average of three determinations.

The data incorporated in Tables 1 and 2 suggest that, in addition to dicrotophos, crotoxyphos, and chlorfenvinphos, other constituents present in grains and soil do not interfere in the proposed method. The proposed method is simple, rapid, reliable, and sensitive and hence can be used in insecticidal formulations. The method does not involve the elaborate clean-up procedures required with the other methods.

Extraction of uranium from aqueous solution by phosphonic acid-imbedded polyurethane foam

S. Katragadda, H.D. Gesser, A. Chow *

Department of Chemistry, University of Manitoba, Winnipeg, MB, R3T 2N2, Canada

Received 14 October 1996; received in revised form 25 February 1997; accepted 4 March 1997

Abstract

Phenylphosphonic acid was imbedded into the matrix of the polyurethane foam during the fabrication process of the polymer. The extraction of uranium by phosphonic acid-imbedded polyurethane foam and blank polyurethane (i.e., foam without phosphonic acid functional groups) was investigated. Phosphonic acid-imbedded foam showed superior extractability of uranium from solutions with $pH = 7.0 \pm 1.5$ over a wide range of temperature. © 1997 Elsevier Science B.V.

Keywords: Aqueous; Phosphonic; Polyurethane; Uranium

1. Introduction

Polyurethane foams have received considerable attention over the past two decades for their use in the separation and concentration of a wide variety of organic and inorganic compounds from aqueous solutions [1,2]. These foams have also been successfully used as inert supports for various extractants [3–9]. In this paper we describe a procedure for the preparation of a polyurethane foam using Hypol™ prepolymer and the incorporation of phosphonic acid groups into the polyurethane foam.

Polyurethane foams that are both elastomeric and hydrophilic, can be made by reacting Hypol™ prepolymer with active hydrogen-containing compounds (i.e., H_2O, ROH, etc.). Hypol™ prepolymers are a mixture of prepolymers derived from toluene diisocyanate. Polyurethane foams can be prepared by mixing equal weights of Hypol™ prepolymers and water. Additives may be introduced in either or both of the organic and aqueous layers [10,11].

A number of papers have been published describing the synthesis of sorbents containing phosphonic acid for the selective sorption of uranium from aqueous systems [12–16]. The synthesis of these sorbents is often tedious and difficult to undertake.

A relatively simple preparation of a phosphonic acid-imbedded polyurethane foam and the evaluation of its ability to extract uranium from aqueous solutions with a wide range of pH and temperatures will be discussed in this paper.

2. Experimental

2.1. Apparatus

Absorbance measurements for the determination of uranium were made with a Hewlett–Packard Model 8452A diode-array spectrophotometer. Sample solutions were pumped through a 0.5 cm pathlength, quartz flow cell using a Piper Pump™ Model P10T peristaltic pump.

The synthesized polyurethane foams were initially cut into small pieces and then placed in liquid nitrogen. The frozen foams were ground into a fine powder in a stainless steel container on a Waring™ blender. Sample solutions at 4 and 22°C were shaken with a Burrell Wrist-Action Shaker. Similarly at 40 and 70°C a Dubnoff Metabolic Shaking Incubator was used for shaking the samples. Measurements of pH were obtained using a Fisher Accumet™ Model 825MP pH meter.

2.2. Reagents

All chemicals were reagent grade and the water used was purified initially by reverse osmosis and then passed through a Barnstead Nanopure II™ system. Uranium solutions ranging from 1 to 10 ppm were prepared by successive dilution of a 2000 ppm uranium solution which was made from uranyl acetate (BDH, England).

Phenylphosphonic acid and the photometric reagent, Arsenazo III, were obtained from Aldrich (WI, USA). The prepolymer used for the production of the polyurethane foams was a sample of Hypol™ FHP2002 provided by W.R. Grace (MA, USA).

2.3. Analysis

The determination of uranium involved the use of Arsenazo III as the photometric reagent. Arsenazo III has been used as the preferred choice of chromogenic reagent for the spectrophotometric determination of uranium over the last three decades [17,18]. In moderately acidic media, uranium forms a 1:1 complex with Arsenazo III with a stability constant, $\log \beta_1 = 5.42$ [19,20]. The Arsenazo III concentration was always kept at levels slightly higher than that of uranium to ensure the complete formation of the complex while keeping the background as low as possible.

A continuous flow spectrophotometric method was employed for the determination of uranium [21]. Analysis by this method involves the simultaneous pumping of the photometric reagent (0.006% Arsenazo III in 0.12 *M* HCl) and the uranium solution into a flow mixing cell to form the uranium-Arsenazo III complex. This complex then enters the analytical flow cell where the absorbance measurements are recorded using the diode-array spectrophotometer.

The choice of dissolving Arsenazo III in 0.12 *M* HCl permitted the analysis of uranium solutions with a wide range of pH values. Acid concentrations greater than 0.12 *M* HCl produced larger errors with low pH uranium solutions due to changes in the uranium species present in highly acidic solutions. Concentrations lower than 0.12 *M* HCl resulted in larger errors with higher pH uranium solutions because this mixture resulted in neutral or basic solutions which affect the solution constituents.

Quantitative analysis of uranium was obtained by using the 'Quantitation' program which was part of the software menu for the Hewlett–Packard system. Internal referencing was used to improve the precision of the readings by reducing the impact on the baseline of any changes due to dust, air or variations in lamp intensity. The absorbance at 768 nm on the baseline was subtracted from the absorbance at the analytical wavelength of 650 nm. The difference in absorbance was used for both calibration and sample analysis. The calibration curve shown in Fig. 1 was obtained by using a second order curvefit for uranium standards ranging from 1 to 10 ppm. A 10 ppm uranium standard solution and a water blank were analysed ten times to determine the precision of the analytical technique. The averages found were 10.0 ± 0.03 and 0.0 ± 0.05 ppm uranium [21].

2.4. Procedure

Polyurethane foams can be made by mixing Hypol™ prepolymers with water and improvements to the foam can be attained by mixing in different additives. In a preliminary study [21], several experiments were performed to investigate the effects of changing the ratio of Hypol™ prepolymer to aqueous layer and the effect of phenylphosphonic acid as an additive in the aqueous layer.

The foams were prepared by mixing 10 ml of Hypol™ prepolymer with various amounts of water in a 150 ml glass beaker and stirring with a glass rod. Phenylphosphonic acid was added to the aqueous layer. Foams were prepared with the aqueous layer adjusted to pH values of 1, 7 and 13. A solution of pH 1 was obtained by simply dissolving phenylphosphonic acid; pH 7 and 13 solutions were prepared by the addition of 2 *M* NaOH.

When the ratio of the polymer to aqueous layer was 1:0.5, the result was a strong but hydrophobic foam. When the ratio was 1:2, the foam produced

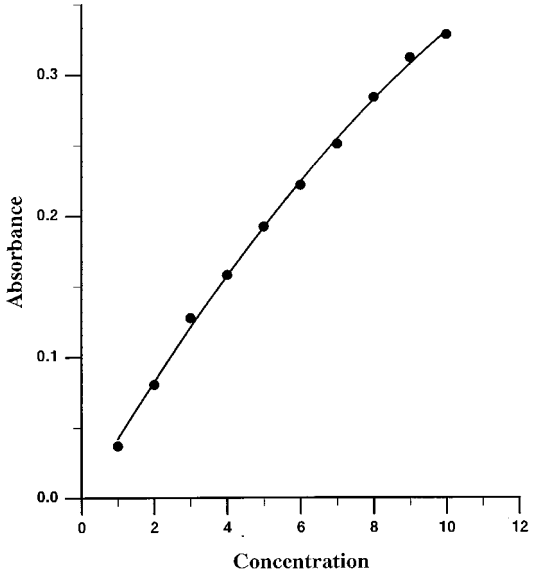

Fig. 1. Calibration graph for uranium standards between 1 and 10 ppm. A 5 mm Markson™ cell and 0.006%. Arsenazo III in 0.12*M* HCl were used.

was weak in mechanical strength but hydrophilic in nature. The optimal foam which is both hydrophilic and strong was obtained when the ratio of reagents was 1:1. Several other variations in polymer to aqueous layer ratios were studied. In some experiments a surfactant was added and/or a weak vacuum applied in an attempt to improve the formation of the foam. Among the various formulations attempted, only one produced a foam that was hydrophilic, elastomeric and capable of sorbing uranium from aqueous solution. This foam, called 'phosphonic acid foam', was used for all subsequent experiments. This phosphonic acid foam was obtained by mixing the prepolymer and water in a 1:1 ratio with 5% wt/wt phenylphosphonic acid in the aqueous layer with this layer at pH 1.0. The mixture was rapidly stirred for 15 s with the use of a glass rod. The mixing resulted in a cloudy emulsion followed by a slow increase in volume due to the release of carbon dioxide.

The resulting phosphonic acid foam became tack-free within 5 min and was air-dried in a fumehood for 8 h. The dried foam was cut into small pieces and immersed in liquid nitrogen. The frozen foam became brittle and was easily ground to a fine powder using a blender. Powdering the foam was necessary to reach equilibrium more quickly between the polymer and the uranium solution and to ensure more reproducible results. The powdered foams were initially soaked in water for 4 h and the resulting slurry was then filtered through a Whatman™ No. 541 filter paper using a Buchner funnel. The foam was recovered from the filter and the complete procedure, soaking and filtering, was repeated twice more. The foam was then cleaned in an identical manner with acetone. This procedure should remove all water or acetone soluble impurities from the foam. The clean, powdered foam was then vacuum dried for 4 h to remove traces of acetone from the foam. Blank polyurethane foam was prepared by a similar process without the addition of phenylphosphonic acid. The colour of the phosphonic acid foam was light brown in comparison to the blank foam which was white.

The capability of the foams to extract uranium was tested by adding 25 ml of 10 ppm uranium

solution to a 60 ml Nalgene™ polypropylene screwtop bottle together with 0.200 ± 0.003 g of the powdered foam. The capped bottles were shaken for 5 h using an automatic shaker. The solutions were filtered and then analyzed for uranium content. The Nalgene™ bottles with standard solutions were used to obtain a calibration curve and Fig. 1 shows that there was no sorption of uranium by the bottles.

2.5. Evaluation of the foam

Uranium solutions with pH values between 1.4 and 11.0 and at different temperatures between 4 and 70°C were used to evaluate the extraction characteristics of the phosphonic acid foam and the blank foam. The pH of the solutions was adjusted with 2 *M* HCl or 2 *M* NaOH using a pH meter. Uranium solutions were equilibrated to the required temperatures for several hours before adding them to the plastic bottles containing the foams. The uranium solutions were shaken at 4 and 22°C using a Burrell Wrist Action Shaker and at 40 and 0°C using a Dubnoff Metabolic Shaking Incubator with a variable temperature-controlled water bath. Temperature measurements were within ± 2°C during the shaking process.

The percentage extraction was calculated as

$$\%E = 100 \times \frac{(I - F)}{I}$$

where $\%E$ is the percent extraction, F is the concentration of uranium remaining in solution after extraction and I is the original concentration of uranium available for extraction. I is the concentration of uranium of a standard solution after treating it to the same filtration, pH and temperature conditions as the foam sample solutions with the exception of the foam.

The concentration of available uranium must be used rather than the calculated initial concentration to adjust for any loss of uranium during filtration due to precipitation of uranium. Uranium precipitation is known to occur at $pH > 2$ although this is not generally visible; Feldman et al. [22] observed the precipitation from uranyl nitrate solutions at $pH > 4.5$ by using centrifugation. Experiments were performed in triplicate at the same pH and temperature and the average values of I and F used to calculate $\%E$.

3. Results and discussion

A study was done at 22°C using various times for the equilibration process. It was found that the extraction increased up to 2.5 h and then stabilized. In all subsequent experiments a time of 5 h was used to ensure equilibrium. Phosphonic acid foam exhibits good extraction capabilities for the sorption of uranium, which exists as various oxycation species of uranium (VI), between pH 5.3 and 8.2. The extraction capability decreases at either end of the pH range as shown in Figs. 2–5. The decrease in extraction is due to the presence of different proportions of several uranium species dependent on the pH of the solution. The species formed in aqueous HCl solutions below pH 3 and UO_2Cl_2 and UO_2Cl^+ [23] which do not seem to be extractable. In basic solutions above pH 10, other species which may not be extractable by the phosphonic acid foam, such as $UO_2(OH)_3^-$ are formed because of the hydrolysis of the uranyl ion [23].

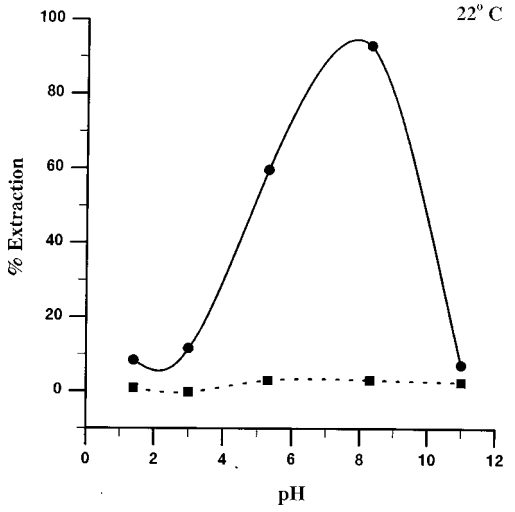

Fig. 3. Comparison of the extraction capability of uranium from aqueous solutions by phosphonic acid-imbedded polyurethane foam and blank foam at 22°C. – • – Phosphonic acid foam – ■ – Blank foam.

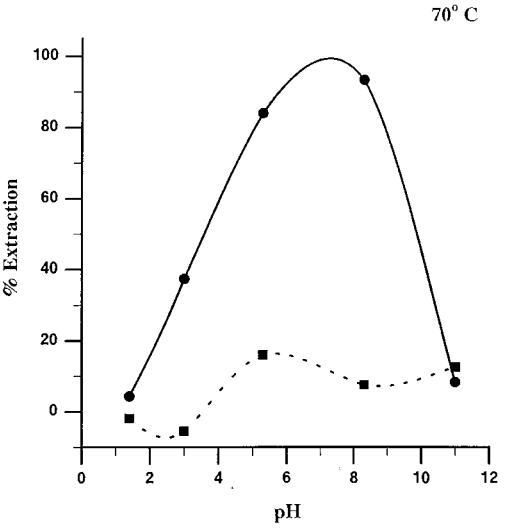

Fig. 5. Comparison of the extraction capability of uranium from aqueous solutions by phosphonic acid-imbedded polyurethane foam and blank foam at 70°C. – • – Phosphonic acid foam – ■ – Blank foam.

The extraction of uranium generally increases with an increase in temperature from 4 to 70°C between pH 3 and pH 8 as shown in Figs. 2–5. For this phosphonic acid foam, the best extraction is achieved at 70°C for aqueous uranium solutions at pH 3 to 8. At this temperature more extraction was observed over a broader pH range. It can be seen that the maximum extraction occurs at pH values close to 7.0 where approximately 95% extraction is obtained. This may be useful as natural waters are generally in the pH range 6–8. Although the discussion above is based partly on interpolated data, the general performance of the phosphonic acid foam can be observed for a wide range of temperatures and pH values. It was also visibly apparent in these studies that uranium is extracted more rapidly at higher temperatures. The decrease in extraction efficiency at either end of the pH range suggests that solutions with pH less than 1 or greater than 11 can be used as eluting agents to desorb uranium from the foam. Blank foams formed without the inclusion of phenylphosphonic acid, showed little capability to extract uranium from aqueous solutions in comparison to the phosphonic acid foam produced as shown in Table 1.

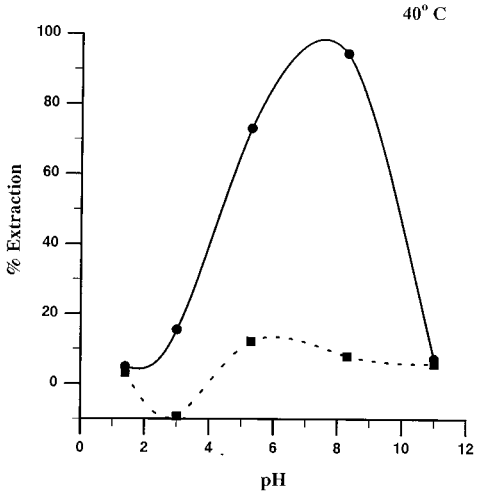

Fig. 4. Comparison of the extraction capability of uranium from aqueous solutions by phosphonic acid-imbedded polyurethane foam and blank foam at 40°C. – • – Phosphonic acid foam – ■ – Blank foam.

Phosphonic acid foam performs better than the β-diketone foam [11] at 4°C in its ability to extraction uranium at natural water pH (i.e., at pH about 7). The ideal temperature for maximum

11.0	8.3 ± 5.7	12.6 ± 10.0	70

extraction using the β-diketone foam [11] was 40°C. The extraction ability decreased with increasing temperature which can be attributed to the instability of the β-diketone foam at these higher temperatures. The phosphonic acid foam material is more stable and extracts uranium effectively from 4 to 70°C.

Preliminary experiments showed that the phosphonic acid was capable of extracting uranium from an artificial seawater [21]. This seawater was prepared by dissolving 750 g of a synthetic salt mixture, 'Instant Ocean' in deionized water to make 20 l. The composition of 'Instant Ocean' is given in Table 2. Laboratory air was bubbled through the seawater solution to adjust the pH to the natural seawater level of 8.4. The resulting solution was spiked with a known amount of uranium and allowed to equilibrate for at least 5 h before use.

The selective extraction capability of phosphonic acid-imbedded foam was determined by equilibrating 25 ml of artificial seawater which was spiked to a level of 16.5 ppm uranium with 0.5 g of foam. The filtered solutions were analysed by direct current plasma emission spectroscopy which minimises any interferences from the salt matrix. The phosphonic acid foam showed 90% extraction of uranium while the blank foams showed no extraction under identical conditions [21].

The experiments in this study were done using a batch process in order to determine the equilibrium extraction results. It is expected that if the phosphonic acid foam material was used in separation columns, that quantitative extraction would be obtained at any temperature over a wide pH range. Column extractions in general would provide improved retention over batch extractions because new sorbent that has not achieved equilibrium is available throughout the length of the column.

4. Conclusions

Phenylphosphonic acid was imbedded the matrix of the polyurethane foam during the fabrication of the foam. The resulting phosphonic acid

foam is most capable of extracting uranium from aqueous solutions with pH between 5 and 8. Phosphonic acid foam is simple to prepare, relatively inexpensive, has high porosity and good chemical and mechanical stability. These qualities make the phosphonic acid foam a good sorbent for the preconcentration of uranium from solutions in the pH range is 6–8. This sorbent appears promising for a number of industrial applications including the nuclear industry and may be usable either as a foamed material or as a separation column for the clean-up of uranium spills or mine wastes. The ability to sorb uranium from solutions at temperature as low as 4°C would make this polymer material attractive for use with environmental water at any time of the year. Phosphonic acid-imbedded foam shows promising results from the selective sorption of uranium from seawater. Future work should investigate the extraction mechanism and obtain a more detailed extraction profile for this new sorbent material.

Received 14 August 1996; received in revised form 24 February 1997; accepted 11 March 1997

Abstract

The sorption coefficients to humic acid of 46 PAC having a wide range in polarity were compared with the capacity coefficients of the PAC to a non-polar HPLC column material (ODS) and a polar one (Diol). It is shown that polar interactions contribute to the sorption of polar PAC in addition to the non-polar interactions. The results also suggest that humic acid may contain different hydrophilic adsorption sites. The non-polar column material was only the best model substrate, if the test materials were limited to the hydrophobic unsubstituted PAC, PAH + O,S-PAC. © 1997 Elsevier Science B.V.

Keywords: Polycyclic aromatic compounds; HPLC; Capacity coefficient; Humic acid; Sorption

1. Introduction

The transport, fate and bioavailability of organic pollutants in the aquatic and terrestrial environment is very dependent of the partitioning of these compounds between water, dissolved humic matter and soil or sediment humic matter [1,2]. Humic and fulvic acids have a very complex composition and show great variations in their composition and properties dependent of their origin and history [3–7].

The major concern in relation to pollution with polycyclic aromatic compounds (PAC) is that many are considered to be carcinogenic [8]. In addition acridine, a N-PAC, has recently been shown to be a strong phytotoxin towards terrestrial plants [9] and some photooxidation products of PAH have been shown to be toxic towards water plants [10]. The PAC cover a group of compounds having a great variation in polarity, water solubility and other physico-chemical properties [11–17]. A number of different PAC have been identified in the environment. The best known group is the hydrophobic, parent polycyclic aromatic hydrocarbons (PAH), but also N-, O-, S-PAC, a number of different derivatives, alkyl, nitro, cyano, chloro, bromo, methoxy, N-oxides and different oxygenated derivatives, phenols, quinones, ketones, aldehydes and carboxylic acid derivatives have been found [13,18–30]. The

PII S00 9-9140(97)00083-0

ubiquitous PAC originates from a number of different sources. The most important ones are oil pollution, combustion processes and the manufacturing and application of creosote and coal tar [31–35]. Photochemical reactions during the transport in the atmosphere and in the aquatic environment [13,21,36–39] and microbiological oxidation in the aquatic and terrestrial system [40–42] contributes to the complexity of the composition of PAC in the environment.

Several studies have investigated the sorption of the hydrophobic PAH to organic matter in the environment, e.g., Refs [5,6,43]. A few studies have dealt with other PAC compounds, e.g., dibenzothiophene, some amino-PAH, anthracene-9-carboxylic acid, 1-naphthol and a few N-PAC compounds [44–48]. These studies show that the sorption is determined by nonpolar interactions between the PAC and the organic matter and increases with diminishing water solubility of the PAC [46] as well as with increasing content of carbon and especially aromatic carbon of the organic matter [5,6]. Some evidences suggest that hydrophobic adsorption rather than phase partitioning is the dominant mode of binding non-polar PAC compounds [49], while some suggest, that both partitioning and site-specific sorption occur both for polar and nonpolar organic compounds [50]. In reversed phase HPLC it appears that retention of non-polar compounds is governed by a partitioning process, rather than by adsorption [51]. Reversed phase HPLC capacity coefficients for a cyanoalkyl column have been shown to correlate with the humic acid K_{oc} values for aromatic hydrocarbons and pesticides [52,53]. This paper shows that the sorption of PAC to humic matter is affected by polar interactions, especially hydrogen bonds, but also ionic interactions and dipole-dipole interactions or charge transfer complexion, in addition to non-polar interactions. Our recent values of the sorption coefficients, K_{oc}, to humic acid of 46 PAC having a wide range in polarity [15] are compared with the capacity coefficients, k', using a HPLC column with a monomeric column material consisting of nonpolar octadecylsilyl groups, ODS, and a Diol-column (Diol, -$CH_2CH_2CH_2OCH_2$-CH(OH)CH_2OH) both applied in the reverse phase mode. It is shown that the HPLC capacity coefficients can be applied to interpret the humic acid sorption mechanism of PAC.

2. Experimental

2.1. Chemicals and materials

The test compounds, listed in Tables 1 and 2, were obtained from several sources as pure compounds. Their identity was confirmed by UV absorption spectra. The preparation of the bromopyrenes is described elsewhere [15,54]. The compounds were dissolved in methanol (Lichrosolv 99.8% or Lab Scan HPLC) with a typical concentration of 0.04 g l^{-1}.

2.2. HPLC method

The HPLC system used was a gradient low pressure Shimadzu LC-10HPLC system with PDA detector, thermostatted column oven and autoinjector. The Diol column (25.0 cm × 4.6 mm ID) was slurry packed with Nucleosil 7 OH from Macherey-Nagel. The ODS columns used were Phenomenex Prodigy ODS-2 columns (15.0 cm × 4.6 mm ID and 5.0 cm × 4.6 mm ID) with a particle size of 5 μm. The ODS columns were endcapped and experiments with *n*-hexane as eluent showed no difference in the retention times of benzene and nitrobenzene confirming a negligible amount of silanol groups. The eluents were mixed from laboratory grade ion exchanged water extra purified on a Millipore-Q water purification system and Lichrosolv methanol 99.8% from Merck or Lab Scan HPLC methanol. The eluent consisted of 35% methanol and 65% water applying the Diol column, and 65% methanol and 35% water applying a ODS column. Appropriate mixtures of the compounds were chromatographed and the retention time (v_r) of each compound was recorded. All measurements were repeated at least three times. The temperature was kept at 30°C for all measurements. The dead volume, v_0, of the system used for calculating the capacity coefficient, $k' = (v_r - v_0)v_0^{-1}$, was determined by chromatographing water (Diol) and $NaNO_3$ (ODS).

2.3. Humic acid sorption coefficients, K_{oc}

The determination of log K_{oc} is described in details elsewhere [15] but in short, the sorption coefficients were achieved by means of the following correlation: log $K_{oc} = (1.50 \pm 0.15)$*log $k' + (4.16 \pm 0.12)$, $r = 0.99$, SE $= 0.27$, where k' is the capacity coefficient for a HPLC column having Aldrich humic acid chemically immobilized to the silica material. The coefficients of the correlation were attained by calibration with the following compounds, quinoline, naphthalene, anthracene, phenanthrene, benz[a]anthracene and benzo[a]pyrene, for which experimental K_{oc} values are known.

3. Results and discussions

3.1. Variation of the capacity coefficients

The capacity coefficients, k', of unsubstituted PAH and N-PAC increased with the molecular size for both types of columns (see Table 1). k' varied a factor of 37 from the bicyclic naphthalene to the pentacyclic dibenz[a,j]anthracene for the ODS column and a factor of 34 for the Diol column. Thus for both columns k' increases with decreasing water solubility of the PAH. The similarity in the PAH k' ratios for the columns suggest perhaps that the retention mechanism on the two columns has been the same. The

N-methylquinolinium iodide	3.10	0.22	0.01

Diol column material consists of a nonpolar part, a silanopropyl group, that joins the polar part, the diol moiety to the silica surface. For the retention of PAH, it appears that the silanopropyl group is the active part.

For the corresponding N-PAC, quinoline and dibenz[a,j]acridine k' varied a factor of 28 for the ODS column and 14 for the Diol-column. Dibenz[a,j]acridine was selected for the comparison, as it is the only one of the dibenzacridines, that do not have any steric shielding of the nitrogen atom [15,16]. The explanation of the minor variation of k' for N-PAC on the Diol-column appears to be that the ability of N-PAC to form hydrogen bonds with the diol surface diminishes with increasing size of the N-PAC, so that bi- and tricyclic N-PAC are bound more strongly than the pentacyclic N-PAC. Thus, the increased water solubility of, e.g. the pentacyclic N-PAC compared to PAH [12] causes the pentacyclic N-PAC to elute faster than the pentacyclic PAH, while the water solubility has only a minor influence on the retention of bicyclic N-PAC compared to that of naphthalene. Therefore, e.g., the ratio $(k'_{\text{quinoline}})/(k'_{\text{napthalene}}) = 0.95$ is larger than the ratio $(k'_{\text{dibenz[a,j]acridine}})/(k'_{\text{dibenz[a,j]anthracene}}) = 0.39$. In contrast to this, the effect of nitrogen for k'(ODS) is independent of the size of the PAH and N-PAC. Thus $k'_{(\text{N-PAC})}/k'_{(\text{PAH})} = 0.16 \pm 0.03$ for quinoline, isoquinoline, 4-azafluorene, acridine, benzo[f]quinoline, phenanthridine, 10-azabenzo[a]pyrene and dibenz[a,j]acridine and the analog PAH. The other N-PAC, e.g. dibenz[c,h]acridine (0.80), have higher ratios than 0.16, because the steric shielding of the nitrogen atom, which diminishes the basicity of the nitrogen atom and increases the hydrophobicity [15,16], affects k'(ODS) much more than it affects k'(Diol). Carbazole has a neutral nitrogen atom in contrast to the other N-PAC. This may be the reason that $k'_{(\text{carbazole})}/k'_{(\text{fluorene})}$ (0.28 for ODS and 1.13 for Diol) is higher than most of the other $k'_{(\text{N-PAC})}/k'_{(\text{PAH})}$ values for both types of columns.

The behavior of the two model compounds for O- and S-PAC, dibenzofuran and dibenzothiophene, on the two columns were similar to that PAH and not to that of N-PAC, although the analog tricyclic aromatics of the fluorene type had

some differences in their retention on the two columns, and the variations of k'(Diol) were much minor than those of k'(ODS). Thus, k'(ODS) decreased in the range dibenzothiophene (15.9) ~ fluorene (14.3) > dibenzofuran (11.0) > carbazole (4.0) > 4-azafluorene (1.4), and k'(Diol) decreased in the range dibenzothiophene (1.19) > carbazole (0.86) > fluorene (0.76) ~ dibenzofuran (0.75) ~ 4-azafluorene (0.70). The k'(ODS) gives a reasonable description of the variations of log K_{oc} for the three hydrophobic PAC, dibenzothiophene (log $K_{oc} = 4.59$, see Table 1), fluorene (4.68) and dibenzofuran (4.15), but the influence of hydrogen bonds between humic acid and N-PAC becomes evident, if carbazole (log $K_{oc} = 4.74$) and 4-azafluorene (3.63) also are taken into account. The k'(Diol) predicts the ranking of the five humic acid sorption coefficients better than k'(ODS) and especially that log K_{oc} of carbazole should be high compared to e.g., that of fluorene. The comparison also suggests that the sorption mechanism of carbazole to humic acid may differ from that of 4-azafluorene and the other N-PAC.

The capacity coefficients, k', of PAH increased with the addition of lipophilic substituents and decreased with the addition of polar substituents for both types of columns (see Table 2). Both column materials gave the same ranking as log K_{oc} of the lipophilic substituents, Br > Cl > CH_3. Previously, it has been shown [15] that the effect of Br substituents on log K_{oc} is additive. Comparing anthracene, 9-bromoanthracene, pyrene and the six bromopyrenes, it appeared log k'(ODS) increased with 0.480 ± 0.014 and log k'(Diol) increased with 0.242 ± 0.013 for each substituted bromo atom independent of the aromatic ring system.

k'(Diol) increased for the substituted polar anthracenes in the range quinone < $CONH_2$ < CHO < $COCH_3$ < OCH_3 ~ CN ~ $COOCH_3$ < NO_2, and k'(ODS) increased in the range $CONH_2$ < quinone < NO_2 < $COCH_3$ < $COOCH_3$ < CHO < CN < OCH_3. The largest difference between the two types of columns is that 9-nitroanthracene elutes relatively early on the ODS column compared to the Diol column. The corresponding ranking for log K_{oc} was CHO ~ $CONH_2$ < $COCH_3$ ~ quinone < OCH_3 ~ $COCH_3$ < NO_2 ~ CN. This ranking is reasonably predicted by means of k'(Diol). The log K_{oc} ranking of 9-formyl- and 9-nitroanthracene are poorly predicted by k'(ODS), and k'(ODS) indicate that 9-anthracenecarboxamide should have a much lower log K_{oc} compared to the other anthracenes than observed.

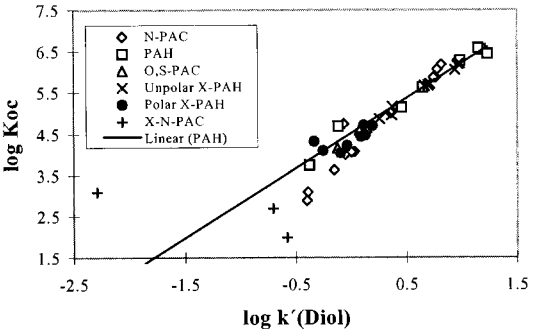

Fig. 1. The log to log correlation between the sorption coefficient (K_{oc}) to humic acid and the capacity coefficient (k') on the HPLC Diol stationary phase for 46 PAC (Table 1). The line showed is the best fit for the correlation of the hydrophobic PAH. All the regression lines are compared in Table 3.

The analyses includes the data in Tables 1 and 2 with the except of N-methylquinolinium iodide.

results of regression analyses (without N-methylquinolinium iodide) for both columns, separate and in combination, are shown in Table 3. The results are shown both for all PAC and for different subgroups (polar and hydrophobic PAC), (unsubstituted and substituted PAC) and (N-PAC, PAH + O,S-PAC, PAH and substituted PAH). The polar PAC includes N-PAC, substituted N-PAC and PAH with polar substituents. The hydrophobic PAC includes PAH, dibenzofuran, dibenzothiophene and PAH with lipophilic substituents (CH_3, Cl and Br). From Fig. 2 and Tables 1 and 2, it can be deduced that the sorption of polar PAC to humic acid are stronger than the sorption of PAH compared to their sorption to the hydrophobic ODS column material. Thus the sorption to humic acid of N-PAC, substituted N-PAC and PAH with polar substituents are affected not only by hydrophobic interactions, but also by polar interactions. From Fig. 1 and Tables 1 and 2, it can be deduced that the sorption to humic acid for PAC with more than two rings generally are reasonably characterized by means of the k'(Diol) values, no matter whether the

compounds belong to the hydrophobic PAH or contain polar atoms or groups. Therefore, the k'(Diol) values give a fair simulation of the hydrophobic interactions between humic acid and hydrophobic PAC, e.g., PAH. The pitfalls of the results applying the Diol column material indicate that some polar PAC are adsorbed to humic acid by another mechanism than the basic N-PAC. Thus it can be seen from Fig. 1 and Table 2 that anthraquinone and especially N-methylquinolinium iodide have relatively high K_{oc} values compared to their k'(Diol) values.

N-methylquinolinium iodide was excluded in the regression analyses in Table 3, as the behavior of the cation was totally different from that of the other polar PAC. The cation forms probably an ion bond to the negatively charged carboxylate groups in humic acid. This means that the sorption mechanisms of N-methylquinolinium iodide to humic acid and to the Diol column material is totally different. The best characterization of the sorption of all PAC to humic acid is achieved by applying a linear combination of k'(Diol) and k'(ODS). The standard error of the log K_{oc} estimate for the linear combination for all PAC was 0.27. It was higher, respectively, 0.30 and 0.38 applying either k'(Diol) or k'(ODS) separately. Table 3 also shows that for the two groups of unsubstituted hydrophobic PAC, PAH and PAH + O,S-PAC, the k'(ODS) standard error of the log K_{oc} estimate is not larger (0.11 and 0.12, respectively) than that of the combined model (both 0.12). However, by including polar and substituted PAC into the comparison the combined model becomes better suited to model the K_{oc} values than the model applying only k'(ODS). Thus, the difference between the standard error of the log K_{oc} estimate for both columns and that for the ODS column increases in the range PAH $(-0.01) \sim$ PAH + O,S-PAC $(0.00) <$ Substituted PAC $(0.04) \sim$ N-PAC $(0.05) \sim$ Polar PAC $(0.06) <$ Substituted PAH $(0.11) =$ All PAC $(0.11) \sim$ Hydrophobic PAC $(0.12) =$ Unsubstituted PAC (0.12). The Diol column is better to simulate the humic acid sorption of polar PAC, e.g. N-PAC and the polar substituted PAH. Thus, the difference between the standard error of the log K_{oc} estimate for both columns and that for the Diol column was below 0.02 for the groups, N-PAC, substituted PAH and substituted PAC. While, the difference increased to 0.04–0.06 for the two groups of unsubstituted hydrophobic PAC, PAH and PAH + O,S-PAC. The group of polar PAC includes N-PAC and the polar substituted PAC. The mixing of these two groups increased the difference to 0.04. The increase, although minor, is expected, as the polar PAC may be adsorbed to humic acid by means of different mechanisms. Thus hydrogen bonds between the nitrogen atom and HO groups of phenolic compartments and carbohydrate residues in humic acid may contribute to the sorption of basic N-PAC. Carbazole may form hydrogen bonds to the negatively charged carboxylate groups in humic acid. Dipole-dipole interactions or charge transfer complexes between, e.g., anthraquinone and phenolic compartments of humic acid appear also to be a possible mechanism. It is interesting that the Diol column appeared to be better to simulate the humic acid sorption than the ODS column, when the unsubstituted and substituted hydrophobic PAC were treated as one group (hydrophobic PAC).

Our findings are supported by the observations of others. Brown and Flagg [55] observed that polar organic compounds did not fit very well into an empirical K_{oc} and K_{ow} relationship for a series of hydrophobic PAH and chlorinated hydrocarbons. Vowles and Mantoura [52], Kördel et al. [53] and Szabó et al. [56] concluded that HPLC columns with semipolar stationary phases are very suitable to simulate the sorption properties of the organic matter content of soils. Our observations agree also with the complex composition of humic acids, as humic materials contain both hydrophobic and different hydrophilic compartments [4]. For PAH and O,S-PAC the most favorable sites appear to be the hydrophobic parts. The ODS column material can be considered to be a model substrate for these parts. The results also suggest that different kinds of humic matter having large variations in their composition will possess different abilities to adsorb different types of polar PAC [57]. Polar functional groups humic acid will be hydrated. Corresponding the Diol moiety will be embedded in the solvent molecules, mainly

the water molecules. The polar interactions can in both cases happen in two ways:

1. The polar PAC competes with the water molecules on the adsorption site.
2. The polar PAC is adsorbed to the adsorbed water cluster.

The pitfall of especially N-methylquinolinium ion, but also carbazole and anthraquinone, indicate that the former mechanism is operating, but probably both mechanisms contribute to the sorption both to the humic acid and to the Diol column.

4. Conclusions

The best simulation of the sorption to humic acid of 46 polycyclic aromatic compounds (PAC) having a wide range in polarity was achieved by applying a linear combination of the retention factors of PAC to a polar and a non-polar HPLC column material. The Diol column material gave generally a better simulation of the sorption of all PAC than the non-polar ODS column material. However, the non-polar column material was the best model substrate, if the test material was limited to the hydrophobic unsubstituted PAC, PAH + O,S-PAC. The comparison shows that polar interactions, e.g., hydrogen bonds, contribute to the sorption to humic acid of polar PAC in addition to the hydrophobic interactions. The results perhaps also indicate that the favorable adsorption sites for polar and unpolar PAC may be different, and that humic acid may contain different types of hydrophilic compartments.

Received 10 October 1996; received in revised form 28 January 1997; accepted 4 March 1997

Abstract

A fast and simple fluorimetric method is described for the simultaneous determination of ampicillin and tetracycline in milk by combining the stopped-flow mixing technique with a T-format spectrofluorimeter. Ampicillin determination is based on its hydrolysis with penicillinase and reaction with mercuric chloride, while the intramolecular energy transfer from tetracycline to europium ions in the presence of thenoyltrifluoracetone is used for tetracycline determination. The similar excitation wavelengths of both systems and the separation between the corresponding emission wavelengths allow the direct determination of both analytes by measuring simultaneously the initial rate of the ampicillin system and the equilibrium signal of the tetracycline system. The relative standard deviations were lower than 2%. The proposed method was applied to the determination of these antibiotics in different milk samples with a recovery of 95.0–103.3% for ampicillin and 93.3–103.3% for tetracycline. © 1997 Elsevier Science B.V.

Keywords: Fluorimetry; Ampicillin; Tetracycline; Stopped-flow; Milk

1. Introduction

The availability of simple and automatic methods to control traces of antibiotics in milk is of great analytical interest as it is known that the continuous intake of these compounds, even at low doses, is a risk to human health. Hazards may include direct toxic effects, development of allergic reactions and production of antibiotic resistance in pathogenic organisms transmissible to man. Generally, the presence of antibiotics in milk arises from their use as part of therapy to treat animal diseases such as bovine mastitis and, sometimes, in low concentrations, as constituents of animal feed to increase feed utilization and thus to accelerate animal growth.

Although immunoassay [1,2] and electrophoretic [3] methods have been described for the determination of antibiotics in milk, liquid chromatography is the most used technique for this purpose [4–7]. A wide variety of clean-up procedures such as ultrafiltration, liquid-liquid extraction, solid-phase extraction, immunoaffinity and deproteination have been described for the sample pretreatment [5]. Because almost without exception these methods are long and time-consuming, the availability of alternative methods is always desirable, specially when the sample is not

PII S00 9-9140(97)00084-2

very complex and only two or three analytes must be determined. This justifies the development of the fluorimetric method described in this paper.

As described elsewhere [8], the simultaneous determination of two analytes by using a T-format spectrofluorimeter with a single excitation monochromator requires that the reaction products of the analytes have similar excitation wavelengths and very different emission wavelengths in order to avoid spectral emission overlap. This allows to obtain independently quantitative data of each analyte from its corresponding emission channel in a very simple way, avoiding the use of mathematical methods. On the other hand, the experimental conditions such as pH and temperature must be compatible for the adequate development of the chemical systems involved and no interaction between the reactants must occur. Although these requirements limit the general use of this approach for multicomponent determinations, the high number of presently available fluorescence derivatization reactions facilitates its application.

This paper shows the usefulness of this instrumentation for simultaneous determination of two antibiotics, namely ampicillin and tetracycline, in milk. The determination of ampicillin is based on its transformation into α-aminobenzylpenicilloate and formation of a fluorescent product with mercuric chloride [9], while the reaction between tetracycline, thenoyltrifluoracetone (TTA) and europium (III) in the presence of Triton X-100 [10] has been chosen for tetracycline determination. Both systems fulfil the requirements above indicated, which allows to obtain separately the data concerning each analyte in the corresponding emission channel. In addition, the coupling of stopped-flow mixing technique to the T-format spectrofluorimeter allows to achieve the automation of the measurement step of the method. Owing to the different kinetic behaviour of the two chemical systems involved, kinetic and equilibrium measurements have been carried out to obtain quantitative data for penicillin and tetracycline, respectively.

2. Experimental

2.1. Instrumentation

An SLM-Aminco (Urbana IL) Model 8100 photon-counting spectrofluorimeter was used in a T-format configuration. The excitation wavelength was set at 342 nm via the excitation monochromator. The wavelength of one of the optical emission arms (channel A) was set at 410 nm through the emission monochromator and that of the other emission arm (channel B) was selected by placing a Schott OG-550 filter. The instrument was fitted with an SLM-Aminco Milliflow stopped-flow reactor which was furnished with an observation cell of 0.2 cm path length. This module was controlled by the associated electronics, the computer and a pneumatic syringe drive system. The solutions in the stopped-flow module were kept at a constant temperature of 30°C by circulating water from a thermostated tank.

2.2. Reagents

All chemicals used were of analytical reagent grade. Stock solutions (100 μg ml^{-1}) of ampicillin and tetracycline (Sigma) were prepared in distilled water. The following aqueous solutions were also prepared: 10^{-3} M europium (III) nitrate pentahydrate (Aldrich), 1.5×10^{-3} M mercuric chloride (Merck), 0.1% Triton X-100 (Serva) and 0.1 M Tris [tris(hydroxymethyl)-aminomethane] (Merck) buffer solution (pH 7.4). An 1 unit ml^{-1} solution of penicillinase (Sigma) was daily prepared in this Tris buffer. Finally, a 4.5×10^{-3} M solution of TTA (Aldrich) was made in 2% ethanol.

2.3. Procedure

Two solutions were prepared to fill the two 5-ml reservoir syringes of the stopped-flow module. One of the solutions contained ampicillin (0.01–15 μg ml^{-1}), tetracycline (0.04–10 μg ml^{-1}), Triton X-100 (0.01%) and Tris buffer (1.5×10^{-2} M). The other syringe was filled with an aqueous solution containing europium (III) (2×10^{-5} M), TTA (5.4×10^{-6} M), mercury (II)

(1.5×10^{-4} M), penicillinase (0.15 U ml^{-1}) and Tris buffer (1.5×10^{-2} M). After the two 2-ml drive syringes were filled, 0.04 ml of each solution was mixed at a flow-rate of 20 ml s^{-1} in the mixing chamber in each run. The excitation wavelength used was 342 nm. The variation of the fluorescence intensity with time throughout the ampicillin reaction was monitored on channel A at 410 nm. The initial rate method was applied to the values acquired from this detector, which were processed by the microcomputer, furnished with a linear regression program for application of this kinetic method. The initial rate of the ampicillin reaction was determined in about 5 s and the blank signal was found to be negligible. The equilibrium signal obtained in channel B, by using a 550-nm cut-off filter was related to the tetracycline concentration through the formation of the Eu (III)-tetracycline-TTA complex. In this case, the contribution of the blank signal was substracted from the equilibrium fluorescence intensity obtained for the sample. All measurements were carried out at 30°C and each sample was assayed in triplicate.

2.4. Determination of ampicillin and tetracycline in milk samples

A volume of 10 ml of milk was treated with 1 ml of 1.7 M acetic acid, 1 ml of 1 M sodium acetate and 75 ml of distilled water heated at 40°C and the solution was stirred for 5 min. Then, it was cooled to room temperature, carefully and quantitatively transferred into a 100-ml calibrated flask, diluted to the mark with distilled water and subsequently filtered. A volume of the filtrate (4 ml) was finally treated as described above. The concentrations of each antibiotic in the samples were determined by interpolation from the working curves prepared by adding 4 ml of a previously prepared antibiotic-free milk whey to each standard.

3. Results and discussion

As indicated above, a requirement to attempt the simultaneous determination of ampicillin and tetracycline by using the stopped-flow/T-format spectrofluorimeter combination is to achieve the experimental conditions which allow the adequate development of both chemical systems. The fluorimetric method for ampicillin based on its alkaline hydrolysis and reaction of the penicillonate formed with mercuric chloride [9] was improved by applying kinetic methodology [11] where the use of stopped-flow mixing technique and the addition of hydrogen peroxide allowed to obtain analytical data in only few seconds. However, the basic medium required cannot be used for the determination of tetracycline based on its reaction at pH 7.0–7.5, with europium (III) and TTA, which gives rise to an intramolecular energy-transfer process from the ligands to the lanthanide ion [10]. With the aim of using both chemical systems together, the alkaline hydrolysis of ampicillin was changed to the enzymatic hydrolysis using penicillinase, which takes place at pH close to 7.0. The excitation and emission spectra obtained for both systems under these conditions (Fig. 1) show the complete overlaping of the excitation bands and the resolution of the emission bands.

The study of the kinetic behaviour of both ampicillin and tetracycline systems together by using stopped-flow mixing technique, showed that

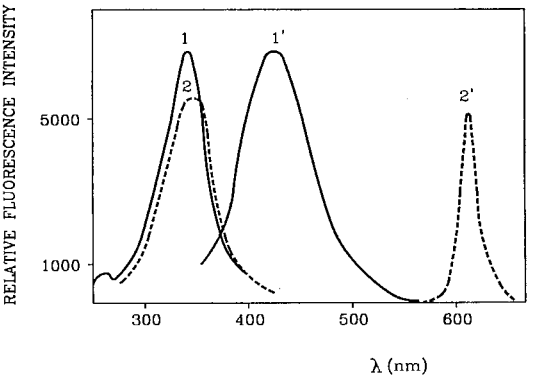

Fig. 1. Excitation (1, 2) and emission (1′,2′) spectra obtained for ampicillin and tetracycline systems. [ampicillin] = [tetracycline] = 0.05 μg ml^{-1}, [Hg (II)] = 1.5×10^{-4} M, [penicillinase] = 0.15 unit ml^{-1}, [Eu (III)] = 2×10^{-5} M, [TTA] = 5.4×10^{-6} M, [Triton X-100] = 0.01%, [Tris buffer] = 1.5×10^{-2} M.

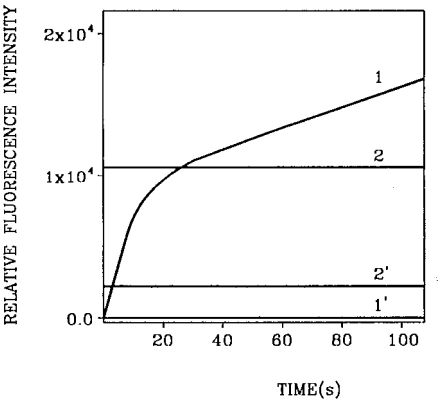

Fig. 2. Kinetic behaviour of the ampicillin (1) and tetracycline (2) systems in the presence of whey matrix. 1′ and 2′: blank of ampicillin and tetracycline systems, respectively. λ_{ex} 342 nm, λ_{em} 410 nm for ampicillin and 610 nm for tetracycline. [ampicillin] = [tetracycline] = 0.1 μg ml^{-1}, [Hg (II)] = 3×10^{-5} M, [penicillinase] = 0.15 unit ml^{-1}, [Eu (III)] = 2×10^{-5} M, [TTA] = 5.4×10^{-6} M, [Triton X-100] = 0.01%, [Tris buffer] = 1.5×10^{-2} M.

it is possible to obtain simultaneously the kinetic curves of both systems by selecting the corresponding emission wavelength in each emission channel. No chemical interaction between the reagents involved in both systems was found. However, as the aim of this study was to know the possible application of this approach to the determination of both antibiotics in milk, it was also carried out in the presence of this matrix, after removing casein. Under these conditions, the same kinetic behaviour was obtained for the ampicillin system but the initial rate of the tetracycline system was increased so that the equilibrium was instantaneously reached and it was impossible to obtain the kinetic curve. However, both chemical systems can be jointly used with analytical purposes by using kinetic measurements for ampicillin determination and equilibrium measurements for tetracycline determination. This is possible thanks to the availability of two emission channels where an adequate instrumental sensitivity can be used for each chemical system and the resolution achieved for both analytes does not depend on the relative values of the rate involved. Fig. 2 shows the kinetic curve obtained for the ampicillin system, where can be seen that the initial rate can be obtained in only 5 s and the blank signal is negligible. In addition, the kinetic curve obtained under these conditions does not show the short induction period found when the alkaline hydrolysis was used [11]. Unlike this system, the tetracycline system reaches instantaneously the equilibrium and the blank signal, which can be ascribed to the europium (III)-TTA reaction, must be substracted to obtain the net signal for tetracycline.

3.1. Optimization of variables

The variables affecting each system were optimized by the univariate method. All concentrations given are initial concentrations in the syringes (twice the actual concentrations in the reaction mixture at time zero after mixing). Each result was the mean of three measurements.

The study of the optimal experimental conditions for the development of the tetracycline system showed these are the same than those previously described [10] where the positive effect of TTA and Triton X-100 was widely discussed. Under these conditions, the detection limit obtained by using equilibrium measurements was lower than by kinetic measurements, although an advantage on the use of kinetic methodology lies in the negligible effect of the blank signal, unlike the equilibrium method where all measurements need to be corrected for the blank signal. However, as indicated above, only equilibrium measurements can be obtained for the tetracycline system in the presence of the whey matrix.

With regard to the ampicillin system, the requirements for working to a pH suitable for both ampicillin and tetracycline systems compelled to change the alkaline hydrolysis previously described [9,11] by the enzymatic hydrolysis by using penicillinase. Unlike the alkaline hydrolysis where hydrogen peroxide was used to increase the initial rate, it was not required in this case. Fig. 3 shows the effect of the penicillinase concentration on the kinetic behaviour of the ampicillin system at pH 7.4, where can be seen the initial rate is independent of this variable from a concentration of 0.15 unit ml^{-1}. The study of the effect of mercury (II) concentration showed that this vari-

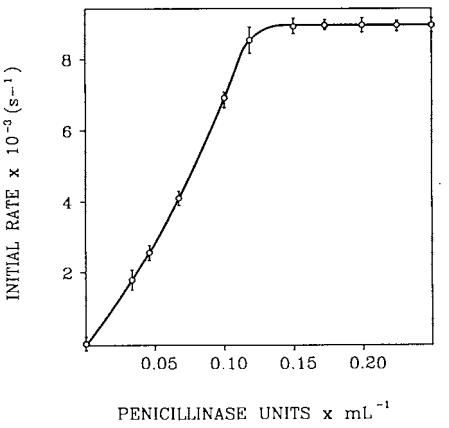

Fig. 3. Effect of penicillinase concentration on the initial rate obtained for the ampicillin system. [ampicillin] = 0.1 μg ml^{-1}, [Hg (II)] = 3×10^{-5} M, [Tris buffer] = 0.01 M.

able does not affect the initial rate when the concentration is larger than 10^{-4} M, which is ca. three times higher than when the alkaline hydrolysis is used [11].

Different assays were carried out for deproteination of the milk samples. Sodium tungstate and trichloracetic acid were unsuitable because the milk serum obtained in the first case was cloudy and the tetracycline reaction was inhibited in the presence of the second reagent. However, it was possible to use the conventional method for casein separation based on the insolubility of this protein in weakly-acidic media while whey proteins are soluble.

3.2. Analytical features

Under the optimum experimental condition described above, kinetic data corresponding to the ampicillin system were obtained from channel A with the emission monochromator set at 410 nm. These data were processed by the initial-rate method. Simultaneously, equilibrium data corresponding to the tetracycline system were obtained from channel B by placing a 550-nm cut-off filter. The excitation wavelength for both kinetic and equilibrium measurements was set at 342 nm via the excitation monochromator.

All ampicillin and tetracycline standards solutions used to obtain the calibration graphs were prepared in the presence of 4 ml of milk whey, in order to compensate the matrix effect on the samples. Under these conditions, the calibration graphs were linear over the ranges 0.01–15 μg ml^{-1} ampicillin and 0.04–10 μg ml^{-1} tetracycline. The wide linear ranges obtained required using three different instrumental sensitivities on each emission channel. Table 1 summarizes the figures of merit of the different calibration graphs. The detection limits obtained for ampicillin and tetracycline, in the presence of the milk whey volume indicated above and calculated according to IUPAC's recommendations [12], were 0.003 and 0.01 μg ml^{-1}, respectively, which corresponds to 0.04 and 0.125 μg ml^{-1}, respectively, in milk.

The separation between the emission wavelengths of both ampicillin and tetracycline systems and the lack of contribution of each analyte to the analytical signal of the other, allows the direct resolution of the mixture. The simultaneous

[a] (1) Whole milk, (2) Skimmed milk, (3) Raw milk.
*Average of three determinations ± SD.

method can be applied to a wide range of concentrations of both analytes thanks to the lack of overlapping of the emission spectra and the independent behaviour of each chemical system. In addition, the fast development of both systems allows the instantaneous measurement of the equilibrium signal corresponding to tetracycline, while the measurement of the reaction rate of ampicillin takes only 5 s. Hence the method is a useful alternative to routine determination of these analytes.

The precision of the method was evaluated at two concentrations of each analyte by assaying replicates of milk samples, which were treated as described under Procedure, so that the final concentration of each analyte was 0.05 and 0.1 μg ml^{-1}. The relative standard deviation thus obtained was 1.1 and 0.5% for ampicillin and 1.9 and 1.0% for tetracycline.

In order to study the selectivity of the method and its possible general use for tetracyclines and penicillins determination in milk, several of these compounds were assayed. All the tetracyclines examined showed luminescence signal in the presence of europium (III) and TTA, giving tetracycline the highest signal (100), oxytetracycline (92), doxitetracycline (60) and chlortetracycline (49). However, among the different penicillins assayed (ampicillin, amoxicillin cloxacillin, dicloxacillin and oxacillin), only amoxycillin gave a slight initial rate with the ampicillin system, about 15-times lower than that obtained for ampicillin. Also, several cephalosporins (cephalexin, cephradine, cephaloridine, cephalozin) were assayed by using this system, but no reaction was observed with any of them. These results show that the kinetic determination of ampicillin based on enzymatic hydrolysis is more selective than the one based on alkaline hydrolysis [11] where other penicillins and cephalosporins such as cloxacillin and cephradine interfered with the ampicillin determination.

3.3. Analysis of milk samples

The proposed method was applied to the simultaneous determination of ampicillin and tetracycline in three spiked milk samples. For this purpose, different amounts of these antibiotics were added to each sample in order to carry out the recovery study. The treatment of the samples to obtain the milk whey is described in the Procedure. Table 2 summarizes the recoveries obtained which ranged from 95.0 to 103.3% (average 99.4%) for ampicillin and between 93.3 and 103.3% (average 98.1%) for tetracycline.

4. Conclusions

According to the results obtained, the joint use of stopped-flow mixing technique and a T-format

spectrofluorimeter provides a simple and fast approach for the simultaneous determination of mixtures. While the former allows the automation of the measurement step and the simple adaptation of the method to routine analysis, the availability of two emission channels allows to obtain analytical data from the chemical systems involved whichever is the kinetic behaviour of each one provided that mutual kinetic effects are absent. Thus, the proposed method is the first application of the combined use of kinetic and equilibrium measurements.

This method also shows that it is possible to obtain analytical results by mixing two relatively complex systems. Thus, the fluorescence of the ampicillin system is obtained after a multi-step process which involves the enzymatic hydrolysis of the antibiotic and the reaction of its mercapto group with mercuric chloride, while the tetracycline determination is based on the formation of the ternary complex with europium (III) and TTA in the presence of Triton X-100 and the intramolecular energy-transfer precess from the ligands to the lanthanide ion. However, the lack of interaction between the reagents of both systems allows the individual development of each system. The main limitation of the method is its application to the analysis of milk samples containing very low concentration levels of these antibiotics. In this case, a pre-concentration step such as solid phase extraction would be required.

The methods reported in the literature for the determination of antibiotics in milk involve in most cases the determination of several penicillins such as ampicillin, amoxicillin and cloxacillin [6,7,13,14], or several tetracyclines such as tetracycline, oxytetracycline and chlortetracycline [15–17], by using liquid chromatography. However, no methods for the simultaneous determination of a penicillin and a tetracycline have been described up to date. Generally, the chromatographic methods show lower LODs than those obtained in the proposed method, as they involve the pre-concentration of the analytes, but it is faster and is the first automatic method described for the simultaneous determination of these antibiotics in milk.

Abstract

The hydrolysis of praseodymium III in 2 M sodium chloride at 303 K was studied. Two methods were used: pH titration followed by a computational refinement and solvent extraction in the presence of a competitive ligand. The hydrolysis constants obtained by pH titration were: $\log \beta_{1,H} = -7.68 \pm 0.07$, $\log \beta_{1,2H} = -15.10 \pm 0.03$, and $\beta_{1,3H} = -23.80 \pm 0.04$. The stability constants of praseodymium carbonate complexes were determined by pH titration as well and were: $\log \beta_{1,CO_3^{2-}} = 5.94 \pm 0.08$ and $\log \beta_{1,2CO_3^{2-}} = 11.15 \pm 0.15$. Praseodymium carbonate species were taken into consideration for calculating the first hydrolysis constants by the solvent extraction method and the value obtained was: $\log \beta_{1,H} = -7.69 \pm 0.27$. The values for $\log \beta_{1,H}$ attained by both methods are the same. The species-distribution diagram was obtained from the stability constants of praseodymium carbonate complexes and hydrolysis products in the conditions of the present work. © 1997 Elsevier Science B.V.

Keywords: Carbonate complexes; Hydrolysis; Praseodymium

1. Introduction

It is observed in the lanthanide series, from the published data, that the values of the first hydrolysis constant for the same metal ion differ widely [1,2]. Further work in this field is highly desirable in view of the basic importance of the problem by itself, as well as for understanding the chemical behaviour of these metal ions in various natural and artificial environments [3,4]. The differences among the values can be attributed to the various experimental conditions used, such as the concentration of the element or the pH range, and probably to the contribution of the affinity of lanthanide and carbonate ions, which has been regarded as negligible.

The hydrolysis constants of praseodymium III have been determined mainly by pH titration (Table 1) [5–10]. The concentration of praseodymium III and the ionic strength ranges used in all these works are wide. However, little information is available regarding the behaviour of praseodymium in aqueous solution.

Present work	Solvent extraction, 303	2 M NaCl	1.45×10^{-5} M, $Pr(NO_3)_3$	-7.69 ± 0.27

The aim of this paper was therefore to determine the hydrolysis constants of praseodymium III, in 2 M sodium chloride ionic strength, at 303 K. According to the suggestions of the IUPAC, in this work the first hydrolysis constant was determined by two methods, the solvent extraction in the presence of a competitive ligand and pH titration.

2. Theory

In general, the reaction for the formation of a hydrolysis product can be written as follows:

$$x\mathrm{M}^{z+} + y\mathrm{H_2O} \rightleftarrows \mathrm{M}_x(\mathrm{OH})_y^{zx-y} + y\mathrm{H}^+ \qquad \text{(a)}$$

where the equilibrium constant is $\beta_{x,y}$. In the present work the polynuclear species are neglected due to the low concentration values of praseodymium (1.45×10^{-5} M for the solvent extraction and up to 1.7×10^{-4} M for the pH titration). Therefore, only $\beta_{1,H}$, $\beta_{1,2H}$ and $\beta_{1,3H}$ have been considered, which correspond to the first, second and third hydrolysis global constants, respectively.

2.1. pH Titration

Potentiometric titration is a precise and direct technique that allows the experimental determination of the stability constants, through the analysis of the titration curves by graphic or numeric methods. If the indicator electrode is sensitive to pH, it is important to distinguish between the minus logarithm of the hydronium concentration (pC_H) and the experimental pH value measured in systems with high ionic strength.

The analysis of the titration curve can be performed with the aid of a computational program. SUPERQUAD is a program created by Gans et al. [11] that refines equilibrium constant values by a least-squares method from the cell potential (or pH) obtained during potentiometric titrations.

The Marquardt algorithm is applied in SUPERQUAD in order to achieve the minimum of the cell potential (E) quadratic residual sum of Eq. (1):

$$U = \sum(\Delta E)^2 = \sum(E_{\text{calculated}} - E_{\text{experimental}})^2 \qquad (1)$$

The cell potential for each added volume from the titrant solution is calculated by SUPERQUAD with the aid of: (a) experimental normal (or zero-pH) potentials and slopes of the electrodes used; and (b) metal cations, ligands and/or proton concentration values obtained from cations, ligands and charge balance equations for the system. In general, it is necessary to follow an iterative procedure in order to obtain precise solutions of the system of equations formulated.

The input file data that should be feed to SUPERQUAD includes the added volumes and the cell potentials (or pH) measured, as well as a chemical model that includes stoichiometry and the values of the formation constants of the species present during the titrations. The refined values the formation constants and a very complete statistical analysis of data are obtained in the output file.

2.2. Solvent extraction

The principle of the solvent extraction method, in the presence of a competitive ligand, has been described previously [12,13] Hence, only the main equations are included here, particularly those concerning the reactions of praseodymium with hydroxide and diglycolate ions, the latter being the competitive ligand in the extraction.

The extraction of praseodymium to an organic phase can be achieved with an extracting agent ($\overline{HX}$) and in many cases it can be considered that the extractant is only present in this phase. The extraction equilibrium of praseodymium can be represented by the following equation:

$$Pr^{3+} + 3\overline{HX} \rightleftarrows \overline{PrX_3} + 3H^+ \quad \text{(b)}$$

with:

$$K_{ext} = \frac{[\overline{PrX_3}][H^+]^3}{[Pr^{3+}][\overline{HX}]^3} \quad (2)$$

where $[\overline{PrX_3}]$, $[\overline{HX}]$, $[Pr^{3+}]$ and $[H^+]$ represent the total concentrations of praseodymium and the extractant in the organic phase, and the concentration of praseodymium and hydronium in the aqueous phase, respectively. The distribution coefficient is:

$$D_0 = \frac{[\overline{PrX_3}]}{[Pr^{3+}]} = \frac{K_{ext}[\overline{HX}]^3}{[H^+]^3} \quad (3)$$

When pC_H is low and a competitive ligand, such as a diglycolate ion (L^{2-}), is added, the distribution coefficient is modified. According to Grenthe and Tobiasson [14], PrL^+ is the most important species; then the equation for the distribution coefficient in the absence of hydrolysis products, D_1, is:

$$D_1 = \frac{[\overline{PrX_3}]}{[Pr^{3+}](1+\beta_{1,L}[L^{2-}])} = \frac{D_0}{1+\beta_{1,L}[L^{2-}]} \quad (4)$$

Therefore, a graph of $1/D_1$ versus $[L^{2-}]$ led us to calculate the stability constant of the praseodymium diglycolate complex ($Pr(DG)^+$), by means of the following equation:

$$\frac{1}{D_1} = \frac{1}{D_0} + \frac{\beta_{1,L}}{D_0}[L^{2-}] \quad (5)$$

The presence of the hydrolysis complexes also modifies the distribution coefficient (D_2). When Pr^{3+}, $Pr(OH)^{2+}$, and $Pr(DG)^+$ are present in the aqueous phase, Eq. (4) can be written as:

$$D_2 = \frac{[\overline{PrX_3}]}{[Pr^{3+}](1+\beta_{1,OH}[OH^-]+\beta_{1,L}[L^{2-}])} \quad (6)$$

In the absence of diglycolate ions, D_0' can be defined as follows:

$$D_0' = \frac{[\overline{PrX_3}]}{[Pr^{3+}](1+\beta_{1,OH}[OH^-])} \quad (7)$$

From Eqs. (6) and (7), it is found that:

$$\frac{1}{D_2} = \frac{1}{D_0'} + \frac{\beta_{1,L}'}{D_0'}[L^{2-}] \quad (8)$$

where $\beta_{1,L}'$ represents a conditional stability constant which is equal to

$$\beta_{1,L}' = \frac{\beta_{1,L}}{1+\beta_{1,OH}[OH^-]} \quad (9)$$

If pC_H is constant, the denominator of the previous equation is also constant.

The conditional stability constant ($\beta_{1,L}'$) can be evaluated from Eq. (8) and a graph of $1/D_2$ versus $[L^{2-}]$. Finally, according to the Eq. (9), $\beta_{1,OH}$ can be calculated as follows:

$$\beta_{1,OH} = \frac{(\beta_{1,L}/\beta_{1,L}')-1}{[OH^-]} \quad (10)$$

3. Experimental

3.1. Reagents

All reagents were analytical grade and deionized water was used to prepare the solutions. In all cases, the aqueous solutions were 2 M NaCl ionic strength. The extraction vials were treated as described elsewhere [15] in order to minimize adsorption of the tracers.

The praseodymium oxalate was prepared from the nitrate; it was calcined at 693 and then at 1063 K, according to the literature [16], to obtain Pr_6O_{11}, which was identified by X-ray diffraction. The oxide was treated with nitric acid and finally dissolved in 10^{-3} M nitric acid. ^{142}Pr was ob-

tained for solvent extraction experiments by irradiating the solution in a TRIGA MARK III nuclear reactor for 1 h at a thermal neutron flux of 1×10^{13} cm^{-2} s^{-1}. This isotope was identified [17] by its gamma radiation spectrum (1570 keV) using a GeH detector and no interfering radiation was observed. The half-life was also verified (19.2 h).

3.2. pH Titration

A high precision pH-meter (Taccussel-Radiometer, model LPH430T) equipped with a glass electrode, which has low interference coefficients for alkaline ions, and an AgCl/Ag reference electrode together with a digital burette (Brand II) were used for these experiments. Nitrogen was bubbled in the solutions and the nitrogen atmosphere was kept during measurements. The experiments were done at 303.0 ± 0.1 K and this was controlled by a constant temperature circulator (Cole Parmer, Polystat).

Solutions of 0.1, 0.01, and 0.001 M sodium hydroxide and hydrochloric acid were prepared in 2 M sodium chloride ionic strength. The pH values were measured in these solutions and the calibration lines were obtained by plotting $pC_H = -\log[H^+]$ against measured pH.

The pH titrations carried out were as follows:

(i) Determination of the appropriate concentration of Pr^{3+}. It was determined by titration of praseodymium nitrate solutions, 7.3×10^{-3}, 3.6×10^{-3} and 4.5×10^{-4} M, with sodium hydroxide solutions: 1×10^{-2} M for the first and the second and 1.25×10^{-3} M for the third. The precipitation of praseodymium hydroxide was observed for praseodymium nitrate concentration higher than 4.5×10^{-4} M. This fact was therefore taken into account, in order to avoid precipitation during the pH titrations.

(ii) Praseodymium nitrate solutions, 1.7×10^{-4} M, with sodium hydroxide solutions, 1.25×10^{-3} M.

(iii) A 7.3×10^{-5} M solution of praseodymium nitrate was left open to the air for 24 h and was then titrated with 1×10^{-3} M sodium hydroxide. In this case, nitrogen was not bubbled, and only the nitrogen atmosphere was kept over the solution.

(iv) Solutions of 0.05 M diglycolic acid (DGA) were titrated with 0.1 M sodium hydroxide.

The data obtained from the pH titrations were refined with the program SUPERQUAD to obtain the equilibrium constants and at least three experiments were done in the same conditions to analyze reproducibility.

3.3. Solvent extraction

The solvent extractions of praseodymium were done at the following pC_H values: 2.91, 3.52 and 7.64. The organic and aqueous solutions were pre-equilibrated between them until the pC_H did not change. The aqueous solutions for the experiments were composed as follows: 5 ml of the solution 2 M NaCl, 10 μl of the irradiated praseodymium solution and the required volume of diglycolic acid solution, for each concentration. The organic phases were 5 ml of a solution of dibenzoylmethane (DBM) and tri-*n*-octyl phosphyne oxide (TOPO) in benzene. The ratio [TOPO]/[DBM] and their concentrations were determined experimentally in order to get D_0 and D'_0 around 1 to enhance accuracy of measurements. The concentrations of DGA, DBM and TOPO used in each batch of experiments are shown in Table 2. The shaking time to attain the equilibrium in the phases was determined experimentally. The vials were then shaken for 20 h, in a thermostated bath (Cole Palmer, Polystat) at 303 K. The concentration of praseodymium in each experiment was 1.45×10^{-5} M. After shaking, the samples were centrifuged for 5 min and then 4 ml of each phase were taken out. The radioactivity of ^{142}Pr was measured in both phases by means of a NaI(Tl) well detector, coupled to a monochannel analyzer (Picker Spectroscaler). The value $1/D$ was calculated from the radioactivity in the aqueous phase divided by that in the organic phase. On the other hand, the total radioactivity was measured by means of 10 μl of the radioactive solution added to 4 ml of 1 M hydrochloric acid. A pH-meter (Orion) with a combined (glass AgCl/Ag) electrode was utilized for measurements in the aqueous phases.

4. Results and discussion

According to the X-ray diffraction, the prepared praseodymium oxide was $PrO_{1.83}$, which had a high crystallinity. This compound is a mixture of Pr^{3+} and Pr^{4+} oxides and it forms only Pr^{3+} in aqueous solution [10].

The equations obtained to correct the pH measurements to pC_H values were the following. In the solvent extraction method, it was:

$$pC_H = (1.019 \pm 0.005)pH + (0.314 \pm 0.047)$$
$$r = 0.999 \quad (11)$$

and the equation used for pH titration was:

$$pC_H = (1.005 \pm 0.012)pH + (0.276 \pm 0.060)$$
$$r = 0.999 \quad (12)$$

The slight difference between these empirical equations can be attributed to the equipment used for the determination of each one.

Ion product of water values ($\log K_w$) for 2 M NaCl ionic strength and 303 K were calculated using the literature value [1] for $I = 2$ M ($\log K_{w,288\,K} = -13.96 \pm 0.01$) and the Van't Hoff equation. The obtained value was $\log K_{w,303\,K} = -13.80$. This parameter was also calculated using values [2] for $I = 2.01$ and 3.00 m at 298 K by linear interpolation. The ionic strength of the NaCl solution was converted to the molal scale (2 M = 2.08 m), taking into account the density (1.077 g ml^{-1}) which was measured. The $\log K_{w,298\,K}$ value deduced was -13.85 and the corrected value at 303K was -13.69.

Table 2
Concentrations of the utilized solutions

Parameter	Batch number		
	1	2	3
2 M NaCl, pC_H	2.99	3.65	7.64[a]
[DGA] (M)	0.45	0.055	0.011
[DBM] (M)	0.003	0.002	0.002
[TOPO] (M)	0.029	0.023	0.004
$[OH^-]$ (M)	–	–	8.3×10^{-7}
$[CO_3^{2-}]$ (M)	–	–	2.5×10^{-6}
$\beta_{1,DG}$	61 855	74 355	–
$\beta'_{1,DG}$	–	–	10 797

DGA, aqueous solution of diglycolic acid; DBM and TOPO, solutions of dibenzoylmethane and tri-*n*-octyl phosphine oxide in benzene. Hydroxide and carbonate ion concentrations, $\beta_{1,DG}$ and $\beta'_{1,DG}$ obtained in each batch of solvent extraction experiments.

[a] A total of 0.01 m of *N*-Tris[hydroxymethyl]methyl-2-aminoethane sulfonic acid (TES) was added as buffer.

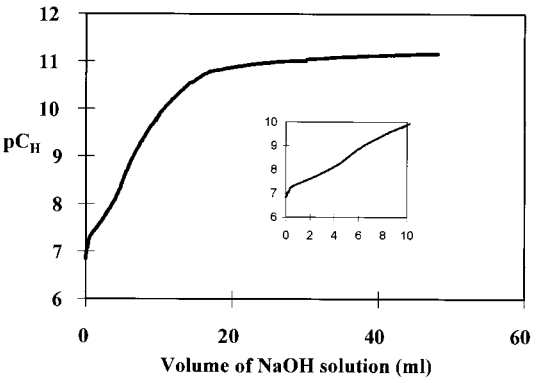

Fig. 1. Typical pC_H titration curve of 1.7×10^{-4} M praseodymium nitrate with 1.25×10^{-3} M sodium hydroxide in 2 M sodium chloride ionic strength at 303 K in the absence of carbonate ions.

4.1. Hydrolysis constants by pH titration

Fig. 1 shows a typical curve of praseodymium nitrate titration in the absence of carbonate ions. Precipitation was observed when the praseodymium concentration was between 7.3×10^{-3} and 3.6×10^{-3} M and it was not observed at or below 4.5×10^{-4} M. It was found that the successive hydrolysis constant values of the three complexes formed are closer than expected; however, the third inflection can be observed, as shown in the inset of Fig. 1. Analysis of data showed that three equivalents of NaOH are consumed per mole of praseodymium.

The three hydrolysis constants obtained from the pH titration data (Fig. 1) and the refinement

achieved with the program SUPERQUAD were: $\log \beta_{1,H} = -7.68 \pm 0.07$, $\log \beta_{1,2H} = -15.09 \pm 0.03$ and $\log \beta_{1,3H} = -23.80 \pm 0.40$. The $\log K_w$ could be well refined simultaneously (-13.68); for this refinement, $\sigma_{total\,(mV)} = 21.69$ and $\chi^2 = 17.96$. The $\log K_w$ value was in good agreement with the values calculated as described above and it was used for calculations. It is important to note that, to the best of our knowledge, values of $\beta_{1,2H}$, and $\beta_{1,3H}$ for praseodymium had not been reported before for any ionic strength. The distribution diagram of the species present through the titration, obtained from the three hydrolysis constants, is shown in Fig. 2. It is observed that the Pr^{3+} species is found at $pC_H < 9$, the $Pr(OH)^{2+}$ species between 5.5 and 9, the $Pr(OH)_2^+$ species between 6.5 and 11, and finally the $Pr(OH)_3$ from $pC_H \geqslant 7.5$. It is important to note that the $Pr(OH)^{2+}$ species is not a predominant species in this system.

4.2. First hydrolysis constant by solvent extraction

Fig. 3 shows the plots of $1/D$ against $[DG^{2-}]$ for all batches of experiments. The concentration of diglycolate ion in the solutions was calculated, taking into account the amount of diglycolic acid added to the aqueous phases, the pK values and the pC_H measured in the aqueous phases after the extractions, for each batch of experiments. Points in Fig. 3 represent the mean value from 6–10

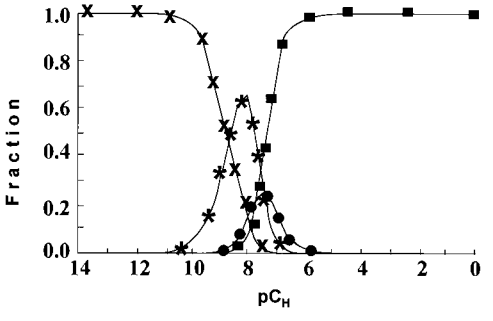

Fig. 2. Species-distribution diagram obtained from the stability constants of hydrolysis products of praseodymium. $[Pr^{3+}]_{TOT} = 0.17$ mM; (■) Pr^{3+}; (●) $Pr(OH)^{2+}$; (*) $Pr(OH)_2^+$;X) $Pr(OH)_3$.

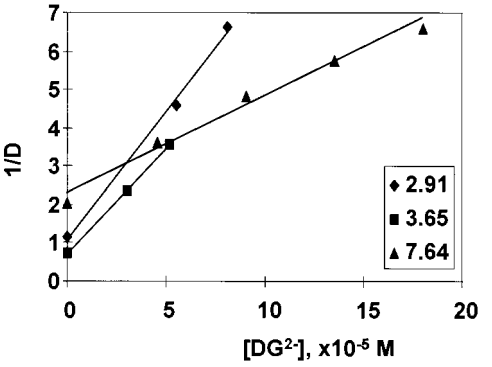

Fig. 3. $1/D$ vs. DG^{2-} concentration at different pC_H values.

independent experiments. The error bars of $1/D$ measurements, not indicated in the figure, were about 10% of the mean values for the experiments. Taking into account Eqs. (5) and (8), from the least-square regression analysis of data the following relations were obtained:

$$pC_H = 2.91{:}1/D_1 = 63\,441[DG^{2-}] + 1.12 \quad (r = 0.998) \tag{13}$$

$$pC_H = 3.52{:}1/D_1 = 54\,606[DG^{2-}] + 0.73 \quad (r = 0.9999) \tag{14}$$

$$pC_H = 7.64{:}1/D_2 = 24\,916[DG^{2-}] + 2.31 \quad (r = 0.991) \tag{15}$$

The value $\beta_{1,DG}$ was calculated from data of Eqs. (13) and (14) and $\beta'_{1,DG}$ was calculated from data of Eq. (15); the values are shown in Table 2. The $\log \beta_{1,OH}$ was calculated from $\beta_{1,DG}$, $\beta'_{1,DG}$ values and Eq. (10). It was 6.80 ± 0.05 and $\log \beta_{1,H} = -6.89 \pm 0.05$. This value is similar to the one obtained by Guillaumont et al. [7] ($\log \beta_{1,H} = -7.1 \pm 0.15$) by solvent extraction and at 0.1 M $LiClO_4$ ionic strength. However, it is different from the value obtained by pH titration in the present work. This difference was attributed to the presence of praseodymium carbonate complexes in the solvent extraction solutions.

The remaining radioactivity in the aqueous and organic solutions after the solvent extraction was between 90 and 98% of the original radioactivity. According to these values, the loss of praseodymium by adsorption on the vials was regarded as negligible.

4.3. Stability constants of carbonate complexes

A solution of praseodymium nitrate left open to the air was titrated as described above. Fig. 4 shows a typical pC_H titration obtained in these conditions. It is important to note that at the same concentration of Pr^{3+}, the pC_H values at the beginning of the titration are lower in the presence of CO_2. This effect is an evidence of the formation of praseodymium carbonate complexes.

Table 3 shows two models refined with SUPERQUAD from pC_H titration (Fig. 4), in the presence of carbonate ions. In the first case, the praseodymium carbonate complexes were neglected and in the second case, they were considered. The best model is the later, because the σ_{total} value is almost half of that found in the first model. This demonstrates the presence of the praseodymium carbonate complexes. It is observed that the log K_w was well refined and was in good agreement with the calculated values given above. This agreement supports the validity of the values obtained for the praseodymium carbonate complexes. The standard deviation for log $\beta_{1,2CO_3^{2-}}$ is high in comparison with the other refined values, and it should therefore be taken carefully.

Fig. 5 shows the species-distribution diagram obtained from the stability constants of praseodymium carbonate complexes and hydrolysis products. According to this diagram, at $pC_H = 7.64$, the working value for the solvent extraction experiments, the following species: $PrOH^{2+}$, $Pr(OH)_2^+$, $Pr(CO_3)^+$ and $Pr(CO_3)_2^-$, are present in the solutions. All these species have to be considered in Eq. (6) and therefore Eq. (10) becomes:

$$\beta_{1,OH} = ((\beta_{1,L}/\beta'_{1,L}) - 1 - \beta_{1,CO_3^{2-}}[CO_3^{2-}] - \beta_{1,2CO_3^{2-}}[CO_3^{2-}]^2 - \beta_{1,2OH}[OH^-]^2)/[OH^-] \quad (16)$$

The dissociation of carbonic acid were found in the literature [4] for 1 M $NaClO_4$

Table 3
Statistical refinement obtained by the program SUPERQUAD for pH titrations of 7.3×10^{-5} M $Pr(NO_3)_3$ in the presence of CO_2 with 1×10^{-3} M NaOH

Equilibrium	log β	σ
1st Model: praseodymium carbonate complexes were not considered		
$Pr^{3+} + H_2O \rightleftarrows PrOH^{2+} + H^+$	−7.68 (Fixed)	
$Pr^{3+} + 2H_2O \rightleftarrows Pr(OH)_2^+ + 2H^+$	−15.09 (Fixed)	
$Pr^{3+} + 3H_2O \rightleftarrows Pr(OH)_3 + 3H^+$	−23.80 (Fixed)	
$CO_3^{2-} + H^+ \rightleftarrows HCO^{3-}$	9.96	0.02
$CO_3^{2-} + 2H^+ \rightleftarrows CO_2 + H_2O$	16.96	0.02
$H_2O \rightleftarrows H^+ + OH^-$	−13.71	0.01
σ_{total} (mV) = 5.60 mV; $\chi^2 = 19.37$		
2nd Model: praseodymium carbonate complexes were considered		
$Pr^{3+} + H_2O \rightleftarrows PrOH^{2+} + H^+$	−7.68 (Fixed)	
$Pr^{3+} + 2H_2O \rightleftarrows Pr(OH)_2^+ + 2H^+$	−15.09 (Fixed)	
$Pr^{3+} + 3H_2O \rightleftarrows Pr(OH)_3 + 3H^+$	−23.80 (Fixed)	
$Pr^{3+} + CO_3^{2-} \rightleftarrows Pr(CO_3)^+$	5.94	0.08
$Pr^{3+} + 2CO_3^{2-} \rightleftarrows Pr(CO_3)_2^-$	11.15	0.15
$CO_3^{2-} + H^+ \rightleftarrows HCO_3^-$	9.90	0.02
$CO_3^{2-} + 2H^+ \rightleftarrows CO_2 + H_2O$	16.94	0.01
$H_2O \rightleftarrows H^+ + OH^-$	−13.72	0.01
σ_{total} (mV) = 3.95 mV; $\chi^2 = 15.03$		

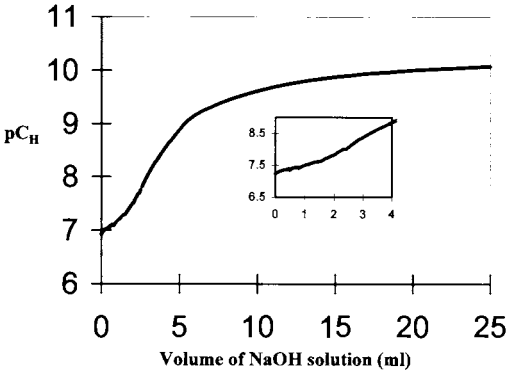

Fig. 4. Typical pC_H titration curve of 7.3×10^{-5} M praseodymium nitrate with 1×10^{-3} M sodium hydroxide in 2 M sodium chloride ionic strength at 303 K, in the presence of carbonate ions.

ionic strength and they were also adjusted by the SUPERQUAD program to our experimental conditions (see Table 3). The above mentioned program also let us to calculate the CO_2 concentration in the solutions (6.02×10^{-4} M). Dissociation constants of carbonic acid, CO_2 concentration and pC_H were used to calculate the carbonate ion concentration in the aqueous phases of the solvent extraction system. This last value, the stability constants of praseodymium carbonate complexes and the values obtained in the solvent extraction for $\log \beta_{1,DG}$ and $\log \beta'_{1,DG}$ (Table 2) were applied in Eq. (16). The $\log \beta_{1,OH}$ was 6.02 ± 0.27 and $\log \beta_{1,H}$ was -7.69 ± 0.27. This value is equal to the one obtained by pH titration in the present work.

4.4. Comparison with other works

In general, the $\log \beta_{1,H}$ value obtained in this work is lower than those values reported previously and this difference can be attributed to the following: the concentration of praseodymium plays an important role for the pH titrations. It was observed in this work that praseodymium hydroxide precipitates during pH titration in concentrations higher than 1.7×10^{-4} M and this effect may give erroneous values. The data found in the literature (Table 1) were obtained with praseodymium concentrations higher than the one used in this work, for pH titrations; however it was not indicated whether precipitation was observed.

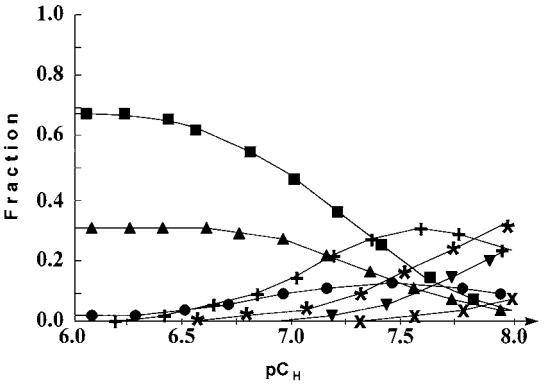

Fig. 5. Species-distribution diagram obtained from the stability constants of praseodymium carbonate complexes and hydrolysis products shown in Table 3. The diglycolate species is also included. $[CO_3^{2-}]_{TOT} = 0.60$ mM; $[Pr^{3+}]_{TOT} = 14.5$ μM; $[DGA^{2+}] = 11.00$ μM. (■) Pr^{3+}; (▲) $Pr(DGA)^+$; (●) $Pr(OH)^{2+}$; (+) $Pr(CO_3)^+$; (*) $Pr(OH)_2^+$; (▼) $Pr(CO_3)_2^-$;X) $Pr(OH)_3$.

Polynuclear complexes have been only considered by Burkov et al. [8] and Ciavatta et al. [10]. However, in most cases praseodymium concentrations used were high and polynuclear species were probably formed in the systems studied.

The value of $\log \beta_{1,H}$ found in the present work is higher than the one reported elsewhere at 333 K [10]. This difference could be attributed to the fact that the complexes are more stable at lower temperature.

The $\log \beta_{1,H}$ has been determined before by solvent extraction [7]; however, in that work carbonate complex formation was neglected. It is important to note that when this last effect was not considered in the present work, for the solvent extraction system, a value similar to that reported before [7] was obtained.

The values of the hydrolysis constant at different ionic strengths have been related to each other by an empirical relation [2]. According to this relation, $\log \beta_{1,H}$ for praseodymium should be -9.2, in 2 M NaCl ionic strength. However, our experimental results indicated, by both the solvent extraction and pH titration methods, that $\log \beta_{1,H}$ is higher, (-7.68). This value is similar to -8.1 reported for $I = 0$ [2]. These results are not surprising, considering that Lundqvist [4] obtained higher values for the hydrolysis constants than expected when working with europium and americium.

Lundqvist [4] suggested that the hydrolysis studies are generally complicated by simultaneously occurring disturbing processes like sorption, precipitation and/or formation of polynuclear and colloid species. In the present work, the sorption and precipitation did not affect the measured distribution values after the solvent extraction, since the loss of praseodymium by adsorption on the vials may be regarded as negligible. As mentioned above, more than 90% of praseodymium was found in solution after the solvent extractions. On the other hand, the concentration of praseodymium was decreased until

no precipitation was observed and the curve shape remained unchanged during the pH titrations. Furthermore, in the solvent extraction method, the concentration of praseodymium was even lower than for pH titrations, and precipitation and polynuclear species formation are therefore very unlikely to occur in the experiments. Colloidal formation has not been considered in any of the published works on the hydrolysis constant of praseodymium and it could be an important parameter to understand the behaviour of lanthanides in solutions.

Acknowledgements

The authors wish to express their sincere thanks to Dr A. Vacca for the copy of the SUPERQUAD program and to Mr V.H. Lara for the X-ray diffraction data.

Abstract

This work deals with the application of artificial neural networks to two common problems in spectroscopy: the identification of distorted UV-visible spectra of a specific class of organic compounds, and the quantitative determination of single components in binary mixtures of these compounds. The examined species were six organic indicators, whose spectra are very similar to each other; the trained networks have proven to be very powerful in both applications. © 1997 Elsevier Science B.V.

Keywords: Mixtures; Networks; Neural; Spectra

1. Introduction

Artificial neural networks [1–4] have been proven to be a suitable tool for the automated interpretation of spectral data. Some previous applications included the identification of a wide range of functional groups from the infrared spectra of organic compounds [5–9], the verification of peak-shaped signals from IR spectral data [10], the identification of carbohydrates on the basis of their ^{1}H NMR spectra [11,12], the classification of mass spectra [13]. Neural networks have also been used to model quantitative measurements from ultraviolet-visible spectroscopic data [14–16].

The advantages of the neural network approach to the spectral interpretation are well-known: the network architecture is easily programmed, with the aid of some freely-available computational packages; the computational effort ends with the learning session, after which the response is immediate: then the trained network can operate in real-time, which is of great importance in many applications. Moreover, the correlations between spectral features and structural categories need not to be known in advance: the neural network can 'learn by example', i.e., no a priori assumptions need to be made on the behavior of the data. This leads to the ability to process input data containing some degree of uncertainty. Spectrophotometric data (e.g., in vivo and in vitro measurement) often contains a high degree of noise, either inherent in the measurement or in the variation of the spectral pattern itself; the difficulties in the interpretation of such distorted

PII S00 9-9140(97)00088-X

spectra can lead to errors either in the identification and in the quantitative measurements. If used properly, the neural networks performances, compared with other approaches, are less influenced by subtle perturbations and noise in the input signals. If the only purpose is to obtain accurate classifications and/or quantitative predictions, the trained network can be used as a 'black box': the connection weights stored after the learning procedure represent the 'knowledge' acquired through the examples, which permits to give accurate evaluations on new data. It is important to note that the trained network can discriminate between 'objects' in some way connected to those from which it has learned, but when 'extraneous' objects are presented to it, its responses are no more reliable. In other words, the network has the ability to interpolate, not to extrapolate, between the training patterns. However, the network should be trained in such a way to classify an extraneous object as 'unknown', i.e., it must not be confused with one of the learned patterns.

From this perspective, this work aims at testing the performances of neural networks in two distinct problems: the identification of distorted UV-visible spectra of a specific class of organic compounds, and the quantitative determination of single components in binary mixtures of these compounds. In the latter case, from the complete set of 15 possible two-component combinations of six pure compounds, we chose to study in particular two binary mixtures, which well represent the full set. This simplification was done because our purpose was only to test the performances of a neural approach to these kind of problems; then, in our opinion, a full analysis of all the possible mixtures is not needed.

Three neural networks, each one with a different task, were constructed. The first can be used to identify a pure compound (out of a group of six) from its absorbance spectrum; we have verified that the recognition is reliable also in the eventual presence of an 'extraneous' pattern. The other two systems work on binary mixtures of known components: each network can predict the composition of a specific mixture.

2. Network description

A three-layered, full connected FF-network was used in both problems. Each neuron of the input layer is fully interconnected with all the neurons of the hidden layer, which in turn are interconnected with each neuron of the output layer. There are no connections between the neurons within a layer, nor any direct connections between those of the input and output layer. Each connection has a weight associated with it, representing the connection strength, which is adjusted during learning.

A sigmoidal activation function was used, with a bias associated to each unit; therefore the output of the j-th neuron (belonging to the hidden or to the output layer) is:

$$o_j = \frac{1}{1 + \exp\left(-\sum_i w_{ij} \cdot o_i - \vartheta_j \right)} \tag{1}$$

where w_{ij} is the weight of the connection between i and j units, o_i is the output of an i unit in the preceding layer, and θ_j is the bias of the j unit. The connection weights were initialized randomly in the $[-1, 1]$ range.

3. Learning

The standard back-propagation algorithm [1] was used to train the networks; the weights update rule reads as follows:

$$\Delta w_{ij}^{n} = \eta \cdot \delta_j^{n} \cdot o_i^{n-1} \tag{2}$$

where η is the learning rate (constant); the change of the weight $\Delta w_{ij}^{\mathrm{n}}$ of the connection between the neuron j (on the layer n) with the neuron i (on the preceding layer) will be proportional to the error δ_j^{n} produced on the neuron j, and to the signal $o_i^{\mathrm{n}-1}$ coming from neuron i. The problem of how to calculate the delta values for each layer is discussed in [2].

In supervised learning the training patterns are iteratively presented to the network together with the desired output vector (target or teaching output). The input is propagated forward in the until the output layer is reached; the errors (δ's)

on the output neurons are then calculated and propagated backward to the inner units, updating all the weights. One learning iteration (epoch) is defined as the input, the check, and the correction of weights in all layers of all training vectors. The iteration proceeds until the output error falls below an acceptable level; then the resulting connection weights matrix may be used to classify previously unseen patterns, i.e., patterns which have not been used to train the network. The learning rate η adopted in this work is 0.2: this value is little enough to avoid local minima in the training session, but leads however to a fast convergence (i.e., a low training mean square error, see below).

4. Input

The number of input neurons was varied between 90 and 450. The latter value corresponds to the whole spectrum with a resolution of 1 nm (the wavelength varies in the range 250–700 nm). In the trials with a lower number of input data, we selected a subset from the whole spectrum by sampling the required number of points at regular intervals.

5. Output

Usually the dimension of the output vector corresponds to the number of classes to be separated (six in our case). In the classification problem the target vector had only one non-zero element, corresponding to the class of the associated pattern: this element has value one. In this way, the first output neuron represents the first compound (red cresole), and so on. In the mixture case, the target vector has only two elements, whose values range between 0 and 1 (while in the classification problem the only possible values for each element of the target vector were 0 and 1), representing the fraction of component 1 and component 2 in the mixture.

6. Spectra

The source of the spectral data is [17]; it reports the parameters of the gaussian bands of six sulfonephtalein indicators, in acid and basic form. The basic forms of these indicators were chosen for the present study, and the relative abbreviations which will be used in the following are reported in Table 1. The complete spectra are shown in Fig. 1. The two mixtures studied were: 3′,3″,5′,5″-Tetraiodophenolsulfonephtalein (abbreviation, ind7B) mixed in various proportions with 3,4,5,6-Tetrabromophenolsulfonephtalein (ind2BrB), and ind2BrB mixed with Clorophenol red (ind4B). As stated above, these two mixtures should well represent the full set (from six pure compounds one can obtain 15 possible binary combinations); actually, the pure spectra are rather similar to each other, and the two selected mixtures represent two ‘extreme’ cases, in terms of overlapping: the peaks in the spectra of ind2BrB and ind4B considerably overlap, while the overlap is lower for the other mixture. In other words, the complete range of overlapping should be covered in this way.

We reconstructed the original spectra by linear combining the above-mentioned gaussian bands, and by renormalizing each single spectrum. Random noise, gaussian-distributed, was added to each spectrum, in such a way as to reproduce the experimental noise (see the Appendix A).

The training set for the classification problem was made of 60 samples of each spectrum, with different random noise added. Thus, the training set, in this case, is made of 360 patterns. Moreover, a test set of another 360 distorted spectra (60 patterns for each of the six compounds, as for

Table 1
Compounds and abbreviations

Abbreviation	Compound
ind1B	Cresol red
ind4B	Clorophenol red
ind7B	3′,3″,5′,5″-Tetraiodophenolsulfonephtalein
ind1CH_3B	Xylenol
ind2BrB	3,4,5,6-Tetrabromophenolsulfonephtalein
ind6BrB	Tetrabromophenol blue

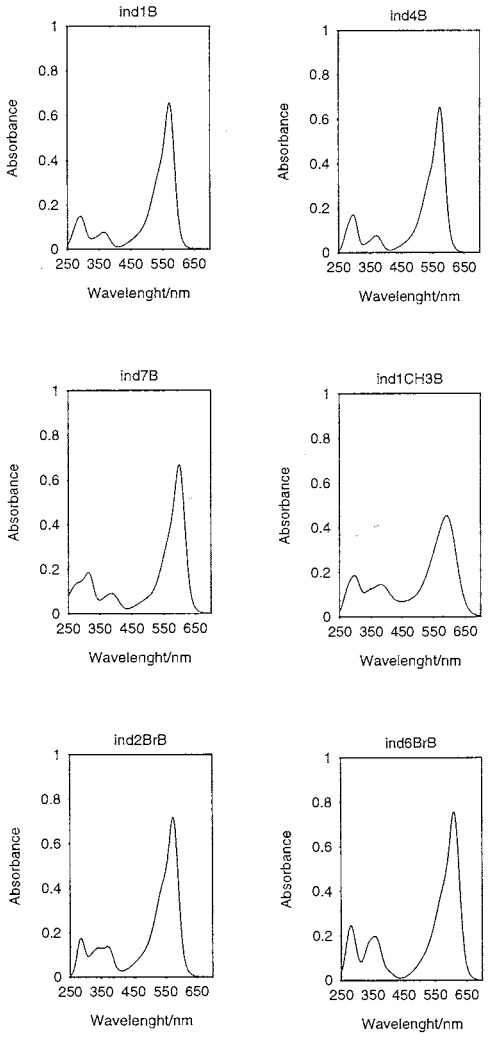

Fig. 1. Absorbance spectra of the six compounds studied (samples taken from the training set).

the training set) was generated. This set was used to test the generalization ability of the trained net, by presenting to it some samples which were not used in the training session. The distorted spectra can be divided in three groups: they are reported in Table 2, together with their relative abbreviations. Finally, a validation set made of 60 patterns generated in the same way as the '01' group of the test set, but with a different random noise compared it, was used, together with the training set, in the training session (see below). In Fig. 2 one of the '01' distorted spectra of ind7B is shown, to be compared with the non-distorted spectrum in Fig. 1.

Table 2
Test patterns and abbreviations

Patterns	Abbreviations
10×6 Spectra with added noise ten-fold greater than the experimental one	001
10×6 Spectra with added noise 50-fold greater than the experimental one	05
10×6 Spectra with added noise 100-fold greater than the experimental one	01
5×6 Spectra left-shifted one data point	L1
5×6 Spectra left-shifted four data points	L4
5×6 Spectra right-shifted one data point	R1
5×6 Spectra right-shifted four data points	R4
5×6 Spectra with intensities reduced by a factor of 1,5	S15
5×6 Spectra with intensities reduced by a factor of 2	S2

The training set for the mixture problem is slightly different: for each mixture, two spectra were rescaled and superimposed, in such a way to reproduce 11 different percentages of component 1 and component 2, i.e.,: 0–100, 10–90,..., 100–0. Then, random noise was added to the mixture spectrum, in order to obtain ten samples for each composition, resulting in a training set made of 110 patterns for each mixture. Fig. 3 shows the

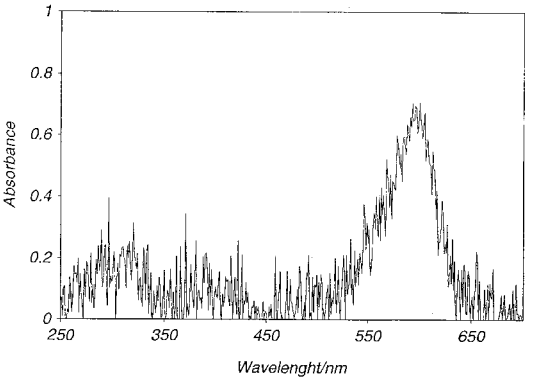

Fig. 2. Spectrum of ind7B with superimposed noise 100-fold greater than the experimental one.

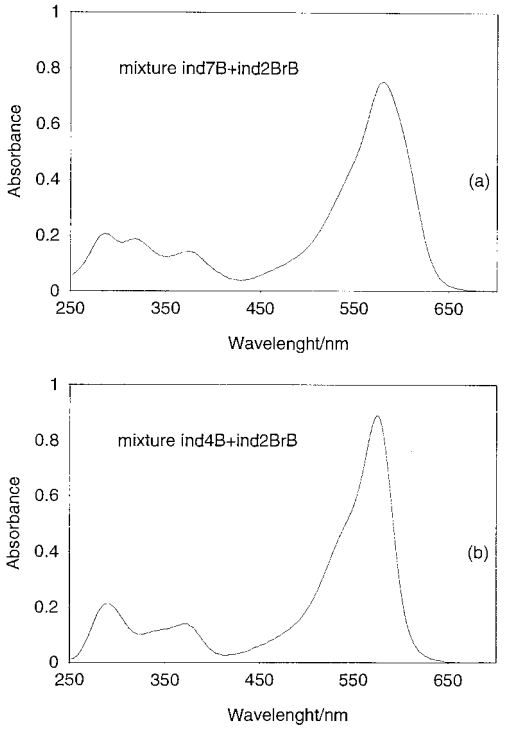

Fig. 3. (a) Absorbance spectrum of 1:1 mixture of ind7B and ind2BrB; (b) absorbance spectrum of 1:1 mixture of ind4B and ind2BrB.

spectra of 1:1 mixtures of the above-mentioned compounds. The test set, for both mixtures, was made of another 50 patterns: five samples for ten spectra, having different percentages with respect to the training set: 5–95, 15–85,..., 95–5. The validation set was generated in the same way as the test set, yet with a different random noise added.

To summarize, the used patterns were:

Classification problem:

Training set: 360 patterns (60 samples × 6 spectra)

Test set: 360 distorted patterns (60 samples × 6 spectra, see Table 2)

Validation set: 60 patterns (10 samples × 6 spectra)

Mixtures problem:

Training set: 220 patterns (10 samples × 11 compositions × 2 mixtures)

Test set: 100 patterns (5 samples × 10 compositions × 2 mixtures)

Validation set: 100 patterns (5 samples × 10 compositions × 2 mixtures).

7. Criteria adopted in the training session

During the training session the training patterns were presented in random order to the network, monitoring the mean square error (MSE), as defined by:

$$\mathrm{MSE} = \frac{1}{N_\mathrm{p}} \sum_{\mathrm{p}=1}^{N_\mathrm{P}} \sum_{i=1}^{N_0} (o_i - t_i)^2 \qquad (3)$$

where N_p is the total number of patterns, N_o is the number of output neurons, o_i is the output of the neuron i and t_i is the teaching output of the same neuron. The double sum (not divided by the total number of patterns) is the standard square error (SSE). The MSE done by the network on the training set was monitored together with the MSE on the corresponding validation set.

The training session ended when the MSE on the training set fell below 4×10^{-4} units; this choice was made because of the following observations: after a steep fall, the two error curves continue to decrease very slowly (Fig. 4). There is an increase in the validation SSE only after 20 000 or more epochs, so we can state that, for the particular problem studied, overfitting is absent if we stop the training before that time. Moreover, the performances of the network which satisfy the above-mentioned criterion are very similar to

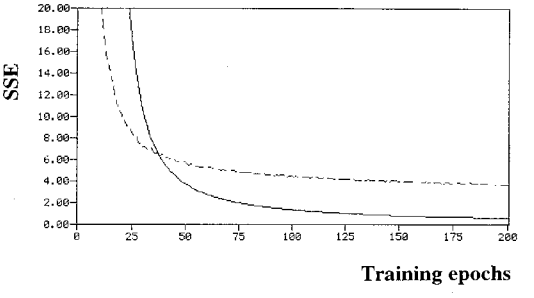

Fig. 4. Trend the standard square error on the training set (continuous curve) and on the validation set (dashed curve).

those of the network trained just before the overfitting (stopped-training method [18]); then the chosen criterion seems to be a good one, because it requires less training epochs and leads to similar results compared with the stopped-training method.

The calculation time required by the training sessions was 30–40 min for the classification problem, while the response of the trained network to the test patterns was immediate.

8. Criteria for output interpretation

The interpretation of the output values was made with the ANALYSE program, included in the SNNS package; by comparing the teaching output and the actual output, one could obtain three kinds of response, on the basis of two fixed threshold parameters, h and l:

right: the network classified correctly the test pattern if:

(a) the output of exactly one output unit is $\geq h$;

(b) the teaching output of this unit (target equal to 1) is the maximal teaching output for the pattern;

(c) the output of all other output units is $\leq l$;

wrong: the network identified a wrong compound if:

(a) the output of exactly one output unit is $\geq h$;

(b) the teaching output of this unit is NOT the maximal teaching output for the pattern;

(c) the output of all other output units is $\leq l$;

unknown: a test pattern is unclassified in all other cases.

There are no exact rules for determining the parameters h and l. Usually a trial procedure is adopted (as for the choice of the learning parameters): the best parameters are those which give the best results. In this case, we observed an improvement when passing from $h = 0.9$, $l = 0.1$, to $h = 0.8$, $l = 0.2$, to $h = 0.7$, $l = 0.3$, while using $h = 0.6$, $l = 0.4$ the percentages of correct classifications worsened again. Therefore, the thresholds adopted in this work were $h = 0.7$ and $l = 0.3$. With this criterion, the percentage of correct responses has been calculated. In the mixture case, as we stated before, the actual output was the fraction of the two components in the test spectrum, then the calculation of the error was easier: one has only to average the absolute residuals (differences between the real output and the 'wanted' output).

9. Results and discussion

9.1. Classification problem

We tried to reduce the number of input neurons in order to optimize the generalization ability of the network. In fact, every additional input neuron increases the size of the network by six connections, resulting in a larger amount of calculations to be made in the training session, which leads in turn to a poor generalization: the network is 'too well' fitted to the training data. On the other side, a sufficient amount of data points should be provided to the network in order to adequately represent the spectral details. We trained three networks with 450, 222 and 90 input neurons; the number of epochs needed was 750, 920 and 950, respectively. As stated above, the test set was made of 60 distorted patterns for each of the six compounds. The ability of the network in the recognition of each compound was first investigated, by separately observing the network responses to each group: in Table 3 the percentage of correct classifications for each compound (calculated over its 60 test patterns) is shown, together with the MSE on the test set. The best overall performances result from the network with 450 input nodes (over 91% of patterns are correctly classified, see Fig. 5). We also optimized the number of hidden nodes by training and testing three other networks with 4, 8 and 12 hidden neurons and 222 input neurons. The results are shown in Table 3: the best performances (in terms of percentage of right classifications) are those of the network with six hidden neurons: over 86% of responses are correct. We can then state that, among the tested architectures, the best network for the classification problem should have 450 input and six hidden neurons. have then investigated the accuracy of this architecture in the classification of each group of patterns, shown

Table 3
Performances of the trained networks (classification problem)

Network	1B	4B	7B	1CH3B	2BrB	6BrB	MSE
450-6-6	83.3	80	100	100	83.3	100	0.086
222-6-6	86.7	85	90	98.3	65	91.7	0.1
90-6-6	65	68.3	100	81.7	63.3	91.7	0.214
222-12-6	68.3	60	98.3	100	70	95	0.13
222-8-6	70	81.7	100	91.7	63.3	100	0.126
222-4-6	78.3	66.7	100	98.3	75	91.7	0.152

in Table 4. For comparison, the same data for the 222-6-6 architecture are shown. As expected, the ability of the network to correctly classify the test patterns decreases with the increase of the random noise. The one-point shifted spectra are all classified correctly, while when the four-points shifted spectra are presented as input, the errors increase considerably. The trained network recognizes all the spectra with intensities reduced by a factor of 1.5, while only 66.7% of the patterns with intensities reduced to a half is recognized. If we excluded from the test set the 01, L4, R4, S2 patterns, which are less common from an experimental point of view, we would obtain a percentage of right responses of 99.5% for the 450-6-6 network, and of 97.1% for the 222-6-6 architecture. Then the performances of both networks in the recognition of the less-distorted patterns are excellent.

The response of the net to an extraneous spectrum was tested with the spectrum shown in Fig. 6: it is the absorbance spectrum of the E100 candy dye, obtained from the Color Spectra Database (available via Internet at address ftp.lut.fi). The wavelength resolution of the spectrum is 2 nm, therefore we had to present it to the 222-6-6 network. The network classifies the spectrum as 'unknown', and the output vector is (0, 0, 0.905, 0.916, 0.967, 0). If we wanted six zero values as output vector, we should include in the training set also some 'negative' patterns, i.e., extraneous spectra with a (0, 0, 0, 0, 0, 0) teaching output vector. However, the 'unknown' response obtained is fully satisfactory to our aims.

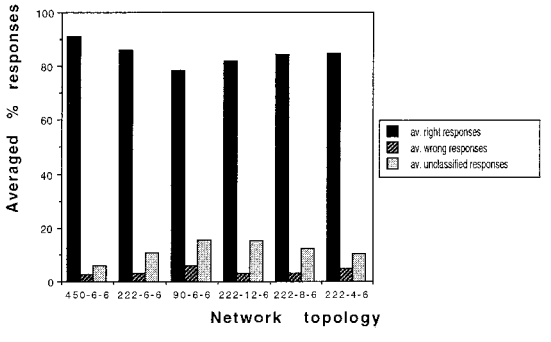

Fig. 5. Responses of the networks: for each topology, the three bars represent the percentages of right, wrong and unknown responses, respectively.

9.2. Mixtures problem

The training of the ind7B/ind2BrB mixture network was easier than that of the ind4B/ind2BrB mixture network; it could be explained by observing the spectra of the 50:50 mixtures (Fig. 3). In the first case, the two spectra show little overlapping in the low-wavelength region, while in the second case the two spectra considerably overlap in that region. Therefore the network encounters more difficulties to learn the mixed patterns of ind2BrB and ind4B; actually, it showed overfitting before the learning criterion adopted (training set MSE < 0.0004) was satisfied. In order to compare the performances of the two networks, we stopped the training sessions when the training set MSE fell below 0.0006 units, for both networks. The ind7B/ind2BrB network needed only 600 epochs to be trained, while the other one needed 3500 epochs. There are five samples of each test mixture, and for each sample the trained networks give the predicted amounts of the two components, whose averages are shown in Table 5,

Table 4
Percentage of correct responses for each test pattern group

Network	001	005	01	L1	R1	L4	R4	S15	S2
450-6-6	100	98.3	90	100	100	83.3	66.7	100	66.7
222-6-6	100	98.3	85	100	100	50	66.7	83.3	66.7

together with the exact amounts. The total average errors are 0.61% for the ind7B/ind2BrB network, and 0.72% for the ind4B/ind2BrB network. Both networks seem to make greater errors with the mixtures with one almost-pure component (see Fig. 7). The maximum absolute errors found are lower than 1.5%.

10. Technical notes

The simulation of the network was carried out with the SNNS (Stuttgart Neural Network Simulator) program, version 4.0, which is distributed by the University of Stuttgart (Institute for Parallel and Distributed High Performance Systems) as 'free software'. Information about it and the ANALYSE program included are available at the Internet address http://www.informatik.uni-stuttgart.de/ipvr/bv/projekte/snns/snns.html. The calculations were made on a IBM-RISC 6000 workstation with 32 Mbytes of memory, running AIX 3.2.5 and X-Windows.

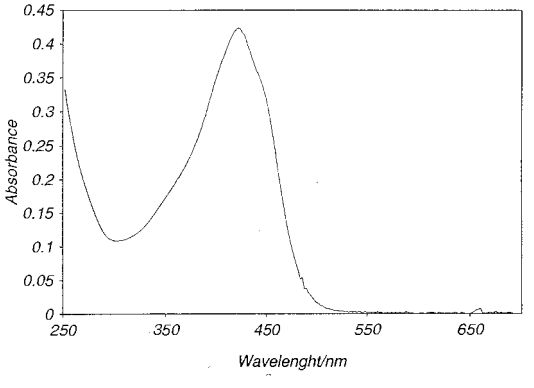

Fig. 6. Absorbance spectrum of E100 candy dye.

11. Conclusions

A multilayer network with a large number of input nodes has been shown to be capable to discriminate between spectra very similar and with few spectral details, as the UV-visible spectra in Fig. 1. In addition, the percentage of right recognitions is quite satisfactory also when highly distorted patterns are presented to the network. Moreover, we demonstrated that a specific network can be trained to give accurate estimates of the concentrations of two components in a binary mixture. It must be remarked that no preliminary transformation or reduction of data is needed: the input patterns are the absorbances at each wavelength in the spectral range chosen. Then the neural 'black box' as is could be useful in order to obtain a fast and accurate response in the identification and/or quantitative determination of real data.

Appendix A

The noise added to each point was given by $y = \tilde{A} + \mathrm{rnd} \cdot \sigma$, where rnd is a random number sampled from a normal gaussian distribution; using $\tilde{A} = 0.0015$ and $\sigma = 0.001$, the experimental noise is reproduced, as for the training spectra. The width of the gaussian is always constant in every group of spectra; the distorted spectra with greater noise have been generated simply with a greater σ value (e.g., $\sigma = 0.01$ for the spectra with added noise ten-fold than the experimental one).

Received 28 August 1996; received in revised form 6 March 1997; accepted 12 March 1997

Abstract

The gas chromatographic detection and quantitative determination of various chlorophenolics as well as resin and fatty acids have been carried out in the chlorination and caustic extraction stage effluents generated in the laboratory by bleaching a bamboo pulp. A number of chlorinated phenols, catechols, guaiacols, syringaldehydes and resin acids as well as non-chlorinated saturated and unsaturated fatty acids together with resin acids have been detected. The concentration of various compounds detected have also been compared with the reported $^{96}LC_{50}$ values. © 1997 Elsevier Science B.V.

Keywords: Bamboo; Bleaching effluent; Chlorophenolics; Gas chromatography; Pollutants; Resin and fatty acids

1. Introduction

The dwindling forest cover and increasing demands of the paper, industry worldwide is increasingly requiring the use of hardwoods and nonwoods (agroresidues and grasses) for making paper. Bamboo (Bambusa), a grass, has been one of the most popular raw materials used by the Indian paper industry. It gives a long fibered pulp (comparable to softwoods) that forms a strong paper. With the diminishing forests in India bamboo has also, become scarce but is still used by a large number of paper mills, particularly in eastern and southern India.

The paper industry is a high pollution load industry. Among the various sections, bleaching often accounts for the largest fraction of toxicity. The pulp produced by digestion with chemicals is brownish in color and requires bleaching to produce pulps of acceptable brightness. In developing countries the use of chlorine and other chlorinated compounds such as calcium or sodium hypochlorite with an intermediate caustic extraction is common for nonwoody materials.

The compounds responsible for the toxicity of chlorination (C) and caustic extraction (E) stage effluents are chlorophenolics together with resin and fatty acids [1,2]. The chlorophenolics are formed during the C-stage of pulp bleaching and

PII S00 9-9140(97)00090-8

are solublized in the E-stage. The nature and amount of chlorophenolics formed will depend upon the nature of the lignin and the bleaching conditions [3,4]. The resin and fatty acids found in bleach plant effluent originate from the fibrous raw material. Their amount depends on the species and on the degree of washing of the unbleached pulp.

During the last two decades intense research efforts have been devoted to the identification of the various compounds [5–10] in bleach plant effluents and to the investigation of their possible biological effects [11–15]. These studies have been performed mostly on softwoods. Very little information is available on the nature and the quantities of various compounds present in bleach plant effluents formed from Indian varieties of hardwoods or agroresidues. In the present investigation we report the results of the detection and quantitative determination of various pollutants formed during the chlorination and extraction stages of the bleaching of bamboo pulp.

2. Experimental

The chlorophenols and fatty acids used were obtained from the Sigma Chemical Company (St. Louis, USA) and Aldrich Chemical Company (Milwaukee, USA). The chlorocatechols, chloroguaiacols, chlorovanillins, chlorosyringaldehydes, chlorosyringols, resin acids and chloro fatty acids were supplied by Helix Biotech. Corporation (Richmand, B.C. Canada). Solvents comprising *n*-hexane, acetone, diethyl ether and methyl tertiary butyl ether used were HPLC grade. Analytical grade acetic anhydride was used after redistillation. Other reagents used for detection studies were of analytical reagent grade. Standard solutions of chlorophenols were prepared in acetone/water (10:90), resin and fatty acids in methanol/diethyl ether (10:90) solution.

Unbleached washed (bamboo) kraft pulp was provided by Central Pulp and Paper Research Institute (CPPRI), Saharanpur. Tappi Test method T_{236} cm-85 was used to determine the residual lignin content (kappa number = 37.4) of the pulp.

Pulp bleaching was carried out in more than one bleaching stages. A fraction (70%) of the chlorine demand (0.25 × kappa number) was applied as elemental chlorine in chlorination stage. All chemicals were applied as %O.D. (oven dried) pulp.

Unbleached pulp (35 g O.D. basis) was bleached under the conditions shown in Table 1. The volumes of effluent generated in the C and E stage were 1.81 and 2.02 l, respectively. The effluents were characterized by pH, total dissolved solids, BOD_5 (biochemical oxygen demand), COD (chemical oxygen demand) [16] and color measured on a Shimadzu spectrophotometer model UV 2100/S.

Extraction of chlorophenols from the effluents was performed by simple modification of the procedure suggested by Lindstrom and Nordin [5]. The E-stage effluent (500 ml) or the C-stage effluent (1000 ml) was adjusted to pH 2 and extracted with 200 and 400 ml of 90:10 diethyl ether/acetone mixture for 48 h, respectively with intermittent shaking. Extraction of resin and fatty acids from effluents has been achieved as suggested by Voss and Rapsomatiotis [8]. The effluent (E-stage 50 ml or C-stage 100 ml) was adjusted to pH 9 and extracted with equal volume of methyl tertiarybutyl ether for 1 h.

Chlorophenols as acetyl derivatives [17], resin and fatty acids as methyl esters [18] were analysed using Shimadzu gas chromatograph (Model GC-9A). The GC conditions are given in Table 2. Retention times (RT) were determined using standard solutions of various chlorophenolic compounds, resin and fatty acids. In each case 1 ml sample was derivatized and 1 μl of the derivatized extract was injected into the column.

3. Derivatization procedure

3.1. Chlorophenolics

To 4.5 ml of sample (or diluted sample) taken in teflon lined screw capped glass tube, 0.5 ml of 0.5 M Na_2HPO_4 and 0.05 ml of acetic anhydride were added. After adding 1 ml of *n*-hexane, the mixture was shaken for 3 min and 0.5–1.0 μl of the hexane extract was injected into the HR-1 column.

3.2. Resin and fatty acids

Resin and fatty acids were derivatized with dropwise addition of etheral solution of diazomethane to 1 ml of the sample till a yellow color persisted for some time. The excess diazomethane was destroyed by dropwise addition of glacial acetic acid. The resulting solution was evaporated to dryness with a current of nitrogen gas. The dried mass was dissolved in methanol/diethylether (10:90) solution and making the total volume 1 A 0.5 μl of this solution was injected into OV-101 column.

3.3. Extraction efficiency determination

3.3.1. Chlorophenolics

The standard solution of 0.1 mg chlorophenolics (1000 ml) was extracted and derivatized. Another solution of 0.1 mg chlorophenolics (1 ml of 100 mg l^{-1}) was derivatized without extraction. The extracted and nonextracted chlorophenolics derivatives were injected into HR-1 column (0.5 μl each) and the peak areas were determined in both the cases. The extraction efficiency (EF) was calculated from the equation:

$$\mathrm{EF}(\%) = \frac{\text{Peak area of extracted sample}}{\text{Peak area of nonextracted sample}} \times 100 \quad (1)$$

3.3.2. Resin and fatty acids

The standard solution of resin and fatty acids (50 ml of 0.1 mg l^{-1}) was extracted and derivatized. Another solution (1 ml of 5 mg l^{-1}) containing 5 μg of resin and fatty acid was derivatized without extraction. The extracted and nonextracted resin and fatty acid were injected into OV-101 column (0.5 μl each) and the peak areas were determined in both the cases. The extraction efficiency was calculated using the Eq. (1).

The various chlorophenolics, resin and fatty acids were detected by matching the retention time with those of pure standards within ± 0.1 min. For some compounds the value of RT were nearly the same. In these cases the average quantities were determined. For carrying out quantitative analysis, response factor (RF) and extraction efficiency (EF) of various compounds were determined.

4. Results

The characteristics of effluents generated in laboratory are shown in Table 3. The values of RT and concentration of various detected chlorophenolics, resin and fatty acids are given in Table 4 and Table 5, respectively. The values of RT show that most of the chlorophenolics and resin and fatty acids can be separated on Ulbon HR-1 glass

capillary and fused silica OV-101 capillary columns, respectively. The quantities of various categories of chlorophenolics, resin and fatty acids expressed as g per tonne of oven dried pulp (g odt^{-1}) are given in Table 6 and Table 7, respectively.

5. Discussion

5.1. Chlorophenols

Six categories of chlorophenolics are present in spent bleach liquor obtained from Indian variety of bamboo pulp. These are chlorophenols, chlorocatechols, chloroguaiacols, chlorosyringols, chlorosyringaldehydes and chlorovanillins. The retention times and concentration of various chlorophenolics observed in the bamboo spent bleach liquor are given in Table 4.

The structure of lignin is very complex. It is a polymer formed by an enzyme initiated dehydroabietic polymerization of a mixture of three different *p*-hydroxy cinnamyl alcohols (*p*-coumeryl, coniferyl and sinapyl alcohols). Compared with wood lignin, the structure of grass lignin has been less studied. It varies significantly with source. Some grass lignins are thought to contain mainly *p*-coumaryl units but other grass lignins appear to approximate the hardwood lignin [19]. During pulp chlorination lignin is chlorinated and breaks down to simpler chlorophenolic compounds. The solubility of chlorophenolics is low in acidic condition (C-stage) and they are solubilized in alkaline condition (E-stage). The nature and concentration of different chlorophenolic compounds formed that ultimately end up in SBL depend upon quantity of lignin i.e., kappa number of pulp, nature of lignin, and bleaching conditions, i.e., chlorine charged, pH, temperature and consistency (expressed as g O.D. pulp per 100 g pulp suspension).

Among the various chlorophenolics found in C-stage effluent the maximum contribution came from 3,4,5-trichlorocatechol (35.67 g odt^{-1}). Other significant contribution came from 3,5-dichlorocatechol (23.78 g odt^{-1}), 2-chlorosyringaldehyde (20.68 g odt^{-1}), tetrachlorocatechol (17.06 g odt^{-1}). Small contributions were made by 2,6-dichlorosyringaldehyde (7.24 g odt^{-1}), 3,6-dichlorocatechol (7.75 g odt^{-1}). Minor quantities of 2,4/2,5-dichlorophenol (3.62 g odt^{-1}), 2,4,6-trichlorophenol (2.58 g odt^{-1}), pentachlorophenol (2.07 g odt^{-1}), 3,4,6-trichlorocatechol (1.55 g odt^{-1}), 2,4,5-trichlorophenol (1.03 g odt^{-1}) were also present. Other chlorophenolic compounds detected in the effluent had concentration about 0.5 g odt^{-1} or less.

In E-stage maximum contribution came from 2,6-dichlorosyringaldehyde (46.16 g odt^{-1}) and pentachlorophenol (46.16 g odt^{-1}). Significant contribution came from 2,4,6-trichlorophenol (25.38 g odt^{-1}), 2,5/2,4-dichlorophenol (19.04 g odt^{-1}), 3,4,5-trichlorocatechol (16.15 g odt^{-1}).

Table 6
Quantity of various categories of chlorophenolics in the bleaching effluent

Chlorophenolics	C-stage (g odt^{-1})	E-stage (g odt^{-1})	(C+E)	
			(g odt^{-1})	%
Chlorine substitution				
Monochlorophenols	21.28	8.75	30.03	9.53
Dichlorophenols	43.26	70.44	113.70	36.09
Trichlorophenols	42.40	53.29	95.69	30.38
Tetrachlorophenols	17.57	9.80	27.37	8.69
Pentachlorophenols	2.07	46.16	48.23	15.31
Reactive group				
Phenols	11.36	96.63	107.99	34.28
Catechols	85.81	22.49	108.30	34.38
Guaiacols	1.05	17.98	19.03	6.04
Other phenols	28.36	51.34	79.70	25.30
Total chlorinated phenolics	126.58	188.44	315.02	100.00

Minor quantities of tetrachlorocatechol (6.34 g odt^{-1}), 3,4,5-trichloroguaiacol (6.35 g odt^{-1}), 3,4,6-dichloroguaiacol/6-chlorovanillin (5.76 g odt^{-1}), 3-chlorophenol (4.61 g odt^{-1}), trichlorosyringol (2.3 g odt^{-1}), tetrachloroguaiacol (3.46 g odt^{-1}), 4,5-dichloroguaiacol (2.88 g odt^{-1}), 4-chlorophenol, 4,6-dichloroguaiacol and 3,4-dichloroguaiacol (1.15 g odt^{-1} each) were also present. Other chlorophenolic compounds detected in the effluent had concentrations about 0.5 g odt^{-1} or less.

The chlorophenolics can be categorized on the basis of chlorine substitution. The total quantities of mono, di, tri, tetra and penta chlorophenolic compounds (g odt^{-1}) in C-stage, E-stage and combined spent bleach liquor (C stage + E stage) are given in Table 6. Dichloro and trichloro compounds contribute 66% of the total detected chlorophenolic compounds in the combined SBL. Similarly the components can be categorized based on the reactive groups. Catechols, vanillins, syringaldehydes and syringols contribute 60% of the total chlorophenolics components in the combined SBL. The concentration of chlorinated guaiacols is higher in the E-stage liquor than in the C-stage liquor. The chlorinated catechols predominate in C-stage effluent. This behavior is similar to the behavior observed with effluents of wood pulps. This is presumably, due to the low solubility of chlorinated guaiacols at low pH and the sorption of these compounds on the fibers. Alternatively these chloroguaiacols may form only upon the alkaline hydrolysis of chlorinated lignin in the E-stage.

5.2. Resin and fatty acids

Table 5 gives various categories of resin and fatty acids detected in the effluent. These are saturated fatty acids, unsaturated fatty acids, resin acids chlorinated resin and fatty acids. The quantities of resin and fatty acids are higher in E-stage effluent than in C-stage effluent. This is due to the higher solubility of resin and fatty acids in alkaline media. The quantities of various chlorinated and non-chlorinated resin and fatty acids in C-stage, E-stage and combined spent bleach liquor (C stage + E stage) are given in Table 7. From the table we can conclude:

1. The quantities of fatty acids are much higher than resin acids.
2. The quantities of total saturated fatty acids are much higher than unsaturated fatty acids.
3. The quantities of chlorinated resin acids are much higher than chlorinated fatty acids.

The palmitic acid was the most significant saturated fatty acid (203 g odt^{-1}) of the detected resin and fatty acids. Other major saturated fatty acids

Table 7
Quantity of various categories of resin and fatty acids in the bleaching effluent

Acids	C-stage (g odt^{-1})	E-stage (g odt^{-1})	(C+E)	
			(g odt^{-1})	%
Non-chlorinated				
Saturated fatty acids	59.18	196.84	256.02	77.74
Unsaturated fatty acids	5.16	16.14	21.30	06.47
Resin acids	6.51	23.36	29.87	09.07
Chlorinated				
Chloro fatty acids	2.06	1.73	3.79	01.15
Chloro resin acids	5.68	12.68	18.36	05.57
Total resin and fatty acids (both chlorinated and non chlorinated)	78.59	250.75	329.34	100.00

were lignoceric (22.5 g odt^{-1}) and stearic acid (18.33 g odt^{-1}). Minor quantities of heptadecanoic, arachidic, tricosanoic acid (3.4–4.8 g odt^{-1}) were also detected. Among the various unsaturated fatty acids oleic/linolenic acids were found in significant amounts (about 21 g odt^{-1}).

Isopimaric was the major resin acid (18.73 g odt^{-1}) detected. Significant amount of sandaracopimaric acid (7.32 g odt^{-1}) was also detected. Minor quantities (0.5–2.7 g odt^{-1}) of pimaric, dihydroisopimaric and neoabietic acid were detected. Both the isomers of monochlorodehydroabetic acid contributed major share (16.18 g odt^{-1}) to the detected chloro resin acids. Minor quantities of 12,14-dichloroabetic acid (2.18 g odt^{-1}) and 9,10,12,13-tetrachlorostearic acid (3.79 g odt^{-1}) were also detected.

6. Toxicity

The toxicity of the effluent was evaluated by comparing the quantities of various chlorophenolics, resin acids and fatty acids detected in the effluent with the values reported in the literature [4,20,21]. $^{96}LC_{50}$ is the lethal concentration at which 50% of the test organisms will get killed when the test organism is exposed to the toxicant for a period of 96 h under standard test conditions. Reported $^{96}LC_{50}$ values indicate that chlorophenolics, resin acids, unsaturated fatty acids and chlorinated resin and fatty acids are toxic. Resin acids are more toxic than unsaturated fatty acids.

The concentrations of 2,4,6-trichlorophenol (0.44 mg l^{-1}) and pentachlorophenol (0.80 mg l^{-1}) in E-stage and dichlorocatechols (0.61 mg l^{-1}) in C stage were found to be higher than the reported respective $^{96}LC_{50}$ values. The concentrations of all other chlorophenolics, resin and fatty acids were less than the respective $^{96}LC_{50}$ values.

The $^{96}LC_{50}$ value indicates the toxic concentration of a particular compound when present alone. However, when a number of toxic compounds are present, interfering effect may be observed. Substantial evidence now exists which indicates that the threshold toxic concentration may be as low as 5–10% of $^{96}LC_{50}$ values [22].

Apparently concentrations of a large number of chlorophenolics, resin and fatty acids may exceed their respective threshold concentrations. So it can be inferred that the untreated spent bleach liquor of bamboo is of environmental concern.

Abstract

The effect of a cylindrical impactor in the spray chamber of a flame photometer on the characteristics of the aerosol formed, on the transport-efficiency of the nebulizer—spray chamber system, as well as on the analytical signal has been investigated. The variables were: the diameter Φ of the cylindrical impactor and its position, i.e., the distance d in front of the tip of pneumatic nebulizer capillary where the impactor was fixed. The performance characteristics of an 1 mm Φ impactor was fixed at $d = 5$ mm was superior to that of a conventional 8 mm Φ spherical bead. © 1997 Elsevier Science B.V.

Keywords: Flame photometry; Impactor; Pneumatic nebulization

1. Introduction

Pneumatic nebulization is the most frequently used technique to introduce the sample solution into the flame in flame photometric determinations. This is a decisive step of the analysis, because the concentration and the physical properties of the resulting aerosol essentially influences the resulting analytical signal and thus the sensitivity and reproducibility of the determinations. In order to obtain aerosols with small droplets in high concentrations, high performance nebulizers have been recently developed [1–5]. In the spray chamber, the fragmentation of the larger droplets is generally promoted by means of impact beads placed at some distance in front of the droplet forming capillary. Mostly the impactors used are spherical glass beads of 8 mm Φ placed at ~25 mm before the nebulizer capillary. During our experiments with such systems, it was observed that the stability of the analytical signal could be improved by using an impactor of adequate shape, placed at a certain distance from the nebulizer capillary in the spray chamber. In our preliminary experiments, the attention was directed towards cylindrical impactors, scarcely mentioned in the literature [6–8] and not used in commercial instruments.

PII S00 9-9140(97)00074-X

The aim of this work is to investigate the effect of a cylindrical impactor on the characteristic of the resulting aerosol, on the transport-efficiency of the nebulizer—spray chamber system and on the analytical signal, respectively, as a function of the diameter of the cylinder and the impactor distance from nebulizer capillary tip.

2. Experimental

As cylindrical impactors, pieces of enamelled copper wires of 20 mm length and of 0.6, 1, 2, 4 and 8 mm diameter, were used. They were properly mounted on the pneumatic nebulizer, in an AAS-1 (Karl Zeiss Jena) commercial flame spectrophotometer in place of the original spherical impactor. They could be moved vertically at several distances (d) in front of the tip of the capillary in steps of 1 ± 0.1 mm. The schematic diagram of the nebulizer-impactor assembly is shown in Fig. 1.

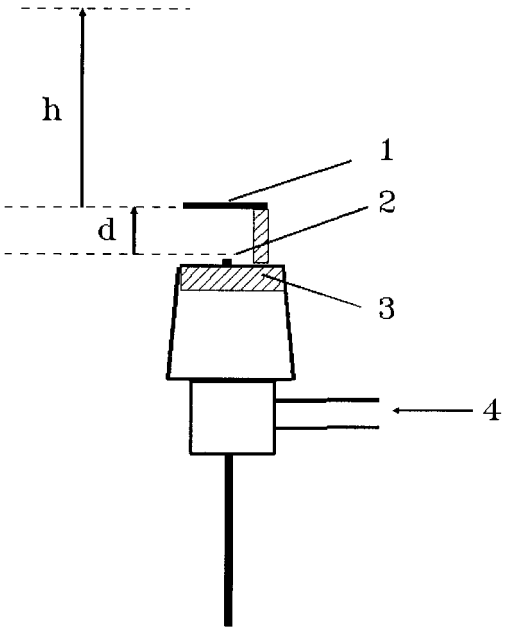

Fig. 1. schematic diagram of the nebulizer-impactor assembly: (1) impactor; (2) capillary tip; (3) holder; (4) air inlet.

The nebulizer was operated with an air stream of 500 l h^{-1}, triply distilled water being used as the sample solution. The primary and secondary aerosols formed were observed with the nebulizer removed from the spray chamber, the tertiary ones with the nebulizer in the spray chamber.

The concentration of the aerosols formed was determined by light scattering measurements. According to Mie scatter theory, the intensity of the scattered light is proportional to the total surface of the droplets, i.e., with the concentration of the aerosol [9]. For this purpose, the aerosol was illuminated with a 300 W mercury vapour lamp, the scattered light intensity of the Hg 453.5 nm line being measured at a right angle to the incidence light beam. Because of a lack of suitable aerosol standards, we only obtained information about the variation of the aerosol's concentration. The transport-efficiency of the nebulizer-spray chamber system was determined by weighing the mass of the empty system and after nebulization of 10 ml of water, respectively. The effect of the impactor on the flame emission signal was determined by measuring the emission of a 10 μg l^{-1} NaCl solution, at the 589.5 nm Na line, in a methane-air flame [10].

3. Results and discussion

The intensity of the scattered light was measured at several heights in the (secondary) aerosol (h) without impactor (I_0) and with impactors (I_d) of different diameters (Φ) being placed at various distances (d) from the tip of the nebulizer capillary. The relative intensity ($I_{rel} = I_d/I_0$) was then calculated for each Φ, d and h values. The data were processed further by using the MicroCal Origin Software package, version 3.0 (MicroCal Software, MA, USA) and plotted as 2D contour map (Fig. 2).

One can observe that the concentration of the aerosol depends both of d and h. At $h > 40$ mm, the aerosol is homogeneous, its final concentration being virtually constant. With the impactor of $\Phi = 0.6$ mm the concentration of the aerosol was maximal at $d = 4$ mm and $h = 11$ mm. The plots obtained with thicker impactors ($\Phi =$

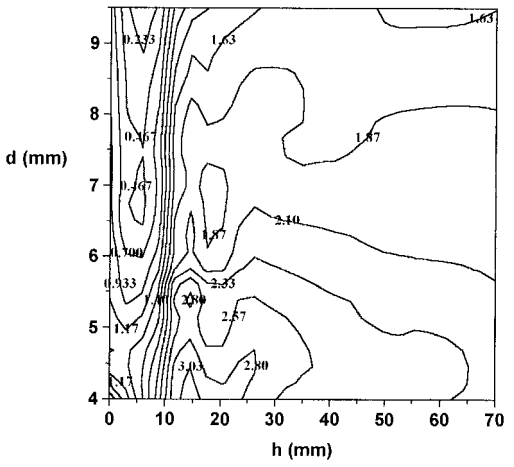

Fig. 2. The 2D contour map of the I_{rel} vs. h and d relation. Impactor $\Phi = 0.6$ mm. The data labels on the plot indicate the grid matrix values.

1, 2, 4, 8 mm) were similar to those represented in Fig. 2. The efficiency of impactors of different diameters was estimated by determining the I_{rel} values at $h = 55$ mm in the aerosol for different d values and plotted as 2D contour map (Fig. 3).

One can observe the different behaviour of impactors of different diameters. Each impactor is

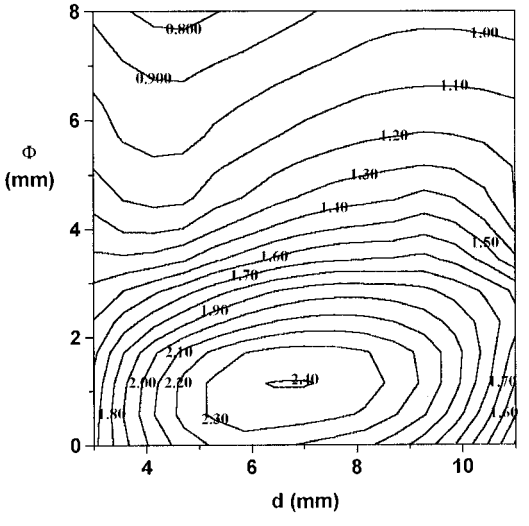

Fig. 3. The 2D contour map of the I_{rel} at $h = 55$ mm vs. Φ and d relation. The data labels on the plot indicate the grid matrix values.

the most efficient being placed at a given d distance from the nebulizer capillary. Impactors with small diameter ($\Phi = 0.6$, 1, 2 mm) were more efficient than the thicker ones ($\Phi = 4$, 8 mm). The maximal secondary aerosol concentration was obtained with the impactor of $\Phi = 1$ mm, being placed at $d = 5$ mm distance from the nebulizer capillary tip. If we assume that the $\Phi = 8$ mm diameter cylindrical impactor has the same effect as a spherical one of the same diameter, one can state that a smaller cylindrical impactor is more efficient than the 8 mm Φ spherical one. The plots obtained for the variations of the tertiary aerosol concentration with Φ and d, were similar to those represented in Fig. 3, the optimal Φ and d values being the same.

The impactor increased the transport-efficiency (TE) of the nebulizer-spray chamber system too. The maximal increase was obtained with an impactor of $\Phi = 4$ mm; at $d = 7.5$ mm. In this case, 21% of the nebulized liquid entered in the flame. For comparison, the TE of the system without the impactor was 7.5% with the commercial spherical one the TE was 9.8% and with a cylindrical one of the same diameter, the TE was 13%.

Finally the effect of impactors on the flame emission signal of Na was investigated. For this purpose, the emission signal was determined first without the impactor in the spray chamber (I_0) and then with impactors of different diameters placed at different d distances (I_d). Then it was calculated the $I_{rel,\,Na}$ and the data (average of four parallel determinations) were plotted as 2D contour map (Fig. 4).

The map shows that the impactor increased the emission signal too. The effect of the distance d is relatively small, but that of the impactor's diameter is considerable. The greatest increase was observed with thin impactors. Being placed at $d = 5$ mm, the 1 mm Φ cylindrical impactor increased the analytical signal by a factor 2.6; that of 8 mm by 1.1; and the usual spherical one by a factor of 1.4 against a spray chamber without impactor.

The precision (reproducibility) of the data is influenced by the exact centering of the impactor, in this aspect the thin impactors are more sensitive than the thicker ones. From the data ob-

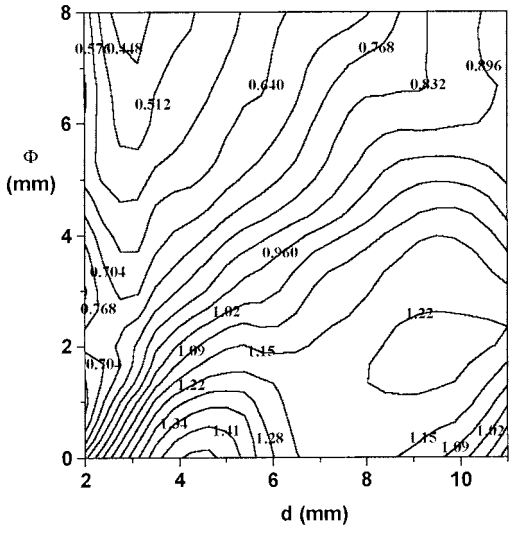

Fig. 4. The 2D contour map of the emission of 10 μg l^{-1} Na, $I_{rel, Na}$, vs. Φ and d relation. The data labels on the plot indicate the grid matrix values.

tained, the S/N ratios of the emission signals were computed too. The greatest value of S/N = 247.3 was obtained with the impactor of Φ = 1 mm placed at a distance of $d = 5$ mm. In comparison, the same S/N ratio without impactor was 108.7, and with the spherical one the S/N ratio was only 83.4. In this last case, the standard deviation more than double of that observed with the cylindrical impactor.

4. Conclusions

The results obtained proved the efficiency of a cylindrical impactor in the nebulizer spray chamber of an emission flame photometer. The cylindrical impactor increased both the analytical signal and its S/N ratio, decreasing the standard deviation. The best value (S/N = 247.3) was obtained with the cylindrical impactor of Φ = 1 mm, placed at $d = 5$ mm distance from the nebulizer tip. The same value for the usual 8 mm Φ spherical impactor was S/N = 83.4. Substitution of the spherical impactor in commercial apparatus with the cylindrical one will increase its performance characteristics.

Short communication

Simultaneous voltammetric determination of uric and ascorbic acids in urine

E.M Strochkova, Ya.I. Tur'yan, I. Kuselman *, A. Shenhar

Received 25 October 1996; received in revised form 24 February 1997; accepted 27 February 1997

Abstract

Anodic voltammetric method for simultaneous determination of uric acid (UA) and ascorbic acid (AA) in urine has been developed with the use of a commercial working rotating glassy carbon electrode. UA may be determined in a sample diluted by the buffer supporting electrolyte ($HOAc + NH_4OH$; pH 5.1–5.2) $\approx$ 100 times, and AA-in a sample diluted $\approx$ 20 times. Before obtaining the analytical signal the electrode should be maintained in the diluted sample during 3 min at potential 0 V and the working electrode rotating 100 rpm, for achievement of the adsorption equilibrium of inhibitors from the urine matrix. For UA the electron transfer is close to reversible, for AA it is an irreversible one. Optimal voltammetric techniques are the square-wave for UA and the differential pulse for AA. Calibration curves, detection limits and recoveries for both determinations were evaluated as satisfactory. © 1997 Elsevier Science B.V.

Keywords: Anodic voltammetry; Ascorbic acid; Urine; Uric acid

1. Introduction

Determination of uric acid (UA) and ascorbic acid (AA) in urine by anodic voltammetry for UA [1–5] and polarography for AA [6] is an important biochemical analysis. These methods are more selective than colorimetric (spectrophotometric) ones [6–8] including the method using a spectrophotometric autoanalyzer [7]. Comparison of the voltammetric and HPLC methods [9] showed either close results, although the selectivity, naturally, in each case should be proved. On the other hand, the voltammetric methods are simpler, cheaper and less time-consuming.

In spite of separation of the UA and AA voltammetric anodic signals in urine on carbon-based working electrodes [3,5] a simultaneous voltammetric determination of UA and AA in urine was not carried out up today. For determination of UA in urine with low detection limit, the working electrode surface was specially activated by the anodic pretreatment in alkaline medium and voltammetric analysis in the same

* Corresponding author.

PII S00 9-9140(97)00087-8

solution has been carried out [3]. Modification of a glassy carbon surface by ruthenium catalyst was also used [5].

In our work a method for simultaneous anodic voltammetric determination of UA and AA was developed with the use of a commercial working rotating glassy carbon electrode (RGCE) without any special activation of the electrode surface.

2. Experimental

Anodic voltammetric measurements were performed with the use of commercial potentiostat-galvanostat 263 EG and G PAR (USA) with rotating disk electrode system model 616 and working RGCE having the diameter of 4 mm. A Pt wire was used as auxiliary electrode, while the reference electrode was Ag/AgCl, KCl 3 M. Three different voltammetric techniques were estimated: direct current (DCV), square-wave (SWV) and differential pulse (DPV). Conditions for DCV were the followings: scanning rate 40 mV s^{-1} in the range from -100 to 800 mV, scanning increment 2 mV; for SWV: scanning rate 100 mV s^{-1} in the range from -100 to 700 mV, scanning increment 2 mV, pulse height 5 mV, frequency 25 Hz; and for DPV: scanning rate 40 mV s^{-1} in the range from -100 to 700 mV, scanning increment 4 mV, pulse height 25 mV.

The cleaning of the working electrode by 3 M HNO_3 and then rinsing with water, polishing with aluminium oxide (1 and 0.05 μm) and again rinsing with water in an ultrasonic bath (Astrason, USA) were carried out before each analysis.

Water used in the experiments was deionized. AA and UA for biochemistry, and analytical grade reagents HNO_3, HCl, HOAc, NH_4OH, $NaNO_3$, NaOH were purchased from Merck (Darmstadt, Germany). Aluminium oxide was purchased from BDH (Poole, England).

Two types of buffer solutions for the supporting electrolyte were studied: the 0.2 M acetate buffer (HOAc + NaOH, pH = 3.6–6.3) and the analogous buffer where NaOH was replaced by NH_4OH in the same pH range. The electrolytes with lower pH values: 0.01 M HCl + 0.1 M $NaNO_3$ (pH ≈ 2) and 0.1 M HCl (pH ≈ 1) were studied too. The pH measurements were carried out with a pH/ion meter PH M95 (Radiometer; Copenhagen, Denmark).

Stock solutions of UA $5.0 \cdot 10^{-3}$ M were prepared by dissolving in 0.01 M KOH, and of AA $1.0 \cdot 10^{-2}$ M in water.

Samples of urine from laboratory personnel were filtered through triton-free 0.45 μm Millipore membrane filter (mixed esters of cellulose; Bedford, MA) and stored at 4°C [5].

All measurements were performed in the positive potentials range without removing of dissolved oxygen, at room temperature, in triplicates.

3. Results and discussion

Components of the urine matrix have a significant inhibiting influence on the analytical signal detected on the glassy carbon electrode (the peak current i_p in SWV and DPV or the limiting current i_l in DCV). The inhibition effect is observed even at large (1 + 499) dilution of the sample. Note, this effect was not observed on carbon paste electrodes [1,3] and glassy carbon electrodes modified by the ruthenium catalyst [5]. The working electrode rotation accelerates the achievement of a stable analytical signal. Therefore the inhibition effect is most likely caused by the adsorption of urine matrix components on the electrode surface. It is possible that at the same time simultaneous adsorption of UA and AA and their corresponding preconcentration take place, although earlier the adsorption of UA was detected on a carbon paste electrode at potential 0.15 V and was not detected on glassy carbon electrode [1]. The stable analytical signal was obtained at RGCE velocity 100 rpm and potential 0 V within 3 min. The increase of the velocity in SWV and DPV practically did not influence neither i_p nor resolution, which is depended, in the main, on $\Delta E_p = E_p(UA) - E_p(AA)$, where E_p is peak potential of UA or AA correspondingly. In DCV the resolution $\Delta E1/2$ was worsened, where $\Delta E_{1/2} = E_{1/2}(UA)\text{-}E_{1/2}(AA)$ and $E_{1/2}$ is the half-wave potential. So, the relatively low working electrode rotating rpm was used for beginning of the analysis and then was maintained during the analysis also.

The effect of urine matrix is significant especially for UA at SWV measurements (Table 1). The electrolytic oxidation of UA and AA is described by a two-electron process [10–12]. Since the chemical reactions follow the electron transfer step [10–12], i_l/C values (C is a concentration) in DCV are dependent only on diffusion rate. Therefore the i_l/C values for UA and AA are close at the same dilution of the sample (Table 1).

For UA the electron transfer step is close to the reversible one and its rate is independent from dilution of the sample. It follows from the closeness of the half-width of the peak $\Delta E_{p/2}$ to the 3.52 RT/2F in SWV [13] and DPV [14] (Table 1). Some increase of $\Delta E_{p/2}$ in the presence of the urine sample shows that the reversibility is not complete. The electron transfer for AA is irreversible (Table 1). The closeness to the reversibility for UA and the irreversibility for AA explains [13,14] the following relations: i_p/C_{UA} higher than i_p/C_{AA} in SWV and DPV, i_p/C_{UA} in SWV higher than in DPV for greatly diluted samples, and i_p/C_{AA} in DPV higher than in SWV. The decrease of i_l and i_p under the influence of the sample matrix can be explained by both the increase of the irreversibility of the electrons transfer and the decrease of the active surface of the working electrode because of the adsorption of matrix components.

As is seen from Fig. 1 sufficient resolution is observed for the analytical signals of UA and AA in all voltammograms obtained, but in SWV and DPV the resolution is better than in DCV. Therefore SWV for UA and DPV for AA should be preferred taking also into account the relations: i_p for UA in SWV higher than in DPV, and i_p for AA in DPV higher than in SWV.

The peak potential E_p in SWV and DPV, and the half-wave potential $E_{1/2}$ in DCV for the given acid and dilution of the sample are close. Decrease of the sample dilution displaces the values E_p and $E_{1/2}$ of AA to the positive direction because of the increase of irreversibility, but E_p and $E_{1/2}$ of UA remain almost unchanged. For example, for DPV at pH 5.1 ($HOAc + NH_4OH$) in the electrolyte without urine $E_p(UA) = 428$ mV and $E_p(AA) = 181$ mV, the same with urine diluted $1 + 204$: $E_p(UA) = 426$ mV and $E_p(AA) = 188$ mV, while if dilution is $1 + 19$, $E_p(UA) = 439$ mV and $E_p(AA) = 258$ mV.

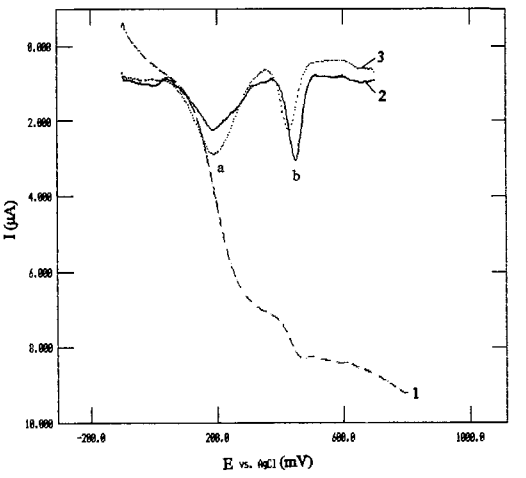

Fig. 1. Anodic voltammograms: 1. direct current; 2. square wave; and 3. differential pulse for fortified urine sample diluted 205 times. (a) AA, $C_{AA} = 28$ mg l^{-1}; b) UA, $C_{UA} = 4$ mg l^{-1}.

The $i_p(UA)$ value is decreased in electrolyte without urine, when pH is increased in the range 2.0–3.5 (Fig. 2), that corresponds to the data by Zen et al. [5]. In the presence of urine the dependence shown in Fig. 2 is opposite: increase of pH from 1–2 to 5–6 causes doubling of $i_p(UA)$. The resolution in the buffer $HOAc + NaOH$ is de-

Results of determinations of ascorbic and uric acids (DPV and SWV, correspondingly) in an urine sample diluted by HOAc + NH_4OH buffer having pH 5.1

Acid	Dilution	C ± S, mg l^{-1}
AA	1+18	57 ± 3
UA	1+99	554 ± 12
UA	1+199	550 ± 7
UA	1+499	543 ± 15

C ± S are mean concentration (of triplicates) and corresponding standard deviation of the replicate measurements.

creased with pH increasing to 5–6. In case of the buffer $HOAc + NH_4OH$ the resolution is sufficiently high also at pH 5–6 (≈ 200 mV). The influence of NH_4^+-ion on ΔE_p is caused by decreasing E_p(AA), i.e., by the acceleration of the electron transfer. Moreover, acceleration of AA oxidation by dissolved oxygen with pH increasing (>5) should be taken into consideration also. Therefore the buffer $HOAc + NH_4OH$ with pH 5.1–5.2 was chosen for the analysis.

Relatively low dilution of the sample (1 + 19) was used to obtain sufficiently high signal of AA. For UA the dilution of the sample was 1 + 99, by analogy with Ref. [5], because of limited solubility of UA. It was shown that higher dilution do not influence on the analysis results (Table 2).

Thus, the technique of the analysis described below was formulated.

3.1. Analytical procedure

The procedure consists of two steps. The first step is UA determination by SWV, the second one is AA determination by DPV in one and the same urine sample. In the first step the sample is diluted up to around 1 + 99 by 0.2 M supporting buffer electrolyte $HOAc + NH_4OH$ having pH = 5.1–5.2. The conditions of the analysis are: RGCE is maintained in the electrolyte during 3 min at potential 0 V, than the potential is scanned from 250 to 600 mV in SWV; the working electrode rotating is 100 rpm. In the second step (AA determination) a new portion of the sample is added into the voltammetric cell with the previous sample solution to increase the ratio between sample and electrolyte from 1 + 99 up to around 1 + 19. The analysis conditions in this step are: RGCE is maintained during 3 min at potential 0 V, than the potential is scanned from 0 to 400 mV in DPV; the working electrode rotating is maintained the same, as in first step (100 rpm). This succession of operations allows to minimize the change of the supporting electrolyte volume during analysis. The calibration 'peak current i_p versus acid concentration C_{ad} added to the sample' is based on the method of standard additions. Calibration curves for UA and AA (e.g., Fig. 3) are plotted by the regression analysis. According to standard addition method, the results of the analysis (C_{AA} and C_{UA}) are the absolute values of concentrations at the intersection points of the extrapolated calibration curves (dotted lines) with the abscissa.

3.2. Evaluation of the metrological characteristics

The regression calibration curves 'peak current versus acid concentration added to the sample' have squares of correlation coefficients higher than 0.999. The sensitivities i_p/C are shown in Table 1.

The repeatability (the standard deviations of the replicate measurements) shown in Table 2 satisfy the AOAC requirements [16].

The detection limit, calculated from the calibration curves [15] for UA is 3×10^{-8} M and for AA

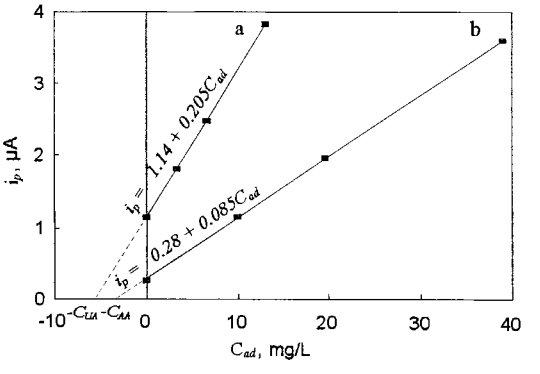

Fig. 3. Calibration curves for determinations of UA (a) and AA (b) in an urine sample by the standard additions method. The dilution's of the sample are: (a) 1 + 99; 1 + 18. Other conditions see in the analytical procedure (Section 3.1).

Table 3
Evaluation of the recovery for ascorbic and uric acids (DPV and SWV, correspondingly) in urine

Acid	Measured conc. in unfortified sample, %	Spike, %	Measured conc. in fortified sample, %	Recovery, %
AA	0	0.01	0.0085	85
AA	0	0.01	0.0092	92
AA	0	0.01	0.0088	88
AA	0	0.03	0.0283	94
AA	0	0.03	0.0280	93
AA	0	0.03	0.0288	96
AA	0	0.1	0.0939	94
AA	0	0.1	0.0983	98
AA	0	0.1	0.1007	101
UA	0.0549	0.0273	0.0833	106
UA	0.0549	0.0273	0.0834	104
UA	0.0549	0.0273	0.0839	106
UA	0.0549	0.0546	0.1107	102
UA	0.0549	0.0546	0.1038	104
UA	0.0549	0.0546	0.0994	99
UA	0.0549	0.0820	0.1406	105
UA	0.0549	0.0820	0.1406	105
UA	0.0549	0.0820	0.1360	99

is 3×10^{-6} M. Thus, the detection limit for UA obtained by us on a commercial glassy carbon electrode is lower than for glassy carbon electrode with ruthenium catalyst coating (1.1×10^{-7} M [5]). At the same time UA detection limit may be decreased up to 1×10^{-9} M due to the anodic pretreatment in alkaline medium [3]. However, it is noted above, the use of alkaline supporting electrolyte can accelerate the oxidation of AA by the dissolved oxygen.

The recovery, as an index of accuracy was estimated using spiked urine samples with certain amounts of AA and UA (the concentration of UA was fortified on 50, 100 and 150% from the initial one in the sample themselves). The recovery values for average of triplicates are given in Table 3. The results satisfy the AOAC requirements [16] too.

Received 20 June 1996; received in revised form 22 July 1996; accepted 22 July 1996

Abstract

The performance characteristics of an electrochemical detector for liquid chromatography based on a sol–gel carbon composite working electrode in a wall-jet configuration are described. The new detector combines the versatility of sol–gel processes with several favorable characteristics, including fast electron-transfer kinetics, mechanical rigidity and renewability. Factors influencing the amperometric response are explored and optimized. Detection limits of 58–170 pg are reported for various neurotransmitters. Repetitive injections yield peak heights with relative standard deviations of 2.6–3.7%. The prospects of using sol–gel derived electrochemical detectors are discussed. © 1997 Elsevier Science B.V.

Keywords: Amperometry; HPLC detector; Sol–gel carbon; Electrode

1. Introduction

The coupling of liquid chromatography with electrochemical detection (LCEC) offers a highly sensitive and selective tool for the determination of a wide variety of electroactive compounds [1,2]. The success of the electrochemical detection scheme is strongly influenced by the working electrode material. The selection of such material depends mainly on the redox behavior of the target analytes and the background current (and associated noise) at the operating potential. Other considerations include the potential window, mechanical properties, chemical inertness, electrical conductivity and cost.

Carbon-based electrodes have typically served as working electrodes for the detection of oxidizable species in the anodic region. A variety of carbon electrode materials have been developed for LCEC, with glassy carbon and carbon paste being most popular. Yet, the development of new and improved electrode materials remains a very important need in LCEC [2].

In this report we describe the performance characteristics of a wall-jet amperometric detector employing a sol–gel derived carbon composite

PII S0039-9140(96)02051-6

working electrode. Sol–gel carbon composites represent a new class of carbon–based electrodes, that are composed of graphite powder homogeneously dispersed in modified silica ceramics [3]. Recent electroanalytical applications of these carbon ceramic electrodes include amperometric biosensing [4,5] and gas-phase monitoring [6]. As desired for LCEC, such sol–gel derived carbon electrodes display favorable electron-transfer kinetics and a wide potential window, are physically rigid, have renewable surface, are amenable to chemical or biological (bulk) modification, and are stable in various solvents. Such attractive features are combined with the versatility of sol–gel processes [7]. Sol–gel carbon materials thus, appear to be a viable alternative to other carbon-based working electrodes used in LCEC. The opportunities accrued from the development of LCEC detectors based on sol–gel carbon composite electrodes are explored in the following sections.

2. Experimental

2.1. Reagents

All the solutions were prepared in HPLC grade water. Catechol, epinephrine, arterenol (norepinephrine) and 3-hydroxytyramine (dopamine) were purchased from Sigma. Methyltrimethoxysilane (Fluka), ethanol (200 proof, Quantum Chemical Company) and graphite powder (grade # 38, Fisher Scientific) were used for the preparation of the sol–gel carbon composite electrodes. Chloroacetic acid (Aldrich), ethylenediaminetetraacetic acid (EDTA) disodium (Fisher Scientific) were used for the preparation of the mobile phase. Nylon membranes (0.2 μm pore size, 47 mm diameter, MF 5621) were used for filtering the mobile phase. Micro filters (MF 5500) and microfilter membranes (MF 5658) were used for filtering the samples. All were obtained from Bioanalytical Systems Inc. (BAS). Ultrahigh purity helium gas (Agile Welding Supply, Albuquerque, NM) was used as received for degassing the mobile phase and solutions.

2.2. High performance liquid chromatography

All experiments were performed on a reverse phase HPLC system (BAS, Model 480) in connection with a dual reciprocating pump (PM-80, BAS) and an amperometric detector (BAS, Model LC-4C) along with a homemade wall-jet electrode configuration. Injections were made through a Rheodyne valve with 20 μl loop onto a C_{18} column (ods-3, BAS, Model MF 6213, 3 μm, 3.2 × 100 mm). Chromatograms were recorded on an Ominiscribe strip-chart dual pen recorder (Houston Instruments). The sol–gel carbon working electrode, the Ag/AgCl (RE-1, BAS) reference electrode and the platinum wire counter electrode were joined through the holes in the Teflon cover of the wall-jet cell.

2.3. Electrode preparation

Sol–gel derived carbon electrodes were prepared by mixing 500 μl methytrimethoxysilane, 750 μl ethanol and 50 μl 11 M hydrochloric acid, sonicating the mixture for 1 min and adding 2.0 g of graphite powder. This mixture was sonicated, mixed thoroughly and filled into the cavities of 3 mm i.d. glass tubes. These composites were dried under ambient conditions for 24 h. Similar procedures were used for making more porous sol–gel electrodes, except for the fact that the initial mixture (before the addition of graphite) was sonicated for the longer times of 15 and 30 min. The sol–gel carbon electrodes were polished after drying on a 400 grade emery paper and polished again on weighing paper. The resulting electrode surfaces were shiny and smooth. Carbon-paste electrodes were prepared by thoroughly mixing graphite powder and mineral oil in the ratio of 70:30. This mixture was filled into the cavities of 3 mm i.d. glass tube. The connections were made by inserting a copper wire through the other end of the capillary in both sol–gel and carbon paste electrodes.

2.4. Procedure

All the measurements were carried out under ambient conditions. Amperometric measurements

were carried out after applying the appropriate potential to the electrode and allowing the transient signal to reach the steady-state value. The mobile phase used was 0.1 M chloroacetic acid solution containing 0.2 g of disodium EDTA adjusted to pH 3.5 with phosphoric acid. All analyte standard solutions were prepared in mobile phase. All mobile phase, standard solution, samples were filtered and degassed prior to use. Urine samples were obtained from healthy volunteers, filtered by passing through 10–15 μm glass filters, and diluted (1:50) with mobile phase solution.

3. Results and discussion

The sol–gel process involves a low-temperature production of ceramic materials through the hydrolysis and polycondensation of alkoxides [7]. By incorporating graphite powder in the initial sol–gel mixture, it is possible to obtain black rigid xerogels with percolating graphite powder in the silica backbone [3]. The preparation conditions (e.g. hydrolysis time, water/silica ratio) can be controlled to manipulate the physical characteristics (particularly the microporosity) of the resulting electrodes [8]. Because of the composite carbon character of these sol–gel derived electrodes, their performance is compared with that of common carbon-paste based detectors.

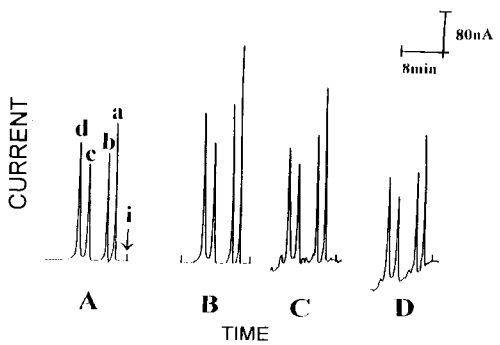

Fig. 1. Chromatograms of 100 μM norepinephrine (a), 100 μM epinephrine (b), 100 μM dopamine (c) and 100 μM catechol (d) at a carbon-paste electrode (A) or sol–gel carbon composite electrodes with 1 min (B) or 15 min (C) or 30 min (D) hydrolysis times. Applied potential: 0.75 V; flow rate: 0.5 ml min^{-1}; mobile phase: 0.15 M chloroacetic acid with 0.2 g EDTA.

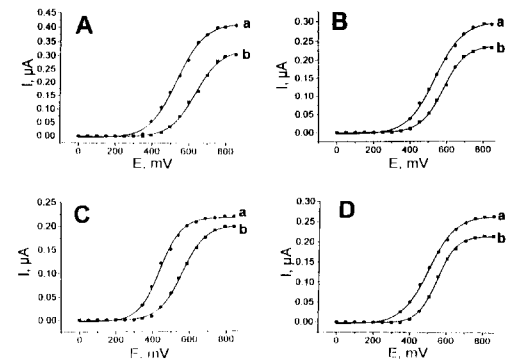

Fig. 2. Hydrodynamic voltammograms of 100 μM norepinephrine (A), 100 μM epinephrine (B), 100 μM dopamine (C) and 100 μM catechol (D) at sol–gel carbon composite electrodes with 1 min hydrolysis (a) and a carbon-paste electrode (b) in HPLC detection. Other conditions as in Fig. 1.

Fig. 1 compares chromatograms for a mixture of 0.1 mM norepinephrine, epinephrine, dopamine and catechol, obtained with a conventional carbon-paste electrode and using sol–gel carbon composite surfaces of different porosities. The well-defined peaks and low noise level of the nonporous sol–gel carbon composite compare favorably with those of the carbon–paste detector (compare B and A). In contrast, the porous composite electrodes display a large noise level and drifting baseline, and overall an inferior performance (associated with the penetration of mobile phase into the electrode interior). All subsesquent work was thus, carried out using the nonporous sol–gel carbon composite detector.

Fig. 2 shows hydrodynamic voltammograms at the sol–gel derived carbon and carbon-paste wall-jet detectors for norepinephrine, epinephrine, dopamine and catechol. The carbon–ceramic composite detector displays well-defined waves and potential-independent transport limited currents for all four compounds. The anodic wave starts at +0.25 V, and rises rapidly. A limiting-current plateau is reached at potentials higher than +0.65 V (C) and +0.7 V (A,B,D). The sol–gel carbon detector offers a substantial decrease in the potential of the voltammetric wave for all four compounds, compared with the carbon-paste surface ($\Delta E_{1/2}$ ranging from 67 mV (D) to 155 mV (A). In addition, an increase in the

mass-transport controlled response (up to 38% in the case of norepinephrine) is observed in comparison to the carbon-paste detector. In view of the use of the same graphite powder, the more favorable redox behavior observed at the sol–gel detector may be attributed to a catalytic action by the silicon oxide component. Enhanced electron-transfer kinetics by metal-oxide surface catalysts has been used previously to lower the operating potential of LCEC detectors [9]. While the sol–gel network is negatively charged, it does not appear that the cationic catecholamines interact with the surface under the chromatographic conditions employed in this study. (Note that the enhanced signal for the neutral catechol offered by the sol–gel carbon detector, vs. the carbon paste one, is similar to that observed for the cationic neurotransmitters.) Similarly, there is no indication of electrostatic repulsion of anionic compounds, in view of the similar data for ascorbic and uric acids (not shown). Based on the data of Fig. 2, a potential of +0.75 V was used throughout this study.

The dependence of the chromatographic peak currents upon the flow rate is shown in Fig. 3. The peak heights increase linearly with the flow rate at first (between 0.2 and 0.3 ml min^{-1}) and then more slowly up to 0.5 ml min^{-1}. The peaks decrease slightly between 0.5 and 0.8 ml min^{-1}, and then rise slightly. Such profiles reflect the combined flow rate effect upon the chromatographic peak (band) broadening and on the mass transport towards the detector surface. Unlike continuous wall-jet electrodes where the steady-state current is proportional to $U^{3/4}$, the composite character of the present sol–gel derived electrode reduces the influence of forced convection upon the response. A flow rate of 0.5 ml min^{-1} was chosen as optimum for all further studies.

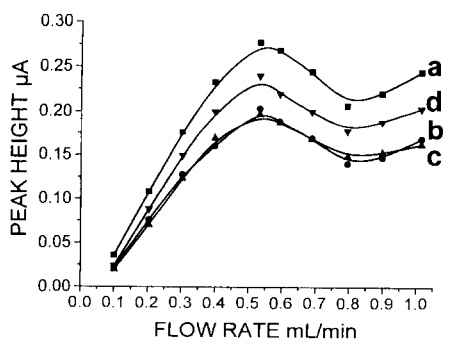

Fig. 3. Effect of flow rate on the amperometric peak current in the HPLC detection of 100 μM norepinephrine (a), 100 μM epinephrine (b), 100 μM dopamine (c) and 100 μM catechol (d) at a sol–gel carbon composite electrode. Other conditions as in Fig. 1.

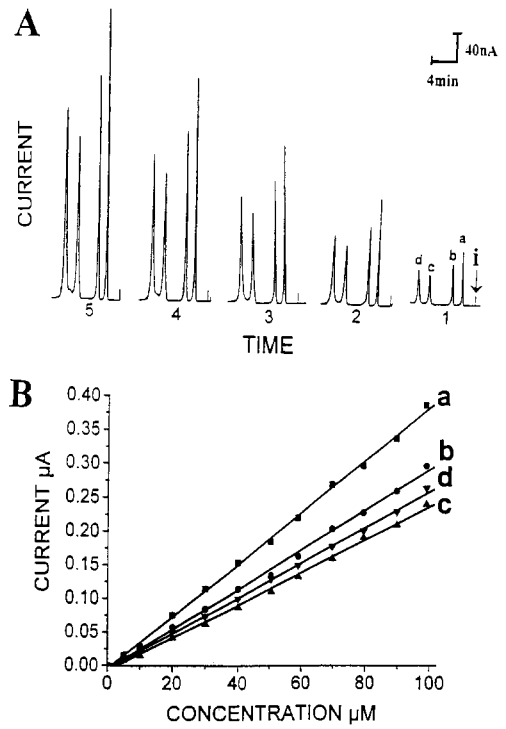

Fig. 4. Current–time recordings (A) and calibration plot (B) of norepinephrine (a), epinephrine (b), dopamine (c) and catechol (d) at a sol–gel carbon composite electrode for the successive additions of the analytes in HPLC detection. 1–5 represents the concentrations of 20–100 μM, respectively. Other conditions as in Fig. 1.

The sensitivity and linearity of the response were evaluated using 11 successive injections of mixtures containing increasing concentrations of various catecholamines (from 5 to 100 μM). Well-defined peaks were obtained at the micromolar level (Fig. 4A). The peak response increased linearly upon increasing the concentration of these analytes (Fig. 4B). The slopes of these calibration plots correspond to sensitivities of 3.84 (nore-

pinephrine), 2.95 (epinephrine), 2.43 (dopamine) and 2.62 (catechol) nA μM^{-1} (correlation coefficients, 0.999).

An injection of a 0.5 μM mixture of the catecholamines was used to estimate the minimum detectable quantities (Fig. 5A). Based on a signal-to-noise ratio of three, the detection limits were 25 (norepinephrine), 32 (epinephrine), 50 (dopamine) and 25 (catechol) nM. Such levels correspond to 85, 110, 170 and 55 pg, respectively, in the 20 μl injected volumes. Such extremely low detection limits are attributed to the composite character of the sol–gel derived carbon surface.

The suitability of the sol–gel detector for assays of body fluids is illustrated in Fig. 5B. The chromatogram for the diluted (1:50) urine sample displays defined ascorbic acid and uric acid peaks at retention times of 2.0 and 3.5 min, respectively.

The reproducibility was assessed from a series of 20 successive injections of a mixture containing 100 μM of the various catechol compounds during an unbroken 200 min period (conditions, as in Fig. 1). The mean peak currents found were 405 (norepinephrine), 288 (epinephrine), 218 (dopamine) and 256 (catechol) nA, with relative standard deviations of 2.6, 3.1, 3.2 and 3.7%, respectively.

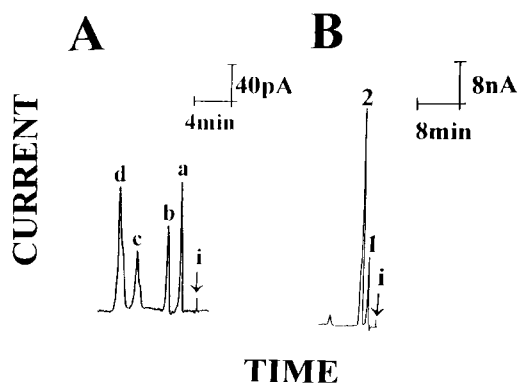

Fig. 5. Chromatograms for submicromolar concentrations of catecholamines (A) and a urine sample diluted (1.50) in mobile phase (B) at a sol–gel carbon composite electrode. 1 and 2 represents ascorbic acid and uric acid, respectively; a–d represent norepinephrine, epinephrine, dopamine and catechol, respectively, at 0.5 μM. Other conditions, as in Fig. 1.

In conclusion, the experiments described above clearly indicate that sol–gel carbon composites can provide versatile, easy-to-prepare, renewable LCEC detectors, possessing high sensitivity, selectivity and stability. While such features are presented in connection with a wall-jet detector, other detector configurations could benefit from the attractive properties of sol–gel carbon composites. The shape and form of the sol–gel derived electrodes can be controlled to suit the specific application. Application of this detector for monitoring other eleectroactive compounds in chromatographic effluents appear promising. Enzyme-based detectors (e.g. for phenols, amino acids or carbohydrates) could also benefit from the attractive, low-temperature encapsulation of biocomponents within sol–gel networks. Doping of the sol–gel carbon composite with an electrocatalyst (e.g. dispersed metal particles) could offer additional detection advantages.

Potentiometric determination of stability constants of Lanthanon(III) complexes with some Schiff bases and benzothiazolines

Perihan Gürkan *, Nurşen Sarı

Gazi Üniversitesi Fen Ed. Fakültesi, Kimya Bölümü Teknikokullar, 06500 Ankara, Turkey

Received 29 November 1995; received in revised form 3 July 1996; accepted 9 August 1996

Abstract

The protonation constants of five Schiff base and two benzothiazoline type ligands and stability constants of their complexes with six lanthanide ions were determined by potentiometrically in ethanol–water solution (1:1, v/v) at 25 ± 0.1°C. The Schiff base-type ligands were salicylidene 2-iminopyridine (SAPy), salicylidene-5-methyl-2-iminopyridine (SAPyMe), salicylidene-5-chloro-2-iminopyridine (SAPyCl), 2-(2-pyridylmethyleneamino) phenol (PyOH), 2-(2-quinolylmethyleneamino) phenol (QuOH) and the benzothiazoline-type ligands were pyridine-2-carbozaldehydebenzothiazoline (PyS) and quinoline-2-carboxaldehydebenzothiazoline (QuS). The order of stability constants was found to be for metal ions La(III) < Pr(III) < Nd(III) < Eu(III) < Ho(III) < Yb(III), and for ligands SAPyCl < SAPy < QuS < QuOH < PyS < PyOH < SAPyMe. The FORTRAN programs PKAS and BEST were used for the calculation of protonation constants and stability constants, respectively. © 1997 Elsevier Science B.V.

1. Introduction

Potentiometric studies on and the coordination chemistry of lanthanide cations with Schiff bases have been investigated and reviewed over the last few years [1–4]. The stability constants of 1:1 complexes of Pr(III), Nd(III), Sm(III) and Gd(III) with SAPy have been reported [5]. The characterization of cobalt, manganese, nickel and some lanthanide complexes of PyOH and QuOH [6–10] and silicon, niobium, manganese and lead complexes of PyS have also been reported [11–14], but a literature survey indicated that no work has been done on complex formation equilibria of

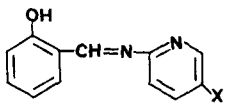
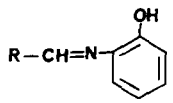
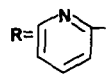
these ligands. Such studies have now been undertaken and are reported in this paper. The structures of the ligands are shown below.

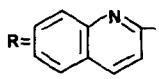


X=H SAPy
X=Cl SAPyCl
X=Me SAPyMe

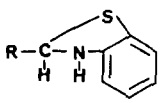


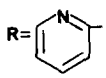


PyOH

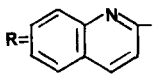


QuOH





PyS



QuS

2. Experimental

2.1. Synthesis of ligands

SAPy, SAPyCl and SAPyMe were synthesized by condensing 1:1 molar amounts of salicylaldehyde with 2-aminopyridine, 2-amino-5-chloropyridine and 2-amino-5-methylpyridine, respectively in ethanol as reported earlier [15–17]. PyOH and QuOH were synthesized by condensing 2-hydroxaniline in 1:1 molar ratio with pyridine-2-carboxaldeyde and quinoline-2-carboxaldehyde, respectively, as reported earlier [6–10]. PyS and QuS were prepared by the condensation of 2-mercaptoaniline with pyridine-2-carboxaldehyde and quinoline-2-carboxaldehyde respectively in a 1:1 molar ratio in benzene [11–14].

The ligands were fully characterized by their melting points, elemental analysis (C, H, N) IR and NMR spectra.

2.2. Reagents and solutions

Ethanol–water (1:1, v/v) prepared from triply distilled water and absolute ethanol was used as a solvent. All metal ion solutions were prepared from their analytical-grade chlorides (Aldrich) and were standardized by EDTA titration [18]. Carbonate-free KOH solution was standardized with potassium hydrogen phthalate. KCl (Merck, extra pure) and concentrated HCl (Merck, extra pure) were used for the preparation of 1.00 M KCl and 0.017 M HCl solutions. The HCl solution was standardized with standard KOH.

2.3. Potentiometric measurements

Measurements were carried out using a Corning M-240 pH-meter equipped with a Corning semimicro combined glass electrode. The system was calibrated to read hydrogen ion concentration by titration of hydrochloric acid solution at 25 ± 0.1°C and 0.2 M KCl ionic strength with KOH solution according to Gran's method [19]. Small amounts of ($\Delta v = 0.05$ cm^3) titrant KOH solution were added with a microburette. The waiting period was 3 min. Sample solutions were titrated in a double-walled glass cell maintained at 25 ± 0.1°C by circulating water and were stirred magnetically under a continuous flow of nitrogen. Titration were performed over the pH range 2.0–12.0 using 25 ± 0.01 cm^3 samples in a medium of constant ionic strength (0.20 M KCl). There were no precipitation in the pH range in which the titration were performed. The concentration of the ligands was 5.0×10^{-4} M and the metal-to-ligand molar ratios was 1:4. Corrections for pH measurements in the aqueous–organic system were performed as described by van Uitert and Haas [20].

2.4. Calculations

The protonation constants of the ligands and stability constants of the complexes were computed form titration data using the FORTRAN programs PKAS and BEST, respectively [21]. The number of experimental (v, pH) points was more than 39 (maximum 62) for each titration. In

refining the overall constants, some experimental points, especially, around the equivalent points, were neglected. The error estimate for each constant was between 0.01 and 0.07 log units.

3. Results and discussion

3.1. Protonation constants of ligands

The protonation constants of the ligands and stability constants of the complexes are given in Table 1. For Schiff base ligands, the first constants refer to protonation of phenolate ions and the second constants to protonation of pyridine or quinoline nitrogens.

As can be seen from Table 1, the first protonation constants of PyOH and QuOH are higher than that of SAPy. This means that the electron densities of the phenolic oxygen atoms of PyOH and QuOH are higher than that of SAPy. This can be explained as follows. The lone pair on the nitrogen atom of the imino group participates in the resonance of the phenol (or quinolinol) ring and increases its electron density. The $\log K_2^H$ values of these ligands also support this observation, because the second protonation constant of SAPy is higher than those of PyOH and QuOH, contrary to the $\log K_1^H$ values of these ligands. For SAPy, SAPyCl and SAPyMe ligands, both of the protonation constants follow the order SAPyCl < SAPy < SAPyMe. Because of the inductive electron withdrawing effect of the chlorine atom, the basicity of the pyridine nitrogen in SAPyCl is lower than that of SAPy. On the other hand, the inductive electron-donating effect of the methyl group increases the basicity of the pyridine nitrogen in SAPyMe. The more basic the pyridine nitrogen is, the more stable is its proton–ligand complex.

As can be seen in Table 1, pyridine-2-carboxaldehyde benzothiazoline and quinoline-2-carboxaldehydebenzothiazoline ligands also have two protonation constants.

The potentiometric titration curve of PyS is given in Fig. 2. The high values of the first protonation constants (11.46 for PyS and 11.30 for QuS) indicate a very weak acidic proton in these molecules; it might be a methynic hydrogen atom in thiazoline ring. Since the methynic carbon is bonded to nitrogen and sulphur atoms in the thiazoline ring and to the pyridine (or quinoline) ring, the inductive electron-withdrawing effect of these three enhances the acidity of the methynic hydrogen atom to some extent.

The second protonation constants of PyS and QuS ligands (2.61 and 2.48, respectively) are lower than those of PyOH ad QuOH ligands. These lower values indicate that the second protonation occurs on either the nitrogen or sulphur atom of thiazoline ring, but not on the pyridine (or quinoline) nitrogen, although the pyridine (or quinoline) nitrogen is more basic than sulphur and nitrogen atoms of the thiazoline ring. No reasonable explanation can be given for this result.

3.2. Stability constants of complexes

First, the complex-forming reactions of Schiff base and benzothiazoline-type ligands with metal ions were investigated. For this purpose, 1:1 and 1:2 molar ratios of Pr^{3+} ion to PyOH Schiff base ligand and La^{3+} ion to PyS benzothiazoline ligand were titrated against 0.084 M KOH. The data are plotted in Fig. 1 and Fig. 2, respectively.

A break near $m = 2$ for all 1:1 systems can be explained by the release of two hydrogen ions from protonated form of the ligand molecules for each metal ion when complexes were formed. The 1:2 M:L systems contain four titratable protons per metal ion, and further there is a break in each of the curves near $m = 4$.

The complex-forming equilibria can be given as follows:

$$Ln^{3+} + H_2L^+ \rightleftharpoons LnL^{2+} + 2H^+$$

$$LnL^{2+} + H_2L^+ \rightleftharpoons LnL_2^+ + 2H^+$$

The stability constants of the Lanthanon(III) chelates of all ligands are given in Table 1. For the same ligand, the $\log K_1$ values were found to increase in the order La(III) < Pr(III) < Nd(III) < Eu(III) < Ho(III) < Yb(III), which is in accordance with the order of increasing acidity of the metal ions.

The stability constants of the complexes of three salicylidenpyridine ligands with the same metal ion also followed the same order as the proton ligand stability constants of the ligands, i.e. SAPyCl < SAPy < SAPyMe. This may be attributed to the different basicities of the donor atoms of the ligands caused by the inductive substituent effects as discussed earlier. The ML_3-type complexes of SAPyCl were not observed in the pH range in which the titration were performed, because of their low stabilities. The order of log K values of the other four ligands with the same metal ions expected is as PyOH < QuOH < PyS < QuS. Because the donor oxygen atom present in PyOH and QuOH ligands is a harder base than the donor sulphur atom present in PyS and QuS ligands, the lanthanon(III) ions, being hard acids should preferentially bond to oxygen donor ligands. Contrary to these expectations, the order of log K values of four ligands with the same metal ion was found to be PyOH < PyS < QuOH < QuS. This might be attributed to steric hindrance of quinoline ring.

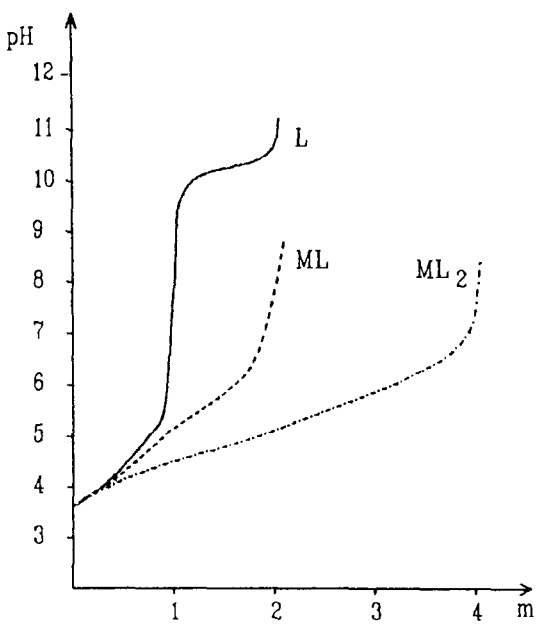

Fig. 1. Potentiometric titration curves for PyOH (L) and 1:1 and 1:2 stochiometries of Pr^{3+} to PyOH (ML and ML_2) as a function of added KOH. m = Moles of base added per mole of metal ion (or ligand) present.

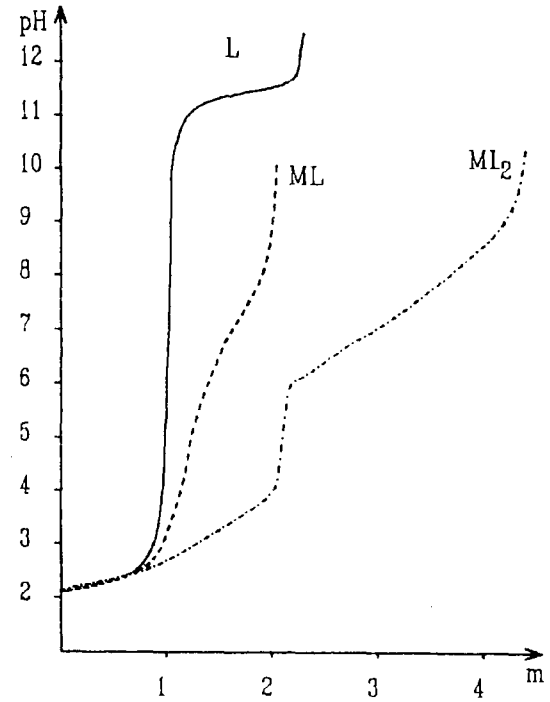

Fig. 2. Potentiometric titration curves for PyS (L) and 1:1 and 1:2 stochiometries of La^{3+} to PyS (ML and ML_2) as a function of added KOH. m = Moles of base added per mole of metal ion (or ligand) present.

The stability constants of the ML-type complexes of all ligands with the same metal ion except La(III) were found to increase in the order SAPyCl < SAPy < QuS < QuOH < PyS < PyOH < SAPyMe. The log K value of PyOH with La(III) ion was higher than that of SAPyMe.

3.3. Thermodynamic parameters

The stability constants of three salicylidenepyridine ligands with metal ions were also determined 50 ± 0.01°C and the thermodynamic parameters ΔG and ΔH for complexation reactions of their ML-type complexes were evaluated. The proton–ligand and metal–ligand stability constants decreased with increasing temperature, as expected. The thermodynamic parameters were calculated using the following relationships:

$$\Delta G = -RT \ln K$$

$$\mathrm{d} \ln K/\mathrm{d}(1/T) = -\Delta H/R$$

Table 2
Thermodynamic parameters of ML-type complexes of SAPy SAPyCl and SAPyMe with Lanthanon(III) ions at 25 ± 0.1°C and μ = 0.2 M KCl

Metal ion	Ligand	$-\Delta G$ (kJ mol^{-1})	$-\Delta H$ (kJ mol^{-1})
La^{3+}	SAPyMe	36.3 ± 0.3	36 ± 11
	SAPy	26.8 ± 0.2	28 ± 6
	SAPyCl	21.4 ± 0.4	23 ± 9

Received 1 April 1996; received in revised form 27 August 1996; accepted 27 August 1996

Abstract

Mass spectrometry was used to detect transfer of deuterium from labeled reagents to arsines following hydride-generation reactions. The arsine gases liberated from the reactions of arsenite, arsenate, methylarsonic acid, and dimethylarsinic acid with HCl and $NaBD_4$ in H_2O, or with DCl and $NaBH_4$ in D_2O, were examined. Differences in the mode of deuterium incorporation for the various arsines were detected. These results may help explain some of the observed variations in arsine-generation efficiency for various arsenic compounds present in environmental and biological samples. © 1997 Elsevier Science B.V.

Keywords: Arsenate; Arsines; Arsenic; Arsenite; Dimethylarsinic acid; Hydride generation; Mass spectrometry; Methylarsonic acid

1. Introduction

Hydride-generation (HG) methodology coupled to element-specific detectors has been used extensively for the trace determination of hydride-forming elements such as arsenic, bismuth, selenium, and antimony [1], germanium [2], tellurium and tin [3], and lead [4]. Such analyses are accomplished by first converting the metal or metalloid into its corresponding gaseous hydride followed by transfer to a spectrometric detector. HG coupled to atomic absorption spectrometry (AAS) or inductively coupled plasma mass spectrometry (ICPMS) has been used extensively for the determination of arsenic in a variety of sample types [5–10]. These methods allow the separation of analytes from the sample matrix, and provide high sensitivity and low limits of detection. For these reasons, HG techniques are widely used by the U.S. Environmental Protection Agency for the determination of the toxic elements arsenic and selenium. Hydride generation can also be interfaced with gas chromatography for the speciation of organometallics [11–13]. Because of the efficient analyte introduction into the detector afforded by HG, it may also improve the sensitivity of liquid chromatographic arsenic speciation techniques [14].

Despite its many advantages, a number of problems are associated with the HG approach. Interferences caused by transition metals have been extensively reported [15–17]. Variations in the hydride-generation efficiency for different compounds of the same element have also been reported [17–21]. To compensate for these variations, digestions usually must be performed to convert all species of an element into the same form. Even though these effects are well documented, little effort has been made to elucidate their relationship to the mechanisms involved in hydride formation.

In this report, we describe experiments in which deuterium-labeled reagents and mass spectrometry were used to study the generation of arsines from aqueous solutions. The objective was to investigate differences in the reactions generating arsine, methylarsine, and dimethylarsine. Deuterium transfer from the reagents to the generated arsines was monitored by using a mass spectrometric detector.

2. Experimental

2.1. Instrumentation

A Finnigan-MAT TSQ 700 Gas Chromatograph (GC)/Mass Spectrometer (MS) system was used for most of the experiments in this study. The instrumental operating conditions were as follows: electron impact (EI) ionization mode, electron energy 70 eV, tuning and calibration with perfluorotributylamine (FC43). A Varian 3400 GC system was equipped with a fused-silica column 0.18-mm I.D. × 20-m Crossbond® phenylmethylpolysiloxane (Restek, USA) column. A GC ion-trap mass spectrometer (Finnigan-MAT Magnum™) was also used for some of the experiments.

2.2. Reagents

The following arsenic reagents were used: dimethylarsinic acid (Sigma Chemical, St. Louis, MO), disodium methylarsonate (Chemical Service, West Chester, PA), sodium m-arsenite (Sigma Chemical), and sodium arsenate (Sigma Chemical). Solutions of each of the arsenic compounds were made up in H_2O or D_2O, depending on the experiment.

Sodium borohydride (98 atom %deuterium), deuterium oxide (99.8 atom %D), and a deuterium chloride solution in D_2O (37% w/v) were purchased from Aldrich Chemical Company, (Milwaukee, WI, USA). Hydrochloric acid (double sub-boiling distilled in quartz) was obtained from Seastar Chemical (Sidney, B.C., Canada), and sodium borohydride was obtained from J.T. Baker Chemical (Philipsburg, N.J.).

2.3. Procedures

Reactions were carried out in 2 ml glass vials with rubber septa. Unless stated otherwise, reaction conditions were as follows: 50 μl of 100 ppm arsenic solution for each of the arsenic compounds investigated, along with 50 μl of HCl (20% w/v) were added initially to the reaction vial. The vial was flushed with argon and sealed prior to the injection of 70 μl of 2% w/v $NaBH_4$. Sampling of the headspace was accomplished by inserting a syringe needle through the cap septum and withdrawing a 2 μl gas sample. The sample was immediately injected, in the splitless mode, onto the GC/MS. The following GC temperature program was used: 0.5 min at 50°C, ramped up to 150°C in 3.5 min, and held at 150°C for 3 min.

3. Results and discussion

When arsenite was reacted with DCl and $NaBH_4$ in D_2O, most of the arsine detected was non-deuterated. The mass spectrum of the gaseous products of this reaction is presented in Fig. 1a. The ion at m/z 79 (8%) indicates the presence of a small amount of AsH_2D. An experiment was conducted to examine variations in product formation over time. Hydride-generating reactions were carried out in four separate vials. Hydrides were sampled and injected onto the GC/MS at 0, 8, 18 and 28 min. The spectra obtained were identical to the one presented in Fig. 1a. From the above data it can be proposed

that hydrogen is transferred from borohydride to the arsenic atom without any further reaction of the arsine with the deuterated acid present in D_2O. To confirm this assumption, arsenite was reacted with HCl and $NaBD_4$ in H_2O. The generated arsine was deuterated, as indicated by its mass spectrum presented in Fig. 1b. The ion at m/z 80 (6%) indicates a small amount of AsD_2H present in the gaseous products. Identical mass spectra were obtained when arsenate, instead of arsenite, was used for these reactions.

When methylarsonic acid (MAA) was reacted with DCl and $NaBH_4$ in D_2O, the resulting methylarsine was a mixture of $MeAsH_2$, $MeAsD_2$, and MeAsHD (Fig. 2). To confirm the presence of these arsine species, a time-series study was conducted. Four identical reactions were carried out in separate vials, which were sampled after 0.5, 7, 14 and 22 min, respectively. The mass spectrum

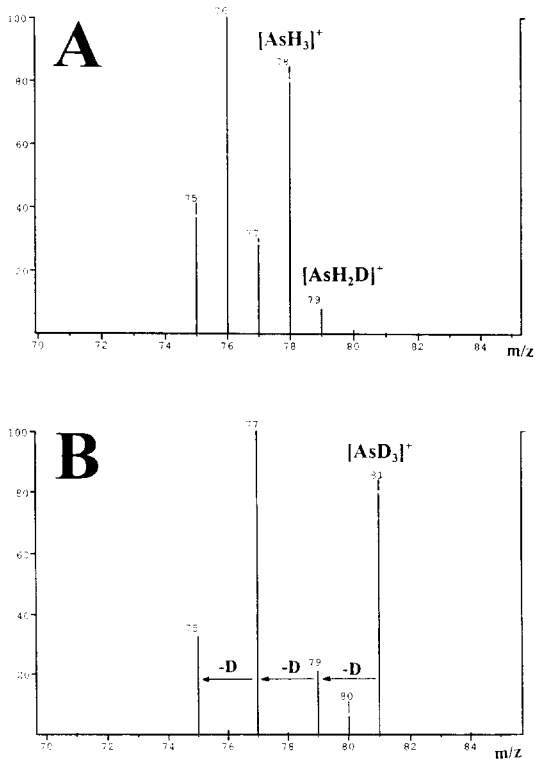

Fig. 1. A: mass spectrum of arsine generated from arsenite, DCl, and $NaBH_4$ in D_2O, B: mass spectrum of arsine generated from arsenite, HCl and $NaBD_4$ in H_2O.

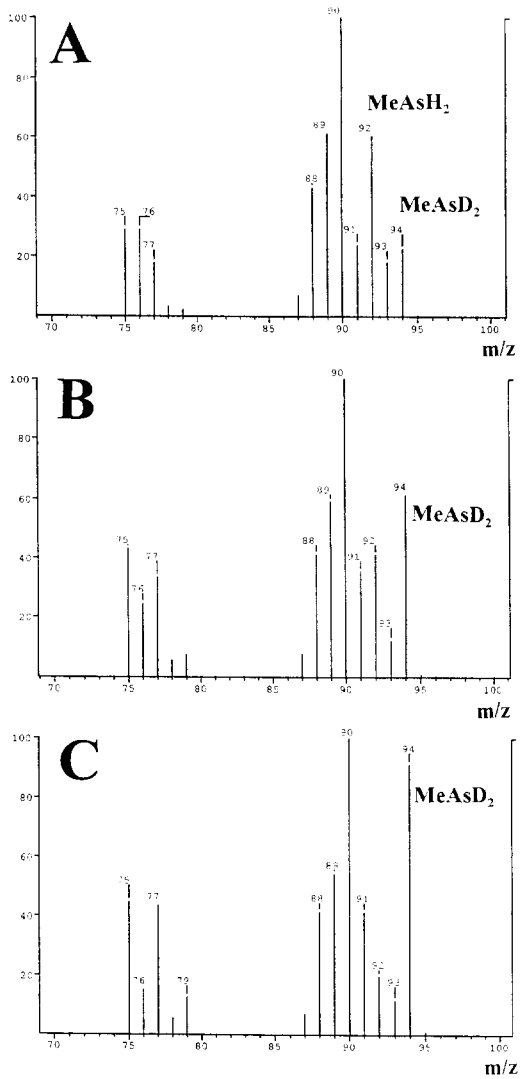

Fig. 2. Mass spectrum of methylarsine generated from methylarsonic acid, DCl, and $NaBH_4$ in D_2O, after reacting for; A: 0.5 min, B: 7 min and C: 14 min.

after 7 min is presented in Fig. 2b, and the mass spectrum after 14 min is shown in Fig. 2c. This time-series study clearly demonstrates the formation of $MeAsD_2$ (m/z 94) and the disappearance of $MeAsH_2$ (m/z 92) over time. The sample injected after 22 min did not produce a mass spectrum that matched those obtained for methylarsine. This may be due to extensive decomposition or adsorption of the methylarsine gas in the reaction vial.

Further evidence for the presence of the mixture of deuterated and non-deuterated methylarsines was extracted from the mass spectrum of $MeAsH_2$ generated from HCl and $NaBH_4$ in H_2O (Fig. 3a) and from the mass spectrum of $MeAsD_2$ generated from DCl and $NaBD_4$ in D_2O (Fig. 3b). The combination of these two mass spectra results in a mass spectrum containing ions of similar relative intensity to those shown in Fig. 2b. Similar observations were made when MAA was reacted with HCl and $NaBD_4$ in H_2O; initially $MeAsD_2$ was detected, along with a smaller amount of $MeAsH_2$. The ratio of non-deuterated to deuterated methylarsine increased with time. The gradual conversion of $MeAsH_2$ to $MeAsD_2$, and vice versa, indicates that arsines once generated may further react with acids present in the reaction mixture, thus, allowing for hydrogen-deuterium exchange.

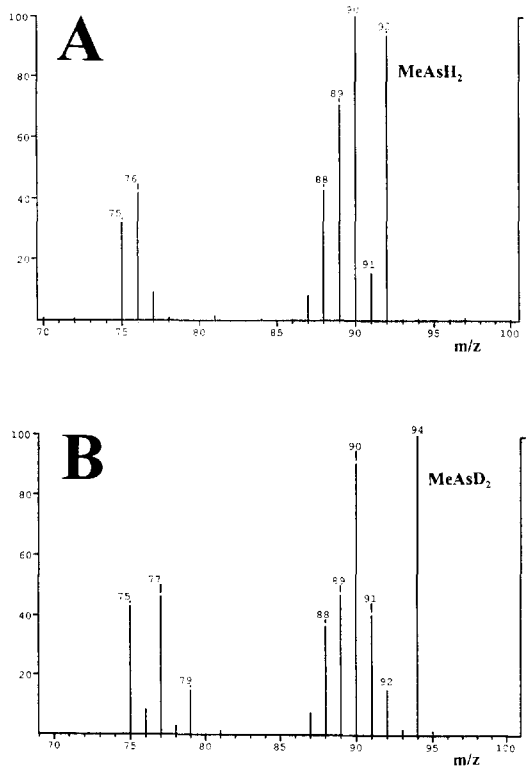

Fig. 3. Mass spectra of monomethylarsines generated from; A: HCl and $NaBH_4$ in H_2O, and B: DCl and $NaBD_4$ in D_2O.

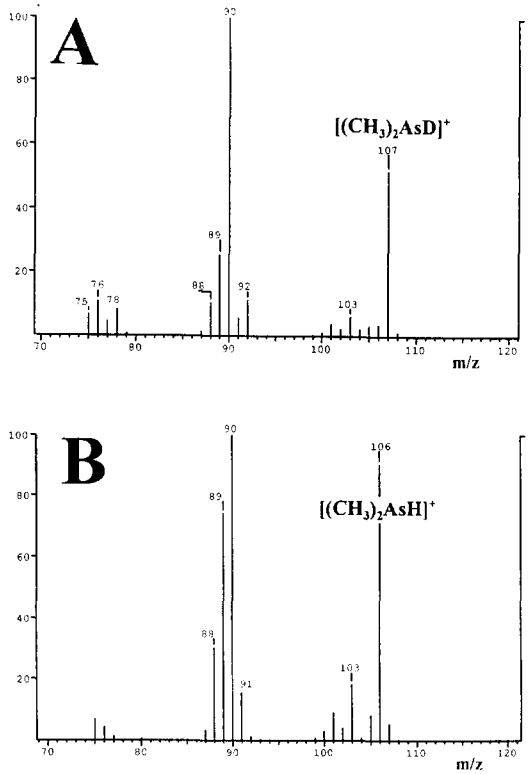

Fig. 4. A: mass spectrum of dimethylarsine generated from dimethylarsinic acid, DCl, and $NaBH_4$ in D_2O, and B: mass spectrum of dimethylarsine generated from methylarsinic acid, HCl, and $NaBD_4$ in H_2O.

When dimethylarsinic acid (DMAA) was reacted with DCl and $NaBH_4$ in D_2O, the resulting dimethylarsine was identified as Me_2AsD (Fig. 4a). When DMAA reacted with HCl and $NaBD_4$ in H_2O the resulting arsine was Me_2AsH (Fig. 4b). The products of these reactions formed rapidly and did not change over time, indicating that any hydrogen-deuterium exchange in these products is rapid. Table 1 contains a summary of the data obtained from these experiments. The reactions in Table 1 are based on data presented in this paper along with the reaction schemes proposed by others [5,22,23].

The relative rates of hydrogen-deuterium exchange for the arsines in these experiments varies in the same order as their basicity ($AsH_3 < MeAsH_2 < Me_2AsH$) [24]. Because Me_2AsH is the most basic of the three arsines, the following

protonation reaction would be expected to be the most favorable:

$$Me_2AsH + H^+ \rightleftarrows Me_2AsH_2^+ \quad (1)$$

To test the hypothesis that this protonation is involved in the observed hydrogen–deuterium exchange, an experiment was conducted in which Me_2AsD was generated in a sealed vial (vial A), and a 800-μl gas sample was then removed from vial A and bubbled through a 250-μl HCl/H_2O solution present in another sealed vial (vial B). A gas sample was immediately removed from vial B and injected onto the GC column. The resulting mass spectrum is presented in Fig. 5a. The molecular ion present at m/z 106 indicates that reaction Eq. (1) takes place rapidly, relative to the time-scale of the experiment. In a similar experiment, Me_2AsD was injected into the headspace of a vial

Table 1
Summary of arsine generating reactions carried out in this study

Arsenic compound	Proposed reactions[a]
$As(OH)_3$	**$As(OH)_3$ (aq) + BH_4^- (aq) + D^+ (aq) + D_2O** → $\underline{AsH_3\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)
$As(OH)_3$	**$As(OH)_3$ (aq) + BD_4^- (aq) + H^+ (aq) + H_2O** → $\underline{AsD_3\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)
H_3AsO_4	**H_3AsO_4 (aq) + BH_4^- (aq) + D^+ (aq) + D_2O** → $\underline{AsH_3\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)
H_3AsO_4	**H_3AsO_4 (aq) + BD_4^- (aq) + H^+ (aq) + H_2O** → $\underline{AsD_3\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)
$CH_3AsO(OH)_2$	**$CH_3AsO(OH)_2$ (aq) + BH_4^- (aq) + D^+ (aq) + D_2O** → $\underline{CH_3AsD_2(g)/CH_3AsH_2\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)
$CH_3AsO(OH)_2$	**$CH_3AsO(OH)_2$ (aq) + BD_4^- (aq) + H^+ (aq) + H_2O** → $\underline{CH_3AsD_2(g)/CH_3AsH_2\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)

$(CH_3)_2AsO(OH)$	**$(CH_3)_2AsO(OH)$ (aq) + BD_4^- (aq) + H^+ (aq) + H_2O** → $\underline{(CH_3)_2AsH\ (g)}$ + H_3BO_3/D_3BO_3 (aq) + H_2/D_2 (g)

[a] Boldface indicates reagents, underline indicates products identified by using mass spectrometry.

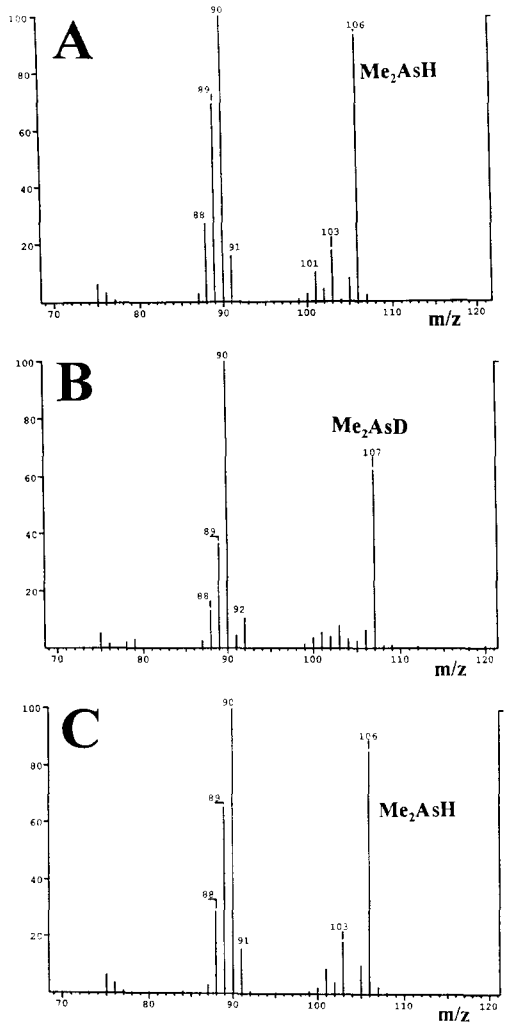

Fig. 5. Mass spectrum of gaseous products formed after bubbling; A: Me_2AsD through a HCl/H_2O solution, B: Me_2AsH through a DCl/D_2O solution, and C: Me_2AsH through a D_2O solution.

containing HCl/H_2O, rather than being bubbled through the solution. The mass spectrum obtained was identical to the one shown in Fig. 5a, thus, indicating that reaction Eq. (1) occurs even though the arsine is not bubbled through an acid containing solution. An additional series of experiments was conducted with Me_2AsH bubbled through a D_2O/DCl solution. As expected, the molecular ion appeared at m/z 107 (Fig. 5b). To further understand the acid effect on dimethy-

larsine, an experiment was conducted in which the Me_2AsH was bubbled through D_2O, in the absence of DCl. The resulting mass spectrum (Fig. 5c) did not show evidence of reaction Eq. (1) taking place because of the molecular ion present at m/z 106, not 107. These results clearly demonstrate that the protonation of dimethylarsine occurs only under acidic conditions. Also, to check if hydrogen-deuterium exchange occurs in the gas phase, a 250 μl sample of HCl/H_2O vapor was withdrawn, by using of a 500 μl gas-tight syringe, from a reaction vial containing 200 μl of HCl/H_2O. Subsequently, a 250 μl sample of Me_2AsD was withdrawn into the same syringe along with the HCl/H_2O vapor. A portion of this mixture was then analyzed by using GC/MS. The mass spectrum of dimethylarsine showed no Me_2AsH. Thus, hydrogen-deuterium exchange appears to occur only in the aqueous phase, further supporting exchange through reaction Eq. (1).

Reaction Eq. (1) can thus explain the formation of Me_2AsD when generated from DCl and $NaBH_4$, and the formation of Me_2AsH when generated from HCl and $NaBD_4$. Protonation of $MeAsH_2$ similar to that of Me_2AsH in reaction Eq. (1) would be expected to be less favored, due to the lower basicity of $MeAsH_2$. This hypothesis is supported by the more gradual hydrogen–deuterium exchange indicated by the mass spectra shown in Fig. 2. Apparently, protonation of AsH_3 does not occur to any appreciable degree. These conclusions can be further supported by the results obtained from the following experiment. A mixture of arsines (AsH_3, $MeAsH_2$, Me_2AsH) was generated in one vial, a sample of which was immediately injected onto the GC/MS. Subsequently, a 1 ml gas sample was removed from the vial and then injected into the headspace of a second vial containing 200 μl of HCl/H_2O. After 4 min, a gas sample was removed from the second vial and injected onto the GC/MS. The purpose of this experiment was to investigate any loss of arsines as a result of their dissolution in the HCl/H_2O solution. To a first approximation, if the protonation of the arsines varies in the order $Me_2AsH > MeAsH_2 > AsH_3$, then the solubility of the arsines in the aqueous acid should vary the same way. The results obtained from this experiment indicated a greater loss of Me_2AsH compared with $MeAsH_2$ and AsH_3. This was clearly observed when comparing the relative amounts of the arsines detected in the two chromatograms (Fig. 6) obtained from the arsine samples taken from the first and second vial. This experiment was conducted in triplicate, and a control was carried out in which the second vial only contained 200 μl of H_2O. The control experiment demonstrated that the arsine solubility variations observed in HCl/H_2O do not occur in H_2O.

Hinners [18] emphasized the critical effect of acid concentration on the hydride-generation responses from arsenite, arsenate, MAA, and DMAA. He was unable to find a compromise acid concentration at which the same response could be obtained for the four arsenic species. For HCl concentrations of 4–10 M, DMAA gave only 15% or less of the signal that was obtained from the same amount of arsenite. Other studies have clearly indicated that when using 5 M hydrochlo-

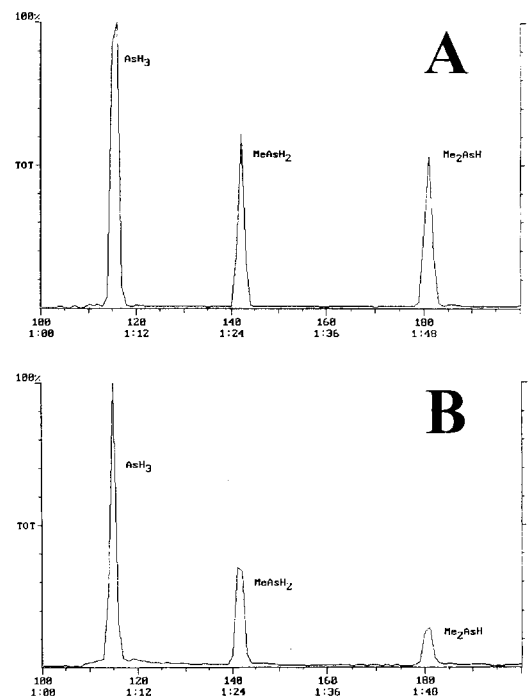

Fig. 6. GC/MS chromatograms of an arsine mixture; taken before (A) and after (B) injection of the arsine mixture into the headspace of a vial containing an HCl/H_2O solution.

ric acid, DMAA is underestimated [19]. A number of studies have demonstrated that each arsenic species has a different acid concentration for optimal efficiencies of hydride generation [14,19–21]. The results presented in this paper indicate that generated Me_2AsH further reacts with hydrochloric acid, producing a water-soluble dimethylarsonium species in equilibrium with gaseous dimethylarsine. This observation could help explain why the efficiency of generating Me_2AsH is reduced compared with the efficiency obtained when generating other, less basic, arsines.

Le et al. [7] demonstrated that by using 2% cysteine and 0.3–0.7 M HCl, maximum and identical results are obtained from all four arsenic species. It was proposed that arsenate, MAA, and DMAA, all in the As(V) state, are reduced to the As(III) state as organo-sulfur-arsenic(III) compounds through reaction between the arsenic species and thiol. These products, organosulfur derivatives of As(III), easily react with tetrahydroborate(III) under similar conditions to afford the arsines without interference from cysteine. It is our intention to further study the proposed mechanism of action of cysteine on hydride-generation of arsines, by using deuterium labeled reagents and mass spectrometric techniques.

4. Conclusion

In this study we have investigated differences governing the process of arsine generation for various arsenic compounds. The results obtained indicate that Me_2AsH reacts with hydrochloric acid forming water-soluble arsonium species. This is also expected to occur to some extent with $MeAsH_2$. However, this is not the case when arsines are generated from arsenite and arsenate. Furthermore, it was demonstrated that mass spectrometry can be a useful tool for investigating the mechanisms responsible for hydride generation.

Spectrophotometric determination of trace water in organic solvents with a near infrared absorbing dye

Mingshu Li, Gilbert E. Pacey

Chemistry Department, Miami University, Oxford, OH 45056, USA

Received 26 April 1996; received in revised form 23 September 1996; accepted 23 September 1996

Abstract

A spectrophotometric method for the determination of trace water in organic solvents using a near infrared absorbing dye has been developed. This method is based on the effect that a minor change in polarity of the solvent caused by trace water content determines the extent of aggregation of a near-infrared dye monomer. This change can be detected spectrophotometrically. The calibration curves for methanol, ethanol, and isopropanol were determined. This method has the highest sensitivity (em = 16.73 unit) for water in isopropanol and the lowest sensitivity (em = 2.806 unit) for water in methanol. The correlation coefficient $(R)^2$ values for the regression lines ranges from 0.990–0.998. The linear range of the method for ethanol is 0.001–0.5%, for isopropanol is 0.001–0.1%, and for methanol is 0.001–1.0%. The limit of detection for ethanol, isopropanol, and methanol are 0.0001, 0.0001, and 0.005% water, respectively. The developed method is sensitive, simple and easy to operate, and the cost of analysis is low. © 1997 Elsevier Science B.V.

Keywords: Infrared absorbing dye; Organic solvents; Trace water

1. Introduction

The determination of water in organic solvents has been of interest to chemists for many years [1]. The majority of water determinations in organic solvents are performed by the Karl Fisher titration [2]. The Karl Fisher titration method requires special equipment and expertise to obtain good accuracy and precision [3]. The method exhibits interferences from oxidizing agents, unsaturated compounds, and sulfur compounds [4–6]. The Karl Fisher titration method is not considered a low level method [7]. In addition, there are safety concerns about the highly toxic reagent. Recent refinements in the Karl Fisher method have concentrated on improving accuracy and extension to other solvent systems [2,4,6,8]. The Karl fisher method has been automated using flow-injection analysis [9] where improved precision and accuracy were observed, but the detection limit was a disappointing 0.03%.

Other methods that are used include thermal conductivity detection gas chromatography [10]; electrochemical sensors based on thin-film perfluorosulfonate ionomer (PFSI) coated with cellulose triacetate; polyvinyl alcohol (PVA)-H_3PO_4; or PVA-PFSI-H_3PO_4 composite films operated in a pulsed voltammetric mode [1]; an organic phase

PII S0039-9140(96)02111-X

enzyme electrode [11] where the enzyme activity has been shown to be strongly dependent upon the water content; an FIA-spectroscopic method [12] based on the reaction between group IV and V metal halides and water; HPLC methods where the water peak was detected by either electric conductivity [5] or optical absorption [13]; Solvatochromic effect [3,14,15]; and a spectrofluorimetric method [7] based on formation of the exciplex of pyridoxal. More recently, FIA-NIR spectrophotometry [16] was used for the direct determination of water in organic solvents by using the O–H stretch absorbance bands. In most of these methods either the detection limits were too high or the method did not work in highly polar solvents.

During investigations of near infrared dyes in this laboratory, it was observed that these dyes appeared to be unstable in alcohol solvents at room temperature. However, this instability was not observed in extremely dry alcohols. Upon further investigation, it was discovered that the dye dimerized or polymerized in the alcohol solutions. The extent of polymerization depends on the solvent polarity, temperature, and the basicity. Trace amount of water in the solvent alters the polarity of the solvent and that the polymerization reaction was directly proportional to the water concentration in the alcohol. This paper discusses a new near infrared dye, spectrophotometric method for the determination of low level water in polar organic solvents.

2. Experimental

2.1. Chemicals

Methanol was purchased from Fisher Scientific (acetone free, absolute methanol with water concentration of 0.02%). This methanol was further purified as suggested by Lund and Bjerrum [17]. A 200 ml volume of methanol reacted with 24 g of magnesium turnings for 6 h (reaction is vigorous under heating). A 3 l amount of methanol was added and the mixture was refluxed for 5 h and then the methanol was distilled into 500 ml glass bottles containing 5 g of molecular sieves. The first 50 ml of collected methanol was discarded. This procedure produced about 2 l of dry methanol. Ethanol was obtained from Quantum Chemical Corporation (200 proof dehydrated alcohol with water concentration of 0.02%) and was further purified with the same method as used for methanol. Isopropanol was purchased from fisher Scientific (suitable for electronic use, water concentration was 0.04%) and was dried with molecular sieves for 2 weeks.

2.2. Synthesis of the near infrared dye

The near infrared dye, 2-[4′-chloro-7-(3″-ethyl-2″-benzothiazothiazolinylidene)-3′,5′-(1″,3″-propanediyl) - 1′3′5′ - heptatrien - 1′ - yl] - 3 - ethylbenzothiazolium iodide as shown in Fig. 1, was prepared as the bromide analog [18]: ethyl iodide and 2-methylbenzothiazole were refluxed in dimethlyformamide at 153°C overnight. The mixture was refrigerated for 2 h and then slowly added diethyl ether to initiate crystallization of the product. The crystals were filtered, washed with diethyl ether, and dried under reduced pressure. The dried product, 3-ethyl-2-methyl-benzothiazolium iodide, was refluxed with *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohene-1-yl)-methylene]analene momohydrochloride in ethanol under the presence of anhydrous sodium hydrochloride for 1 h and kept in a refrigerator for 1 h. The crystals were filtered off, washed with distilled water, benzene, and ether and dried under a vacuum. The product was recrystallized in ethanol and dried under a vacuum at 50°C for 6 h. The nuclear magnetic resonance spectrometry (NMR) and matrix assisted laser desorption ionization mass spectrometry (MALDI-MS) spectra were presented in Fig. 2 and Fig. 3.

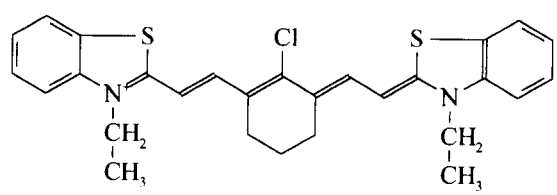

Fig. 1. Structure of dye 1.

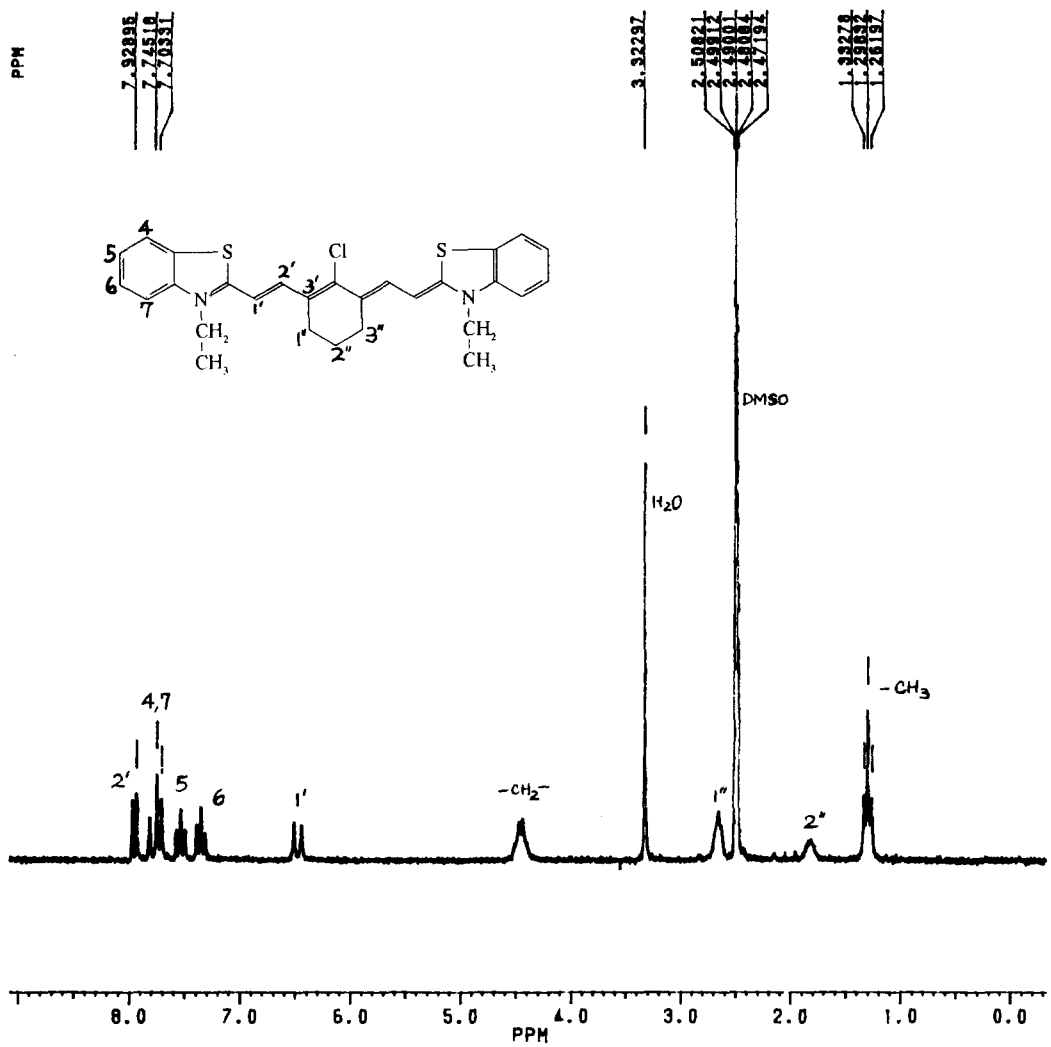

Fig. 2. NMR spectrum of dye 1. 200 MHZ NMR, DMSO as solvent.

2.3. Safety consideration

Methanol, ethanol, and isopropanol are highly flammable and toxic by inhalation, in contact with skin, and swallowed. Chloroform is volatile at room temperature and is highly toxic cancer suspect agent.

2.4. Apparatus

A Hewlett Packard 8452A Diode Array Spectrophotometer was used to scan the spectra and absorbance measurements. Tekmar utility bath was used for heating and temperature control. All glassware was cleaned with detergent, rinsed with distilled water, rinsed with acetone, dried in the oven at 100°C for 1 h and cooled in a dedicator before use. MALDI-MS spectra were obtained with the Bruker Reflex II TOF-MS mass spectrometer equipped with a Nd:YAG laser model Minilase-10. NMR spectra were acquired with Bruker AC-200 MHZ NMR spectrometer.

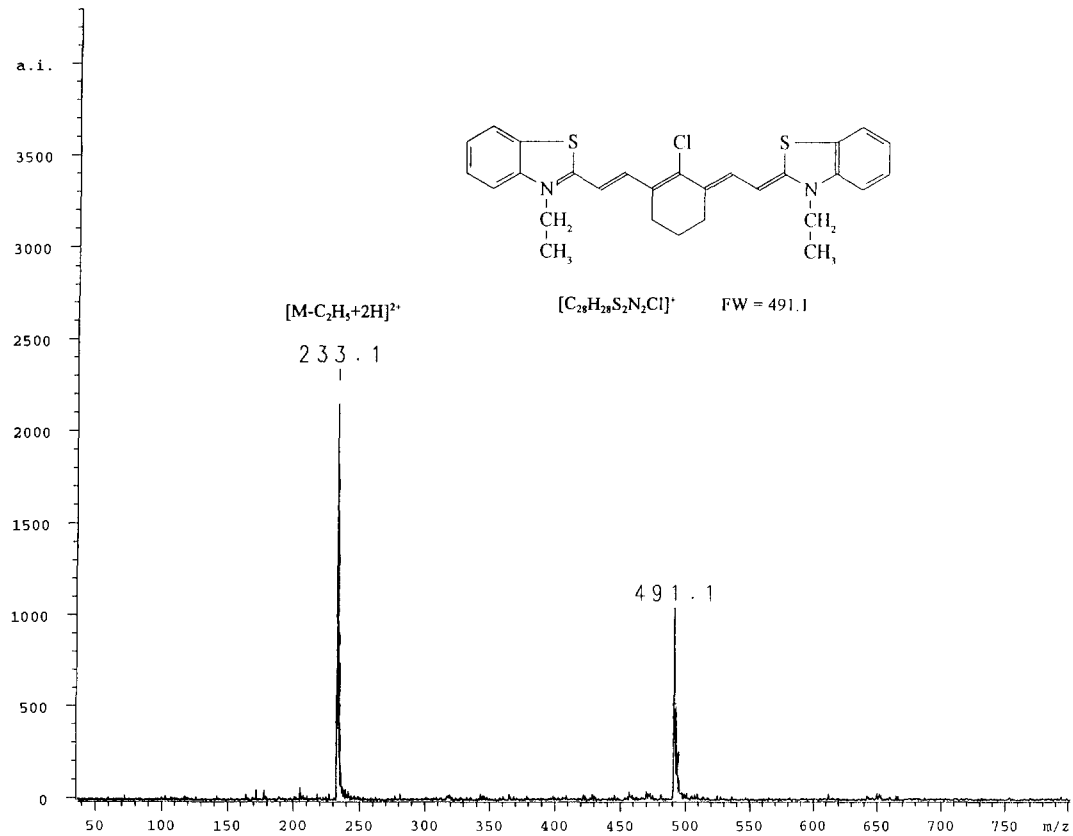

Fig. 3. MALDI-MS spectrum of dye 1. Nd:YAG laser (355 nm), matrix was α-cyano-4-hydroxy cinnamic acid, and CH_3CN as the solvent. Number of shots was 40.

2.5. Reagents

1.125×10^{-3} M dye solution was made in methanol–chloroform (50:50) solution and was kept in the refrigerator. Upon storage, aggregates of the dye were formed and the solution was no longer useful for the analysis. The solution can be dept up to 2 months in a refrigerator and 1 week at room temperature. A 1.0×10^{-3} M potassium hydroxide solution was prepared as follows: dissolve a certain amount of potassium hydroxide in dried ethanol, filter the solution, and dilute to the volume with ethanol. The standard stock solution of 1% water was made with dried solvents and deionized water.

2.6. Procedure

A 10 ml volumetric flask was filled about half full with the sample solution, add 0.2 ml of KOH solution and 0.2 ml of dye solution, and then dilute with the sample to the volume and mix well. The solution mixture was placed into a hot water bath with the cap on at 60–70°C for 10 min and cooled at room temperature for 15 min. The reduction of absorbance was measured at about 800 nm depending on the solvents. The water concentration in the solvents was derived from the calibration curve. The calibration curve was obtained by measuring the absorbance of 0, 50, 100, 200, 300, and 500 ppm (v/v) standard solutions.

These standard solutions were prepared in 10 ml volumetric flasks adding 0, 0.05, 0.10, 0.20, 0.30 and 0.50 ml water working solution (10 000 ppm) and following the same procedure of sample analysis described above.

3. Results and discussion

Near-infrared dyes absorb light between 600–1200 nm and exhibit large molar absorptivities ($\approx 200\,000$ Abs cm^{-1} M^{-1}), thereby enhancing their potential for low level detection. In addition, most NIR dyes are strongly fluorescent in solution [18–20]. When NIR dyes are used for analytical applications, detection can be carried out in the longer wavelength regions creating a reduced background and interferences from coexisting species. Despite these attributes and the large number of NIR dyes available, the use of NIR dyes has not gained much attention in analytical applications. Dye I has been used as a hydrophobicity probe for aliphatic alcohols and other water-miscible organic solvents [18] with water/organic solvent ratio ranged from 50–100 (pure water). This dye has a molar absorptivity of 1.83×10^5 [18] and absorbance maximum wavelength of 800 nm in ethanol. Absorption spectra of the dye changed significantly depending on the solvent hydrophobicity. With higher concentration (over 50%) methanol, the maximum absorption band of the dye solution was at 811 nm. When the methanol concentration was decreased from 50% to 0 (pure water), the absorption peak at 811 nm disappeared and a new peak at 698 nm appeared. It was suggested that the observed change in the NIR absorption spectra is a result of dye dimerization [18].

It is known that aqueous NIR dye solutions, especially at higher dye concentrations, exhibit an absorption band different from the absorption band that can be observed in less concentrated solutions or in less polar organic solvents. These spectral changes have long been attributed to dye molecule aggregation. The NIR dyes also display this type of behavior in water, where they tend to form dimmers ($\lambda = 698$ nm) or higher aggregates ($\lambda = 450 - 500$ nm) because of the strong dispersion forces associated with the high polarizability of the polymethane chain [21]. Experimental results in this lab revealed that dimerization conditions for the cyanine dyes depend on the following factors: dye concentration, water concentration, temperature, reaction time, exposer to light, and the basicity of the solution. The dependence of the dimer formation on the dye concentration and water content in the solution has been proven by West and Pearce [21] and Patonay et al. [18]. Dimmers usually do not form in pure organic solvents. The dimmersband and the higher-aggregate band were observed at 698 and 450 nm, respectively, in 1×10^{-5} M aqueous solutions. Fig. 4 presents the spectra obtained in this lab for the dye in 60% water/ethanol solution with increasing basicity and reaction time. Five peaks are observable in the wavelength range of 320–820 nm. The peak at 800 nm is the dye monomer, 692 nm is the dimer peak, and the rest are the peaks for higher aggregates of the dye. As the solution basicity increased, the 656 nm and 380 nm aggregate peaks were decreased and the 496 nm peak increased, the 692 nm dimer peak initially persisted and then started to decrease when the 656 nm peak disappeared. As the 656, 698, 380 nm aggregate peaks decreased, the 800 nm monomer peak increased until the dimer peak became a shoulder of the monomer peak and then decreased with increasing basicity.

These changes in the spectra indicate that dimers form in neutral solutions at high concentrations of water in aliphatic alcohols. When a small amount of base is added, the polymer at 656 nm and the dimer decompose to their monomer. When the basicity is further increased, polymerization to higher aggregates happens. Using the optimized conditions for the method, the 656 and 698 nm peaks did not exist (Fig. 5), instead, higher aggregates represented by the peak at 496 nm were formed.

There are at least three isosebestical points at 575, 405 and 363 nm. These points indicate that there are three equilibrium systems in the solution. In the solution without added basicity (spectrum 1 in Fig. 4(a)), dimers and the aggregates at 656 nm were formed and there is equilibrium between the aggregate of 656 nm and the monomer. With increasing basicity (spectra 2–5 in Fig. 4(a)), the dye is distributed between the dimers and the aggregates at 496 nm. When the

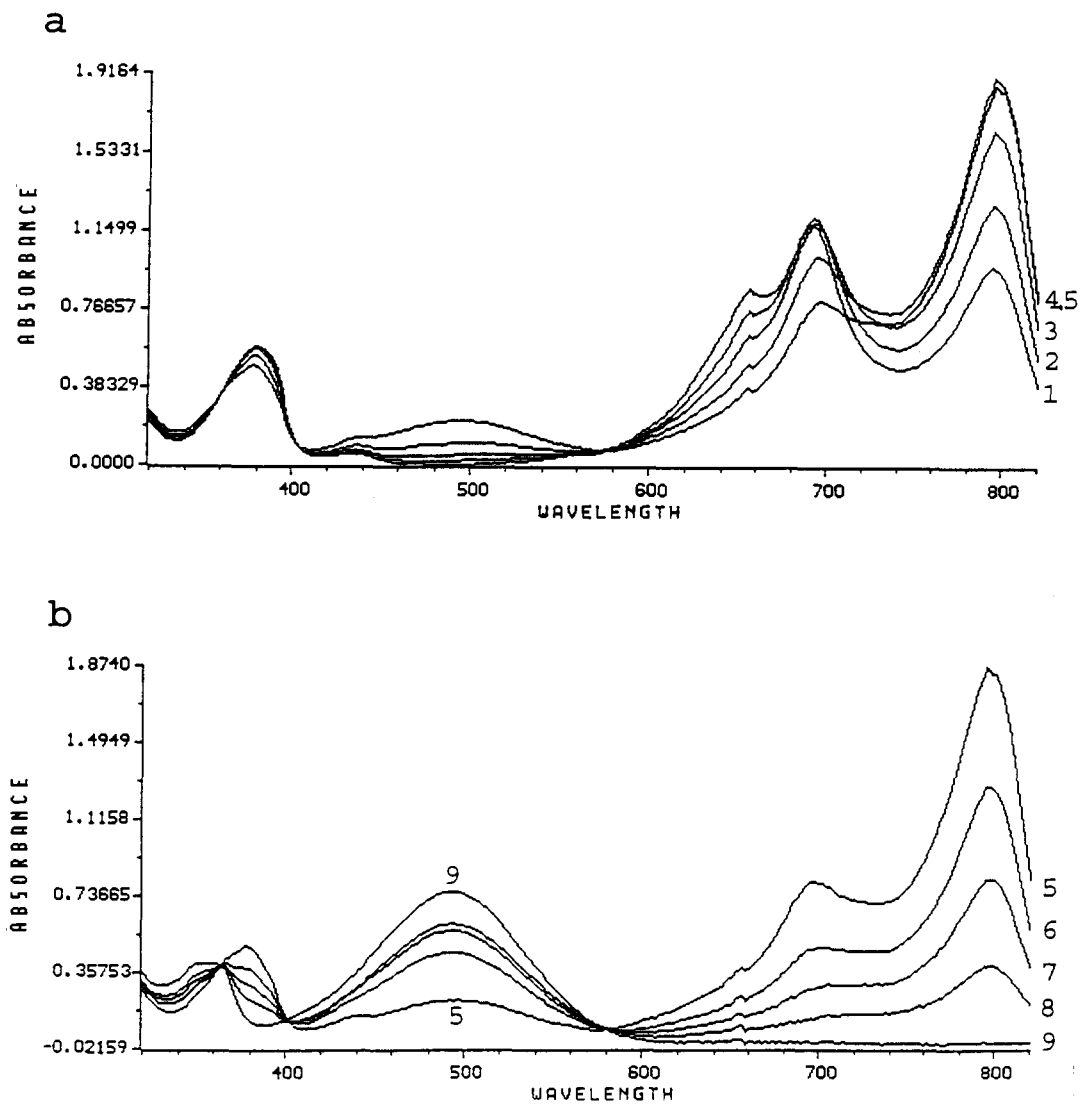

Fig. 4. Absorption spectra of the dye in 60% water/ethanol solution: (a) with different KOH concentration: 1-neutral solution; 2–2.8 × 10^{-4} M; 3–8.4 × 10^{-4} M; 4–1.4 × 10^{-3} M; 5–2.8 × 10^{-3} M; (b) under different reaction time: 5–5 min; 6–10 min; 7–20 min; 8–35 min. Spectrum 9 was obtained after heating the solution of 2.8 × 10^{-3} M in KOH 10 min at 70°C.

basicity of the solution was further increased or the basic solution sat for long time (spectra 6–8 in Fig. 4(b)), the equilibrium shifted toward the monomer and the polymer at 496 nm. The polymerization rate of the monomer to the aggregate at 496 nm is slow. It took 30 min to convert spectrum 5–8 in Fig. 4(b) at room temperature. But when the solution was heated for 10 min at 70°C, the conversion was completed almost immediately (spectrum 9 in Fig. 4(b)).

When the system was going through higher-aggregation and a reduction of the monomer peak was observed, the sensitivity was higher than the dimerized system. This was one of the reasons that the determination of trace amount of water in organic solvents is possible in this method. Representative absorption spectra of the dye in dry ethanol (spectrum 1) and in 0.05% water in ethanol solution (spectrum 2) are presented in Fig. 5. The peak reduction at 800 nm was used for

the quantitative analysis of trace water concentrations in organic solvents.

As it was mentioned earlier, besides the dye concentration and water content in the system, basicity of the solution is an important factor for the process being dimerization or higher-aggregate formation. It can be seen in Fig. 4(a) that dimers were formed in neutral ethanol solutions and with increasing basicity the dimer peaks would disappear. When the solution was basic and heated at a certain temperature for a period of time, even a little change in polarity by trace amounts of water in the solvent caused aggregation of the dye in the solution. The extent of aggregation was proportional to the water concentration in the solvent. Both monomer and *H*-aggregate peaks can be used for the measurement, but he monomer peak at 800 nm is the most sensitive.

Basicity of the solution was adjusted by adding different amount of KOH/ethanol solution. Reagent grade KOH was kept in a desiccator and the carbonate impurities were insoluble in alcohols and were removed by filtration. The result of the basicity experiment is shown in Fig. 6. With increasing KOH concentration from $0–8.0 \times 10^{-4}$ M, the net absorbance of 0.05% water/ethanol solution increased, reaching a maximum at 4×10^{-4} M of KOH. Therefore, the KOH concentration of 4×10^{-4} M was chosen.

It was pointed out [18] that formation of *H*-aggregates of the dye was observable in 1×10^{-4} M aqueous solution. If the concentration is lower

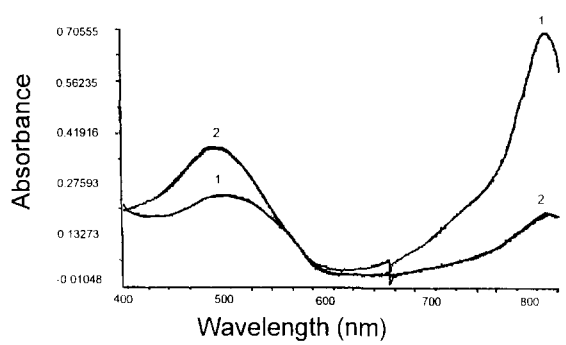

Fig. 5. Absorption spectra of the dye in dry ethanol [1] and in 0.05% water/ethanol solution [2].

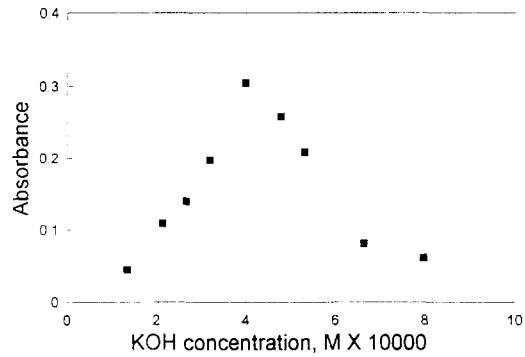

Fig. 6. Effect of KOH concentration on the absorbance of the dye in water/ethanol solution.

than 1.25×10^{-5} M, then the higher aggregate band diminished. In the range of dye concentration tested, no dimer peaks were seen. When the dye concentration increased from $0–1.3 \times 10^{-4}$ M, the absorbance for both blank and 0.2% water/ethanol solutions increased (Fig. 7(a)) and reached the maximum absorbance. The rates of absorbance increases were different. Blank absorbance was increasing faster than the water solution. The absorbance difference between blank and water solution was biggest at the dye concentration of 6.8×10^{-5} (Fig. 7(b)). Since at this concentration the absorbance of dry solvent was about three absorbance unit, accurate absorbance measurement is questionable. Therefore, a dye concentration of 4.5×10^{-5} M was selected.

Heating prevented dimer formation and catalyzed the higher aggregation process. Heating was also the main factor for the dye responding to trace water concentration. At room temperature, the lowest water concentration measurable was 1% in ethanol after 45 min. When the solution was heated, there were some changes in the spectral properties of the dye (Fig. 8). Both in dry ethanol and 0.05% water/ethanol solution, the peak at 800 nm shifted to 816 nm and the peak at 460 nm move to 495 nm when the temperature increased from 43.2–62.3°C. The peak reduction at 800 nm was much bigger in the water/ethanol solution than in dry ethanol. When the temperature of the solution was increased, the absorbance for both blank and 0.05% water/ethanol solution decreased (Fig. 9). After about 50°C, the blank

absorbance persisted and remained constant up to 85°C. The absorbance of 0.05% water solution was further decreased and kept constant between 60–85°C. The maximum absorbance difference occurred between 60–70°C. Therefore, heating at 60–70°C was utilized. The aggregation reaction under elevated temperature was a reversible process. Heating provided the energy for shifting the reaction equilibrium toward the formation of the aggregates. When the solution was cooled at room temperature, absorption peak of the monomer increased with decreasing temperature and was stable after 15 min at room temperature.

Formation of the aggregates at 496 nm from their monomers was a relatively slow process.

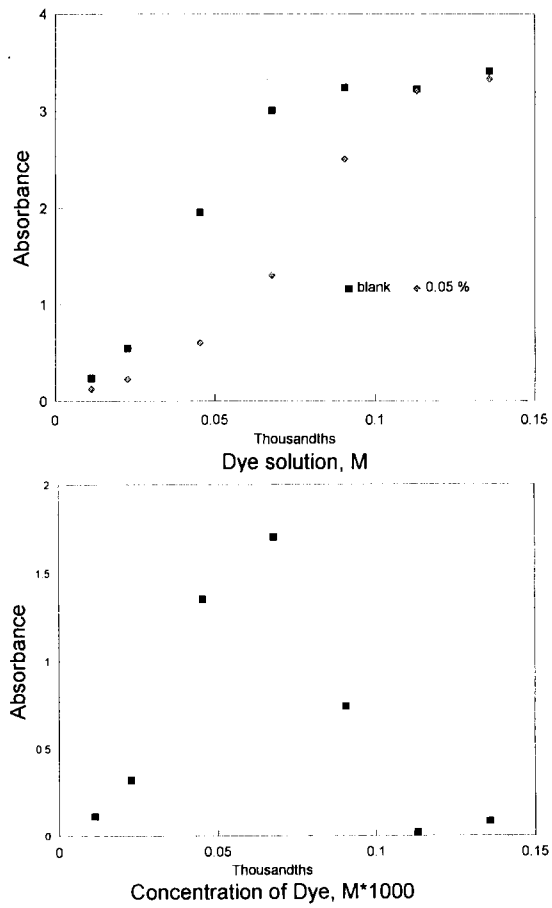

Fig. 7. Effect of the dye concentration. (a) Absorbance of the dye in dry ethanol and 0.05% water/ethanol solution. (b) Net absorbance of the 0.05% water solution.

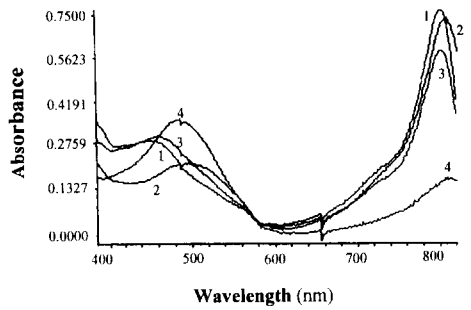

Fig. 8. Absorbance spectra of the dye at different temperature and water contents. Spectra 1 and 2 are for dye in dry ethanol at 43.2 and 62.3°C, respectively. Spectra 3 and 4 are for the dye in 0.05% water in ethanol solution at 43.2 and 62.3°C, respectively.

After 30 min at room temperature, the conversion process was still active (Fig. 4(b), spectrum 8). At higher temperature, aggregate formation immediately complete in higher concentration of water/ethanol solution. When water concentration is very low (0.1–0.001%), heating was needed to catalyze the aggregation process. Fig. 9 is the result of the experiment to determine the reaction time needed at 70°C. With increasing heating time from 0–30 min, the absorbance of the blank solution was decreased at almost a constant rate. But 0.05% water solution exhibited rapid reduction in absorbance between 0–10 min heating at 70°C was utilized, Fig. 10.

Calibration curves (Fig. 11) were obtained under the optimized conditions for methanol,

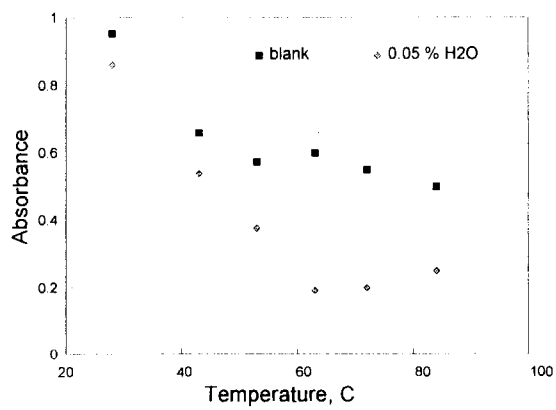

Fig. 9. Temperature effect of the dye in dry ethanol and 0.05% water/ethanol solution.

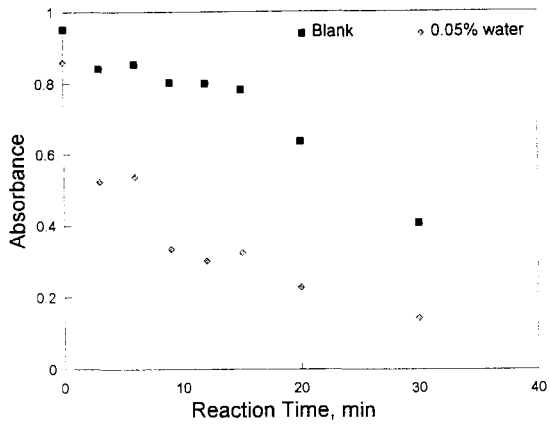

Fig. 10. Effect of heating time on the dye absorbance dry ethanol and 0.05% water/ethanol solution.

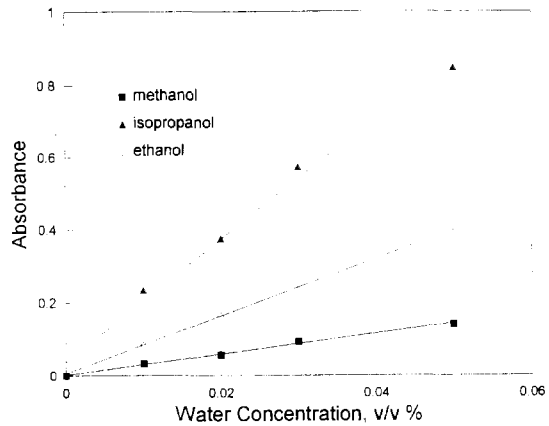

Fig. 11. Calibration curves.

ethanol, and isopropanol and the results of the curves are summarized in Table 1. This method has the highest sensitivity (em = 16.73 unit) for water in isopropanol and the lowest sensitivity (em = 2.806 unit) for water in methanol. The correlation coefficient $(R)^2$ values for the regression lines ranged from 0.990–0.998. The linear range of the method for ethanol is 0.001–0.5%, for isopropanol is 0.001–0.1%, and for methanol is 0.001–1.0%. The limit of detection for ethanol, isopropanol, and methanol are 0.0001, 0.0001 and 0.005% water with relative standard deviations of 2.62, 2.25 and 2.59% at 0.05% water concentration, respectively. The limits of detection depend mostly on the preparation of dry solvents.

4. Conclusions

In this study we demonstrated for the first time that trace amount of water in polar organic solvents can be determined by the fact that a minor change in polarity of the solvent caused by trace water content determines the extent of aggregation of a near-infrared dye monomer, which can be detected easily by measuring the absorbance reduction at 800 nm. By using a NIR dye, the detection was moved to longer wavelength where background interferences were minimized. Sensitivity of the method was very high, owing to the high molar absorptivity of the dye solution and formation of a higher aggregate in the system. The limits of detection were lower than that of most reported methods. The developed method is simple, easy to operate, and the cost of analysis is low. Current work in our laboratory concerns the possibility of applying this method to different organic solvents.

Table 1
Results of calibration curves

Solvent	Equation A = $a+b$ [C]	R^2	Linear range v/v, %	LOD v/v, %
Methanol	$a = 0.002649 \pm 0.004509$ $b = 2.806 \pm 0.117$	0.991	0.001–1.00	0.005
Ethanol	$a = 0.006375 \pm 0.006375$ $b = 7.825 \pm 0.153$	0.998	0.001–0.10	0.001
Isopropanol	$a = 0.03783 \pm 0.03462$ $b = 16.73 \pm 0.82$	0.995	0.001–0.50	0.001

Simultaneous determination of mebendazole and pyrantel pamoate from tablets by high performance liquid chromatography–reverse phase (RP-HPLC)

A.P. Argekar *, S.V. Raj, S.U. Kapadia

Analytical Laboratory, Department of Chemistry, The Institute of Science, 15 Madam Cama Road, Mumbai 400 032, India

Received 3 June 1996; received in revised form 19 September 1996; accepted 27 September 1996

Abstract

A new, simple, precise, rapid and stability indicating RP-HPLC method has been developed for the simultaneous determination of mebendazole and pyrantel pamoate from tablets. Chromatography was carried out on a Shodex C8 column using a mixture of 0.05 M monobasic sodium phosphate: acetonitrile: triethylamine (60:40:1.5, v/v), adjusted to pH 6.8 with phosphoric acid. Detection was carried out at 290 nm using a UV detector. Retention times for pamoic acid, pyrantel base and mebendazole were 3.61, 6.41 and 12.81 min, respectively. Linearity was obtained in the concentration range of 20–160 μg and 30–240 μg for pyrantel pamoate and mebendazole, respectively. The method after its application for the assay of pyrantel pamoate and mebendazole from tablets, was statistically evaluated for its accuracy and precision. © 1997 Elsevier Science B.V.

Keywords: High performance liquid chromatography; Mebendazole; Pyrantel pamoate

1. Introduction

Mebendazole (MEB) chemically, methyl 5-benzoyl 1-H-benzimidazol-2-ylcarbamate,is an anthelmintic drug [1]. It is official in I.P. [2], B.P. [3], U.S.P. [4]. Various methods, such as spectrophotometry [5] and HPLC [6,7] are reported in the literature for its determination from formulations and biological fluids.

Pyrantel pamoate (PYP) chemically, 1,4,5,6-tetrahydro-1-methyl-2-[(E)-2-(2-thienyl)vinyl]-pyrimidine 4,4′-methylenebis (3-hydroxy-2-napthoate), is an anthelmintic drug [1]. It is official in U.S.P. [4]. Various methods, such as Ion selective electrode [8] and HPLC [9,10] are reported in the literature for its determination from formulations and biological fluids Fig. 1.

Fixed dose combinations containing MEB and PYP are widely available in the market, however there is no reported method for the simultaneous determination of these two drugs from formulations.

We report in this paper a new RP-HPLC method for the simultaneous determination of MEB and PYP from tablets, which is simple, precise, rapid and stability indicating.

2. Experimental

2.1. Instrumentation

High pressure liquid chromatograph (HPLC) Tosho CCPE pump equipped with a universal injector and an integrator (Oracle-2) were used.

2.2. Solvents and chemicals

Reference standards of mebendazole and pyrantel pamoate procured from Tata Pharma, Patalganga, Maharashtra, India. These standards were tested as per U.S.P. Monographs, 23, and were found to be 98.93 and 99.07% pure, respectively. Tablet formulations were procured from the market. A.R. Grade diethylamine (DEA), triethylamine (TEA), phosphoric acid, monobasic sodium phosphate were used. Acetonitrile and methanol were of HPLC grade, supplied by S.D. Fine Chemicals, Thane, India.

2.3. Mobile phase

A mixture of 0.05 M monobasic sodium phosphate: acetonitrile: triethylamine (60:40:1.5, v/v), adjusted to pH 6.8 with dilute phosphoric acid was used as a mobile phase.

2.4. Stationary phase

C_8 Shodex column (3.9 mm × 25 cm) (5 μ).

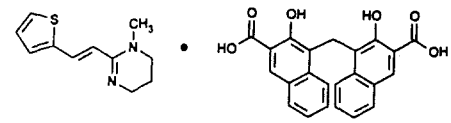
2.5. Diluents

Acetonitrile: diethylamine: acetic acid (90:10:10, v/v).

2.6. Standard stock solution

Accurately weighed 50 mg of standard PYP and 75 mg of standard MEB were taken in a 50 ml volumetric flask. Glacial acetic acid, 15 ml, was added and kept in an ultra sonic bath for 30 min, then it was kept on a boiling water bath for 15 min. The solution was cooled,then 30 ml of diluent was added in a hood and kept in an ultra sonic bath for 10 min. Volume was made upto the mark with the diluent. Standard stock solution, 3 ml, was taken in a 50 ml standard volumetric flask, diluted upto the mark with the mobile phase and used as a working standard.

Pyrantel Pamoate



Mebendazole

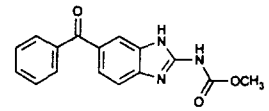


Fig. 1. Structure of pyrantel pamoate and mebendazole.

2.7. Sample solution

Tablets, 20, were weighed and finely powdered. An accurately weighed portion of the powder equivalent to 50 mg of PYP and 75 mg of MEB

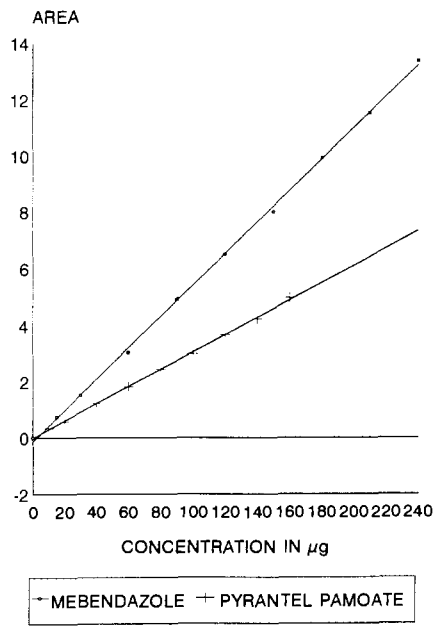

Fig. 2. Calibration curve of mebendazole and pyrantel pamoate.

Table 1
Parameters of system suitability

Sr. No.	Parameters	PYP	MEB
1.	Theoretical plates	5000	8000
2.	Resolution factors	1.64	2.28
3.	Tailing factor	1.3	1.1
4.a.	R.S.D.—Brand I (%)	1.23	0.95
4.b.	R.S.D.—Brand II (%)	0.97	0.89
5.	Relative retention time of pyrantel base to pamoic acid	—	1.0:0.53
6.	Limit of detection (μg)	10	15
7.	Limit of quantification (μg)	40	60

was taken in a 100 ml volumetric flask. About 25 ml of glacial acetic acid was added and kept in an ultrasonic bath for 30 min. It was then kept on a waterbath for 20 min, cooled and diluted with 65 ml of diluent A in a hood and then sonicated for 20 min. Volume was made upto the mark with the diluent and mixed—(Solution A). This solution was filtered through Whatman No. 42 filter paper. The filtrate solution, 6 ml aliquot, was taken in a 50 ml volumetric flask, diluted upto the mark with mobile phase and then used for the analysis.

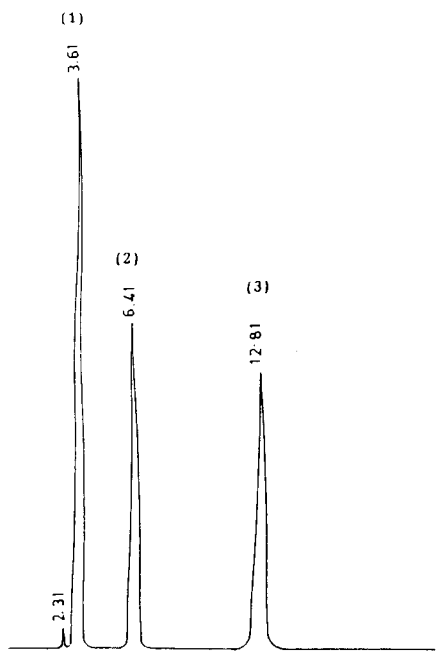

Fig. 3. Typical chromatogram of mebendazole and pyrantel pamoate.

2.8. Calibration

Aliquots of standard stock solution of MEB and PYP were taken in different 10 ml standard volumetric flasks and diluted upto the mark with mobile phase such that the final concentrations of MEB and PYP were in the range of 30–240 μg and 20–160 μg, respectively. Evaluation of both drugs were performed with a UV detector at 290 nm. Peak areas were recorded for all the peaks Fig. 2.

2.9. Assay

Each of the standard and the sample solutions were injected into the chromatographic HPLC system and peak areas were recorded as described in the calibration procedure.

From the peak area of MEB and PYP, the respective amounts were computed as,

$$\text{Amount of MEB and PYP*} = \frac{\text{Rspl} \times C \times D \times \text{Average wt.}}{\text{Rstd} \times W} \times \text{Factor*}$$

where,

Rspl = area of MEB or PYP in sample solution.

Rstd = area of MEB or PYP in standard solution.

Table 2
Results of HPLC assay from tablets

	Sr. No.	Pyrantel base (mg Tab^{-1}) (label claim: 100 mg Tab^{-1})	Mebendazole (mg Tab^{-1}) (label claim: 150 mg Tab^{-1})
Brand I	1	98.02	150.33

	2	98.17	150.81
	3	98.75	150.47
	4	100.62	148.35
	5	98.45	148.72
	Mean	98.96	149.95
	R.S.D.	0.97%	0.89%

C = concentration of standard in mg ml^{-1}.
D = dilution factor.
W = weight of tablet in mg.
Factor = 0.347, conversion factor for PYP to PYRANTEL base.

3. Results and discussion

3.1. System suitability

According to U.S.P. 23, method (621), system suitability tests are an integral part of gas and liquid chromatographic methods. They are used to verify that the resolution and reproducibility of the chromatographic system are adequate for the analysis to be done. To ascertain its effectiveness system suitability tests were carried out on freshly prepared standard stock solution of MEB and PYP and the parameters obtained are shown in Table 1. The results are in concurrence with U.S.P. 23 requirements.

3.2. Chromatography

The mobile phase resolved the two drugs very efficiently into three distinct peaks of pamoic acid, pyrantel base and mebendazole as shown in Fig. 3. The retention times of pamoic acid, pyrantel base and mebendazole were about 3.61, 6.41 and 12.81 min, respectively. The relative retention times of pamoic acid and pyrantel base were about 0.55 and 1.0 min, respectively, which corresponds to relative retention times given for the same in U.S.P. monographs for PYP. A wavelength of 290 nm was selected for the detection purpose to match the sensitivities of these two drugs.

3.3. Linearity, limit of detection and determination

The plot of peak area, versus the respective concentrations of MEB and PYP were found to be linear in the range of 30–240 and 20–160 μg (Fig. 2). They were represented by linear regression equations:

$$Y_{MEB} = 50.56555 \times + 0.37205 \quad (r = 0.999)$$

$$Y_{PYP} = 30.33034 \times + 0.38508 \quad (r = 0.999)$$

The limit of detection (LOD) and the limit of quantification (LOQ) of MEB and PYP were calculated on the peak area using the following equations:

$$LOD = 3 \times N/B; \; LOQ = 10 \times N/B$$

Table 3
Results of recovery analysis from tablets

Brand	Drug	Amount of drug added (mg)	Amount found* (mg)	S.D. (±)	R.S.D. (%)
I	PYP	0	99.23	0.85	0.85
		20	118.28	1.31	1.11
		40	138.16	0.92	0.67
		60	158.22	1.28	0.81
% Recovery = 98.43%					
II	PYP	0	98.68	0.92	0.93
		20	118.62	1.09	0.92
		40	138.15	0.98	0.71
		60	158.33	0.97	0.61
% Recovery = 98.90%					
I	MEB	0	150.11	1.54	1.02
		30	179.18	1.46	0.81
		60	208.24	1.65	0.79
		90	237.26	1.64	0.69
% Recovery = 98.53%					
II	MEB	0	149.94	1.27	0.85
		30	177.84	1.59	0.89
		60	207.79	1.68	0.81
		90	237.89	1.55	0.65
% Recovery = 98.29%					

*Average of three experiments.

Where N, the noise estimate, is standard deviation of the peak areas (five injections) of the drugs, B is the slope of the corresponding calibration curve. The limit of detection/the limit of quantification for MEB and PYP were found to be 15 μg/60 μg and 10 μg/40 μg respectively.

3.4. Assay

The contents of MEB and PYP (equivalent to pyrantel base) per tablet for two commercial brands found by the proposed method were 150.43 mg Tab^{-1} (R.S.D. = 0.95%) and 99.36 mg Tab^{-1} (R.S.D. = 1.23%) for Brand I and 149.95 mg Tab^{-1} (R.S.D = 0.89%) and 98.96 mg Tab^{-1} (R.S.D. = 0.97%) for Brand II, respectively, as shown in Table 2. The low values of R.S.D. indicate that the method is precise and accurate.

Table 4
Stability indicating ability

Degradation with respect to	Labelled amount MEB (150 mg Tab^{-1})/ PYP (100 mg Tab^{-1})
Heat @100°C for 1 month	141.26 (mg Tab^{-1})/94.51 (mg Tab^{-1})
Sunlight for 1 h	149.83 (mg Tab^{-1})/92.67 (mg Tab^{-1})

3.5. Accuracy and precision

To study the accuracy and precision of the proposed method, recovery experiments were carried out by standard addition technique, by adding standards at four different levels to the preanalysed sample. Each level was repeated thrice.

A plot of the drug found in mg by the proposed method (Y-axis) against the amount of the standard drug added (X-axis) was drawn. Intercept on the Y-axis indicates the amount of the drug found in mg per tablet.

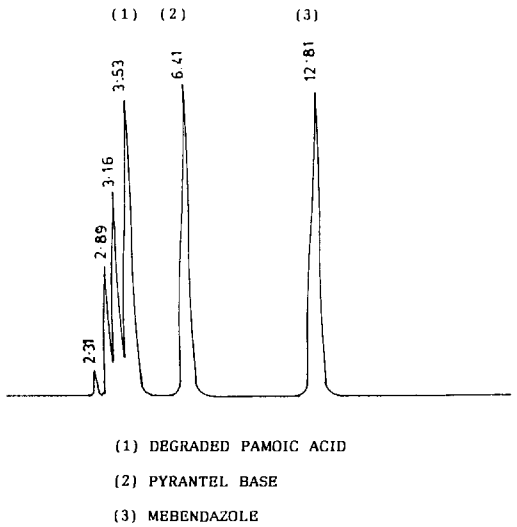

Fig. 4. Chromatogram of mebendazole and pyrantel pamoate on degradation with respect to sunlight.

From the amount of the drug found, % recovery was calculated using the formula:

$$\%\ \text{Recovery} = \frac{N(\Sigma XY) - (\Sigma X)(\Sigma Y)}{N(\Sigma X^2) - (\Sigma X)^2} \times 100$$

where,

X = amount of standard drug added.

Y = amount of drug found by the proposed method.

N = number of observation.

The recoveries of PYP and MEB obtained were 98.43 and 98.53% for Brand I and 98.90 and 98.29% for Brand II, respectively as shown in Table 3. This shows that there is no interference from the excipients present in the tablets.

3.6. Stability indicating ability

Stability indicating ability of the method was studied with two different parameters:

(a) Degradation with respect to heat.

(b) Degradation with respect to sunlight.

3.6.1. Degradation with respect to heat

Tablets were kept in an oven at 105°C for 1 month and analysed according to the proposed method. There was no secondary degraded peak, but the assay values were found to be less for MEB and PYP as reported in Table 4.

3.6.2. Degradation with respect to sunlight

The solution of the tablets used for assay preparation (Solution A) were prepared and before it was analysed by the proposed method was kept in sunlight for 1 h and the degradation profile was studied. Pyrantel pamoate is a salt of pamoic acid and pyrantel base as shown in Fig. 1. It was observed that pamoic acid degraded and showed degraded peaks as shown in Fig. 4. Pyrantel base did not show any degraded peaks but the assay values were low (92.67 mg Tab^{-1}), MEB remained unaffected on photodegradation.

4. Conclusion

The proposed RP-HPLC method is accurate, precise, rapid and stability indicating for the simultaneous determination of MEB and PYP in tablets. Hence it can be easily and conveniently adopted for routine quality control analysis.

Complexant efficiency of 2′-hydroxy-4-R-chalcones for Aluminium (III) and substituent's effect

Nora B. Debattista *, Nora B. Pappano

Department of Chemistry, San Luis National University, Chacabuco 917, 5700 San Luis, Argentina

Received 30 May 1996; received in revised form 12 September 1996; accepted 26 September 1996

Abstract

The complexant efficiency with aluminium of 2′-hydroxy-4-R-chalcones, which depends on the nature and positions of the substituent was studied by a spectrophotometric method. The apparent formation constant was determined. The quantitative analysis of the substituent's influence on the complexation reaction equilibrium was made using the Hammett relation. The constant σ magnitudes of groups OH, OCH_3, Cl and F in the 4-position agree with values reported in the literature. © 1997 Elsevier Science B.V.

Keywords: Aluminium; 2′-hydroxy-4-R-chalcones; Spectrophotometric

1. Introduction

Chalcones and their analogues are well known for having variable bactericidal [1], fungicidal [2] and carcinogenic activity [3]. Moreover, 2′-hydroxychalcones have been employed as analytical reagents for some metal ions [4,5].

Considering their complexant efficiency, which depends on the substituent character and position, the 2′-hydroxychalcone—aluminium (III) systems were studied by a new spectrophotometric method. The combining ratio and kinetic behaviour were described, determining the apparent formation constants. The quantitative analysis of the substituents influence on the complexation reaction equilibria was made using the Hammett relation.

2. Experimental

2.1. Apparatus

All the absorption spectra were measured by a UV-160 spectrophotometer (Shimadzu, Japan) at constant temperature.

2.2. Reagents

The substances studied were the following:

I. 2′-hydroxychalcone,
II. 2′,4-dihydroxychalcone,
III. 2′-hydroxy-4-methoxychalcone,
IV. 2′-hydroxy-4-chlorochalcone,
V. 2′-hydroxy-4-fluorochalcone,

Their structures and the numbering system are shown in Fig. 1.

PII S0039-9140(96)02123-6

2′-hydroxy-4-R-chalcones were prepared by reaction of 2-hydroxyacetophenone with substituted benzaldehydes according to a method reported in the literature [6]. They were purified by LH 20 Sephadex column chromatography with methanol as eluent and identified according to physical, chromatographic and spectroscopic properties.

2′-hydroxychalcone: Rf(TLC): 0.38; mp 88–88.5°C; UV λ_{max}^{MeOH} nm 312, 350, 220; IR $\nu(CCl_4)$ cm^{-1}: 1639(C=O), 3480 (OH).

2′,4-dihydroxychalcone: Rf(TLC): 0.23; mp 158–159°C; UV λ_{max}^{MeOH} nm: 365, 240; IR $\nu(CCl_4)$ cm^{-1}: 1641 (C=O), 3600 (OH).

2′-hydroxy-4-methoxychalcone: Rf(TLC): 0.32; mp 90–91°C; UV λ_{max}^{MeOH} nm: 360, 240; IR $\nu(CCl_4)$ cm^{-1}: 1635(C=O), 3480 (OH).

2′-hydroxy-4-chlorochalcone: Rf(TLC): 0.28; mp 137–138°C; UV λ_{max}^{MeOH} nm: 318, 355 sh; MS m/z 258 M^+, 165, 147, 137, 120, 102.

2′-hydroxy-4-fluorochalcone: Rf(TLC): 0.38; mp 116–117°C; UV λ_{max}^{MeOH} nm: 316, 353 sh, 224; MS m/z 242 M^+, 149, 147, 121, 120, 102.

The complex solutions in methanol were prepared by mixing variable concentrations of aluminium (III) and 2′-hydroxy-4-R-chalcones (10^{-4} M–10^{-5} M). Ionic strength (0.01 M), temperature (32°C ± 0.1) and a metal:ligand ratio (3:1) were maintained constant. The equilibrium solution absorbances were measured at the maximum absorption wavelength of the complexes (λ_{max}).

3. Results and discussion

The molar composition for all the complexes was determined by a molar-ratio method [7] and a 1:1 (metal:ligand) stoichiometry was found (see Fig. 2).

Semiquantitative kinetic experiments allowed to establish more suitable reaction times (1–4 h) for each system.

The values of the apparent formation constants were determined by a new linear graphical method [8]. This method, applicable to mono and polynuclear complexes does not have the limitations of the other methods proposed [9,10]. It is easy and of extensive applicability. Its application only requires: analytical concentrations of reactants, ligand molar absorbtivity and absorbances for equilibrium solutions.

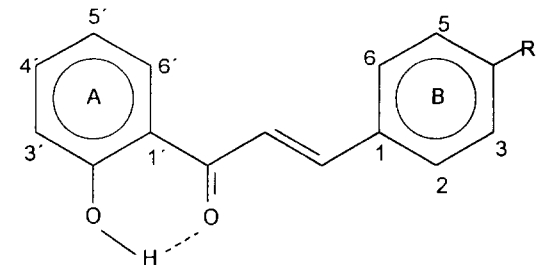

Fig. 1. Structure and numbering system of 2′-hydroxy-4-R-chalcones.

In a chemical reaction

$$n\,LH + M^{n+} \rightleftharpoons LnM + n\,H^+ \quad (1)$$

where LH is the complexant reagent, M^{n+} is the metallic ion and n is the stoichiometry coefficient, the equilibrium thermodynamic constant (K_a) is:

$$K_a = \frac{a_{H^+}^n \cdot a_{L_nM}}{a_{LH}^n \cdot a_{M^{n+}}} = K_c \cdot K_\gamma \quad (2)$$

where a, c and γ are the species activities, molar concentrations and activity coefficients, respectively [11].

In the considered system, at ionic strength and pH constant, the apparent formation constant (K'), is

$$K' = \frac{[L_nM]}{[LH]^n[M^{n+}]} = \frac{K_c}{[H^+]^n} \quad (3)$$

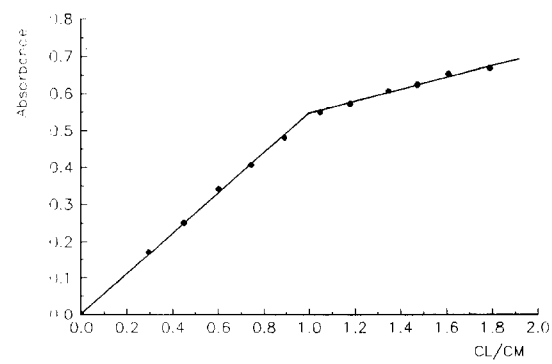

Fig. 2. Application of Yoe-Jones method to 2′-hydroxy-4-Cl-chalcone—Al(III) system.

where the brackets refer to the substance molar concentrations. If a and b are the ligand and metal molar analytic concentrations, respectively, and x is the complex equilibrium molar concentration, the apparent formation constant can be written as:

$$K' = \frac{x}{(a - \mathrm{n}x)(b - x)} \tag{4}$$

Considering the Newton binomial expansion [12]

$$(\alpha + \beta)^{\mathrm{m}} = \alpha^{\mathrm{m}} + \mathrm{n}\alpha^{\mathrm{m}-1}\beta + \frac{\mathrm{n}(\mathrm{n}-1)\alpha^{\mathrm{m}-2}\beta^2}{2!} + \frac{\mathrm{m}(\mathrm{m}-1)(m-2)\alpha^{\mathrm{m}-3}\beta^3}{3!} + \ldots \tag{5}$$

Starting from Eq. (4) the following polynomial is obtained

$$\frac{(\mathrm{n}-1)(\mathrm{n}-2)a^{\mathrm{n}-3}}{3!}(\mathrm{n}x)^4 - \frac{(\mathrm{n}-1)}{2}\left[\frac{b\mathrm{n}(\mathrm{n}-2)a^{\mathrm{n}-3}}{3} + a^{\mathrm{n}-2}\right](\mathrm{n}x)^3 + \left[a^{\mathrm{n}-1} + \frac{b\mathrm{n}(\mathrm{n}-1)a^{\mathrm{n}-2}}{2!}\right](\mathrm{n}x)^2 - [a^{\mathrm{n}} + b\mathrm{n}^2a^{\mathrm{n}-1} + K'']x + ba^{\mathrm{n}} = 0 \tag{6}$$

with $K'' = 1/K'$.

On the other hand, according to Beer's law, the reacting solution absorbance (A) can be expressed as

$$A = \epsilon_{\mathrm{L}}(a - \mathrm{n}x)l + \epsilon_{\mathrm{M}}(b - x)l + \epsilon_{\mathrm{C}}xl \tag{7}$$

where ϵ_{L}, ϵ_{M} and ϵ_{C} are the ligand, metal and complex molar absortivities, respectively, and l is the path length. If $\epsilon_{\mathrm{M}} = 0$ at the selected wavelength, then

$$x = \frac{A - A_{\mathrm{L}}}{l(\epsilon_{\mathrm{C}} - \mathrm{n}\epsilon_{\mathrm{L}})} \tag{8}$$

where, A_{L} (ligand absorbance) is

$$A_{\mathrm{L}} = \epsilon_{\mathrm{L}}al \tag{9}$$

From Eq. (8) it is evident that the complex concentration ratio (D) of two equilibrium solutions 'j' and 'r', is

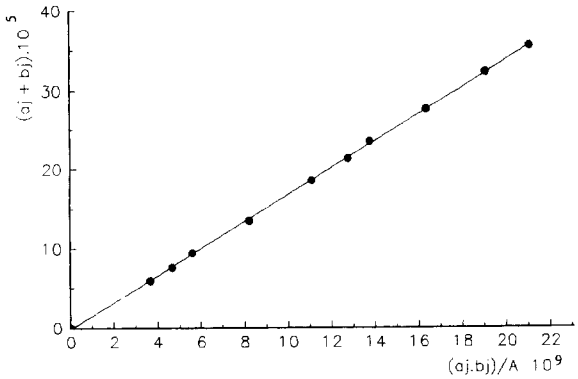

Fig. 3. Formation of 2'-hydroxy-4-F-chalcone—Al(III) in methanol at 32°C.

$$\mathrm{D} = \frac{x_j}{x_r} = \frac{(A - A_{\mathrm{L}})_j}{(A - A_{\mathrm{L}})_r} \tag{10}$$

Now,

1. applying the polynomial Eq. (6) to the 'j' and 'r' solutions;
2. expressing the 'j' polynomial solution in terms of x using Eq. (10);
3. confronting the two polynomials in x and formulating the equations that link equal degree terms;
4. combining and reordering the previous expressions, Eq. (11) is obtained

$$a_j^{\mathrm{n}} + \mathrm{n}^2b_ja_j^{\mathrm{n}-1} = \frac{(a_r^{\mathrm{n}} + \mathrm{n}^2b_ra_r^{\mathrm{n}-1} + K'')(A - A_{\mathrm{L}})_r}{a_r^{\mathrm{n}}b_r}\frac{a_j^{\mathrm{n}}b_j}{(A - A_{\mathrm{L}})_j} - \frac{1}{K'} \tag{11}$$

It is the general validity and for the particular cases is simplify. For example, the expression for complexes LM (n = 1) is

$$(a_j + b_j) = \frac{(a_r + b_r + K'')(A - A_{\mathrm{L}})_r}{a_rb_r}\frac{a_jb_j}{(A - A_{\mathrm{L}})_j} - \frac{1}{K'} \tag{12}$$

Fig. 3 shows the graphic representation of this equation for the system 2'-hydroxy-4-fluorochalcone-Aluminium(III). The values for apparent formation constants of different complexes studied are listed in Table 1.

Table 1
Apparent formation constants(K') of 2'-hydroxy-4-R-chalcones—Al(III) in methanol at 32°C

System	λ_{max}	Slope	Intercept $\times 10^6$	$K' \times 10^{-5}$
I-Al	424	16153	8.40	1.26[a]
II-Al	443	42372	3.70	2.69
III-Al	437	33807	4.80	2.09
IV-Al	355	21364	3.64	2.75
V-Al	427	16952	2.61	3.41

[a] Ref. [13].

The general expression of the Hammett equation, [14] applicable for aromatic compounds with the same reaction centre, is as follows:

$$\log K' = \log K'_0 + \rho\sigma \quad (13)$$

where K'_0 is the equilibrium constant of the standard compound, K' is the equilibrium constant of a particular derivative, σ is the substituent constant present in the derivative, ρ is the reaction constant. This constant ρ, which depends on the reaction characteristics and the external conditions, shows a negative value for a reaction that is hindered by electron withdrawal of the benzene ring. The complexation reactions of the 2'-hydroxy-4-R-chalcones with Al(III) present this behaviour. Substituents that withdraw ring B electrons hinder the complex formation by an electronic density decrease of the oxygen atoms that are involved in the chelate (carbonylic oxygen and hydroxylic oxygen bound to C'_2).

If Eq. (2) is applied to the systems studied, using the I-Al(III) complex as the standard reaction and $\rho = -1$ to the complexation reactions of 2'-hydroxy-4-R-chalcones, then:

Table 2
Constant σ values for 4-substituted 2'-hydroxychalcones

System	Experimental σ value	Reported σ value[a]
II-Al	−0.33	−0.37
III-Al	−0.22	−0.27
IV-Al	−0.34	−0.31
V-Al	−0.43	−0.48

[a] Refs. [15] and [16].

$$\sigma = \log \frac{K'_0}{K'} \quad (14)$$

from which the substituent constant was estimated for OH, OCH_3, Cl and F groups in the ring B 4-position of 2'-hydroxychalcones (see Table 2).

4. Conclusions

According to the above results, the following conclusions may be drawn:

Under the working conditions taken up, 2'-hydroxy-4-R-chalcones—Al(III) chelates are found to be stable for at least 48 h and to have a ligand:metal stoichiometric relation 1:1.

The original method used is suitable for the mono-nuclear (and polynuclear) complexes studied and only analytical concentrations of reactants, absorbances for equilibrium solutions and ligands molar absortivity are requested for its applications.

The constant magnitudes of groups OH, OCH3, Cl and F in the 4-position (2'-hydroxychalcones ring B), evaluated by application of the Hammett equation, agree with the values reported in the literature.

Analytical properties of 5,5-dimetyl 1,3-cyclohexanedione dithiosemicarbazone monohydrochloride; spectrophotometric determination of chromium(VI) in alloy steels and industrial effluents

C.S. Devaragudi, K. Hussain Reddy *

Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515 003, India

Received 6 May 1996; received in revised form 16 October 1996; accepted 18 October 1996

Abstract

The analytical properties of 5,5-dimethyl 1,3-cyclohexanedione dithiosemicarbazone monohydrochloride (5,5-DiMe-1,3-CHDT.HCl) are described. The reagent gives pink coloured solutions with chromium(VI) in acetic medium. The maximum colour intensity is observed in 0.5–2.5 pH range. This colour reaction (molar absorptivity, 1.63×10^4 l mol^{-1} cm^{-1} at 360 nm) has been used for the spectrophotometric determination of total chromium in alloy steels and industrial effluents. © 1997 Elsevier Science B.V.

Keywords: Alloy steels; Chromium(VI); Industrial effluents; Spectrophotometric

1. Introduction

Thiosemicarbazones are interesting analytical reagents [1–3]. Although monothiosemicarbazones have been widely used for the spectrophotometric determination of metal ions, dithiosemicarbazones are not exploited much possibly due to their lower solubilities in aqueous medium. However, 1,3-cyclohexanedione dithiosemicarbazone monohydrochloride (1,3-CHDT.HCl) has been extensively used for the spectrophotometric determination of Chromium(VI) [4], osmium(VIII) [5], palladium(II) [6] and nickel(II) [6]. In the light of good analytical potentialities of 1,3-CHDT.HCl, herein we report the synthesis, characterization and analytical properties of a derivative of 1,3-CHDT.HCl viz. 5,5-dimethyl 1,3-cyclohexanedione dithiosemicarbazone monohydrochloride (5,5-diMe-1,3-CHDT.HCl). The determination of chromium(VI) using this reagent is also included in this paper.

2. Experimental

2.1. Preparation of 5,5-diMe-1,3-CHDT.HCl

The reagent was prepared by simple condensa-

tion of 1 mol of dimedone with 2 mol of thiosemicarbazide. In a 250 ml round bottom flask, a hot ethanolic solution of 5,5-dimethyl 1,3-Cyclohexanedione (dimedone) (0.031 mol) and aqueous solution of thiosemicarbazide (0.062 mol) were mixed. Then 6 ml of conc. HCl was added and heated to reflux for 1 h on water bath. On cooling and slow evaporation of the reaction mixture, a white product was separated out, collected by filtration, washed with cold methanol, yield 76%, m.p. 208°C.

2.2. Characterization of 5,5-diMe-1,3-CHDT.HCl

The purity of the product was found to be 99.5% by direct titration with 0.05 M NaOH using phenolphthalein indicator. Elemental analysis, found C, 39.48%, H, 5.35% and N, 25.53%. Calculated for $C_{16}H_{19}N_6S_2Cl$ C, 37.09%, H, 5.56% and N, 25.96%.

The pK_a values are determined by recording the UV–Visible spectra of μM (4×10^{-5} M) solutions of ligand at various pH values and by taking the arithmetic mean of the values obtained from the measurements at four different wavelengths. The values of the deprotantion of the ligand are 6.5 (pK_1) and 9.3 (pK_2).

The ^{1}H-NMR spectrum of the reagent was recorded in DMSO solvent. It shows signals corresponding to $-CH_3$ (gem), CH_2 (ring), NH and NH_2 protons at 1.96 (S, 6H); 2.43 (d, 6H, $J=4$); 5.57 (S, 2H) and 7.90 (d, 6H), respectively.

The reagent solution (0.01 M) was prepared by dissolving 325 mg of the compound in 100 ml of distilled water and it is stable for at least 12 h.

Hydrochloric acid (1 M)—sodium acetate (1 M) (pH 0.5–3.5); 0.2 M NaOAc–0.2 M AcOH (pH 4–6) and 2 M NH_4Cl–2M HN_4OH solutions were used. The standard chromium(VI) solution (1×10^{-2} M) was prepared using analytical reagent grade potassium dichromate (previously dried at 140°C). Solutions of diverse ions of suitable concentrations were prepared using AR grade chemicals.

2.3. Reactions with metal ions

The reactions of some important metal ions were tested at different pH values. The samples were prepared in 25 ml volumetric flasks by adding 10 ml of buffer, metal ion, 2.5 ml of dimethylformamide (DMF) and 1 ml of 0.01 M 5,5-diMe-1,3-CHDT HCl solution. The reaction mixture was diluted to the mark with distilled water. The absorbance was measured in 350–600 nm range against the reagent blank. The results are summarized in Table 1.

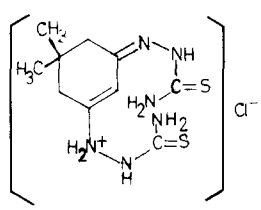
2.4. Recommended procedure for the determination of chromium(VI)

An aliquot of the solution containing 0.15–1.5 μg ml^{-1} (or ppm) of chromium(VI), 10 ml of NaOAc–HCl (buffer) solution (pH, 1.5), 2.5 ml of DMF and 1 ml of 0.01 M 5,5-diMe-1,3-CHDT.HCl were combined in a 25 ml volumetric flask and the mixture was diluted to the mark with distilled water. The absorbance of this solution was read at 360 nm against reagent blank. The measured absorbance is used to compute the amount of chromium from the predetermined calibration curve.

2.5. Apparatus

Schimadzu 160A UV-visible spectrophotometer equipped with 1.0 cm quartz cells and an ELICO, model LI-120 pH meter were used in the present study.

3. Results and discussion



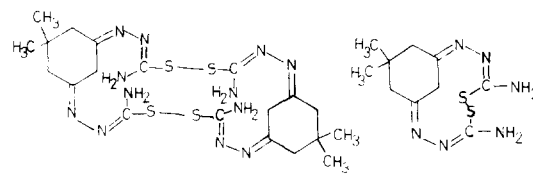
I

5,5-Dimethyl-1,3-cyclohexanedione dithiosemicarbazone monohydrochloride is as easily obtained as the ∞-dithiosemicarbazones [7], probably because it is stabilized as the hydrochloride(I). A 0.01 M solution of this reagent solution is stable for 12 h. The bathochromic shift of strong absorption band from 215 to 310 nm indicates that in solution on increasing the pH, the acid is neutralized and the >C=S group is enolized and dissociated [8].

The colour reactions of some important metal ions with 5,5-diMe-1,3-CHDT.HCl are summarized in Table 1. Two types of colour reactions are implicated. They are: 1. redox reactions; and 2. complex formation reactions. The former type of reactions take place with metal ions such as Cr(VI) and Os(VIII) as dithiosemicarbazones are easily oxidized. But this property is infrequently used for the determination of metal ions [4,9] in higher oxidation state. The redox reaction between Cr(VI) and the reagent may be written as

$$2Cr(VI) + 3(\text{reduced reagent}) \rightleftharpoons 2Cr(III) + 3(\text{oxidized reagent})$$

Two electrons are involved for each reagent molecule and the oxidation of the two >C=S groups give $>\dot{C}-S-S-\dot{C}<$. The oxidation products are formed by either intermolecular (II) or intranolecular (III) sulphur sulphur bonding.



II III

The latter type of reactions occur with divalent metal ions such as Ni(II), Zn(II), Pb(II) and Cd(II) in basic medium to give intense coloured complexes. In basic medium, the ligand presumably exists in enolic form and coordinates the metal ion as dianion to give neutral complex [10,11].

3.1. Determination of chromium(VI)

Chromium(VI) reacts with 5,5-diMe-1,3-CHDT.HCl in acidic pHs to give pink coloured species. No colour reactions of the reagent with Cr(III) is observed. However, the colour reaction of Cr(VI) with the reagent is instantaneous even at room temperature (28 ± 2°C) in the pH range 1–5. The absorbance of the pink coloured species (λ_{max}, 360 nm) remains constant for 1 h. The maximum colour intensity is observed in the pH range 0.5–2.5.

A 20-fold molar excess of the reagent is adequate for full colour development. Addition of

M/S. Electrochemical Metal Finishes, Bangalore	2.38	2.19

excess reagent has no adverse effect on the absorbance. The order of addition of metal ion, reagent and buffer solution has no effect on the absorbance, provided DMF is added prior to the reagent solution.

3.2. Analytical characteristics

The system obeys Beer's law over the concentration range 0.16–1.49 μg ml^{-1}. The optimum range for the determination of chromium(VI) from Ringbom's plot was found to be 0.30–1.40 μg ml^{-1}. The molar absorptivity and Sandell's sensitivity of the method were 1.63×10^4 l mol^{-1} cm^{-1} and 0.0031 μg cm^{-2}, respectively. The relative standard deviation for ten replicate analyses of a solution containing 0.83 μg ml^{-1} cobalt was 1.62%.

3.3. Nature of oxidation reaction

Job's and Molar ratio methods gave the composition of pink coloured species as 2:3 (metal:ligand). Hence 2 mol of chromium(VI) reacts with 3 mol of reagent. Accordingly and in analogy with previous observations [4,12] the redox reaction is proposed (Section 3).

3.4. Interferences

The effect of some of the ions which often accompany chromium has been studied by adding different amounts to 0.84 μg ml^{-1} of chromium in solution. The colour is developed as described in the standard procedure. An error of ±2% in the absorbance reading is considered tolerable. The results are given in Table 2. Higher amounts of iron(III) (95-fold molar excess) could be tolerated with fluoride.

3.5. Analysis of alloy steels

Alloy steel sample solutions were prepared by following the procedure given in the literature [13]. A sample containing 0.5 g of steel sample was dissolved in 30 ml of 1:4 sulphuric acid. A 5 ml volume of nitric acid was added to remove the carbaneous residue. The solution was boiled to

[c] Methods involving heating of the reaction mixture.

remove excess of nitric acid, cooled and diluted to 80 ml. A 2 ml volume of a 1.5% silver nitrate solution and 2 g of potassium persulphate were added and the solution was swirled for dissolution to occur and the reaction mixture heated at 80°C for 15 min. The purple colour of manganese was destroyed by the addition of a few drops of 1:1 hydrochloric acid. The solution was evaporated to almost dryness, cooled and diluted in order to obtain the required concentration of chromium in the stock solution.

To 10 ml of NaOAc–HCl solution of pH 1.5, 1.5 ml of 0.1 M sodium fluoride, steel sample solution (in the optimum concentration range), 2.5 ml of DMF and 1 ml 0.01 M reagent solution were added. The solution was diluted to volume (25 ml) with distilled water and the absorbance was measured at 360 nm against reagent blank. The results are presented in Table 3.

3.6. Analysis of effluents

Effluents samples were collected from three different electrometal (Chrome plating) and metal finishing industries located in Bangalore city, India. The sample (150 ml) was acidified with 2 ml of conc. HCl. Then 25 mg of ferric chloride was added and the pH was adjusted to 7.5 with borate buffer solution. The solution was allowed to stand overnight and filtered. Then 2 ml of 30% H_2O_2 was added and evaporated to dryness. The dried mass was dissolved in 1 ml 1:1 H_2SO_4 and diluted to 25 ml. Known aliquots of this sample was taken and colour was developed as described in the recommended procedure. The results are given in Table 4.

3.7. Conclusions

Most of the spectrophotometric methods [14,15] involve either heating of the reaction mixture [16–18] or extraction [19–22]. However, heating at a specific temperature and for a long time is laborious and time consuming. Also for some methods tolerance limit for associated ions is low. The present method compares (Table 5) favourably with come recently reported spectrophotometric methods [4,23–26] for the deter-

mination of chromium(VI), published in standard international journals. Further, the reagent is easy to synthesize using commercially available dimedone. The most favourable feature of 5,5-diMe-1,3-CHDT.HCl is its solubility in water. Moreover, the present method is simple, rapid, reasonably sensitive and selective without the need for heating or extraction.

Direct determination of cadmium at parts-per-billion level in waters by derivative atomic absorption spectrometry using atom trapping technique

Hanwen Sun *, Lili Yang, Deqiang Zhang, Jianmin Sun

Department of Chemistry, Hebei University, Baoding, 071002, People's Republic of China

Received 24 July 1996; received in revised form 18 October 1996; accepted 29 October 1996

Abstract

A method has been described for the direct determinations of trace cadmium using derivative atom trapping flame atomic absorption spectrometry with an improved water-cooled stainless steel trapping equipment. The characteristic concentration (gave a derivative absorbance of 0.0044) and detection limit (3σ) of cadmium were 0.028 and 0.02 ng ml^{-1} when collecting for a 1 min, respectively, which were 992 and 145-fold better than those of the conventional flame atomic absorption spectrometry. The detection limit and sensitivity of the proposed method for a 2 min collection time were 1 and 2 orders of magnitude higher than those of conventional flame atomic absorption spectrometry. The present method was applied to the determinations of cadmium in water samples with a recovery range of 91 ~ 111% and a relative standard deviation of 4.7 ~ 5.6%. © 1997 Elsevier Science B.V.

Keywords: Derivative atomic absorption spectrometry; Atom trapping; Cadmium

1. Introduction

There is an increasing number of studies dealing with the determination and quantification of heavy metals in various waters, because even low concentrations of them can cause serious toxic effects to organisms. From a public health viewpoint, it is necessary to determine the heavy metal contents in various potable waters. Methods reported for the determinations of trace levels of cadmium in water samples include spectrophotometry [1–6], anodic stripping voltammetry (ASV) [7–9], electrothermal atomic absorption spectrometry (ETAAS) [10–16], flame atomic absorption spectrometry (FAAS) [17–23] and atom trapping flame atomic absorption spectrometry (ATFAAS) [24–30].

The atom trapping technique developed by Lau et al. is a method of preconcentrating the analyte atoms in the flame. This technique was applied to the determination of cadmium with a characteristic concentration of 0.4 ng ml^{-1} for a 2 min collection [24]. In another paper reported by Lau et al., cadmium was determined using ATAAS with a detection limit of 0.1 ng ml^{-1} and a relative standard deviation (RSD) of 7.4% at 10

PII S0039-9140(96)02157-1

ng ml^{-1} level of cadmium when collection for 2 min [25]. Khalighie et al. [26] studied the determination of Cd with atom-trapping technique, the characteristic concentration was found to be 1.3 ng ml^{-1} for 8 min collection. For the determination of Cd in soil, Fraser et al. [27] described the use of atom-trapping technique with a detection limit (2σ) of 0.0016 mg ml^{-1} and the RDS was found to be 11.8% at 0.007 mg ml^{-1} level of cadmium. Roberts and Kahokola [28] described the use of V_2O_3 as the coating material in atom-trapping, the best characteristic concentration of 0.26 ng ml^{-1} was obtained. Turner et al. [29] studied the determination cadmium with atom-trapping technique and the sensitivity was found to be 0.3579 ng ml^{-1}. In our previous paper, the use of water cooled stainless steel tube as an atom collector has been described for the direct determination of cadmium by FAAS, the sensitivity for a 2 min collection were nine-fold better than that of conventional FAAS [30]. Derivative flame atomic absorption spectrometry (D-FAAS) was found by combining the laboratory derivative measurement system with atomic absorption spectrometer. The sensitivity and detection limit of D-FAAS were enhanced 50 and 10 times compared with those of conventional FAAS, respectively [31]. The requirement for analysis at trace and ultra-trace concentration of cadmium has demanded increasingly lower detection capabilities from modern analytical methods.

The main purpose of this paper is to establish a sensitive, simple and reproducible method that affords low determination limit with low analytical costs. For this purpose, the laboratory derivative measurement system was used and the original atom trapping equipment [30,32,33] was improved. The method was applied successfully to the determinations of cadmium in water samples.

2. Experimental

2.1. Apparatus

A WYX-402 atomic absorption spectrometer (Shenyang Analytical Instrument Factory, Shenyang, China) was employed for the measurement of the absorbance. A spectral slit width of 0.2 nm was used to isolate the 228.8 nm resonance line.

The improved atom trapping equipment with a water-cooled stainless steel trap tube in an air-acetylene flame and the laboratory derivative measurement system were used throughout the experiments. The derivative measurement system consists of two parts, i.e., magnification and differential unit. Five sensitivity grades, expressed by 2, 5, 10, 20 and 50 mV min^{-1}, were designed in the derivative measurement system. Increase in the derivative signal intensity of the same cadmium solution is accompanied by a decrease in the number of the sensitivity grade. The derivative measurement system was connected between the atomic absorption spectrometer and the double-pen recorder. The derivative and conventional signals were recorded simultaneously by the recorder set at the 10 mV range.

2.2. Reagents

A cadmium stock solution, 1000 μg ml^{-1}, was prepared by dissolving 1.1423 g of cadmium oxide (analytical reagent grade) in 20 ml of 5 mol l^{-1} HCl and diluting to 1000 ml with sub-boiling distilled water. Working solutions were prepared daily by serial dilution of the stock solution with sub-boiling distilled water just before use.

All the other reagents were of analytical-reagent grade. Sub-boiling distilled water was used throughout.

2.3. Procedure

A stainless steel trap tube (5 mm o.d.) was positioned 7 mm above the burner and 2 mm under the light path. The cooled tap water at a flow rate of 2 l min^{-1} was passed through the tube during the collection cycle. Cadmium solutions were aspirated normally into the flame with an air flow of 6 l min^{-1} and acetylene flow of 1.5 l min^{-1} for an appropriate collection time. An appreciable proportion of the analyte condensed on the cool surface of the tube. After the collection cycle, the tap water was shut off, and then the coolant water flow out of the tube automati-

cally. Cadmium was released into the flame by rapidly heating of the trap tube. The signals of conventional and derivative atom-trapping atomic absorption spectrometry were recorded simultaneously by the double-pen recorder. Sensitivity grade, 20 mV min^{-1}, and 1 min collection time were used during the optimization of experimental conditions, unless otherwise stated. The recommended experimental conditions are summarized in Table 1.

3. Results and discussion

3.1. Characteristic of D-AT-FAAS signal

The laboratory derivative measurement system consists of magnification and differential unit. The input signal was magnified through the measurement system and there is a rigorous derivative relation between the output and input signal. The output signal of the system will keep in base-line when the variation of the input signal is zero, and when the variation of the input signal is not zero, the output signal is in direct proportion to the variation of the input signal. The absorption signals of conventional AT-FAAS and D-AT-FAAS recorded simultaneously by a double-pen recorder were shown in Fig. 1.

Fig. 1 (I) showed the absorption signal of cadmium obtained by conventional AT-FAAS during the collection, $A \rightarrow C$, followed by the aspiration of the blank solution $D \rightarrow E$ and the release $E \rightarrow G$. The derivative absorption signal consists of four peaks, i.e., *a*, *b*, *c* and *d* (Fig. 1 (II)). The peak *a* and *b* are corresponding to the cycle $A \rightarrow B$ and $C \rightarrow D$ of the conventional signal, respectively. The peak *c* and *d* correspond to the releasing cycle $E \rightarrow F \rightarrow G$. The peak-height measurement was used in the present work. The total height of peak *c* and *d*, which is in direct proportion to the concentration of cadmium according to our experimental results, was considered as the absorbance of D-AT-FAAS.

Table 1
Recommended experimental conditions

Wavelength (nm)	228.8	Coolant water (l min^{-1})	2
Lamp current (mA)	3	Recorder grade (mV)	10
Air flow rate (l min^{-1})	6	Trap position	
Acetylene flow rate (l min^{-1})	1.5	Above the burner (mm)	7
		Below the burner (mm)	2

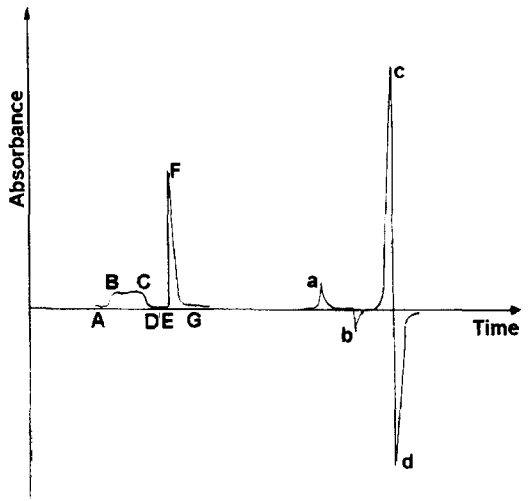

Fig. 1. The absorption signals of conventional AT-FAAS (I: left) and DAT-FAAS (II: right).

3.2. Modification of trapping equipment

Up to now, all of the atom trapping methods found in the literature required to flush the cooled water out of the trap tube rapidly by a blast of air via the control tap system during the releasing cycle. If the air blast was continuously passed or the cooled water was not flushed out of the tube completely and rapidly, the surface of the trap tube would not be heated up rapidly, which will influence the signal intensity of cadmium. Thus, it is important to keep the air flow high enough and optimum air-passing time in each operation. In order to simplify the trapping equipment and operation procedure, the original trapping equipment was improved in our work. The sketch of the improved equipment was shown in Fig. 2.

The coolant water was passed through the trap tube during the collection cycle. During the release cycle, the tap water was shut off by turning the three-way valve and the coolant water auto-

matically flow out of the trap tube through I and II without a blast of air. Under the same instrumental conditions, the sensitivity and precision for the determination of cadmium with the improved system were compared with those with the previous system. The signals of conventional AT-FAAS and D-AT-FAAS were recorded and the analytical results indicated that the precisions obtained with the improved equipment are consistent with that obtained from the original equipment without loss in sensitivity. Although the improved system does not give a higher sensitivity and a lower detection limit than the original one, the former simplified the analytical procedures in the release cycle. Thus, the improved trapping equipment was used in the sequent experiments.

3.3. Effect of trap position

The tube position was optimized with respect to both the light path and the flame. This is done by varying its distance from the burner or the light path, one at a time, and measuring the derivative signal from cadmium solution of 0.05 μg ml^{-1} in each position until the maximum derivative signal is obtained. Effect of the position of the trap tube between the light path and the burner on the peak height of the derivative absorption signal was shown in Fig. 3.

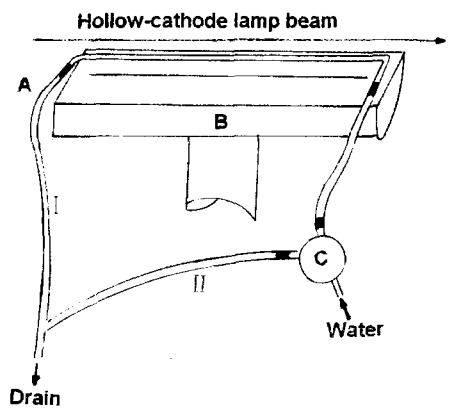

Fig. 2. The sketch of the improved trapping equipment: A, trapping tube; B, burner; and C, water control system.

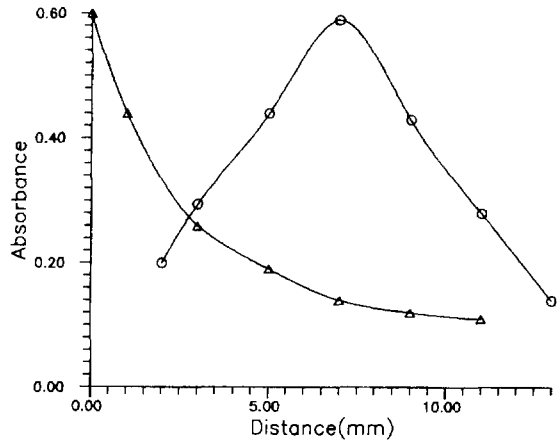

Fig. 3. Influence of the position of the tube trap on absorbance of cadmium: (△) absorbance versus distance of the trap from the lamp beam; (○) absorbance versus distance of the trap from the burner slot.

As shown in Fig. 3, the maximum derivative absorption signal was obtained by raising the trap tube until its intersection with the absorption beam caused about a 5% intensity loss, but it will be achieved with sacrifice in precision. The optimum position of the trap tube corresponded to the distance of 2 mm under the light path and 7 mm above the burner.

3.4. Effect of flame condition

The influence of flame condition on the sensitivity of cadmium with D-AT-FAAS was investigated by altering the acetylene flow rate with a fixed air flow rate of 6 l min^{-1}. The derivative signals obtained by aspirating 0.05 μg ml^{-1} cadmium standard solution varied over the range 0.48, 0.52, 0.58 and 0.57 for the acetylene flow rates of 0.5, 1.0, 1.5 and 2.0 l min^{-1}, respectively. The derivative absorbances of cadmium were not very different for collecting or releasing in a lean and full-rich flame. The sensitivity of D-AT-FAAS for cadmium appeared to be virtually independent of the flame condition. The acetylene flow rate of 1.5 l min^{-1} and air flow rate of 6 l min^{-1} were used for further experiments during the collection and release cycles.

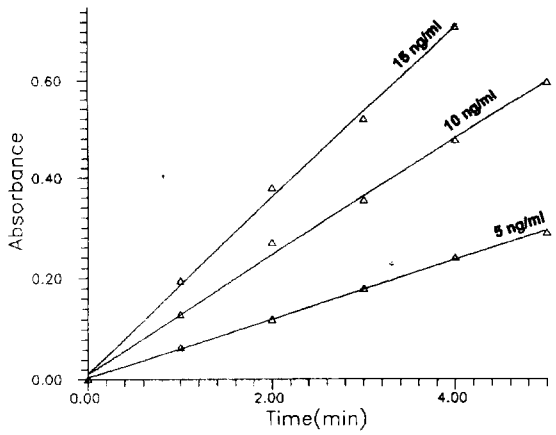

Fig. 4. Collection of cadmium as a function of time.

3.5. Effect of coolant water flow

Effect of coolant water flow on derivative absorbance was studied with cadmium solution of 0.05 μg ml^{-1}. The results showed that the temperature of the outlet water increase with the decrease of the flow rate when the temperatures of inlet water remain constant. At a temperature of 17°C of the inlet water, when the flow rate is of 2.5 and 0.3 l min^{-1}, the temperature of outlet water is 19°C and 31°C, respectively. No significant differences were found in the derivative absorbance when a coolant water flow rate of 0.3–2.5 l min^{-1} were used during the collection cycle of cadmium solution.

3.6. Effect of collection time

The deposition of cadmium on the trap tube surface is not a one-way process, but will eventually reach an equilibrium. To test the efficiency of collection from different dilution, aqueous solutions of cadmium were collected for different time. Fig. 4 shows the effect of collection time on the analytical growth curves for various concentration of cadmium standard solutions.

The plot (Fig. 4) illustrated that the derivative absorbance is linearly dependent on collection time for cadmium solution. For a 1 min collection time, the characteristic concentration of D-AT-FAAS was 0.37 ng ml^{-1}, which was improved 6.2 times compared with 2.3 ng ml^{-1} obtained by AT-FAAS. The sensitivity could be further enhanced when 2, 5 and 10 mV min^{-1} sensitivity grades were used.

3.7. Effect of derivative sensitivity grade

The derivative measurement system is an electric differential apparatus. The output signal of the atomic absorption spectrometer was magnified at first and then differentiated. The derivative measurement system has five sensitivity grades, 2, 5, 10, 20 and 50 mV min^{-1}. In order to examine the influence of the sensitivity grade on sensitivity of D-AT-FAAS, the derivative absorption signals were measured using different sensitivity grades with cadmium standard solutions. The results are given in Table 2.

As shown in Table 2, the smaller the number of derivative sensitivity grade, the bigger the derivative absorbance with the same cadmium solution.

Table 2
Effect of derivative sensitivity grade on the derivative absorbance

Sensitivity grade (mV min^{-1})	Absorbance			
	2 ng ml^{-1}	5 ng ml^{-1}	10 ng ml^{-1}	20 ng ml^{-1}
50		0.028	0.057	0.120
20	0.030	0.065	0.140	0.295
10	0.062	0.133	0.312	0.641
5	0.131	0.272	0.645	
2	0.340	0.668		

Table 3
Comparison of sensitivity (S) and detection limit (D.L.)

Method	Sensitivity grade (mV min^{-1})	Collection time (min)	S (ng ml^{-1})	D.L. (ng ml^{-1})	Improvement factor[a]	
					S	D.L.
FAAS			27.8	2.9		
AT-FAAS		1	2.3	0.8	12	3.6
	50	1	0.95	0.39	29	7
D-AT-FAAS	20	1	0.37	0.15	75	19
	10	1	0.17	0.11	163	26
	5	1	0.08	0.06	347	48
	2	1	0.028	0.02	992	145
		2	0.014		1985

		4	0.008		3475	
		5	0.006		4633	

[a]Compared with S and D.L. of FAAS.

The highest and lowest sensitivity were obtained by 2 and 50 mV min^{-1} sensitivity grades, respectively. The derivative sensitivity grade could be selected according to the amount of cadmium in real samples.

3.8. Analytical performance of D-AT-FAAS

For a 1 min collection of the cadmium solution, the linear regression equations of D-AT-FAAS obtained at the sensitivity grades of 50, 20, 10, 5 and 2 V min^{-1} were $A = 0.0046C + 0.001$, $A = 0.0119C-0.004$, $A = 0.0258C + 0.009$, $A = 0.0550C-0.010$ and $A = 0.1571C-0.051$ with the coefficients of 0.9935, 0.9945, 0.9947, 0.9989 and 0.9971, respectively, where the A = derivative absorbance and C = concentration of cadmium solution (ng ml^{-1}).

The concentration ranges were $0 \sim 180$, $0 \sim 70$, $0 \sim 34$, $0 \sim 17$ and $0 \sim 7$ ng ml^{-1} at 50, 20, 10, 5 and 2 mV min^{-1} sensitivity grade, respectively. The good linearity is the basis of quantitative analysis by D-AT-FAAS.

Under the optimal instrumental conditions, the sensitivities of D-AT-FAAS, AT-FAAS and FAAS were compared, where sensitivity is defined as the concentration of analyte that provides the peak absorbance of 0.0044. The detection limits of the three methods, based on the triple value of the standard deviation of the blank ($n = 11$), were determined, respectively. The results were shown in Table 3. At the sensitivity grades of 50, 20, 10, 5 and 2 mV min^{-1}, the sensitivities of D-AT-FAAS were 0.95, 0.37, 0.17, 0.08 and 0.028 ng ml^{-1} for a 1 min collection time, respectively, which were 29, 75, 163, 347 and 992-fold better than that of FAAS. The sensitivities of different sensitivity grades could be further enhanced with the extension of collection time. At 2 mV min^{-1} grade, the sensitivities of D-AT-FAAS was three orders of magnitude higher than that of FAAS for a 2 min collection time, the detection limit was improved for two orders of magnitude for 1 min collection.

For a 1 min collection of standard cadmium solution, the precisions (relative standard deviation) of D-AT-FAAS, AT-FAAS and FAAS were evaluated by seven replicate determinations, respectively. The results showed that the relative standard deviation (RSD) of D-AT-FAAS method is in the range of 2.6–4.5% at the cadmium concentration level of 50–2 ng ml^{-1}, that of AT-FAAS method is 2.5% at the cadmium concentration level of 100 ng ml^{-1} and that of FAAS method is 1.9% at the cadmium concentration level of 1000 ng ml^{-1}.

The above results indicated that D-AT-FAAS had better sensitivity, lower detection limit and

good reproducibility compared with those of AT-FAAS and FAAS.

3.9. Sample analysis

The proposed method was applied to the determinations of cadmium in several water samples. The recovery results of cadmium spiked to water samples are in the range of 90–111% which indicated that the proposed method is reliable.

The slope of the calibration graphs prepared with standard curve method for water samples was found to be almost identical with that of the standard additions plot. The standard curve method was used in the determinations of various samples.

The accuracy of the proposed method was checked by comparing the sample analysis results with those of ETAAS. The results of sample analysis are listed in Table 4.

The content of cadmium in samples given in Table 4 showed that the concentration of cadmium determined by D-AT-FAAS was in good agreement with that obtained by ETAAS. A 't' test has been done on the results listed in Table 4, which indicates that no significant difference was found at the confidence level of 95%. The precision of the method, when applied to real samples, was in the range of 4.7–5.6% expressed as RSD%. The results showed the applicability of the proposed method for the determinations of ng ml^{-1} level cadmium in water samples.

Table 4
Comparison of the results obtained with D-AT-FAAS and ETAAS for cadmium content in water samples[a]

Water sample	Content in sample (ng ml^{-1})	
	D-AT-FAAS	ETAAS
1	0.25 ± 0.13	0.23 ± 0.024
2	0.18 ± 0.010	0.20 ± 0.009
3	0.32 ± 0.015	0.31 ± 0.027
4	0.21 ± 0.012	0.23 ± 0.019
5	0.35 ± 0.018	0.35 ± 0.030

[a]2 mV min^{-1}, collecting for 5 min, average of seven determination and standard deviation.

4. Conclusions

The combination of AT-FAAS with the derivative technique significantly improved the sensitivity and detection limit compared with those obtained with AT-FAAS and FAAS for the determination of cadmium. The obtained results point to the feasibility of using D-AT-FAAS for the routine determinations of trace cadmium in water samples. The advantages of the present method include simplicity of the procedure, shorter time required for analysis, less risk of contamination and less analytical cost.

DC arc vaporization as a sample introduction technique for analysis of solids by ICP-OES

D.A. Rusak, R.L. Litteral, B.W. Smith, J.D. Winefordner *

Department of Chemistry, University of Florida, Gainesville, FL, 32611, USA

Received 8 August 1996; received in revised form 24 October 1996; accepted 25 October 1996

1. Introduction

In a continuing search to find the most advantageous method for the analysis of solid samples, many methods for the introduction of solids into an inductively coupled plasma (ICP) have been developed. These methods span from early techniques such as direct insertion [1,2] to the more recent approach of laser ablation [3–5], with nebulization [6], electrothermal vaporization (ETV) [7–9], arcs and sparks [10,11], and various types of slurry sampling [12,13] in between. The ideal method for the analysis of solid samples would eliminate sample dissolution, minimize sample preparation, and maximize transport into the ICP. These goals are yet to be realized with any of the introduction techniques currently used for the ICP.

The main complication that hinders the various nebulization techniques is the need for lengthy sample preparation involving digestion procedures. When preparing aqueous solutions of solid samples for these introduction methods, many problems can be encountered, such as incomplete dissolution, precipitation of insoluble analyte elements, loss of volatile analytes during heating and contamination of the sample [3]. In order to avoid these difficulties, slurry sample introduction techniques have been used. However, slurry nebulization, unlike nebulization of aqueous solutions, can result in an aerosol that is unrepresentative of the original sample. Because of irregular particle size distributions, larger particles are removed from the spray chamber. This is especially true for geological samples which contain minerals that are more resistant to grinding [12]. Nebulization also suffers from poor transport efficiency which can lead to memory effects if the sample is deposited in the transport tubing. This problem has been addressed by other ICP sample introduction techniques.

ETV, laser ablation, and arc and spark ablation rely on direct analysis of solid samples with minimal to no sample preparation. These methods were developed for sample vaporization and transport to the ICP and therefore separate species based on their volatility. ETV is superior to nebulization for analysis of most solids because it has low sample consumption and high transport efficiency [5]. However, ETV is hindered by spectral and nonspectral interferences that may occur when sample matrices reach the plasma and is limited by the kinds of samples that can be analyzed [9]. In contrast, laser ablation offers direct solid sampling for almost any sample and can also be used to determine spatial distribution of elements in a solid [1]. A disadvantage of laser

PII S0039-9140(96)02159-5

ablation is that it is difficult to know how much sample is being ablated or whether the ablated sample is representative of the entire solid [1]. Spark ablation may be used as an alternative to laser ablation, but requires that the sample be a conducting solid [10]. The direct current (DC) arc, historically used as an excitation source for optical emission experiments [14], is capable of vaporizing 7 mg of many solid samples in a short (10–20 s) period of time. If these vapors are collected and transported to an ICP, the DC arc then becomes a viable sample introduction technique.

This paper presents a method for determining magnesium in geological samples by DC arc-ICP optical emission spectroscopy (DC arc-ICP-OES). Minimal sample preparation is required and detection limits in the ppm range are obtainable. A method of standard additions is used in conjunction with internal standardization for the Mg determinations.

2. Experimental

2.1. Apparatus

Fig. 1 is a schematic of the experimental setup. The power supply (Cat. # 2001-30, Zeebac, Barea, OH.) is a constant current device capable of yielding a continuous range between 4 and 30 A at an open circuit voltage of 300 V. Ignition is automatic and a timer can be set to terminate the current at any time less than 120 s after ignition.

Because the vapors generated by the DC arc must be transported to the ICP, the design of the arc chamber has several unique requirements. First, it must be essentially air tight to prevent the escape of analyte. Second, it must have an inlet and an outlet through which argon can pass to carry the analyte vapors to the plasma. Third, it should have as small a volume as possible to minimize dilution of the analyte vapor and thus loss in sensitivity. Finally, the chamber must provide for easy sample manipulation and must also be constructed of a material which can withstand the heat produced by the arc but which does not produce any interferences when heated.

Several chamber designs constructed of water cooled glass or ceramic chambers with brass electrode holders were evaluated. Because of the inherent differences in the thermal expansion coefficients of these materials, it was difficult to maintain an air-tight enclosure. Vaporized analyte could not be effectively contained, and ambient air could enter the chamber and subsequently the plasma. The design used in the present experiments consisted of a glass dome, with an inlet and an outlet, which was sealed onto a ceramic disk. The ceramic disk had two holes in it which allowed connection of the power supply to the cathode and the anode. The total volume of the chamber was about 100 cm^3 and it was found that water cooling was not necessary. This design was air-tight, mechanically robust, and simple to use.

The power supply was connected to the arc chamber by a positive and negative lead, both of which connect to the bottom of the chamber. The

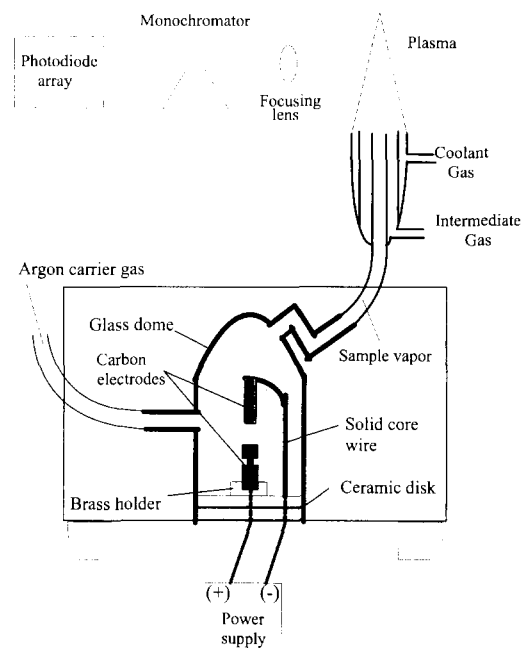

Fig. 1. Schematic of DC Arc Vaporization for ICP-AES. The two carbon electrodes are enclosed by the glass dome which forms an air-tight seal with a ceramic disk. Argon carrier gas flows through the glass dome and carries vaporized sample to the plasma torch. At the torch, intermediate and coolant gas (both argon) are introduced.

sample containing electrode (anode) fit into a holder and was secured with a set screw while the upper electrode (cathode) screwed into a holder supported by 4 ga. solid core wire. The anode was a crater electrode (Ultra Carbon, Bay City, MI) with an outer diameter of 0.185 in. and a sample capacity of 0.025 cm^3. The upper electrode was a post electrode (Ultra Carbon, Bay City, MI) which had been snapped off behind the taper so that it was a simple cylinder of uniform diameter 0.125 in. It was observed that this geometry minimized arc wandering on the sample electrode. The electrodes and electrode holders were enclosed by the glass dome which sealed to the ceramic base, allowing collection of vaporized sample and transport to the plasma by a sample gas flow.

The inductively coupled plasma (Thermo Jarrell Ash, Franklin, MA) was a 40 MHz argon plasma which operated at forward powers between 700–1500 W. The lower portion of the enclosure (just below the torch) was removed to allow for easy switching between sample introduction techniques.

The detector used was an intensified photodiode array (ST-120, Princeton Instruments, Trenton, NJ) which was fitted to a monochromator (82020 Scanning Monochromator, Thermo Jarrell Ash) containing a grating of 1180 lines mm^{-1} blazed at 250 nm. The plasma was imaged onto the entrance slit by a lens mounted in the plasma enclosure. The linear dispersion of the monochromator was 1.2 nm mm^{-1} and the 1024 diode array had a total length of 25 mm, so that a spectral window of about 30 nm could be viewed when the photodiode array was in the focal plane of the monochromator.

2.2. Technique

In early experiments, the arc chamber was connected to the plasma torch by a 20 cm length of 6 mm i.d. Tygon tubing. This length was intentionally kept short to minimize diffusion of analyte vapor during transfer. Integration of the emission signal from the ICP was initiated at the same time the arc was ignited and continued until approximately 2 s after the arc was terminated, a total of 12 s. In this way, the emission from an entire 2 mg sample of Mg in graphite was collected.

One problem with this technique which immediately became evident was that the argon plasma was noticeably unstable during the operation of the arc, which led to large fluctuations in the emission signal obtained at any given instant. Integration of the signal over the total time of 12 s gave relative standard deviations of $\sim 50\%$. The problem of plasma stability was solved by coupling the arc chamber to the plasma with a 2 m length of Tygon tubing. With this longer length of tubing, it was found that the analyte vapors did not arrive at the plasma until ~ 10 s after the arc was ignited. The vaporization of sample was complete by this time, so the arc was extinguished before the arrival of analyte at the plasma. The emission could then be collected from the much more stable plasma, and it was found that sample dilution was not significant as the signal still lasted a total of about 10 s, and was of roughly equal intensity to that with the shorter transfer tube.

Initial characterization of the experimental setup was performed on Mg standards prepared in graphite powder. Initially less than 0.2 g of $MgCl_2$ was weighed into a plastic vial and mixed with graphite powder (Ultra Carbon, Bay City, MI). Serial dilutions of the sample with graphite powder were carried out to achieve a range of Mg concentrations from 1 to 88 ppm. Different weights of the graphite matrix standards could be reproducibly loaded into the sample electrodes by use of a solids pipette (Drummond, Broomall, PA).

The current, electrode gap, and sample size were evaluated to find a combination of these three parameters which would provide total vaporization of the analyte with maximum reproducibility. The range of current available was 0–30 A and the electrode gap range (limited by the chamber) was 0–15 mm.

The voltage drop across the electrodes was measured for different electrode gaps. At a gap of 10 mm and a current of 10 A, the voltage between the electrodes was 25 V; the voltage decreased to 14 V at a gap of 5 mm. Temporal profiles of vaporized Mg in graphite powder for different gap and current settings showed that the time required to vaporize a given mass of sample was

more dependent on the gap length than the arc current. At a gap of 5 mm, a minimum current of 8 A was required to produce a smooth vaporization of a 2 mg sample of Mg in graphite. The Mg emission from the ICP was transient over a 10 s period. At a current of 10 A, the temporal profile remained largely unchanged but the emission intensity increased slightly. Further increases in current for the 5 mm arc gap produced little change in the signal observed. With the arc gap set to 10 mm, the signal from the vaporized analyte was considerably more intense but also more unstable. At an electrode gap of 10 mm, the arc tended to wander around the sample electrode causing discontinuous vaporization and erratic emission. The time required to vaporize a 2 mg sample could not be well-defined. For this reason, and because this larger gap greatly increased the heating of the chamber and reduced the life of the electrodes, it was decided that a gap of 5 mm would be used with a current of 10 A.

The intermediate gas flow rate had little effect on the signal intensity over the range in which a stable plasma could be formed, and a value of 1 l min^{-1} was used for all experiments. Similarly, the coolant gas flow rate affected the signal insignificantly, and was set to a value of 10 l min^{-1} which gave the most symmetrical plasma shape. The carrier gas flow rate, however, had a large effect on signal intensity. A minimum of 1 l min^{-1} was needed to puncture the plasma and form a sample channel; this flow rate provided the greatest signal level which dropped rapidly with increasing flow rates. In an effort to examine carrier gas flow rates of less than 1 l min^{-1}, an auxiliary flow was coupled to the flow through the chamber so that a sample channel could be maintained at flow rates of less than 1 l min^{-1} through the chamber. However, it was found that the signal intensity did not increase and so a carrier flow of 1 l min^{-1} was used with no auxiliary flow.

The effect of the forward power of the plasma on emission intensity was examined over the range 1000–1400 W and a value of 1250 W was chosen as much for plasma stability as for signal intensity. The image of the ICP was focused onto the entrance slit of the monochromator, and the effect of plasma viewing height on signal and background intensities was measured. Fig. 2 is a plot of background versus viewing height for the nebulizer and DC arc sample introduction. The background during nebulization falls sharply with increased viewing height while the background with DC arc introduction is fairly constant over the entire height of the ICP plasma. This phenomenon is probably due to the large amount of water introduced to the plasma with the nebulizer as compared with the DC arc. The result is that the optimum S/N ratio for DC arc sample introduction is found at a somewhat lower viewing height (14 versus 18 mm above the load coil) than for nebulization, although the maximum signal for both types of sample introduction is found at 14 mm. The width of the entrance slit was set at 50 μm giving a spectral resolution of 0.1 nm.

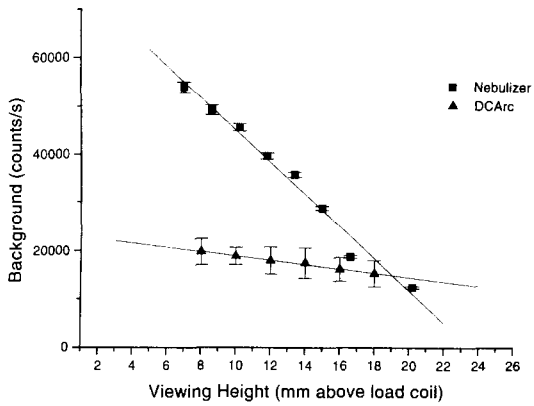

Fig. 2. Backround versus viewing height for nebulizer and Dc Arc. The background counts obtained at low plasma viewing heights are much higher for aqueous nebulization than for DC arc vaporization. As a result, the optimum viewing height is lower in DC arc vaporization than in nebulization.

The photodiode array was set to collect emission for a total of 10 s and to display a spectrum of average intensity over the 10 s integration. The Mg 279.6, 280.3, and 285.5 nm lines could all be viewed simultaneously in the window which extended from 260–290 nm. The 279.6 nm line was the strongest line observed for Mg emission in the UV/VIS region.

3. Results and discussion

Two different experiments were performed to test the feasibility of calibrating based on a total energy procedure in which emission is integrated for the entire sample [14]. First, different masses of sample of the same Mg concentration were vaporized, then equal masses of samples of different Mg concentrations. The plot of signal versus mass was linear over a mass range of 0.5–2.0 mg and the plot of signal versus concentration was linear over a concentration range of 1–100 ppm. The slope of the signal versus concentration shows that the arc is capable of determining analytes in solids with a sensitivity superior to that found in nebulization of liquids. However, large relative standard deviations indicated that this calibration technique was not sufficient to perform determinations with precision better than about 20%. The sensitivity of the DC arc technique is due to the high transport efficiency relative to nebulization. For comparison, a calibration curve was generated by nebulizing aqueous Mg standards. Table 1 is a comparison of the analytical figures of merit. A comparison of the sensitivities (counts ng^{-1}) for nebulization ICP-OES and DC Arc-ICP-OES can be done as follows.

With a nebulizer flow rate of 1 ml min^{-1}, 16 ng s^{-1} ppm^{-1} of Mg enter the nebulizer. Dividing the slope of the nebulization calibration curve by this factor gives (3175 counts s^{-1} ppm^{-1})/(16 ng s^{-1} ppm^{-1}) = 198 counts ng^{-1}. The nebulization ICP-OES gives 198 counts ng^{-1} of Mg consumed.

With a 2 mg sample of Mg in graphite powder in the DC arc, 2 ng ppm^{-1} of analyte are vaporized. Dividing the slope of the DC arc vaporization calibration curve by this factor gives (23272 counts ppm^{-1})/(2ng ppm^{-1}) = 11635 counts ng^{-1}. The DC arc gives 11635 counts ng^{-1} of Mg consumed.

Table 1
Comparison of analytical figures of merit for nebulization ICP-OES and DC Arc-ICP-OES

	Nebulization	DC arc vaporization
Sensitivity (slope)	3175 counts s^{-1} ppm^{-1}	23 272 counts ppm^{-1}
Precision (RSD)	4%	23%
Limit of detection	5×10^2 ppb	4×10^2 ppb

The DC arc system therefore produces 60 times as much emission ng^{-1} of Mg as the nebulizer system. If the transport efficiency of the nebulizer is assumed to be 1–2%, then the transport efficiency of the arc introduction is approaching unity. This high efficiency provides increased sensitivity.

A common technique for analysis of solids by ICP-OES is dissolution of the solid into an aqueous solution followed by nebulization of the solution. This technique inherently dilutes the analyte concentration usually by several orders of magnitude. Because the DC arc has a limit of detection roughly equal to that of the nebulizer but requires far less sample dilution (samples may be mixed with graphite powder to aid vaporization), it is a much more efficient sample introduction method for analyzing trace concentrations in solids, especially when only a small amount of sample is available.

For instance, a 10 mg solid sample containing 1 ppm of analyte could be analyzed five times by DC arc sample introduction of 2 mg samples containing 1 ppm of analyte. If the same 10 mg sample were to be analyzed by nebulization, it would first have to be dissolved in a minimum of 10 ml of solution which would then contain the analyte at a concentration of 1 ppb. Clearly, if both methods have equal limits of detection, the DC arc sample introduction is more desirable. The disadvantage is poor precision.

To improve the precision, an internal standard was used. Initial investigations were carried out with phosphate rock and coal fly ash as samples. The Si line at 288.1 nm was used as the internal standard because it corresponded to a fairly strong transition of a major element which could be viewed in the 30 nm window containing the Mg transition at 279.6 nm. It was found that when the intensity of the Mg 279.6 nm line was ratioed to the intensity of the Si 288.1 nm line, RSD's of less than 10% could be obtained for successive measurements on both types of samples.

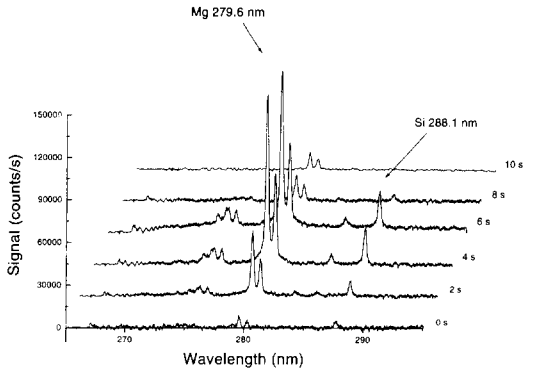

Fig. 3. Temporal profile of emission from NIST Coal 1632b. The signal is transient over about 10 s. The Mg 279.6 nm line intensity is ratioed to the Si 288.1 nm line intensity.

Because the amount of silicon varied from sample to sample, internal standardization did not aid calibration. However, because it reduced run to run deviation, it could improve precision if standard additions were used in the determination. This possibility was examined with two new NIST samples, coal and estuarine sediment, both mixed with graphite. These samples, like the coal fly ash and phosphate rock contained Si which could be used to standardize analyte emission. By spiking the prepared samples with a known amount of analyte, the original analyte concentration was found by plotting the Mg 279.6 nm/Si 288.1 nm intensity versus concentration in a standard addition plot.

The coal standard, NIST Coal 1632b, was mixed with an equal amount of graphite powder (1.00 g/1.00 g) and mixed in a ball mill to give a sample which was 50% by weight coal. The same standard was mixed with an equal amount of a 218 ppm Mg in graphite powder standard prepared from $MgCl_2$ (1.00 g/1.00 g). In this way, the second sample had a Mg concentration 109 ppm greater than the first.

The arc gap was set to 5 mm and the power supply was set to provide 12 A of current for a 10 s duration. At these settings, the signal produced from the vaporized coal was transient over about a 10 s period. The temporal profile was similar to that observed for the Mg standards. Fig. 3 shows spectra taken at 2 s intervals when a 2 mg sample of 50% coal was introduced by the arc. A 2 mg portion of the first sample was placed in the sample electrode by means of the solids pipette and the arc was ignited. The analyte vapors reached the plasma just as the arc was extinguished (as evident by the appearance of the Mg 279.6 nm line) and the signal integration was initiated. After 10 s, the emission had decayed almost to background and signal collection was terminated. The average emission intensity of the Mg 279.6 nm and Si 288.1 nm lines over the 10 s integration were recorded.

This procedure was repeated a total of five times for the first sample and then the spiked sample was run five times in an identical manner. The Mg/Si intensity ratio was determined for each of the runs. The certified value for the Mg concentration in the coal sample was 385 ppm. The value determined for the 50% coal sample by extrapolation of the standard addition plot was 175 ppm. When this value is doubled (to account for sample dilution with graphite powder), the Mg concentration determined is 350 ppm, an error of 9%. When a second point was added to the standard addition curve, by preparing a sample to be plotted at 55 ppm added, the intercept was at -200, giving a concentration in the coal of 400 ppm, with error of 4%.

NIST Estuarine Sediment 1646 was mixed with graphite powder to give a sample which was 10% sediment (0.20 g sediment/1.80 g graphite) and mixed with 280 ppm Mg (0.20 g sediment/1.80 g 280 ppm Mg) to give a spiked sample to be plotted at 252 ppm added. The analysis was carried out the same way as the coal analysis and the standard addition plot gave an intercept of -1005 ppm. Correction for the dilution factor of 10 gave a Mg concentration of 1.01% in the original sample. The certified value for Mg in the estuarine sediment was 1.08%, a 6% error.

4. Conclusions

The DC arc-ICP-OES method involving standard additions to an internally standardized sample allows quantitation of Mg with good accuracy and precision, as evidenced in the determination in two NIST standards. The disadvantages of

such a technique are that some sample preparation is required and some a priori knowledge of the analyte concentration is required in order to make appropriate additions. Furthermore, simultaneous determinations of more than one analyte would require additions of more than one element to the spiked samples. Nevertheless, the technique is capable of performing accurate determinations in solids without dissolution, and if the run to run variations in the transport efficiency can be reduced, simultaneous multi-element determinations should be possible in non-conductive solids with no sample preparation and no internal standardization.

Laser ablation has the potential to do similar determinations, but because the mass of material introduced to the plasma is small and varies greatly between matrices, detection limits are seldom below ppm (for emission experiments) and an internal standard must often be used.

In direct sample insertion techniques, the vaporization, atomization, and excitation all take place in the plasma, and independent optimization of any one of these parameters is impossible. Determinations at the sub-ppm level by emission can be done only in select matrices, and fractionation makes multi-element determinations extremely challenging.

Electrothermal vaporization is perhaps the technique most similar to DC arc introduction. Larger sample loadings can be introduced to the plasma, and detection limits for emission experiments are into the ppb range. Precision on the order of 5–15% is obtainable [9]. ETV sample introduction is very sensitive to matrix effects, however, and temperature programs must be optimized for each matrix to be analyzed.

It has been shown in this work that an inductively coupled plasma can tolerate 2 mg of solid vaporized by a DC arc over a period of 10 s. Determination of Mg in graphite powder by atomic emission gave a detection limit of 400 ppb, and determination of Mg in NIST Coal 1632b and Estuarine Sediment 1646 by standard additions using similar experimental parameters gave an average precision of 5%.

Future work will include the redesign of the arc chamber and possibly of the transfer tubing in an attempt to stabilize the transport efficiency. Use of fluxing agents (NaF, etc.) to act as carriers, and of additions of O_2 to the argon carrier gas, are being investigated at present for determinations in ceramics. Ultimately the arc may be connected to an ICP-MS for mass spectrometric detection of vaporized analytes.

Abstract

In this paper, the optimization of gas chromatographic experimental parameters is investigated using a three layer feed-forward neural network with the back-propagating. The design, development, and testing of the neural network are described in detail. The chosen structure is 4-6-2 system with a learning rate η of 0.6 and a momentum constant μ of 0.4. The results of several simulations are very satisfactory. Network results are compared with the results obtained by the orthogonal method. © 1997 Elsevier Science B.V.

Keywords: Gas chromatographic; Neural network; Optimization

1. Introduction

Optimization of chromatographic operating conditions is a complicated process which requires much time and effort because many parameters must be taken into consideration. In general, the determination of optimal experimental conditions is based on either the orthogonal testing or the simplex optimization method. The orthogonal testing is a method using an 'Orthogonal Table' to arrange the multifactors testing, which can find the better analytical conditions with relatively few testing times. But, in general, it is only the self effects but the mutual cross effects of the factors are considered that it is not easy to reach the global optimization. The optimizing process of Simplex Optimization Method, in a sense, just likes 'a blind person climbing a mountain', to observe the much conditions, such as the best point, worst point, expansive point, reflective point and so on, before every experiment. So it is time-consuming and costly, especially if a large number of parameters is involved. Thus, there is a need for a new optimizing method to select the optimum experimental conditions.

Recently, much attention has been paid to the application of the novel method of artificial neural networks (ANN's) in chemistry and some satisfactory results have been achieved [1–4]. In analytical chemistry, ANN's have been used for calibration [5–8], parameter estimation [9–11],

prediction [12–15], spectrophotometric research [16–19], and optimization of analytical conditions [20,21].

ANN's utilize the weight matrices to perform the mathematical transformation of the input vector to the output vector. The feed-forward neural networks trained by back-propagation of errors have one obvious advantage: there is no need to know the exact form of the analytical function on which the model should be built. That is, neither the functional type (linear, polynomial, exponential, logarithmic etc.) nor the number and position of the parameters are required. Therefore, ANN's are suitable for experimental condition optimization since the relationship between evaluating indices and the experimental input parameters is complex, nonlinear, and often cannot be expressed with a certain mathematical formula.

In this paper, optimizing conditions of the thermal desorption-gas chromatography experiments were studied. The task consists of handling the information on three levels or layers: an input layer; an output layer; and a hidden layer. The input layer consists of four chromatographic experimental parameters, which are column temperature (T_c), carrier gas flow (F_c), and the temperature and time of thermal desorption (T_d and t_d). The output layer consists of the two output signals of peak height (H) and resolution (R). A third level with a certain number of nodes, the hidden layers, is inserted between the input and output layers. The number of nodes in the hidden layers is not fixed but is itself to be adjusted for optimal results, six in the case. As shown in Fig. 1, every node on a lower level sends a signal to every node on the next level above, constituting a feed-forward network. A so-called backward propagating algorithm was applied to arrive at specific result. For the purpose of mathematical treatment, the four input parameters and the two output signals are regarded as nodes. The optimizing results from the network having hidden layer nodes from 2 to 10 are compared. A 4-6-2 system was selected as the most suitable structure. The simulation of the experimental results was very satisfactory. The optimal ranges of values for the experiment obtained from the neural network were compared with that obtained by the orthogonal method.

2. Theory

The topological architecture of the three-layer feed-forward neural networks is shown in Fig. 1. The numbers of input layer and output layer, in the study, are four and two, which are referred to as the chromatographic experimental parameters and as the evaluating indices or output signals. The number of hidden layer nodes is discussed in Section 4.1.

For an input layer node, the output is equal to its input:

$$X_i = O_i \tag{1}$$

In Eq. (1), the subscript i indicates the ith input layer node. The output from the input layer are weighted and fed to the hidden nodes. The net input of jth hidden node is:

$$\text{net}_j = \sum_{i=0}^{m} O_i \times W_{ij} \tag{2}$$

where W_{ij} indicates the weight of the connection between the ith input node and the jth hidden node. The outputs of the hidden layer nodes (O_h) are given after transformation by the sigmoidal function:

$$O_{hj} = f(\text{net}_j) \qquad f(x) = \frac{1}{1+e^{-x}} \tag{3}$$

The subscript hj in Eq. (3) represents the jth hidden layer node. The output of the bias node in both input and hidden layer is a constant, 1.

The output of the last layer (output layer) nodes are given by the sum after weighted input from the hidden layer nodes and the transformation:

$$O_j = f\left(\sum_{j=0} O_j \times W_{ij}\right) \tag{4}$$

where W_{jl} is the weight connecting the jth hidden node to the lth output layer node. The relative error between the output value and the target value for the evaluation indices H and R is

$$E_l = \frac{Y_l - O_l}{Y_l} \tag{5}$$

where Y_l is the target value of lth index, i.e., the experimental value of H and R. The calculation repeated after moving to another experimental point.

After carrying out the procedure about for all combination of input signals, the root-mean-square error (RMSE) was given by Eq. (6).

$$\text{RMSE} = \sqrt{\sum_{s=1}^{n} \sum_{l=1}^{n_i} \frac{E_l^2}{n_i n}} \tag{6}$$

where n is the number of trained samples, and n_i is the number of output layer nodes.

The every weight, which initial value is given by the computer randomly and remained equal in all systems with different hidden nodes in order to compare them conveniently, is changed automatically via Eq. (7) and then the training's are re-

[b] The initial weights were different from c group.

peated until RMSE falls into a acceptable region, the trained network is obtained.

$$\Delta W_{ij}(t) = \eta \delta_j O_i + \mu \Delta W_{ij}(t-1) \quad (7)$$

In Eq. (7), t is the number of iterations of the neural computation. The proportionality constant η is the learning rate and determines how fast the changes $\Delta W_{ij}(t)$ should be implemented in the iteration cycles. The momentum constant μ prevents sudden changes in the direction in which corrections are made. The error δ can be expressed as:

$$\delta_l = E_l f'(\mathrm{net}_l) \quad (8)$$

for output layer lth node and:

$$\delta_j = \left(\sum_{l=0}^{n_l} \delta_l l_{lj} \right) f'(\mathrm{net}_{hj}) \quad (9)$$

for hidden layer jth node. Here $f'(\mathrm{net}_{hj})$ is the partial derivative with respect to W_{ij} of the transformation function.

We let trained network scan automatically and intensively near the range of experimental points, and give a series of vectors of calculation results, which must include optimal point(s).

3. Experiment

The thermal desorption-gas chromatography experiments were done on a 8701 model thermal desorber manufactured by Shanghai Fourth Analytical Instrument Factory, China and a GC-9002 model gas chromatograph with a 100 cm length of stainless steel column manufactured by Shanghai Xinhu Precision Analytical Instrument Factory, China. The chromatographic indices were recorded and calculated by Chromatopac C-R3A, a data processor for chromatographs, Shimadzu, Japan. The neural computation was run on a 486-PC micro-computer.

Nine group parameters were selected as gas chromatographic experimental conditions by means of the orthogonal method (see Table 1), taking $CHCl_3$ and another impurity in drugs as test sample. The experimental results were trans-

formed to the evaluating indices: peak height (H) and resolution (R). The experimental parameters and devaluating indices were used in the neural computational program as straining data. The optimized experimental parameters were selected from the output of the computational results.

4. Results and discussion

4.1. Selection of the number of hidden layer nodes

In order to obtain the best neural network structure, several ANN systems with different number of hidden nodes were tested in the study. The RMSE values after iterating ten thousand times are listed in Table 2. From the RMSE values the 4-4-2 and 4-6-2 systems are better than the others. In the two systems, the RMSE's of 4-6-2 system are all smaller than that of 4-4-2 systems except for the case $\eta = 0.6$ and $\mu = 0.4$. After iterating the two structure neural network ($\eta = 0.6$ $\mu = 0.4$) 30 000 times, the RMSE's of the two networks were further decreased from 0.02531 to 0.00861 (for 4-6-2 system) and from 0.02092 to 0.01038 (for 4-4-2 system), respectively.

For these reasons, we chose 4-6-2 structure as the optimized system.

4.2. Selection of the η and μ

The initial architecture of the neural network (the number of layers, neurons, and especially for weights) is only an initial guess, it must be modified after performing calculations. Since the feed-forward neural networks is a non-linear optimization system, there is the problem of local minimal, in other words, there is the possibility that the procedure may end in a local minimum, if the learning rate η and the momentum constant μ are not selected very carefully. The steepest way downhill dose not necessarily lead to the global minimum, and it is not possible in the back-propagation approach to justify the weights infinitesimally [22]. In training process, if the value of the learning rate and the momentum constant were too small (< 0.4), RMSE would show large fluctuation, and could not reach a global minimum quickly. The same would occur when the chosen values were too large (see Fig. 2).

The another phenomenon to be noted found from Fig. 2(b) and Table 2 and Table 3 is that RMSE was smaller when the values of η and μ are close to each other but not equal. If η was greater than μ, the RMSE's were oscillatory for a certain range in training. Good values for the learning rate η lie between $0.5 \sim 0.7$ in the study, the optimal momentum constant μ was slightly smaller.

Another problem for modifying weights was how to determine the η' and μ' when the RMSE$(t) >$ RMSE$(t-1)$. It cannot be assured that the RMSE decreases smoothly in the training process for all neural networks. If RMSE$(t) >$ RMSE$(t-1)$, the direction of the modifying weights value (ΔW_{ij}) must be changed, i.e., the η and μ (denoted as η' and μ') have to be changed. The test results are listed in Table 4, and the best value are $\eta' = 1.0$ and $\mu' = 0$.

4.3. Evaluation of the stability of the network

After settling the optimal values of $\eta = 0.6$ and $\mu = 0.4$, the network was trained 200 000 times, Table 5 showed the results obtained from chromatographic experiment and neural computation. It should be noted that the predicted results are satisfactory, and that the difference between experimented and calculated values is small: 8 (1.10%) for peak height and -0.12 (-6.49%) for resolution. If initial weights are chosen differently, the agreement between the experimental results and the computational values is very much the same.

Table 8
Comparison between the experimental and the computational values

No.	Optimal region				Calculation		Experimental	
	a	b	c	d	H	R	H	R
1	145	15	80	2	875	2.79	882	2.76
2	145	15	86	2	863	2.62	866	2.65
3	123	40	80	1	896	2.62	890	2.60
4	138	40	86	1	890	2.70	891	2.73
5	145	40	105	1	853	2.27	860	2.30
6	153	40	100	1	870	2.48	865	2.52
7	135	40	93	1	876	2.38	866	2.44
8	145	40	93	2	787	2.47	770	2.38

a Column temperature (°C).
b Carrier gas flow (ml min^{-1}).
c Thermal desorption temperature (°C).
d Thermal desorption time (min).

The corrected reliability coefficient [23] was calculated in order to test the reliability between the neural computation and the chromatographic experiment. The results are listed in Table 6, they show that the results of the neural network calculation have a high degree of reliability.

4.4. The determination of optimal experimental regions

Fig. 4 shows the relationship of peak height (H) and resolution (R) to the four chromatographic parameters in the orthogonal method. Though the resolution was influenced slightly by changes in thermal desorption time and column temperature, changes in thermal desorption temperature and carrier gas flow had larger effects on R. The peak height was influenced significantly by all four parameters. Additionally, the experiment showed that the column efficiency decreased if the carrier gas flow was greater than 45 ml min^{-1}.

From these observations, the optimal operating region selected was: column temperature: 148°C; carrier gas flow: 40 ml min^{-1}; thermal desorption temperature: 93°C; thermal desorption time: 2 min. Because the effects of the four parameters were considered independently and their mutual cross effects were overlooked, it cannot be guaranteed that the selected region is globally optimal.

As opposed to the orthogonal method, the neural network method scanned the whole range of experimental parameters intensively, i.e., it took the mutual influence of the four parameters into account. Therefore much more faith may be placed in the optimal region obtained by the neural network method.

Based on the neural computational data, there are four favorable regions with higher values of peak height and resolution (Table 7). Only one region was found by the orthogonal method, and it is second worst of the four found by the ANN. Additionally, the ANN revealed some general trends: (1) long thermal desorption times are

needed in combinative relatively low thermal desorption temperatures; (2) short thermal desorption times are needed in combinative relatively high thermal desorption temperatures; and (3) the peak height and the resolution will be much smaller ($H < 50$ and $R < 0.6$) if the thermal desorption temperature is higher than 130°C and the carrier gas flow is less than 30 ml min^{-1}.

After further experiments and researching, we found that the experimental results of H and R were nearly the same to the computational values (Table 8). It is proved that the ANN can be used to optimize the chromatographic conditions.

5. Conclusion

Based on the discussion above, it can be concluded that the neural network method is very suitable for optimizing chromatographic experimental conditions, especially for multi-parameter experiments. It provides a new, efficient, and optimal approach in analytical chemistry.

Received 24 October 1996; received in revised form 26 November 1996; accepted 26 November 1996

Abstract

An electrochemical hybridization biosensor was developed for the detection of short DNA fragments specific to the deadly waterborne pathogen *Cryptosporidium*. The sensor relies on the immobilization of a 38-mer oligonucleotide unique to the *Cryptosporidium* DNA onto the carbon-paste transducer, and employs a highly sensitive chronopotentiometric transduction mode for monitoring the hybridization event. Variables of the probe-immobilization, hybridization and indicator-detection steps are optimized to offer convenient quantitation of ng ml^{-1} levels of the *Cryptosporidium* DNA target, in connection with short (3–15 min) hybridization times. The suitability for direct detection of the spiked *Cryptosporidium* DNA target in untreated drinking and river water samples is demonstrated. Similar performance characteristics are observed at DNA-coated microfabricated thick-film carbon strips. This and similar developments hold great promise for field screening of *Cryptosporidium* and other microorganisms in environmental samples. © 1997 Elsevier Science B.V.

1. Introduction

Protozoans of the genus *Cryptosporidium* are obligate intracellular parasites which invade the gastrointestinal systems of their mammalian hosts [1]. Infection by *Cryptosporidium* can cause debilitating, and sometimes life-threatening gastroenteric and diarrheal illness. In humans, *Cryptosporidium* can spread from person to person through direct contact, as has been observed in hospitals [2] or, as has been subsequently recognized, through waterborne outbreaks [3]. A recent, highly-publicized example of the latter occurred in Milwaukee in 1993, in which *Cryptosporidium* caused illness in some 400 000 people, and out of which there were 104 deaths [4]. Five other waterborne outbreaks of *Cryptosporidium* were reported in N. America since 1985 [5].

In particular, the species *Cryptosporidium parvum* has been recognized as a significant global health threat, one of several critical etiologic agents causing severe diarrheal illness, particularly in developing countries [6]. According to the World Health Organization, this debilitating syndrome, resulting in dehydration and malnutrition, is responsible for the deaths of 11 000 children each day and 5 million people a year worldwide, making it the second leading cause of death behind cardiovascular disease [7]. The EPA estimates that 155 million people in the United States are at risk of exposure to *Cryptosporidium* [4]. There currently exists no effective drug treatment for this infection [5], and routine chlorination treatment does not eradicate dormant *Cryptosporidium* organisms in drinking water [4].

Due to the environmental health threat posed by waterborne *Cryptosporidium parvum*, there is an urgent need for a routine test that reliably detects the presence of the pathogen in water supplies. Yet, despite these major concerns and increasing efforts by the EPA, no analytical method satisfactorily detects the *Cryptosporidium* microorganism. The current indirect fluorescence antibody (IFA) assay, prescribed by the EPA, often fails to detect oocysts in spiked samples [4,8]. A variety of other methods, ranging from flow cytometry to immuno-(ELISA or electrorotation) ones, have been proposed, but to date are still in early developmental stage [4,8]. Accordingly, nonspecific turbidity assays commonly serve as the best indicator for the presence of *Cryptosporidium*. A direct, fast and specific sensing scheme, with minimal sample manipulations, is desired for minimizing losses of the oocysts, and providing a rapid warning capability essential for a quick corrective/preventive action by water utilities.

The present article describes the characterization and optimization of a new DNA electrochemical biosensor for detecting *Cryptosporidium* DNA sequences. Genetic methods, relying on the high specificity of DNA hybridization/recognition reactions, hold great promise for environmental monitoring of microorganisms. A highly sensitive protocol for *Cryptosporidium*, based on the coupling of DNA PCR amplification, electrophoretic separation and chemiluminescent measurement, has been developed recently for detecting this protozoan in water samples [5]. Faster and simpler DNA sensing schemes are highly desired for effective wide-scale monitoring at drinking water facilities. Miniaturized hybridization electrochemical sensors, coupling the inherent specificity of DNA recognition reactions with the remarkable sensitivity and portability of electrochemical transducers [9], are particularly attractive for on-site detection of drinking-water pathogens. The new electrochemical biosensor relies on the immobilization, onto the carbon electrode transducer, of a 38-mer oligonucleotide probe, unique to *Cryptosporidium parvum* DNA [5,10] (taken from the gene which codes for the small (18S) subunit of rRNA). Highly sensitive constant-current chronopotentiometry [11,12], is used for transducing the hybridization event, along with the $Co(phen)_3^{3+}$ redox indicator. The use of the $Co(phen)_3^{3+}$ indicator and carbon paste transducers for sequence-selective electrochemical detection was illustrated by Mikkelsen's group [13].

2. Experimental

2.1. Materials

The 38-mer probe (5′-GGG GAT CGA AGA CGA TCA GAT ACC GTC GTA GTC TTA AC-3′, P-sequence) and 38-mer target (5′-GTT AAG ACT ACG ACG GTA TCT GAT CGT CTT CGA TCC CC-3′, T-sequence) were purchased from Life Technologies (Grand Island, New York, USA) as their ammonium salts.

Other oligonucleotides were also received from Life Technologies, and their sequences are given in the Table 1. Single-stranded calf thymus DNA (ssDNA, lyophilized powder, Catalog No. D8899) and double-stranded calf thymus DNA (dsDNA, activated and lyophilized, Catalog No. 4522) were purchased from Sigma (St. Louis, MO). Guanidine hydrochloride (Catalog No. G3272), sodium chloride (Catalog No. S3014), monosodium phosphate (Catalog No. S3139), sodium acetate buffer (3 M, pH 5.2 ± 0.1 at 25°C, Catalog No. S7899), Tris–HCl buffer (1.00 ± 0.05

M, pH 7.00 ± 0.05 at 25°C, Catalog No. T2413) and Tris–EDTA (TE) buffer (100 × concentrate, 1.0 M Tris–HCl, 0.1 M EDTA, pH 8.0, Catalog No. T9285) were also received from Sigma. The above reagents were free of DNase and RNase. Tris(1,10-phenanthroline) cobalt(III) perchlorate was synthesized at NMSU using the method of described by Dollimore and Gillard [14].

DNA stock solutions (nominally 1000 μg ml^{-1}) were prepared with the TE buffer (1 × concentrate, 10 mM Tris–HCl, 1 mM EDTA, pH 8). Sterile distilled water was used for preparing all the solutions. A diode array spectrophotometer (Model 8452A, Hewlett Packard) was employed to correct the concentration of nucleic acids by measuring optical density ($\lambda = 260$ nm).

All glassware, containers, pipette tips and the cell (with exception of the electrodes) were sterilized by autoclaving for 30 min. Sterilized water were used to rinse the electrodes prior to use.

A river water sample was taken from the Rio Grande River (Picacho Bridge, Las Cruces, NM); a tap water sample was collected in this laboratory; waste water samples were collected from the influent and effluent water of the waste water plant of Las Cruces, NM.

Table 1
Effect of various nucleic acids on the hybridization response

Nucleic acid[a]	Concentration (μg ml^{-1})	Signal change (%)
ssDNA	1	+7.7
dsDNA	1	+4.6
totalRNA	1	−4.0
42-mer DNA	1	−0.1
	2	−3.3
36-mer DNA	1	+0.2
	2	+4.1
27-mer DNA	1	+6.2
	2	+10.0
25-mer DNA[b]	1	+1.7
	2	+7.6
15-mer DNA	1	+6.2
	2	−13.2

The CPE with the immobilized 38-mer DNA (P-sequence) was immersed into the hybridization solution containing the complementary strand (1 μg ml^{-1} 38-mer DNA (T-sequence)) alone or its mixture with the interferent given in the table. After 5 min incubation, the electrode was rinsed and transferred into 0.1 mM Co(phen) indicator for 2 min, followed by the chronopotentiometric measurement. The enhancement of the chronopotentiometric signal due to the hybridization of the probe (P-sequence) with the complementary target (T-sequence) served as 100%. Other conditions as in Fig. 1.

[a] The sequence of the DNA oligomers are as below: 42-mer DNA 5′-ACT GCT AGA GAT TTT CCA CAC TGA CTA AAA GGG TCT GAG GGA-3′, 36-mer DNA 5′-CCA CAT GGC CTG TAC TTT AAA AGC TTC CGG ATG ACC-3′, 27-mer DNA 5′-GTC GTC AGA CTC AAA ACC ACG AGA GGG-3′, 25-mer DNA 5′-CAG GAT ATG TGG CGG ATG AGC GGC A-3′, 15-mer DNA 5′-TGT ACG TCA CAA CTA-3′.

[b] The sequence corresponds to a portion of *E. coli* DNA.

2.2. Electrode preparation

Carbon paste was prepared in the usual way by hand-mixing graphite powder (Catalog No. G67-500, Fisher Scientific, Pittsburgh, PA) and mineral oil (Catalog No. M5904, free of DNase, RNase and protease, Sigma) in a 70:30 ratio. The surface was polished to a smoothed finish before use. The body of the working electrode was a Teflon sleeve (3.5 mm, i.d.) tightly packed with the carbon paste. The electrical contact was made with a stainless steel screw.

Some experiments employed screen-printed carbon strip electrodes (SPEs), prepared using a semiautomatic screen printer (Model TF-100, MPM, Franklin, MA). Commercial carbon ink (Product No. C10903D14, Gwent Electric Materials, UK) was printed onto the alumina ceramic plate (33.5 × 101.5 mm, Coors Ceramic Company, Golden, CO) through a patterned stencil to give a group of ten printed carbon electrodes with each carbon strip consisting of a 1.5 × 30 mm area. The electrodes were subsequently cured for 1 h (at 180°C), and were allowed to cool. A layer of an insulator was then placed onto part of the printed carbon strip, leaving a nominal 1.5 × 5 mm working area.

2.3. Chronopotentiometry

Constant-current chronopotentiometric measurements were performed in a three-electrode electrochemical cell (2 ml, Kimble Glass, Vineland, NJ), using a TraceLab potentiometric stripping unit (PSU 20, Radiometer, Denmark) in

connection with an IBM PS/2 55SX computer. According to the TraceLab protocol, the potentials were sampled at a frequency of 30 kHz and the derivative signal (dt/dE) versus potential (E) was recorded following baseline fitting. The analytical signal was evaluated using the peak areas; the reported result is the peak area for the duplex DNA minus the peak area for the probe DNA alone (Δ PSA). The three-electrode system consisted of a carbon-paste working electrode, Ag/AgCl reference electrode (Model RE-1, BAS, W. Lafayette, IN), and a platinum wire auxiliary electrode. The three electrodes entered the cell through a Teflon cover.

2.4. Procedure

2.4.1. Probe immobilization

The 38-mer DNA probe was immobilized on a freshly smoothed CPE by applying a potential of +1.7 V (or +1.8 V in the case of the printed strip) for 1 min followed by 2 min at +0.5 V in a stirred acetate buffer solution (0.2 M, pH 5.2) containing 5 μg ml^{-1} of the DNA probe (P-sequence). The electrode was then rinsed with a solution containing 0.5 M NaCl and 0.02 M phosphate buffer (pH 7.0) for ca. 10 s.

2.4.2. Hybridization

For hybridization reactions, the probe-coated electrode was immersed into the stirred hybridization solution (1 M guanidine HCl, 0.5 M NaCl, 0.02 M phosphate buffer, pH 7.0; 1 or 2 ml) containing the DNA target for the desired time (depending on the target concentration), while holding the potential at +0.5 V. Then the electrode was rinsed with 0.02 M Tris–HCl buffer (pH 7.0) for 10 s.

2.4.3. Indicator binding

The $Co(phen)_3^{3+}$ was accumulated onto the surface hybrid by immersing the electrode into the stirred Tris–HCl buffer solution containing 0.1 mM $Co(phen)_3^{3+}$ for 2 min while holding the potential at +0.5 V. Then the electrode was rinsed with the Tris–HCl buffer for 10 s.

2.4.4. Chronopotentiometric transduction

The surface-accumulated $Co(phen)_3^{3+}$ was measured, after transfer to a blank Tris–HCl buffer solution, using constant-current chronopotentiometry with an initial potential of +0.5 V and a constant current of −6 μA (−3 μA for the screen-printed electrode).

Repetitive measurements were carried out by renewing the surface of the CPE, or by using a new carbon strip, and repeating the above procedure. All operations were carried out at room temperature (22.0 ± 0.5°C).

3. Results and discussion

The 38-mer *Cryptosporidium*-DNA specific probe displayed a strong adsorptive accumulation at the carbon (paste or strip) electrodes. Such interfacial accumulation was exploited for immobilizing the probe onto the surface. Conditions for attaining a full surface coverage and a stable probe layer were explored. Using a 5 μg ml^{-1} solution of the 38-mer probe (P-sequence), surface saturation was achieved following a 2 min accumulation while holding the electrode at +0.5 V. The surface-confined oligonucleotide layer was stable for at least 30 min upon immersing the electrode into the stirred hybridization solution, and maintains the conformation essential for efficient binding of its complementary target strand.

Fig. 1 displays chronopotentiograms for the $Co(phen)_3^{3+}$ at the 38-mer probe coated electrode after immersion in the 1 μg ml^{-1} *Cryptosporidium* target sequence solution for different periods (1–7 min, a–f). The longer the hybridization time, the more duplex is formed, and the more indicator is 'collected' at the surface, leading to larger chronopotentiometric signals. In contrast, no peak enhancement is observed upon repeating this time-dependent experiment in the absence of the *Cryptosporidium* target (dotted lines). Such target-independent blank response reflects the association of the indicator with the ss-probe. The increased peak area in the presence of the target thus serves as the hybridization signal. The resulting plot of the signal versus hybridization time is also shown in Fig. 1 (inset). The response in-

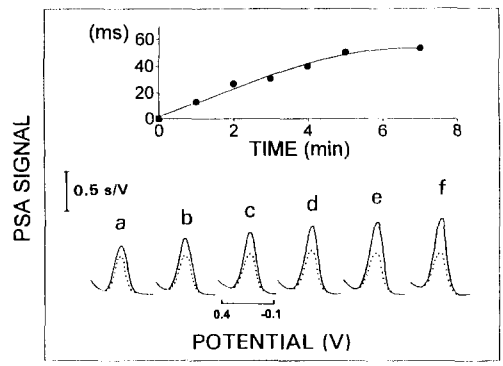

Fig. 1. Chronopotentiograms for $Co(phen)_3^{3+}$ at the probe 38-mer DNA (P-sequence)-modified CPEs towards the target 38-mer DNA (T-sequence) following increasing hybridization times: 1 (a), 2 (b), 3 (c), 4 (d), 5 (e) and 7 (f) min. Dotted traces denote the corresponding blank responses. Also shown (inset) is the resulting plot of chronopotentiometric (PSA) signal versus hybridization time. Probe immobilization: 1 min at +1.7 V followed by 2 min at +0.5 V in 0.2 M acetate buffer (pH 5.2) containing 5 μg ml^{-1} 38-mer (P-sequence); hybridization: 0–7 min at +0.5 V in 0.5 M NaCl, 1 M guanidine HCl, 0.02 M phosphate buffer solution (pH 7) containing 1 μg ml^{-1} 38-mer DNA (T-sequence); indicator binding: 1 min at +0.5 V in 0.02 M Tris–HCl buffer (pH 7) containing 0.1 mM $Co(phen)_3^{3+}$; PSA transduction: in the blank Tris–HCl buffer solution with a constant current of −6 μA and an initial potential of +0.5 V.

creases linearly with hybridization time at first (up to 4 min), and then more slowly. Overall, these data indicate that μg ml^{-1} levels of the *Cryptosporidium* DNA target can be readily quantified following short hybridization times.

Hybridization conditions (other than the time) have a profound effect upon the performance of the *Cryptosporidium* DNA biosensor. Fig. 2 displays the influence of hybridization solution conditions, such as the ionic strength (A) and accelerator level (B). The response rises slowly upon changing the sodium chloride concentration between 0 and 0.2 M and then more rapidly up to 0.5 M; a sharper decline is observed at higher salt levels. The hybridization signal also increases slowly upon raising the concentration of the guanidine accelerator between 0 and 1.0 M, and decreases gradually at higher levels. All subsequent work thus employed a 0.5 M sodium chloride solution containing 1.0 M guanidine. Other potential hybridization accelerators, including several polyethylene glycols (MW 1000–22 000) and dextran sulfate (MW 500 000), were also tested, but did not produce the expected signal enhancement effect. The operating potential also affects the hybridization response. The signal increases slowly from 28 to 47 ms upon changing the potential from 0.0 to +0.5 V, and decreased to 38 ms at +0.6 V (not shown; conditions, as in Fig. 1e). Electrostatic attraction of the negatively-charged target sequence, as well as improved retention of the probe, may account for this potential dependence. The decreased response at very positive hybridization potentials can be ascribed to the direct oxidation of the probe (guanine moiety).

The influence of the $Co(phen)_3^{3+}$-indicator concentration and its association time is shown in Fig. 3. The response increases gradually upon increasing the marker concentration up to 1×10^{-4} M, and decreases rapidly above 2.0×10^{-4} M (A). Very short indicator association times are sufficient for obtaining high sensitivity (B). The response increases rapidly with the association time up to 1 min, and decreases gradually above 2 min. The decreased hybridization signal at high indicator levels or for long indicator-association times is due to a larger indicator response at the

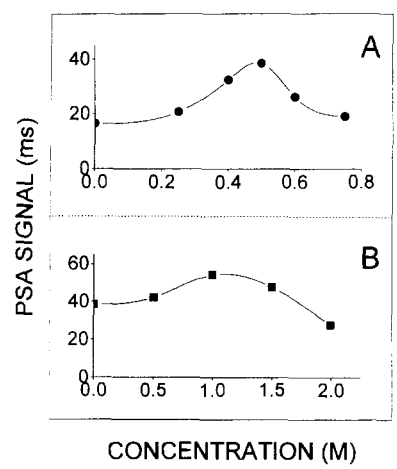

Fig. 2. Effect of sodium chloride (A) and guanidine HCl (B) in the hybridization solution on the response of the target 1 μg ml^{-1} 38-mer DNA (T-sequence) at the probe 38-mer DNA (P-sequence)-modified CPEs using $Co(phen)_3^{3+}$ as indicator. Hybridization time: 5 min; concentration of guanidine HCl: 0 (A) and 0–2 M (B); other conditions as in Fig. 1.

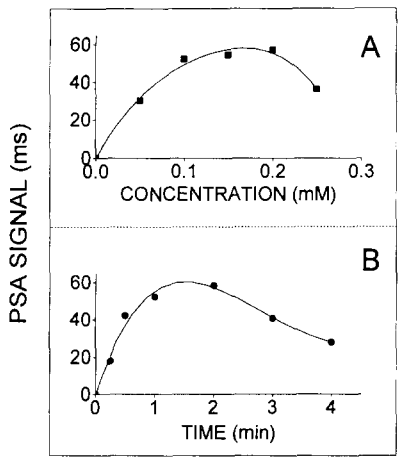

Fig. 3. Effect of $Co(phen)_3^{3+}$ concentration (A) and indicator-binding time (B) on the response of the target 1 μg ml^{-1} 38-mer DNA (T-sequence) at the probe 38-mer DNA (P-sequence)-modified CPEs. Hybridization time: 5 min; other conditions as in Fig. 1.

ss-probe modified electrode (and does not reflect a decrease of the absolute signal).

Fig. 4 displays calibration data for ng ml^{-1} and μg ml^{-1} concentrations of the target *Cryptosporidium* sequence following different hybridization times (1(a), 3(b) and 5(c) min). As expected for saturation of the probe binding sites, shorter hybridization times allow extension of the linear range. For example, while with a 5 min hybridization period linearity prevails up to 500 ng ml^{-1}, the linear range extends to 2.0 μg ml^{-1}

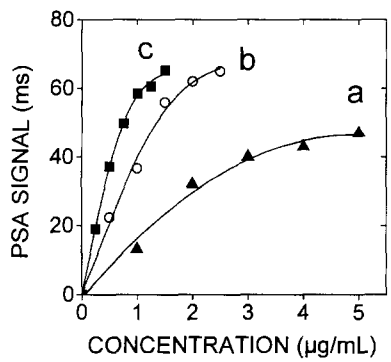

Fig. 4. Calibration plot for the target 38-mer DNA (T-sequence) at the probe 38-mer DNA (P-sequence) modified CPEs using $Co(phen)_3^{3+}$ as indicator. Hybridization time: 1 (a), 3 (b) and 5 (c) min; indicator-binding time, 2 min; other conditions as in Fig. 1.

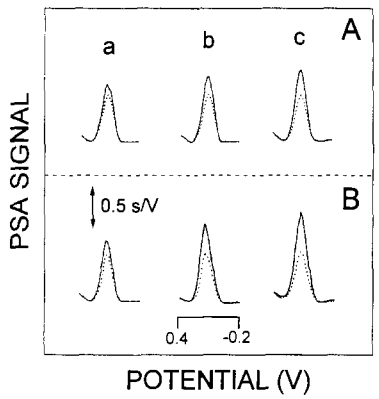

Fig. 5. Chronopotentiograms for the tap water (A) and river water (B) samples spiked with different concentrations of the target 38-mer DNA (T-sequence): 0.5 (a), 1.0 (b) and 1.5 (c) μg ml^{-1} at the probe 38-mer DNA (P-sequence) modified CPEs using $Co(phen)_3^{3+}$ as indicator. Dotted traces denote the corresponding responses of the unspiked solutions. Volume percentage of the water samples in the hybridization solution: 95%; hybridization time: 5 min; indicator binding time: 2 min; other conditions as in Fig. 1.

using a 1 min hybridization. The sensitivity (slope of the linear portions) corresponds to 13.9, 36.4 and 59.2 ms.ml $μg^{-1}$ for the 1, 3, and 5 min hybridization. The data of Fig. 4c indicates convenient measurements of the *Cryptosporidium* DNA target over the 250–1500 ng ml^{-1} range using a 5 min hybridization. Significantly lower levels of 100 and 50 ng ml^{-1} were readily detected using 15 and 30 min hybridization periods, respectively (not shown). Despite these extremely low detection limits, coupling of the sensor with a PCR amplification unit would be required for the detection of a few *Cryptosporidium* parasites in environmental samples.

Fig. 5 demonstrates the suitability of the DNA sensor for direct measurement of the *Cryptosporidium* sequence in untreated drinking-water (A) and river-water (B) samples. Small (500 ng ml^{-1}) increments in the target concentration yield a well-defined hybridization response in connection with a short (5 min) hybridization period. Such defined peaks are similar to those observed in 'synthetic' samples (e.g., Fig. 1c), indicating a lack of major interferences in these environmental samples. In contrast, large interferences were observed in the presence of waste-water matrices.

For example, adding a 12.5% (v/v) and 50% (v/v) sample of the waste water influent and effluent, respectively, to the hybridization solution resulted in 80- and 45% diminution of the hybridization response to the 1 μg ml^{-1} target (not shown; 5 min hybridization). Such severe interference is attributed to competitive adsorption by numerous surfactants present in large excess in waste water samples.

The sensor offers a very good discrimination against non-complementary nucleic acids (Table 1). These selectivity data were obtained by challenging the sensor with various noncomplementary oligomers of different lengths (ranging from 15 to 42 mer), including one corresponding to a portion of the *E. coli* DNA, as well as with chromosomal DNA. The response to the *Cryptosporidium* DNA target increases only slightly (7.7- and 4.6%) in the presence of ss- and dsDNA, respectively. The various oligomers also display a small effect upon the target sequence peak, with signal changes ranging from −3.3 to −13.2% in the presence of excess of the 42- and 15-mer oligomers, respectively. The small changes reported in Table 1 are also attributed to nonspecific adsorption (and its effect upon the attached probe), and not to base-pair recognition.

As desired for on-site environmental applications, we also examined the suitability of microfabricated carbon strips for transducing the recognition of the Cryptosporidium DNA target. Several performance characteristics of the screen-printed DNA biosensor are shown in Fig. 6. The response increases nearly linearly with the hybridization time up to 3 min, and decreases gradually above 4 min hybridization (A). The response also increases linearly with the target concentration up to 750 ng ml^{-1}, and then more slowly (B). While the sensitivity of the strip is lower compared with that of the carbon-paste based device (e.g., versus Fig. 4b), the microfabricated sensor offer extremely low (ng) detection limits. This is indicated from Fig. 6C that displays chronopotentiograms in the absence (a) and presence (b) of 50 ng ml^{-1} *Cryptosporidium* DNA target. Such detectability is similar to that reported above for the carbon paste electrode. The operation of these disposable *Cryptosporidium* sensors may be coupled with the hand-held chronopotentiometric analyzer [15] or microfabricated PCR units [16], for further facilitating their field operation.

In conclusion, we have described a new hybridization biosensor for electrochemical detection of sequences specific to *Cryptosporidium* DNA. Such effort addresses the urgent needs and analytical challenges of detecting *Cryptosporidium* in drinking-water and natural water samples. It should be pointed out, however, that the new device is still in the developmental stage, and additional work is required prior to adaptation for routine environmental testing. In addition to coupling with compact PCR units, attention should be given to the sample collection/treatment step, and to the minimization of nonspecific adsorption effects. Simple freeze-thaw lysis methods should be sufficient for releasing the target nucleic acid from the oocysts. New probes, based on the peptide nucleic acids (PNA) DNA mimics [17] should offer improved biosensor performance, including greater specificity. Work is in progress

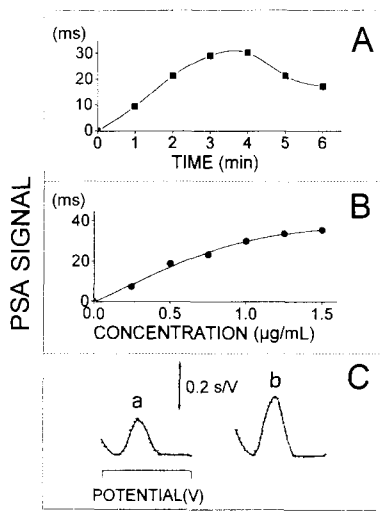

Fig. 6. Response of the microfabricated DNA biosensor: (A) Effect of hybridization time on the the response of the target 1 μg ml^{-1} 38-mer DNA (T-sequence) at the probe 38-mer DNA (P-sequence)-modified SPE using $Co(phen)_3^{3+}$ as indicator. (B) Calibration plot for 0–1.5 μg ml^{-1} 38-mer DNA (T-sequence) at the SPEs following a 3 min hybridization. (C) Chronopotentiograms for 0 (a) and 0.05 (b) μg ml^{-1} target 38-mer DNA (T-sequence) at the SPE following a 30 min hybridization; indicator binding time, 2 min; other conditions as in Fig. 1.

towards the development of similar devices for detecting *E. coli* DNA sequences. Ultimately, we wish to design high-density arrays of microelectrodes coated with probes specific for different bacterial and viral pathogens. This and similar developments should have a profound impact upon environmental monitoring of microorganisms. The miniaturized and nonradioactive nature of electrochemical devices, coupled with their low-power requirements, should further facilitate their adaptation for field-screening of waterborne pathogens. The procedure should also prove useful for clinical diagnostic testing for *Cryptosporidium*.

Abstract

Electrodes modified by the electrodepozition of conducting organic polymers such as poly(3-methylthiophene)(PMT), polypyrrole (PPY) and polyaniline (PAN) were used as chemical sensors for voltammetric analysis and flow injection detection of some organic and biological molecules. The electrochemical behaviors of catechol, ascorbic acid, hydroquinone, dopamine, epinephrine, acetaminophen and *p*-aminophenol were examined by differential pulse voltammetry. The electrochemical behavior of these molecules at different electrodes was compared and the effects on behavior of electrolyte type and its pH and the film thickness were systematically examined. The results showed that the proposed modified surface catalyzes the oxidation of these compounds. Electrocatalytic 'efficiency' decreases in order of poly-3-methylthiophene, polypyrrole and polyaniline. Voltammetric peak positions were affected by the nature of the electrolyte and its pH. Also, the effect of increasing film thickness was to observe increased peak heights. Polymer coated electrodes were also used in an amperometric detector for flow injection analysis of most of the these compounds. The responses of the polymer electrode were 5–15 times larger as compared with those of bare platinum. PMT showed improved performance as an amperometric detector for flow injection analysis systems over other types of polymer electrodes. Detection limits as low as 10^{-8}–10^{-9} M were achieved using the PMT, compared with 10^{-6}–10^{-8} M using platinum electrodes. In the flow injection analysis, with increasing molecular weight of analyte molecules was to observe decreased peak heights. © 1997 Elsevier Science B.V.

1. Introduction

The electrode materials most commonly used in amperometric systems are glassy carbon [1], platinum and gold electrodes [2]. Mercury electrodes, namely; dropping, thin-film mercury and amalgam electrodes have a relatively wide potential range because of the high hydrogen overvoltage at their surfaces [3]. However, several limitations were reported in the application of mercury electrodes in flowing solutions such as their poor mechanical stability and the dissolution of mer-

* Corresponding author. Fax: +90 422 3410034.

PII S0039-9140(96)02196-0

cury at low potentials, which resulted in their inadequacy in the detection of organic and biological compounds. On the other hand, the performance of gold, platinum, glassy carbon and pyrolytic graphite electrodes depends mainly on the method and quality of surface polishing and pretreatment [4].

Recently, the concept of chemically modifying the electrode surface has gained extensive attention among analytical chemists and others. The properties of the modifying 'layer' coated onto the substrate are deliberately designed to alter the sensitivity and the selectivity of the measurement [5–10].

In the last two decades, the need for high sensitivity and selectivity for the analysis of biomolecules has been increasing [11]. Poly(3-methylthiophene) (PMT), Polypyrrole (PPY) and Polyaniline (PAN) are electronically conducting organic polymers which are easily deposited onto electrodes by the electrooxidation of their monomers. Their applications have been discussed and emphasized in terms of electrochromic effects and energy storage and conversion [12–14].

The use conducting polymers as electrode modification agents for voltammetric determination of some biologically important compounds has been demonstrated in a very limited number of works. PMT-coated electrodes were used by Wang and Li [15] to eliminate the passivation problems, in voltammetric measurements of phenolic compounds. They also observed significantly larger oxidation peaks for acetaminophen. In a different study Wang et al. [16] showed that conducting polymers could be used for controlling size exclusion selectivity.

However, these studies concerning the use of conducting polymers for non-mediated electron transfer were limited to a small number of compounds. Also, no observations were made regarding the effects of film thickness and electrolyte properties on the electrocatalytic ability of the conducting polymer electrodes.

Previous work by Atta and coworkers [17] examined the electrochemical behavior of a large number of biologically important compounds at a PMT electrode. The electrocatalytic property of the PMT was demonstrated as well as the effect of the nature and pH of the base electrolyte. Galal and coworkers [18] examined and compared the electrochemical behavior of some neurotransmitters and other organic compounds at different conducting polymer electrodes.

In this paper we examine the electrochemical behavior of a large number of biologically important compounds at PMT, PPY and PAN modified electrodes. Although limited, the effects of the nature and pH of the supporting electrolyte and film thickness were also studied. Electrocatalysis effects of polymer coated electrodes are clearly demonstrated and selective voltammetric determination of binary mixtures were shown to be possible. Additionally, the polymer coated electrodes were also used for sensitive determinations in a flow injection analysis amperometric detection regime. It is observed that the larger the molecular weight of the substance, the smaller the peak heights obtained.

2. Experimental

2.1. Chemicals

3-methylthiophene, pyrrole (Sigma), dopamine, ascorbic acid, epinephrine, *p*-aminophenol, catechol, acetaminophen, aniline, tetrabutylammonium tetrafluoroborate, acetonitrile, sodium sulphate, sodium chloride, sodium nitrate, sodium perchlorate, lithium chloride, calcium chloride, magnesium chloride, sodium phosphate and sodium fluoride (Merck) were used as received. Acetonitrile and H_2SO_4 were used as solvent for electrochemical polymerization. 3-methylthiophene and pyrrole freshly distilled before use. Flow injection analysis of mentioned compounds were performed using Sörensen buffer (pH = 6.9) as mobile phase.

2.2. Apparatus

Electropolymerization with bulk electrolysis (BE) mode was conducted with a BAS (Bioanalytical Systems) 100BW electrochemical analyzer, in

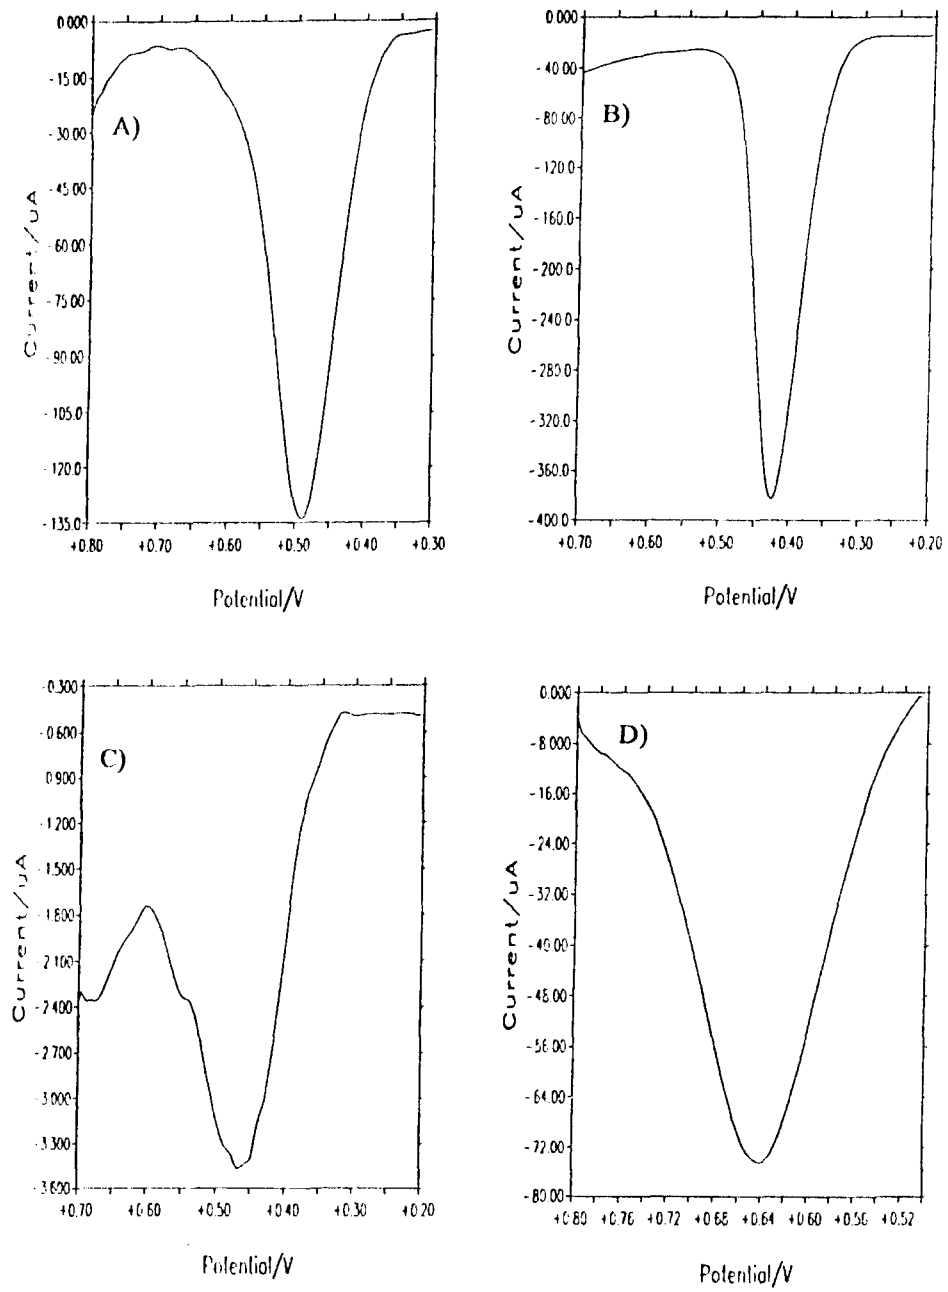

Fig. 1. Differential pulse voltammetry of 20 mM hydroquinone in 200 mM Na_2SO_4 (pH = 2) at PMT (A), PPY (B), PAN (C), and Au (D) electrodes. All films were prepared under similar conditions.

a three electrode cell with gold (BAS, MF-2013) and platinum disk (BAS, MF-1012) as working electrodes, Ag/AgCl (BAS, MF-2063) reference electrode and a Pt wire coil auxiliary electrode. The pH of the solution was measured with a Hanna HI 8314 pH-meter.

Table 1
Differential pulse voltammetric peak potentials for *p*-aminophenol at conducting polymer electrodes[a]

Electrolyte	pH	PMT/Au (mV)	PPY/Au (mV)	PAN/Au (mV)	Au (mV)
$CaCl_2$	2	408	548	520	676
$NaClO_4$	2	281	424	432	460
Na_2SO_4	5	424	392	372	448
NaCl	5	279	436	330	432
LiCl	5	400	470	456	472
NaF	8	184	342	324	348
$NaNO_3$	8	236	399	314	420

[a] *p*-aminophenol and electrolyte concentrations were 20 and 200 mM, respectively.

2.3. Preparation of polymer electrodes

The gold and platinum disk electrodes were cleaned according to standard procedure; namely, polished with successively finer grades of diamond polishing compounds and aqueous alumina slurry (Johnson Mathey Catolog, USA) down to 0.5 μm.

Electrochemical polymerization was carried out in a one compartment cell containing deaerated acetonitrile, 100 mM tetrabutylammonium tetrafluoroborate and 150 mM monomer (in case of 3-methylthiophene, pyrrole) and 0.1 M H_2SO_4 and 485 mM of aniline. The polymer films were grown on gold electrode by bulk electrolysis at a constant potential of 1650 mV versus Ag/AgCl for poly-3-methylthiophene, 950 mV versus Ag/AgCl for polypyrrole and 1700 mV versus Ag/AgCl for polyaniline. The polymer films were grown on platinum disk electrode by bulk electrolysis at a constant potential of 1700 mV versus Ag/AgCl for poly-3-methylthiophene and polyaniline, 1000 mV versus Ag/AgCl for polypyrrole. Electrolysis period was normally 10 s in each case.

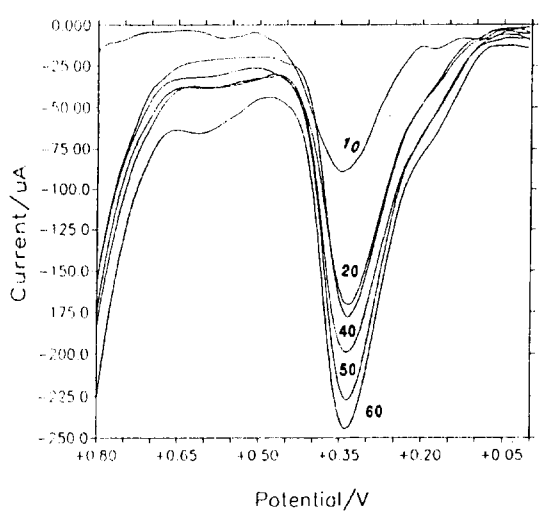

Fig. 2. Effect of film thickness on anodic peak potential for 20 mM catechol on PMT film. The period for film growth with bulk electrolysis is given on each voltammogram. Electrolyte, 200 mm Na_2SO_4 (pH = 2).

3. Results and discussion

3.1. The electrochemical behavior at different polymer electrodes

Fig. 1 shows the differential pulse voltammograms of hydroquinone in Na_2SO_4 at PMT, PPY, PAN and gold electrodes. As can be seen in Fig. 1, the anodic peak potential of hydroquinone at all the polymer electrodes was always much lower than those obtained at the bare gold electrode in the electrolyte chosen for this study (200 mM Na_2SO_4). The comparison of the oxidation peak potential E_{ox} depicted in Table 1, at these electrodes for 20 mM *p*-aminophenol showed two important facts: (i) all the polymer electrodes have relatively lower E_{ox} values as compared with that obtained at Au; and (ii) for the series of polymer electrodes studied, the E_{ox} values increase in the order of PMT < PAN < PPY < Au.

3.2. Effect of film thickness

The effect of film thickness on the anodic peak potential for catechol at conducting electrodes is

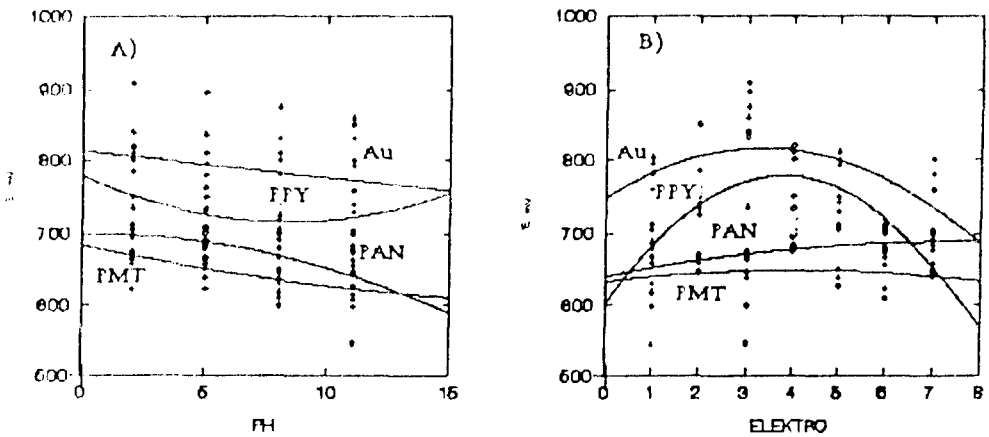

Fig. 3. Effect of (A) pH and (B) electrolyte type on the anodic peak potential of 20 mM epinephrine at different electrodes. Elektrolitler: 1 = NaF; 2 = NaCl, 3 = LiCl, 4 = $CaCl_2$; 5 = $NaNO_3$, 6 = $NaClO_4$ and 7 = Na_2SO_4.

given in Fig. 2. Film thickness had an effect, not only on the peak potentials, but also on the peak current magnitudes. This is expected as with the increasing film thickness surface area of the electrode increases almost regularly.

3.3. Effect of electrolyt type and it's pH

Earlier works involving the use of conducting polymer coated electrodes [19] employed only one type of base electrolyte with a defined pH value to examine the behavior of a certain class of compounds. Although extensive studies have been conducted on the effect of supporting electrolyte for the test substances examined in this work, electrolyte effect will be demonstrated for all these molecules.

Fig. 3 shows effects of pH and electrolyte type on the anodic peak potential of 20 mM epinephrine at different electrodes. As can be seen Fig. 1, the anodic peak potential of catechol at all the polymers electrodes was always much lower than those obtained at bare gold electrodes in all the electrolyte types.

The comparison of the oxidation peak potential E_{ox} at these electrodes for analytes in various electrolyte types showed two important facts: (i) at all the electrodes E_{ox} values shifted to more negative potentials with increasing pH; (ii) in general, with electrolytes containing perchlorate, nitrate and sulphate as anions peak positions for both analytes seem to have shifted to more positive potentials with respect to those electrolytes having fluoride or chloride.

3.4. Stability of the electrode response

The electrodes were prepared under similar conditions, the results showed that the three polymers studied exhibited improved electrocatalytic activity when compared with Au electrode. When the same polymer electrode was used for repetitive runs, stability of the PMT electrode was exceedingly superior over other polymers as depicted in previous work [20].

3.5. Amperometric detection/flow injection analysis of test substances

Amperometric measurements under flow injections or liquid chromatographic conditions are particularly beneficial since the fouling problems are not as severe as in batch experiments, because of small amount of product that is generated. This is especially true for works at low concentrations.

Flow injection analyses of catechol, ascorbic acid, dopamine, epinephrine, *p*-aminophenol, hydroquinone and acetaminophen were performed using Sörensen buffer as mobile phase, 20 μl of

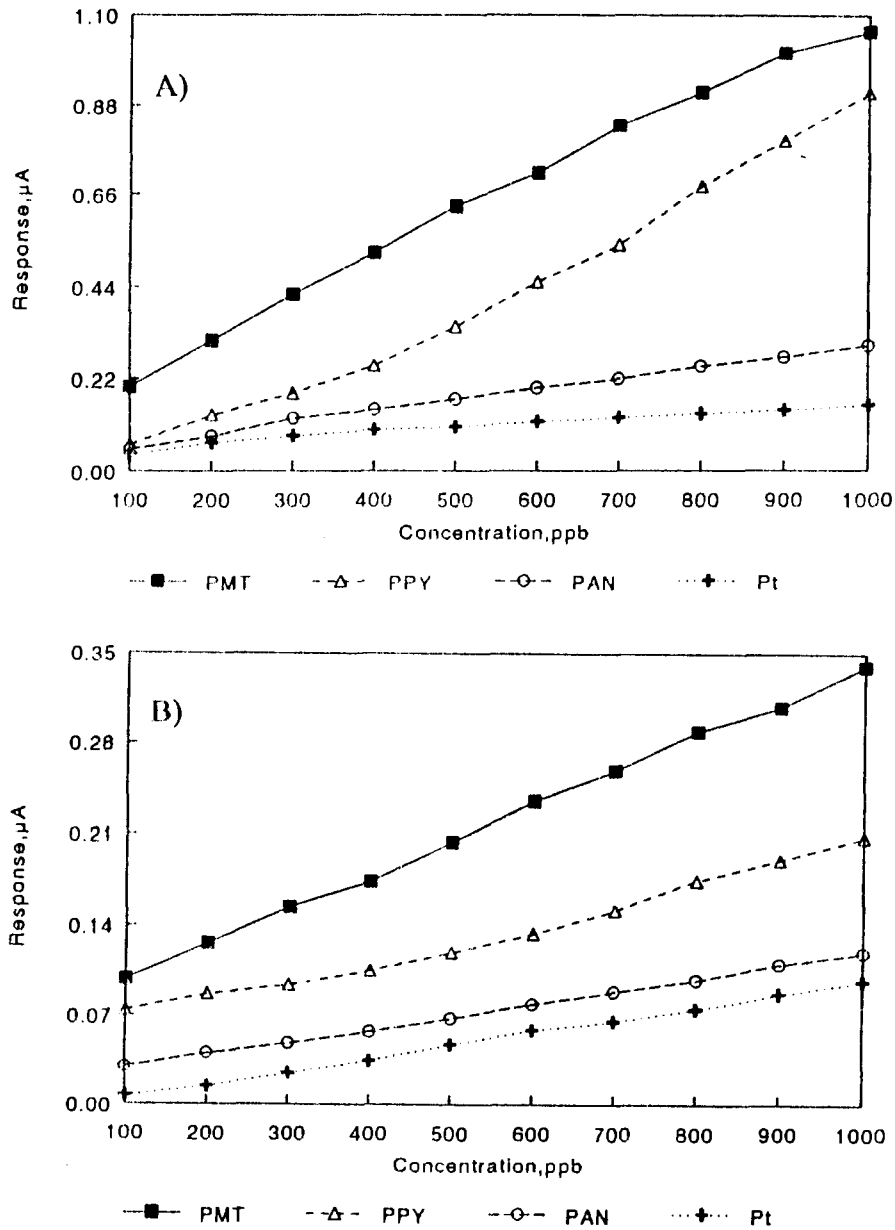

Fig. 4. Flow injection-amperometric detection calibration curves for hydroquinone (A) and ascorbic acid (B) at PMT (■), PPY (Δ), PAN (o) and Pt (+) electrodes. Sample size, 20 ml; mobile phase, Sörensen buffer (pH = 6.9); flow rate, 0.229 ml min^{-1}. Working electrode potential, 0.400 mV.

each test substance having concentration levels of 1–100 ppm with 10 ppm increments were injected and current signals were measured from the recorded peak heights. Working electrode potential for each substance was set at a value that was slightly above the anodic peak potentials of each compounds shown for the polymer electrodes in flow injection analysis responses.

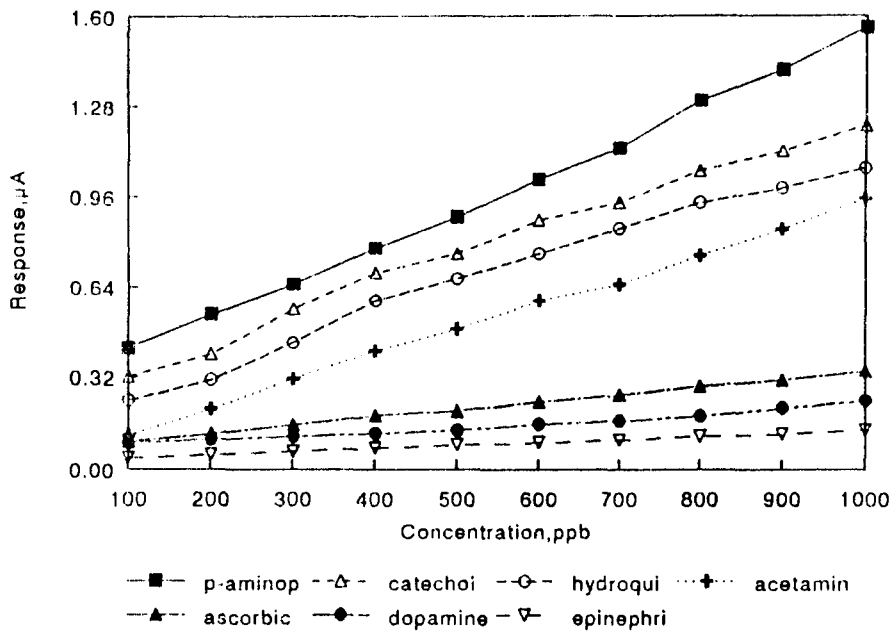

Fig. 5. Flow injection-amperometric detection at PMT electrode. ■: *p*-aminophenol, △: catechol, o: hydroquinone, +: acetaminophene, ▲ ascorbic acid, ●: dopamine and ▽: epinephrine. Sample size, 20 ml; mobile phase, Sörensen buffer (pH = 6.9); flow rate, 0.229 ml min^{-1}. Working electrode potential, 0.400 V.

Fig. 4 shows the calibration curves for hydroquinone and ascorbic acid obtained on polymer electrodes and platinum electrodes. Current responses at polymer electrodes were 5–15 times higher (depending on analyte type) than those obtained on platinum, and excellent linearity was observed for all of the substances for the concentration range studied. For the estimation of detection limits 1, 10 and 100 ppb solutions of respective test substances were injected and the concentration, which produced a current signal with a magnitude at least 2–5 times as high as the signal that is caused by the injection of buffer itself is accepted as a practical limit for detectability. Fig. 5 shows the calibration curves for these compounds on PMT. Detection limits estimated from the procedure described above were 10 ppb for catechol, hydroquinone, dopamine, epinephrine, *p*-aminophenol, ascorbic acid, 5 ppb for acetaminophen and 20 ppb for *p*-aminophenol.

4. Conclusions

In this work, we compared the electrochemical behavior of some organic and biological molecules at different conducting polymer electrodes. The electrodes were prepared under similar conditions, the results showed that the three polymers studied exhibited improved electrocatalytic activity when compared Au or Pt disk electrode.

In the flow injection analysis, with increasing molecular weight of analyte molecules was to observe decreased peak heights.

However, the PMT electrode showed better reversibilty and stability over the other polymers studied. The use of polymer electrodes in flow injection analysis proved to be superior the use of Pt. PMT electrode showed to be stable and more sensitive than Pt. The detection limits obtained using the PMT electrode were as low as 0.1–0.2 ng ml^{-1}. This polymer electrode showed promising results for the resistance surface active agents.

Abstract

For the fundamental study on the development of novel extractants, extraction behavior of divalent first row transition metals such as manganese, nickel, copper and zinc was studied with using *N*,*N*′-bis(2-hydroxyphenylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanediamine (H_2bbpen) and its derivatives as extractants. From the numerical analysis of the intricate extraction behavior of the metals, it was found that they were extracted into chloroform not only as uncharged chelate complexes but also as ion-pairs of charged complexes with a counter anion in aqueous solution. In other words, these ligands seemed to act not only as divalent hexadentate extractants but also as monovalent tri- or tetra dentate ligands, forming positively charged complexes. Furthermore, the order of the extractabilities between the metals did not coincide with the Irving-Williams series of stability because of the 'cavity size' in the ligands and the structural rigidity of them. © 1997 Elsevier Science B.V.

1. Introduction

Solvent extraction [1–4] is a very effective method for the separation of metal species in solutions and a lot of extraction systems have been developed for the separation, the concentration and the selective determination of many kinds of metal ions. As the method has operational convenience and needs no specific instrument, it is also very effective for analyzing some complexation reactions in aqueous solutions.

The compound *N*,*N*′-bis(2-hydroxyphenylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanedi-

amine (H_2bbpen) [5,6] is a divalent hexadentate ligand having amine nitrogen, pyridine nitrogen and phenolate oxygen donor atoms. This ligand has been reported as models for manganese- [6], vanadium- [5,7,8] and ruthenium-containing [9] metalloenzymes. Furthermore, the coordination structures of gallium(III) and indium(III) [10,11] complexes with the derivatives of the ligand have been studied. These researches, however, were performed without focusing the complexation reactions in solution.

In the previous study, we investigated extraction behavior of lanthanoids(III) with H_2bbpen and β-diketones and it was found that the structural rigidity of H_2bbpen leads to strict size recognition of lanthanoids [12]. However, the complexation reactions between divalent metals and these ligands have not been investigated in spite that the formation of neutral complexes is expected.

In this study, we investigated extraction behavior of divalent first row transition metals into chloroform with H_2bbpen and its derivatives, *N*,*N*′-bis(5-bromo-2-hydroxyphenylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanediamine (H_2Brbbpen), *N*,*N*′-bis(5-chloro-2-hydroxyphenylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanediamine (H_2Clbbpen) and *N*,*N*′-bis(3,5-dichloro-2-hydroxyphenylmethyl)-*N*,*N*′-bis(2-pyridylmethyl)-1,2-ethanediamine (H_2dClbbpen), as fundamental approach for the development of novel extractants. The structures of these ligands are shown in Fig. 1. As a result, it was found that, in the extraction system, these ligands act not only as divalent hexadentate extractants but also possibly as monovalent tri- or tetra-dentate ligands, forming positively charged complex. Furthermore, the rigid structure of them influenced the extraction behavior.

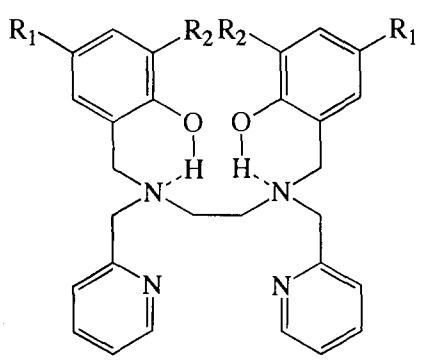

Fig. 1. Structure of the ligands used in this study. $R_1 = R_2 =$ H, H_2bbpen; $R_1 =$ Br and $R_2 =$ H, H_2Brbbpen; $R_1 =$ Cl and $R_2 =$ H, H_2Clbbpen; $R_1 = R_2 =$ Cl, H_2dClbbpen.

2. Experimental

2.1. Reagents

The syntheses of H_2bbpen, H_2Brbbpen, H_2Clbbpen and H_2dClbbpen were performed according to the methods of Neves et al. [6] and Wong et al. [10]. All other chemicals were reagent-grade materials and distilled deionized water was used throughout.

2.2. Distribution of the metals

The distribution of metal ions were studied as follows: in a 30 cm^3 centrifuge tube, an aliquot of chloroform (10 cm^3) containing 1×10^{-2} M of a ligand (H_2L) and equal volume of an aqueous phase containing 1×10^{-4} M of M^{2+} (M = Mn, Fe, Co, Ni, Cu and Zn), 1×10^{-1} M of sodium nitrate or perchlorate and 1×10^{-2} M of the buffer (chloroacetic acid ($2.0 < pH < 4.0$), acetic acid ($3.5 < pH < 6.0$), 2-(*N*-morpholino)ethane-sulfonic acid (MES, $5.5 < pH < 7.0$), *N*-(2-acetamido)-2-aminoethanesulfonic acid (ACES, $6.0 < pH < 7.5$), 3-(*N*-morpholino)propanesulfonic acid (MOPS, $6.5 < pH < 7.9$), 3-[4-(2-hydroxyethyl)-1-piperazinyl]propanesulfonic acid (EPPS, $7.5 < pH < 8.5$), *N*-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid (TAPS, $7.7 < pH < 9.1$), 2-(cyclohexylamino)ethanesulfonic acid (CHES, $8.6 < pH < 10.0$), or 3-(cyclohexylamino)propanesulfonic acid (CAPS, $9.5 < pH < 10.0$)) were shaken at 25 ± 1 °C for 12-72 h. After the two phases were separated by centrifugation, pH and the metal concentration in the aqueous phase were determined with a Hitachi-Horiba F-12 pH meter and a Shimadzu ICPS-1000 III inductively coupled argon plasma spectrometer. In addition, it was established that all of used buffers has no influence on the extraction judged from the obtained smooth extraction curves.

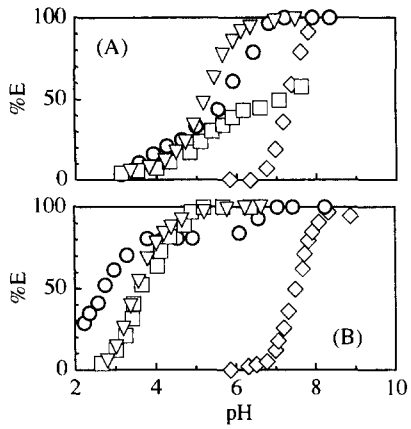

Fig. 2. Plots of the extracted percentages (%E) of some divalent transition metals as a function of the aqueous phase pH equilibrated with organic phase (chloroform) in H_2bbpen–$NaNO_3$ (A) and H_2bbpen–$NaClO_4$ (B) systems. Initial concentrations were 1×10^{-3} M for H_2bbpen in chloroform and 1×10^{-1} M for $NaNO_3$ or $NaClO_4$ in aqueous phase. ◇, Mn^{2+}; ○, Ni^{2+}; □, Cu^{2+}; ▽, Zn^{2+}.

Linear and non-linear least-squares fits to obtain the equilibrium constants were performed using an Apple model Power Macintosh 8100/80 personal computer system and a Delta Point model Delta Graph Pro Ver.3.5 data analysis software package.

3. Results and discussion

3.1. Extraction behavior of divalent first row transition metal ions

The extracted percentages (%E) of Mn^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} in H_2bbpen–$NaNO_3$ and H_2bbpen–$NaClO_4$ systems were plotted as a function of the aqueous phase pH in Fig. 2. The %E became constant with shaking for more than 6 h for Mn^{2+} and Zn^{2+} and 60 h for Ni^{2+} and Cu^{2+} in all of H_2L–NaX (X$-$ = NO^{3-} or ClO_4^-) systems investigated. The relationship between %E and pH was not simple and the result suggested that plural kinds of the complexes were extracted. (The extraction behavior of Fe^{2+} and Co^{2+} was more complicated possibly because the extraction reaction was accompanied with the irreversible oxidation process of these metals to trivalent species. Therefore, further study concerning Fe^{2+} and Co^{2+} was not performed).

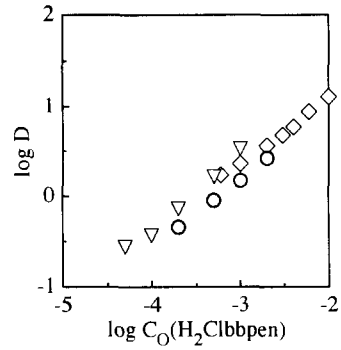

Fig. 3. Plots of the logarithmic distribution ratios (log D) of some divalent transition metals as a function of the concentration of H_2Clbbpen in H_2Clbbpen–$NaClO_4$ system at a fixed equilibrium pH. The value of [ClO_4^-] was 1×10^{-1} M. ◇, Mn^{2+} (pH 6.9); ○, Ni^{2+} (pH 2.1); ▽, Zn^{2+} (pH 3.7).

The extractability of these metals, except for Mn^{2+}, in H_2L–$NaClO_4$ system was higher than that in H_2L–$NaNO_3$ system at lower pH region. This phenomenon means the extracted species at the pH region is an ion-pair of a positively charged metal complex with X^-.

To analyze the composition of these extracted species, the values of the logarithmic distribution ratios (log D) of these metals were plotted as a function of the logarithmic equilibrated concentrations ($[H_2L]_o$) of H_2L in the organic phase, where subscript 'o' means organic phase, or the aqueous phase pH. (From very high hydrophobicity of H_2L [12], $[H_2L]_o$ can be regarded as equal to initial concentration of H_2L in organic phase.) Fig. 3 and Fig. 4 show the plots in H_2Clbbpen–$NaClO_4$ or H_2Clbbpen–$NaNO_3$ system as examples. As shown in Fig. 3, all of the plots of log D versus log$[H_2L]_o$ gave straight line with slope close to 1 (the obtained slopes ranged from 0.8 to 1.0), which means that the extracted species is obtained by the reaction between one M^{2+} cation and one H_2L molecule. To the contrary, as shown in Fig. 4, the plots of log D versus pH gave several kinds of curves. To put it concretely, the plots were grouped into the following four classes:

(i) straight line with slope $\simeq$ 1,
(ii) straight line with slope $\simeq$ 2,
(iii) curve with increasing slope from 1 to 2,

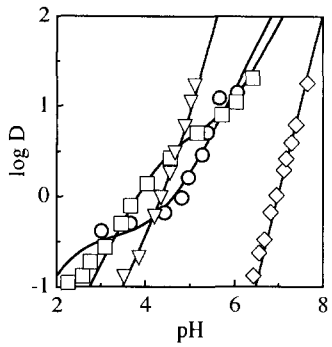

Fig. 4. Plots of the log D of some divalent transition metals as a function of the equilibrium pH in H_2Clbbpen–$NaNO_3$ system. The values of $[H_2Clbbpen]_o$ and $[NO^{3-}]$ were 1×10^{-3} M and 1×10^{-1} M, respectively. ◇, Mn^{2+}; ○, Ni^{2+}; □, Cu^{2+}; ▽, Zn^{2+}. Solid curves were obtained by a non-linear least-squares fit.

(iv) zigzag curve having two slope $\simeq 1$ regions.

For example, Mn^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} in Fig. 4 were classified as (ii), (iv), (iv) and (iii), respectively. The overview of each plot is summarized in Table 1. From the results, it was considered that one or two protons are released by the extraction reactions. The extraction mechanism is detailed in the following section.

Table 1
Overview of the log$D$ versus pH plot in M^{2+}-H_2L-NaX extraction system

H_2L	H_2bbpen	H_2Brbbpen	H_2Clbbpen	H_2dClbbpen
$M^{2+} = Mn^{2+}$				
$X^- = NO_3^-$	(ii)	(ii)	(ii)	(ii)
$X^- = ClO_4^-$	(ii)	(ii)	(ii)	(ii)
$M^{2+} = Ni^{2+}$				
$X^- = NO_3^-$	(iv)	(iv)	(iv)	(iv)
$X^- = ClO_4^-$	(iv)	(iv)	(iv)	(iv)
$M^{2+} = Cu^{2+}$				
$X^- = NO_3^-$	(iv)	(iv)	(iv)	(iv)
$X^- = ClO_4^-$	(i)	(iv)	(i)	(iv)
$M^{2+} = Zn^{2+}$				
$X^- = NO_3^-$	(iii)	(iv)	(iii)	(iv)
$X^- = ClO_4^-$	(i)	(iv)	(i)	(iv)

(i), straight line with slope $\simeq 1$.
(ii), straight line with slope $\simeq 2$.
(iii), curve with increasing slope from 1 to 2.
(iv), zigzag curve having two slope $\simeq 1$ regions.

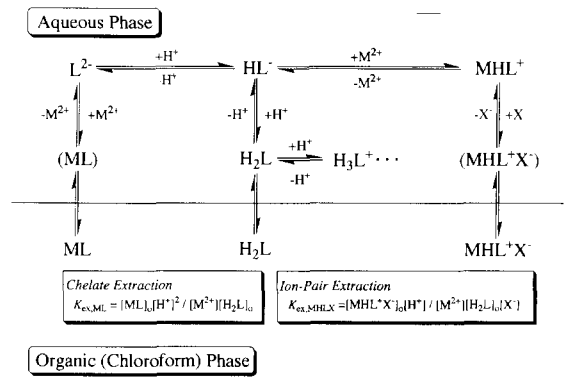

Fig. 5. Equilibria existing in the M^{2+}–H_2L–NaX extraction systems. The existence of ML and MHL^+X^- in aqueous phase was negligible in this study.

3.2. Determination of extraction constants

To interpret the intricate extraction behaviors mentioned above, we considered the chemical equilibria shown in Fig. 5. Since distribution behavior of H_2bbpen into $NaClO_4$ solution was the same as that into $NaNO_3$ solution, the extraction of an ion-pair of the protonated ligand with a counter anion, such as $H_3L^+X^-$ was negligible in the system.

In practice, the ligand H_2L acts as divalent hexadentate ligand (L^{2-}). However, as reported previously [12], the acid dissociation constants of H_2bbpen in aqueous solution, defined as

$$K_{ai} = [H^+][H_{6-i}\text{bbpen}^{(4-i)+}]/[H_{7-i}\text{bbpen}^{(5-i)+}] \quad (1 \le i \le 6) \qquad (1)$$

were determined as $pK_{a1} \ll 2$, $pK_{a2} \ll 2$, $pK_{a3} = 3.35$, $pK_{a4} = 6.08$ and $pK_{a5} + pK_{a6} = 24.4$ and the logarithmic distribution constant ($\log K_D$) between chloroform and aqueous phases were 5.12. (The other ligands seem to have similar pK_{ai} and $\log K_D$ values). Furthermore, Schwingel et al. [13] reported the pK_a values of H_2bbpen in 70% (v/v) ethanol as $pK_{a3} = 3.11$, $pK_{a4} = 5.99$, $pK_{a5} = 12.00$ and $pK_{a6} = 13.26$. These values show the high hydrophobicity of H_2L and the hard dissociability of phenolic proton in H_2L by the formation of six-membered ring including hydrogen bond. It was considered that, in relatively acidic condition, H_2L can act as monovalent tridentate (or tetra-

dentate) ligand (HL^-) and form the charged complex (MHL^+) with M^{2+}, having hydrophobicity enough to be extracted into chloroform as the ion-pair (MHL^+X^-). In this case, it is presumed that one phenolate-O, one amine-N and one (or two) pyridine-N atoms coordinate to M^{2+}.

On considering the equilibria shown in Fig. 5, D is expressed as follows:

$$D = ([MHL^+X^-]_o + [ML]_o)/([M^{2+}] + [MHL^+])$$
$$= (K_{ex,\,MHLX}[H_2L]_o[X^-]/[H^+] + K_{ex,\,ML}[H_2L]_o/[H^+]^2)/(1 + \beta'_{MHL}[H_2L]_o/[H^+]) \quad (2)$$

where K_{ex}, ML means the chelate extraction constant of the following reaction:

$$M^{2+} + H_2L_o \rightleftarrows ML_o + 2H^+ \quad (3)$$

$$K_{ex,ML} = [ML]_o[H^+]^2/[M^{2+}][H_2L]_o \quad (4)$$

$K_{ex,MHLX}$ means the ion-pair extraction constant of the following reaction:

$$M^{2+} + H_2L_o + X^- \rightleftarrows MHL^+X_o^- + H^+ \quad (5)$$

$$K_{ex,MHLX} = [MHL^+X^-]_o[H^+]/[M^{2+}][H_2L]_o[X^-] \quad (6)$$

and β'_{MHL} means the equilibrium constant of the following charged complex formation reaction:

$$M^{2+} + H_2L_o \rightleftarrows MHL^+ + H^+ \quad (7)$$

$$\beta'_{MHL} = [MHL^+][H^+]/[M^{2+}][H_2L]_o \quad (8)$$

Eq. (2) reproduces the (iv)-type log D versus pH plot with experimentally determined values of $K_{ex,ML}$, $K_{ex,MHLX}$ and β'_{MHL}.

In the case that $[MHL^+]$ is negligible, Eq. (2) can be transformed as

$$D = ([MHL^+X^-]_o + [ML]_o)/[M^{2+}]$$
$$= K_{ex,MHLX}[H_2L]_o[X^-]/[H^+] + K_{ex,ML}[H_2L]_o/[H^+]^2 \quad (9)$$

and the (iii)-type log D versus pH plot can be analyzed numerically by using Eq. (9). Furthermore, the (i) and (ii)-type log D versus pH plots can be interpreted by considering simple ion-pair extraction system shown in Eq. (5) and simple chelate extraction system in Eq. (3), respectively. In these cases, Eq. (2) can be transformed as

$$D = [MHL^+X^-]_o/[M^{2+}] = K_{ex,MHLX}[H_2L]_o[X^-]/[H^+] \quad (10)$$

and

$$D = [ML]_o/[M^{2+}] = K_{ex,ML}[H_2L]_o/[H^+]^2 \quad (11)$$

respectively.

The equilibrium constants of $K_{ex,ML}$, $K_{ex,MHLX}$ and β'_{MHL} values were obtained from log D versus pH plots by a non-linear least-squares fit using Eq. (2), Eq. (9), Eq. (10) or Eq. (11). These obtained values are listed in Table 2. Since the values of stability constants of $M(OH)^+$ are $10^{3.4}$, $10^{4.1}$, $10^{6.3}$ and $10^{5.0}$ for M = Mn, Ni, Cu and Zn, respectively [14], the hydrolysis of the M^{2+} was negligible at pH < 6 for Cu^{2+} and pH < 8 for the others.

The solid curves in Fig. 4 were obtained from the fits. All of the experimental data was reproduced accurately by the curves. (In all cases studied, correlation coefficients were more than 0.98). The results shows the extraction model mentioned above is suitable for the extraction system in this paper.

In the chelate extraction, the order of $K_{ex,ML}$ on a fixed H_2L was about Mn < Cu < Zn < Ni, which differs from the Irving-Williams series of stability, Mn < Ni < Cu > Zn. Previously, it was suggested that the 'cavity' formed by the two pyridylmethyl and the two hydroxyphenylmethyl groups in H_2L is suitable for metal ions having ionic radii of ~60–80 pm [10]. The six-coordinate ionic radii of Mn^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} are 83.0, 69.0, 73.0 and 74.0 pm, respectively [15] and the above-mentioned order seems to show the size recognition effect of these ligands. The result shows one possibility that a polydentate ligand having structural rigidity acts as high-selective extractant originated from its size recognition ability similar to crown ethers or calixarenes. In addition, the order Cu < Zn is possibly caused by Jahn-Teller distortion of divalent six-coordinate Cu complex.

On the formation of charged complex MHL^+, the order of β'_{MHL} was Ni > Cu. When H_2L acts as monovalent tridentate (or tetradentate) ligand,

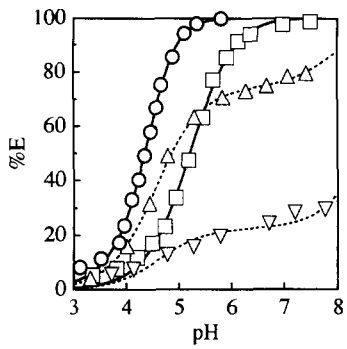

Fig. 6. Comparison between %E-pH plots for divalent zinc in several H_2L–$NaNO_3$ systems. Initial concentrations were 1×10^{-3} M for H_2L in chloroform and 1×10^{-1} M for $NaNO_3$ in aqueous phase. $H_2L = H_2$bbpen (□), H_2Brbbpen (△), H_2Clbbpen (○) and H_2dClbbpen (▽). Curves were obtained by a non-linear least-squares fit.

N.D., not determined.
[a] The mean of the values in M^{2+}–H_2L–$NaNO_3$ and M^{2+}–H_2L–$NaClO_4$ systems (the difference between them is less than 0.2.).
[b] The value in M^{2+}–H_2L–$NaNO_3$ system.

the coordination number of acceptor M^{2+} seems to be four. On forming square-planer complex of Cu^{2+} with HL^-, the complex is possibly instabilized by the steric distortion of the ligand for the formation of phenolate-O–amine-N–pyridine-N-M plane.

3.3. Effect of substituent on the extractability

Fig. 6 shows comparison between %E-pH plots for divalent zinc in several H_2L–$NaNO_3$ systems as an example. Whether X^- was NO_3^- or ClO_4^-, the order of extractability for a metal was about H_2bbpen–NaX < H_2Brbbpen–NaX < H_2Clbbpen–NaX > H_2dClbbpen–NaX. Also the orders of $K_{ex,ML}$, $K_{ex,MHLX}$ and β'_{MHL} shown in Table 2 were almost the same manner. The order H_2bbpen–NaX < H_2Brbbpen–NaX < H_2Clbbpen–NaX corresponded to that of the ability of the release of phenolic proton in H_2L, which is necessary step for the formation of ML. The relative low extractability in H_2dClbbpen–NaX system was possibly originated from the steric hindrance by o-Cl substituent on the phenolic group.

Received 12 April 1996; received in revised form 29 December 1996; accepted 29 December 1996

Abstract

Total phosphorus in five soils with different compositions which were obtained from different places were extracted by using Na_2CO_3 fusion, $HClO_4$ digestion, $HClO_4 + HNO_3$ digestion, $HF + HClO_4$ digestion or NaOBr oxidation methods. In order to test the suitability of the $HF + HClO_4$ digestion the results obtained by this method were compared with the others above, especially the Na_2CO_3 fusion which is accepted as a standard method. The phosphorus amount found with the $HF + HClO_4$ digestion method were almost the same as the phosphorus amount by the Na_2CO_3 fusion method, while the superiority in extracting phosphorus when compared to other methods were obvious. The methods used in the study were evaluated according to the recovery of total phosphorus, ease of application and rapidity with which they were performed. Orthophosphate in the soil extracts was determined by the molybdenum blue colour method. The relationships between methods are examined statistically. © 1997 Elsevier Science B.V.

Keywords: Phosphorus extraction; Soil analysis; Spectrophotometry; Total phosphorus

1. Introduction

The determination of total phosphorus in soils is very important for agricultural studies. It is important to know the phosphorus status of soil for predicting the need to apply phosphatic fertilizers. The determination of total phosphorus in soils involves extraction of solubilized inorganic phosphorus and mineralized organic phosphorus and subsequent determination of orthophosphate in the extracts of soils. The Na_2CO_3 fusion procedure is relatively lengthy and also requires considerable technical skill [1]. Perchloric acid digestion procedures are more amenable to routine estimation of total phosphorus in a large number of soil samples. However, these digestions are conducted commonly in either semimicro-Kjeldahl flasks [2] or tubes using the aluminum digestion block [1]. Of these, the Na_2CO_3 fusion and $HClO_4$ digestion methods as described in 'Methods of Soil Analysis' Part 2 are the recognized standards [3]. Dick and Tabatabai used an alkaline hypobromite

PII S0039-9140(97)00014-3

(NaOBr) oxidation, thereby eliminating the potential for explosions with hot $HClO_4$ oxidations [4].

Orphanos studied the extraction of phosphorus from the five major types of Cyprus soils ranging in $CaCO_3$ content from 0 to 71% using the water and bicarbonate methods. Bicarbonate extracted more phosphorus from the highly calcareous soil and less phosphorus from the igneous soil relative to the water method [5]. A potassium persulfate–sulfuric acid autoclave digestion was used to determine phosphorus in 10–50 mg soil and sediment samples by Nelson [6]. This safe, convenient digestion method released a larger fraction of the phosphorus than that released by the hazardous $HClO_4$ digestion method. A rapid and precise extraction procedure was developed in which sequential additions of concentrated H_2SO_4, H_2O_2, and HF were made to soil samples [7]. Although this method is more quantitative than the $HClO_4$ method, it is not easily used with a large number of samples because of the need to use teflon beakers instead of the calibrated glass tubes used with block digestion. Digestion with $HClO_4$ has been shown to give low results unless the digestion mixture contains HF to ensure destruction of silicates containing phosphatic mineral inclusions [1,8].

Schoenau and Huang evaluated and compared the following available *P* indices as to their ability to predict *P* availability and suitability for routine testing: a novel anion-exchange membrane (AEM) technique, water extraction and 0.5 M $NaHCO_3$ (pH 8.5) extractable total and inorganic *P*. They found that these methods showed identical abilities of the tests to predict soil *P* availability in the range of soils examined and that in testing for *P* alone, AEM was considered superior to the other methods due to low cost, simplicity, independence of soil type and high correlation with plant uptake [9]. Cihacek and Lizotte studied the use of an Al digestion block for the alkaline oxidation method for routine analysis of large numbers of soils. They claimed that using an Al digestion block for NaOBr–NaOH oxidation of soils for total *P* determination allows for a simple, precise alternative to sand bath digestion and to potentially hazardous $HClO_4$ procedures [10].

In this work the results from the different methods used in the determination of total phosphorus in soils were examined. The $HF + HClO_4$ digestion method was not more rapid than other methods but extracted phosphorus amounts were found to be larger than others and there was not any significant difference in terms of precision accuracy.

2. Experimental

2.1. Reagents

All the following chemicals were made of Merck.

(1) Dissolved 15 g of ammonium molybdate in 300 ml of distilled water. Added to 290 ml concentrated H_2SO_4 and diluted to 1 l in a calibrated flask.

(2) Dissolved 17.5 g of stannous chloride in 125 ml glycerine and diluted to 250 ml in a calibrated flask.

(3) A 0.4393 g amount of potassium dihydrogen orthophosphate (KH_2PO_4) was dissolved in water and diluted to 1 l in a calibrated flask. Standard working solutions were prepared by diluting the above stock solutions.

(4) Dissolved 60 g of ascorbic acid, 100 mg ethylene diaminetetra acetate (Na_2EDTA) and 4 g of formic acid in distilled water and completed to 1 l with distilled water.

(5) Reducing agent: the reducing agent was prepared by mixing 5 ml of (4) 5 ml of (2) and 10 ml concentrated H_2SO_4.

(6) NaOBr solution: prepare this reagent immediately before use by adding 3 ml of bromine slowly (approximately 0.5 ml min^{-1}), and with constant stirring, to 100 ml of 2 M NaOH. The NaOBr solution must be prepared in a fume hood, because bromine is very toxic.

2.2. Procedure

Calibration: blank solutions were prepared for all the methods and 1 ml of which were added into 50 ml calibrated flasks. For the standard working solutions, dilute 25 ml of the standard *P*

stock solution to 1000 ml with distilled water and mix the solution thoroughly. Then pipette 0.0, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0 ml aliquots of this standard working solution into 50 ml calibrated flasks. Then add 2 ml of reagent (1) and 35–40 ml of distilled water. Add 2–3 drops of (5) and diluted to 50 ml. The pH of these solutions are approximately 3. After 7 min the absorbance of each solution was measured by using a Hitachi Model 100-20 UV-VIS spectrophotometer with 1 cm cell at 660 nm against a reagent blank and a calibration curve (absorbance versus concentration) was plotted.

2.3. Preparation of sample solution

The Na_2CO_3 fusion method [11]: place 1 g of Na_2CO_3 in a platinum crucible and add 0.8–1.0 g of soil sample and then 4 g of Na_2CO_3 and cover the upper of the crucible content with 1 g of Na_2CO_3. The fusion was continued in an electrical furnace for 60 min. The remainder was dissolved with H_2SO_4 and evaporated to dryness. Then the remainder was dissolved with distilled water, filtrated and diluted to 250 ml.

The $HClO_4$ digestion method [11]: place 0.2 g of soil sample in a Kjeldahl flask and add 3 ml of 60%, d: 1.54 g ml^{-1} $HClO_4$. Place it in sand bath and digest the sample at 203°C for 75 min. The digest was cooled, filtrated and diluted to 100 ml in a calibrated flask. However this method is worked with the tubes in the aluminum block which contained holes in which test tubes and a termometer are placed.

The $HNO_3 + HClO_4$ digestion method: place 0.2 g of soil sample in a Kjeldahl flask and add 1 ml of 65%, d: 1.4 g ml^{-1} HNO_3. Place it in sand bath and heat the flask until its content was evaporated to dryness. Then add 3 ml of 60% d: 1.54 g ml^{-1} $HClO_4$ and digest the sample at 203°C for 60 min. The digest was cooled, filtrated and diluted to 100 ml in a calibrated flask. However this method was worked with the tubes in the aluminum block which contained holes in which test tubes and a termometer are placed.

The $HF + HClO_4$ digestion method: place 0.2 g of soil sample in a platinum crucible and add 1–2 ml of 45%, d: 1.14 g ml^{-1} HF and evaporate to dryness. Weight the crucible, again digest with HF until constant weight. Then add 3 ml of 60%, d: 1.54 g ml^{-1} $HClO_4$ and digest for 60 min. The digest was cooled, filtrated and diluted to 100 ml in a calibrated flask.

The NaOBr oxidation digestion method [4]: place 0.2 g of soil sample in a Kjeldahl flask and add 3 ml of the NaOBr solution. Place it in a sand bath and heat the flask until its content was evaporated to dryness and continue heating for an additional 30 min. Remove the flask from the sand bath, allow it to cool for about 5 min, add 4 ml of distilled water and 1 ml of formic acid, mix the contents and then add 25 ml of 1 N H_2SO_4. Filtrate the content and dilute to 100 ml. However, this method was worked with the tubes in the aluminum digestion block which contained holes in which test tubes and a termometer are placed.

Determination of orthophosphate in soil extracts: for the determination of phosphorus in samples solutions, add 1 ml of the sample into a calibrated flask. Add 2 ml of (1) and 10–15 ml of distilled water and bring the solution to pH 3 by checking with 2,4 dinitrophenol indicator. Add 2–3 drops of the reducing agent and dilute to 50 ml. The absorbance of the solution was measured.

3. Results and discussion

The results obtained from the methods used for five different soil samples are shown in Table 1. As seen total phosphorus values obtained by $HF + HClO_4$ digestion method were essentially a bit greater than those obtained by Na_2CO_3 fusion. The more phosphorus was recovered from soils digested by the Na_2CO_3 fusion method than by the conventional $HClO_4$ method [1,8,12]. This also was found to be the case in this study (Table 1). For the $HF + HClO_4$ method, efficiency in recovery was greatest for the sample II, which has the highest organic phosphorus content.

The comparison of the phosphorus contents of five soils samples obtained by different extracting methods were made by using t-test [13].

The test results shown in Table 2 indicate that there is a significant difference between the HF +

II	18.1	72.6	9.7	12.13	7.50	8.0
III	44.8	36.0	19.2	—	7.87	—
IV	29.8	37.2	33.0	—	7.80	26.4
V	26.9	33.2	39.9	1.74	7.30	—

$HClO_4$ digestion and the Na_2CO_3 fusion methods for only sample II, while there are significant differences for sample II and III by comparing $HF + HClO_4$ digestion with other methods. There was no significant difference between the methods for other three samples. If we consider the high clay and organic content of the sample II, the fact that higher phosphorus values were extracted by the $HF + HClO_4$ methods shows that this extraction method may be more suitable for this kind of soils.

The equations of the straight lines obtained by plotting the total phosphorus amounts by the $HF + HClO_4$ digestion against that of by other methods and relevant correlation coefficients can be given as following.

$$P_{HF+HClO_4} = 1.014P_{Na_2CO_3} - 0.2914 \quad r = 0.9991$$

$$P_{HF+HClO_4} = 1.0096P_{HClO_4} - 3.5400 \text{ (in tube)} \quad r = 0.9995$$

$$P_{HF+HClO_4} = 1.0202P_{HClO_4} + 3.1866 \text{ (in flask)} \quad r = 0.9987$$

$$P_{HF+HClO_4} = 1.0109P_{HNO_3+HClO_4} + 3.4310 \text{ (in tube)} \quad r = 0.9978$$

$$P_{HF+HClO_4} = 1.0134P_{HNO_3+HClO_4} + 3.3946 \text{ (in flask)} \quad r = 0.9981$$

$$P_{HF+HClO_4} = 0.9976P_{NaOBr} + 4.7880 \text{ (in tube)} \quad r = 0.9991$$

$$P_{HF+HClO_4} = 1.0018P_{NaOBr} + 4.9575 \text{ (in flask)} \quad r = 0.9978$$

These equations give what amount of total phosphorus found by the $HF + HClO_4$ digestion method can be determined by other extraction methods. If two results by two methods had been equal, the slope of the line would have been equal to 1, the intersection 0 and $r = 1$. According to these equations the $HF + HClO_4$ digestion method is the best fitted method with the Na_2CO_3 fusion method, Table 3.

The interferences from silica was hindered by evaporating the silica in these two methods each of these methods gives higher total phosphorus amount than those obtained by the other methods. When worked in tubes and Kjeldahl flasks with $HClO_4$ digestion, $HNO_3 + HClO_4$ digestion and NaOBr oxidation methods, it was observed according to t-test that there was no significant difference between the methods, however the time required when worked in tubes were shorter than in Kjeldahl flasks.

The good precision of the method described is illustrated by Table 4, which gives the average results of three independent determinations, which were selected by Q-test [13] among a number of replicated analysis. The total phosphorus values of these samples ranged from 226.3 to 68.7 mg P 100 g^{-1} soil and the coefficient of variation ranged 0.84–3.1%.

The fact that higher phosphorus amounts can be extracted and that interference effects of silica can completely be prevented may be mentioned as advantages of the $HF + HClO_4$ digestion method and therefore this extraction procedure may be selected in quantitative studies.

Table 4
Precision of $HF+HClO_4$ digestion for total phosphorus in soils (results are the averages of three independent determinations)

Soil No.	Average (x) mg P 100 g^{-1} soil	Range (w) mg P 100 g^{-1} soil	Standard deviation P 100 g^{-1} soil	Coefficient of variation

Identification of combustible material with piezoelectric crystal sensor array using pattern–recognition techniques

Xi-Wen He *, Wan-Li Xing, Yan-Hong Fang

Department of Chemistry, Nankai University, Tianjin 3000071, People's Republic of China

Received 29 April 1996; received in revised form 22 August 1996; accepted 30 December 1996

Abstract

A promising way of increasing the selectivity and sensitivity of gas sensors is to treat the signals from a number of different gas sensors with pattern recognition (PR) method. A gas sensor array with seven piezoelectric crystals each coated with a different partially selective coating material was constructed to identify four kinds of combustible materials which generate smoke containing different components. The signals from the sensors were analyzed with both conventional multivariate analysis, stepwise discriminant analysis (SDA), and artificial neural networks (ANN) models. The results show that the predictions were even better with ANN models. In our experiment, we have reported a new method for training data selection, 'training set stepwise expending method' to solve the problem that the network can not converge at the beginning of the training. We also discussed how the parameters of neural networks, learning rate η, momentum term α and few bad training data affect the performance of neural networks.

Keywords: Artificial neural networks (ANN); Piezoelectric crystal sensor array; Stepwise discriminant analysis (SDA)

1. Introduction

Potentially, piezoelectric detectors are very attractive sensors of gaseous species due to the wide availability of the principle quartz crystal component and the relatively simple electric instrumentation. The possibility of their application has been demonstrated for the detection of several inorganic species, such as sulfur dioxide [1], nitrogen dioxide [2], ammonia [3], hydrogen cyanide [4], hydrogen chloride [5], hydrogen sulfide [6]. But, the piezoelectric crystal sensor, as with most chemical sensors, is susceptible to interfering analytes, since the adsorptive coating employed is rarely totally selective for a single component. In real environment, it is impossible for only one kind of pure gas to exist. The combustible materials detected in our experiment are just the case. Being burned, the combustible materials decompose and produce various gases, e.g., plastic, which contain chlorine, may produce hydrogen chloride; grain, which contain nitrogen, may produce nitrogen dioxide, ammonia and hydrogen cyanide; wood, which contain sulfur, may produce sulfur dioxide, etc. Different material will produce gas mixture which has different gas com-

ponents. So, an array of sensors was constructed by coating with a different partially selective material. The advantage of an array device of this kind is that the array's response for each analyte corresponds to a fingerprint response pattern with component identification analogous to spectrometry. In this experiment, we investigated the application of artificial neural networks (ANN) and conventional multivariate techniques to the classification of signals from sensor array to identify four kinds of combustible materials.

Artificial neural networks are a form of artificial intelligence that mathematically simulate biological nervous systems. They have been employed in a diverse range of applications in recent years [7] including signal processing of sensor array [8]. The ANN approach was selected because it possess several advantages over conventional methods in terms of adaptability (learning, self-organization, generation and training), noise tolerance, fault tolerance, distributed associated memory, inherent parallelism generating a high speed of operation subsequent to training [9]. The application of ANNs to signal classification problems requires far less restrictive assumptions about the input signal than traditional multivariate techniques. The results of our experiment show that the prediction ability of ANN is superior to stepwise discriminant analysis (SDA) for the four kinds of combustible materials. This method is hoped to be an effective measure for fire alarm.

2. Experimental

2.1. Instrument

The apparatus consisted of seven AT-cut piezoelectric quartz crystal with a fundamental frequency of 9 MHz, 12.0 mm in diameter, with gold or silver plated electrodes of 6.0 mm in diameter on both sides. The oscillator circuit was designed by our laboratory, and its power was supplied by a PL2002A d.c. voltage regulator. The frequency change of each sensor was monitored in sequence by a N3165-type frequency counter and collected by a data acquisition system made in our laboratory. The programs for data acquisition were written in Turbo C. The BP network of ANN in data analysis was also written in Turbo C. SDA program was obtained commercially from SPSS program package. All data were treated by a PC-DX486 computer.

2.2. Reagents

The coating material used for sensors are: polyvinylpyrrolidone (PVP); triethylamine; Vitamin B6 hydrochloride; L-glutamic acid hydrochloride; ascorbic acid; triacetin glycerol triacetate and polychlorobiphenyl. All the reagents are of analytical-reagent grade. The coating of the crystals was performed by preparing a 5% w/w solution of the coating material in a highly volatile solvent such as chloroform or ethanol. Each solution was brushed onto both sides of a crystal with a cotton swab until a frequency shift of approximately 2000–5000 Hz was obtained after evaporation of the solvent.

2.3. Measurement method

The scheme of the measuring system can be seen in Fig. 1. Smoke was generated from a certain amount (1.5 g) of different materials (paper, wood, plastic, grain, et al.) by electric heating in the first box (smoke generator). The sensor array was mounted in the second (measuring) box connected to the first one by pipes and prefilter. The prefilter consisted of calcium chloride and silica gel was set after the smoke generator to

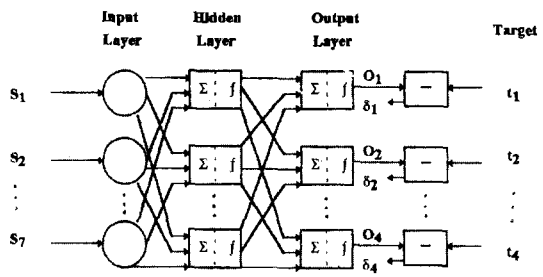

Fig. 2. Two-layer back-propagation model.

move water vapour produced during burning. Soot, liquid and other solid particle burning products were moved using defatting cotton and filter paper put inside the pipes. A small electromagnetic pump forced a continuous gas flow through the system (80 ml min^{-1}). Approximately 5 min after burning of the combustible material, the frequency of the sensors began to fall. The frequency response of each sensor was measured in sequence by a data acquisition system made in our laboratory. The sampling time for each sensor is 0.1 s. The frequency response difference between sample and blank (air) was calculated and displayed in real time on the computer screen and stored on disk for later analysis. After the frequency shift maximum was observed and became stable, the chamber was purged with clean air for 30–60 min. The largest frequency shift of each sensor was used as input for ANN and SDA. Every sample was measured in triplicate to estimate the precision of the sensor array.

2.4. Network design

Fig. 2 shows a generalized two-layer back-propagation network used in our experiment that has seven inputs (sensors) in the input layer, an arbitrary number of artificial neurons in the hidden layer (six, in this experiment) and four artificial neurons in the output layer (combustible materials). Each of the inputs ($O_{(l-1)i}$) is multiplied by an associated weight (w_{lji}), where l is the actual layer of the network, i is the neuron of the layer before, j is the neuron of the actual layer. Each weight has a value that reflects the strength if the synaptic link and thus the importance of a particular input (e.g., sensor). The output signal (y_{lj}) is further processed by a non-linear activation function that 'squashes' the data. In our study, we have used a sigmoid activation function so the neural output O_{lj} is given by

$$O_{lj} = 1/[1 + \exp(-y_{lj})] \qquad l = 1, 2 \tag{1}$$

and

$$y_{lj} = \sum_{i=1}^{n} w_{lij} O_{(l-1)i} \tag{2}$$

The back-propagation training algorithm uses a gradient search technique to minimize a cost function E equal to the mean square difference between the desired output t_j and the actual output vector O_{2j} (two layers).

$$E = 0.5(O_{2j} - t_j)^2 \tag{3}$$

The backward pass starts with the calculation of $\partial E/\partial O_{lj}$ (an example calculation for the two-layer network is given in parentheses):

$$\delta^*_{lj} = \partial E/\partial O_{lj} \qquad (\delta_{2j} = O_{2j} - t_j) \tag{4}$$

The next step is the estimation of $\partial E/\partial y_{lj}$:

$$\delta_{lj} = \partial E/\partial y_{lj} \qquad (\delta_{2j} = f'(O_{lj})\delta^*_{2j} = O_{2j}(1 - O_{2j})\delta^*_{2j} \tag{5}$$

The previous terms δ^*_{l-1} can be computed from δ_l:

$$\delta^*_{(l-1)i} = \sum_{j}^{k} w_{lji}\delta_{lj} \tag{6}$$

where k is the number of neurons in layer l.

Finally, $\partial E/\partial w_{lji}$ can be calculated:

$$\partial E/\partial w_{lji} = \delta_{lj} O_{(l-1)i} \tag{7}$$

So the weights can be adapted:

$$\Delta w_{lji}(m+1) = \eta\delta_{lj} O_{(l-1)i} + \alpha\, \Delta w_{lji}(m) \tag{8}$$

$$w_{lji}(m+1) = w_{lji}(m) + \Delta w_{lji}(m+1) \tag{9}$$

Where m means the number of training iterations. So the weights are adjusted by one term that is propagational to the error with a constant of the proportionality, called the learning rate (η). The second term is used to improve the stability of the learning process and is called the momentum term (α).

3. Results and discussion

3.1. Data selection method to avoid unconvergence at the beginning of networks training, 'training set stepwise expanding method'

For the performance of networks, the property of initial data is quite important. In the area of data selection and effects of bad data upon performance of networks, no system investigation has been studied. In our experiment, we discovered that, in the case where the identification problem was complicated or there was large similarity between the categories we wanted to identify and some difference or bad data existed among data in certain category, the effects of particular bad data on performance of networks were considerable, sometimes, the error of the network increased suddenly and it was quite difficult for the network to converge. These data are not sure to be bad ones to be deleted. It is possible that the difference of these data with other data in certain category is somewhat large. For this case, if we use all the samples of training set to train at the same time, the network can not converge. At this time, we can adopt 'training set stepwise expanding' method. The details are as following steps: firstly, we compared the response patterns of training samples, in each category, we selected one or two samples as initial training set whose difference with data of samples of other categories was relatively large. If the network could converge indeed, then after several hundred to thousand iterations, training set could be expanded by selecting again one or two samples which were relatively similar to the data in the forward training set of certain category, and the weights of last training should be used to train the network continuously. These steps were done until training set had included all the samples which were prepared to be as training set. Adopting this method, if the network still can not converge when using initial training set, conclusion may be drawn that the similarity among categories is too large to be discriminated by the networks. Measures should be taken to select more selective input variables. If the error increased suddenly and the network became difficult to converge due to a certain expanding, then there may be at least one bad data in this expanding data set. Check those data one by one, the bad data can be found and might be deleted. If we did not select the expanding sample according to the principle of similarity mentioned above, the data whose difference with the other data in certain category is relatively large may be deleted mistakenly. In fact, these data can make the network converge if we select them according to the above principle.

The data in our experiment is just the case as above. To guarantee the generalization of sampling, we made the data in certain category have somewhat difference. Additionally, the input layer only have seven neurons which makes the network difficult to converge. There are 52 samples in the training set, 13 samples in every category. The means of response of every category from sensor array are shown in Fig. 3. If we use them as training set altogether at the beginning to train the network, it did not converge at all, the error of the network was very large, though various data normalization methods had been tried. In contrast, it converged well when using the method mentioned above. The logarithm of the frequency shift was used as input, in order to accommodate the actual values, which spanned more than two orders of magnitude (from 20 to 5000 Hz). The prediction results are quite well as shown in Table 2. This method is suitable not only to the case where network can not converge at all at the beginning of training, but also to the case where the error of the network is relatively large or the network converge very slowly.

3.2. Prediction results for ANN and SDA

In order to avoid the dependence between independent variables leading to low precision of data computation and unstable discriminant functions, SDA was adopted. As can be seen in Table 1, the 64 samples were divided into calibration set, consisting of 52 samples, 13 samples in each category, and test set, consisting of 12 samples, three samples in each category. After processing with SDA, from the calibration set six discriminant variables which supplied more information were selected. The prediction correct rates were 98% for calibration set and 83% for test set. Fig. 4 shows the plot of discriminant Function 1 against 2.

It is customary to adopt an output element value of 0.9 to show reasonable convergence, however, a slightly lower level, 0.8, is also accepted for reasonable convergence from Gardner's experience [10]. Table 2 lists the prediction results for ANN, which used the same training set and test set as that used for SDA. It can be seen that outputs generated during testing were typically of the order of 0.8 or above compared with an ideal value of 1.0, and of the order of 0.2 or below compared with an ideal value of 0. These results show that the network discriminates well

between these chemical species and compare favorably with the result of SDA. In addition, because of adopting 'training set stepwise expanding' method mentioned above, training time which took only several minutes was far less than usual approaches.

3.3. Effects of learning rate and momentum term

Values of the learning rate η and momentum coefficient α affect the performance of a network. It is generally recommended that the ratio of these parameters is 1.5. Fig. 5 and Fig. 6 show the variation of the network performance with momentum coefficient ($\eta = 0.9$) and learning rate ($\alpha = 0.6$), after the training set has been expanded to contain all the initial data and training has process 400 iterations, where the performance of the network is presented by network error, ϵ, the sum of difference between ideal output and actual output of every neuron in the output layer of training set, and 10 000, 20 000, 30 000, 40 000 are training iterations. From Fig. 5 we can see that when momentum coefficient arrives 1.0, error of network arrives minimum and keep constant when momentum coefficient continue to increase. Fig. 6 shows that the minimum does not appear when learning rate arrives 1.4. We also have tested even larger learning rate up to 16 which are not shown in the figure, but minimum was still not found, though the decreasing rate of the error of network became slow gradually. The above phenomena are different with that in Gardner's work [10], (he found error minimums with learning rate $\eta = 0.9$ and momentum coefficient $\alpha = 0.7$, respectively), which may be attributed to the difference of data structure.

4. Conclusion

We have shown that ANN was able to identify the four combustible materials correctly from an array of seven piezoelectric sensors and superior to multivariate techniques, such as SDA. If we want to identify more combustible materials, we can select more sensors with more coating materials which have appropriate selectivity. The data

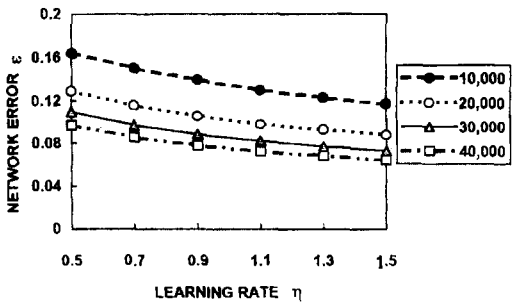

Fig. 6. Variation in network performance with learning rate ($a = 0.6$).

selection method 'training set stepwise expanding' has been put forward to improve convergence of the networks and increase training speed, which is believed to be an encouraging method for the applications of ANN.

Abstract

Measurement of iron and manganese is very important in evaluating the quality of natural waters. We have constructed an automated Fe(II), total dissolved iron(TDI), Mn(II), and total dissolved manganese(TDM) analysis system for the quality control of underground drinking water by reverse flow injection analysis and chemiluminescence detection(rFIA-CL). The method is based on the measurement of the metal-catalyzed light emission from luminol oxidation by potassium periodate. The typical signal is a narrow peak, in which the height is proportional to light emitted and hence to the concentration of metal ions. The detection limits were 3×10^{-6} μg ml^{-1} for Fe(II) and the linear range extents up to 1.0×10^{-4} and 5×10^{-6} μg ml^{-1} for Mn(II) cover a linear range to 1.0×10^{-4} μg ml^{-1}. This method was used for automated in-situ monitoring of total dissolved iron and total dissolved manganese in underground water during water treatment. © 1997 Elsevier Science B.V.

Keywords: Dissolved iron; Manganese; Water

1. Introduction

Measurement of iron and manganese is very important in evaluating the quality of natural waters. It is well known that excessive intake of iron and manganese influences human health [1]. So a simple and rapid method is required for iron and manganese detection. Chemiluminescence (CL) methods are a means of enabling the rapid, simple and economical detection of various substances.

Several CL systems have been proposed for the sensitive determination of iron and manganese on the basis of CL reaction. The most famous CL system is the luminol reaction. The intrinsic sensitivity of the luminol system to small metal concentrations makes it very attractive for trace analysis. Fe(II) [2–4], Fe(III) [5–7], Mn [8–12] can be determined by its reported catalytic effect on the oxidation of luminol by oxidants, such as

PII S0039-9140(97)00029-5

dissolved oxygen [11–16], hydrogen peroxide [8,9,17–25] and potassium periodate [26,27]. One of the most extensively studied of this system is to determinate Fe(II), which has been developed as an analytical method for Fe(II) in many materials [28,14], but seldom application [28] to natural sample was reported. Kalinichenko [22,23] determined 0.05–5 ng of manganese using luminol, but many other transition metal interfered. Dubovenko and Tovmasyan [24] reported a similar system for determining 0.1–1 μg ml^{-1} manganese with photographic rather than photoelectric detection. Geng et al. [26] obtained a detection limit 8×10^{-6} μg ml^{-1} manganese using a luminol-KIO_4 system, but Co(II) and Cr(III) interfered. Ibusuki [29] discussed the interference of trace manganese(II) and Fe(III) in the luminol system. So selectivity is the most important thing in CL reaction for a technique to be used for analytical purpose.

Lucigenin can be used in place of luminol [30–32]. Photographic detection enables manganese at the 1–3 μg ml^{-1} level to be determined, but again, many metal ions interfere [30,31]. Fe(III), Cu(II), Tl(III) and Mn(II) can be simultaneously measured by its catalytic effect on the oxidation of lucigenin by hydrogen peroxide, but Cu(II) and Tl(III) are interferences in analytical methods for Fe(II) and Mn(II) [31]. So even this system can not be utilized to simultaneously determine Fe(III) and Mn(II) in practice.

The brilliant sulfoflavine(BSF) was used to determined Fe(II)/Fe(III), Cr(III) based on the Fenton or Fenton-like reaction, the reaction with hydrogen–peroxide [33]. Yamada [33] described the CL reaction resulting from the addition of Fe(II) to solution of H_2O_2 and alkaline BSF. Johnson [34] modified this system and used it to determine subnanomolar levels of iron(II) and total dissolved iron in seawater.

Yamada [35] demonstrated that 0.01–10 ng Mn(II) can be determined with high sensitivity by exploiting the Mn(II) catalyzed oxidation of 7,7,8,8-tetracyanoquinodimethane(TCNQ) by O_2. Johnson [36] adapted the method and applied it to the shipboard determination of manganese in seawater, but Fe(III) and Mg(II) interfered.

Babko et al. [37,38] determined 0.1–10 μg of manganese by oxidation to permanganate with peroxodisulphate and reaction of the permanganate with siloxene to produce chemiluminescence. Lin [39] determined Co(II) and manganese(II) simultaneously by CL oxidation of gallic acid and formaldehyde in the presence of thiourea by alkaline H_2O_2.

A CL method has not been proposed to simultaneously determinate Fe and Mn. Until now, separation or elimination of interfering species has been required prior to the determination of an analyte. Several pretreatment procedures have been reported: ion exchange [40], for example 8-hydroxy-quinoline resin was used to preconcentrate Fe [36] and then detected in TCBQ CL system and Mn [34] in BSF CL system. Nakayama [10] have developed a method based on the combination of selective electrolytic preconcentration and luminol CL system to determine Mn(II) in seawater. Addition of masking agents such as sodium citrate, quinolin-8-ol [27] for metal interferences to form inactive complexes and then detected in a luminol-KIO_4 system or using activator in luminol CL system, for example TETA(Fe(III) [4], Mn [10]), DETA(Fe(III)) [19,20], EDTA(Fe(II)) [16], TEA(Mn(II)) [26], phenanthrolin (Mn(II)) [22,23], TETA or TEPA(Fe(II), Fe(III) Cr(III)) [33] and sodium dodecylsulfonate [41].

This paper reports a simple and automatic method for specifically measuring trace concentration of TDI and TDM in the presence of other metal ions with the luminol-KIO_4 CL reaction by rFIA. Specificity for TDI is achieved by adding *o*-phenanthrolin(*o-p*) and taking advantage the Fe(*o-p*) complex formed as activator. In the same way, specificity for TDM is achieved by adding TEA and H_3PO_4 with most metal ions including iron ion being masked. The proposed method was applied to monitor TDI and TDM in underground water during the water treatment process for the quality control of drinking water.

2. Experimental

2.1. Apparatus

The rFIA system was illustrated in Fig. 1 and was constructed to realize automated Mn and Fe detection in underground drinking water in collaboration with the Daqing Water Supply. It employed a eight-channel peristaltic pump and a microprocessor-controlled Teflon rotary injection valve. All manifold tubing was Teflon (0.8 mm i.d.) except for the standard peristaltic pump tubing (poly(vinyl chloride)(PVC)). A transparent spiral tube with 12 cm length and 1.08 mm i.d. was employed as the CL flow cell in this system. Light intensities were measured with a R212UH photomultiplier operated at -729 volts. All the experiments were performed at room temperature at a flow rate of 2.1 ml min^{-1} for each pathway. The flow rate was determined from later studies. In this research, the experiments for optimization of the measuring conditions were performed during construction and adjustment of this system.

2.2. Procedure for CL measurements

The system was operated as follows. For Fe(II) the CL reagent I passes through a 30 μl sample loop and the excess is fed to a waste vessel. The sample and $NaHSO_3$ are mixed at mixing just prior to the injection valve and then mixed with the luminol CL reagent I. The reaction mixture reacts for 20 s in the mixing coil before being injected by the three way valve to the detection. The CL is measured in a transparent spiral tube by a neighboring photomultiplier. For determination of TDM the procedures with almost the same as above except the three-open valve was turned to position 2.

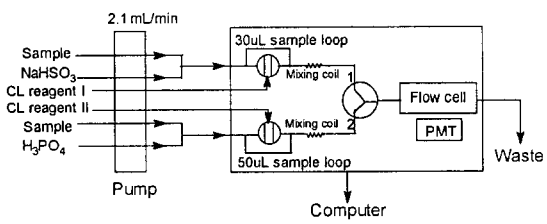

Fig. 1. Schematic diagram of the reaction manifold used for the rFIA-CL determination of iron and manganese.

Underground water samples were collected automatically and directly pumped into flow cell after water treatment. The samples were at natural pH and did not need to be acidified. No loss of TDI and TDM due to wall adsorption was observed.

2.3. Reagents

Luminol was purchased from Merck-Schuchardt. Potassium periodate from Beijing Center-union Chemical. Triethanolamine from Shanghai Chemical. *o*-phenanthrolin hydrochloric acid was from Merck Darmstadt and potassium hydroxide from Beijing Chemical. The other reagents were all A.R. grade. Reagent solutions were made with doubly distilled water from a quartz apparatus.

Stock solutions of luminol were prepared in 0.1 mol l^{-1} KOH solution, adjusted to 0.01 mol l^{-1} and stored at 4°C. A 0.1 mol l^{-1} H_3BO_3-KOH buffer was used to control the pH. CL reagent I (for determination of TDI) contained: 6×10^{-4} mol l^{-1} luminol, 2.5×10^{-4} mol l^{-1} *o*-phenanthrolin hydrochloric acid(*o*-*p*) and 10^{-4} mol l^{-1} KIO_4 in 0.1 mol l^{-1} H_3BO_3-KOH buffer(pH 10.0), and was left for at least one hour to stabilize. CL reagent II (for determination of TDM) contained: 2×10^{-3} mol l^{-1} luminol, 1.125% triethanolamine(TEA) and 2×10^{-3} mol l^{-1} KIO_4 in 0.125 mol l^{-1} NaOH and was also left for at least one hour to stabilize.

3. Results and discussion

3.1. Investigation of the measuring system

Initial investigation was performed with standard solution in distilled water using a reverse flow injection manifold.

3.1.1. Effect of length of mixing coil

To ensure the efficient reaction between CL reagent I or CL reagent II with the sample, a mixing coil with length from 16 to 90 cm was used

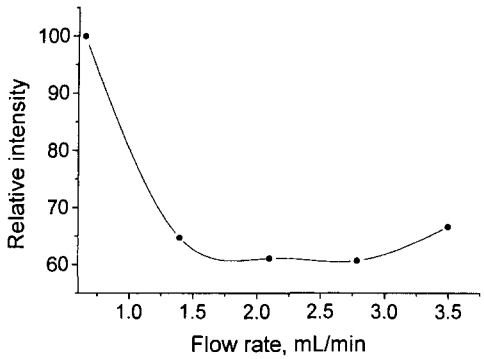

Fig. 2. Effect of flow rate on the CL intensity of 0.010 μg ml^{-1} Fe(II) in the presence of 6×10^{-4} mol l^{-1} luminol, 2.5×10^{-4} mol l^{-1} *o-p* and 1×10^{-4} mol l^{-1} KIO_4 in 0.1 mol l^{-1} H_3BO_3-KOH buffer solution, pH 10.0.

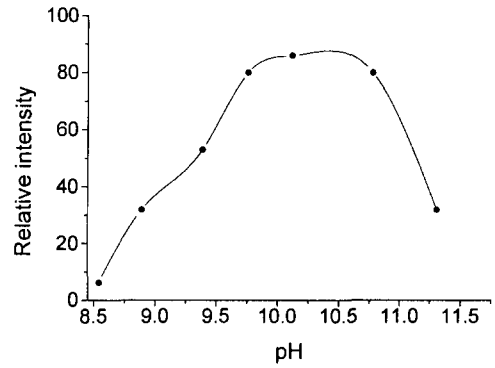

Fig. 3. Effect of pH on the CL intensity from 0.005 μg ml^{-1} Fe(II) in the presence of 6×10^{-4} mol l^{-1} luminol, 2.5×10^{-4} mol l^{-1} *o-p* and 1×10^{-4} mol l^{-1} KIO_4 in 0.1 mol l^{-1} H_3BO_3–KOH buffer solution, pH 10.0.

for comparison. It was found that a suitable length with a high CL intensity was 60 cm for both systems, shorter or longer than this length would cause the decrease of CL intensity because of the deficient reaction or a considerable dilution.

3.1.2. Effect of flow rate

We investigated the effect of flow rate for the Fe(II) system. The signal did not vary significantly from 1.75–2.8 ml min^{-1} as shown in Fig. 2. In addition, the pump can be adjust to only one flow rate for eight channels, so the 2.1 ml min^{-1} was chosen as the optimum flow rate for both systems.

4. TDI measurement

4.1. Effect of pH

Light emission did not vary significantly from 9.75–11.0 (Fig. 3). The optimal pH for CL reaction was pH 10.0 and the 0.1 mol l^{-1} H_3BO_3-KOH buffer was used to control the pH of CL reagent I solution. Since pH control is not critical, the buffered Fe(II)-KIO_4-luminol system may be characterized by using a calibration curve rather than the standard additions.

4.2. Optimization of reagents

The concentrations of luminol, KIO_4, *o-p* and potassium hydroxide were all optimized for the rFIA-CL system. The concentration of each reagent was varied independently.

4.2.1. Effect of luminol concentration

The intensity of light catalyzed by 0.01 μg ml^{-1} Fe(II) as a function of luminol concentration showed that the reaction is most efficient at $6 \times 10^{-4} \sim 7 \times 10^{-4}$ mol l^{-1} luminol, as shown in Fig. 4. The decrease of light at the highest luminol concentrations may be due to Fe(II) complexing with luminol or with the aminophthalate product of the luminol oxidation.

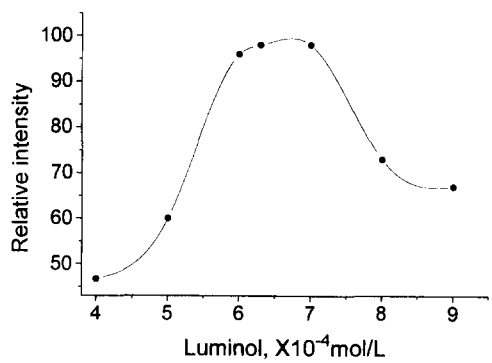

Fig. 4. Effect of luminol concentration on the CL intensity from 0.01 μg ml^{-1} Fe(II) in the presence of 2.5×10^{-4} mol l^{-1} *o-p* and 1×10^{-4} mol l^{-1} KIO_4 in 0.1 mol l^{-1} H_3BO_3–KOH buffer solution, pH 10.0.

Table 1
Interference of other metals to chemiluminescence for Fe(II)

Metal	Concn. μg ml^{-1}	Recovery(%)	Metal	Concn.	Recovery(%)
Mn(II)	0.1	100.6	Co(II)	0.1	147.9
Ni(II)	0.1	100.8	Cd(II)	0.1	100
Hg(II)	0.1	104.1	Fe(III)	3.0	104.3
Cr(III)	0.1	102.2	Cu(II)	0.2	100.4

Intensities are relative to the intensity of 0.01 μg ml^{-1} Fe(II).

4.2.2. Effect of potassium periodate concentration

The optimum potassium periodate concentration was 1×10^{-4} mol l^{-1}. Although hydrogen peroxide as an oxidant reagent instead of KIO_4 was tested, the result showed that it was easily bubbled in tubing and also the peak was too wide than that of KIO_4.

4.2.3. Effect of o-phenanthrolin hydrochloric acid concentration

o-p Itself did not give any CL signal. It must be an activator for the CL reaction of luminol with potassium periodate by Fe(II), after formation of Fe(II)-*o-p* complexes, *o-p* may be oxidized by KIO_4 and weak CL was produced as it is oxidized by H_2O_2 [17]. When the *o-p* concentration was $5 \times 10^{-5} - 2.5 \times 10^{-4}$ mol l^{-1}, the system had better selectivity than that of without *o-p* and good reproducibility for Fe(II).

4.3. Iron(III) reduction

Total dissolved iron can be determined by reducing Fe(III) to Fe(II) prior to analysis. The aqueous chemistry of iron is rather complex, since this metal enters into several protolysis and oxidation–reduction reactions [2,6,7]. When the groundwater comes to the surface, Fe(II) may be oxidize to Fe(III) by oxidants such as O_2 in the air and is subsequently precipitated as $Fe(OH)_3$. Sodium hydrogen sulfite was a suitable reagent due to its rapid and efficient reducing power [42,28]. The optimal concentration of sodium hydrogen sulfite for the reduction of Fe(III)–Fe(II) was dependent on the iron concentration. A 0.1% sodium hydrogen sulfite was chosen for 0.01 μg ml^{-1} Fe(III).

4.4. Interference studies

The ions which are thought interfere with luminol-KIO_4 CL of Fe(II) are Mn(II), Ni(II), Hg(II) and Cr(III), Fe(III), Cd(II), Cu(II). Table 1 shows the recovery of these elements at indicated concentration. Metal solutions for these studies were prepared from A.R. salts. Except for a substantial interference was observed when Co(II) was present at 0.1 μg ml^{-1}, none of the above elements significantly affected the iron signal when their concentrations equaled to or ten times higher than that of Fe(II).

4.5. CL kinetic property and analytical parameters

With all of the above established conditions, the CL intensity reached the maximum value in only 1–2 s, and the half peak width is 2.5 s when 0.005 μg ml^{-1} Fe(II) was injected.

Various concentrations of Fe ions were measured under these experimental conditions. The calibration curve was linear in the range $1 \times 10^{-4} - 0.6$ μg ml^{-1} of Fe(II): signal(relative intensity) = 455[Fe(II)] + 59.25 ($r = 0.998(n = 5)$). The relative standard deviation was 0.93% for 0.005 μg ml^{-1} ($N = 9$). Repeatability was measured with standard solutions. Since this system employed reverse flow injection analysis, the blank was zero, 3×10^{-6} μg ml^{-1} was the lower limit that can be detected.

5. TDM measurement

Manganese and iron have similar chemistry in water [43]. Mn(II) and Fe(II) both exist in an anaerobic environment. They can be oxidized by oxygen to MnO_2 and $Fe(OH)_3$ respectively, which exist as colloids and can be removed by filtration. If a sample to be analyzed for Fe(II) is filtered, then manganese in the form of Mn(II) will interfere with the Fe(II)-catalyzed CL. In the absence of dissolved oxygen and other oxidants, Mn(II) is the stable form in aquatic systems [44], so after filtering the concentration of Mn(II) is equivalent to TDM.

5.1. Effect of pH

The influence of the pH on CL intensity was investigated. The maximum and stable intensity of light for determination of Mn(II) was obtained when pH was 12.9, as shown in Fig. 5.

5.2. Optimization of reagents

5.2.1. Effect of luminol concentration

The intensity of light as a function of luminol concentration showed that the reaction is most efficient for luminol between 2×10^{-3} and 3×10^{-3} mol l^{-1} (Fig. 6).

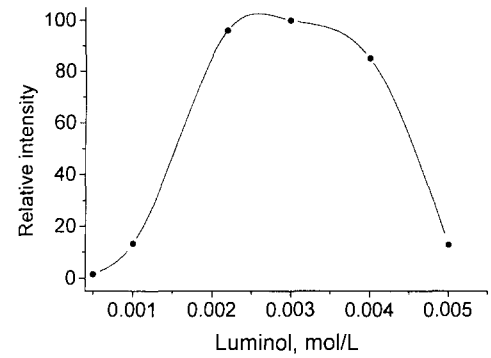

Fig. 6. Effect of luminol concentration on the CL intensity from 0.01 μg ml^{-1} Mn(II) in the presence of 1.125% mol l^{-1} TEA and 2×10^{-3} mol l^{-1} KIO_4 at pH 12.9.

5.2.2. Effect of potassium periodate concentration

The optimum potassium periodate concentration was more than 2×10^{-3} mol l^{-1}, as shown in Fig. 7.

5.2.3. Effect of TEA concentration

Various amines increase the CL observed from luminol-oxidant-Mn mixtures [33,5,10,19,29,22, 23], TEA was found the suitable activator for the CL system of luminol-KIO_4-Mn(II) [26]. TEA can also acts as masking reagent for a lot of metal ions, so it was chosen as an activator and masking reagent for determination of Mn(II). The optimum TEA concentration was 1.125% (Fig. 8).

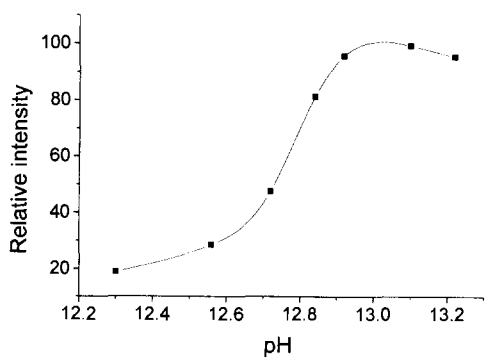

Fig. 5. Effect of pH on the CL intensity from 0.01 μg ml^{-1} Mn(II) in the presence of 2×10^{-3} mol l^{-1} luminol, 1.125% mol l^{-1} TEA and 2×10^{-3} mol l^{-1} KIO_4.

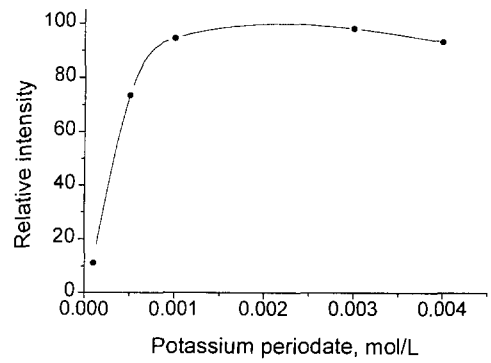

Fig. 7. Effect of KIO_4 concentration on the CL intensity from 0.01 μg ml^{-1} Mn(II) in the presence of 1.125% mol l^{-1} TEA and 2×10^{-3} mol l^{-1} luminol at pH 12.9.

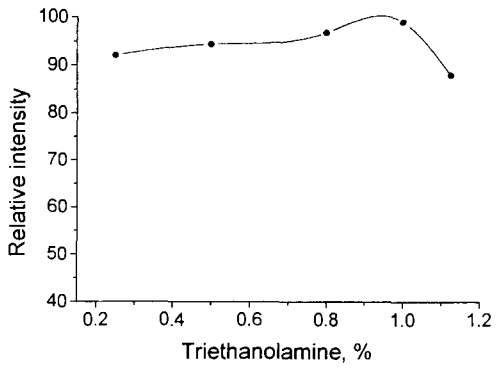

Fig. 8. Effect of TEA concentration on the CL intensity from 0.01 μg ml^{-1} Mn(II) in presence of 2×10^{-3} mol l^{-1} KIO_4 and 2×10^{-3} mol l^{-1} luminol at pH 12.9.

5.3. Interference studies

Besides Mn(II), several metal ions, such as Co(II), Fe(II), Fe(III), Ti(IV) and Mo(VI) catalyze the luminol-periodate CL reaction. Others, such as Cu(II), Pb(II), Ni(II), Cd(II), In(III) and Ce(IV), inhibit the CL [27]. In the presence of 1.125% TEA, commonly encountered ions, except Mn(II), can be masked (Table 2). In addition, 0.292 mol l^{-1} H_3PO_4 was chosen as a masking reagent on iron. So two kinds of masking reagent TEA and H_3PO_4 were used in this system.

5.4. CL kinetic property and analytical parameters

Using established conditions, the CL kinetic curve showed a CL signal reaching the maximum value in only 1–4 s, and the half peak width is 1.5 s for a 0.01 μg ml l^{-1} Mn(II) sample.

The system response for Mn(II) was linear in the range $1 \times 10^{-4} - 0.6$ μg ml^{-1} of Mn: $I = 702.714[Mn(II)] + 16.627$($r = 0.999$($n = 6$)). The relative standard deviations was 0.37% for 0.01 μg ml^{-1} ($n = 11$). The blank of this system was also zero. The lower limit that can be detected was 5×10^{-6} μg ml^{-1}.

6. Analysis

We have developed a CL system for the measurement of TDI and TDM in underground water. Table 3 gives the results obtained for different samples of underground fresh water. This method was used in monitoring the TDI and TDM in underground water during water treatment [45]. In practical use, as TDM concentration is more than 0.3 mg l^{-1} and TDM 0.1 mg l^{-1}, the system will give alarm in order to control the process of water treatment. We had been keeping watch on this system for one month. It performed very stable.

7. Conclusion

The proposed method is very sensitive and shows good reproducibility. The use of KIO_4, unlike hydrogen peroxide, prevents the formation of bubble in the tubing system. This method can be used to determine TDI and TDM at ng ml^{-1} level in water and also for water quality control in Daqing Water Supply, in China.

Table 2
Interference of other metals to chemiluminescence for Mn(II)

Metal	Conc. μg ml^{-1}	Recovery(%)	Metal	Conc. μg ml^{-1}	Recovery(%)
Co(II)	0.1	103.5	Cu(II)	20	98

Received 27 August 1996; received in revised form 6 January 1997; accepted 14 January 1997

Abstract

Peroxidase entrapment in different Sol-Gel matrices was successful. The enzyme did not show a decrease in activity for at least 2 months as well as storage at room temperature and dry condition for periods exceeding 3 weeks. It was evident that the enzymatic activity was a function in the type of the alkoxysilane precursor. In addition, the optimum temperature which resulted in maximum enzymatic activity was also dependent on the type of Sol-Gel matrix. Excellent results were obtained for the determination of glucose in serum samples using soluble glucose oxidase in conjunction with the Sol-Gel entrapped peroxidase. The enzymatically produced hydrogen peroxide is oxidized by the entrapped peroxidase yielding oxygen which oxidizes the faint blue variamine blue into the intensely violet colored species (the molar absorptivity is about 1.8×10^4 l mol^{-1} cm^{-1}). The characteristics of this chromogenic system as well as optimized conditions for its use in the spectrophotometric determination of enzymatically generated hydrogen peroxide were investigated. Excellent agreement between the results obtained by the proposed method and the widely used standard method, utilizing a commercial reagents kit, was always observed. © 1997 Elsevier Science B.V.

Keywords: Sol-Gel; Enzyme immobilization; Peroxidase; Variamine blue

1. Introduction

The high specificity of enzymes in catalyzing some chemical reactions is an important feature that has been utilized for the selective and accurate determination of many substrates. Analytes are usually selectively converted into other species which can be easily monitored. Many enzymatic reactions result in the generation of hydrogen peroxide as a by-product of the conversion of appropriate substrates. Therefore, there has been a great deal of emphasis on the development of sensitive and highly reliable methods for the quantitative determination of hydrogen peroxide concentration which is an indirect indication of analyte concentration [1–3]. Several electrochemi-

* Corresponding author.

PII S0039-9140(97)00032-5

cal, spectrophotometric, and luminescence methods were suggested and procedures based on these methods were optimized for such systems. However, enzymes are usually expensive and their use as homogeneous catalysts is, most of the time, costly. In addition, the disposal of these active catalysts can impose environmental problems in many situations. Therefore, it is justified that efforts be directed towards designing approaches to immobilize these biomolecules so that they can be reused as well as be confined to a specific matrix [4]. Several methods for the immobilization of enzymes were suggested using different approaches. Physical adsorption of enzymes to an activated solid support is an important method of enzyme immobilization. However, these preparations are usually unstable and enzymes tend to come off in solution. Covalent binding of enzymes to solid surfaces like membranes or other solid supports is one of the most widely used approaches. However, several steps for the preparation of an adequate functional group on the solid support are usually involved prior to the final crosslinking step. These procedures are usually complicated and require good experience in this field. In addition, the enzymatic activity decreases appreciably and the immobilized enzymes do not retain their activity over long periods, beside some other disadvantages [4]. Recently, some biomaterials were trapped into a silicate glass matrix under mild conditions [5–8]. This was accomplished by the Sol-Gel method where room temperature polymerization of an alkoxysilane, after partial hydrolysis of the alkoxy groups results in a silicate polymer gel. The thus obtained gel solidifies with time as the polymerization continues and ultimately a glass-like silicate solid matrix is obtained. When an enzyme or any biomaterial is added to the silane precursor after partial hydrolysis, these materials can be entrapped into the polymeric matrix after complete solidification. Fortunately, enzymes show considerable retention of their activity in such immobilization matrices. Small substrate molecules can diffuse into the pores of the polymeric matrix and reach the active site of the enzyme and thus be converted to other simpler species which can diffuse back into solution where it can be detected. The relatively large size of the enzyme assures minimum leaching from the solid matrix. The Sol-Gel process for enzyme immobilization seems very promising especially due to the mild conditions that are used for the immobilization process as well as the simplicity of the procedure involved. In addition, the immobilization matrix can be optimized so that transparent monoliths, thin films or fine particles are formed depending on the ultimate application of the preparation. Detailed description of the Sol-Gel process can be found in the many books and reviews on this topic [9–16].

Braun et al. [6] suggested that the encapsulation of glucose oxidase in conjunction with peroxidase and a chromogen in a tetramethoxysilane Sol-Gel matrix was good for the determination of glucose. However, no analytical data was presented. Yamanaka et al. [7] investigated the activity of glucose oxidase entrapped in a Sol-Gel matrix using a conventional photometric scheme for detection of the generated peroxide. The turnover number and the dissociation constant were reported to be similar and two-fold greater than the corresponding values for the native enzyme, respectively. Also, storage conditions were reported to have significant influence on the activity of the enzyme.

In this study, we present results on a new chromogenic system for the determination of hydrogen peroxide as well as results of peroxidase entrapment in different silicate glass matrices prepared by the Sol-Gel method. The system is optimized for the determination of enzymatically generated hydrogen peroxide produced from the bioconversion of glucose by glucose oxidase. Details of the system characterization as well as results of the determination of glucose in serum blood samples will be presented.

2. Experimental section

2.1. Instrumentation

Absorbance measurements were recorded using a double beam Perkin-Elmer Lambda 15 UV-Vis spectrophotometer. The instrument is microprocessor based with excellent performance char-

acteristics. Also, a Spectronic 20D spectrophotometer was occasionally used for absorbance measurements. The pH of the different solutions was adjusted using a Hanna digital pH meter. Temperature controlled studies were conducted using a conventional water bath.

2.2. Chemicals and reagents

3-[Trimethoxysilyl]-1-propanthiol (TMSP), triethoxypropylsilane (TEPS), 3-aminopropyltriethoxysilane (APES), 3-chloropropyltriethoxysilane (CPES), triethoxyvinylsilane (TEVS), horseradish peroxidase (180 U mg^{-1}), and glucose oxidase from *Aspergillus niger* (100 U mg^{-1}) were purchased from Merck Chemical Company, Germany. Disodium hydrogen phosphate, citric acid, sodium citrate, and succinic acid were obtained from Reidel de Haen, Germany. Variamine blue was obtained from UCB Chemicals, Belgium. Glucose standards and controls as well as commercial kits for glucose determination were purchased from Sigma Chemical Company, USA. Thymol-indophenol, thionine, methylviologen, phenosafranine, and 7,8-benzoflavone were from BDH, England. All chemicals and reagents used in this study were of the analytical grade and were used as received without further purification. Distilled, deionized water was used throughout this work.

3. Procedures

3.1. Preparation of a variamine blue working solution

Variamine blue is slightly soluble in water yielding a light bluish solution which darkens with time. The procedure for the preparation of a working solution of variamine blue involved the transfer of about 90 mg of the material into a beaker followed by the addition of about 40 ml of distilled water. The solution was heated with stirring to about 80°C. The solution was then filtered and the final volume was then adjusted to 50 ml by addition of distilled water. The thus prepared solution contains about 80 mg of variamine blue. This solution was kept for 1 week before use since it was observed that the absorbance of this solution increased with time for the first 5 days before stabilization. Therefore, we recommend the storage of the freshly prepared variamine blue for a period exceeding 5 days before actual use so that reproducible readings can be achieved.

3.2. Preparation of the Sol-Gel matrix

3.2.1. Sol stock solution

First, 2.25 ml of the appropriate alkoxysilane derivative was transferred into a small glass bottle followed by addition of 0.7 ml of distilled water and 50 μl of 0.1 M HCl. The bottle was firmly capped and the mixture was shaken for about 3 h. At this stage, partial hydrolysis of the alkoxysilane derivative was accomplished. The thus prepared partially hydrolyzed silane derivatives were kept in capped bottles at room temperature.

3.2.2. Peroxidase entrapment

The entrapment procedure involved the mixing of a 1:1 ratio of the previously prepared Sol stock solution and a buffered peroxidase solution (0.1 M phosphate buffer at pH 6). The solution was then shaken so as to obtain a homogeneous mixture which was allowed to solidify at room temperature. The formation of the Sol-Gel starts few minutes after mixing and complete solidification (constant weight) after about 5–10 days. The Sol-Gel immobilized peroxidase was kept at room temperature for at least 2 weeks before washing with successive solutions of 1.0 M NaCl, 0.1 M phosphate buffer at pH 6, and plenty of distilled water, respectively. This washing procedure is necessary to wash out any residual or surface adsorbed peroxidase.

3.3. Analytical procedure for peroxide determination

The general procedure for the quantitation of hydrogen peroxide involved the transfer of 2–4 ml of the buffer solution into a test tube containing the Sol-Gel entrapped peroxidase. An appropriate known amount of peroxide (or glucose and glucose oxidase) was then added and the enzy-

matic reaction was allowed to proceed for 10 min. Just before the absorbance measurements, a 100-μl portion of the variamine blue working solution was added. The absorbance of the oxidized variamine blue (violet color) was measured immediately at 550 nm against a blank.

4. Results and discussion

Initially, experimental conditions were optimized in order to obtain a sensitive chromogenic system for the determination of hydrogen peroxide using soluble peroxidase. Several redox systems were tried in an attempt to find a good system for such determinations. Variamine blue resulted in a very sensitive system for the determination of hydrogen peroxide while thymol-indophenol, thionine, methylviologen, phenosafranine, and 7,8-benzoflavone did not result in any appreciable signal. Therefore, all the following experiments were done using variamine blue.

4.1. Effect of pH on absorbance

Variamine blue is oxidized by hydrogen peroxide in presence of peroxidase. The resulting violet color was found to be highly dependent on the pH of the buffer solution. Fig. 1 shows the relationship between the absorbance signal and the pH of the buffer solution. It can be concluded from the figure that very little oxidation takes place at pH values above pH 7 and essentially no observable oxidation takes place at pH values above pH 8. Lower pH values result in more improved absorbance signals than measurements performed at higher pH values while optimum pH of the buffer solution occurs at about pH 5. Therefore, all subsequent studies were performed with buffer solutions at pH 5 even though this pH value does not match the optimum pH for maximum peroxidase activity. This could possibly be justified since the activity of peroxidase used at pH 5 is still very high although not highest possible.

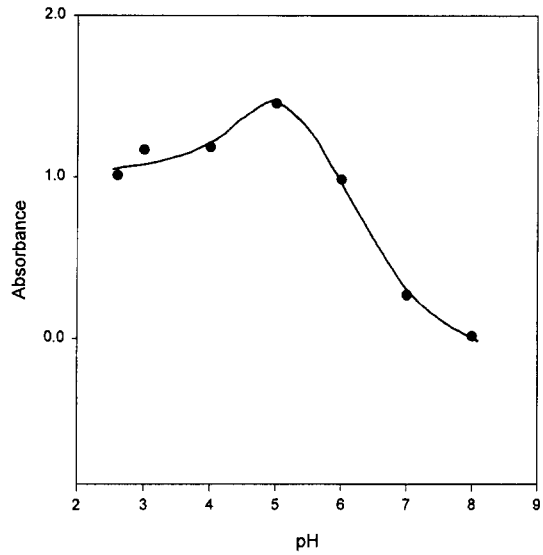

Fig. 1. Effect of the pH on the absorbance. Conditions: 0.1 M buffer solution, 5×10^{-5} M peroxide, 2.5 U peroxidase, and 3×10^{-4} M variamine blue. The absorbance signal was monitored at 550 nm.

4.2. Effect of buffer concentration

The concentration of the buffer solution used also affects the value of the absorbance signal as can be seen in Fig. 2. It can be shown from this figure that there was an increase in the ab-

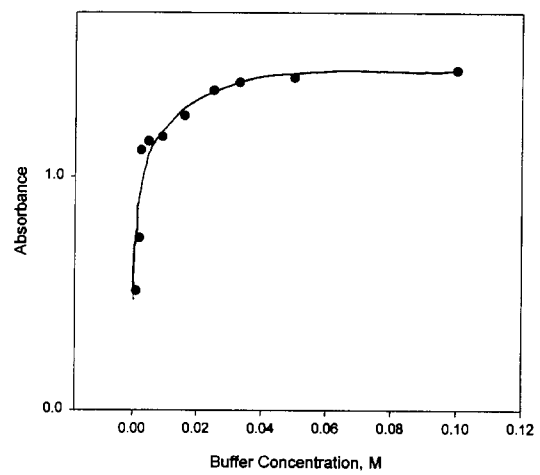

Fig. 2. Effect of buffer concentration on the absorbance signal. Conditions: buffer solutions at pH 5 but different concentrations. Other conditions are the same as in Fig. 1.

sorbance signal as the concentration of the buffer solution was increased at pH 5. However, the increase in the absorbance signal with concentration was not linear and absorbance increased only slightly at buffer concentrations greater than 3.3×10^{-2} M, and a plateau is essentially obtained at buffer concentrations exceeding 3.6×10^{-2} M. It is also clear from the figure that large increase in the absorbance signal was obtained as the buffer concentration was increased in the lower range of buffer concentration. Therefore, it seems advantageous to use higher buffer concentrations as low concentrations of buffer result in lower absorbance signals. A 0.1 M buffer concentration was judged suitable and was thus used in all further experiments.

It should also be indicated that buffer type was found to affect the absorbance signal where it was observed that buffers containing acetate or citrate resulted in improved absorbance signals while those containing succinate resulted in lower results.

4.3. Effect of variamine blue concentration

As expected, an increase in the variamine blue concentration resulted in an increase in the value of the absorbance signal. This is due to formation of more of the oxidized chromogen so that the equilibrium expression could be satisfied. Fig. 3 shows the dependence of the absorption signal on the variamine blue concentration. However, it is noteworthy to indicate that the background absorbance increased as the concentration of variamine blue was increased. Therefore, a variamine blue concentration of about 3×10^{-4} M was selected and was thus used in all subsequent experiments.

4.4. Effect of temperature

It is well established that temperature has pronounced effects on the activity of enzymes and thus the rate of enzymatic reactions. The temperature effects on peroxidase activity is depicted in Fig. 4. It can be shown from this figure that the optimum temperature for the determination of hydrogen peroxide, in presence of peroxidase and

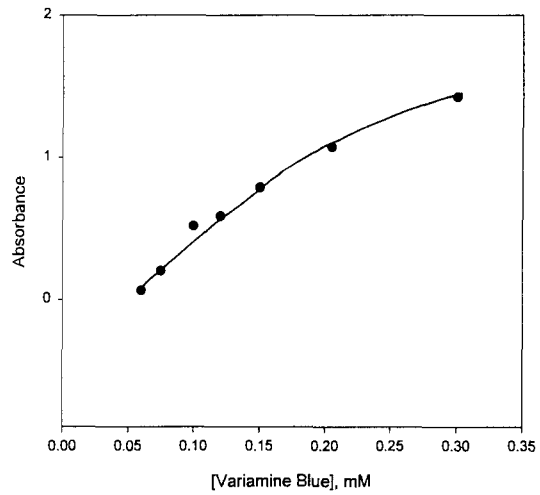

Fig. 3. Effect of the concentration of variamine blue on the absorbance signal. Conditions: 0.1 M buffer solution at pH 5. Other conditions are the same as in Fig. 1.

using variamine blue as the chromogenic material, is about 30°C. However, Fig. 4 also suggests a relatively small dependence of the absorbance signal on temperature at lower temperatures. Abrupt changes in the value of the absorbance signal was observed at temperatures exceeding about 33°C. Unless otherwise indicated, room temperature, 25°C was used throughout this work.

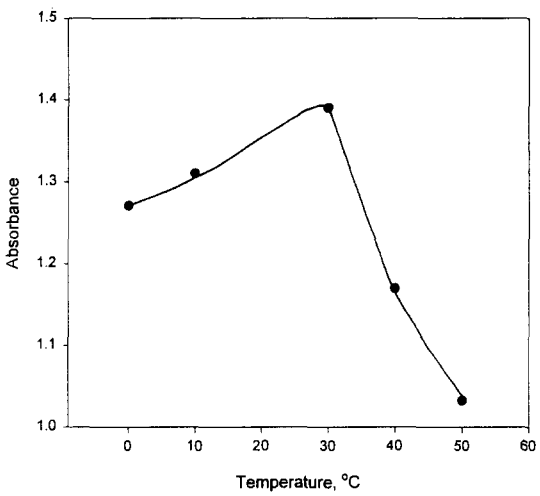

Fig. 4. Effect of temperature on the absorbance signal. Conditions: same as in Fig. 3.

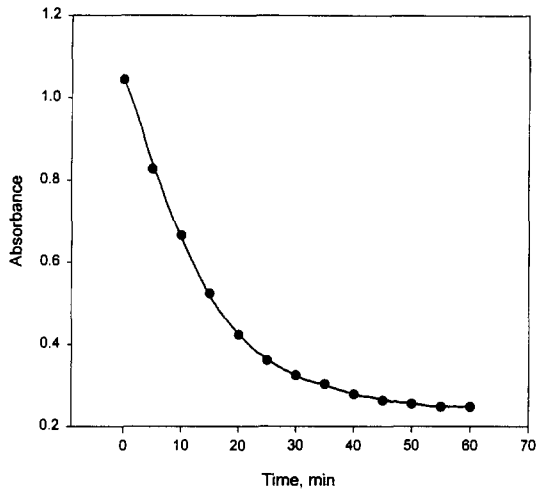

Fig. 5. Stability of the oxidized variamine blue with time. Conditions: same as in Fig. 4 except for the peroxide concentration (3.6×10^{-5} M).

4.5. Stability of the oxidized variamine blue

A very interesting behavior of oxidized variamine blue absorption with time can be seen in Fig. 5. It is clear from this figure that sensitive results can only be obtained when measurements are done immediately after the addition of the last reagent. This is because the absorbance signal starts to deteriorate with time. Initially, we suspected that the oxidized variamine blue was light sensitive. However, running a parallel experiment in a system completely isolated from light resulted in the same absorbance as that which was exposed to light. Therefore, this roles out the possibility of light instability of the oxidized chromogen. Unfortunately, the instability of the oxidized species can not be explained at this time. Throughout this study, absorbance measurements were done immediately after the addition of variamine blue, peroxidase, or hydrogen peroxide, depending on the experiment of interest.

4.6. Sensitivity of the variamine blue system

The variamine blue system showed a higher sensitivity for the determination of hydrogen peroxide, in presence of peroxidase, than the 4-aminophenazone system which is used, in a commercial kit, as the chromogen for hydrogen peroxide determination in presence of peroxidase. The molar absorptivity of the oxidized variamine blue (1.8×10^4 l mol^{-1} cm^{-1}) was about twice that of the 4-aminophenazone. Therefore, the optimized variamine blue system was subsequently used for the determination of enzymatically generated hydrogen peroxide using entrapped peroxidase.

4.7. Dependence of peroxidase activity on the entrapment matrix

Four different entrapment matrices were used to check whether peroxidase activity changes with the type of matrix in which it is immobilized. The composition of these matrices is detailed below:

Matrix I: 200 μl of the Sol containing 3-[trimethoxysilyl]-1-propanthiol was mixed with 300 μl of the Sol containing 3-chloropropyltriethoxysilane, 300 μl of peroxidase, and 200 μl of a papain solution (0.4 mg).

Matrix II: 500 μl of the Sol containing 3-chloropropyltriethoxysilane was mixed with 400 μl of peroxidase and 100 μl of papain (0.2 mg).

Matrix III: 300 μl of the Sol containing triethoxyvinylsilane was mixed with 200 μl of the Sol containing 3-chloropropyltriethoxysilane, 250 μl of peroxidase, and 250 μl of papain (0.25 mg).

Matrix IV: 400 μl of the Sol containing triethoxyvinylsilane was mixed with 100 μl of the Sol containing 3-chloropropyltriethoxysilane and 300 μl of peroxidase, but no papain.

All four matrices were left in a desiccator, at room temperature, for 20–23 days although full solidification occurred within 5–10 days. The weights of the samples after washing and drying were 0.168, 0.183, 0.096, and 0.201 g, respectively.

It is worth mentioning that the preparation of the Sol-Gel matrices was always reproducible under the specified conditions. Throughout this work, many different matrices were successfully and reproducibly prepared using the described procedures.

The procedure for the determination of hydrogen peroxide concentration involved soaking the appropriate solid matrix in 2.5 ml of buffer solution at pH 5 followed by addition of 30 μl of the

peroxide solution. The reaction was allowed to proceed for a specific period of time then a 100 μl portion of the variamine blue solution was added. The absorbance signal of oxidized variamine blue was immediately measured at 550 nm. Fig. 6 shows the relationship between the absorbance value and reaction time. It is clear from the figure that Matrix II shows highest absorbance value and lowest reaction time. This may suggest that hydrogen peroxide can easily diffuse through that matrix and reach the active site of the enzyme and thus be converted to oxygen which oxidizes the chromogenic material, resulting in the intense violet color. The three other matrices show approximate equilibration times but still the absorbance value varies for each one, where the absorbance measured using Matrix I was greater than that produced when Matrix III was used. The absorbance value was lowest when Matrix IV was used. It may be interesting to indicate that peroxide activity appears to be proportional to the amount of the 3-chloropropyltriethoxysilane precursor in the entrapment matrix. Therefore, it is clear that the entrapment matrix significantly affects the enzymatic activity and thus the value of the absorbance signal and the equilibration time as well.

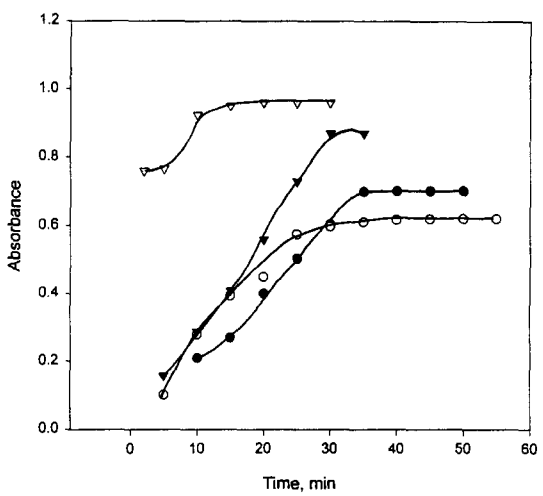

Fig. 6. Effect of the Sol-Gel matrix on the immobilized peroxidase activity. Matrix I (▼), Matrix II (△), Matrix III (●), and Matrix IV (○).

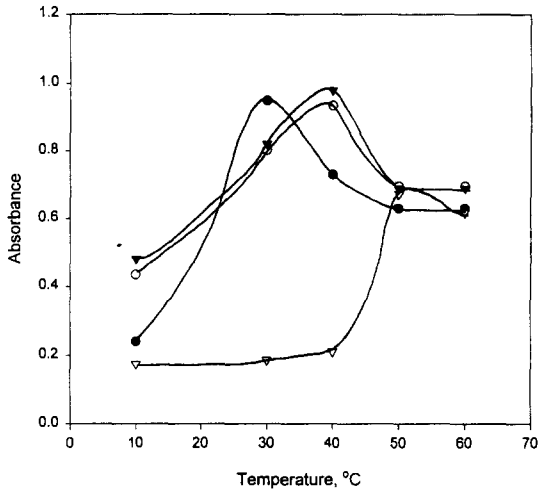

Fig. 7. Effect of temperature on the Sol-Gel entrapped peroxidase. Matrix I (●), Matrix II (▼), Matrix III (○), and Matrix IV (△).

4.8. *Effect of temperature on immobilized peroxidase*

Immobilized peroxidase in different matrices showed a rather interesting behavior at different temperatures as compared to the behavior of the enzyme in solution. The matrix composition seems to be very influential in the determination of the optimum temperature which results in maximum enzymatic activity. The optimum temperature for peroxidase was very similar to that of the soluble enzyme when the TMSP silane derivative was used. However, a significant shift in the optimum temperature of peroxidase (about 20°C) was observed when peroxidase was entrapped in a matrix which has TEVS as the predominant silane derivative but without papain as an additive (Fig. 7). Using comparable amounts of papain with the CPES or a mixture of TEVS and CPES silane derivatives resulted in a comparable shift in the optimum temperature of peroxidase that is about 10°C. Papain was used as an additive to the silane matrix hoping to improve the stability and enhance the activity of peroxidase in the Sol-Gel matrix. According to our experience and observations, proteins like papain or bovine serum albumin (BSA) improve the stability of some enzymes especially at solid surface matrices. We attribute

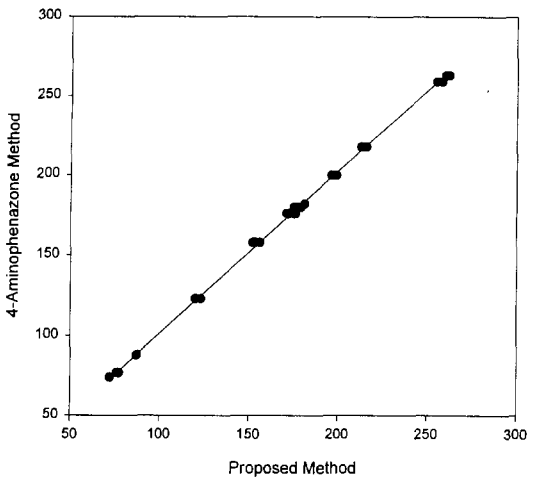

Fig. 8. Determination of serum glucose by the proposed method and the 4-aminophenazone method (34 experiments).

this to decreased interactions of the enzyme with the solid support due to competition between the enzyme and the additive for the very active surface of the solid support.

4.9. Determination of glucose in serum samples

The Sol-Gel immobilized peroxidase was used for the determination of glucose in serum. The blood samples were collected from a nearby clinic and were analyzed by both the standard method as well as our proposed method. The standard method uses a commercially supplied kit with 4-aminophenazone as the chromogenic material while the proposed method uses variamine blue in addition to Sol-Gel immobilized peroxidase. Excellent agreement between the two methods was always observed which is demonstrated in Fig. 8. The absolute difference between the results in the two methods was always less than 3% for any individual sample which can also be attributed to delay in doing the measurement by the proposed method due to time required to transfer the serum samples from the clinic to our laboratories.

4.10. Stability of the Sol-Gel immobilized peroxidase

After the formation of the solid matrix incorporating the enzyme, the Sol-Gel enzymatic matrix was kept in a desiccator, at room temperature, for 2 weeks. Then the different Sol-Gel preparations were used for the analysis of the peroxide/glucose samples for 35 days. No change in the performance characteristics of the Sol-Gel immobilized enzyme was observed. This may suggest excellent stability of the entrapped enzyme inside the Sol-Gel matrix. Although a long-term stability study was not performed, it is anticipated from initial results of about 2 month that these enzymatic preparations will be stable for longer periods. Even after the analysis of about 50 serum samples for glucose, consistent and reproducible results were always obtained. The relative standard deviation for repetitive determinations ($n = 10$) was less than 1% in all cases. It should also be indicated that the Sol-Gel enzymatic preparations were kept refrigerated at the end of each working day.

Received 7 August 1996; received in revised form 21 January 1997; accepted 4 February 1997

Abstract

Formation constants of the silver(I) complexes with some amino-alcohols have been determined at 25°C in 0.5 M KNO_3 by means of two independent potentiometric measurements employing glass and silver electrode. The ligands considered are: sec-butylamine, 2-amino-1-propanol, 2-amino-1-methoxy-propane, 2-amino-2-methyl-1-propanol, 2-amino-1-butanol, 2-amino-1-pentanol, 2-amino-1-hexanol, 2-amino-1,3-propanediol, 2-amino-1,3-hexandiol, 2-amino-2-methyl-1,3-propanediol and Tris(hydroxymethyl)–aminomethane. Protonation constants of the selected ligands have also been determined. Calculations were made using HYPERQUAD computer program. The influence exerted by the introduction of hydroxy groups and by the presence of alkyl residuals in the ligand structure on the formation equilibria, is discussed. © 1997 Elsevier Science B.V.

1. Introduction

The amino-alcohols represent a largely diffused class of biologically active substances. They characterise the moiety of several drugs and natural substances like ephedrine, adrenaline and noradrenaline and of some naturally occurring sphingoid like sphingosine and sphinganine. Due to the coordinating properties of amino and hydroxy groups, the study of formation equilibria of complex species with metal ions can help to clarify the biological role of these substances. The knowledge of complexing properties of amino-alcohols is not yet exhaustive and only a few data related to their complex equilibria are known [1–14]. In particular sphingosine and sphinganine in the last few years have received great attention because of their activity as inhibitors of tumoral cells growth [15–18]. Notwithstanding this, the mechanism of their biological activity has not yet been clarified and their pharmaceutics application is nowadays hampered by the cytotoxic effect shown at high concentration [19]. However, it is known that the antitumoral effect of these sphingoids depends on the structure of their polar head and in particular on the presence of an amino-group, positively charged, in position 2 [15,20], so that when the $-NH_2$ is chemically bonded, as an example by acylation, the inhibiting effect does not occur.

Then, is presumable that a coordination bond involving the amino group also influences the pharmacological activity of these compounds. Furthermore, as the interaction with metal ions is usually reversible and rapid, the study of complex formation equilibria may allow an efficient regulation of active species concentration.

In this context, the present paper is concerned with the study of complexation equilibria of some amino-alcohols with Ag(I). The considered ligands are: sec-butylamine (L_I), 2-amino-1-propanol (L_{II}), 2-amino-1-methoxy-propane (L_{III}), 2-amino-2-methyl-1-propanol (L_{IV}), 2-amino-1-butanol (L_V), 2-amino-1-pentanol (L_{VI}), 2-amino-1-hexanol (L_{VII}), 2-amino-1,3-propanediol (L_{VIII}), 2-amino-1,3-hexandiol (L_{IX}), 2-amino-2-methyl-1,3-propanediol (L_X) and Tris(hydroxymethyl)-aminomethane (L_{XI}).

The ligands, which have a structure similar to the polar head of sphingosine and sphinganine, have been chosen in order to evidence the effect of the number of substituent hydroxy-groups and of the addition of alkyl residual on the coordinating properties of 2-amino-alcohol moiety.

The study has been extended to Tris(hydroxymethyl)-aminomethane (TRIS, THAM), whose complexing properties have been not sufficiently documented even if it is often added as a buffer to solutions prepared to investigate biochemical reaction involving transition metal ions [12–14,21–24].

Among the elements of the same periodic group, silver has been the least studied one, probably due to its extremely low presence in biological systems. However, our attention has been focused on silver(I) compounds, firstly because of the lack of thermodynamic data and secondly because, as already observed for other metal ions whose presence is not relevant in biological systems [25–27], their applicative importance can not be excluded.

2. Experimental

2.1. Materials

All the commercial products employed for the preparation of L_{III} and L_{IV}, were by Fluka.

Twice distilled and deionized water was used for preparing all solutions. All the reagents were obtained in high purity. Ultra pure KNO_3 (Suprapur grade, Merck) was used as ionic strength buffer.

Silver(I) nitrate (Carlo Erba) stock solutions were standardized by titration with standard reagent NaCl (Merck) and using K_2CrO_4 (Merck) as indicator following the Mohr's method [28].

Ligand stock solutions. As all the considered ligands are highly hygroscopic and uptake easily CO_2, the direct weighing was not possible and all the solutions had to be handled in strictly air-free conditions. Stock solutions were then prepared by taking a volumetric sample in a glove-box under an argon atmosphere and diluting with appropriate volumes of water. The titre was successively controlled from series of crossed acid–base titrations with a potentiometric end point detection.

2-Amino-1,3-propanediol has been supplied as oxalate salt. The quantitative precipitation of oxalate ion with calcium(II) was then performed before preparing stock solutions. The presence of a 0.5% excess of calcium(II) nitrate, needed in order to assure the quantitative precipitation of oxalate, has been checked by EDTA titration.

Potassium hydroxide 0.1 M (CO_2-free solution, Merck) was standardized by potentiometric titrations against a solution of potassium hydrogen phthalate (Merck pro analysis, dried at 120°C) using the Gran method [29] for the evaluation of the end point.

Nitric acid solution (0.1 M) was prepared by diluting the pure concentrated product (Merck) and standardized by potentiometric titrations against tris(hydroxymethyl)aminomethane (Merck), dried at 100°C for 24 h.

An independent check of the analytical procedure was also carried out by a direct titration of potassium hydroxide solution against the nitric acid.

2.1.1. Synthesis of 2-amino-1-hexanol and 2-amino-1,3-hexandiol

As 2-amino-1-hexanol and 2-amino-1,3-hexandiol are not commercially available, these products were prepared following the synthetic path summarized in Scheme 1 [30].

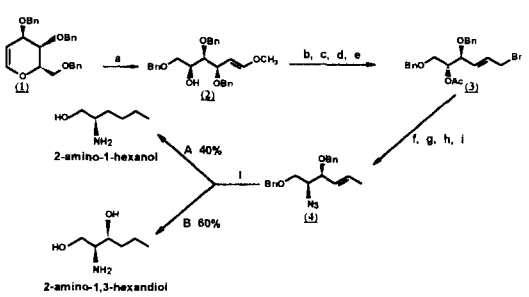
2.1.2. EMF measurements

Glass electrode. The alkalimetric titrations were carried out adding KOH to the test solution placed in a thermostatic vessel, under agitation and under a stream of purified argon presatured with a 0.5 M KNO_3 solution. The temperature control (25 ± 0.1°C) was achieved by means of water circulation in the jacketed vessel from a water thermocryostat (thermostat HAAKE DC3 and chryostat HAAKE K15). The initial volumes of the titrated solutions were 25 ml.

The KOH solution was delivered in the titration vessel by a Metrohm Dosimat 655 digital burette with a total volume of 5 ml. In order to have CO_2-free potassium hydroxide, the solution was preserved in a bottle stopped by a soda lime plug and kept under argon atmosphere. In these conditions the solution was stable up to 1 month.

Potentiometric titrations were carried out using a Metrohm mod. 665 pH/mVmeter, with a glass electrode (INGOLD) and a double junction Ag/AgCl electrode (INGOLD) as a reference. The outer solution of the reference electrode was 0.5 M KNO_3.

The potentiometric apparatus was made completely automatic by applying an IBM mod.30 personal computer with a parallel interface and using an appropriate software program. [31]



Scheme 1.

The electrode standard potentials E° were determined every day from the acid region of the titration of a 0.005 M HNO_3 solution (0.5 M ionic strength buffer) against 0.1 M KOH. Similarly the response of the glass electrode was checked every week evaluating the value of pK_W from the basic portion of the calibration curve. The linearity of E versus pH function was also checked; the slope of the straight line obtained was, within the experimental errors, coincident with the theoretical value.

For the evaluation of the protonation constants, solutions 0.5 M in KNO_3 containing different quantities of ligand and acidified with a known excess of HNO_3 were titrated with potassium hydroxide solution.

For the formation constant determination of Ag(I) complexes, solutions at various concentrations of Ag(I) nitrate and ligands were titrated with KOH. Before the titrations all the solutions were acidified with a known excess of nitric acid. The ionic strength was always adjusted to 0.5 M by adding solid potassium nitrate.

Ag electrode. All the measurements regarding Ag(I) complexation equilibria were repeated also by employing an Ag electrode (Metrohm) in order to have an independent measurement.

The calibration of the Ag electrode was performed by measuring the potential of five solutions at different Ag(I) concentration containing KNO_3 0.5 M as ionic strength buffer. E° and slope were determined by linear regression of data ($r^2 = 0.99$) and the obtained values were in good agreement with the theoretical ones (error < 1%).

The operative conditions employed for the determination of stability constants were the same as those related to glass electrode measurements.

All the calculations for the calibration of the glass electrode and for the determination of ligand protonation and complex formation constants were carried out by employing HYPERQUAD least squares computer program [32].

3. Results and discussion

Particular attention had then to be paid to the choice of concentration ranges, considering the

Table 1
Initial analytical concentrations (mM) of ligand (C_L) and acid (C_H) and $-\log[H^+]$ ranges for the determination of the protonation constant of 2-amino-1-hexanol at $I = 0.5$ M KNO_3 and $T = 25°C$

Ligand	Expt. no	C_L	C_H	$-\log[H^+]$ ranges
2-Amino-1-hexanol	1, 2, 3	1.8	3.0	3.08–10.61
	4	3.7	5.0	3.07–10.34
	5	6.7	10	3.08–10.43

method sensitivity and the best operative conditions for the calculation of the constants. Good results were obtained in all the examined systems when the ligand concentration was maintained lower than 7 mM.

In fact, by a preliminary examination of the experimental data, turns out that the ligand concentration influences the results. In particular, there is a progressive worsening of the fit on increasing the ligand concentration in the titration vessel.

3.1. Protonation equilibria

The calculation of the protonation constants has been performed by elaborating the data obtained by five titration runs for each system. In Table 1 the operative conditions are reported for 2-amino-1-hexanol as an example. Similar conditions have been employed for all the other ligands. As can be noted, one of the titrations has been repeated three times in order to check the reproducibility of the experimental measurements. Repeated runs also allowed a better control of the ligand concentrations, whose determination requires particular care (Section 2). In fact the amounts of ligands in the titration vessel (C_{0L}) have been refined by HYPERQUAD program and the resulting values were in a good agreement with the calculated ones (2% error).

In Table 2 the pK_a values obtained by the simultaneous elaboration of all the titration curves are reported. The error between brackets is the standard deviation provided by HYPERQUAD calculations. The statistical parameters are satisfactory also considering that, due to the basicity of ligands, E.F.M. measurements had to be performed in the basic region.

The pK_a values related to sec-butylamine [33], 2-amino-1-butanol [34] and THAM [12–14,21–24] are in a good agreement with literature data.

From the examination of the reported data, two main effects on the acidity of protonated ligands can be evidenced. Firstly, the insertion of hydroxy group causes a relevant lowering of pK_a values. This effect could be caused either by the intramolecular hydrogen bond formation [35], which is stronger in the deprotonated form than in the protonated one, or by an electron-withdrawing polar effect due to the hydroxy group. Comparing the pK_a values related to L_{II} and L_{III} it is evident that the second effect is prevalent. Furthermore, the methoxy group seems to be more effective than hydroxy group, in spite of the lower electronic-withdrawing capabilities of this group with respect to hydroxy one. This reversal, already observed for similar compounds [36] was ascribed to the modification of the true inductive effect of the hydroxy group by solvation.

Secondly, the addition of alkyl residuals in the ligand structure causes an increase of the pK_a values. The effect is mainly ascribable to a field effect of the alkyl group, which results in an increase in the electron density on the nitrogen atom [36]. Furthermore, from the results it can be

7	2.00	0.69	3	2.20	7.65–9.75
8	4.05	0.81	5	6.10	7.54–10.20

noted that the insertion of methyl group in position 2 in L_{IV} and L_X causes an increase of pK_a lower than the one expected on the basis of the field effect. This is in agreement both with the steric hindrance on the quaternary carbon, which could stabilize the intramolecular hydrogen bond with the consequent lowering in basicity and with the differential hydration [37] which is less effective when a $-CH_3$ group is added in position 2.

3.2. Complexation equilibria

In order to evidence both mononuclear and polynuclear species, the determination of complexation constants has been carried out for each considered system on a stock of eight solutions containing various C_L/C_M ratios and at different ligand and metal initial concentrations. In Table 3 are reported, as an example, the operative conditions for 2-amino-1-hexanol-Ag(I) system.

As can be noted, the $-\log[H^+]$ ranges are variable depending on experimental conditions and have been identified considering all the equilibria involved, in order to avoid precipitation equilibria.

All the experimental runs were firstly elaborated by HYPERQUAD one by one, afterwards an elaboration of each set obtained with glass or Ag electrode was performed. Finally all the titration curves were elaborated simultaneously. Different equilibrium models were examined. The species ML, ML_2 M_2L, M_2L_2, MLOH, ML_2OH and ML_3, were systematically considered in different combinations. These species were either rejected by HYPERQUAD or caused a worsening of the statistical parameters σ and χ^2 [38] or lead to not acceptable chemical models.

The absence of systematic errors was tested refining also the dangerous parameters as C_{0M}, C_{0L}, C_{0H} (total mmoles of metal, ligand and proton, respectively, in the reaction vessel). The deviation of calculated values from input ones can be considered within the experimental error (about 2%).

Hydrolysis constants [39] were considered in the calculation. However they do not influence the $\log \beta$ values, apart from a slight ($\sim 1\%$) effect on the results related to the titration curves with $C_L/C_M = 1$.

The calculations related to Ag electrode measurements give statistical parameters better than those obtained with glass electrode, probably due to the working pH range in which the alkaline error is not negligible. Anyway, the stability constants obtained with the two independent measurements are in good agreement as evident in Table 4 in which the results related to Ag and glass electrode measurements for Ag(I)-2-amino-1,3-propanediol system are reported.

In Table 5 the results of the overall elaboration obtained for all the considered systems, are summarized. Two different models, i.e., ML-ML_2 (model 1) and ML-ML_2-MLOH (model 2), are reported as the most significative ones. Is worth noting that is not possible from the potentiometric measurements, to deduce whether the species indicated as MLOH is a hydroxy complex or a complex where ligand acts as a chelate, with the deprotonation of the hydroxy groups. Due to steric reasons and considering $\log \beta$ values the first alternative seems to be more probable [21]. On the other hand, the enhancement of the affinity for OH-compared with the hydrated silver ion has been already observed from other authors in the presence of aromatic [40] or aliphatic [21,41] *N*-ligands.

From a critical view of the Table 5 it is evident that the model 2 is the most representative at least for the ligands L_{VIII}, L_{IX}, L_X and L_{XI}, in which two or three hydroxy groups are present. The

presence of the MLOH species is evident in Fig. 1 in which the comparison between the two models for Ag(I)-THAM system is reported as a plot of experimental and calculated data. For all the other systems, the presence of ternary species MLOH is uncertain and its addition to the speciation model does not improve significantly the fitting. This may be due both to the reduction in acidity of the bonded water (see $\log K_a(AgL^+)$ values in Table 5) and to the formation constant values, so that the presence of ML_2 species is predominant in the examined experimental conditions (Fig. 2 and Fig. 3).

As far as the stability order of the complexes is concerned, the same trend as observed for pK_a values has been found. It is then evident that the coordination is due to the aminic nitrogen and that no chelate structures are formed. As found

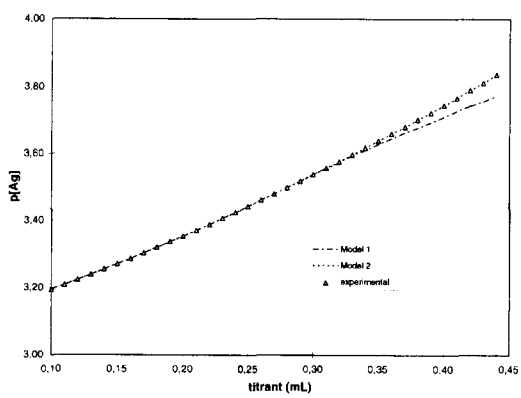

Fig. 1. Comparison between experimental and calculated curves related to either model 1 (ML, ML_2) or model 2 (ML, ML_2, MLOH) for the Ag(I)-THAM system with Ag electrode. $C_L = 3.2$ mM, $C_M = 1.1$ mM, $C_H = 3.5$ mM, I = 0.5 M KNO_3 and $T = 25$°C.

for other systems [6,42], $(\log K_1)/pK_a$ ratio is constant for all the considered ligands, the average value being 0.37 ± 0.02.

It is worth noting that in the systems containing L_{IV} and L_X as ligands, the stability of the ML species is lower than the one expected considering the pK_a values. These results can be ascribed to the steric hindrance which is more influent on the tetrahedral structure of ML species with respect to the linear one characteristic of ML_2 species in silver(I)-aliphatic amines systems.

Furthermore, it can be noted that $\log K_2$ values are higher than $\log K_1$ ones, with the exclusion of 2-amino-1,3-hexandiol and 2-amino-1,3-propane- diol. This different behaviour can be explained assuming that the K values, as suggested by Orgel [43] and interpreted in detail by Martin [44] in terms of cooperative effect, are made up of two parts which are in competition each other. The first is mainly due to a statistical-electronic effect and causes a fall off of stability from K_1 to K_n. The second part can be attributed to an energetic effect associated to the change of the complex structure from tetracoordinate to linear and determinates an increasing of stability. Depending on which is the prevalent effect, K_2 value will be lower or higher than K_1.

In-situ FTIR spectroelectrochemical investigation of cobalt(II)-cyanoferrate polymeric film coated on a glassy carbon electrode

Hong-Qiang Zhang, Xiang-Qin Lin *

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Changchun 130022, People's Republic of China

Received 25 July 1996; received in revised form 27 January 1997; accepted 4 February 1997

Abstract

Cobalt(II)-cyanoferrate polymeric film has been electrochemically deposited on a glassy carbon electrode and investigated by cyclic voltammetry and in-situ reflection FTIR spectroscopy. A reorientation of the terminal C≡N groups upon redox reactions was proposed. The stretching vibration mode of the terminal C≡N groups associated with Fe(III) was observed at 2122 cm^{-1}, however, the stretching vibration mode for terminal groups associated with Fe(II) did not appear. This process could result in a switch between lattice-closed and lattice-opened surface structure.

Keywords: Cobalt(II)-cyanoferrate; Glassy carbon electrode; Stretching vibration

1. Introduction

Cobalt hexacyanoferrate (CoHCF) is an important member of the family of mixed-valence transition metal hexacyanometallates. The CoHCF polymeric film has excellent properties in electrocatalysis, zeolitic towards specific cations, bichromic and chemical stability. All of these traits and low cost of such inorganic polymeric film coated electrode make it obvious candidate for electroanalytical applications such as electron transfer mediation, electrochromism devices and ion selective electrode [1]. Several electrochemical and spectroscopic techniques have been employed to characterize the CoHCF polymeric film and its analogues.These methods include cyclic voltammetry [1], in-situ UV-vis spectroscopy [2], in-situ Mossbauer Spectroscopy [3], AC Impedance [4], XPS [4], ex-situ IR Spectroscopy [1,5,6], etc. Ex-situ IR investigations can provide useful information, but it also leads to a question as to whether or not the observed spectra correspond to the actual electrochemical surface species. Unfortunately, no in-situ IR investigation has been reported for this problem in the literature. In-situ IR technique have attracted considerable atten-

tions of many research groups [7] since the pioneer work at the beginning of the 1980s [8]. Owing to the fact that it allows the electrochemical environment of the reactive centers to be preserved, in-situ IR method becomes a powerful tool in studies of film-coated electrodes.

The CoHCF film has 3-dimensional inorganic network which may contain coprecipitated or occluded ions, possibly hydrolyzed ferrocyanide and indefinite amounts of water. Such a complex materials may have variable stoichiometry and structural disorder. There are still interesting questions to be answered concerning the film structure, ion permeability and correlation of redox potential with supporting electrolyte cations.

The present work reports the by using in situ IR technique study the structure of the in-situ reflection FTIR spectroelectrochemical study of the CoHCF film on glassy carbon electrode and try to correlate the film structure to the property of the film-coated electrode.

2. Experimental

Analytical grade $K_3Fe(CN)_6$, $NaNO_3$ and NaCl were used without further purification. Solutions were prepared with doubly distilled water.

The CoHCF film was prepared on glass carbon (GC) electrode (8 mm diameter) by electrochemical deposition similar to that reported in literature [1]. Perio to film deposition, the GC electrode was polished to a mirror finish on an optical flat using 1.0, 0.3 and 0.05 mm alumina, then rinsed and ultrasonicated with 1:1 water-methanol mixture, and finally thoroughly rinsed with distilled water. The film was obtained by cycling the electrode potential between 1.0 and 0.0 V (vs SCE) at 100 mV s^{-1} for 5 min in 1.0 M $NaNO_3$ solution containing 1 mM $Co(NO_3)_2$ and 1 mM $K_3Fe(CN)_6$. Then the film-coated electrode was thoroughly rinsed with the supporting electrolyte solution for further experiments.

A home-made in-situ external reflection FTIR spectroelectrochemical cell was used [9]. A Nicolet 520 SX FTIR spectrometer with a DTGS detector, and a variable angle specular reflectance attachment (Spectra Tech Inc.) was used. The instrument was calibrated using a polystyrene film. The IR beam was aligned for 66° incidence angle at the electrode/solution interface. All spectra were collected by using potential modulation method [7]. Two hundred scans were averaged for a spectrum. Larger number of scan average times can be used for further reduction of noise level. However, longer acquisition time may cause significant baseline distortion.

A home-built cyclic voltammetric analyzer coupled with a series 60000 X-Y recorder (Liaoning Precision Instruments MFY, China) was used. All potentials were reported with respect to the saturated calomel electrode (SCE). $E^{0\prime}$ was estimated as $(E_{pc} + E_{pa})/2$, and ΔE_p was measured as $E_{pa} - E_{pc}$.

3. Results and discussion

3.1. Voltammetric measurements

Fig. 1 shows the typical cyclic voltammogram (CV) of the prepared CoHCF/GC electrode in 1M NaCl solution. As seen in Fig. 1, a couple of symmetric redox peaks appeared at $E^{0\prime}$ of 0.45 V (vs. SCE) with peak-to-peak separation ΔE_p of zero at 100 mV s^{-1}. The half width for both of

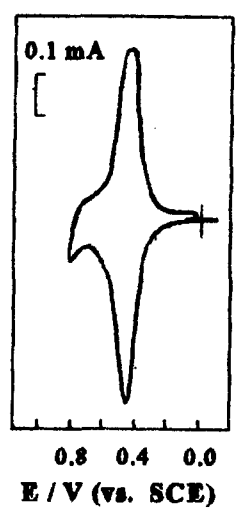

Fig. 1. Cyclic voltammograms at CoHCF/GC electrode in 1.0 M NaCl solution at scan rate of 100 mV s^{-1}.

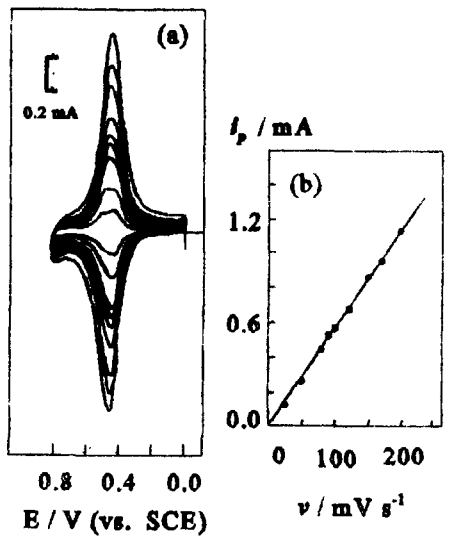

Fig. 2. (a) Cyclic voltammograms of CoHCF/GC electrode in 1.0 M NaCl solution at different potential scan rates (25, 50, 80, 90, 100, 120, 150, 170, 200 mV s^{-1}); (b) Scan rate dependence of the reduction peak current for CoHCF/GC electrode in 1.0 M NaCl solution.

the reduction and oxidation peaks was about 140 mV. It is known that the cobalt center is not electrochemically active in this potential region. The redox step at 0.45 V is attributed to the electron transfer processes of the Fe center [1].

The CVs upon variation of potential sweep rate are shown in Fig. 2(a). The peak current was linearly proportional to the sweep rate as shown in Fig. 2(b). These typical characteristics of surface wave are well expected for this system.

3.2. In-situ IR spectroscopic measurements

Fig. 3 shows the in-situ reflection-absorption difference spectra on the CoHCF/GC electrode. As shown in this figure, the IR band extending upwards at 2068 cm^{-1} indicates the disappearance of the stretching vibration mode of bridging C≡N ligand associated with Fe(II) and the downward peak at about 2098 cm^{-1} indicates the appearance of stretching vibration mode of bridging C≡N ligand associated with Fe(III) [1,10–12]. The transformation of these two vibration modes with the potential jumping from 0 to 0.50 V indicates the redox step of the Fe(II/III) in the CoHCF film. It is also seen in this figure that when the potential increased from 0.50 to 0.70 V, the downward band at 2090 cm^{-1} decreased and shifted to 2098 cm^{-1}. Meanwhile, a well defined downward peak appeared at 2122 cm^{-1}. The little shift of the 2090 cm^{-1} band may be resulted from the Stark effect, however, it is also consistent with the fact that the oxidation of Fe(II) to Fe(III) weakens the π back donation from metal d orbital to the cyanide π^* orbital and thus enhances the carbon–nitrogen bond strength and results in shifting toward higher wavenumber for the C≡N stretching frequency.

Of particularly interesting, the new band arising at 2122 cm^{-1} can be assigned to the characteristic band of terminal cyanide associated with Fe(III). Because the stretching frequency in free $Fe(CN)_6^{3-}$ anions is at 2114 cm^{-1} [13], only +8 cm^{-1} shift may be resulted from the fact that the

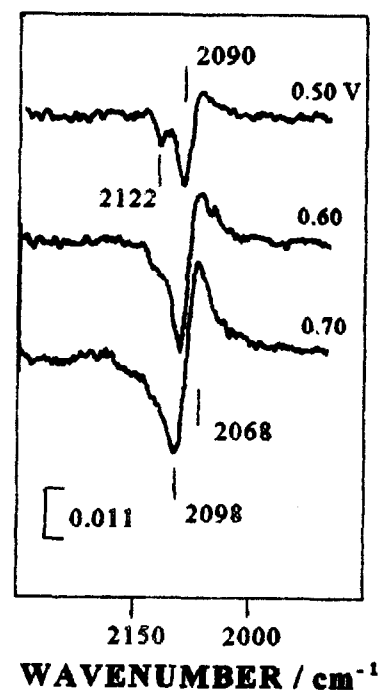

Fig. 3. FTIR potential difference reflection-absorption spectra obtained at CoHCF/GC electrode in 1.0 M NaCl solution. Reference potential: 0.0 V (vs. SCE). Sampling potential: as indicated, V (vs. SCE). 200 interferograms were averaged.

terminal cyanide is connected to the polymeric network of the CoHCF. When the potential increases positively, the electrode withdraws electrons from Fe center through the polymeric network. This weakens the π back donation from Fe to the cyanide π^* orbital and enhances the strength of C≡N bond.

The 2122 cm^{-1} band emerged at the potential of 0.50 V. It became less visible because of the increasing intensity of the wings of the broad band at 2098 cm^{-1} with potential increasing from 0.50 to 0.70 V. It is reasonable to observe an upward band for the disappearance of the stretching vibration mode for the terminal C≡N associated with Fe(II). This band can be expected to appear at about 2040 cm^{-1} [13]. However, no such an upward peak in this region was found, only a small upward spike can be seen at about 2050 cm^{-1} at 0.6 V spectrum.

This phenomenon probably arises from the effect of the surface selection rule [14]. Among the normal modes of a molecule, only the vibrational modes having a non-zero component of the dipole derivative perpendicular to the reflection surface, $(\delta R/\delta Q) \neq 0$, are able to interact with the IR radiation. Although, the Surface Selection Rule has been well established at metal surfaces, because of the excellent electric conductivity of the GC electrode, we may expect the same applicability. According to the face-centered cubic lattice structure of mixed-valance heavy-metal hexacyanometallates [1,15],the surface of CoHCF film adjacent to the solution can be described as shown in Fig. 4.

In the cubic lattice structure of CoHCF, cobalt and iron atoms alternate at the cubic corners. The bridging cyano groups located in such a way that all irons coordinated to carbon and all cobalt to nitrogen [1]. We consider that the terminal cyano groups should connect to the iron atoms and like whiskers growing on the surface of this film. However, when the electrode potential was lower and the film was in reduced state, the terminal cyano groups could be oriented on the surface forming a 'closed' lattice. Such an orientation in the surface selection rule is IR-inactive and led to the 'disappearance' of the stretching mode for the C≡N associated with Fe(II).

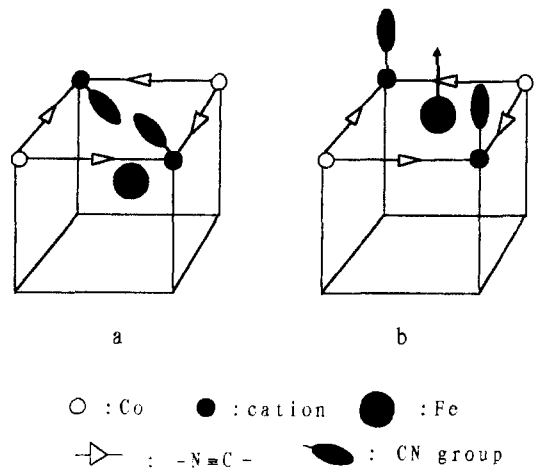

Fig. 4. Closed (a) and opened (b) lattice mode for the surface structure of CoHCF film adjacent to the solution

With the potential increasing positively, the orientation of these terminal cyano groups may become perpendicular to the cubic surface. This reorientation process could be related to the releasing dopant lattice cations. When the potential reached to 0.50 V, the oxidation process of the lattice was completed, the lattice became 'opened' with the terminal C≡N group vertical to the surface. This mechanism consists with the appearance of 2122 cm^{-1} band in Fig. 3.

The transition of orientations for the terminal C≡N groups could also be influenced by electric field of the double layer. Because the Fe(II) center prefers C-coordination, however, the Fe(III) center prefers N-coordination, it is possible that the oxidation of the CoHCF film results in a reoriented-coordination of the terminal C≡N. When the film was in the reduced state the partially negative charged free N-end of the terminal C≡N group could be forced down by the electrostatic field as shown in Fig. 5(a). However, when the electrode potential shifting positively, the oxidation of the Fe(II) to Fe(III) could release the partially positive charged C-end. The electrostatic field could force the C-end up forming the vertical orientation as shown in Fig. 5(b).

The redox potential of the surface film is significantly influenced by the property of electrolyte cations, however, the electrolyte anions have been

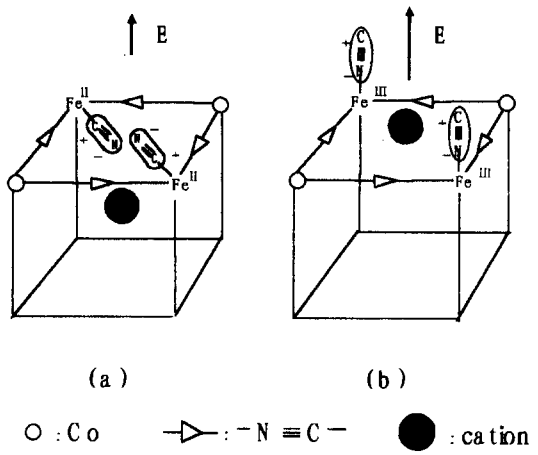

Fig. 5. Reorientation of terminal C≡N group in CoHCF film in (a) reduced and (b) oxidized state.

found to play scarcely role on CoHCF electrochemistry [1]. Besides the size effect, the existing of the whiskers-like terminal cyano groups on the lattice surface can be expected to play a subtle role on the ion channeling kinetics of the film.

4. Conclusion

In-situ IR spectra of the cobalt(II)-cyanoferrate polymeric film coated glassy carbon electrode revealed a transformation band at 2122 cm^{-1} for the terminal C≡N groups. It is expected that the orientation of the terminal C≡N groups on the lattice surface can be reoriented upon redox reaction of the Fe center and switched between on-surface state and whiskers-like state. This process may result in ion-channel closed or opened lattice. This switch-adjustment effect to the ion channeling process of the polymeric film may be interesting.

Fourier transform infrared spectroscopic determination of cypermethrin and deltamethrin in emulsifiable concentrate formulations

K.K. Sharma *, Suman Gupta, S.K. Handa

Division of Agricultural Chemicals, Indian Agricultural Research Institute, New Delhi 110 012, India

Received 1 July 1996; received in revised form 28 January 1997; accepted 6 February 1997

Abstract

Fourier tranform infrared (FT-IR) spectroscopic method has been developed for determination of cypermethrin and deltamethrin in emulsifiable concentrate formulations. The known concentration of formulation was subjected to preparative thin layer chromatography and the active ingradient zone was scrapped from the plate. Pyrethroids were eluted from the adsorbent with chloroform and estimated by measuring the ester carbonyl absorption band at 1749 cm^{-1} in cypermethrin and at 1743 cm^{-1} in deltamethrin using base line technique. Recoveries of cypermethrin and deltamethrin from commercial and laboratory prepared formulations were 90 to 97% in both the cases. The validity of FT-IR method was confirmed by comparing the results with standard HPLC method. © 1997 Elsevier Science B.V.

Keywords: Fourier tranform infrared spectroscopy; Cypermethrin; Deltamethrin

1. Introduction

Cypermethrin (RS)-α-cyano-3-phenoxybenzyl (1RS)-*cis*, *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropanecarboxylate and deltamethrin (S)-α-cyano-3-phenoxybenzyl (1R)-*cis*-(2,2-dibromovinyl)-2,2-dimethylcyclopropanecarboxylate are non-systemic stomach and contact synthetic pyrethroids effective against broad range of pests. These pyrethroids are commercially available as emulsifiable concentrate (EC), wettable powder (WP) and ready-for-use ultra low volume formulations (ULV).

The active ingradient in technical material and commercial formulations is determined by either high performance liquid chromatography (HPLC) or gas liquid chromatography (GLC) [1–4]. In the present Fourier transform infrared (FT-IR) spectroscopic method, the active ingredient was separated from commercial formulation by preparative thin layer chromatography (TLC) and the ester carbonyl absorption band was estimated by FT-IR. The method is simple, rapid and has been applied satisfactorily for the estimation of active ingradient of cypermethrin and deltamethrin in EC formulations.

2. Experimental

FT-IR spectrophotometer (Nicolet, Impact 400) matched liquid cells with NaCl window having optical path length of 0.05 mm. HPLC, Waters HPLC pump (501), Rheodyne injector (7125) equipped with 20 μl loop, variable wavelength tunable absorbance detector (Waters, 484), Stainless steel reverse phase column, RT 250-4; packed with 10 μM Lichrosorb RP-8 (Hiber); mobile phase, acetonitrile, flow 0.5 ml min^{-1}, detection wavelength 235 nm.

TLC equipment: variable thickness chromatofilm spreader, No. 20011 (Warner Chilott Laboratories, Instruments Division); Cypermethrin and deltamethrin, both analytical grade (99%) obtained from Institute of Organic Chemistry Warsaw, Poland; Cymbush (25 EC), cypermethrin formulation obtained from ICI (India) Ltd, Madras; Decis (2.8 EC), deltamethrin formulation obtained from Hoechst (India) Ltd, Bombay.

2.1. *o-Dinitrobenzene solution*

Prepared by dissolving 0.25 g of *o*-dinitrobenzene in 10 ml methyl cellosolve.

2.2. *p-Nitrobenzaldehyde solution*

Obtained by dissolving 0.30 g *p*-nitrobenzaldehyde in 10 ml methyl cellosolve.

2.3. *Preparation of laboratory prepared formulations*

Cypermethrin (25 EC) and deltamethrin (2.8 EC) were prepared by mixing 2.5 g of cypermethrin and 0.28 g of deltamethrin separately with 100 mg of Tween-80 and making upto 10 g with cyclohexanone.

Solvents acetone, chloroform, hexane, benzene, toluene, ethyl acetate, diethyl ether (all analytical grade), carbon tetrachloride (IR grade), acetonitrile (HPLC grade) were used.

Silica gel (G) for TLC (S.D. Fine Chemicals, Bombay).

Sodium hydroxide: 2N in methyl alcohol.

2.4. *Stock solutions*

Standard solution of cypermethrin and deltamethrin were separately prepared by dissolving 0.4 ± 0.01 g of sample in CCl_4 and volume made upto 10 ml and was further diluted to different concentrations.

2.5. Solution of cypermethrin formulation

Dissolve 0.8 ± 0.01 g sample of cypermethrin formulation (25 EC) in 10 ml of CCl_4 (~ 20 mg ml^{-1}) and dilutions were made accordingly.

2.6. Solution of deltamethrin formulation

Dissolve 7.14 ± 0.01 g sample of deltamethrin formulation (2.8 EC) in 10 ml of CCl_4 (25 mg ml^{-1}) and dilutions were made accordingly.

2.7. Preparation of TLC plate

Preparative TLC plates (200 × 200 mm) were prepared by coating with a slurry of silica gel G in distilled water (1 + 2) to a thickness of 0.75 mm. Plates were air dried for 1 h and activated by heating it at 110°C for about 1 h.

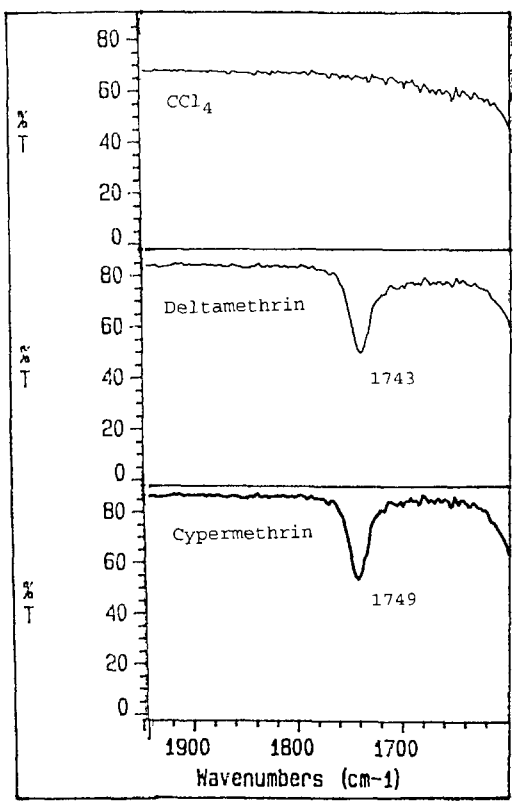

Fig. 1. FT-IR percentage transmittance of CCl_4, deltamethrin and cypermethrin in the ester carbonyl region.

2.8. Procedure

Standard solution of cypermethrin (20 mg ml^{-1}) in CCl_4 was spotted on the preparative TLC plate together with a marker spot (100 μg) of pure cypermethrin at the end of plate. Loaded plate was developed in a presaturated TLC chamber using hexane–acetone (4 + 1, v/v) as a solvent. After the solvent front had reached the distance of about 170 mm, the plate was removed from the chamber and dried in air. Developed plate was partially covered with another glass plate leaving the marker spot exposed. The marker spot was sprayed with NaOH solution (2N) followed by chromogenic reagent [5] consisting of *o*-dinitrobenzene and *p*-nitrobenzaldehyde which gave pink colour spot for the pyrethroids. The corresponding band of cypermethrin was scrapped off and eluted with chloroform. The solvent was evaporated in Kuderna Danish evaporator and diluted to 1 ml with CCl_4. The absorbance of the sample and the standard was measured against CCl_4 using base line technique.

Table 3
Recovery of cypermethrin and deltamethrin

Serial number	Added (mg)	Cypermethrin		Deltamethrin	
		Found (mg)	Recovery (%)	Found (mg)	Recovery (%)
1	20	18.75	93.75	17.82	89.12
2	20	18.91	94.55	18.16	90.82
3	20	19.24	96.20	17.87	89.33
4	20	19.14	95.70	18.08	90.41
5	20	19.17	95.85	18.41	92.03

In the present FT-IR method, the spectral resolution was 4 and 32 scans were recorded for each sample. The percentage of cypermethrin was calculated by the following formula [6]:

$$\% \text{ cypermethrin (by weight)} = \frac{A_f \times W_s}{A_s \times W_f} \times \% \text{ purity of standard}$$

where A_s and A_f are absorbances of standard and formulation respectively; W_s and W_f are weight in g per 100 ml of standard and formulation.

The same experimental procedure was repeated for the determination of % deltamethrin in its formulation. In the later case, hexane–diethyl ether (9 + 1, v/v) was used as a developing solvent for preparative TLC.

3. Results and discussion

The Rf value of cypermethrin and deltamethrin were recorded in different solvent systems (Table 1). For cypermethrin, hexane–acetone (9 + 1, v/v) with Rf 0.64 and for deltamethrin hexane–diethyl ether (9 + 1, v/v) with Rf 0.50 were found to be satisfactory solvent systems.

Scan of 20 mg cypermethrin and deltamethrin ml^{-1} in CCl_4 from 4000 to 400 cm^{-1} showed the presence of ester carbonyl band at 1749 and 1743 cm^{-1} respectively.

In the present study, the ester carbonyl band was selected for the quantitative determination of synthetic pyrethroids as this band is very strong and appears at transparent region of CCl_4 (Fig. 1). The base line of the absorption spectrum was established between 1770 and 1720 cm^{-1} in both the cases. The method is applicable to 1–40 mg of these synthetic pyrethroids in 1 ml of solution. Commercial cypermethrin (25 EC) and a laboratory prepared formulation (25 EC) were analysed with five determination of each sample (Table 2). Carbon tetrachloride from the samples was evaporated, residues were dissolved in acetonitrile and diluted to 200 ppm before analysing by reverse phase HPLC method. Similarly commercial deltamethrin (2.8 EC) and a laboratory prepared formulation (2.8 EC) were also analysed (Table 2).

The percentage recovery was checked by loading a known amount of analytical grade material (20 mg) on the preparative thin layer chromatographic plate and subjecting the plate to above described procedure. Recoveries in both the cases were in the range of 90 to 97% (Table 3) and by HPLC method, it was found to be 92–96%. The results of analysis of commercial and laboratory prepared formulation by FT-IR were compared with standard HPLC method (Table 2) and were found to be comparable. The method described for analysis of cypermethrin and deltamethrin emulsifiable concentrate formulations is simple, specific, rapid and precise.

An automatic photometric method with high precision by gradually diluting a sample

Aimin Tan *, Cailin Xiao

Department of Chemistry, Central South University of Technology, Changsha 410083, People's Republic of China

Received 3 January 1997; accepted 12 February 1997

Abstract

An automatic photometric method to increase the precision of measurement is proposed, which is based on the injection of a very small volume of sample by rotary valve and the subsequent homogeneous mixing in a small reaction cell made of glass of the sample with a color-developing reagent gradually delivered by a syringe piston pump until the absorbance of the mixture approaches 0.434, where the lowest relative error in the concentration locates. This photometric method is characteristic of uniformly high precision, low sample and reagent consumption, and high sampling rate of 30 samples per h. The other advantages of this method include easy calibration with only one standard solution and no strict requirements on photometric components. While applied for the determination of cobalt ranging from 0.21 to 1.43 g l^{-1}, the relative standard deviations are all below 0.4%. © 1997 Elsevier Science B.V.

1. Introduction

Absorption spectroscopy in the visible region is one of the most useful tools available to the chemist for quantitative analysis. Although it is mainly employed for the determination of the analytes with low concentrations, concentrated components may also be determined with one of the several precision spectrophotometric (differential spectrophotometric) methods [1].

Hiskey [2] proposed a precision spectrophotometric technique that involves comparing an unknown solution with a reference. The reference scale is set at zero using a solution of a highly colored (radiation-absorbing) species in place of a reagent blank. Concentrations of the unknown higher than the reference are then measured against this zero in the usual way. However, a standard solution with a higher concentration than the unknown may be used for the adjustment of 0% T, whereas the 100% T is adjusted as usual [1,3]. The latter method is less frequently used than the former, since the measured absorbance is not linearly related to the unknown's concentration, and repeated adjustments of 0 and 100% T are required.

PII S0039-9140(97)00061-1

Reilley and Crawford [3] described a precision spectrophotometric method that involves the use of two standard solutions to set the 0 and 100% T readings of the photometer. By this means, the full scale can be used for a concentration range much narrower than usual, and precision is thus, increased. This method generally requires two standard solutions and several other standard solutions of intermediate concentration to construct a calibration curve, since the measured absorbance is often not a linear function of concentration. For the improvement of this method, Du zhikun [4] and Guan zongjie [5] introduced a new method, which employs a counter micro-current in place of the higher standard solution in Reilley and Crawford's method for the extension of transmittance scale in 0% T direction, with the adjustment of 100% T maintained unchanged. Some instruments based on the above principle have been developed [6], and many applications have been reported [1].

Common to all the above methods, linear relation between absorbances and concentrations is required, and several standard solutions are usually necessary for the construction of a calibration line. Furthermore, stricter restrictions on both the differences among different cuvettes and the intensity of radiation sources are generally required. A method described by Ramaley and Enke [7] replaces the two-standard and calibration-curve procedure with only one standard and isomation. This method involves a titration in which the absorbance of the unknown determines the endpoint. A known amount of the solvent is placed in an absorption cell. A standard solution of the sample substance is then added to the cell until the absorbance, and hence the concentration, is identical to that of the unknown solution. To obtain the maximum accuracy, the cell lengths are calibrated. This method has some good characteristics, however it is limited in applications because of the elaborate procedure and no corresponding instruments available for its automation. In addition to this, since the concentration of a sample is unknown, its absorbance may be large or small dependent upon its concentration, which results in ununiform errors in determining the endpoint for titration.

In this paper, a similar but different approach is proposed, which employs the instrument components in flow injection analysis [8] for the automation of solution handling and the reduction of reagent and sample consumption. Moreover, the titration with standard is substituted by gradually diluting a sample with a color-developing reagent, just like the automatic micro-titration method proposed by us previously [9], until the absorbance of the product formed by the analyte with the reagent approaches 0.434, where the highest precision for concentration measurement is located. The concentration of the analyte is calculated from the volume of the reagent added and the concentration of a standard solution corresponding to an absorbance of 0.434. Neither the calibration procedure with a series of standard solutions nor linearity between absorbances and concentrations in a wide range is necessary.

2. Experimental

2.1. Reagents and solutions

Cobalt chloride solution, containing 100 g l^{-1} of cobalt. The other standard solutions with lower concentrations are prepared by dilution.

Nitroso R salt solution, 0.2%

Sodium acetate-acetic acid buffer at pH 5.7 is prepared by dissolving 100 g of $NaCH_3COO \cdot 3 H_2O$ in distilled water containing 13 ml of acetic acid (6 mol l^{-1}), and diluted to 500 ml.

Reagent solution for the determination of cobalt is prepared by mixing nitroso R salt, the buffer, and distilled water at a ratio of 1:1:8.

All the reagents except otherwise stated are of analytical grade.

3. Apparatus

The automatic dilution system depicted in Fig. 1 were constructed from the following components: a 16-port rotary valve (Zhaofa Automatic Analysis Research Institute, Shenyang, China), a self-designed variable-speed,linear flow piston pump, equipped with 3 disposable plastic syringes

of 10 ml (diameter 17 mm); a self-constructed reaction cell; a photometer; a magnetic stirrer (Model GSP-80-04, Taixian Radio Factory, Jiangsu, China), and an intel 8031 based single-chip microcomputer system for pump, valve and magnetic stirrer control, data acquisition and processing. The valve is driven by a stepper motor (Model 45BF3/3A, Shanghai Instrument Motor Factory, China) through two gears with a diameter ratio of 1:4.5. Through the control of the microcomputer, the valve can be turned to either load or inject position. The piston pump, also driven by two stepper motors, can be controlled to a precision of 2 μl. Since syringes need to be refilled, the pump's movements should be in accordance with the valve's position. The piston's forward wavement requires the valve in inject position, while backward wavement needs the valve in load position. Each measurement always begins with the piston's backward movement for filling the syringes, and ends with the piston's forward movement to deliver reagent. The reaction cell, made of glass, has a volume about 12 ml and a inner diameter of 18 mm. In its outside, above the mixing rod are mounted a photo-

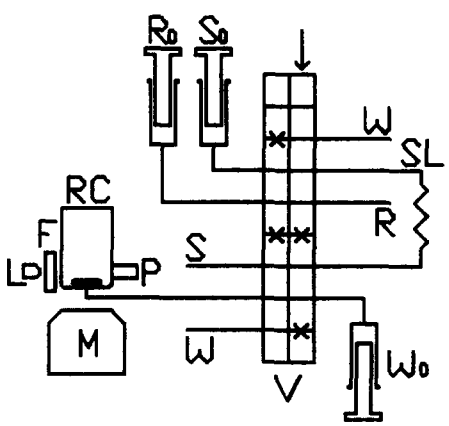

Fig. 1. The system configuration, R_0, S_0 and W_0 are the syringes for reagent (R), sample (S), and the drainage of the reaction cell (RC), respectively. V is the value, W is the waste. M is the magnetic stirrer. SL is the sample loop, L, F and P are the tungsten lamp, the filter, and the phototransistor, respectively.

transistor and a small tungsten lamp with a focusing head (6 V, 0.5 A). A light beam of 530 nm is selected from its irradiations by a filter for absorbance measurement, which falls onto the phototransistor after being absorbed by the solution in the reaction cell. The electric signal generated is then amplified and digitized by an A/D converter, AD574, whose output is sent to the microcomputer for further processing. The reaction cell together with the photometric components are put in a light-tight box to prevent the influence of ambient lights.

There are two distinct steps in the procedure, sample loading and reagent addition. During the first step, the valve turns to the load position, the syringes move backward, the reagent taken into the reagent syringe directly, while the sample flowing through the sample loop first and then to the sample syringe. The reaction cell is also drained by another syringe, which is driven by a separate stepper motor and should be operated a little bit longer than the reagent syringe to secure the complete drainage of the reaction cell. After sample loading step, the valve is turned to inject position, followed by the forward movement of the syringes. The reagent delivered by syringe R_0 propels the loaded sample into the reaction cell, where homogeneous mixing of the sample and the reagent is obtained magnetically. After 1 ml of reagent is added, the mixture in the reaction cell reaches the height of light beam, and the mixture's absorbance is then monitored quickly by the photometer. The absorbance will gradually decrease with the increased amount of reagent. Once the absorbance reaches 0.434, stop the addition of reagent and read out the volume of the reagent added.

All the absorbance measurements are made against the reagent blank, which is produced by the above procedure with distilled water in place of a sample.

A spectrophotometer (Model 721, Shanghai No. 3 analytical Instrument Factory, China) is also employed for absorbance measurements in some experiments.

4. Results and discussion

4.1. Calibration and dynamic range

Since both sample analysis and calibration are stopped at the same absorbance of 0.434, the analyte's concentrations in the reaction cell at endpoint are thus the same for all measurements if linearity between absorbance and concentration in the neighbourhood of 0.434 exists, i.e.,

$$V_oCs/(V_o + V_s) = V_oC_x/(V_o + V_x) \quad (1)$$

where V_o is the volume of the sample loop; C_o and C_x are the analyte's concentrations in the standard and sample solutions, respectively; V_o and V_x are the volumes of reagent delivered to obtain an absorbance of 0.434 in calibration and sample analysis.

To maintain the consistence of reagent concentration and pH for all measurements, both in calibration and sample analysis, the sample volume should be selected as small as possible while compared with the reagent volume, otherwise, some volume corrections should be made. In this experiments, a sample loop of 8 μl is constructed by the inner connection of the two corresponding ports on the rotary valve, whereas the reagent volume are above 1.5 ml. Therefore, the analyte's content in the sample may be readily determined by the following equation, without the necessity of constructing a calibration line with a series of standard solutions.

$$C_x = C_sV_x/V_s \quad (2)$$

Even though both the readout and the procedure are the same as a photometric titration, the principle is different because the reagent is not chemically equivalent to the analyte in this method.

Considering that the mixing rod will block light; a minimum of 1.5 ml reagent solution must be delivered before accurate absorbance measurement can be made. As the maximum reagent volume is 10 ml, the dynamic range in this method is from C_s $(1.5/V_s)$ to C_s $(10/V_s)$.

4.2. The carry-over effect

As the reaction cell and the tube connecting the reaction cell to the valve is drained, the carry-over effects in this method depend mainly on the volume of residual solution after drainage. To determine this volume approximately, a sample containing 100 g l^{-1} of cobalt is injected and diluted to 10 ml, the residual solution after drainage is then washed with distilled water and the resulting solution is transferred to a 25 ml calibrated flask. The cobalt content is determined by spectrophotometry with nitroso R salt [10], from which the volume of residual solution can be determined. The residual solution's volume, as the results of 11 measurements done this way determine, ranges from 0.01 to a maximum of 0.1 ml.

The relative error caused by the residual solution can be calculated by the following equation,

$$RE = (A1/A2 - 1)V_r/(V_r + V_x) \quad (3)$$

where V_r is the volume for the residual solution; A1 and A2 are the real absorbances at the endpoint for the two neighbouring samples. Because A1 and A2 are almost the same and V_x is at least 15 times larger than V_r, the carry-over effect will be negligible.

4.3. The precision

It is evident that the precision of this method is influenced by the dilution factor and endpoint determination. Since homogeneous mixing is achieved by magnetic stirring, the precision for dilution is dependent upon both the sample volume and the reagent added.

Since the sample loop's volume, albeit as small as a few μl, could be maintained as constant over a very long period, the precision is therefore only dependent on the volume of reagent added. To measure the precision for reagent delivery, the reaction cell is substituted by a small clean dry weighing bottle accurately weighted before use. After the addition of the required volume of reagent, the weighing bottle is weighted again, and the reagent added is calculated from the difference of the two weights. For the experiments done this way with increasing volumes of reagent

from 1 to 10 ml with 1.5 ml interval, the regression equation between the reagent volume (V, ml) and the steps (S) the motor takes is as following,

$$V = 1.9580 \times 10^{-3} S \quad (6)$$

whose regression coefficient is 0.99999. The linearity error in the whole range is below 0. 21%. The relative standard deviation for delivering a known volume of reagent is 0.033%, which is much better than the linearity is because of the small variations of inner diameter of the syringe, which, however, could be calibrated to increase the precision, if one wishes.

The precision for endpoint determination is related to absorbance measurement's precision near the absorbance of 0.434. Because samples are diluted differently to produce the same concentration, the result for a sample may be regarded as the product of its reagent volume by the analyte's concentration corresponding the absorbance of 0.434. In other words, the relative errors caused by endpoint determination for all samples should be identical to that in concentration measurement at the absorbance of 0.434, i.e., uniform precision is obtained for different samples. In this experiment, the precision for transmittance measurement is estimated as $\pm 0.1\%$, which corresponds to a relative error of 0.27% in the concentration measurement.

4.4. The influence of reagent concentration

In conventional photometric analysis, including precision spectrophotometric techniques, the reagent, particularly the chromogenic agent, should be in large excess so that the color development reactions go well to completion and linearity may be maintained. While in this method, lower chromogenic agent's concentration might be used and no evil influence on the determination will be produced so long as the linearity near the absorbance of 0.434 is maintained. As shown in Fig. 2, a steady state is recorded with lower reagent concentration, but the endpoint determination is not affected. However,if different product is formed with low reagent concentration, the reduction of reagent concentration should be avoided.

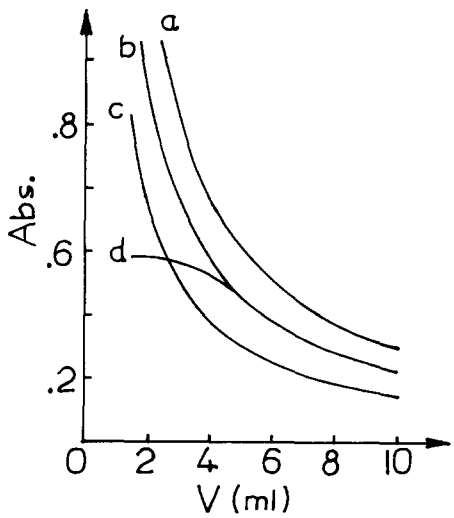

Fig. 2. Absorbance as the function of reagent volume. Curve a, b and c are recorded for the samples containing 1.0, 0.75 and 0.5 g l^{-1} of cobalt, respectively. Curve d is the same as curve c except for that the concentration of nitroso R salt is only one fifth of that in curve c.

4.5. The sampling frequency

A typical analysis cycle include sampling and reagent delivery. Among them, the sampling can be operated very quickly to increase sampling rate. the reagent delivery step is performed quickly at first, and then gradually slow down when the endpoint approaches in order to obtain better accuracy and enough reaction time. Since the flow rates could be easily adjusted with the microcomputer control, the above requirements might be readily met. In this method, 0.5 and 1.5 min are assigned for sampling and reagent delivery, respectively, with a sampling rate of 30 samples per h.

4.6. Sample analysis

Concentrated cobalt chloride in metallurgical samples in the production of cobalt are determined by this method, and the results obtained (Table 1) match well with those by complexometric titration method with EDTA. The relative standard deviations by this method is less than 0.4%.

Table 1
The results of sample analysis (g l^{-1})

Sample No.	EDTA method	This method					Average	RSD (%)
1	0.2531	0.2541	0.2533	0.2526	0.2540	0.2523	0.2533	0.32
2	0.4875	0.4885	0.4902	0.4888	0.4862	0.4858	0.4879	0.38
3	1.026	1.030	1.031	1.023	1.025	1.029	1.028	0.33
4	1.254	1.248	1.257	1.253	1.250	1.247	1.251	0.32

5. Conclusions

Uniformly high precision for photometric determinations is obtained by gradually diluting a sample with color-developing agent until the product formed by the analyte with the reagent produces an absorbance of 0.434, where the lowest relative error in concentration locates. To maintain the consistence of reagent concentrations in all measurements, the sample's volume should be much smaller than the volume of the reagent added. This new method is characteristic of high precision, easy calibration, low sample and reagent consumption, and no requirement for wide linear range. If higher precision and accuracy is required, precision spectrophotometry may be employed for more accurate determination of endpoint and the variations in syringe's diameter should be compensated.

Accurate values of stability constant of Ca^{2+}-murexide complex

Tapan Kumar Khan, Pinaki Gupta-Bhaya *

Department of Chemistry, Indian Institute of Technology, Kanpur 208016 (UP), India

Received 9 October 1996; received in revised form 12 February 1997; accepted 24 February 1997

Abstract

In published reports, the values of stability constants of 1:1 complex of Ca^{2+} and the dye ammonium purpurate (murexide) were not determined under controlled conditions and were not properly corrected for the binding of Ca^{2+} with ions of buffer used to maintain pH and that of the background electrolyte used to maintain ionic strength. We report the molar absorptivities (ε) of murexide at pH 7.0, 7.5, 8.0, as well as the differential molar absorptivities ($\Delta\varepsilon$). Using these, we calculate the stability constants of the Ca-murexide complex at pH 5.0, 6.0, 6.5, 7.0, 7.5 and 8.0 at 15, 25 and 35°C and 0.100 M ionic strength using KCl as background electrolyte. No buffer was used and the complication arising from buffer binding is thus avoided. These values are compared with those determined in the presence of buffers that bind metal ions negligibly (Tris at pH 7.5 and 8.0) or whose binding constant to Ca^{2+} is reported and therefore can be corrected for (acetate at pH 5.0, Bistris at pH 6.5). Agreement is obtained within errors of measurement. The reported values are not true stability constants but can be used to calculate the concentration of free Ca^{2+} ion in a metal–ligand mixture with high precision and accuracy. The effect of K^+ binding to murexide is considered and is found not to alter the calculated value of free calcium concentration in a mixture. © 1997 Elsevier Science B.V.

1. Introduction

Ammonium purpurate (murexide) has been extensively used as a colorimetric indicator of Ca^{2+} ion concentration in thermodynamic and kinetic studies of Ca^{+2} ion binding to macromolecular systems [1–6]. More recently, its rate of decomposition has been used as an indicator of proton activity in mixed solvents and microemulsions [7]. Other metallochromic indicators have also been used recently [8–14]. The dyes have different thermodynamic properties and spectral characteristics upon metal-complex formation. Each dye has its own advantages. Murexide is particularly suitable for the study of weak complex formation where a high metal concentration ($\approx 10^{-2}$ M) is needed to saturate the ligand. In our laboratory, we have found it useful for the study of Ca^{2+} ion binding to lipid vesicles in which mM concentration of free Ca^{2+} is needed in order to titrate to saturation. Other dyes used more recently, BAPTA and its brominated derivatives [12–14] and arsenazo III and antipyrylazo III [11], are less suitable for this purpose because they would saturate at the

PII S0039-9140(97)00078-7

Ca^{2+} concentration needed to obtain titration data over the whole range of ligand saturation. The need for precision and accuracy of K_{CaMu} is particularly important in those experiments where a small amount of bound Ca^{2+} ion is calculated as a difference of two comparable concentrations of Ca^{2+} ion, viz when the Ca^{2+}-ligand stability constant is small. The precision of reported data of K_{CaMu} determined under not very precisely controlled condition is however low, making the present study necessary. In earlier reports on the stability constant of the Ca^{2+}-murexide complex, a buffer was used to maintain pH but binding of buffer anions to Ca^{2+} was either not considered [15] or incorrectly taken into account [16]. The problems related to taking the buffer and the background electrolyte into account have been discussed in detail in a recent paper from our group on the stability constant of Eu^{3+}-murexide complex formation [17]. Shamsipur et al. [18] have reported values of the Ca^{2+}-murexide stability constant in non aqueous solvents. In this paper, we report the values of stability constant of Ca^{2+}-murexide complex at several values of temperature and pH. Different electrolytes (KCl, NaCl, $NaClO_4$) were used to maintain constant ionic strength in order to test if the chemical nature of background electrolyte influences the measured stability constant.

2. Experimental

2.1. Reagents

$CaCl_2$ was obtained from BDH. The purity of murexide (analytical grade, Koch-Light) was checked by C,H,N analysis. Ca^{2+} concentration was determined by weight titration against EDTA and the standardization error was about 0.5%. Other materials used were analytical grade. In all experiments, high precision was achieved by using mass to calculate the volumes of reagents dispensed, with careful adjustment to desired values by dispensing from calibrated μl pipettes with maximum error of ≈ 1 μl. The absorbance measurements were done in a Shimadzu Spectrophotometer calibrated using spectroscopic grade Cobaltammoniumsulphate solution (with absorbance at 470, 506 and 520 nm) as prescribed in the literature [19].

2.2. Buffer solutions and pH measurements

Buffer solutions of precisely known concentrations were prepared by weighing. Sodium acetate–acetic acid buffer was prepared by addition of acetic acid to sodium carbonate preheated to 230°C for 2 h.

2.3. ε values of murexide

Murexide solution was prepared in 0.100 M KCl with buffer (10.0 mM Tes ([*N*–tris (hydroxymethyl) methyl-2-aminoethane sulfonic acid] at pH 7.0; 10.0 mM Tris (Tris (hydroxymethyl) aminomethane) at pH 7.5 and 8.0). A weighed quantity of murexide was dissolved in 1000 ml of buffer and 0.100 M KCl. The absorbance was measured at 520 and 506 nm against the corresponding buffer blank. Two independent measurements agreed within $\approx 0.1\%$ (Table 1). The two reported pK_a values of proton dissociation for murexide are 9.2 and 10.5 at room temperature [15]. As expected, the ε of murexide reported here does not change in going from pH 7.0 to 8.0 and it is equal to its values at pH 5.0 and 6.5 within error [17]. At pH 8.0, $\approx 6\%$ of singly deprotonated murexide forms, but results in a negligible difference in ε.

[a] Average of six independent measurements. Concentration of murexide being saturated is in the range 3.0×10^{-5}–9.0×10^{-5} M. The $\Delta\varepsilon$ values are independent of the absolute value of the concentration of murexide.

2.4. Determination of $\Delta\varepsilon$:

An identical volume of murexide solution in buffer (8.840 mM sodium acetate–acetic acid at pH 5.0, 18.210 mM and 6.860 mM Bistris ([bis (2-hydroxyethyl) imino-tris (hydroxy-methyl) methane]) at pH 6.0 and 6.5, respectively, 18.320 mM Tes at pH 7.0 and 12.135 mM Tris at pH 7.5 and 5.752 mM Tris at pH 8.0) and KCl solution were added to sample and reference cuvette to achieve an ionic strength of 0.100 M. A precalculated volume of 0.1 M $CaCl_2$ solution was added to the sample cuvette till murexide is fully saturated by $CaCl_2$. The absorbance of the sample solution (ΔA) was measured at 473 nm (the maximum of the difference spectrum) and divided by the total murexide concentration (which is equal to the concentration of Ca-Mu complex) to give $\Delta\varepsilon$. The value was checked by adding another 100 μl $CaCl_2$ solution to the sample and buffer/KCl solution and to the reference cell and redetermining ΔA. The differential molar absorptivity of calcium–murexide complex at three different temperature and a range of pH are given in Table 2. The presence of ≈0.100 M KCl does not affect measured $\Delta\varepsilon$ significantly. The concentrations of free murexide, $[Mu]_f$, and hence the K^+-murexide complex (KMu), differs between the sample and reference cells; however, this has negligible effect on $\Delta\varepsilon$, because at 473 nm, KMu and Mu_f absorb nearly equally. We have checked that 473 nm is at the tail end of the difference spectrum of murexide in the presence and in the absence of 100 mM KCl (the difference is ≈2%). The maximum in the difference spectrum is at 518 nm, where the difference is 8% [17]. The presence of buffer does not alter $\Delta\varepsilon$, since the Ca^{2+}-buffer complex, the free Ca^{2+} ion and the Ca^{2+}-Cl^- complex absorb negligibly at 473 nm. Values of $\Delta\varepsilon$ determined in the absence of buffer differ from those reported in Table 2 negligibly. Schwarzenbach and Gysling [15] reported $\Delta\varepsilon$ at $\lambda = 480$ nm, pH 8.53 and room temperature in veronal buffer to be 1.13×10^4 which is close to that reported here, 1.033×10^4 at $\lambda = 473$ nm, pH 8.0 and 25°C. Some difference is expected because of a change in pH from 8.0 to 8.53, a shift towards the pK_a of 9.2. The difference is consistent with the trend of decrease of $\Delta\varepsilon$ with increasing pH observed in Table 2. The pH dependence of $\Delta\varepsilon$ even at those values of pH where ε of murexide is not pH dependent arises from the presence of pH dependent equilibria involving the Ca^{2+} complex of murexide.

2.5. Metal-murexide stability constant

The determination of stability constants of Ca^{2+}-murexide complex in the absence of buffer were carried out using a method described by Jain and Gupta-Bhaya [17]. Briefly, identical volumes of murexide solution were added to the two cuvettes followed by the addition of metal ion solution to the sample cell and identical volume of KCl solution to the reference cuvettes. The pH of the solution in the sample cell was adjusted by addition of dilute sodium hydroxide solution (pH ≈9.0), the approximate volume of base needed having already been estimated in a separate experiment. The solution was mixed and the final pH checked with a microelectrode inserted into the cuvette. The pH was almost always within 0.05 of

the pH of the murexide solution in the reference cuvette. If it was slightly outside this range, a small measured volume (1–2 μl) of base or acid was added by μl pipette to bring the pH closer to the desired value. The liquid lost when the microelectrode is removed after the pH measurement, does not alter the concentration. In spite of a small difference in pH (≈ 0.05) between the two cuvettes the reproducibility is not affected. The absorbance of the test solution in the sample cell (ΔA) was measured against the murexide reference solution at the desired temperature at 473 nm.

Using

$$\Delta A = \Delta\varepsilon[\mathrm{CaMu}] \quad \text{(unit path length)} \tag{1}$$

$$[\mathrm{Mu}]_f = [\mathrm{Mu}]_t - [\mathrm{CaMu}] \quad \text{(t denotes total)} \tag{2}$$

$$[\mathrm{Ca}]_f = [\mathrm{CaMu}]/K_{\mathrm{CaMu}}[\mathrm{Mu}]_f \tag{3}$$

we calculate K_{CaMu} determined in the absence of buffer. The values at pH 5.0, 6.0, 6.5, 7.0, 7.5 and temperature 15, 25, 35°C are given in Table 3.

The determination of K_{CaMu} in the presence of buffers (5.752 mM Tris at pH 8.0, 12.135 mM Tris at pH 7.5, 18.210 mM Tes at pH 7.0, 6.860 mM Bistris at pH 6.5, and 8.840 mM Sodium acetate–acetic acid buffer at pH 5.0) whose binding to Ca^{2+} are weak and/or well characterized is done using essentially the same method, except that no adjustment of pH in the cells is necessary. Also, the sample murexide solution and the blank solution are buffered and as metal ion in buffer is added to the sample cell, buffer solution is added to the blank. The values of K_{CaMu} so determined have been corrected for metal–buffer binding (in cases where values of $K_{\mathrm{metal-buffer}}$ are known) as described later in this paper. The corrected values are given in Table 3.

Table 3
Stability constants K of Ca^{2+}-murexide association equilibria

pH	Temperature (°C)	$\log K \pm \sigma$ (buffer free expt.)	$\log K_{\mathrm{corr}}$
5.0	15	$2.454_1 \pm 0.008_4$	2.446 ± 0.011
	25	2.384 ± 0.011	2.361 ± 0.013
	35	$2.300_7 \pm 0.008_3$	2.176 ± 0.011
6.0	15	$2.521_7 \pm 0.004_4$	
	25	2.452 ± 0.012	
	35	2.371 ± 0.011	
6.5	15	2.642 ± 0.011	
	25	2.615 ± 0.011	2.601 ± 0.013
	35	2.534 ± 0.013	
7.0	15	$2.680_0 \pm 0.008_6$	
	25	$2.637_3 \pm 0.006_2$	
	35	2.590 ± 0.011	
7.5	15	2.732 ± 0.011	2.729 ± 0.011
	25	$2.666_6 \pm 0.004_3$	2.665 ± 0.002
	35	2.643 ± 0.010	2.643 ± 0.013
8.0	15		2.955 ± 0.013
	25		2.848 ± 0.011
	35		2.722 ± 0.013

All measurements are at $\mu = 0.100$ M.

2.6. Instability of murexide

Murexide in KCl solution, in the presence and in the absence of buffer decomposes very slowly. The deterioration is significantly more rapid at lower pH (5.0 compared with 6.5). At pH 5.0, in the absence of buffer and in the presence of acetate buffer $\approx 3\%$ of murexide decomposes in 1 h at 35°C. This value is $\approx 1\%$ at pH 6.5 in the absence of buffer. At pH > 5.0 in the presence of Bistris, Tes and Tris buffer used in this work, the decomposition is $\approx 2\%$ or less in 1 h at 35°C. These rates are significantly lower at 25 and 15°C. Our results are not significantly affected by this process, because we store freshly prepared murexide in ice bath and make spectral measurements on aliquots taken therefrom. Also, measurement times for both K and $\Delta\varepsilon$ are sufficiently short so that the results are not significantly affected by decomposition of murexide. However, this process of decomposition contributes to the error of measurement, particularly at lower pH (e.g., 5.0) and higher temperature (e.g., 35°C).

3. Results and discussion

3.1. Comparison with published values

The value of $\log K_{\mathrm{CaMu}}$ reported by Schwarzenbach and Gysling [15] at a pH 4.65 (0.1 M $CaCl_2$, unspecified temperature and 0.1 M acetate buffer) is 2.6. This differs from the value (2.367) reported

in this paper at 25°C, pH 5.0. But the value reported by them at pH 7.85 (in veronal buffer) is 2.8 and at pH 8.15 (same buffer) is 2.9 and these values are very close to that reported in this paper at pH 8.0 (Tris buffer, 25°C, 0.1 M KCl, $\log K =$ 2.848). Other values of K_{CaMu} reported by Schwarzenbach and Gysling [15] are in the higher pH range which we have not studied. The values reported by Balaji et al. [16] deviate appreciably from the values given above because the higher concentration of acetate and phosphate buffer used in these studies led to considerable metal–buffer binding, whose effect is not properly corrected for [17]. Schwarzenbach and Gysling [15] have not used KCl in the experiments for maintaining the ionic strength and the values are reported at unspecified temperature.

3.2. Estimate of precision

The maximum error of the volume measurements made by weighing was 5×10^{-5} ml (maximum weighing error 0.05 mg) and is negligible. The error in absorbance measurement was estimated from the fluctuation in the absorbance reading and the standard deviation (σ) is 0.3%. The calcium concentration has a σ of $\approx 0.5\%$, which is largely due to the end-point error. The EDTA concentration has a maximum error of $\approx 0.5\%$, arising from the purity of the EDTA used, weighing error and the error in making up the solution to standard volume. This error does not affect the precision since only one EDTA solution was made. The error in measuring the molar absorptivity depends on the absorbance value ($\sigma \approx 0.3\%$); error in murexide concentration (weighing error $\approx 0.2\%$ and dilution error $\approx$ 0.04%) is $\approx 0.3\%$, equivalent to a relative standard deviation of $\approx 0.1\%$. Using these values, we calculate the precision of K_{CaMu} by use of standard formulae [20] and find that the calculated values of σ are of the same order as the observed values given in Table 3. The experimentally observed σ is only slightly larger. The observed σ is expected to be slightly higher than that calculated, because error in calibration of the spectrophotometer and that due to slow decomposition of murexide (Section 2) are ignored in the calculation. From this analysis we conclude that the adjustment of pH done inside the cuvette does not lead to any additional error. This conclusion is further supported by the agreement between the values of K_{CaMu} determined in the presence and in the absence of buffer at pH 5.0, 6.5, 7.5. The buffers used at pH 5.0 (sodium acetate–acetic acid) and pH 6.5 (Bistris) bind Ca^{2+} significantly. K_{CaMU} determined in the presence of these two buffers when corrected (see below) gives good agreement with K_{CaMu} determined in the absence of buffer. The relative errors of K_{CaMu} values are comparable to those of K_{EuMu} values reported from our laboratory[17].The mean values of K_{EuMu} are orders of magnitude larger.

The data in Table 3 and Table 4 are quoted to one decimal place beyond the last significant digit to avoid the possibility of truncation errors on calculated $[Ca]_f^{2+}$. The precision of calculated $[Ca]_f^{2+}$ is only slightly less than that of K_{CaMu} reported here. The $\log K$ values in Table 3 are quoted to three places of decimal, but wherever the σ of $\log K$ is in the third decimal place, the fourth decimal place of both $\log K$ and σ are written as a subscript.

3.3. Correction of stability constants due to metal–buffer binding

Balaji et al. [16] pointed out that the stability constants determined in the presence of buffer should be corrected for metal–buffer binding. The corrected values (K_{corr}) can be obtained from the conditional values K_{app} calculated by ignoring metal binding by buffer using the relation,

$$K_{corr} = K_{app}(1 + \sum_i K_{MB}[B]^i) = K_{app}\gamma$$

where $\gamma = 1 + \Sigma_i K_{MB_i}[B]^i$ (B is the species that bind the metal ion in a 1:1 complex).

Using the relations:

$[B]_t = [B] + [BH] + [MB]$ and $[MB] = K_{MB}[M]_f[B]$,

(B: acetate ion, neutral Tes, Tris, Bistris; each can bind a proton; BH: protonated B, $[B]_t$: total concentration of buffer in both forms; MB: 1:1 metal-buffer complex, ($i = 1$); K_{BH} and K_{MB} are association constants of B and H^+, Ca^{2+} and B, respectively) one obtains $\gamma = 1 + K_{MB}[B]$, where

Table 4
Typical data to show correction of K due to binding of Ca^{2+} ion to buffer, (ionic strength = 0.100 M)

$[B]_t(\times 10^3)$	$[B](\times 10^3)$	$\gamma(=1+K_{MB}[B])$	K_{app}	K_{corr}	$K_{corr} \pm \sigma$	$K \pm \sigma$(buffer free expt.)
Bistris buffer of pH 6.5 at 25°C						
6.3597	2.819	1.502	271.5	407.8		
6.0552	2.613	1.465	263.7	386.3	398.9 ± 8.6	411.8 ± 9.5
5.7922	2.430	1.432	277.6	397.5		
5.5625	2.280	1.405	282.5	396.9		
5.4118	2.177	1.387	292.7	406.0		
Acetate buffer of pH 5.0 at 25°C						
8.840	7.085	1.027	221.2	227.2		
8.349	6.689	1.025	222.5	228.1	229.4 ± 2.8	242.1 ± 8.1
7.859	6.290	1.024	223.4	228.8		
7.009	5.603	1.021	228.6	233.4		

Ca^{2+}-Bistris: log $K = 2.25$ (25°C, $\mu = 0.1$); Bistris-H^+: log $K = 6.56$ (25°C, $\mu = 0.1$)[21].
Ca^{2+}-Acetate: log $K = 1.24$ (25°C, $\mu = 0$), $\Delta H° = 0.91$ K Cal per mol[22].
Corrected values used in our calculation: K_c at $\mu = 0.100$ and 15, 25 and 35°C: 3.288, 3.759, 4.253, respectively. The value 3.759 agrees very well with log $K = 0.57$ reported in the literature under identical conditions ($\mu = 0.1$)[23].
Acetate-H^+: log $K = 4.55$ (20°C, $\mu = 0.1$) log $K = 4.64$ (25°C, $\mu = 0.2$)[22].
Corrected values used in our calculation: log K_c at $\mu = 0.100$ and 15, 25, 35°C: 4.442, 4.389, 4.102, respectively.

$$[B] = \frac{[B]_t}{1 + K_{BH}[H^+] + K_{MB}[MMu]/K_{MMu}[Mu]_f}$$

The values of K_{corr} so obtained are given in Table 3. The experimental values of K_{app} are found in each case, as expected, to be less than K determined in absence of buffer. Agreement between calculated values of K_{corr} (in those cases, where γ could be calculated) and K of buffer free experiments is good.

Table 4 gives examples of calculation of K_{corr} from K_{app} using actual experimental data at pH 6.5 and 5.0 in the presence of Bistris and acetate buffer, respectively. The values of K_{BH}, K_{MB} are obtained from the literature [21,22] and corrected to our experimental conditions wherever necessary. The corrected value of Ca^{2+}-acetate stability constant at 25°C agrees very well with the experimentally determined value reported in the literature [23] under identical conditions. This agreement verifies the validity of the corrected values. The details are given in Table 4. We could calculate K_{corr} for Bistris only at 25°C, because K_{MB} and K_{BH} are reported only at this temperature. The agreement of the values of K determined in the absence of buffer and K_{corr} is good. For Bistris, the two agree within error. Log K of Ca^{2+}–Tris association is ≤ 0.7 [21]. Using this, we obtain, γ at pH 7.5 and 8.0 to be ≈ 1.0. In agreement with this, K determined in the absence of buffer and that in its presence at pH 7.5 are equal within error of measurement. K of Ca^{2+}-Tes association is not reported. Therefore, the agreement between K_{corr} and K determined in buffer-free experiments could not be verified at pH 7.0; it is however observed, as expected, that K_{app} is less than K determined in buffer free experiments. An estimate of binding constant of Ca^{2+} and Tes (deprotonated neutral form) can be made from the values of K_{CaMu} determined in the presence and in the absence of buffer and is found to be ≈ 18 at 25°C, a reasonable value. The corresponding quantity for Eu^{3+}, determined using murexide as an indicator of free Eu^{3+} concentration is ≈ 110, which is consistent with that for Ca^{2+}-Tes system.

3.4. Effect of binding of potassium by murexide

Potassium chloride of 0.100 M concentration was used to maintain ionic strength constant. Though the affinity of murexide for potassium is less than that for Ca^{2+}, it cannot be ignored. The difference $[Mu]_t - [MMu] = [Mu]'_f$ is not the true value of free murexide $[MU]'_f$, but is related to it

by $[Mu]_f = [Mu]_f + [KMu]$. $[KMu]$ is given by $K_{KMu}[K^+]_f[Mu]_f$. Since $[K^+] \approx 10^4[Mu]$, $[K^+]_f \approx [K^+]_t$ and $[Mu]_f = [Mu]_f'/\alpha_{Mu(K^+)}$, where $\alpha_{Mu(K^+)} = 1 + K_{KMu}[K^+]_t$. Thus, K_{CaMu} calculated by ignoring the presence of KMu is $\alpha_{M(K^+)}$ times that corrected for its presence. In the absence of published values of K_{KMu}, it is not possible to calculate $\alpha_{Mu(K^+)}$. The corrected value of K_{CaMu} therefore cannot be calculated. We now show that in spite of this, the calculated values of $[M]_f$ in a mixture ($[M]_f = [MMu]/K_{CaMu}[Mu]_f$) using the values of K_{CaMu} reported in this paper are correct. Even though K_{CaMu} and $[Mu]_f$ both acquire a correction factor because of the presence of KCl, their product remains unchanged. In addition, the relation $\Delta A = \Delta\varepsilon[MMu]$ holds even when KCl is present. The expression of $\Delta\varepsilon$ however is $\varepsilon_{CaMu} - \{\varepsilon_{KMu}/\alpha + \varepsilon_{KMu}(1 - 1/\alpha)\}$. The quantity $[Mu]_f' = [Mu]$-$[MMu]$ is now partitioned into true $[Mu]_f$ and $[KMu]$. The relative proportion is $(1/\alpha)/(1 - 1/\alpha)$, where α is a constant for a given total concentration of KCl. Thus [MMu] calculated as $\Delta A/\Delta\varepsilon$ in the presence of KCl as background electrolyte is correct.

3.5. Effect of replacing K^+ by Na^+

The buffers contribute Na^+ ions to different extents which replace K^+ ions of the background electrolyte. In order to verify, that this replacement does not alter the results, we have conducted experiments with NaCl and $NaClO_4$ in place of KCl as background electrolyte and find that within errors of measurements the results indeed do not change.

3.6. Nature of the stability constants

The values of K_{CaMu} reported in this paper are conditional constants, because: (a) they are not corrected for the presence of KMu; and (b) the concentrations $[Mu]_f$ and [MMu] are sums of concentrations of different ionised forms of $[Mu]_f$ and their metal complex.

3.7. Need for precise values of K_{CaMu}:

At 25°C, pH 8.0, $\mu = 0.100$ we report $\log K = 2.848$, in contrast to its value reported in [15], namely $\log K = 2.8$ at an unspecified room temperature and pH 7.85. The need for this additional precision is clear from the following example based on experiments performed in our laboratory. The mean value of Ca^{2+} concentration bound to a suspension of lipid vesicles (cardiolipin, lipid concentration = 0.748 mM, concentration of vesicle spheres = 2.0×10^{12} vesicles ml^{-1} solution, total Ca^{2+} ion concentration = 2.2 mM) calculated by using K reported here and that reported in [15] differ by 11%. At lower pH, the difference is larger. We report $\log K = 2.367$ at 25°C, pH = 5.0, $\mu = 0.100$ whereas Schwarzenbach and Gysling [15] report $\log K = 2.6$ at pH = 4.65 and at an unspecified room temperature. The difference between the two calculated mean Ca^{2+} concentration in the same experiment is 72%.

3.8. Potential use of K_{CaMu}:

In addition to their purely analytical use for detection of metal ions, the stability constants of metal-dyestuff complexes are useful for the determination of stability constants and rate constants of metal-ligand systems. In our laboratory we are studying calcium ion induced fusion of phospholipid vesicles. The threshold concentration needed for fusion of vesicle is ≈ 10 mM [24]. For 90% saturation of the metallochromic indicators murexide, ArsenazoIII, AntipyrylazoIII, Quin2 and 5,5′-Br_2BAPTA, the concentration of Ca^{2+} needed are 20.746, 2.1375, 0.3375, 7.5×10^{-4} and 1.43×10^{-2} mM, respectively. So, murexide turns out to be the only choice for the measurement of free Ca^{2+} ion concentration in experiments on calcium ion induced fusion of phospholipid vesicles.

In contrast to Ca^{2+} sensitive electrodes [25], the spectrophotometric method using murexide is free from interference from K^+, Na^+, Tris, Mg^{2+}, chemicals of common occurrence in biochemical experiments. At low pH (< 4), murexide is unstable and the electrode also gives error.

Received 16 September 1996; received in revised form 12 February 1997; accepted 24 February 1997

Abstract

Plutonium from acidic waste solutions has been recovered quantitatively using tri-*n*-octylamine (TnOA) in xylene and americium using a mixture of octylphenyl-*N*-*N*- diisobutylcarbamoylmethylphosphine oxide (CMPO) and TBP in dodecane by extraction and extraction chromatographic methods. The Pu(IV)/TnOA species extracted into the organic phase from higher nitric acid concentrations has been confirmed as $(R_3NH)_2Pu(NO_3)_6$ (where R_3N = TnOA) by employing slope analysis as well as spectrophotometric studies. © 1997 Elsevier Science B.V.

1. Introduction

During the processing of plutonium, several types of acidic liquid wastes are generated through different routes, of which two main routes are (i) anion exchange waste and (ii) Whatman No.1 paper wipings ignited and dissolved in nitric acid. The first one contains Pu and Am in the ranges of 10–40 and 0.2–0.5 mg l^{-1} respectively in 7.5 M nitric acid. In the second stream Pu and Am could be in the ranges of 300–600 and 0.2–0.3 mg l^{-1} respectively in nitric acid concentrations varying between 6 and 12 M. The objective of the present study was to develop a procedure for the recovery of Pu and Am from such highly acidic laboratory waste solutions and to understand the nature of Pu species extracted into the TnOA phase.

Amines are reported to be one of the highly selective extractants for the recovery of actinides [1–6]. Among the various amines, TnOA is reported to extract Pu(IV) from 1–12 M nitric acid [6]. CMPO is a versatile reagent for the extraction of tri-, tetra- and hexavalent actinides and trivalent lanthanides from acidic solutions [7–17]. In an earlier publication by Mathur et al. [17] it was

* Corresponding author.

PII S0039-9140(97)00079-9

shown that three contacts with a mixture of 0.2 M CMPO and 1.2 M TBP in dodecane could extract ~98% of Pu and Am from 7.5 M HNO_3. While stripping, the combined stripped Am fractions contained ~26% Pu. In order to separate Pu and Am in radiochemically pure form from such acidic waste solutions without recourse to any feed adjustments, it was decided to utilize a two step solvent extraction procedure comprising of extraction of Pu(IV) with TnOA–xylene followed by extraction of Am by a mixture of CMPO + TBP.

The extraction chromatographic technique has been utilized for the recovery of actinides and lanthanindes [18–21] and also column separations are easily amenable for purification of nuclides at very high α, β or γ doses. It was, therefore, thought worthwhile to use TnOA adsorbed on chromosorb-102 (TnOAC) and CMPO adsorbed on chromosorb-102 (CAC) for the recovery of Pu and Am respectively in a pure form.

2. Experimental

TnOA supplied by K&K Labs, USA, was used as such. CMPO, solvent extraction grade was synthesised and purified in this lab [14].

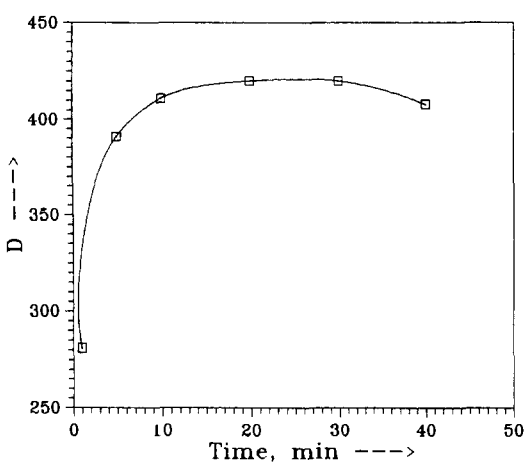

Fig. 1. Extraction of Pu(IV) with 20% TnOA–xylene at different time intervals.

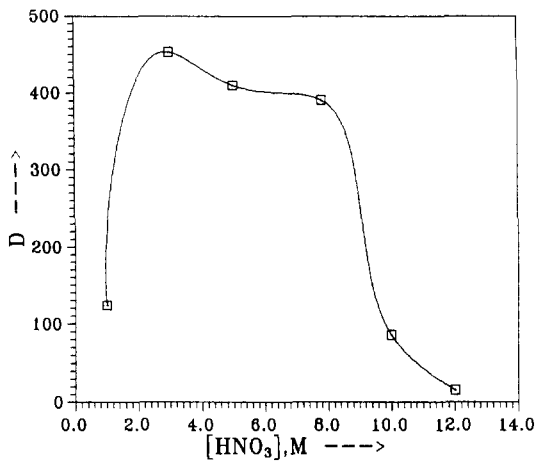

Fig. 2. Extraction of Pu(IV) with 20% TnOA–xylene at various acidities; [Pu] = 33.4 mg l^{-1}.

Chromosorb-102 (100–120 mesh size, styrene-divinylbenzene polymer) was obtained from Johns Manville, USA. Xylene was obtained from BDH, India, and dodecane was obtained from Transware Chemica Handelsgeselschaft, Hamburg, Germany. All other chemicals used were of Analytical Reagent grade. TnOAC and CAC were prepared by contacting the three phase system of TnOA or CMPO, chromosorb-102 (1:1, w/w) with methyl alcohol–water (50:50) for 12 h as reported elsewhere [21]. Throughout this work Pu nitrate solution was conditioned with sodium nitrite and ammonium *meta* vanadate to maintain it in the tetravalent state except for the actual samples where only sodium nitrite was used.

2.1. Procedures employed in solvent extraction

Extraction studies were carried out between 0.5 and 15 min to establish the time period required for attaining the equilibrium. All the solutions were subsequently equilibrated for 15 min in all the extraction studies.

Extraction of Pu(IV) into 20% TnOA–xylene was done at various acidities keeping the Pu concentration fixed and also at varying Pu concentrations at 7.5 M HNO_3. 0.5 ml Pu solutions were contacted with 0.5 ml TnOA solution at 25 ± 0.1°C. Also the Pu solution was contacted with 20% TnOA–xylene in various organic to aqueous phase ratios (1:1–1:10). After settling the phases were centrifuged and samples taken for radioassay by using a liquid scintillation counter.

To ascertain the nature of the species extracted in the TnOA phase, experiments were done by varying the TnOA concentrations while keeping the HNO_3 and Pu concentrations constant.

Pu(IV) spectra were recorded in 3.0, 7.5 and 12 M HNO_3 solutions and also those of the solutions extracted into 20% TnOA–xylene from such acidic solutions.

Total Pu in organic phase: 33.4 mg l^{-1}.

In extraction studies with Am solution, 0.5 ml Am solutions of varying concentrations, were extracted by contacting with 0.5 ml 0.2 M CMPO + 1.2 M TBP in dodecane for 15 min at 25 ± 0.1°C. The phases were centrifuged, separated and assayed for Am by γ counting using a NaI (Tl) detector.

Five ml of the actual laboratory waste solution containing 541 mg l^{-1} Pu and 0.3 mg l^{-1} Am in 7.5 M HNO_3 was first contacted with 20% TnOA–xylene at a 1:1 ratio. The organic phase was removed and the raffinate was contacted once again with 1.5 ml of 20% TnOA–xylene. The raffinate thus obtained contained only Am and was contacted twice with 5 ml portions of 0.2 M CMPO + 1.6 M TBP in dodecane.

In the Pu stripping experiments, 5 ml each of the loaded organic phase was contacted separately with equal volumes of 0.5 M HNO_3, 0.5 M acetic

D	6543.3	4080	2292.3	1707.4	1394.9

acid or 0.2 M ascorbic acid in 0.3 M HNO_3 for 15 min. While in the case of Am, 5 ml of the extracted CMPO phase was contacted with equal volume of 0.008 M nitric acid for 15 min.

2.2. Procedures employed in extraction chromatography

In the extraction chromatographic experiments 5 mg of TnOAC–CAC was equilibrated with 1 ml Pu–Am solutions at different acidities and also varying concentrations of Pu–Am at 7.5 M HNO_3. After centrifuging, aliquots were taken for radioassay. The D values in the batch experiments were evaluated as:

$$D = \frac{A_i - A_f}{A_f} \times \frac{V}{M}$$

where A_i and A_f are the initial and final activities of the solutions, V and M are solution volume and weight of TnOAC or CAC.

In a separate experiment 100 mg TnOAC was taken in a column (4 mm × 450 mm) and the actual waste solution containing 541 mg l^{-1} Pu and 0.28 mg l^{-1} Am was passed through it at a rate of ~2 ml h^{-1}. Periodic assay of the effluent was done for Pu and Am. 10.0 ml Of the solution was passed. The raffinate which did not contain any Pu was passed through another column (4 mm × 450 mm) containing 425 mg of CAC at a rate of ~2 ml h^{-1}. The effluent was periodically analysed for the presence of Am.

TnOAC column loaded with Pu was eluted at the rate of ~2 ml h^{-1} with freshly prepared 0.2 M ascorbic acid solution. The CAC column loaded with Am was eluted at the rate of ~2 ml h^{-1} with 0.008 M nitric acid. The purity of the products (Pu and Am) was checked by α and γ spectrometry. Other cationic impurities were analysed by ICP-AES.

3. Results and discussions

3.1. Extraction and stripping of Pu

Fig. 1 gives the distrbution ratios (D) for Pu (33.4 mg l^{-1}) in 7.5 M HNO_3, equilibrated with 20% TnOA–xylene at various intervals of time. The D values were calculated as:

$$D = \frac{[\text{Pu}] \text{ in organic phase}}{[\text{Pu}] \text{ in aqueous phase}}$$

Even after 1 min the D value was very high but the equilibrium was attained in about 10 min. Fig. 2 gives the plot of D of Pu at varying concentrations of HNO_3. The D increases to 3 M, then it decreases slowly to 7.5 M and then sharply at higher concentrations. It could be explained on the basis that at 3 M HNO_3 the less extractable or inextractable species like $HPu(NO_3)_6^-$ and $H_2Pu(NO_3)_6$ are not formed which results to the maximum D value. The lower D value at 1 M HNO_3 is due to the less availability of nitrate ions for the formation of even the neutral species $Pu(NO_3)_4$, whereas the decrease in the D values between 7.5 and 12 M is due to the formation of species like $HPu(NO_3)_6^-$ and $H_2Pu(NO_3)_6$.

The D values of Pu (Table 1) at its varying concentrations in 7.5 M nitric acid, were almost

Table 7

A. Uptake of Am on CAC, varying HNO_3 concentrations ([Am] = 0.54 mg l^{-1})

$[HNO_3]$ (M)	1.0	3.0	5.0	7.5	10.0
D	1506.9	1786.3	1746.1	1167.2	899.7

B. Uptake of Am on CAC, varying Am concentrations ($[HNO_3]$ = 7.5 M)

[Am] (mg l^{-1})	0.109	0.217	0.326	0.435	0.652
D	941.1	1051.9	999.7	1124.6	1296.0

constant and high indicating nearly 99.8% extraction of Pu under these conditions. Table 2 gives the data for loading of Pu (in 7.5 M HNO_3) in 20% TnOA–xylene at various organic to aqueous phase ratios (1:1–1:10). Very high extraction ($\sim$ 99.7%) even at the ratio of 1:10 was achieved. These results suggest that at such Pu concentrations TnOA does not get loaded to any significant extent such that the percentage extraction may get decreased.

Table 3 gives the D values of Pu with varying concentration of TnOA (5–20%), keeping Pu concentration at 33.4 mg l^{-1}. It can be seen that the D value increased with increasing concentration of TnOA but even at 5% TnOA, the extraction of Pu is $\sim$ 98%. Thus, for near complete recovery of Pu from such solutions of about 10% TnOA–xylene could ideally be used.

It can be seen from Table 4 that while stripping with 0.5 M HNO_3 even after five contacts only about 46% Pu could be stripped. This is understandable since the D values of Pu even at low HNO_3 concentration of 1 M is found to be about 100. With acetic acid in three contacts almost the entire Pu comes to the aqueous phase. Ascorbic acid was found to be the best stripping agent since 99.9% Pu gets stripped just in one contact. Ascorbic acid stripping has an added advantage since Pu gets reduced to the trivalent state during this process which is the ideal valency state for its precipitation as oxalate [22].

3.2. Extraction and stripping of Am

It has been reported that the D values of Am in 0.2 M CMPO + 1.2 M TBP in dodecane increase with increasing acidity to about 2 M and then it remains almost constant ($\sim$ 25) to 6 M HNO_3 [14]. However, at 7.5 M HNO_3, the D decreases to about 10 [17]. In the present study, the D values for Am in 7.5 M HNO_3 was determined at varying Am concentration (0.1–0.6 mg l^{-1}). It can be seen from Table 5 that the D value remains almost constant at all the concentrations of Am studied. The stripping of Am was done with 0.008 M HNO_3 and in three contacts the recovery was quantitative. This is in accordance with the very low D value of Am of nearly 0.01 at such low acidities ($\sim$ 0.01 M) [7,8,14].

3.3. Extraction and stripping of Pu and Am from actual laboratory waste solution

When the actual waste solution (Pu, 541 mg l^{-1} and Am, 0.3 mg l^{-1}) was contacted with 20% TnOA–xylene, $\sim$ 99.8% Pu was extracted into the organic phase in the first contact. A second contact with a small volume of TnOA–xylene was given to ensure complete removal of Pu. The raffinate was subsequently contacted with 0.2 M CMPO + 1.2 M TBP in dodecane which showed the formation of a third phase. However, when the TBP concentration was raised to 1.6 M, keeping the CMPO concentration at 0.2 M, no third phase formation was noticed. The TnOA raffinate was contacted twice with equal volumes of 0.2 M CMPO + 1.6 M TBP in dodecane and the loaded CMPO phase was collected together.

Stripping Pu from the TnOA phase was done with an equal volume of 0.2 M ascorbic acid in 0.3 M HNO_3. Two contacts with the strippant gave nearly complete recovery of Pu (99.99%).

Table 8
Purity of Pu and Am product—spectroscopic result

Element	Detection limit (μg ml^{-1})	Feed (μg ml^{-1})	Pu product (μg ml^{-1})	Am product (μg ml^{-1})	Last effluent (μg ml^{-1})

Zn	<0.02	750	40.0	19.00	685.0

Combined CMPO phase was given three contacts with equal volumes of 0.008 M HNO_3. Am recovered in the aqeous phase was 99.9%.

4. Extraction chromatographic studies

4.1. Uptake of Pu on TnOAC

Table 6a gives the D values for the uptake of Pu at various acidities between 1 and 12 M HNO_3. The D values are high and they increases to about 5 M HNO_3 and then start decreasing.

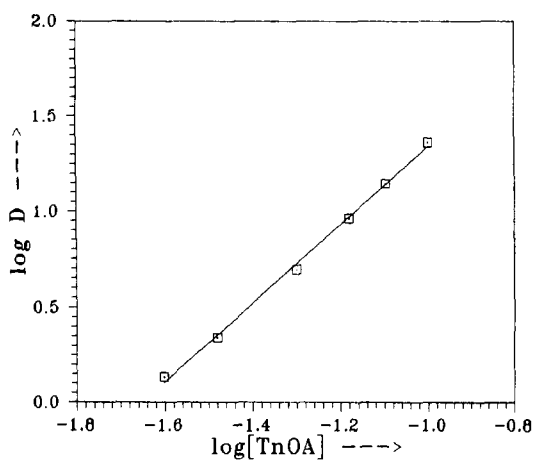

Fig. 3. Plot of log D vs. log[TnOA] for Pu(IV) at 7.5 M HNO_3.

Experiments were also carried out for the uptake of Pu in the range 30–150 mg l^{-1} in 7.5 M HNO_3 on TnOAC and it was found that the D value decreases with increasing Pu concentration (Table 6b).

4.2. Uptake of Am on CAC

Uptake of Am at various acidities by CAC (Table 7a) showed a gradual increase in D value to 3 M, remained almost same at 5 M and then it decreased at higher acidities. Also, experiments were carried out at varying concentrations of Am in the range 0.1–0.6 mg l^{-1} at 7.5 M HNO_3. The D value (Table 7b) at all the Am concentrations was found to be almost constant.

4.3. Column loading and elution

Ten ml of the actual waste solution was passed through the TnOAC column with a breakthrough of 0.009 mg l^{-1}. Thus 5.4 mg Pu was loaded on the TnOAC column. This could be quantitatively eluted in 10 ml 0.2 M ascorbic acid. 9.5 ml Of the raffinate (which did not contain any Pu) was passed through the CAC column and 2.8 μg Am was loaded without any breakthrough. This could be eluted in 8 ml of 0.008 M HNO_3.

The purity of the products was checked by α and γ spectrometry and also by analysing the

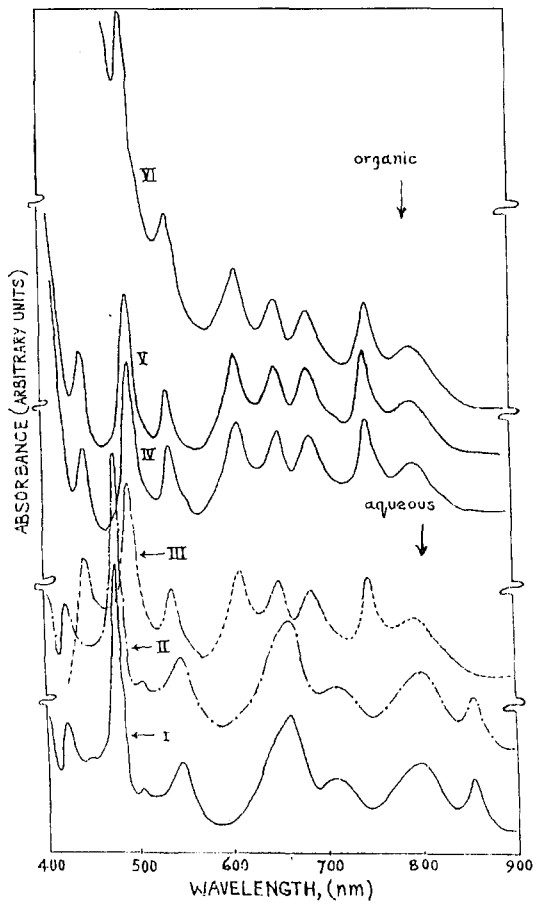

Fig. 4. Absorption spectra of Pu(IV): I. 3 M HNO_3, II. 7.5 M HNO_3, III. 12 M HNO_3 extracted in 20% TnOA–xylene from: IV. 3 M HNO_3, V. 7.5 M HNO_3, VI. 12 M HNO_3.

solutions for metallic impurities using ICP-AES. It was observed that the product, Pu and Am were radiochemically pure and also free from the common metallic impurities (Table 8).

4.4. Slope analysis and spectrophotometric studies of Pu(IV)–TnOA system

The plot of log D versus log[TnOA] (Fig. 3) at a fixed Pu and HNO_3 concentrations gave a straight line with a slope of 2 which suggests that each Pu ion is attached with two molecules of TnOA.

To get a better understanding of the Pu species extracted, visible spectra of Pu in 3, 7.5 and 12 M HNO_3 (using corresponding acid blanks) and Pu extracted from these solutions in 20% TnOA (using corresponding acid treated TnOA as blank) were recorded on a Beckmann DU-7 spectrophotometer using a 1 cm quartz cell. It can be seen from the spectra (Fig. 4) that Pu species in 12 M HNO_3 (absorption peaks at wavelengths 785, 744, 683, 648, 608, 535 and 492 nm) are different than those formed in 3.0 M. At 7.5 M nitric acid the peak positions are nearly the same as those in 3 M HNO_3 but the peak at 659 nm gets broadened and further at 12 M HNO_3 it splits into a triplet. Ryan [23] has reported that the peaks at 608 and 744 nm are due to the formation of hexanitrato complex of Pu(IV). In the case of the species extracted into the TnOA phase from all the three acidities, the nature of spectra was similar to that observed in the case of aqueous Pu in 12 M nitric acid. This suggests that the species extracted from all the acidities (between 3 and 12 M) are the same and similar to that formed in the aqueous 12 M HNO_3. At 12 M HNO_3 considerable amounts of the acidic species $H_2Pu(NO_3)_6$ and $HPu(NO_3)_6^-$ will be present [23,24] and when extracted with TnOA it seems that $Pu(NO_3)_6^{2-}$ is converted to the form $(R_3NH)_2Pu(NO_3)_6$. Thus from the slope analysis as well as Pu spectral studies it could be concluded that the species extracted into the organic phase is only $(R_3NH)_2Pu(NO_3)_6$.

5. Conclusions

Plutonium and americium from high acid laboratory waste solutions could be recovered quantitatively by employing a two stage solvent extraction procedure using TnOA in xylene for Pu and then 0.2 M CMPO + 1.6 M TBP in dodecane for Am. The loaded Pu from the TnOA phase could be stripped quantitatively either by 0.5 M acetic acid or 0.2 M ascorbic acid. Am from the CMPO phase could easily be stripped by 0.008 M HNO_3.

To avoid the problems encountered during the handling of organic solutions inside glove-boxes extraction chromatographic technique using

TnOAC for Pu and CAC for Am can be used for near complete recovery of Pu and Am from high acidic waste solutions. This can further be modified for remote operations while handling large volumes of such waste solutions. The Pu(IV)/TnOA species extracted into the organic phase has been confirmed as $(R_3NH)_2Pu(NO_3)_6$ by slope analysis as well as by spectrophotometric studies.

The determination of wear metals in used lubricating oils by flame atomic absorption spectrometry using sulphanilic acid as ashing agent

E.J. Ekanem *, J.A. Lori, S.A. Thomas

Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

Received 5 November 1996; received in revised form 24 February 1997; accepted 27 February 1997

Abstract

A simple and reliable ashing procedure is proposed for the preparation of used lubricating oil samples for the determination of calcium, magnesium, zinc, iron, chromium and nickel by flame atomic absorption spectrometry. Sulphanilic acid was added to oil samples and the mixture coked and the coke ashed at 550°C. The solutions of the ash were analysed by flame AAS for the metals. The release of calcium, zinc, iron and chromium was improved by the addition of sulphanilic acid to samples. The relative standard deviations of metal concentration results in the initial oil samples were 1.5% for Ca (1500 mg l^{-1} level), 0.3% for Mg (100 mg l^{-1} level), 3.1% for Zn (1500 mg l^{-1} level), 0.7% for Fe (500 mg l^{-1} level), 0.02% for Cr (50 mg l^{-1} level) and 0.002% for Ni (10 mg l^{-1} level). The optimum sample size for efficient metal release was 20 g while the optimum sulphanilic acid to oil ratio was 0.05 g per gram of oil for Zn and Cr and 0.10 g for Ca and Fe. Results obtained by this procedure were highly reproducible and comparable with those obtained for the same samples using standard procedures. © 1997 Elsevier Science B.V.

Keywords: Aided-ashing; Lubricant; Metal determination

1. Introduction

The performance characteristics of lubricating oils are usually improved by the additives incorporated to improve the colour, pour point, viscosity, antiwear, antifrictional, antifoaming, oxidation and corrosion inhibition properties. These additives contain various metals in varying amounts. In use, a lot more of some of these metals are added to the lubricating oils from friction and wear [1,2]. A simple, rapid and accurate analytical procedure is needed for routine determination of these elements in order to provide an indication of the degree of wear of the oil wetted parts within an engine. A specific application is in the analysis of used lubricating oils to indicate potential failure in internal combustion engines as well as the metal pollution potentials of such oils if they are disposed directly into surface water or on land.

Although wear metal particles are not uniformly distributed in oils, they are generally deter-

PII S0039-9140(97)00086-6

mined by using techniques traditionally applicable to the determination of metals in homogeneous solutions [3]. Various methods have been reported for the preparation of samples prior to instrumental analysis [3–7]. The possible loss of certain naturally occurring volatile constituents during unaided ashing of petroleum or its products has been reported [8–10]. Hence, the determination of trace metals in petroleum oils has relied on ashing procedures that aim at preventing metal losses by volatilization [11,12] during ashing.

Benzenesulphonic acid has been applied as ashing agent for the determination of Ni and V in petroleum distillates [11,13] while *p*-xylenesulphonic acid has been used for ashing petroleum distillates [12] and crude petroleum [14] for the determination of trace metals. Unlike these reagents which are hygroscopic and difficult to handle and store [15], sulphanilic acid has a very long shelf life and was investigated as ashing reagent in this work. The purpose of the present work was to establish the optimum conditions for the ashing of used lubricating oils applying sulphanilic acid to contain any volatilization losses.

2. Experimental

2.1. Reagents, apparatus and samples

All reagents used in this work were of analytical grade. Sulphanilic acid was obtained from BDH. Doubly distilled water was used in preparing all aqueous solutions. The muffle furnace used was a Carbolite (Sheffield, UK) capable of maintaining constant temperatures in the range 20–1200°C. The Perkin Elmer 290 B atomic absorption spectrophotometer, equipped with a premix chamber and a single slot burner head operated on air-acetylene flame, with automatic background correction and mono-element hollow cathode lamps was used for solution analysis. The parameters selected on the spectrophotometer for the determination of the test metals conform with those recommended by Perkin Elmer for this spectrometer. The oil samples analysed were collected from private vehicles and automechanic workshops in Zaria, Nigeria.

2.2. Working standard solutions

$CaCO_3$, $MgCl_2 \cdot 6H_2O$, ZnO, $(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$ and chromium powder were dissolved appropriately and diluted with water to obtain 1000 mg l^{-1} stock solutions of Ca, Mg, Zn, Fe, Ni [16] and Cr [17]. Working standard solutions were obtained from the respective stock solutions by appropriately diluting them with water introducing 5% (m/v) lanthanum as the nitrate in the case of Ca and Mg to control the interferences of ions like phosphate, aluminate and silicate.

2.3. Recommended procedure

A mixture of 10.0 g used lubricating oil and 1.0 g sulphanilic acid in a 250 cm^3 pyrex beaker was heated in a heating mantle in the fume cupboard. The smoke issuing from the beaker was ignited and the set-up left until the flame was extinguished. The coke formed was muffled at 550°C until the ash was free of carbon particles; this required 45 min. The ash was allowed to cool before it was dissolved in 20 cm^3 of 6M HCl and digested in a boiling water bath to obtain a clear solution. This solution was made up to 50 cm^3 with distilled water in a volumetric flask, introducing 5% (m/v) La and analysed by FAAS for Ca, Mg, Zn, Fe, Cr and Ni against a blank solution prepared by digesting 20.0 cm^3 of the 6M HCl in the boiling water bath in the same way as the sample digests and making up to 50 cm^3 with distilled water as done for the sample solution.

3. Results and discussion

3.1. Optimization of ashing conditions

3.1.1. Temperature and time

Optimization of parameters was based on 10 g replicates [18] of samples. Temperatures were observed in the range 400–650°C for durations of 15–120 min. The progress and completeness of ashing was visually determined.

The lowest muffling temperature that yielded carbon-free ash was 550°C and this was achieved

Effect of ignition

Sample treatment	Coking time (min)	Metal concentration (mg l^{-1})					
		Ca	Mg	Zn	Fe	Cr	Ni
Without ignition	20	1470	88	1350	387	32.5	9.5
With ignition	18	1470	88	1390	426	35.6	9.6

in the shortest time of 45 min. Though a higher muffling temperature could be selected for a more rapid ashing, 550°C was regularly applied in this work to avoid the disfiguration of the pyrex beakers that may occur at higher temperatures [19]. The oxides of the metals determined are known to be stable even above 1000°C [20], hence volatilization of the metals would be prevented by rendering them as oxides in the ash at 550°C. This ashing temperature has been recommended by the Institute of Petroleum [21] in a procedure that does not specify coking and muffling times and includes an overnight delay and a filtration step. The present procedure has eliminated the need for ash solution filtration and the attendant delay by achieving carbon-free ash in a short time. The chances of error arising from contamination during the filtration are removed in this procedure.

3.1.2. Ignition of samples

Coking time was the duration up to the cessation of smoke when the smoke issuing from the samples was not ignited. In the cases where the smoke was ignited as it issued from the sample, coking time was the time taken for the smoke to finish burning and the flame to be extinguished.

Satisfactory coking was achieved in 20 min without ignition and in 18 min when the smoke was ignited. Ignition did not, however, alter muffling time because the coke derived with and without ignition both yielded good ash in 45 min of muffling.

The ashes obtained were completely soluble in 20 cm^3 of hydrochloric acid and a clear solution was obtained after 2 min of digestion. Therefore, there was no need to filter the solution as recommended by the direct ignition method for the determination of additive metals in unused lubricating oils [21]. The results presented in Table 1 for the determination of the test metals in sample number 1 were typical of those obtained for all samples in this work and show that there was increased metal retention in the ignited sample particularly for Zn, Fe and Cr. For these metals, the ignition allows metal complexes that would have escaped in the smoke to burn and return their metal constituents to the coke as metal oxides. The differences in the determinant levels of ignited and unignited samples give an indication of which determinants are more prone to volatilization losses in lubricating oils. Though there was no change in the levels of some of the test metals, the enhancement in the levels of even a few of the test metals advised the adoption of ignition of lubricating oils for determining trace metals. A similar advantage of sample ignition while coking has been reported for petroleum crudes [14] and petroleum distillates [22].

3.2. Sulphanilic acid as ashing reagent

Various levels of sulphanilic acid were added to 10 g replicates of oil analysed by the recommended procedure and yielded results as detailed in Table 2. The addition of sulphanilic acid to the samples did not alter the ashing efficiency of the samples: it did not alter either the ignition time or the muffling time and the ash produced in the presence of it was still completely soluble in 20.0 cm^3 of 6M HCl. The muffling of 1.0 g of sulphanilic acid alone at 550°C under similar conditions to those applied for ashing oil samples left no residue at the end of 45 min. This implies that SA did not contribute to the ash. The digest of 2.0 g of sulphanilic acid in 6 M HCl yielded blank levels of all the metals determined. The sulphanilic

Table 2
Sulphanilic acid (SA) as ashing reagent

Mass of SA added (g)	Metal concentration (mg l^{-1})					
	Ca	Mg	Zn	Fe	Cr	Ni
0	1470	88	1390	426	35.2	9.6
0.1	1472	88	1390	428	35.7	9.6
0.2	1475	87	1393	428	36.1	9.6
0.3	1485	88	1395	434	36.3	9.7
0.4	1498	88	1397	455	36.7	9.7
0.5	1500	88	1400	456	37.3	9.7
0.6	1500	89	1400	457	37.3	9.7
0.8	1501	89	1400	458	37.0	9.7
1.0	1502	89	1400	468	37.0	9.7
1.5	1500	89	1400	468	37.3	9.7
2.0	1501	89	1400	468	37.3	9.7

acid was therefore shown to be free from the determinants.

The results presented in Table 2 for 10.0 g of oil sample 1 show that there was an improvement in metal release especially for Ca, Zn, Fe and Cr as the sulphanilic acid to oil ratio increased until peak values were obtained at 0.05 g of SA for Zn and Cr and 0.1 g for Ca and Fe per gram of oil. Once obtained, the peak determinant levels persisted when higher ratios of sulphanilic acid were applied, up to 0.2 g of SA per gram of oil. The same trend was observed also for samples other than sample number 1. That peak metal release is achieved at different ratios of releasing agent for different determinants reflects the differences in stabilities of the metal complexes in which the determinant species are encaged in the oil samples [23]. These results suggest that the zinc and chromium metallocomplexes are less thermodynamically stable than the calcium and iron ones. Similar differences in the stabilities of porphyrins and metallocomplexes of metals occurring in crude oil have been reported [14]. The addition of 0.1 g of sulphanilic acid per gram of oil to samples was adopted in this work and is recommended for the ashing of used lubricating oils for the determination of trace metals by FAAS. Its stability and long shelf life make it preferable to other similar reagents like benzene-sulphonic and *p*-xylenesulphonic acids, which are hygroscopic and require special handling [14].

3.3. Evaluation of the procedure

When the same oil was ashed in six replicates and the ash analysed for the test metals in the replicates, the results showed that the recommended procedure is highly reproducible with relative standard deviations (% rsd) of 1.5, 0.3, 3.1, 0.7, 0.02 and 0.002 for Ca, Mg, Zn, Fe, Cr and Ni, respectively at the respective concentration levels 1500, 100, 1500, 500, 50 and 10 mg l^{-1}.

All five samples were analysed in triplicates by this procedure, the direct ignition procedure [22] and the Universal Oil Product (UOP) method 800-79 [24] and the average results are compared in Table 3. From observation, the results indicate that the values obtained by the direct ignition procedure are generally lower than those obtained by either the recommended or UOP method 800-79 procedures; the values obtained by the recommended procedure are generally closer to those obtained by the UOP procedure. A regression analysis of the results reveals a closer fit between the recommended procedure and the standard UOP procedure than between the direct ignition and the UOP procedures. The respective regression lines are

$$y = 1.004x^{r} - 1.884 \qquad r = 0.9993$$

and

$$y = 1.017x^{i} + 5.356 \qquad r = 0.9982$$

Table 3
Comparison of sample results obtained by three ashing procedures

Sample No.	Determinant	Measured levels (mg l^{-1})		
		Recommended procedure	Direct ignition procedure	UOP method 800-79
1	Ca	1508.4	1503.4	1513.4
	Mg	90.0	87.7	90.7

	Zn	1475.5	1446.1	1446.1
	Fe	440.5	428.6	452.4
	Cr	28.0	26.0	28.0
	Ni	9.3	9.3	9.3
3	Ca	1638.5	1621.6	1706.1
	Mg	85.0	82.0	88.7
	Zn	1441.2	1446.1	1446.1
	Fe	412.7	412.7	420.6
	Cr	22.0	22.0	21.0
	Ni	9.3	9.3	9.3
4	Ca	878.4	810.8	844.6
	Mg	32.1	30.5	31.1
	Zn	1034.3	1029.4	1012.8
	Fe	281.8	264.8	281.8
	Cr	64.0	63.0	64.0
	Ni	11.3	10.3	11.3
5	Ca	641.9	608.1	641.9
	Mg	28.5	29.8	29.5
	Zn	872.6	853.0	857.9
	Fe	388.9	388.9	388.9
	Cr	67.0	66.0	69.0
	Ni	11.7	11.3	11.7

where y represents UOP values, x^r represents values from the recommended procedure, x^i represents values from the direct ignition procedure and r is the correlation coefficient.

The application of Student's t-test to the data of Table 3 reveals that the results obtained by the direct ignition procedure are significantly different from those obtained by the UOP method 800-79 while there is no significant difference between the results obtained by the recommended and the UOP procedures.

These statistics support the argument that while the UOP method 800-79 and the recommended procedures realise maximum release of metals, the direct ignition procedure fails to achieve maximum metal release, hence the generally low values obtained by the latter procedure and the significant difference between it and the former two procedures. The advantage of sulphanilic acid causing enhanced metal release as indicated in Table 2 is reflected in the results of these statistical analyses. The recommended procedure has an additional advantage in being faster than the UOP method 800-79.

4. Conclusion

Used lubricating oil may be conveniently coked and ashed at 550°C in 45 min for determining

wear and other metals by flame atomic absorption spectrometry. Sulphanilic acid applied as ashing agent improves the release of metals and the accuracy of the analytical results. The procedure reported is simple, rapid and precise.

Coordination properties of cefadroxil antibiotic: synthesis and equilibrium studies of the binary and ternary complexes involving amino acids and DNA units

Mohamed M. Shoukry *, Wafaa M. Hosny, A. Abd Razik, Ramadan A. Mohamed

Department of Chemistry, Faculty of Science, Cairo University, Giza, Egypt

Received 4 November 1996; received in revised form 10 March 1997; accepted 11 March 1997

Abstract

The formation equilibria for the binary complexes of Cu^{II}, Ni^{II}, Co^{II}, Zn^{II}, Mn^{II}, Hg^{II}, Cd^{II}, Ca^{II}, and Mg^{II} with cefadroxil (Cef) and for the ternary complexes Cu(Cef)(L), where L refers to amino acid or DNA, were investigated. The protonation constants of cefadroxil and formation constants of the formed complexes were determined at 25°C and $\mu = 0.1$ M $NaNO_3$. Copper(II) and cobalt(II) complexes of cefadroxil were isolated in solid state and characterized by elemental analysis, infrared and electronic spectral, conductivity and magnetic measurement. © 1997 Elsevier Science B.V.

Keywords: Amino acid complexes; Binary and ternary complexes; Cefadroxil complexes; DNA complexes; Stability constants

1. Introduction

Much interest has been shown in the chemistry of β-lactam antibiotics in relation to their useful biological activities in recent years [1–4]. β-Lactam antibiotics, such as penicillins, cephalosporins and oxacephalosporins, represent the most important class of drugs against infectious diseases caused by bacteria. Following the recent evidence of the important roles of calcium and magnesium in the transport of these drugs in blood plasma [5], it is suggested that copper can act as a cofactor of their antibiotic activity: first, the structural flexibility of copper binary complexes is expected to favour mixed-ligand coordination with bacterial nucleic acids; then, through the formation of such ternary complexes, copper may induce the attack of free radicals known to damage these nucleic acids [6].

In continuation of our previous studies of the metal complexes of antibiotics [7–10], the present investigation reports equilibrium studies of the binary and ternary complexes of some metal ions with cefadroxil and amino acids or DNA units (see Scheme 1). Copper(II) and cobalt(II) complexes with cefadroxil were synthesized and characterized.

2. Experimental

2.1. Materials and reagents

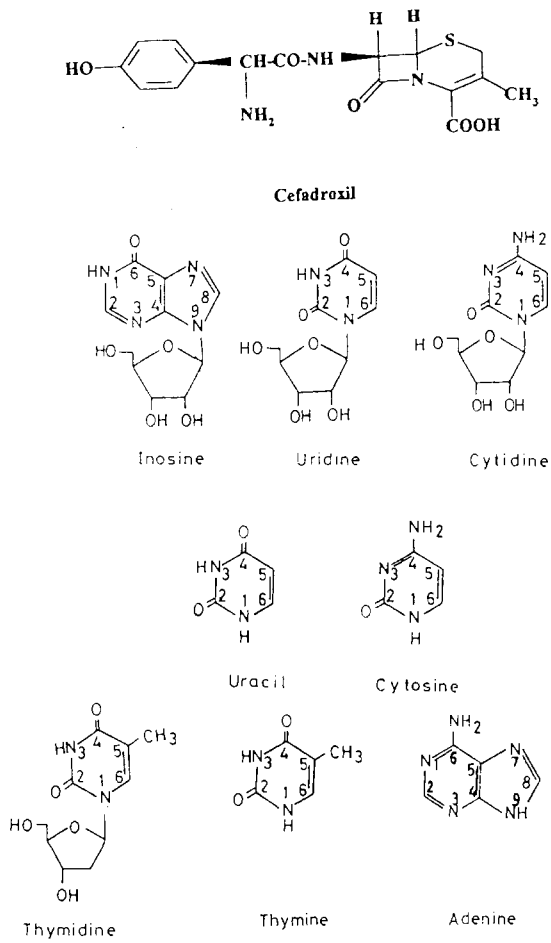
The metal salts, in the form of nitrates, were provided by BDH. Concentrations of stock solutions of metal ions were determined by conventional analytical methods [11]. Cefadroxil monohydrate (Bristol Standard 99%) was supplied by Bristol–Myers–Squib, Egypt. According to its elemental analysis, it was sufficiently pure and, therefore, used without further purification. Due to the instability of antibiotics in aqueous media [12], fresh solutions were prepared immediately before use by dissolving it in aqueous equimolar nitric acid solution. The amino acids and DNA units used were: glycine, alanine, proline, valine, β-phenylalanine, *S*-methylcysteine, iso-leucine, threonine, methionine, serine, 2-amino-*n*-butyric acid, histidine·HCl, histamine·2HCl, aspartic acid, ornithine·HCl, imidazole, inosine, uracil, uridine, cytosine, cytidine, thymine, thymidine and adenine. These materials were from Sigma Chemical. Imidazole, cytosine, cytidine and adenine were prepared in the protonated form by dissolution in nitric acid. All solutions were prepared in deionized water.

2.2. Apparatus

Potentiometric titrations were performed by means of a Metrohm 686 titroprocessor equipped with a 665 dosimat (Switzerland-Heriaue). The titroprocessor was calibrated using standard buffer solutions prepared according to NBS specifications [13]. All pH–metric titrations were carried out at 25.0 ± 0.1°C in a purified nitrogen atmosphere using a titration vessel described previously [14]. Conductance of solutions were measured on a WTW LBR conductivity bridge (Germany). Infrared absorption spectra were taken by a Perkin–Elmer 1430 spectrophotometer using a KBr disc. Electronic spectra were scanned on Shimadzu UV-160 A recording spectrophotometer. Magnetic susceptibility of the solid complexes were determined by using Gouy's powder technique.

2.3. Procedure and techniques

The protonation constants of the ligands, in the protonated form, were determined by titrating 40 ml of aqueous ligand solution (2.5×10^{-3} M) and $NaNO_3$ (0.1 M). The conditions of measurements for the determination of the stability constant of the binary complexes were the same as for the protonation constants, but a part of $NaNO_3$ was replaced by M^{II} ion with the concentration ratio 1:1 and 1:2 (M:Cef) for Cef (where $M = Cu^{II}$, Ni^{II}, Co^{II}, Zn^{II}, Mn^{II}, Hg^{II}, Cd^{II}, Ca^{II} and Mg^{II}, and 1:2 for Cu^{II}–amino acids complexes. The conditions of measurements for the titration of the ternary complexes were the same as for the



Scheme 1. Structural formulae of the investigated ligands.

binary ones, but the solutions contained equivalent amounts of Cef, Cu^{2+} and the other ligand (L).

The calculations were performed using the computer program MINIQUAD-75 [15] loaded on an IBM 486 computer. The stoichiometries and stability constants of the complexes formed were determined by trying various possible composition models for the system studied. The calculations were restricted to data obtained in a pH range where no precipitation occurred. The model selected was that which gave the best statistical fit to and which was chemically consistent with the titration data, without giving any systematic bias in residuals, as described elsewhere [15]. Tables 1–3 list the formation constants together with their standard deviations and the sum of the square of residual as obtained from the program MINIQUAD-75. The concentration distribution diagrams were obtained with the program SPECIES [16] under the experimental conditions used.

2.4. Metal chelates of cefadroxil (Cef)

The metal chelates of cefadroxil (Cef) with copper(II) and cobalt(II) were prepared in the ratio 1:1 (metal:ligand). The metal carbonate (1 mmol) is mixed with the antibiotic (1 mmol) in the least amount of water. The resulting mixture was refluxed for 1–2 h. The solid complexes were precipitated, filtered, washed with water, ethanol and finally with ether.

3. Results and discussion

3.1. Proton–cefadroxil equilibrium

A maximum number of three protons can be released from the cefadroxil in the fully protonated form ($Cef = H_3L^+$) on titration with a strong base. The titration data indicates the presence solely of simple HL^-, H_2L, H_3L^+ complexes. The differential log protonation constants were found to be 1.70, 7.07 and 9.14. In considering the nature of the donor groups involved in the successive protonation reactions, it is helpful to invoke the protonation constants of amoxycillin (2.41, 7.19 and 9.38) [9] analogue, where the protonation centres are the carboxylic, amino, phenolic groups. In acid medium, cefadroxil is protonated to give a cationic species H_3L^+. Addition of base produces, in the first stage, the deprotonation of the carboxylic group ($pK_{a1} = 1.70$) yielding the zwitter ion species $H_2L^{\pm}$, existing in the pH range 4–6. When the pH is increased, the deprotonation of the amino group $-NH_3^+$ ($pK_{a2} = 7.07$), followed by that of the phenolate group ($pK_{a3} = 9.14$).

3.2. Metal ion–cefardoxil complexes

Potentiometric titration curves of cefadroxil and its copper(II) complexes, taken as being representative, are shown in Fig. 1. In the metal complex curve, there is a significant lowering from that of the free cefadroxil, indicating formation of metal complexes by release of protons. Different equilibrium models have been tried to fit the experimental potentiometric data for the M^{II}–(cefadroxil). The model that best fits the potentiometric data is found to consist of $[MHL]^+$ and [ML] species. The validity of the same is proven where an excellent fit can be observed between the experimental data points from the titration of metal ion–cefadroxil complex, and the theoretical curve calculated from the values of the protonation constants of cefadroxil and the formation constants of the corresponding complexes.

The acid dissociation constant of the protonated complex, [MHL] is given by Eq. (1) [17]:

$$pK^{(H)}_{M(L)(H)} = \log K^{M}_{M(L)(H)} - \log K^{M}_{M(L)} \quad (1)$$

The value of pK_H of the protonated complexes is in the range 4.78–8.73. This value may compare with the protonation constant of the phenolic group. Coordination to the amino group lowers the pK_a of the phenolic group. A lowering of up to 2 units was reported for the coordination of DNA units to a series of divalent earth alkali and transition metal ions [18].

The protonation constants of amino acids and DNA units and the formation constant of the copper(II) complexes with amino acids were determined under conditions identical to those for ternary systems, i.e., at 25°C and ionic strength of

0.1 M (KNO_3). The results (Table 1) are in good agreement with the literature data [19], after allowing for changes in experimental conditions and calculation methods.

3.3. Ternary complex formation equilibria

The general four-component equilibrium can be written as follows (charges are omitted for simplicity):

$$l\mathrm{Cu} + p(\mathrm{Cef}) + q(\mathrm{A}) + r\mathrm{H} \rightleftarrows \mathrm{Cu}_l(\mathrm{Cef})_p(\mathrm{A})_q(\mathrm{H})_r \quad (2)$$

where l, p, q and r are the stoichiometric coefficients corresponding to the copper(II), cefadroxil, amino acid and H^+, respectively.

The overall formation constants are defined as:

$$\beta_{lpqr} = \frac{[\mathrm{Cu}_l(\mathrm{Cef})_p(\mathrm{A})_q(\mathrm{H})_r]}{[\mathrm{Cu}]^l[\mathrm{Cef}]^p[\mathrm{A}]^q[\mathrm{H}]^r} \quad (3)$$

The ternary complex formation may proceed through step-wise or simultaneous mechanism, depending on the chelating potentiality of cefadroxil and amino acid or DNA unit. The formation constants of the 1:1 copper(II) complexes with cefadroxil and amino acids are of the same order (Table 1). Consequently the ligation of the antibiotic and amino acid will occurs simultaneously. The titration data of the mixed-ligand complexes with amino acids and cefadroxil fit satisfactorily on the basis of the complexes Cu(Cef)(A) and Cu(Cef)-(A)(H). The formation constants obtained for the mixed ligand complexes are given in Table 2.

The relative stability of the ternary complexes formed through a simultaneous mechanism, as compared to those of the corresponding binary complexes, is expressed in terms of $\Delta \log K$ as defined by Eqs. (4) and (5).

$$\mathrm{Cu(Cef)} + \mathrm{Cu(A)} \rightleftarrows \mathrm{Cu(Cef)(A)} + \mathrm{Cu} \quad (4)$$

$$\Delta \log K = \log K^{\mathrm{Cu}}_{\mathrm{Cu(Cef)(A)}} - [\log K^{\mathrm{Cu}}_{\mathrm{Cu(Cef)}} + \log K^{\mathrm{Cu}}_{\mathrm{Cu(A)}}] \quad (5)$$

Since more coordination sites are available for bonding of the first ligand to a metal ion than for the second ligand, $\Delta \log K$ should in general be negative. With Cu^{II} usually having a coordination number of four, the expected value for $\Delta \log K$ would be -0.6 [20,21]. The reported $\Delta \log K$ values for most Cu–cefadroxil–amino acids complexes are of the same order.

The potentiometric titration curve of the ternary system Cu^{II}–cefadroxil–inosine (as a representative of DNA) coincides with the 1:1 Cu^{II}–Cef curve in the region $0 < a < 2$ (a = number of moles of base added per mole of ligand), Fig. 2. In this region, the Cu^{II}–Cef–complex is formed firstly due to its high stability compared to that of the Cu^{II}–DNA complex (Table 1). Beyond $a = 2$, the formation of a ternary complex was ascertained by comparison of the mixed-ligand titration curve with the composite curve obtained by graphical addition of inosine titration data to that of the Cu^{II}–Cef titration curve. The mixed-ligand system was found to deviate considerably from the resultant composite curve, indicating the formation of a ternary complex. Thus, formation of ternary complex can be described by the following equilibria (charges are omitted for simplicity) [6,7]:

$$\mathrm{Cu} + \mathrm{Cef} \rightleftharpoons \mathrm{Cu(Cef)} \quad (6)$$

$$\mathrm{Cu(Cef)} + \mathrm{Ino} \rightleftharpoons \mathit{Cu(Cef)(Ino)} \quad (7)$$

The relative stability of the ternary complexes formed through a step-wise mechanism, as com-

[b] Standard deviations are given in parentheses.
[c] Sum of square of residuals.

pared to those of the corresponding binary complexes, is expressed in terms of Δlog K as defined by Eq. (8).

$$\Delta\log K = \log K^{Cu(Cef)}_{Cu(Cef)(D)} - \log K^{Cu}_{Cu(D)} \quad (8)$$

The Δlog K values given in Table 3 are invariably negative. This means that the DNA units form more stable complex with the free copper(II) ion than with the Cu(Cef) complex.

Inosine has two donor sites, N_1 and N_7. In the acidic pH range, N_1 remains protonated, while the metal ion is attached to N_7. The gradual change from N_7-binding to N_1-binding with increasing pH has been rather extensively documented by nuclear magnetic resonance (NMR) [22] and electron paramagnetic resonance (EPR) [23] spectroscopic measurements. The proposed structure for the mixed ligand complex studied in the pH range 7–9 involves N_1-binding.

The protonation constant of uridine, uracil, thymine and thymidine is that of the [N(3)–C(4)O] group. The values obtained from this study have been compared with those of the protonation of the analogous [N(1)–C(6)O] grouping in inosine. The purinic derivatives are slightly more acidic than the pyrimidinic ones, a property which can be related to the existence in the anion of the purinic derivatives of a higher number of resonance forms in equilibrium because of the presence of two condensed rings in this ligand. Based on the existing data, uracil, uridine, thymine and thymidine ligate in the deprotonated form, through N_3. The thymine and thymidine complexes are more stable than those of uracil and uridine, most probably due to the higher basicity of the N_3 site of thymine and thymidine resulting from the inductive effect of the extra electron-donating methyl group.

Acid–base equilibria of adenine in the protonated form (H_2D^+) involve deprotonation from N(1) and N(9) sites. The accepted model for the mixed-ligand titration of adenine consists of Cu(Cef)(D) species. The question of the point or points of attachment of adenine to a metal centre has been discussed by a number of workers, notably by Hodgson [24] and Marzilli [25]. They discussed both solution and solid complex studies which have indicated that N(9) is the ligating site.

From the potentiometric titration curves for Cu(Cef)–cytosine or –cytidine, the horizontal addition procedures showed the absence of any significant interaction between the Cu–Cef complex and cytosine or cytidine. Similar behaviour was found for the system M–EDTA–cytosine or –cytidine [26].

Estimation of equilibrium concentrations of various complex species as a function of pH provides a useful picture of metal ion binding in the biological fluids. The species distribution patterns

for the Cu–Cef–proline, taken as a representative of amino acids and given in Fig. 3, indicate that the mixed-ligand complex starts to form at pH ≈ 6 and reaches a maximum concentration (60%) at pH = 9. Mixed-ligand complexes formed with DNA units are less favoured; they reach the maximum concentration of approximately 50% at pH = 11. Thus, the amino acid will compete with the DNA for the reaction with the Cu–Cef complex.

3.4. Composition and structure of solid complexes

Elemental analysis data of the investigated metal complexes obtained in the solid state (Table 4) indicate that cefadroxil acts as a dibasic ligand. The proposed general chemical formulae of the complexes may be represented by $ML \cdot xH_2O$, where L is the deprotonated form of the ligand and M is Cu^{II} and Co^{II}. The molar conductance values of 0.001 M DMF complex solutions are in the range 9–12 $cm^2\ (\Omega \cdot mol)^{-1}$, which indicates their non-electrolytic nature.

The infrared spectrum of cefadroxil exhibits bands at 2585, 1759 and 1686 cm^{-1}, assigned to $-NH_3^+$, β-lactam carbonyl and amide carbonyl groups [27]. In the spectra of the complexes, the NH_3^+-band disappeared and the two carbonyl bands were significantly shifted to lower wave numbers, a behaviour which provides a convincing evidence for coordination through the amino and the two carbonyl groups. The OH band oc-

Table 4
Analytical data and physical properties of the metal complexes of cefadroxil (Cef)

Complex	Colour	Yield (%)	Dec. point (°C)	Found (calc.) (%)					Λ (mhos·cm²·mol⁻¹)	μ_{eff} (BM)
				C	H	N	S	M		
$CuL \cdot 2H_2O$ $[C_{16}H_{19}N_3O_7SCu]$	Grey	80	> 290	41.9 (41.7)	4.3 (4.1)	9.2 (9.1)	7.0 (6.9)	13.6 (13.8)	12	1.95
$CoL \cdot 4H_2O$ $[C_{16}H_{23}N_3O_9SCo]$	Dark brown	90	> 270	39.0 (39.0)	4.6 (4.7)	8.5 (8.5)	6.6 (6.5)	12.0 (12.0)	9	4.50

curring at 3506 cm^{-1} in the spectrum of the cefadroxil disappeared upon complexation. This indicates that the hydrogen ion of the cefadroxil OH group is released to neutralize the positive charge of the metal ion, forming a neutral complex.

The electronic absorption spectrum of the copper(II) complex consists of a broad band in the region 14 400–14 900 cm^{-1}, which is assigned to $^2B_{1g} \leftarrow {}^2A_{1g}$ transitions as well as a shoulder in the range 21 600–22 200 cm^{-1}, characteristic of a square planar geometry for the copper(II) complex [28]. The complex has a magnetic moment that amounts to (1.95) BM, which justified the square planar configuration.

The electronic spectrum of the cobalt(II) complex exhibits three bands at 8058, 16 000 and 19 048 cm^{-1}, which are assigned to ν_1: $^2T_{2g} \leftarrow {}^4T_{1g}$, ν_2: $^4A_{2g} \leftarrow {}^4T_{1g}$ and ν_3: $^4T_{1g}(p) \leftarrow {}^4T_{1g}$ transitions, respectively, indicating an octahedral configuration around the Co(II) ion [29]. The octahedral geometry of the Co^{II} complex is further confirmed by the value of the magnetic moment (4.5 BM).

Further investigation to provide more convincing evidence for the structure of these complexes requires further studies including, e.g., X-ray diffraction studies and other structural investigations.

4. Conclusion

The present investigation may have important biological implications. The structural flexibility of bioactive cefadroxil as well as its capacity to coordinate copper(II) via three different donor sites may favour the formation of ternary complexes with various ligands occurring in vivo. In particular, such mixed-ligand coordination is likely to occur with bacterial nucleic acids.

Determination of ammonium in Kjeldahl digests by gas-diffusion flow-injection analysis with a bulk acoustic wave-impedance sensor

Xiao-Li Su, Li-Hua Nie, Shou-Zhuo Yao *

College of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

Received 4 November 1996; received in revised form 11 March 1997; accepted 12 March 1997

Abstract

A novel flow-injection analysis (FIA) system has been developed for the rapid and direct determination of ammonium in Kjeldahl digests. The method is based on diffusion of ammonia across a PTFE gas-permeable membrane from an alkaline (NaOH/EDTA) stream into a stream of diluted boric acid. The trapped ammonium in the acceptor is determined on line by a bulk acoustic wave (BAW)-impedance sensor and the signal is proportional to the ammonium concentration present in the digests. The proposed system exhibits a favorable frequency response to 5.0×10^{-6}–4.0×10^{-3} mol l^{-1} ammonium with a detection limit of 1.0×10^{-6} mol l^{-1}, and the precision was better than 1% (RSD) for 0.025–1.0 mM ammonium at a through-put of 45–50 samples h^{-1}. Results obtained for nitrogen determination in amino acids and for proteins determination in blood products are in good agreement with those obtained by the conventional distillation/titration method, respectively. The effects of composition of acceptor stream, cell constant of conductivity electrode, sample volume, flow rates and potential interferents on the FIA signals were discussed in detail. © 1997 Elsevier Science B.V.

Keywords: Ammonium determination; Bulk acoustic wave sensor; Gas-diffusion flow-injection analysis; Kjeldahl digestion

1. Introduction

Developed in 1883, the Kjeldahl procedure remains one of the most accurate and widely used methods for determining nitrogen. By this procedure, almost all organic nitrogen-containing substances are converted to ammonium. The ammonium is often quantified by distillation in alkaline medium followed by titration or colorimetry, or by means of micro-diffusion method [1]. All these methods, however, are time-consuming and suffer from inadequate sensitivity and reproducibility. Direct spectrophotometric determination of ammonium in the digest is possible and is implemented in some automatic analyzers. But this direct determination may suffer from changes in acid concentration, presence of metal ions and sample turbidity [2].

Flow injection analysis based on gas-diffusion separation (GD-FIA), characterized by its high selectivity, promising sensitivity, excellent precision and rapidity, has proven useful in determining ammonium in complex matrices including Kjeldahl digests [3–7]. In this technique, the sample is injected into, or merged with an alkaline solution, and the ammonium formed diffuses across a gas-permeable membrane into a recipient stream. The trapped ammonium has been determined spectrophotometrically with an acid–base indicator, potentiometrically with an ammonium-selective electrode, or conductometrically. The conductometric method has some important advantages over the others without the sacrifice of sensitivity, selectivity and precision, the equipment as well as the reagent required is simpler and less expensive. A drawback, however, is that the high background conductivity of the recipient stream can cause an unacceptable noise level [4]. Hence, distilled water is the most often used acceptor, and sometimes it is designed to flow through a small column of mixed-bed ion exchanger for final purification before it enters the gas-diffusion cell [3], which makes the FIA system more complicated and expensive.

The bulk acoustic wave (BAW)-impedance sensor, as described previously [8], is constructed by connecting an AT-cut piezoelectric quartz crystal and a conductivity electrode in series, and has particular advantages over the classical conductometry, e.g., it can detect a slight change in solution conductivity in the presence of an excess of a foreign electrolyte, and the sensitivity and accuracy are better than those obtained in the absence of the foreign electrolyte. Moreover, it possesses the same sensitivity to the conductivity and permittivity of the solution as the normal piezoelectric sensor, in which the quartz crystal is in direct contact with the solution, and a better frequency stability, lower frequency-temperature coefficient and much lower frequency dependence on the density and viscosity of the solution because only the electrode is immersed in the liquid and the crystal is out of contact with the solution. Thus, it is not surprising that BAW-impedance sensor has been used so widely, e.g., for end-point determination in titration [9], for determination of microorganism [10], and for biochemical and physiological study of blood [11,12]. To the best of our knowledge, there has been no publication that combines FIA with piezoelectric detection except a feasibility study of the combination of FIA with the thickness-shear mode acoustic wave sensor [13]. This paper is a preliminary report describing the development of a novel FIA system based on the conjunction of BAW-impedance sensor with GD-FIA technique, and its practical application for the rapid and direct determination of ammonium in Kjeldahl digests obtained from amino acids and blood products.

2. Experimental

2.1. Apparatus

Schematic diagram of the FIA manifold is illustrated in Fig. 1(a), it is composed of a peristaltic pump (Xiangshan Dingshan Instrument Factory,

Iwatsu, Japan) was used to record its oscillating frequency, and a computer (Model 4192 A, Hewlett-Packard) was used for data analysis. The conductivity electrode was made from two stainless-steel needles (diameter 1 mm) inserted parallely and oppositely in a 15 μl-flow-through cell (5 mm × 2 mm i.d.). Design of the oscillator was given in a previous paper [8]. Temperature control (25 ± 0.1°C) was achieved with a constant temperature water bath.

2.2. Reagents

Amino acids were of biochemical-reagent grade (Shanghai Biochemical-reagent Factory). Albumin and *r*-globulin were of pharmaceuticals. All other chemicals were of analytical-reagent grade or better quality. Doubly distilled/deionized water was used throughout. Standard ammonium solutions were made by serial dilution of a 0.1 mol l^{-1} ammonium chloride stock solution. The carrier stream was water, the alkaline reagent stream was 0.1 mol l^{-1} NaOH for optimization tests and 2 mol l^{-1} NaOH containing 1% EDTA for real samples, respectively, for composition of the acceptor streams, see Section 3.

2.3. Procedure

To a given quantity of amino acids or a given volume of blood products water was added to produce a solution equivalent to 0.2–1.0 mg ml^{-1} nitrogen. To 1 ml of the resulted solution 3 ml of concentrated sulfuric acid and 0.3 g of a mixture of potassium sulphate and cupric sulphate (3:1) was added, mixed and heated until a clear solution was obtained. After cooling, the mixture was diluted to 100 ml. A blank for blood products was prepared by precipitating the proteins therein with trichloroacetic acid, the clear supernatant thus obtained underwent digestion as described above. The concentration of ammonium was calculated from a calibration graph based on its peak height (the maximum frequency decrease). Then the nitrogen content in amino acids and the protein content in blood products were obtained (each mmol of ammonium is equivalent to 14.01 mg of nitrogen or 87.56 mg protein).

3. Results and discussion

3.1. Theoretical considerations

The proposed method described here is based on diffusion of ammonia across a PTFE gas-permeable membrane from an alkaline stream (pH > 11), which causes conversion of ammonium to ammonia and creates a medium where ammonia is only slightly soluble, it is trapped into a stream of diluted boric acid, and the trapped ammonium in the acceptor is determined on line by a BAW-impedance sensor.

The oscillating frequency (F) of the BAW-impedance sensor can be expressed as [8]

$$F = F_0\left[1 + \frac{\pi F_0 C_q(2\pi F_0 C_s - YG)}{G^2 + 4\pi^2 F_0^2 C_s(C_0 + C_s) - 2\pi F_0 C_0 YG} - \pi F_0 C_q R_q Y\right] \quad (1)$$

where F_0, C_q, C_0, and R_q are the resonant frequency, motional capacitance, static capacitance and motional resistance of the piezoelectric quartz crystal, respectively. $G = k\chi$ and $C_s = k\epsilon + C_p$ are the conductivity and capacitance of the solution, k the cell constant of the conductivity electrode, χ the specific conductivity and ϵ the solution permittivity, C_p the parasitic capacitance between the

Table 2
Interference in determination of ammonium

Interferent	Interferent concentration (μM)	Ammonium concentration (μM)	
		Added	Measured

n-Butylamine	50	100	109.6
Cyclohexylamine	100	100	110.3

leading wires of the electrode, and Y a parameter related to phase shift of the oscillator. For a diluted electrolyte solution, the change of F is chiefly dependent upon solution conductivity because the change in permittivity is negligible and other above-mentioned parameters were always kept unchanged. The sensitivity of BAW-impedance sensor to conductivity, i.e., the slope of the plot of oscillating frequency F versus conductivity χ, can be calculated by differentiating Eq. (1) F with respect to χ

$$\frac{\partial F}{\partial \chi} = \frac{\pi k F_0^2 C_q (4\pi^2 F_0^2 C_s^2 Y + 4\pi F_0 C_s G - YG^2)}{[4\pi^2 F_0^2 C_s (C_0 + C_s) - 2\pi F_0 C_0 YG + G^2]^2} \quad (2)$$

From this equation, it can be deduced that the sensitivity is determined by the solution conductivity G and the cell constant k. In the proposed GD-FIA system, conductivity of the solution flowing through the flow-cell is directly related to composition of the acceptor and concentration of the ammonium trapped in it. Obviously, the latter is determined by the mass transfer of the ammonia formed across the membrane and the recipient volume, i.e., that part of the acceptor stream passing the cell during diffusive sample transport across the membrane. The mass transfer (m) is given by the equation $m = Jt$, where t is the residence time (s) in the donor channel. J is the diffusive flux (mol s^{-1}), it can be derived from Fick's law, based on a simple diffusion model, leading to the equation

$$J = kD(A/L)\Delta c \quad (3)$$

where A is the contact area (m^2) between donor and acceptor stream, L the membrane thickness (m), D the diffusion coefficient (m^2 s^{-1}) of ammonia in air, Δc the concentration difference (mol m^{-3}) and k a lump constant including gas transport in the aqueous phase, and partition of ammonia between aqueous and gaseous phase [4]. At high donor flow rates, the diffusive flux is high but the ammonia transfer efficiency is low. Thus, in FIA, where sample volumes are commonly small, sufficiently low flow rates of the donor stream are appropriate and should guarantee high transfer efficiency. Besides, the sample injected undergoes dispersion resulting in a peak-shaped concentration profile, the intensity and shape of which are influenced by a number of parameters of the FIA manifold.

3.2. Operational parameters

With regard to the above-discussed aspects, the effect of several parameters on the performance of the proposed FIA systems were studied.

Fig. 2(a) shows FIA profiles of the proposed BAW-impedance sensor system obtained with the same manifold except the acceptor being water and diluted boric acid, respectively. In both cases, the injection of ammonium results in a decrease in the oscillating frequencies, which is attributed to the increase in conductivity of the acceptor solution due to the dissociation of the ammonia diffused from the donor stream. However, the acceptor of boric acid gives a stabler baseline and larger frequency shift. Further optimization of the composition of the acceptor resulted in a 0.01 mol l^{-1} boric acid (Fig. 2(b)). When the concentration of boric acid (C_{BA}) is lower than 0.01 mol l^{-1}, the sensitivity of the proposed method increases with the increasing C_{BA}, when $C_{BA} > 0.01$ mol l^{-1},

however, the sensitivity decreases with the increasing C_{BA}.

Influence of cell constant of the electrode, k, was investigated under the same FIA condition while the cell constant varied from 0.4 to 4.0 cm. Various values of k result in a marked difference in the sensitivity to the conductivity (χ), and alter the solution capacitance (C_s). When k increases, the sensitivity to the conductivity increases ($G = k\chi$); meanwhile, the solution capacitance also increases ($C_s = k\epsilon + C_p$) which reduces the sensitivity of the frequency response of the sensor to solution conductance. The sensitivity of the sensor is determined by these two opposing factors. As can be seen in Fig. 3, the sensitivity of the proposed method increases with increasing cell constant at first, then begins to decrease. The maximum sensitivity was obtained with the cell constant 1.05 cm.

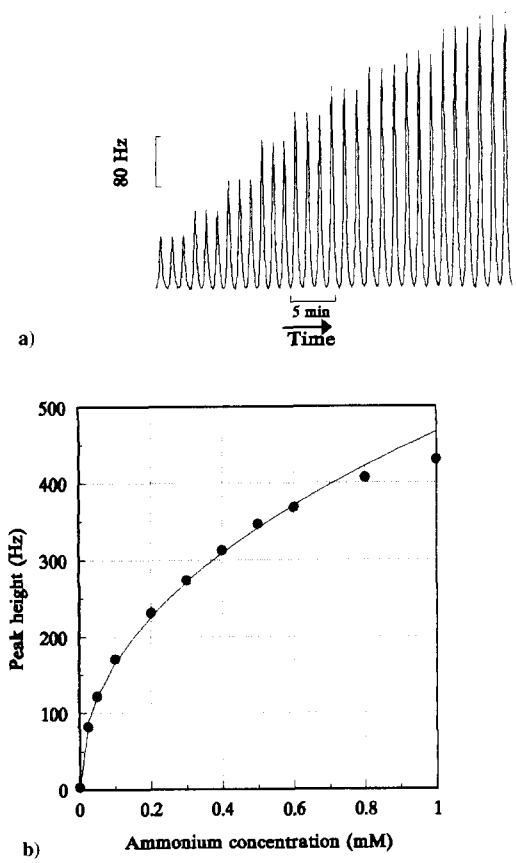

Fig. 5. (a) Calibration run for ammonium standards. From left to right: triplicate signals for 0.025, 0.05, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.80 and 1.00 mM ammonium, respectively. Conditions as given in Fig. 1(a). (b) Calibration graph for the determination of ammonium in Kjeldahl digests.

As shown in Fig. 2(b) and Fig. 3, the proposed system exhibits a favorable response to 5.0×10^{-6}–4.0×10^{-3} mol l^{-1} ammonium, with a detection limit of 1.0×10^{-6} mol l^{-1}. All calibration graphs obtained demonstrate the same features even with different manifold parameters, e.g., the graphs are not linear, and the sensitivity is higher at the lower ammonium concentration.

The influences of sample volume and flow rates are illustrated in Fig. 4 and Table 1, respectively. In Fig. 4, the frequency decrease is plotted as a positive signal to yield a conventional FIA profile, and it is shown that increasing injection volume increased the intensity of the signal, but also increased the time necessary for the signal to return to baseline. As shown in Table 1, the sensitivity is inversely proportional to both of the acceptor flow rate and the donor flow rate, and a significant enhancement of sensitivity can be achieved especially by decreasing the acceptor flow rate. But the sampling rate had to be reduced, for example, when the acceptor flow rate was decreased from 2.0 to 0.15 ml min^{-1} with the same donor flow rate 1.5 ml min^{-1}, a seven-fold enhancement in the signal intensity was achieved, but the analysis time for per sample increased from 1 to 5 min. Additionally, the baseline stability as well as the signal reproducibility became worse. Further experiments lead to the final design of the FIA manifold illustrated in Fig. 1(a), which offered the adequate sensitivity, excellent reproducibility and required throughput for real samples.

3.3. Potential interference

The interference arises from the presence of those substance that can pass through the membrane and then cause change in conductivity of the acceptor solution. It has been established previously that PTFE membranes used in the FIA gas-diffusion studies are effective barriers for ionic species [14,15]. In the described method,

Table 3
Results for nitrogen and protein determination[a]

Sample	Nitrogen (%)		Protein (%, g ml^{-1})	
	Proposed method	Conventional method[b]	Proposed method	Conventional method[b]
Glycine	18.90 ± 0.16	19.21 ± 0.28		
DL-aspartic acid	10.73 ± 0.09	10.87 ± 0.15		
L-glutamic acid	9.72 ± 0.07	9.54 ± 0.19

γ-Globulin injection			10.37 ± 0.10	10.28 ± 0.26

[a] All measured results are average values with standard deviations from five determinations of the same digest.
[b] Distillation/titration method.

with the use of alkaline reagent, the interference from volatile acids is negligible, and with addition of the complexing agent EDTA into the alkaline reagent, interference from the metal ions, which can form hydroxide precipitates with the alkaline reagent, can be prevented [3,6]. A test of interference from some volatile amines is given in Table 2, the thresholds were obtained at an interference level (relative error > 5%) considering the precision of the proposed method is within 1% RSD (described below). It is shown that the interference from methyl-, dimethyl-, and diethylamine had to be considered if these volatile amines present at levels of 10–20% of ammonium, and *n*-butylamine and cyclohexylamine interfere if present at 50–100% of ammonium.

3.4. Analysis of samples

The described method was applied to the determination of ammonium in Kjeldahl digests obtained from amino acids and blood products. As the volatility of ammonia depends on its solubility and partial pressure which in turn are influenced by temperature, pressure and ionic strength, a constant temperature bath was used, and standards as well as blanks for these determinations were prepared to contain sulfuric acid, potassium sulfate and cupric sulfate at concentrations similar to those of the samples. A typical output for standards in the range 0.025–1.0 mM is shown in Fig. 5(a). The calibration graph is not linear (Fig. 5(b)), it fits the following equation:

$$y = 461.3x^{0.45}$$

where y is the height of the FIA profile (the maximum frequency decrease in Hz) and x the ammonium concentration in mM. Table 3 shows that results for nitrogen determination in amino acids and for proteins determination in blood products are in good agreement with those obtained by the conventional and distillation/titration method, respectively, and the average precision of the proposed method is within 1% (RSD), better than that of the titration method.

4. Conclusion

For an overall evaluation of the GD-FIA/BAW-impedance sensor system for the ammonium determination, a comparison of the proposed method and other methods is given in Table 4. GD-FIA provides a selective, precise and rapid determination of ammonium in Kjeldahl digests. In combination with BAW-impedance sensor, the method proposed here has some advantages over other detection modes, e.g., the reagents and equipment required are simpler and cheaper than that required by spectrophotometric method, the background conductivity of the acceptor stream can improve the detection sensitivity while it may cause an unacceptable noise level in the conductometric method, and the stability of the analytical signals is better than that of the signals obtained by the conductometric method or potentiometric method. The advantages of the new method, GD-FIA/BAW-impedance sensor system, should make it an attractive alternative to

Enhanced spectrophotometric determination of chromium (VI) with diphenylcarbazide using internal standard and derivative spectrophotometry

Katarzyna Wróbel *, Kazimierz Wróbel, Pedro Luis López-de-Alba, Leticia López-Martínez

Instituto de Investigaciones Científicas, Universidad de Guanajuato, 36000 Guanajuato, Mexico

Received 4 December 1996; received in revised form 11 March 1997; accepted 12 March 1997

Abstract

In the present work, erioglaucine A was applied as internal standard to enhanced spectrophotometric determination of chromium (VI) with diphenylcarbazide. The following procedure was used: (1) addition of internal standard and formation of ion pairs of Cr (VI) with benzyltributylammonium bromide (BTAB) (sample volume 100 ml), (2) extraction to 10 ml of methylene chloride, (3) evaporation in nitrogen stream, and (4) redissolution in a micro-volume with addition of diphenylcarbazide for color development (final volume 200 μl). The preconcentration factor achieved was about 400 and it was shown that, using internal standard, the analytical errors due to sample treatment were reduced. The analytical signals for chromium and internal standard were obtained at 591.30 and 653.50 nm from first derivative spectra, normalized against $^{1}D_{653.50nm}$. The analytical characteristics evaluated were: detection limit = 0.06 μg l^{-1}, quantification limit = 0.19 μg l^{-1}, precision for 1 μg l^{-1} 14.2%, and for 10 μg l^{-1} 3.2%, correlation coefficient of linear regression was 0.9985. The proposed procedure was applied to determination of chromium (VI) in tap water. Total chromium was determined by electrothermal atomic absorption spectrometry, the recovery of hexavalent chromium added was then evaluated and compared with the results of the proposed procedure. In this experiment, good agreement was obtained between results obtained by the two methods. © 1997 Elsevier Science B.V.

1. Introduction

Speciation of chromium in environmental and biomedical materials has extensively been studied. The need for such analyses has increased after reports on different biological role of chromium (III) and chromium (VI) species in plants, animals and humans [1–5]. Trivalent chromium is considered as the essential nutrient, because of its specific action in metabolism of carbohydrates [6,7]. On the other hand, strong evidence exists on chromium (VI) toxicity. The mechanism of this toxicity is often related with the formation of free

PII S0039-9140(97)00092-1

radicals during the reduction of Cr (VI) occurring inside the cells [6,8]. Thus, for reliable evaluation of environment contamination with chromium, the selective and sensitive analytical tools are needed for discrimination and quantification of different chromium species. Great majority of the procedures reported for chromium speciation in natural waters include preconcentration and/or separation step prior to detection. Extraction [5,9–11], high performance liquid chromatography (HPLC) [2–4,12], sorption on membranes [13,14] or in microcolumns [1,15–18] in flow system were used for separation, and detection was carried out by spectrophotometry or atomic spectroscopy techniques. Spectrophotometric detector has some advantages over the atomic spectrometry. It is more available, easy to automation and to on-line interface with separation system. Although the detection limit for direct spectrophotometric determination of hexavalent chromium with diphenylcarbazide is relatively poor (10 μg l^{-1} [12]), this reagent has been frequently applied in speciation studies. Thus, post column derivatization was used for spectrophotometric detection of chromium (VI) in ion chromatography [19,20], and in flow analysis [1,13,14,18].

On the other hand, the extraction-spectrophotometric procedures were reported for hexavalent chromium, based on the ion pair formation with some surfactants [21–23]. Recently, we have shown that addition of internal standard (IS) at the beginning of such complicated, many-steps spectrophotometric procedure had improved the analytical performance [24]. In the cited work, analytical errors due to sample manipulation were reduced by taking the ratio of analyte to internal standard signals. First derivative spectral data were obtained to assure better resolution of absorption signals corresponding to analyte and internal standard.

In the present work application of internal standard is proposed for extraction-spectrophotometric determination of hexavalent chromium at ppb level. The preconcentration was carried out by extraction of ion pairs (Cr (VI)-benzyltributylammonium bromide) to organic phase, evaporation, and redissolution in the micro-volume. Diphenylcarbazide was used for spectrophotometric detection.

2. Experimental

2.1. Apparatus

A Spectronic 3000 Diode Array Milton Roy spectrophotometer was used (resolution 0.35 nm), coupled to a 486 PC. User Data version 2.01 (Milton Roy Inst. Co.) software was used for acquisition, storage and manipulation of spectral data. All data treatment operations was carried out using a Hewlett-Packard Vectra 486/66 VL microcomputer equipped with the GRAMS/386 TM software package, version 3.01A (Galactic Ind. Co., Salem, MA).

A model 3110 Perkin-Elmer atomic absorption spectrometer with HGA 600 and autosampler AS60 was used.

2.2. Reagents

Chromium (VI) stock solution, 1000 mg l^{-1}, was prepared by dissolving 2.8287 g of $K_2Cr_2O_7$ in deionized water and diluting to a final volume of 1 l. Working solutions were prepared daily by appropriate dilution.

A stock diphenylcarbazide solution, 0.25% in acetone, was prepared daily from Merck reagent.

Hexadecyltrimethylammonium bromide (CTAB) was from Sigma and benzyltributylammonium bromide (BTAB) was from Aldrich. Stock solutions, 2%, were prepared of the two surfactants.

Phosphate buffer solution (1 mol l^{-1}, pH 4) was prepared from the respective sodium phosphate salts (Sigma) with addition of CTAB or BTAB (final concentration 1.0%).

Sulphuric acid solution (2 mol l^{-1}) was prepared by diluting the concentrated acid (Aldrich) in deionized water.

Erioglaucine (A) solution, 0.1%, was prepared from analytical grade reagent (J.T. Baker Chemicals) by dissolution in deionized water. Working solution contained 2.5 10^{-4}% of erioglaucine (A) and was prepared daily.

Methylene chloride, acetone, methanol, formamide, butanol, chromium (III) chloride, copper sulphate, mercury (II) sulphate, sodium molybdate, sodium sulphate and sodium chloride were from J.T. Baker Chemicals.

Deionized water (Labconco) was used throughout.

2.3. Procedures

For calibration, a series of solutions containing different chromium concentrations was prepared in separatory funnels by adding 0, 10, 20, 50, 100, 150 and 200 μl of intermediate Cr (VI) standard (10 mg l^{-1}) to 100 ml of deionized water. Then, exactly 200 μl of working erioglaucine (A) solution (IS), about 4 ml of phosphate buffer solution (containing BTAB or CTAB) and about 1 ml of butanol (to improve phases separation) were added to each funnel. Extraction was carried out with 10 ml of methylene chloride. After separation of phases, the organic phase was collected in test tubes, which were then placed in water bath (40°C). A glass capillary was introduced to each tube, through which the nitrogen stream was passed to evaporate organic solvent. Then 500 μl of acetone was added and evaporated (to eliminate traces of methylene chloride). The dry residue was redissolved in 80 μl of acetone and color was developed by adding 100 μl of diphenylcarbazide solution and 20 μl of sulphuric acid. The absorption spectra were recorded in the wavelength range 450–700 nm against acetone with diphenylcarbazide as a blank. The obtained spectra were smoothed through 21 experimental points and first derivative spectra were calculated ($\Delta\lambda = 9$ nm) using the Savitzky-Golay procedure [25]. The derivative spectra were normalized against the derivative absorbance at 653.50 nm (IS) and the analytical signals of chromium were obtained as the difference between derivative absorbances taken from normalized spectrum of calibration sample and from normalized spectrum of IS at 591.30 nm.

Tap water was spiked with hexavalent chromium (2, 4 and 8 μg l^{-1}) and analyzed using the same procedure (five repetitions).

These same samples of tap water were analyzed for total chromium by electrothermal atomic absorption spectrometry (conditions given in Table 1). Recovery of hexavalent chromium added (2, 4 and 8 μg l^{-1}) was evaluated.

3. Results and discussion

Diphenylcarbazide is commonly used for spectrophotometric determination of hexavalent chromium. However, the determination at ppb levels requires many fold preconcentration of the analyte. In several papers, the separation/preconcentration of Cr (VI) was achieved by extraction of ion pairs formed between chromium (VI) and different cationic surfactants [21–23,26]. In the present work two quaternary ammines: hexadecyltrimethylammonium bromide (CTAB) and benzyltributylammonium bromide (BTAB) were used for such purpose. Chromium preconcentration was carried out in two steps:

1. extraction to organic phase
2. evaporation of organic solvent and dissolution of the residue in the micro-volume.

3.1. Simultaneous measurement of chromium (VI) with diphenylcarbazide and of internal standard by derivative spectrophotometry

In this work erioglaucine (A) was tested as internal standard and, in Fig. 1, first derivative spectrum of chromium with diphenylcarbazide and first derivative spectrum of erioglaucine (A) are shown. Quite good spectral resolution of the two compounds can be observed in this figure: analyte derivative spectrum has a minimum at 591.30 nm and derivative spectrum of erioglaucine

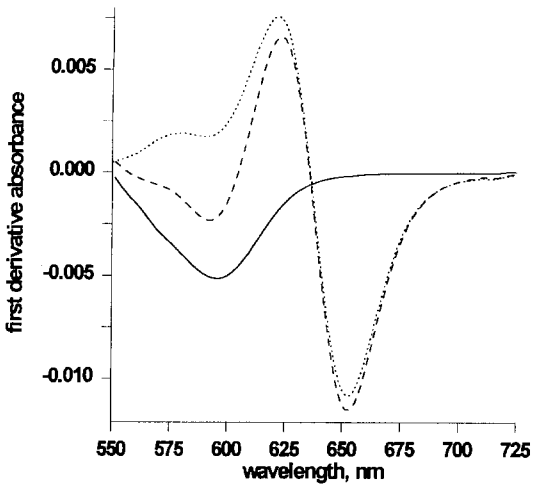

Fig. 1. First derivative spectra of preconcentrated samples: (—) 10 μg·l^{-1} chromium with diphenylcarbazide, (• • •) 5·10^{-7}% IS (erioglaucine (A)), (- - -) 10 μg·l^{-1} chromium with diphenylcarbazide + IS.

(A) has a minimum at 653.50 nm. Zero-crossing conditions exist for IS at 653.50 nm (spectral contribution of the analyte at this wavelength is zero). However, taking analytical signal of chromium at 591.30 nm (spectral minimum), some spectral contribution of erioglaucine (A) can be observed. So, the signal obtained for IS at this wavelength should be rested from the signal obtained for sample containing chromium (VI) and IS. First derivative spectra of IS and of samples containing chromium and IS were normalized against first derivative absorbance at 653.50 nm (Fig. 2). Chromium analytical signal was evaluated as a difference between $^1D_{Cr+IS}$ (first derivative absorbance taken from the normalized derivative spectrum of sample containing chromium (VI) and IS internal standard at 591.30 nm after color development with diphenylcarbazide) and $^1D_{IS}$ (first derivative absorbance taken from the normalized derivative spectrum of IS). The value of $^1D_{IS}$ at 591.30 nm was 0.1541 ± 0.0007 (calculated for 10 repetitions). Under such measurement conditions erioglaucine (A) was used as internal standard in further studies. It was observed that spectrum of erioglaucine (A) was not affected in the presence of: Cr (VI), Cr (III), quaternary amines studied, humic acid, alkaline and alkaline earth metal ions, using their concentrations up to 5000 times higher than that of erioglaucine (A). Moreover, erioglaucine (A) is not a natural component of tap water.

3.2. Preconcentration by extraction

At first, effect of contra-ion on the extraction of hexavalent chromium and erioglaucine (A) was studied. Extraction yields of chromium (VI) and of erioglaucine (A) are presented in Fig. 3, as a function of BTAB or CTAB concentrations. It can be observed that, with increasing concentration of contra-ion in aqueous phase, the extraction yield of chromium increased up to 60% for 0.04% CTAB and up to 82% for 0.04% BTAB. It can also be observed in Fig. 3, that extraction yield of erioglaucine (A) increased in the presence of BTAB and CTAB. It seems possible that sulfonic groups in the molecule of erioglaucine (A) could contribute in formation of ion pairs with cationic contra-ions. Increasing concentration of BTAB had very similar effect on extraction of erioglaucine (A) and chromium (VI) (Fig. 3a) and this effect was more pronounced than effect observed in the presence of CTAB (Fig. 3b). The

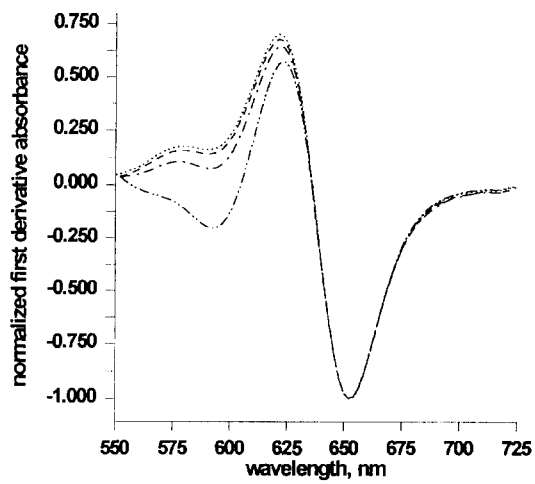

Fig. 2. First derivative spectra of preconcentrated samples, normalized against $^1D_{653.50nm}$. (• • •) 5·10^{-7}% IS (erioglaucine (A)), (- - -) 1 μg·l^{-1} chromium with diphenylcarbazide + IS; (– • –) 2 μg·l^{-1} chromium with diphenylcarbazide + IS; (– •• –) 10 μg·l^{-1} chromium with diphenylcarbazide + IS.

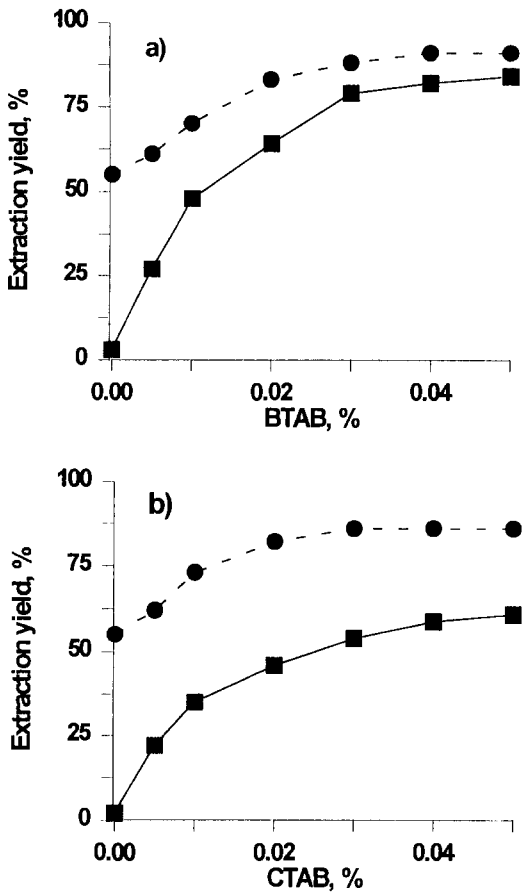

Fig. 3. Extraction yields of: (-■-) hexavalent chromium (0.1 $mg \cdot l^{-1}$) and (-●-) erioglaucine (A) ($5 \cdot 10^{-5}$%) in the presence of: (a) BTAB and (b) CTAB. Aqueos phase: 100 ml, pH 4; Organic phase: 5 ml methylene chloride.

obtained results indicate that using BTAB, the possible extraction errors should be eliminated if relating the analytical signal of chromium to that of IS.

Effect of pH on extraction of chromium and IS in the presence of CTAB and BTAB was also studied. For extraction of chromium (VI), the maximum pH was selected, for which the extraction yield was still about 60% in the presence of CTAB and about 82% in the presence of BTAB (pH 4). Although redox potential of chromium is pH dependent, natural speciation of Cr (VI)/Cr (III) at pH 4 should not be altered, as reported by Sperling et al. [27]. In the range of pH 2 to 7, the extraction yield of erioglaucine (A) was not afected in the presence of the two surfactants (about 80% with BTAB and about 70% with CTAB). This means that, using erioglaucine (A) as IS, possible changes in extraction yield of chromium due to lack of precise pH control would not be compensate (extraction yield of IS does not depend on pH) and, in the proposed procedure, pH must be exactly adjusted.

For further studies 0.04% of BTAB was selected and extraction was carried out at pH 4. Again, it should be stressed out that using erioglaucine (A) as IS there was no need to control the extraction yield, however pH had to be precisely controlled.

3.3. Preconcentration by evaporation and redissolution

After extraction, the organic phase containing chromium (VI), erioglaucine (A) and excess of BTAB, was introduced to test tube and further preconcentration was carried out by evaporation in nitrogen stream. It was observed that methylene chloride hindered color reaction of chromium (VI) with diphenylcarbazide. In order to remove possible residues of this solvent, 500 μl of acetone was added to the residue in each tube and evaporated. Solid residue was then dissolved in micro-volume of acetone with addition of diphenylcarbazide for color development (final volume 200 μl). Analytical errors due to analyte losses, imprecise dilution, etc., expected in this stage of the procedure, should be compensate by the use of IS method [24].

The final solutions obtained were turbid, probably due to excessive amount of BTAB. Such turbidity problems can be partly eliminated by using derivative spectrophotometry [28], however, studies were carried out to select the most adequate solvent. Turbidity of solutions and sensitivities of chromium determination with diphenylcarbazide in the presence of BTAB (2%) were compared using the following solvents: water, acetone, methanol and formamide. In Table 2 the equations of linear regression calibration of chromium (0–2.0 $mg\ l^{-1}$) obtained in these four solvents are presented. The best solubility of BTAB was ob-

Table 2
Effect of solvent on quantification of chromium with diphenylcarbazide in the presence of 2% BTAB

Solvent	Linear regression equation	Correlation coefficient
Water	$A_{542} = 0.6294c_{Cr} - 0.0302$	0.9996
Acetone	$A_{542} = 0.6314c_{Cr} - 0.0174$	0.9998
Methanol	$A_{542} = 0.4302c_{Cr} - 0.0190$	0.9968
Formamide	$A_{542} = 0.5253c_{Cr} - 0.0187$	0.9987

served in acetone and, as can be seen in Table 2, this solvent enabled the best sensitivity of calibration.

The experimental conditions for the second step of chromium (VI) preconcentration are given in Section 2.3: the residue was dissolved in 80 μl of acetone, 20 μl of sulphuric acid (2 mol l^{-1}) and 100 μl of diphenylcarbazide (0.25%) were added.

Using the described two-step procedure the preconcentration factor of about 400 was achieved.

3.4. Analytical performance of the proposed procedure

As described in Section 2.3 and in Section 3.1, the absorption spectra of final solutions were obtained and processed to calculate analytical signal of chromium (related to IS signal by normalizing spectra against first derivative absorbance at 653.50). The analytical performance of the proposed method was evaluated as recommended by IUPAC [29] and, detection limit, quantification limit, linear range and precision at two chromium concentrations are presented in Table 3. If not using IS the correlation coefficient of linear regression did not exceeded 0.9 and

Table 3
Analytical characteristics evaluated for the proposed procedure

r for linear regression ($P<0.05$)	0.9985
Detection limit	0.06 $\mu g \cdot l^{-1}$
Quantification limit	0.19 $\mu g \cdot l^{-1}$
Linear range	0.2–30 $\mu g \cdot l^{-1}$
Precision for 1 $\mu g \cdot l^{-1}$ of Cr(VI)	14.2%
Precision for 10 $\mu g \cdot l^{-1}$ of Cr(VI)	3.2%

precision for 10 μg l^{-1} of Cr (VI) was about 70%. These results clearly confirm that application of erioglaucine (A) improved analytical performance.

3.5. Interference studies

Effect of foreign ions, possible interfering in chromium (VI) determination in natural waters by the proposed procedure, was studied. To do so, solutions (100 ml, 0.04% BTAB, $5 \cdot 10^{-7}$% IS, pH 4) containing 10 μgl^{-1} of hexavalent chromium and increasing concentrations of: chromium (III), copper (II), mercury (II), iron (III), molybdenum (VI), phosphate, sulphate and chloride ions [1,6] were prepared and the described procedure was carried out. Analytical signals of chromium (VI) were evaluated in the absence and in the presence of the foreign ions: the interference was considered significant if the observed change of chromium signal was higher that 5%. The concentration range of interferents was 20 μg l^{-1}–10 mg$\cdot l^{-1}$ and studies were carried out starting from the highest interferent concentration. The obtained results are presented in Table 4. As can be observed in this Table 4, chromium (III), iron (III), copper (II) and mercury (II) did not interfere significantly up to their concentration of 10 mg l^{-1}. Under experimental conditions selected, the selective extraction of anionic species was achieved (formation of ion pairs with BTAB), thus eliminating possible interferences of cations in reaction of chromium (VI) with diphenylcarbazide. It should be noted that, using alumina for preconcentration of chromium (VI), significant interferences were reported for iron (III) [6], while using our preconcentration system such problem can be partly overcome. However, in our procedure we observed important interferences in the presence of anionic species.

3.6. Analytical results

The proposed procedure was applied to analysis of tap water samples. The average chromium (VI) concentration obtained was 0.3 ± 0.1 μg l^{-1} (5 repetitions). These same samples were also analyzed by atomic absorption spectrometry with

Table 4
Relative signals obtained for 20 $\mu g \cdot l^{-1}$ of chromium (VI) in the presence of foreign ions using the proposed extraction-spectrophotometric procedure

Foreign ions	Concentration of foreign ions, $mg \cdot l^{-1}$							
	0.02	0.05	0.1	0.2	0.5	1.0	5.0	10.0
Cr (III)								1.00
Fe (III)							0.97	0.92
Cu (II)								1.01
Hg (II)							0.96	0.99
Mo (VI)		0.98	0.93	0.82	0.78	0.72	0.65	0.52
SO_4^{2-}				0.97	0.90	0.75	0.70	0.62
PO_4^{3-}				0.98	0.94	0.83	0.79	0.66
NO_3^-						0.97	0.93	0.89
Cl^-						0.95	0.90	0.87

electrothermal atomization and total chromium concentration found was 1.2 ± 0.1 $\mu g\ l^{-1}$. Then, these samples were spiked with chromium (VI) (always 5 repetitions) and recovery experiments were carried out using the proposed procedure and ETA-AAS. The obtained recovery results are given in Table 5: satisfactory recoveries and the good agreement with ETA-AAS results can be observed for the proposed procedure. However, the precision of the proposed method is clearly worse as compared with ETA-AAS.

4. Conclusions

In this work erioglaucine (A) is proposed as internal standard for enhanced spectrophotometric determination of chromium (VI) at ppb levels. About 400-fold preconcentration of the analyte was achieved in two steps:

Table 5
Recovery results of chromium (VI) in tap water using the proposed method and ETA-AAS ($n = 5$)

	Mean recovery ± SD (%)	
Cr(VI) added, $\mu g \cdot l^{-1}$	Proposed method	ETA-AAS
2	110 ± 12	108.3 ± 3.4
4	108 ± 5	105.0 ± 4.2
8	96 ± 5	103.8 ± 2.1

1. extraction of chromium (VI) in the presence of BTAB to methylene chloride
2. evaporation of organic solvent, redissolution in micro-volume of acetone and color reaction with diphenylcarbazide.

It was shown that using IS, the expected analytical errors in such complicated procedure can be reduced. Interferences due to cationic species were partly eliminated, however serious interferences occurred in the presence of anionic species. Quite good analytical performance of the proposed method was obtained (see Table 3) and method was successfully applied for the analysis of tap water.

Abstract

A novel method of solventless extraction has been developed based on a combination of solid phase micro extraction and purge and trap methods. In this technique, a hollow needle with either a short length of GC capillary column placed inside it, or an internal coating of carbon, is used as the preconcentration device. Sampling may be performed on ambient air, on solution, or the solution headspace, by passing the gas or liquid through the device either actively with a syringe, or passively via diffusion. The VOC are sorbed and concentrated onto either the carbon layer, or the liquid stationary phase of the capillary column, within the needle. Placing the needle into a heated GC injection port thermally desorbs the organic compounds directly into the GC without the need for solvent extraction. Results suggest that this procedure provides a rapid and sensitive alternative method to those currently available.

Keywords: INCAT; Microextraction; Organic compounds; Volatile

1. Introduction

Volatile organic compounds (VOC) are found as contaminants in both air and water, at concentrations ranging from 1 ppbv–1000 ppmv (part per billion/million by volume) [1,2]. The presence of these compounds in air has been linked to various health problems [3,4] making the analysis and monitoring of these compounds necessary.

Several methods exist for the analysis of VOC [5]. These methods include solid phase micro extraction (SPME) [6], purge and trap, activated carbon cloth (ACC), [7,8] as well as commercial active and passive samplers manufactured by Perkin-Elmer, SKC and 3 M. Each of these methods is based on the sorption of the VOC by a solid or liquid sorbent followed by either solvent extraction, or thermal desorption prior to analysis by gas chromatography (GC).

Here we introduce a novel method for the sorption and solventless extraction of VOC followed by GC analysis. Inside needle capillary absorption trap (INCAT) is a technique that uses a hollow needle with either a short length of GC capillary column placed inside it, or an internal coating of carbon, as the preconcentration medium. Sampling may be performed on ambient air, on solution, or on the solution headspace, by

passing the gas or liquid through the device actively with a syringe, or passively via diffusion. Organic compounds present in the sample are sorbed onto the deposited carbon sorbent, or the liquid stationary phase of the capillary, within the needle. The INCAT device with the sorbed organic compounds is placed into the injection port of a GC. The rapid heating of the metal needle induces the desorption of the organic compounds. This eliminates the need for a solvent extraction step prior to analysis.

In this paper we introduce the INCAT technique for the analysis of VOC including BTEX compounds (benzene, toluene, ethylbenzene, and xylenes). The use of the INCAT device in either an active or passive sampling mode is demonstrated.

2. Experimental

All reagents used in the preparation of solutions were analytical grade. Water used was purified with a Barnstead NanoPure™ water filtration system using a reverse osmosis-treated feedstock.

Gas chromatography was performed on a Varian Aerograph 2100 GC equipped with a flame ionization detector (FID) and a 30 m × 0.25 mm Supelcowax capillary column (Supelco). Analysis of the BTEX compounds was performed on a Hewlett Packard 5710A GC equipped with a FID. Separation was performed using a 2 m × 3 mm packed column; 5% bentone, 5% isodecylphthalate on Chromosorb W. Stainless steel capillary tubing used in the INCAT devices was purchased from Small Parts (Miami Lakes, Fl).

2.1. Preparation of the INCAT device

The INCAT devices were prepared using tubing with inside diameters of 0.250 and 0.406 mm. A 75 mm length of steel capillary tubing was cut from stock material and the ends sanded smooth. The cut length of tubing was then pressed into the end of a common Luer-Lok™ fitting. The junction was sealed with two part epoxy cement. Within the needle, a 2.5 cm length of GC capillary column (DB-5™) was inserted, and held in place by crimping the circumference of the needle. The short length of capillary column with its internal coating of liquid stationary phase provides the media for the preconcentration of sampled VOC.

As alternate methods, coatings of carbon were deposited within the needle to provide a media for the preconcentration of VOC. Two methods of carbon coating were investigated. In the first, colloidal graphite paint (SPI Supplies, West Chester, PA) was drawn within the needle using a syringe and allowed to dry. The needle was then baked at 175°C for 7 min under a flow of nitrogen to remove any traces of solvent from the paint. In the second method a layer of thermally deposited carbon was applied. Deposition of carbon was effected by passing CH_2Cl_2 through the needle via an aspirator while heating the end of the needle with a torch. A diagram of INCAT devices with the two types of preconcentration media is given in Fig. 1.

2.2. Sampling protocol

Two types of samples were investigated in this work; ambient air and the headspace over an aqueous solution. With the INCAT device, sampling may be carried out either passively or actively. Passive sampling is performed simply by

Fig. 1

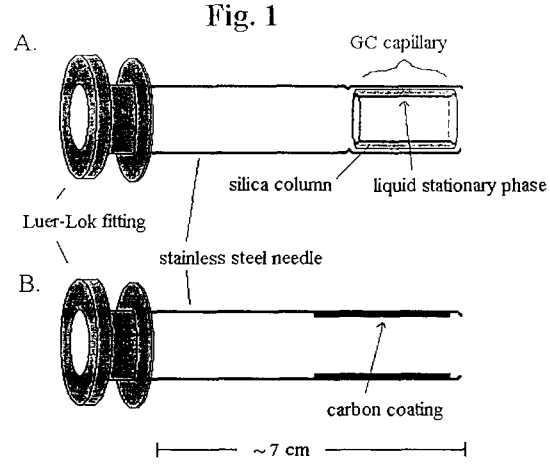

Fig. 1. Diagram of INCAT devices with A; 2.5 cm length of GC column, and B; carbon.

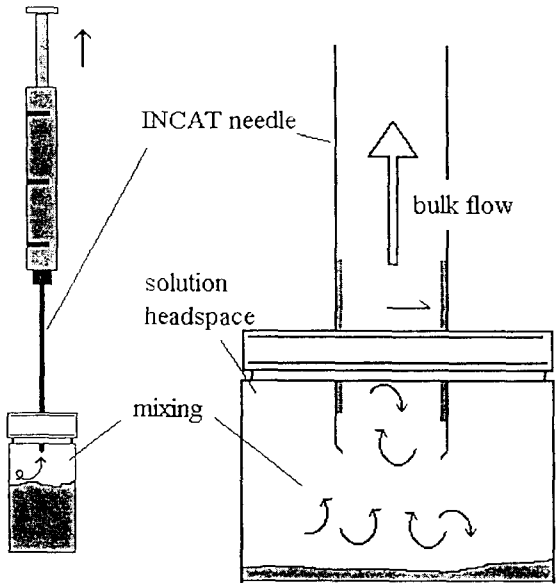

Fig. 2. Diagram showing the active mode of sampling using the INCAT device over the headspace of a solution.

exposing the end of the INCAT device to the sample allowing the sample to diffuse into the needle and onto the sorbent within. Active sampling (Fig. 2) is performed by drawing the sample through the device with either a syringe or pump. In both cases, the VOC are sorbed and concentrated onto the inner surface of the device. Chromatographic analysis of sorbed VOC is performed by clamping a piece of GC septum within the end of the INCAT device at the Luer-Lok™ fitting and then placing the needle into the heated injection port of a GC. Thermal desorption of the VOC then occurs directly within the injection port allowing chromatographic analysis. A desorption temperature of 175°C was used with the time of desorption fixed at 15 s. A cleaning step involving heating the INCAT device to temperatures greater than 175°C between injections eliminated the possibility of sample carryover.

3. Results and discussion

3.1. Headspace sampling of benzene in water

The INCAT technique is based upon the premise that if one could expose a short length of a GC capillary column to a sample of interest and re-connect the column to the GC for analysis, then a very easy and sensitive means of analysis may be obtained. INCAT devices were thus constructed with 2.5 cm lengths of GC capillary columns and tested. Preliminary results indicated that the devices performed well. A chromatogram obtained from the headspace sampling over a saturated solution of benzene in water is given in Fig. 3. The chromatogram shows only the peak for benzene (Rt = 5.4 min) and no peak due to the presence of water in the sample injected. A large degree of peak tailing was observed with the

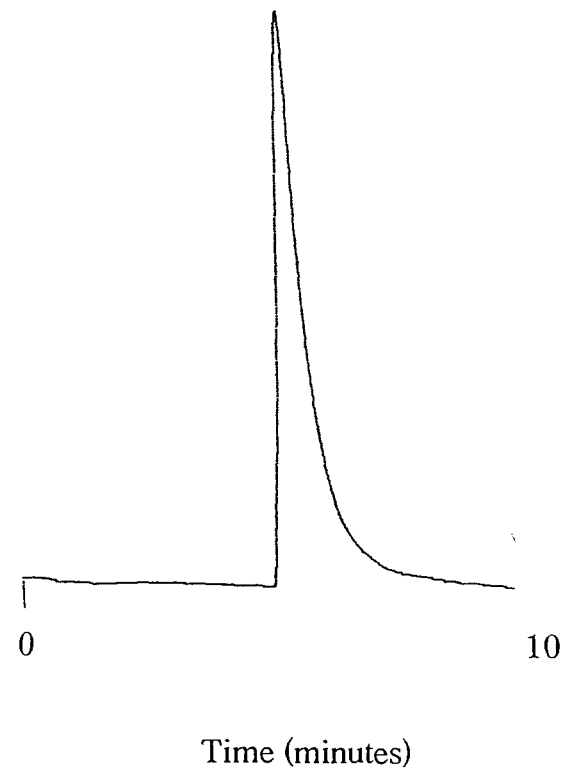

Fig. 3. Chromatogram from the headspace sampled over a saturated solution of benzene in water. Conditions: passive sampling of headspace for 7 min.

initial INCAT devices. This indicated that the transfer of heat from the injection port of the GC to the capillary within the INCAT device was a relatively long process. Initial experiments performed indicated that the time and temperature of desorption were optimized at 15 s and 175°C. Desorption temperatures lower than 175°C and desorption times of less than 15 s resulted in peak tailing due to insufficient heating of the INCAT device within the injection port. Desorption temperatures greater than 175°C or desorption times longer than 15 s did not result in any significant improvement. This resulted in less than a 5% carryover during replicate sampling with the same INCAT device. A cleaning step which involved flushing the INCAT device with N_2 at 175°C for 60 s eliminated the 5% sample carryover between injections.

3.2. Passive and active sampling

Passive diffusive sampling was investigated as it has the same accuracy in analysis as active sampling but does not require the use of a syringe or pump [9]. The analyte is allowed to passively diffuse into the needle and concentrate onto the sorbent within. The limiting step in this case is the diffusion of the analyte from the sample through the end of the needle, a process which may be used to calibrate the passive monitoring of VOC in ambient air [10].

The precision of replicate sampling with a single INCAT device was examined for the passive sampling of the headspace over a saturated solution of benzene in water. The results are presented in Table 1 for sampling times of 3 min. The error involved, ~7% RSD, was attributed primarily to differences in the manual sampling technique in replicate injections which could be improved with automation. However, this precision is sufficient to allow the application of the INCAT device for the passive monitoring of VOC in ambient air [11].

The headspace of a saturated solution of benzene in water was sampled passively for increasing periods of exposure up to 45 min. The amount of benzene sorbed was found to be dependent on the time of exposure. The results are presented in Fig. 4. Initially, a linear correlation is observed with the concentration of benzene in solution, up to ~5 min of exposure ($R^2 = 0.998$). Overall, the sorption profile indicates that after 45 min, saturation or equilibrium has not been reached. This suggests that long exposure times may be possible in an environmental setting without the problems associated with saturation.

Headspace sampling of a saturated solution of benzene in water. Conditions: passive sampling, 3 min exposure.

With active sampling the analyte is drawn through the INCAT device with a syringe at a fixed rate as indicated in Fig. 2. This results in the active transfer of the analyte from the sample through the INCAT device and effectively eliminates the time required for the analyte to diffuse

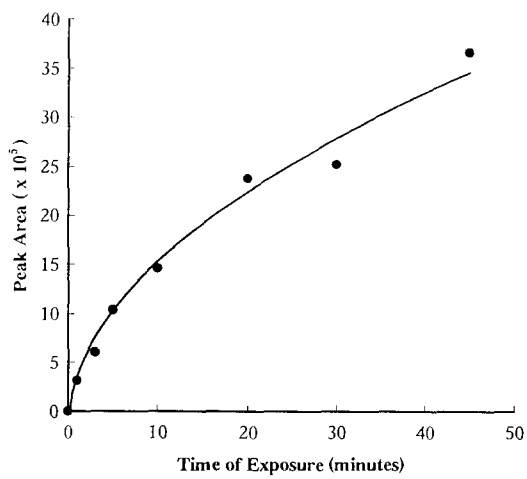

Fig. 4. Sorption characteristics with respect to the time of sampling over a saturated solution of benzene in water. Conditions: passive sampling of headspace.

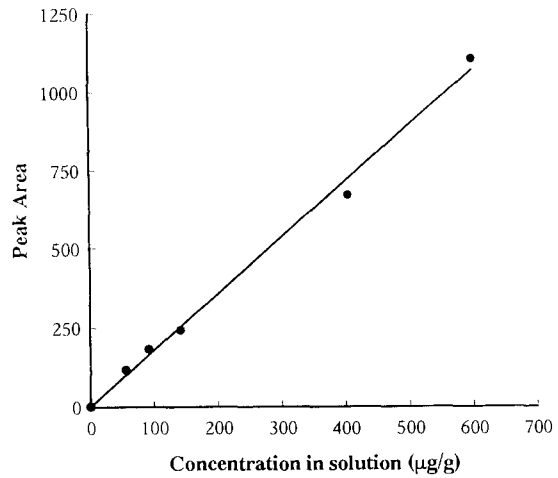

Fig. 5. Concentration dependence on sampling of 1,1,1-trichloroethane. Conditions: active sampling, 50 ml of headspace withdrawn during 60 s.

from the sample to the preconcentration media. Active sampling increases the speed of analysis considerably compared with passive diffusion sampling in which the rate limiting step in sampling is the diffusion of the analyte to the surface of the sorbent.

The dependence of sampling on the concentration of an analyte in solution was investigated. Active sampling of the headspace over solutions containing increasing amounts of 1,1,1-trichloroethane in water was performed. Approximately 50 ml of the headspace was passed through the INCAT device over a 60 s interval using a gas-tight syringe. The 50 ml sample and the 60 s time interval were chosen to ensure that enough sample passed through the INCAT device for analysis. Other sample sizes and times were not investigated at this time. A linear correlation was observed with respect to the initial concentration in solution, $R^2 = 0.998$ (Fig. 5). These results indicate that quantitative analysis is possible with the INCAT device in an active sampling mode.

The active mode of sampling was found to be superior to the passive sampling mode in the case of headspace sampling. This was due to the shorter time required to take up a sufficient amount of sample for analysis by GC in the active mode. In passive sampling the rate of diffusion of the analyte through the end of the needle is slow relative to the rate of analyte transfer within the needle itself during active sampling. This slow rate of sampling in the passive mode is advantages for the determination of long term average concentrations of VOC in air.

3.3. Carbon coated INCAT devices

Use of carbon as the extraction media was investigated as an alternative to the internal piece of GC capillary column. The choice of a carbon sorbent was based upon a number of criteria, foremost of which was the experience in our laboratory with carbon-based passive monitors for VOC in air [7,8]. As well, carbon as a sorbent has several advantages over that of a liquid stationary phase. Carbon fibres exhibit a high level of saturation (> 20% weight of fibre) [12,13] which is greater than the liquid stationary phase available with a short length of gc column. Activated carbon monitors have been found to be essentially independent of temperature and pressure fluctuations during sampling [14–16]. Carbon based coatings have been used previously with SPME for the analysis of environmental air samples [17]. Use of the carbon coating resulted in an improvement in the desorption of VOC from within the INCAT device. This was attributed to an increase in thermal conductivity of the thin carbon film in comparison with the relatively thick fused silica layer and liquid stationary phase of the capillary column.

A colloidal graphite-coated INCAT device was compared with an uncoated INCAT device for the analysis of the headspace over a saturated solution of BTEX compounds. Sampling was performed actively by passing ~ 5 ml of headspace over a 60 s interval using a gas-tight syringe. A 1.0 ml direct injection of the aqueous sample was also performed for comparison. The results in Fig. 6 illustrate that the coated INCAT device performed well in comparison with the uncoated device and the direct injection. The uncoated INCAT device was essentially used as a blank, demonstrating the effectiveness of the graphite-coated INCAT device. The peak due to the presence of water in the direct injection (Rt = 2.5 min)

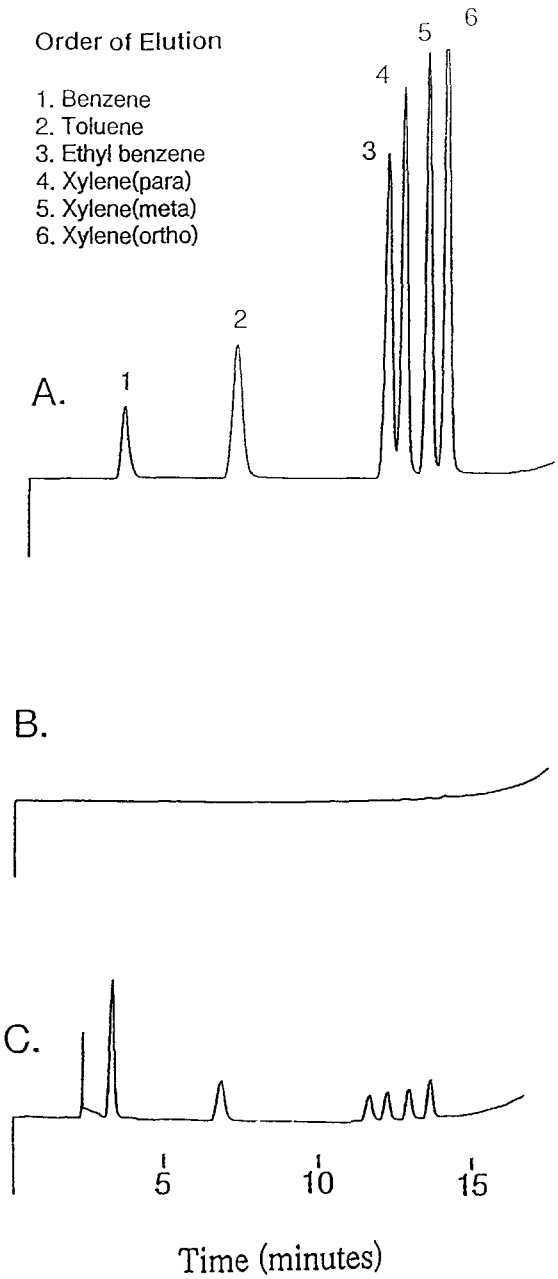

Fig. 6. Comparison between A; colloidal graphite coated INCAT device, B; blank needle and, C; 1.0 μl direct injection of BTEX compounds. Conditions for A and B: active sampling, 5 ml headspace withdrawn through the needle over 60 s; saturated solution of BTEX compounds in water; equivalent GC parameters.

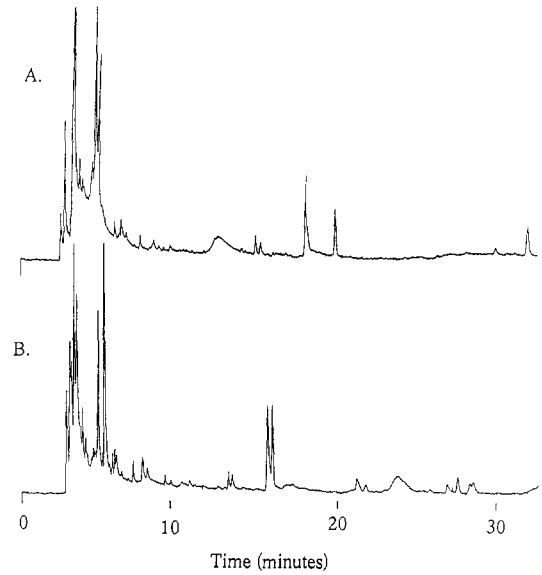

Fig. 7. Chromatograms from a thermally deposited carbon coated INCAT device exposed to ambient air. Sampling locations were: A; the laboratory and B; solvent storage cabinet. Conditions: passive sampling for 24 and 2 h, respectively.

is absent in the chromatograms of both the INCAT injections indicating that water is not taken up by the INCAT device in an observable amount.

The possibility of using the INCAT device as a passive monitor for VOC in air was examined using a needle with thermally deposited carbon. An INCAT device was left exposed to ambient air at various locations within our laboratory and then analysed by GC. Sampling was performed passively with the duration of exposure fixed at 24 h. The chromatogram is given in Fig. 7(a). Several similar chromatograms were obtained at different sampling locations within the laboratory. A chromatogram derived from exposing one of the INCAT devices to the inside of a solvent storage cabinet for 2 h is given in Fig. 7(b). These results indicate that a number of compounds may be taken up by the device in sufficient quantities for analysis by GC. These results demonstrate the feasibility of using the INCAT device as a method for the passive monitoring of VOC in air. Passive sampling of ambient air was attempted using a graphitized carbon without success. This was pre-

sumably due to the lower surface area of the colloidal graphite as compared with the thermally deposited carbon.

4. Conclusions

It is noted that these results are still preliminary. However, some of the possible advantages of such a device are given here. The INCAT device is mechanically simple with no moving parts and inexpensive to produce. The use of solventless extraction ensures maximum sensitivity in analysis. The active mode of sampling with its short diffusion path length may provide for more rapid analysis times in the laboratory as compared with passive diffusive sampling. The passive mode of sampling with a 7% error in replicate measurements would allow for the passive monitoring of VOC in the environment.

Results suggest that the INCAT device may provide for a rapid and sensitive alternate method for the analysis of VOC in both air and water samples in either an active or passive sampling mode. We are currently investigating the physical characteristics and possible applications of this device.

Liquid–liquid distribution of ion associates of tetrabromoindate(III) with quaternary ammonium counter ions

Koichi Yamamoto *, Akiko Matsumoto

Department of Materials Science, Yonago National College of Technology 4448, Hikona-cho, Yonago-shi, Tottori 683, Japan

Received 17 January 1997; received in revised form 18 March 1997; accepted 19 March 1997

Abstract

The solvent extraction of an ion associate of tetrabromoindate(III) ion, $InBr_4^-$, with quaternary ammonium cations (Q^+) has been studied. The extraction constant (K_{ex}) were determined for the ion associates of $InBr_4^-$ with Q^+ between an aqueous phase and several organic phases (chloroform, chlorobenzene, benzene and toluene). A linear relationship was found between log K_{ex} and the total number of carbon atoms in Q^+; from the slope of the lines, the contribution of a methylene group to log K_{ex} was calculated to be 0.91 for the chloroform extraction system and 0.52 for the other extraction systems. The extractability with alkyltrimethylammonium cations was larger than that with symmetrical tetraalkylammonium cations and the mean difference in log K_{ex} for two cations (one of each type) with the same number of carbon atoms was about 1.3. From the extraction constant obtained, the extractability of $InBr_4^-$ among metal-halogeno complex anions was in the order $TlBr_4^- > BiI_4^- > AuBr_4^- > AuCl_4^- > TlCl_4^- > InBr_4^- > CuCl_2^-$. © 1997 Elsevier Science B.V.

Keywords: Solvent extraction; Tetrabromoindate(III); Quaternary ammonium ion; Ion association

1. Introduction

An extraction of indium from an aqueous halide medium into an organic solvent has been frequently used for the spectrophotometric determination of indium. Suzuki et al. reported on the extraction of indium from hydrobromic acid solutions [1] or potassium iodide-sulfuric acid solutions [2] with xylene solution of a high molecular weight amine and its determination. Light-absorbing cationic dyes, such as Malachite Green [3], Victoria Blue [4,5], Pyronine G [6,7], Rhodamine B [8], Ethylrhodamine B [9] and Butylrhodamine B [8,10] have been used as a counter ion of indium bromo complex anions, thus providing sensitive extraction-spectrophotometric methods for indium. However, the extraction behaviour of indium bromo complex anion has not yet been examined in quantitative form.

In the present work, the extraction constants for the ion-associates of tetrabromoindate(III) anion with various quaternary ammonium counter-ions distributed between aqueous and four organic phases (toluene, benzene, chlorobenzene and chloroform) were determined and correlated with the number of carbon atoms in the counter

ions. Extractability of tetrabromoindate(III) was compared with that of other metal-halogeno complex anions. The information concerning the extraction constants and the extractability for tetrabromoindate(III) are useful for designing the novel extraction systems for the separation and determination of indium.

2. Experimental

2.1. Apparatus

A JASCO Uvidec-430 spectrophotometer was used for recording spectra and absorbance measurements in quartz cells of 10 mm light-path length. The pH values were measured with a Hitachi-Horiba (Model F-8 dp) pH-meter. An Iwaki (Model V-SX type KM) shaker was used for horizontal shaking of the 25 ml stoppered test-tubes for extraction.

2.2. Reagents

A standard indium(III) solution (8.71×10^{-4} M) was prepared by diluting 10 ml of a 1000 ppm standard indium(III) solution (8.71×10^{-3} M indium in a 0.5 N nitric acid, Wako Pure Chem.) to 100 ml with distilled water. Hydrobromic acid was used for the formation of a indium(III)-bromo complex. Quaternary ammonium ion (Q^+) solutions were prepared from the salts listed in Table 1, after drying under reduced pressure. Accurately weighed amounts of the dried salts were dissolved in distilled water to give stock standard solutions, which were diluted before use. 1-(2-Pyridylazo)-2-naphthol (PAN) solution (0.1 wt./vol%) was prepared by dissolving 0.1 g of PAN in 100 ml of ethanol. Commercially available toluene, benzene, chlorobenzene and chloroform were used without further purification, and were saturated with distilled water before use. All of the reagents were of analytical-reagent grade and were used as received.

2.3. Procedure

One ml of a 8.71×10^{-4} M indium(III) solution was transferred to a 25 ml stoppered test tube. To it, 3 ml of a concentrated hydrobromic acid solution (8.59 M) was added. The volume of the solution was brought to 5 ml by adding an appropriate amount of aqueous quaternary ammonium salt solution. The aqueous solution was mechanically shaken with 5 ml of an extracting solvent for 20 min at 25°C. After phase separation, the aqueous phase was used for the determination of indium by the extraction-spectrophotometric method with PAN.

Transfer 2 ml of the aqueous solution into a 50 ml beaker and add 18 ml of distilled water and 1 ml of 0.1 wt./vol% PAN solution. Adjust the pH range of the solution to about 5.5–5.9 with sodium hydroxide and acetate buffer solutions.

Transfer this solution into a 50 ml separatory funnel and stand for 5 min. Shake this mixture with 10 ml of chloroform. After phase separation, measure the absorbance of the organic phase at 560 nm against chloroform and calculate the concentration of indium in the original aqueous phase by means of a calibration graph.

2.4. Calculation of extraction constants

In the aqueous phase, indium(III) reacts with bromide to form $InBr_n^{(3-n)}$. The stability constants [11] of the indium(III)-bromo complexes $InBr^{2+}$, $InBr_2^+$, $InBr_3$ and $InBr_4^-$ are $\log \beta_{1,1} = 2.08$, $\log \beta_{1,2} = 3.4$, $\log \beta_{1,3} = 4.0$ and $\log \beta_{1,4} = 4.8$, respectively. These complexes are distributed between the aqueous and organic phases:

$$InBr_3 \rightleftharpoons (InBr_3)_o;$$

$$K_D(InBr_3) = [InBr_3]_o/[InBr_3] \quad (1)$$

$$InBr_4^- + Q^+ \rightleftharpoons (Q^+ \cdot InBr_4^-)_o;$$

$$K_{ex}(InBr_4^-) = [Q^+ \cdot InBr_4^-]_o/[Q^+][InBr_4^-] \quad (2)$$

where K_{ex} is the extraction constant; the subscript o refers to the organic phase and the absence of a subscript indicates the aqueous phase.

The distribution ratio of indium between the aqueous and organic phases (D_{In}) is given by

$$D_{In} = \frac{[InBr_3]_o + [Q^+ \cdot InBr_4^-]_o}{[In^{3+}] + [InBr^{2+}] + [InBr_2^+] + [InBr_3] + [InBr_4^-]} \quad (3)$$

The side-reaction coefficient of the complexes of indium(III) with bromide in the aqueous phase, $\alpha In^{3+}(Br^-)$, is given by

$$\alpha In^{3+}(Br^-) = \frac{[In^{3+}] + [InBr^{2+}] + [InBr_2^+] + [InBr_3] + [InBr_4^-]}{[In^{3+}]}$$

$$= 1 + \beta_{1,1}[Br^-] + \beta_{1,2}[Br^-]^2 + \beta_{1,3}[Br^-]^3 + \beta_{1,4}[Br^-]^4 \quad (4)$$

When the total concentration of bromide in the aqueous phase is 5.15 M, the fifth term on the right-hand side of Eq. (4) has the greatest contribution to $\alpha In^{3+}(Br^-)$ by the calculation with the stability constants. Hence it is reasonable to consider that in the aqueous phase almost all the indium(III) is present as $InBr_4^-$, and Eq. (3) can be written as

$$D_{In} = \frac{[Q^+ \cdot InBr_4^-]_o}{[InBr_4^-]} = \frac{[In^{3+}]_i - [InBr_4^-]}{[InBr_4^-]} \quad (5)$$

where $[In^{3+}]_i$ is the initial concentration in the aqueous phase. In the extraction of tetrabromoindate(III), the concentration of indium in the aqueous phase after extraction was determined based on the extraction-spectrophotometric method with PAN and the concentration of indium in the organic phase after extraction was determined by subtracting the concentration of indium in the aqueous phase after extraction from the initial concentration of indium in the aqueous phase. The distribution ratios of indium at different concentrations of the quaternary ammonium ions were calculated from Eq. (5).

Hence, the following Eq. (6) can be derived from Eqs. (2) and (5).

$$D_{In} = K_{ex}(InBr_4^-) \cdot [Q^+] \quad (6)$$

where

$$\log D_{In} = \log K_{ex} + \log[Q^+] \quad (7)$$

The side-reaction coefficient for the quaternary ammonium ion $\alpha Q^+(Br^-)$ is given by

$$\alpha Q^+(Br^-) = \frac{[Q^+]'}{[Q^+]} = \frac{[Q^+] + [Q^+ \cdot Br^-]_o}{[Q^+]} = 1 + K_{ex}(Q^+ \cdot Br^-) \cdot [Br^-] \quad (8)$$

where $[Q^+]'$ is the total concentration of the quaternary ammonium ion that is not bound in ion associates with tetrabromoindate(III) and $K_{ex}(Q^+ \cdot Br^-)$ is the extraction constant of a quaternary ammonium ion with a bromide ion. $[Q^+]$ can be calculated by

$$[Q^+] = [Q^+]'/\alpha Q^+(Br^-) \quad (9)$$

$[Q^+]'$ is evaluated by the following equation:

$$[Q^+]' = C_T(Q^+) - [Q^+ \cdot InBr_4^-]_o \quad (10)$$

where $C_T(Q^+)$ is the total concentration of the quaternary ammonium ion. $[Q^+]$ can be calculated using Eqs. (8)–(10).

3. Results and discussion

3.1. Effect of the concentration of bromide ion

TBA and chloroform were used as a counter ion of an indium(III)- bromo complex and an extracting solvent, respectively. The effect of the concentration of bromide ion on the formation of the indium(III)-bromo complex was examined by determining indium in the aqueous phase after extraction based on the extraction-spectrophotometric method with PAN. The concentration of indium in the aqueous phase first decreased along with an increase in the bromide concentration, and then became constant. Constant absorbances were obtained at 4.29–6.01 M bromide concentration range. Therefore, 5.15 M bromide was used for the formation of the indium(III)-bromo complex and $InBr_4^-$ was the predominant indium species in the aqueous phase.

3.2. Determination of extraction constants

In a low-polarity solvent (its dielectric constant is less than about 10), the extraction equilibrium is simple and is given by Eq. (2) because the dissociation of the ion associate in the organic phase is negligibly small. Toluene, benzene, chlorobenzene and chloroform were used as a low-polarity extraction solvent. In the extraction of tetrabromoindate(III), the distribution ratios of indium at different concentrations of the quaternary ammonium ions were determined. The values of log D_{In} were plotted against log$[Q^+]$; the results for $Q^+ \cdot InBr_4^-$ extraction systems are shown in Fig. 1 (chloroform and chlorobenzene) and Fig. 2 (benzene and toluene). As expected from Eq. (7), straight lines with a slope of 1 were obtained for all of the extraction systems. This means that the extraction equilibrium of Eq. (2) holds, and that the extracted species is $Q^+ \cdot InBr_4^-$. The extraction constants calculated from Eq. (7) are summarized in Table 2; the standard deviation is small.

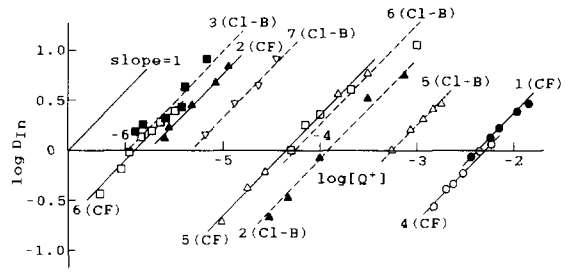

Fig. 1. Plots of log D_{In} vs. log$[Q^+]$. Extracting solvent: chloroform (CF), chlorobenzene (Cl-B); Q^+: (1) TPA, (2) TBA, (3) TAA, (4) OTMA, (5) DTMA, (6) DDTMA, (7) TDTMA.

3.3. Relationship between the extraction constant and the number of carbon atoms in the quaternary ammonium ion

The values of the extraction constants (log K_{ex}) were plotted against the number of carbon atoms in the quaternary ammonium ion (N_c). The results are shown in Fig. 3. For the same carbon number, the extractability (log K_{ex}) with long-chain alkyltrimethylammonium cations (group I) is larger than that with symmetrical tetraalkylammonium cations (group II), and the mean difference in log K_{ex} values between these two groups was about 1.3. The ion association reaction in a low-polar solvent extraction process is based on a hydrophobic interaction and an electrostatic interaction: the effect of the former on the ion association is larger than that of the latter, which contributes to an increase in log K_{ex} value with increasing N_c. However, the differences in log K_{ex}

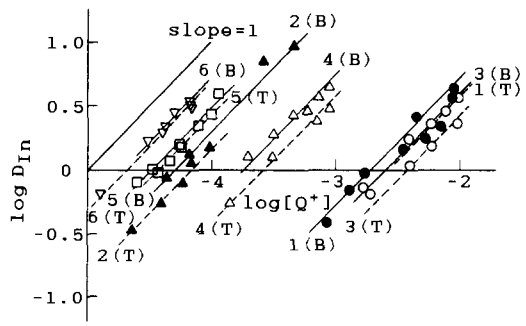

Fig. 2. Plots of log D_{In} vs log$[Q^+]$. Extracting solvent: benzene (B), toluene (T); Q^+: (1) TBA, (2) TAA, (3) DTMA, (4) DDTMA, (5) TDTMA, (6) CTMA.

[c] Ref. [12].

values between these two quaternary ammonium ions for the same carbon number indicates that the electrostatic attraction of the cations in group I for the anionic complex is larger than that of the cations in group II, which can be explained by an effect of a flexibility of a quaternary ammonium ion: the flexibility of the alkyltrimethylammonium ion decreases the distance between the cation and the anion. In the $\log K_{ex}$–N_c plots for the benzene extraction systems, the points for the alkyltrimethylammonium ions having more than 17 carbon atoms (group I–II) deviate from the straight line for those up to 17 carbon atoms (group I–I). In the $\log K_{ex}$-N_c plot for the toluene extraction system, the points for the alkyltrimethylammonium ions having more than 15 carbon atoms (group I–II) deviate from the straight line for those upto 15 carbon atoms (group I–I). These may be because the increment in spread of the hydrophobic alkyl chain of the cations in group I–II is smaller than that of the cations in group I–I. The slopes of the two lines for groups I and II were identical for each extraction system, and from them the contribution of a methylene group to $\log K_{ex}$ ($\Delta \log K_{ex}/-CH_2-$) was found to be about 0.91 for the chloroform extraction system and about 0.52 for the chlorobenzene, benzene and toluene extraction systems on average. The value of $\Delta \log K_{ex}/-CH_2-$ for the chloroform extraction system is larger than those for the other three extraction systems. This may be caused by the effect of the solvation of chloroform on tetrabromoindate(III): tetrabromoindate(III) ion is more solvated by chloroform than by the other extracting solvents, and tetrabromoindate(III) is more easily extracted into chloroform. The values of $\Delta \log K_{ex}/-CH_2-$ for chlorobenzene, benzene, toluene extraction systems are in good agreement with the previously reported values [13–21].

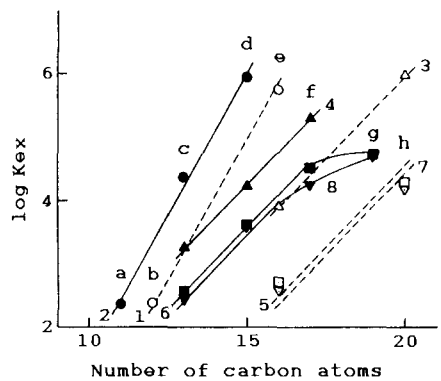

Fig. 3. Relation between $\log K_{ex}$ and the number of carbon atoms in the quaternary ammonium ion. Extracting solvent: (1) and (2) chloroform, (3) and (4) chlorobenzene, (5) and (6) benzene, (7) and (8) toluene; Q^+: (1), (3), (5) and (7) tetraalkylammonium ion (b) TPA, (e) TBA, (h) TAA, (2), (4), (6) and (8) alkyltrimethylammonium ion (a) OTMA, (c) DTMA, (d) DDTMA, (f) TDTMA, (g) CTMA.

Table 3
Extraction constants of ion associates of various metal-halogeno complex anions with octyltrimethylammonium cation in chloroform-extraction

X^-	Metal-halogeno complex	log K_{ex}	Δ log K_{ex}

[a] Ref. [17].
[b] Ref. [18].
[c] Ref. [19].
[d] Ref. [20].

3.4. Extractability of tetrabromoindate(III)

The extraction constants (log K_{ex}) for the 1:1 ion associates of metal-halogeno complex anions with $OTMA^+$ into the chloroform extraction are listed in Table 3. From these values, it was found that the extractability of metal-halogeno complex anions was in the order $TlBr_4^- > BiI_4^- > AuBr_4^- > AuCl_4^- > TlCl_4^- > InBr_4^- > CuCl_2^-$; the differences in log K_{ex} between two metal-halogeno complex anions in this order were 0.02, 0.34, 0.74, 0.57, 1.35 and 0.74.

In the design of new sensitive and selective extraction-spectrophotometric methods for indium utilizing the ion association, the use of the extraction constants and the extractability for tetrabromoindate(III) described above has the advantages of saving of time, low cost and less labour in the experiment, e.g. from the extraction constants obtained, the contribution of some factors to the extraction constants and the extractabilities of cations, anions and extracting solvents, possible extraction systems for a spectrophotometry for indium may be predicted.

Abstract

Carbon-based screen-printed electrodes are suitable for uric acid detection. Xanthine oxidase (XO) was immobilized either directly on the surface of the electrode or in a reactor with CPG aminopropylsilane in a FIA assembly. Higher reproducibility and lifetime was obtained with the reactor. Optimum conditions were found for the determination of Hypoxanthine (Hx), Inosine (HxR) and Inosine monophosphate (IMP). Calibration curves for IMP, HxR and Hx are linear up to 50 μM with detection limit of 1 μM for 50 μl injection. One assay is completed within 30 s. The reproducibility of 20 μM of Hx was obtained with CV 2%. © 1997 Elsevier Science B.V.

Keywords: Screen-printed electrodes; Uric acid detection; Xanthine oxidase; Hypoxanthine detection; Fish freshness

1. Introduction

Rapid non destructive methods would be useful in monitoring fish meat quality during processing, transportation and marketing.

Freshness has been determined on the basis of indicators such as ATP-related compounds which normally don't exist in the living tissues of fish. Adenosine triphosphate (ATP) is decomposed in fish meat, adenosine diphosphate (ADP), adenosine monophosphate (AMP) and related compounds are formed by autolysis and/or microbial actions following the death of fish. ATP is then degraded to uric acid (AU) through the following pathway:

$$ATP \rightarrow ADP \rightarrow AMP \rightarrow IMP \rightarrow HxR \rightarrow Hx \rightarrow X \rightarrow AU$$

Hypoxanthine (Hx) and inosine (HxR) concentrations depend upon the species of fish. Inosine monophosphate (IMP) is one of the major contributing factors to the pleasant flavour of fresh fish. The accumulation of Hx and/or xanthine (X) during the storage results in an 'off-taste'. The concentration of Hx, one of the intermediates of

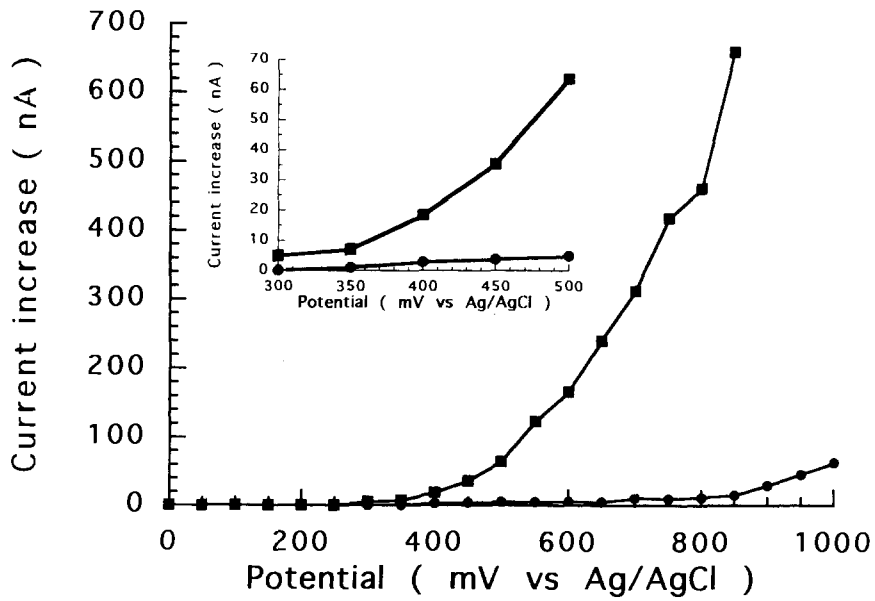

Fig. 1. Hydrodynamic voltammogram of (■) uric acid, 29 μM, and (●) hydrogen peroxide, 3 mM.

these reactions increases with prolonged storage and thus can be used as an indicator of fish meat freshness [1].

Simultaneous determination of these compounds is also necessary for a rapid estimation of freshness.

IMP, HxR and Hx determinations are based on the following enzyme reactions:

$$IMP \xrightarrow{N_T \text{ (or AlP)}} HxR$$

$$HxR + P_i \xrightarrow{N_P} Hx + \text{Ribose} - 1 \text{ Phosphate}$$

$$Hx + 2O_2 \xrightarrow{XO} AU + 2H_2O_2$$

where N_T is 5′-nucleotidase, AlP alkaline phosphatase, N_P nucleoside phosphorylase and XO xanthine oxidase. XO is a flavoprotein which possesses the flavine adenine dinucleotide (FAD) as a cofactor at the active site.

Time consuming, expensive and complex methods such as paper chromatography, anion-exchange chromatography, precipitation, spectrophotometry [2,3] are described for the determination of Hx, X and AU in fish tissue extract.

Electrochemical methods have attracted considerable attention for the determination of Hx and X using an immobilized enzyme-modified oxygen electrode [1,4–12]. Oxygen electrode coupled with bacteria was exploited for evaluation of fish meat quality [13]. These procedures are all based upon the amount of oxygen consumed near the surface of the sensor. A voltammetric procedure for the simultaneous determination of Hx, X and AU has been also reported using a pyrolytic graphite electrode and standard solutions [14]. IMP, HxR and Hx concentrations have been also determined by measuring the hydrogen peroxide formation using a Clark hydrogen peroxide probe [15,16].

An amperometric sensor for Hx and X based on the detection of uric acid with XO adsorbed on a carbon paste electrode has been proposed [17].

Flow Injection Analysis (FIA) has been used combining a reactor with an alkaline phosphatase (AlP) immobilized and a second reactor with a purine nucleoside phosphorylase-xanthine oxidase (N_P–XO) coimmobilized for the determination of purine nucleotides (ATP, ADP, AMP) with a flow through glassy carbon electrode measuring the uric acid produced [18].

A system with double enzyme reactors (XO–N_P and N_T–N_P–XO) coupled with oxygen electrode and FIA apparatus was developed for the determination of fish freshness [19].

An oxygen electrode coupled with three enzymes: 5′-N_T, XO and N_P was introduced in a FIA system at 30°C, pH 7.8 (1.4 ml min^{-1}) for determination of IMP. Calibration curves are linear in the range 1–5 mM for a 50-µl injection [8].

In this paper we report the use in a FIA assembly of a carbon based screen-printed electrode. This sensor is very sensitive and selective for uric acid detection; hydrogen peroxide is not detected by such electrode at the potential of 450 mV (Fig. 1).

The coupling of this disposable sensor with XO enzyme has been realized immobilizing directly the enzyme on the carbon or by use of a glass bead reactor where the enzyme was immobilized. Hx therefore is quantitatively analysed and, by

using the other enzymes in solution (N_P and N_T or AlP), the related compounds, IMP and HxR, could be also evaluated.

Use of real samples indicates that the reactor gave higher reproducible results and with an easy procedure quantitative determination of AU, Hx, HxR and IMP in real samples in few minutes is obtained.

2. Experimental

2.1. Chemicals

Xanthine oxidase (XO) (EC 1. 1. 3. 22; from buttermilk; 0.4 U mg^{-1}; Fluka), 5′-nucleotidase (EC 3. 1. 3. 5; from Crotalus Adamanteus; 110 U mg^{-1}; Fluka), nucleoside phosphorylase (EC 2. 4. 2. 1; bacterial; 9,7 U mg^{-1}; Fluka), hypoxanthine, xanthine, inosine, inosine monophosphate, uric acid, phosphate potassium dihydrogenphosphate, imidazole and BSA were purchased from Sigma Chemical Co., St Louis, MO (USA). Glutaraldehyde (25% aqueous solution) and L-hydrochloride lysine were obtained from Merck.

2.2. Screen-printed electrode

Screen-printing is a simple and fast technique for mass production of disposable electrochemical sensors. These electrodes, single-use, have several

advantages like avoidance of contamination between samples, constant sensitivity and high reproducibility of the different printed sensors. The sensor coupled with enzyme avoided the denaturation effect due to multiple samples.

With this technique, the ink used to print electrodes can be varied easily and therefore different properties of the final sensor can be achieved. Many different inks are commercially available and some of them are based on noble metals. Carbon can also be mixed with different compounds (mediators, enzymes, metal catalytic particles...) and therefore modified sensors and biosensors can be easily mass produced.

The inks can be printed on several kind of supports like glass, ceramic and plastic sheet. In our opinion, the most interesting material for printing electrochemical sensors are the carbon-based inks as they can be printed on plastic sheets at very low firing temperature (from room temperature to 120°C).

Screen-printing technology consists in depositing different inks on a substrate in a film of controlled pattern and thickness. The inks consisted of finely divided particles of different materials in a blend of thermoplastic resins. The printed ink must be heated to polymerize the ink and then it is ready for an ensuing printing step. After every printing step electrodes were heated at 110°C for 10 min.

The screen-printed electrodes were used in a 3-electrode configuration with a Ag/AgCl as reference electrode and a silver electrode as counter. They were realized by several steps corresponding to the deposition of different layers:

- a first layer of silver ink for the conductive pad,
- a carbon pad positioned over a part of the silver track for the working electrode
- a silver/silver chloride over the silver track for the reference electrode
- and finally an insulating layer with openings to allow electrical contact on a polyester flexible film [20].

2.3. Preparation of a XO immobilized electrode

Before enzyme immobilization, the electrode was poised at 1.7 V vs Ag/AgCl for 20 s in order to oxidize the carbon surface. This treatment was found very important for the reproducibility of the biosensor behaviour:

- 3 μl of a solution prepared by mixing
- 20 μl of phosphate buffer 0.05 M pH 7.8 containing 0.023 U XO, 0.015 mg BSA
- and 2 μl of 0.025% glutaraldehyde,

were placed on the carbon surface (geometrical area = 4 mm^2). The membrane was air-dried for about 2 h then washed for 20 min in 0.05 M phosphate buffer pH 7.8 with 0.5 M lysine to remove the excess of glutaraldehyde. The enzyme electrode was stored at 4°C until use. All experiments were performed in 0.05 M Imidazole buffer pH 7.8 containing 50 mM phosphate and 0.1 M KCl.

2.4. Preparation of the XO immobilized reactor

The Xanthine oxidase is immobilized by glutaraldehyde to activated controlled pore glass beads (aminopropyl glass, average pore size 700 Å, particle size 80–120 mesh obtained from Sigma). To a suspension of 50 mg of activated pore glass in 300 μl of buffer, 500 μl of 2.5% glutaraldehyde solution is added. This mixture is gently stirred at room temperature for 1 h, then washed with water. We add 1.2 mg of XO (0.5 U) to the mixture and this is stirred at 4°C for 24 h.

The activated glass (about 20 mg) is packed in Tygon™ tube of 0.60 mm internal diameter and 20 mm long.

The working buffer for the procedure is 0.05 M Imidazole containing 0.1 M KCl and 50 mM KH_2PO_4 at pH 7.8. The reactor is stored at about 4°C in the working buffer when not in use.

2.5. Flow systems and procedure

The system consisted of a pump (Minipuls 3 Peristaltic Pump Gilson), an injector (Rheodyne 5701). An amperometric biosensor detector (Universal Sensors, Inc) was used as potentiostat and connected with an Amel model 868 recorder.

The screen-printed 3 electrode was placed in a suitable flow cell. The working buffer solution is continuously transferred to the flow cell at a constant rate by a peristaltic pump. When the

current reaches a stable value (drift less than 1% in 10 min), a known volume (50 μl) of sample solution is injected through the sampling valve.

2.6. Amperometric determinations

Hypoxanthine and related compounds determination were based on uric acid detection at a potential of 450 mV vs Ag/AgCl with carbon-based screen-printed electrode.

IMP, HxR, Hx and AU standard solutions were prepared by dissolving reagent in Imidazole buffer 0.05 M containing 0.1 M KCl-50 mM KH_2PO_4 and were diluted with the buffer solution. Suitable amount of N_T (or AlP) and N_P enzymes added for the detection of IMP and HxR were optimized according to literature [16].

The 3 electrode system was used in beaker and in the flow cell.

In the beaker, the 3 electrode with immobilized XO was immersed in buffer and standard solution of AU and Hx were added. In the flow system, the 3 electrode was loaded into the flow cell and the standard solutions were injected.

Calibration curves were therefore obtained with the two procedures. Standard solutions of HxR and IMP were added with N_P and N_P-N_T enzymes and after few minutes (5–10) could be employed for calibrations. In the case of IMP we found that the conversion rate was increased at 30°C.

2.7. Preparation of samples for fish freshness determination

Several authors proposed a treatment of fish sample according to Ehira's methods [2]. A simpler method has been used. Exudate of fish muscle (10 μl) obtained by press treatment were diluted with 5 ml of buffer Imidazole 0.05 M pH 7.8 containing 0.1 M KCl and 50 mM KH_2PO_4 and used immediately as the sample.

Samples for the determination of fish freshness were prepared from the specie gilthead bream. AU concentration is determined using the FIA system without the XO reactor.

3. Results and discussion

3.1. Uric acid amperometric response

The carbon electrode gave a very fast and reproducible response to uric acid. The calibration curve obtained with standard solutions added to buffer was perfectly linear in the range 1–50 μM with a standard deviation of 5% and a limit detection of 0.2 μM. This was the basic finding and we tried to exploit such linear behaviour for hypoxanthine determination and then for freshness evaluation.

3.2. Hypoxanthine detection with XO immobilized

Enzyme immobilized on carbon sensor allows a rapid signal when hypoxanthine standard solution was added to the buffer.

However, the signal decreases very soon and the enzyme becomes poisoned just after the addition (Fig. 2a). If we add a second addition, the enzyme results inhibited.

However, if we change the buffer solution and we add a new aliquot of hypoxanthine standard solution, we could obtain a current value proportional to the addition. Therefore we could obtain a linear calibration curve by changing the buffer solution before the addition of hypoxanthine and by monitoring the maximum value of current (Fig. 2b).

The calibration curve obtained with such procedure is linear up to 50 μM and is stable and reproducible for more than 50 assays in this range. Then, the response of the sensor decreases slowly.

The calibration curve with HxR and IMP standard solutions treated respectively with N_P and N_P–N_T enzymes showed a linear range more narrow. Fig. 3 reports the comparison of the calibration obtained from Hx, HxR and IMP.

From these experiments we learned that XO is inhibited by the enzyme product, probably adsorbed by the carbon matrix and only the extensive washing of the electrode allows a new determination. Moreover the presence of the other enzymes N_P or N_P-N_T in the solution inhibits more the XO enzymatic reaction, decreasing the linear portion of the calibration curve.

3.3. Flow injection system with XO immobilized screen-printed electrode

Previous results led to the conclusion that only a FIA procedure could be useful to exploit the linearity of the uric acid probe.

The best flow rate and the sample loop were found 0.5 ml min^{-1} and 50 μl (dispersion coefficient was 1.05).

Fig. 4a reports the calibration curve obtained with hypoxanthine and uric acid standard solutions. We can observe the linearity of the calibration curve and that XO converts hypoxanthine completely up to almost 100 μM. However, Fig. 4b reveals how after 2 h (40 additions) the curve is linear only up to 50 μM. The detection limit is 5 μM.

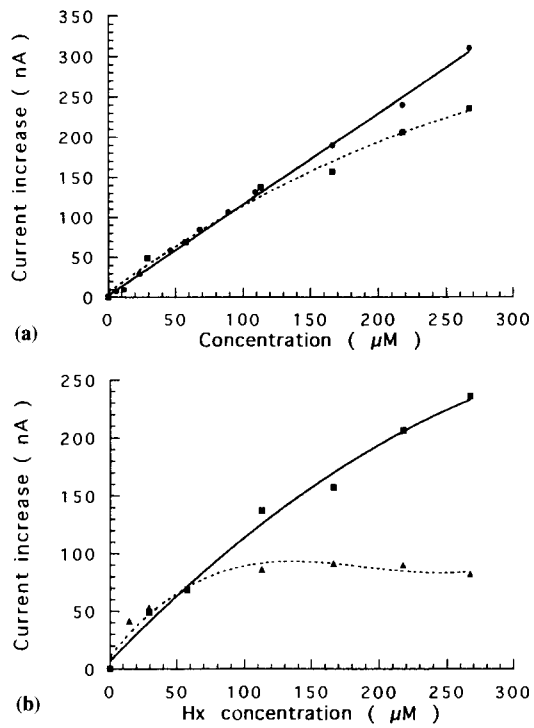

Fig. 4. (a) Amperometric detection with immobilized Xanthine oxidase (XO) screen-printed electrode using Flow Injection Analysis: Calibration curves for determination of (●) AU and (■) Hx. pH 7.8; T, 20°C; flow rate, 0.5 ml min^{-1}; sample volume, 50 μl. (b) Influence of time on output current of the Hx sensor (■: zero time; ▲: after 2 h). Sample volume, pH and flow rate were 50 μl, 7.8 and 0.5 ml min^{-1}, respectively.

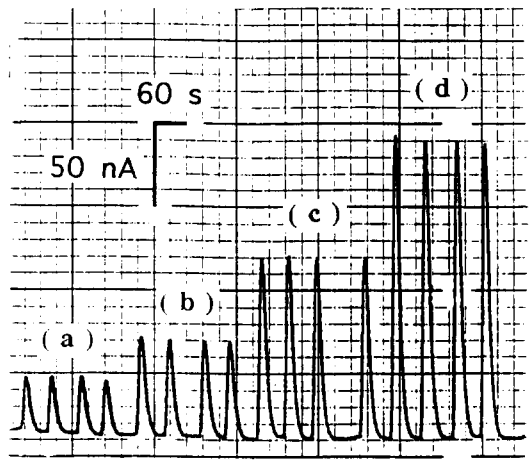

Fig. 5. Amperometric detection utilizing immobilized Xanthine oxidase (XO) reactor and screen-printed electrode: Typical signals for 50 μl injections of standard solution Hx, (a) 8 μM; (b) 16 μM; (c) 32 μM and (d) 62 μM). Carrier solution (0.05 M Imidazole buffer at pH 7.8 containing 0.1 M KCl and 0.05M KH_2PO_4) was pumped at a flow rate of 0.5 ml min^{-1}.

The experiments reveal how the enzyme was still poisoned if high concentration of Hx were flowed.

3.4. FIA with XO reactor and screen-printed electrode

A reactor loaded with XO was introduced into the FIA assembly and results obtained (Fig. 5)

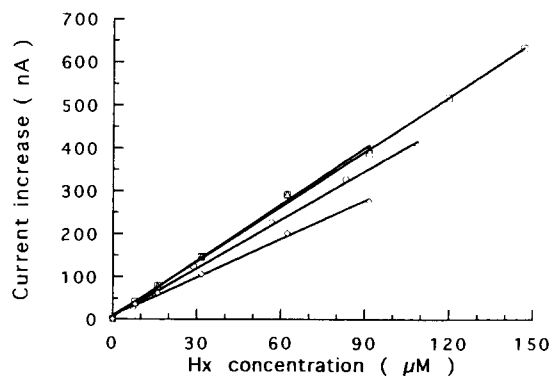

Fig. 6. Hx calibration curve: Effect of the storage time ((□) 0 h, (○) 24 h, (△) 48 h and (◇) 72 h). pH 7.8; T, 20°C; flow rate, 0.5 ml min^{-1}; sample volume, 50 μl.

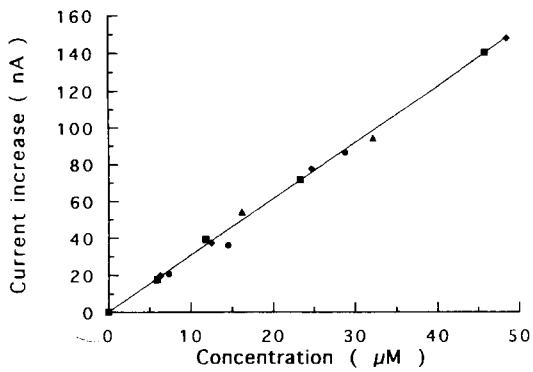

Fig. 7. Amperometric detection utilizing immobilized Xanthine oxidase (XO) reactor and screen-printed electrode: Calibration curves for determination of (■) AU, (●) Hx, (▲) HxR and (◆) IMP. Flow rate, temperature, pH and sample volumes were 0.5 ml min^{-1}, 20°C, 7.8 and 50 μl, respectively.

showed high linearity, high reproducibility and fast recovery. The sampling rate is about 100 samples h^{-1}.

The relative standard deviations for 4 replicate injections were 2% for a concentration of 20 μM.

The XO immobilized enzyme reactor was used repeatedly to evaluate the lifetime (Fig. 6). The system shows linear response after repetitive use even after 2–3 months with standard solutions

The response curves to IMP, HxR and Hx were compared. After the output current reached a steady state, an aliquot of each compound was injected into the sensor system.

Any appreciable difference was observed in the response times for IMP, HxR, Hx and AU.

In Fig. 7 the calibration curves for IMP, HxR, Hx and AU are reported in the range 1–50 μM indicating a total conversion of IMP, HxR and Hx to AU. The responses are linear in this range and the detection limit is 1 μM.

3.5. Real samples

Exudates from fishes are generally diluted, filtered through 0.45 μm pore filters and injected without any pretreatment into the sampling valve.

Preliminary experiments showed a drastic effect on the current obtained after repetite sample injections.

Fig. 8(a) and Fig. 8(b) report the drastic reduction (around 80%) obtained with standard solutions of uric acid and hypoxanthine before and after 100 injections of fish samples diluted 50 times with the buffer.

The decrease is related to the electrode fouling which appears as a reduction of the active area. The calibration curve is still linear for both uric acid and hypoxanthine but much decreased. Therefore it appears that the enzyme reactor is still converting all hypoxanthine in uric acid but it is the electrode which is unable to oxidise uric acid.

Moreover additions of standard solutions of uric acid or hypoxanthine to the samples indicate a nonlinear behaviour of the current obtained.

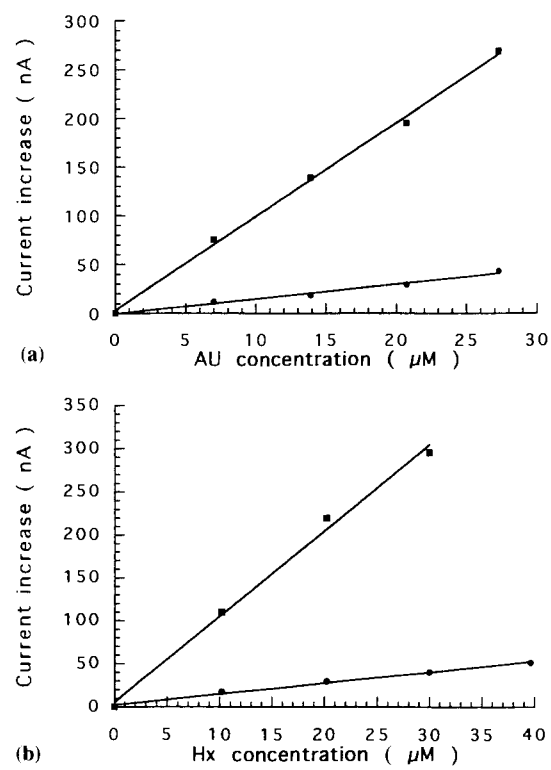

Fig. 8. (a and b) Amperometric detection utilizing immobilized Xanthine oxidase (XO) reactor and screen-printed electrode: Calibration curves for determination of AU and Hx (■) before and (●) after 100 injections of fish samples diluted 50 times with buffer. Flow rate, temperature, pH and sample volumes were 0.5 ml min^{-1}, 20°C, 7.8 and 50 μl, respectively.

Table 1
Results obtained with real samples (Gilthead bream) stored in different conditions

Storage method	Time from death	[AU] (mM)	[Hx] (mM)	[HxR] (mM)	[IMP] (mM)	K (%)
4°C	48	0	1.85	0.5	11.8	17
	72	0.5	2.65	0.3	12.05	22
	96	0.1	1.1	0.1	4	24
	120	-	0.4	0.2	5.45	26
	168	0	0.6	0.45	2.7	28
	192	0.1	2.35	0.25	5.3	34
4°C with ice	48	0	1.25	1.25	20.15	11
	72	0	1.05	0.2	5.7	18
	96	0.15	0.05	0.3	1.9	21
	120	0	0.6	0.35	2.6	27
	168	0	0.5	1	3.95	27.5
	192	0.05	1.05	1.05	6.35	25
	216	0.25	0.25	0.95	3.5	29
	240	0.8	1.15	2.75	9.05	34

However, if the exudates are diluted 500 times or more with the buffer, linear behaviour in the final range 0–10 μM is obtained with a detection limit of 0.2 μM. Therefore a detection limit of 0.1 mM in the exudate can be obtained. Uric acid and hypoxanthine gave the same calibration curve and it was estimated that 40 assays can be realized with a single sensor. After this number of real samples the sensor has to be discarded and substituted with a new one. Therefore a disposable sensor is necessary for such kind of measurement.

Additions of N_P and N_T (or AlP) enzymes to the diluted exudates allow the detection of HxR and IMP in the sample as reported in the experimental section.

The hypoxanthine oxidase reactor showed a good operational stability during 2–3 months for at least 200–300 assays. The CV was around ± 3% for a sample containing 1.20 mM of Hx or HxR and IMP.

Moreover the proposed procedure allows the determination of uric acid in the exudate (by excluding the reactor) and this information could be useful to assess quality studies.

In Table 1 we report a study on the determination of AU, Hx, HxR and IMP of real samples (gilthead bream) stocked in different conditions. Therefore the sensor appeared promising for routine determination of fish freshness.

K value, indicator of fish freshness, based on the degradation of ATP in fish meat is defined as

$$K = 100\,(HxR + Hx)/(IMP + HxR + Hx) \quad (1)$$

as ATP, ADP and AMP disappear around 24 h after the death of the fish.

Species showed a K value of about 11–17%, 48 h after the death. During storage at 4°C, the K value increased to 34% after 192 h while the fish kept at 4°C with ice reached this value after 240 h. These results showed that the degradation is higher at 4°C without ice than with ice.

These preliminary datas were confirmed with an amperometric procedure based on platinum electrode and hydrogen peroxide detection [16].

4. Conclusion

An amperometric detection based on FIA procedure using Xanthine oxidase reactor and a carbon based screen-printed electrode is proposed for freshness detection. Exudates of fish can be only diluted and injected into the system, therefore any preparation step is avoided.

Screen-printed carbon-based electrode can be used for 30–40 assays without further calibration. An oxidase reactor can be exploited for 2–3 months or at least 200–300 samples.

To determine HxR and IMP, relative enzymes converting to Hx should be added in suitable amounts according to a proposed procedure and the sample is then directly injected into the FIA system. AU can be also quantitatively determined without the oxidase reactor.

Therefore AU, Hx, HxR and IMP values can be obtained in 30 s with CV of 2–3% if the concentration is around 1–5 mM in the original sample; quality studies on fish samples can be easily performed.

Announcements

The quantity 'pH'

The growing awareness amongst analytical chemists of the need for expressing the traceability and uncertainty of results has brought new pressure to reconsider the difficult situation of the realisation of the quantity 'pH', IUPAC Commission V. 5, responsible for pH matters [1], is proposing new works towards a unified pH scale. The adoption of a scientifically sounder assumption for activity coefficients in mixed electrolytes, the Pitzer treatment [2], to replace the Bates-Guggenheim Convention, will lead to the best possible definition of pH, the closest to the 'true', unattainable, pa_H value. By this means known standard buffers, with or without background electrolyte, can be assigned calculated pH values on the unified pH scale.

Before this unified pH scale can be formulated, an extensive further programme of experimental work on pH standard buffers is required. It is the intention to enlist the co-operation of some dozen suitably equipped laboratories world-wide to make extensive new e.m.f. measurements of Harned cells with buffer substance components over a wide temperature range to derive the necessary information. A subsequently formed working party will then reconsider the current IUPAC (1985) Recommendations [1]. A number of laboratories have already offered support. Requests for further details, offers of help, and comments on this proposal and on the existing IUPAC Recommendations should be sent to:

The Benedetti-Pichler Award

The American Microchemical Society is pleased to announce that it has chosen Professor John G. Dorsey, from Florida State University, as the 1997 A.A. Benedetti-Pichler Awardee. In general, Professor Dorsey has made outstanding contributions to analytical chemistry and to an understanding of chromatographic retention mechanisms. In particular, he has made seminal contributions to flow analysis, and to the estimation of biological and environmental partitioning processes. The Foley-Dorsey equation is now the recognized standard for calculation of the number of theoretical plates that measure the resolving power of a separation. The paper in which this equation was published, Anal. Chem. 55, 730–737 (1983) has been cited 239 times through June of 1996.

The Award will be presented at the Eastern Analytical Symposium and Exposition 1997, Somerset, New Jersey, USA on Thursday Nov. 20th, 1997 at a symposium in Prof. Dorsey's honor.

8th Symposium on Handling of Environmental and Biological Samples in Chromatography
26th Scientific Meeting of the Group of Chromatography and related Techniques of the Spanish Royal Society of Chemistry

Almería, Spain
October 26–29, 1997

Organized by:
International Association of Environmental Analytical Chemistry Group of Chromatography and Related Techniques of the Spanish Royal Society of Chemistry, Faculty of Sciences, University of Almería, Spain.

This meeting intends to cover new developments and reviews established handling and preparation techniques (such as liquid–liquid, solid phase extraction and supercritical fluid extraction) as well as more recent techniques. These include specific methods utilizing enzymes, immuno interactions and tailor made reagents and membrane techniques. GC, LC, SFC, CE, hyphenated techniques, MS techniques and automation will also be considered. A separate session will be devoted to water monitoring, international regulations and quality assurance principles of pesticide analysis. Subtopics will be introduced by plenary and invited research lectures followed by brief research posters. The symposium language will be English with no translation.

The program will consist of Plenary and Keynote Lectures. An equally important means for exchange of information will be via Poster Sessions. The posters will be selected to complement the series of lectures so that all factors affecting development of new analytical techniques, instrumentation and procedures for environmental and biological studies will be presented.

Schedule of activities

Call for papers, abstracts due	July 1, 1997
Exhibitor registration	September 8, 1997
Conference pre-registration	October 10, 1997
Hotel pre-res ervation	October 10, 1997
Late pre-registration deadline	December 5, 1997
1998 Winter conference short courses	January 2–4, 1998
1998 Winter conference on plasma spectrochemistry	January 5–10, 1998

8th International Symposium on Luminescence Spectrometry in Biomedical and Environmental Analysis—Detection Techniques and Applications in Chromatography and Capillary Electrophoresis
Las Palmas de Gran Canaria (Canary Islands), Spain
26–29 May 1998

Organized by the University of Las Palmas de G.C. (Spain) in collaboration with the University of Ghent (Belgium), the University of Tokyo (Japan) and the Complutense University of Madrid (Spain).

A review of the main factors influencing the FT-IR-PLS abilities exemplified with petrochemical qualimetric applications[1]

J.M. Andrade *, M.V. Garcia, P. Lopez-Mahia, D. Prada

Department of Analytical Chemistry, University of A Coruña, Campus A Zapateira, s/n E-15071, A Coruña, Spain

Received 5 June 1996; received in revised form 11 September 1996; accepted 1 October 1996

Abstract

Quality control usually involves monitoring several variables directly related with industrial necessities using univariate tests. One powerful alternative is to link multivariate analytical techniques and multivariate chemometrics. In this way, Fourier Transform Infrared spectroscopy and Partial Least Squares regression are used to discuss and review several advantages and drawbacks encountered in using such combination in industrial facilities. Typical drawbacks are selection of data pretreatment, errors in reference methods, selection of calibration and validation sets and model-aging. This review is exemplified with petrochemical applications although other fields are also considered (mainly when dealing with data pretreatment). © 1997 Elsevier Science B.V.

Keywords: Infrared; PLS; Qualimetrics; FT-IR; Review

1. Introduction

Qualimetrics is a novel term [1] which can be defined as a subfield of chemometrics concerned with using chemometric methods to improve quality control and quality assurance. Quality control, in turns, usually involves measuring chemically-related properties using some univariate, time-consuming, training-demanding, specific tests.

Qualimetrics, without doubt, is strongly related to Process Analytical Chemistry (PAC) [2–4] being the only shade that not all the PAC methods are statistical but of chemical engineering, too. Qualimetrics and PAC works have been explicity considered at the 4th International Chemometrics Conference (Czech Republic, July 3–7, 1995), the Euroanalysis IX (Italy, September 1–7, 1996) and it was considered as one of the cores of the 4th Symposium on Analytical Sciences (Brussels, June 3–5, 1996), EUCHEM—Conference on Chemometrics (Göteborg, Sweden, June 3–6, 1996) and one of the main focus of the VI International Conference in Chemometrics in Analytical Chemistry (Spain, June 25–29, 1996), just to mention several recent international meetings.

PII S0039-9140(97)00034-9

Qualimetrics comprises a new way of thinking in industry-applied analytical chemistry. This term, to some extent, raise to the traditional univariate, time-consuming tests, though most of them can not be avoided due to contractual agreements. Alternatives should combine well-known multivariate (or state-of-the-art) analytical techniques with some predictive, statistical technique. Such combinations are of great power and useful not only to simultaneously control several parameters but to achieve excellent results as well as indirect benefits (lower delay times, lower workloads, better precision figures, etc.).

This paper deals with combining Fourier Transform Medium-Infrared spectroscopy (FT-MIR) and Partial Least Squares regression (PLS). Such topic is not absolutely recent so the main intention is to bring the industrial point of view our group has been involved with; exposing, briefly, benefits and drawbacks. Examples related with petrochemical properties measured using liquid samples are to be presented since this was our main concern during several years. No problem should exist to broadly extend the discussions to other fields. It should be underlined that the main intention is not to perform a detailed review of all the published works comprising qualimetrics and/or FTIR-PLS applications, instead it was pretended to rely on a half-way between a primer and a typical review. Two recent reviews focused on combining IR spectroscopy and chemometrics [5,6]. Another two reviews will be of interest though they are centered onto spectroscopic applications [7,8].

2. The problem

In the petrochemical arena, some standard tests are time-consuming (e.g. flash point test by the manual method [9]; thermal stability of kerosene [10]; knock indexes of gasolines [11,12], etc.), some are difficult to perform (e.g. % of aromatics and olefins [13]) and, even, others are highly subjective (e.g. freezing point of kerosene [14,15]). One result of these remarks is that precision figures (repeatability and reproducibility) are too broad when compared with current wishes from process control people giving excesive stress on analytical laboratories.

Additionaly, several tests need high amounts of reagents, from which several are harmful (e.g. benzene, toluene, aniline etc.). Standard apparatus are expensive and particular training is needed. The most typical example of a little desirable method is the measurement of the knock characteristics of automotive gasolines. Table 1, partially extracted from [16], resumes the most unsatisfactory characteristics of these two standard methods [11,12] and shows the chemometric method is an interesting alternative. Similar considerations could be determined for other test methods. Indirect costs appear when considering delay time, repeating analysis because a lack of confidence, higher workloads, staff demoralization etc.

3. Overcoming the problem

Assuming that the chemical composition measured by the IR spectroscopy determines, in some way, the physico-chemical parameters, spectral data can be used to calibrate and, then, predict fuel properties. The basic chemical background is the Lambert-Beer's law.

From Table 1, it can be followed that almost all the problems posed above could be avoided in routinary analyses using the FT-IR-PLS approach. Whether this multivariate approach can be used as accepted test method for certifying final products or not is a question of mutual agreement and confidence in quality control. At present, they are not accepted but we have little doubts on their promising future.

Benefits are quite obvious. What about drawbacks? In the following, the main problems found on applying the chemometric approach to daily production activities are to be briefly presented.

4. Spectral pretreatment methods

Two notes have to be posed now, the first one because the following classification is not sharply defined and, so, some techniques could be simul-

Table 1
ASTM methods vs. the FT-IR-PLS method: advantages and disadvantages

Item	ASTM methods	Chemometric method
Initial cost	High (~US$ 180 000)	Medium (~US$ 32 000)
Maintenance/repairs	Frequent/expensive	Infrequent/not expensive
Robustness	Not	Yes
Staff	Highly skilled	Not skilled
Precision	Repeatability, ~0.3 Reproducibility, ~0.9	Repeatability, ~0.1 Reproducibity, ~0.3
Automation	Very difficult	Simple
Connection to LIMS network	Level I (manual)	Level II (automated)
Sample	1 l	20 ml
Reagents	~500 ml blends of isoctane, *n*-heptane, toluene	None
Noise	Quite high	None
Vapours (fumes)	From reagents, from motor performance, from samples	Only from gasoline samples (few amounts)
Delay time to get one characteristic (considering one sample)	35 min	5 min
Residues	Fumes, isooctane, *n*-heptane, toluene, gasoline samples (about 200 ml of useless blends)	Only 10 ml of gasoline per sample. They can be used to clean heavy products from glassware (e.g. fuel, vacuum residues, etc.)
Indirect costs	High	Low

taneously classified in several items. The second warning is that the pretreatment review will not only concentrate on petrochemical applications (mostly made on liquid samples) but will also be extended to other different techniques in an attempt to get a broadest view. In this way, those who are interested in more details are encouraged to refer to the references.

The first decission to be taken is to select the spectral units to work with; i.e. absorption, transmittance, some of their derivatives or any other data transform. Generally speaking, there is not universal criterium in the literature; in fact, it greatly depends on the particular type of IR technique being used. The final objective of every data pretreatment is to simplify the mathematical model, thereby trying to improve the ultimate performance of the method. Some few examples can be considered.

4.1. Fourier Transform

The first step when dealing with Fourier Transform (FT) spectroscopy is the mathematical transformation from the time domain to the wavenumber/wavelength domain. This step can be considered as the first pretreatment of the analytical signal and it has been considered in several works. Brereton [17] reviewed the basics, usefulness and advantages of Fourier methods when used to get the spectroscopic data. Another review comprising FT in UV, VIS and NIR spectroscopy can be found on Williams [18].

Before those two works, Giancaspro and Comisarow [19] had presented a paper taking into account the problems associated to different FT spectra interpolation procedures as a function of both the number of zero-fillings and the ratio of the acquisition time to the relaxation time of the time domain signal. Nowadays, the Fourier Transform is automatically performed and such kind of problems (including, e.g. the sampling interval, resolution, etc.) are minimized.

4.2. Background correction

The simplest background correction is to record a 'blank' spectrum, store it in the computer and

substract it from each recorded spectrum. This is the most common situation since most FT-IR spectrophotometers make use of only one radiation beam. As a practical approach, the blank should consider the cell windows, the optical pathlength, and the background environment, i.e. air-filled or solvent-filled (even solvent mixtures) etc. A new background record should be made each time a change in the environmental conditions is suspected (solvents, room environment etc.).

In spite of this broadly used, simple application, background correction can be much more complicated. Several examples will illustrate this assessment. Karstang and Kvalheim [20] compared three techniques for background correction in quantitative analysis. Using as starting point a principal component analysis (PCA), the PCA model is them combined with a function describing the spectrum of the background constituents. The background methods comprised curve fitting, iterative target transformation factor analysis and local curve fitting.

We think the main objection it could be posed to such work is to find a function defining the background spectrum and that all the matrix constituents are not always known (e.g. when considering very complex mixtures as gasolines, kerosenes etc.). In this way, Gemperline et al. [21] selected a more simple approach. They used principal component regression in order to correct for background absorption. Thus, spectra of the pure background components are not needed. The main idea, of course, is to use only the first factors explaining most of the information in the data and discard the final ones where (hopefully) most random/background/noise will be present. This idea is discussed in more detail by Gillette and Koenig [22].

Kvalheim participated also in another work [23] where background correction was studied in hyphenated chromatographic/spectroscopic data. They also take into account baseline drift.

Karstang and Henriksen [24] included background correction techniques to get a quantitative prediction of additives in high-density polyethylene. They used the same three methods as in [20] and found that spectral substraction did not satisfactory worked due to interferences between all the additives in the prediction step.

4.3. Spectral units

With regard to the petrochemical field, the pioneering work from Honigs et al. [25] was made on absorption values as well as those from Martens et al. [26], Kelly et al. [27], Descales et al. [28], Parisi et al. [29], Blanco et al. [30], Garrigues et al. [31] or Andrade et al. [16]. Far from the refineries, some other applications were also made considering absorbance units as e.g. Zen and Patonay [32] did when preparing a NIR probe for pH-determination or Robert et al. [33] when analysing milk.

On the contrary, Kisner et al. [34] take transmittance (%) for determining triglycerides, phospholipids and cholesteryl ester by IR spectra. Bye [35] found that three silica modifications of quartz, cristobalite and amorphous silica can be quantitatively predicted using the KBr disc procedure, MIR-%T data and PLS regression.

Derivatives (generally, first- and second-order derivatives) were broadly used to correct spectral artifacts. They allow a sharp definition of each maximum possition but their main disadvantage is that noise is also increased, which can be determinant for some applications (e.g. when dealing with weak signals). Hruschka explains [36] that higher-order derivatives are occasionally valuable for increasing peak resolutions although they are rarely used due to difficulty in interpretation (analysis of pharmaceuticals were considered).

Kelly and Callis [37] considered the absorption units and the first and second order derivatives on SW-NIR and LW-NIR; they found no great differences excepting for the second derivative in LW-NIR which was attributed to a problem of sample-positioning in the instrumental (on-line) cell holder.

Evans et al. [38] studied classification rates for discriminant analysis of orange juice applying no transformation, first and second derivatives, multiplicative scatter correction and standard normal variate transformation (see Section 4.4). They found no differences being the 'no transformation' results as good as or better than any other combination; they also pointed out that one rea-

son for this could be the inherent smoothing of the NIR spectrophotometer.

Bertran [39] and Gonzalez [40] concentrated on studying which of the absorption, transmittance, or the first and second order absorption derivatives was the most adequated one to develop PLS and/or PCR models. Their results are not definitive since in some problems they selected the absorption units and in other different situations the first derivative was slightly better.

The following applications clearly reinforce the idea that no recipe can be used for data pretreatment and that each particular situation has to be considered. Esbensen and Martens [41] used PLS for predicting permeability, porosity and other petrophysical core parameters directly from wireline logs in oil wells using discrete variables (in this work IR was not used). According with their kwnowledge and previous studies, they found that one of the variables had to be $\log_{10}$ transformed, two of them, $\log_2$ transformed and another one was recomputed as $x^{1/3}$, where x represents the original values. The main reason to do so was that these variables showed a marked skewness.

Almost as a contrast to the previous application, Bak and Larsen [42] managed a problem where absorbance vs. concentration of CO was found to be highly nonlinear. A linearization step was applied to the spectroscopic data prior to computing the calibration model. It was found that the integrated absorbance areas, rather than the absorbance values, were more useful for modeling. The result was an improved calibration model with increased concentration prediction accuracy over the wide concentrations of CO.

A similar approach was selected by Kueustner et al. [43] when measuring hemoglobin in unlysed blood by NIR. They had to use the 1740/1346 nm ratio of the second derivative spectrum to get a successful calibration vs concentration.

Up to this point, one conclusion can be drawn inmediately, i.e. absorption units were mainly selected to perform multivariate predictions in liquid samples, at least in the petrochemical arena-. Broadly speaking, the first derivative is often used to correct for baseline shifts and the second derivative is used to handling scatter effects [44].

4.4. Baseline correction

In the most common situation, the baseline effects can be attributed to the sample matrix influence and consequently, it is desirable to skip such effect. Closely related to background correction, baseline correction can be made using first- and second-order derivatives (see Section 4.2). One of the disadvantages of using the second derivative is the spectral shape that it is obtained. Without doubt, another more intuitive approach could be desirable to eliminate the matrix effect. Unfortunately, this is far from easy (see e.g. Section 4.6) although Mamantou et al. [45] reviewed a set of analytical applications of matrix isolation in FTIR spectroscopy. They presented practical techniques for obtaining analytically useful results.

Liu and Koenig [46] developed a baseline correction algorith using a least-squares procedure. Linear or quadratic types of baselines are obtained through succesive fitting. After the entire spectrum or a subsection is fitted, the standard error of estimate is utilized as a criterium to determining if the fluctuation of each data point about the line can be thought of as the baseline function.

Lipkus [47] proposed a method for eliminating baseline variation for use on biological FTIR spectra. The expanded espectra in terms of a set of orthonormal polynomials derived from the Legendre polynomials and leading terms of the expansion, which contain most of the baseline variation, are removed.

In a relatively recent work, Dobrowolski et al. [48] made use of the intensian method to account for baselines. In the authors' words, 'the intensian concept leads to simple formulas which can be perceived as a generalization of the Beer-Lambert law'. This method can be extended to chromatography and other similar techniques, as well. The method was explained to be a continuation of the Morton and Stubbs' three point approach, from 1946. Dobrowolski et al. cited more baseline treatments including Gaussian and Lorentzian functions, ultra-low-frequency filtering in the frequency domain, and correction of second harmonic of spectra by fitted baseline.

One typical example of the baseline effect can be encountered in the IR films analysis. Many times polymers are cut in a thin slide (film). Due to errors in such preparation the thickness will vary and, so, originate a baseline shift. Karstang and Henriksen [24] proposed a normalization scheme comparing three normalization/scaling techniques, namely normalization based on selective regions, multiplicative signal correction and optimized scaling. Best results were achieved using the first and the latter options.

Jamroz and Dobrowolski developed the so-called autostandard method [49] which can be complementary of the ratio method (also known, method of the internal standard). The ratio method needs an analytical band that originates from one, and only one, substance in the system; the autostandard method needs a band common to all components into the system. The autostandard method can be applied where the layer thickness is difficult or impossible to measure.

4.5. Smoothing

Smoothing is often used to improve the signal-to-noise ratio of the spectral data. It is effective against noise that it is not correlated between adjacent wavelengths. The first, simplest approach is to average several spectra since noise tend to cancel or, at least, to greatly diminish. Alternatively to this simple way, a lot of options exist.

Among them, one of the simplest ones is to smooth data by a moving average. In this procedure (Moving Average or Boxcar), one chooses a window of a fixed odd number of points and calculates the average of all data points inside the window. The mean value of all points inside the window is recalculated and replaces the central point [50]. Its main disadvantage is that a band widening is obtained. Closely related, exponential averaging is obtained by calculating the weighted average of the points in a moving window of m points. The last point in the window (the point to be smoothed) is given the greatest weight and each preceding point is attributted a lower weight determined by the shape of the exponential function [$\exp(-j/T)$; T = the smoothing constant]. Because of the asymmetry of this smoothing function, a unidirectional distortion is introduced into the smoothed data, producing a lowering and shift of the peak maximum.

One of the broadest used filtering algorithm is that from Savitzky and Golay [7,51]. Despite its usefulness, this kind of filters should be used with care, particularly when severe or repetitive smoothing is required, as it was studied by Madden [7]. This filter works according with the following simplified scheme: consider a window of 9 points, the central one, the 5th, is the datum to be smoothed. The Savitzky-Golay filter (polynomial filter) consists of fitting a polynomial model through all the points in the window (excepting the central one) in the least-squares sense. Predict the value of the central datum using the adjusted polynomial and substitute the value of the central point by this predicted (smoothed) one. The process is repeated until filtering all the spectrum. Computational simplifications can be applied (see [50]). The application of polynomial smoothing has many disadvantages, among them is that for interpolation (smoothing) of physical data the behaviour in a particular interval may differ significantly from the behaviour in adjoining intervals [52]. One of the typical problems of the Savitzky-Golay filters is the non-filtering (truncation) of the end sections of the spectra. Very recently, Hui and Gratzl [53] estudied one of the proposals for addressing truncation. The 1990 Gorry's algorithm was modified to make it able to cope with several undesirable effects. Therefore, for purposes of interpolation and approximation it is more convenient to select locally defined functions that can be connected at the end-point. These functions are called splines, being the B-spline, a base spline with some particular mathematical properties [51].

Gans and Gill [54,55] explained in much more detail the B-splines and compared their performance with that from the Savitzky-Golay technique. Another interesting use of the B-splines can be seen in Section 4.8.

Bussian and Härdle [56] realized that filtering polynomials using the least-squares approach impelled to take care of the existance of outliers. They developed a robust smoothing procedure which rejects the huge noise spikes. The algorithm

has to be tunned with two parameters: the signal-to-noise ratio and the halfwidth of the spectral bands. Several IR-Raman examples are used.

Jones and Shimokoshi [57] studied the most appropriate domain to perform the filtering step: in the wavenumber or in its Fourier transform domain. Depending on the choice of the filter, one may achieve reduction in random noise, reduction of systematic instrumental errors and/or resolution enhancement.

Kawata and Minami [58] proposed an adaptive smoothing method based on a least-squares estimation. The mean and variance of the observed spectrum at a individual sampled point are calculated point by point from its local mean and variance. The resultant spectrum possesses a maximized signal-to-noise ratio at any local section of the entire spectrum. They also found different advantages when compared with conventional smoothing methods based on polynomial curve fitting. Bialkowski [59] used another kind of adaptive data smoothing filter (based on the Gaussian function) to study and correct the instrumental shot noise. Barak [60] worked, also, in one adaptive-degree polynomial filter trying to handle the different spectral characteristics that could be present in different regions of any spectrum.

Fourier Transform can be used as a smoothing technique. Thus, Cameron and Moffatt [61] used Fourier transforms in order to get smoothed even-order derivative spectra.

A digital Fourier filter is used by Hazen et al. [62] in combination with PLS regression to provide a calibration model that is insensitive to temperature when measuring glucose in aqueous solution. Baseline deviations are handled even when they are orders of magnitude greater than the glucose absorption bands. Very recently, Chung et al. [63] followed a similar approach for measure glucose, glutamine, ammonia, lactate and glutamate by NIR. They used both Fourier filtered absorbance spectra and raw data. Prediction abilities are found to be almost equal excepting a reduction in the number of PLS factors when Fourier filtering was used, which is consistent with removal of nonanalyte spectral variations by the filter.

4.6. Infrared reflectance

Reflectance spectroscopy is used for samples that are difficult to analyze by transmission. The samples can usually be analysed without modification. Reflectance measurements are divided into two categories: internal reflectance measurements are made by using an ATR (Attenuated Total Reflectance) element in contact with the sample. Alternatively, external reflectance measurements are made using an infrared beam reflected directly from the sample surface (Diffuse Reflectance, DR). In the former case, the ATR crystal is designed to enable total internal reflection which creates an evanescent wave at the crystal surface. This wave extends into a sample held in intimate contact with the crystal and absorption spectra can be recorded as a result. In DR, incident radiation is focused onto the sample and two forms of reflection occur: diffuse and specular. On a rough surface (e.g. powder) specularly reflected light is a minor contributor to the overall signal.

Some papers will be mentioned regarding ATR, the first one from Huang and Urban [64] because they made an evaluation and analysis of Attenuated Total Reflectance FTIR spectra using Kramers-Kronig transforms. In this work, a comparison is made between different algorithms to handle ATR-FTIR data: (1) the original Bertie's algorithm (suitable for weak bands) and the Dignan's one (more suitable for strong ATR bands); (2) Kramers-Kronig transformation; (3) they refine both algoritms by applying the McLaurin method to the Kramers-Kronig transform.

In the petrochemical field, Fodor [65,66] selected ATR spectra in order to predict two quite conflictive gasoline properties: the MON and RON antiknock indexes.

Depuy et al. [67] measured latex in paper coatings using ATR, as well. Recorded spectra were not modified excepting that first- and second-order derivatives were obtained. In order to avoid a decrease in the signal-to-noise ratio during differentiations, a seven-point moving average smoothing was performed on the profiles. Both treatments, differentiation and smoothing, were simultaneously made using a Savitzky-Golay filter.

4.7. Diffuse reflectance (DRIFTS)

In spite of the application of Shawn and Kratochvil [68] where absorption units were enough to determine bitumen contents in oil and sand, diffuse reflectance needs a wider, detailed exposition. More details have been considered in the specific review from Martin [8] and interested readers are encouraged to gain benefits from his work. In the present paper, we will only consider some topics related to the PLS application and previous steps.

The relationship between diffuse reflectance and concentration is more complex than the Beer-Lambert's law for transmission. DR depends on scatter for remission of the incident energy. More efficient scattering results in less penetration of energy into the sample and, therefore, less absorption. The pathlength is, accordingly, related inversely to the scattering coefficient. Such relation is defined by the theory of Kubelka and Munk being the Fuller and Griffiths' paper one of the first ones [69]. However, the Kubelka-Munk function is valid only for diffuse illumination and over a limited concentration range. From this point, a lot of work has been done trying to solve such problem. Nevertheless, the Kubelka-Munk function is almost universally used to theoretically describe the diffuse-reflectance measurements [8].

Good examples could be those from Cueller et al. [70] and McKenzie et al. [71] combining DRIFTS and the Kubelka-Munk algorithms to directly characterize glass fiber and polymer films and coatings.

Christy et al. [72] determined coal maturity by DRIFTS spectra in a Kubelka-Munk format and PLS as an alternative to the classical vitrinite reflectance method which presents poor precision values.

Birth [73] evaluated the application of the Kubelka-Munk theory to the light- scattering of foods and found significant deviations. Hecht [74] compared the Kubelka-Munk, Rozemberg and Pitts-Giovanelli methods of analysis of diffuse reflectance for several systems. He found that the latter two algorithms are useful alternatives that may be applied to diffusely reflecting samples that fail to conform the Kubelka-Munk theory.

Boroumand et al. [75] presented an adaptation of the Kubelka's general model to nonideal scattering samples. It was applied to quantitative FTIR spectroscopy of nondiluted surface-derivatized silica powders. Corrections were also present in order to take into account two common problems that often prevent a truly quantitative application of DRIFTS, namely background absorption and specular reflection on the surface.

Mandelis and Grossman [76] considered the Kubelka-Munk problem applied to nonhomogeneus optical media with arbitrary depth-dependent absorption and scattering coefficients.

Loyalka and Riggs [77] studied the accuracy of the Kubelka-Munk equations and proposed a new set of equations based on considerations from the radiation transport theory.

Ohta and Ishida [78] compared several numerical integration methods in order to seach for the most effective one for the Kramers-Kronig transformation, being the Kramers-Kronig transform a way to obtain 'constant' spectra from the substancies. Their methods involved the use of (1) MacLaurin's formula, (2) trapezium formula, (3) Simpson's formula, and (4) succesive double Fourier transform methods.

As it can be seen, scatter correction and baseline shifts are important points to deal with when considering diffuse reflectance. More on these subjects can be found onto the next works:

Devaux et al. [79] studied the effects of particle size on the DRIFTS spectra of wheat and Rape Seed Meal mixtures. Applying principal component analysis the first PC described the scattering effect; the second PC, the proportions at the sample surface and the third PC was necessary to make up for the overestimations of the smallest particles.

Downey et al. [80] followed a normalization strategy in order to minimize particle size effects by reducing the area under each spectrum. The same idea was used by Bertrand and Scotter [81] when analyzing gelatinized starch by NIR spectroscopy.

Multiplicative Scatter Correction (MSC) was proposed by Geladi et al. [82,83] as a way for scattering correction. MSC is based on the fact that if the reflectance values of each sample are

plotted against those of the mean for each wavelength the data fall on an approximately straight line. The intercept and slope of this line can be estimated for each spectrum by linear regression and then used to correct each sample spectrum to the intercept and slope values of the mean spectrum. The intercept, or additive effect, was found to be primarily due to specular reflectance effects, while the slope representing the multiplicative effect, was found to be due to sample homogeneity.

MSC is typically applied to linearize $\log(1/R)$ spectra (R = reflectance). Isaksson and Naes [84] have described the advantages of using MSC, indicating that prediction results are improved through better fit to a multivariate linear model and less irregularity in the scatter-corrected data. An advantage over the second derivative method is that the MSC-corrected data maintain the appearance of the original $\log(1/R)$ data.

A similar transform was proposed by Murray and Hall, more details can be found on Martin [8].

MSC was quickly adopted by researchers and some examples will cover quite different areas. Thus, Martens and Martens [85] used DRIFTS and MSC to predict sensory variables (hardness, juiciness and sweetness) of peas. Isaksson and Naes [84] studied the effect of MSC in linearity improvement in NIR. PCR regression was used after MSC correction and it was found that not only spectral interpretation was better but also that prediction was optimized. Three main reasons were argued: (1) MSC removes irrelevant information; (2) MSC increases linearity; and (3) MSC gives a regular and compact distribution of sample scores.

Ilari et al. [86] focused on light scattering effects as a way to determine the mean particle size in powders. The reflectance spectra are MSC-corrected and used for PLS regression. Up to 99% of the particle size variance was explained by the regression.

Vigerust et al. [87] made quantitative analysis of additives in low-density polyethylene using infrared spectroscopy, transforming to absorbance units and correcting with MSC prior to MLR and PLS regressions. The same approach (MSC-corrected spectra) was used by Dahlberg et al. [88] prior to discriminant-PLS and SIMCA classification techniques when classifying vegetable oils.

Blanco et al. [89] compared the performance of several preprocessing methods (absorbance, 1st and 2nd derivatives, normalization and MSC). They found not great differences in the prediction abilities of the different models, which it was ascribed to the weak scatter effect present on the samples.

Isaksson and Kowalski [90] modified the MSC algorithm to a new Piece-wise Multiplicative Scatter Correction (PMSC) one. This new method offers an advantage over the MSC method by correcting for nonlinear additive and multiplicative scatter effects. The PMSC offers linear regression fits to local wavelength regions of the spectra using a moving window of wavelengths.

A sort of spectrum autostandardization called Standard Normal Variate transformation—SNV—was proposed by Barnes et al. [91]. SNV has proved useful for the extraction of nonspecific scatter and particle size effects thanks to its scaling effect. In this way, SNV could be really useful to unify spectra from software libraries. The other dominant factor in NIR diffuse reflectance is the increasing level of the $\log(1/R)$ reflectance values over the 1100–2500 nm.To account for this baseline effect, application of a second-degree polynomial was also proposed being called De-trending (previous SNV transform can or can not be applied). An interesting feature of SNV is that it renders spectral shapes quite similar to the $\log(1/R)$ ones and, hence, interpretability is simplified. Although different in time, the end objectives of this work and that from Isaksson and Kowalski [90] are closely related.

SNV was also used by Blanco et al. [89] encountering that no important advantages are achieved over other simpler data treatments whether weak scatter effects are present.

Remember that Downey et al. [80] and Bertrand and Scatter [81], cited above, proposed a different kind of normalization intented to minimize particle size effects.

4.8. Data reduction

The main objective of data reduction is to diminish the total number of data to be handled by the analyst and computers and, thus, avoiding the usage of huge data matrices.

One of the simplest approaches could be to drawn attention only to that spectral regions where saturation is not achieved and 'good' peaks/bands are observed, discarding all the resting data. This approach needs some knowledge about the system under study to avoid possible pitfalls. This way was taken, e.g. quite recently by Dahlberg et al. [88], to classify vegetable oils.

More objective criteria can be found in literature, for example, Brown [92], Lindgren et al. [93,94] and Xu and Schechter [95] presented different criteria for wavelength selection. Jouan-Rimbaud et al. [96] selected a new, growing tool called genetic algorithms for choosing wavelength sets.

In a previous study, Honigs et al. [97] had described a quantitative criteria for choosing the minimum number of samples and wavelengths to develop a near infrared regression method.

If multivariate methods are considered, factor analysis, singular value decomposition and others constitute one possible solution to data reduction. We will briefly consider this point.

Wang et al. [98] utilized characteristic vector regression analysis (principal component analysis) combined with multiple regression. The key idea is that all the spectra in a data set show relatively restricted variation in form and that there exists a high correlation among them. Under the assumption that the spectra represent the structure of the matter, it is reasonable to break down the measured spectra into several representative spectra to reveal those responsible for the pure structure of the matter and for the measurement conditions. This approach suggests that we could, first, divide the spectra in the database into several representative spectra; second, find the correlation coefficientes between the spectra and the representative spectra; and third, save the representative spectra and correlation coefficients instead of all the spectra. Due to the small number of representative spectra and correlation coefficients, less memory is required for saving both sets than is needed for saving all the spectra.

The maximum entropy reduction method was proposed by Full et al. [99] and it was used by Christy et al. [72] to determine coal maturity and Karstang and Eastgate [100] in order to develop a multivariate calibration of an X-ray diffractormeter using PLS. The main idea of the maximum entropy approach (taken from Full et al., see [100]) is to preserve maximum information about the independent variables (spectra) by creating new 'maximum entropy' spectra with equal total information content (IR-data) in each variable and, so, subjective variable selection is avoided.

The wavelet method is gaining an important role in signal processing. Bos and Hoogendam [101] apply wavelets to evaluate peak intensities in flow-injection analysis and Bos and Vrielink [102] as a preprocessing tool for infrared spectra for the identification of mono- and di-substituted benzenes. In this latter work, the authors demonstrated that the wavelet method reduced IR spectra more than 20-fold with a significant improvement in the classification process. The wavelet theory takes a similar idea to the one posed by Wang et al. [98] since it involves the decomposition of a signal function or vector (i.e. spectrum) into simpler, fixed building blocks at different scales and positions. Like Fourier Transform, wavelet operates on a signal and transforms it linearly from its domain, which is the wavelength, to a different domain. However, unlike FT, whose frequency domain is one dimension only, wavelet generates two-dimensional domains with two parameters: the scale parameter and the position parameter. This property is an improvement of wavelet over FT and provides only the average information of the signal at assigned frequencies along the wavelenght domain. Much more details can be found on two recent books from Chui [103] and the CRC collection [104].

Chau et al. [105] developed a modified algorith named fast wavelet transform. They also studied the side-lobe problems and proposed two algorithms for minimizing them. Examples (UV-VIS spectra) are presented to study the performance of the algorithms. Walczak et al. [106] applied wavelets to NIR spectra and gave

Table 2
Prediction abilities when different measurement units are considered into the PLS-models in order to predict the motor octane number (MON)

	%T	Abs	%T		Abs	
			1st Derivative	2nd Derivative	1st Derivative	2nd Derivative
PLS-1 (SEP, $n = 156$)	0.18	0.25	0.15	0.17	0.18	0.17
PLS-1 (SEC, $n = 30$)	0.19	0.19	0.19	0.19	0.20	0.21

SEP, standard error of prediction; for comparisons, standard errors of calibrations—SEC—are given.

basic ideas in the Section 1 and 'Theory' parts of the paper. Schulz et al. [107] did not use wavelets although they divided the spectra in intervals, the relative entropy of information in the set of intervals is calculated and finally, each information is coded. Algorithms are presented for each step.

Different ways of data compression (reduction) exist, among them those proposed by Alsberg and Kvalheim [108,109], using B-splines (they also compared B-splines and the maximum entropy method) and that from Devaux et al. [110] where fast Fourier Transform is applied as a data compression method before principal component analysis. None of them found essential loss of information using such methods.

As mentioned at the begining of this chapter, the petrochemical applications have been mostly made on liquid samples. In one attempt to select the best choice for our particular problems, we made an extensive survey of the prediction capabilities of several models where absorption, transmittance and different derivatives were considered [111]. Again, results were not definitive though it could be deduced derivatives do not improve prediction values of uncorrelated samples. We have found not important differences between absorption or transmittance units excepting slightly better results if transmittance is used (see Table 2, studies made on untreated gasoline samples taken from production units and predicting antiknock values-broadly known as octane rating numbers). One reason could be, perhaps, the highly satisfactory performance of most nowadays IR spectrophotometers, even more when considering the Fourier Transform techniques. Our samples did not present baseline effects or scatter (we always used clean liquids). In this way, baseline or scatter effects are minimized or negligible, which could not be the same when considering, e.g. meat [112] or other complex matrices.

Of course, an alternative to data pretreatment is not to make data pretreatment at all. But this calls for a totally different approach in the regression step. Thus, Oman et al. [113] proposed to make no data pretreatment and instead, use a non-linear calibration model. This topic is a bit far from our objectives and no more emphasis will be made on it (related topics could be genetic algorithms, neural networks, nonlinear calibrations, and so on).

5. Errors in standard methods

Current regression techniques based on classical least squares assume there is negligible error associated with the predictable values obtained using the reference methods. Unfortunately, this is not always true and 'standard values' could present quite large confidence intervals. Independently of other statistical problems, one of the main consequences is that such uncertainties will contaminate the resulting parameters in the calibration model and, therein, the prediction capabilities. Thought this assumption is not true for PLS since it performs an inverse least squares step, such uncertainties will affect the prediction capabilities. This is nicely covered by Martens and Naes [114] when talking about what beginners should not expect from the PLS-prediction capabilities. The problem is really important in some particular predictions; good examples are two ASTM standard methods for determining both the octane rating and the percentage of aromatics [11–13,16,37,115].

We have to be guarded against this drawback because there is a trend, currently experienced in factories, to demand excellence from the FT-IR-PLS approach. The real fact is there is like a 'background' error difficult to reduce in our predictions. Such value can be grossly (under)-estimated as $SEP >> \sigma_{ref}/\sqrt{n}$ [114], where SEP = Standard Error of Prediction, substitutes the RMSEP from the reference, n = number of samples into the calibration set, and σ_{ref} = precision level of the reference method. Considering the ASTM standard reproducibility values for octane rating ($n = 20$) and % aromatics ($n = 17$), SEP values would be at the very least 0.05 and 0.33, respectively; without doubt, real SEP values can be expected to be bigger which do not necessarily means a bad performance of the chemometric methodology.

This latter rather subjective assessment we had experienced several times was systematically studied by DiFoggio [116] who stated two important corrections for their corresponding misconceptions (another third statement will not apply in the present paper because of its relationship with calibration transferability): (1) IR prediction can be better than the reference method; (2) regression models that only use terms that are linear can account for nonlinear effects, indeed. Briefly (readers are suggested to read DiFoggio's paper), examples are given where the apparent SEC (Standard Error of Calibration) grossly understimatethe real prediction capabilities of the IR-chemometric regression model. The main reason for this advantageous performance of the method itself is that the regression process itself is averaging out most of the random noise in the reference values and yielding an equation whose predictions are more accurate than the noisy data used for calibration.

The second important point is that the usual linear regression methods can cope with nonlinearities since the resultant correlation will account for nonlinear interaction effects and not just for a correlation to spectrometer nonlinearities at high absorbances (an example where up to ca. 3.2 units of absorbance were handled was presented). This paper is an important pillar to objectively justify several satisfactory performance characteristics we have experienced in our petrochemical applications. Generally, we had attributed the good prediction capabilities of the models to the inherent extraction of useful information that PLS is able to get. Now, more reasons can be used.

Aastveit and Marum [117] took into account several mathematical considerations from which better standard deviations for the predicted values than for the reference ones could be expected (when the reference values are obtained using a nonsatisfactory standard method). This fact was confirmed using NIR-reflectance spectroscopy on forage breeding.

A positive fact is the FT-IR-PLS approach offers excellent values either in repeatability and reproducibility [31,65], which is highly advantageous for industrial control. Our experience shows SEP values are generally lower than the standard reproducibility ones showing that predicted values are included into the standard confidence intervals. Exceptions occur when the reference methods are 'excellent' or when they define the property by themselves. Two such situations are the manual standard methods for determining gravity and viscosity in hydrocarbons [118,119]. Both methods are manually performed following exactly the definitions of gravity and viscosity; glassware is well known and calibrations are directly traceable to reference materials; additionally, tests are easy to perform. Under these circumstances, we obtained repeatability and reproducibility values for FT-IR-PLS lower that the manual ones but we have not been able to get SEP values lower than the standard reproducibility values [31] (neither Fodor et al. did, [65]), even with prediction errors of $\sim 0.25\%$ for gravity. One reason could be the validation set was not too broad although ongoing studies considering more samples do not drastically improve our figures. Another reason could lies in the loosening of lighter hydrocarbons from the sample fuels although this should be not important since our spectra were performed almost simultaneously to the ASTM ones and samples were always refrigerated.

In such cases, a good decision could be not to change the analytical approach since classical methods are simple to perform, with simple traceability and simple labware.

Table 3
SEP values found using several models, validation set (n = number of samples)

Gasoline type	PLS-1		PLS-2	
	RON	MON	RON	MON
FCC[a]	0.4 (44)	0.38 (132)	0.39 (50)	0.4 (50)
Platforming A[b]	0.37 (15)	0.33 (61)	0.43 (15)	0.32 (15)
Platforming B[b]	0.42 (36)	0.31 (112)	0.51 (34)	0.45 (35)

Tests for RON are less frequent than MON.
MON, motor octane number; RON, research octane number.
[a] Fluid catalytic cracking (FCC) processes.
[b] A and B are two different types of gasoline samples from Platforming processes, being the A-type quite infrequent.

6. Model validation and running

Calibration is the first step where sample collection is made to get the calibration (learning) set; trivial? We are aiming for a good prediction model so samples have to be selected covering the broadest possible range of production events were acceptable product is obtained in each particular factory. This usually needs time-expanded collections and, of course, the more samples, the better; what could be not easy due to software/production constraints.

Once models were developed (which it is not addressed here), it is time to assess if any of the models work. In D. Steele's words, 'the proof of the pudding is in the eating' [120]. The unique way to verify that your pre-selected model works well is to take new samples and predict them. Esbensen et al. [44] covered several ways of validation including leverage correction, cross-validation using small data sets, leave-one-out cross-validation and testing new samples.

After collecting the initial data set, samples have to be distributed in one calibration and one validation set. This could present one main drawback since in our experience it is rather easy to get 'excellent' models if you collect, say, 50 samples and from them you pick out say, 30, for calibrating and use the resting ones for validation. Since you are modeling what you are predicting, models are good. Problems, surely, will arise when using your model to predict samples after, say, one month.

Consequently, another different approach was used trying to get models having a good predictive ability, but also being robust against small changes. Firstly, calibration and model development using the leave-one-out validation scheme; second, selection of the two or three most promising models; third, testing each model using newly-collected samples (at least, one week after the calibration ones); forth, selection of the best model; fifth, intensive control/maintenance of the model running it with daily samples. Without doubt, this approach has three main drawbacks:

(i) More samples are needed, which could not be easy in some circumstances

(ii) More time is required to get a model. Note that it is assumed that all the samples taken from step 1 to step 4 will cover the habitual production characteristics (which is quite true for our particular situation and, surely, not very difficult to get in other situations). If any sample is strongly different (due to, e.g. an abnormal situation) it is presumed that it will be discovered in the calibration or testing studies. Of course, the models will not be robust to any change

(iii) More work has to be done since more models are discarded and new ones assayed

But, this is the best way to obtain reliable models. Thereby, 46 FCC gasoline samples were used to select the best model for octane rating prediction (stages 3rd and 4th) and 50 new ones for a final test [16]; also, 68 reformed naphthas were used for calibration and 118 ones for testing another similar model [121]. SEP values are presented on Table 3. It also shows that the PLS

Table 4
Prediction capabilities for octane rating models using different analytical techniques

Technique	Reported prediction capabilities	Reference
High resolution gas chromatography	Maximum difference between ASTM and predicted values <0.8 O.N.	[122]
Gas chromatography	SEP(RON) = 0.48 SEP(MON) = 0.32	[123]
NIR	SEP(RON) = 0.29 SEP(MON) = 0.34	[29]
NIR (660–1215 nm) (selecting specific wavelenths)	Using PLS: SEP(RON + MON/2) = 0.30	[27]
	Using MLR: SEP(RON + MON/2) = 0.32	
NIR	SEP(RON) ~ 0.3; SEP(MON) ~ 0.35	[28]
MIR (selecting wavelenths)	SEP(RON) = 1.57	[124]
MIR-GC	SEP(RON) ~ ± 1 O.N.	[125]
MIR (ATR system)	SEP(RON) = 0.50 SEP(MON) = 0.31	[61]

2-block could be suitable for FCC gasolines predictions but PLS 1-block should be selected for predicting Platforming naphthas.

There is another reason to gain confidence in each particular work. As it was noted, and due to several reasons, the MIR region was used to perform these studies. Most of previous works that can be found in the literature (some examples were covered here) refer to the NIR region. Doubts could arise on which IR region (MIR vs NIR) is best suited for developing prediction models. Of course, each one has its advantages and disadvantages, at this point we are not interested on them; but, rather in deciding if our approach could be comparable to the ones using NIR or, even, to other analytical techniques. In this paper one comparison for octane rating predictions is presented because more works have been published on it (see Table 4).

Comparison of Tables 3 and 4 reveal that our approach is good. It should be taken into account that pretty more samples have been considered into the testing sets and they are collected three or four months after development of the calibration models. So, the FT-MIR-PLS way appears to be highly satisfactory for use in off-line or near-line measurements. Besides, MIR advances are occurring quite fast and we can get now fiber optics of several meters with satisfactory performance [126,127].

We would like to pose a final problem that could be defined as model-aging.

When validating the model using daily samples during several months, it can be found that at the long time, the regression model suffers from a lack of fit respecting the standard method values. This is evidenced by, e.g. the absolute difference between figures obtained using the two methods but, also, for a broadening in the calculated confidence intervals. In our opinion, such problem was not too broadly discussed despite of its importance. One reason for this lack of fit in the long term is that factory production is not stable in time, at least, considering medium/long time. It is well known by chemists working in production units that product quality change (little but continuously) with time and corrective actions have to be taken. Such changes modify, to some extent, composition and/or chemical properties. Sometimes, the standard method is not so sensitive to detect these minor variations but the IR spectroscopy does, indeed. It appears as, in some sense, our spectral-chemometric approach could be too sensitive. Our experience in this respect is linked to the octane rating methods and some other fuel properties.

The problem is that calibration has to be limited on time and, therefore, the unique solution to what we called 'model aging' is recalibration. One particular, empirical solution is to be exposed though more efforts are needed. Recalibration was briefly considered also by Gemperline and Salt [128]. Recalibratiion (updating) was also studied by Helland et al. [129]. We have found

that our main problem when updating is the increase in the calibration matrix dimensions. This question was the main focus of the Helland's paper. They proposed a new algorithm for PLS regression (recursive-PLS) designed to keep the size of the matrices entering the PLS algorithm after new samples are added. The main drawback is that the typical autoscaling step is not easy to maintain along the updating steps due to the mathematical treatment and, therefore, centering is not recommended. This will result in one extra factor in the regression models. This paper is an interesting step forward towards simplification of parameter monitoring by PLS models.

When no particular events occured onto the production units, our models usually began to fail during the third or forth month. Failure was detected analyzing both the absolute errors for predicted values (FT-IR-PLS predicted values minus the standard method ones) as well as confidence intervals for several new samples. Once the problems were detected, several new samples were introduced into the learning set, calibration was repeated and ran again. Generally, satisfactory results were obtained for new samples from this point. Unfortunately, a fixed recalibration frequency is not easy to stablish; considering the octane rating prediction and our particular models, recalibration is advisable during the third month of model use, although it depends on many factors, among them on production stability.

Since our examples are not general, it was pretended to open discussions and to get conscientiousness on exercising care to develop industry-focused, statistical models for property prediction. This calls for one analytical chemist, with a chemometric background, working interdisciplinary on both the analytical laboratory and the production units.

7. Conclusion

Several current problems regarding multivariate statistical models for property prediction in quality control have been discussed. Among them, there are four important ones: (i) data pretreatment; (ii) errors in standard methods; (iii) model validation; and (iv) updating the regression model to cope with slightly changes in product composition-recalibration.

Determination and fractionation of sulphur in a contaminated dredged sediment[1]

F.M. Tack *, F. Lapauw, M.G. Verloo

Laboratory of Analytical Chemistry and Applied Ecochemistry, University of Ghent, Coupure Links 653, 9000 Gent, Belgium

Received 5 June 1996; received in revised form 9 October 1996; accepted 14 October 1996

Abstract

Conversion of sulphur compounds in reduced, contaminated sediments that are brought in upland conditions may largely affect the potential mobility of heavy metal contaminants. We applied selected methods for the determination of total sulphur and sulphur fractions in a contaminated sediment in the reduced state and after gradual drying and oxidation during 1 month. Dry ashing, followed by ion chromatographic detection, was reliable for the determination of total sulphur. Good recoveries were obtained in both reference samples and spiked samples. Total sulphur was 14.5 ± 0.6 g kg^{-1} relative to dry sediment. Wet chemical methods that involve the determination of acid-volatile, Zn–HCl-reducible, chromium-reducible, acetone-soluble and HI-reducible sulphur were used to estimate specific sulphur forms. Results for acetone-soluble sulphur were to high and not consistent with results for other fractions. Major part of sulphur in the sediment (90%) was inorganic. Sulphides were converted partially to sulphate and to intermediary oxidised sulphur compounds upon oxidation of the sediment. The results suggested that the intermediary oxidised sulphur pool in the reduced sediment (2.5 g kg^{-1}) mainly consisted of pyrite, that was not converted during drying and oxidation. No significant changes in organic sulphur were detected. © 1997 Elsevier Science B.V.

Keywords: Extraction; Oxidation/reduction; Sulphur compounds

1. Introduction

Contaminated dredged materials that are disposed on the land may be subjected to oxidation. As a result, the mobility of contained metals may change [1–3]. In that context, conversions of sulphur compounds may play an important role. Iron and metals are released when their sulphides are moved into oxidising environments where they are unstable. [1] The oxidation of metal sulphides may also result in acidification in soils that are drained and aerated [4].

Various sulphur compounds occur in soils and sediments. Inorganic sulphur forms include sulphates (SO_4^{2-}), elementary sulphur (S), metal sulphides (e.g., FeS) and pyrite (FeS_2). In between the sulphates (oxidation state VI) and the sulphides, several intermediary oxidised sulphur species can exist or be formed, e.g., bisulphide (S_2^{2-}, oxidation state – I), polysulphide (Sn^{2-}, $-II/n$),

disulphuroxide (S_2O (g), + I), sulphur monoxide (SO (g), + II), thiosulphate ($S_2O_3^{2-}$, + II), dithionite ($S_2O_4^{2-}$, + III), sulphur dioxide (SO_2 (g), + IV), sulphite (SO_3^{2-}, + IV) and sulphur trioxide (SO_3 (g), + VI) [5]. Organic sulphur forms are generally divided into the ester sulphate group and the carbon-bonded sulphur compounds [6–8]. In well drained, well-aerated soils, most of the inorganic sulphur normally occurs as sulphate. Under anaerobic conditions, the main form of inorganic sulphur in soils and sediments is sulphide and often elemental S [7].

Sulphur contents in soils generally are between 0.1 and 0.5 g kg^{-1} [7]. Polluted sediments may contain more than 5 g kg^{-1}. Inorganic sulphur compounds tend to dominate in polluted sediments while organic sulphur compounds normally make up the largest fraction in unpolluted sediments [8,9].

In determination of total sulphur in soils and sediments, the various sulphur forms are converted by oxidation, most often to sulphate. This is achieved by digestion with concentrated acids, ashing with Ag_2O and $NaHCO_3$, [10] oxidation with $NaOBr_7$ or alkaline fusion [11]. For the determination of sulphur in the extract, ion chromatography compared favourably with the methylene blue method [10,12]. Indirect atomic absorption [13] and ICP [14,15] may also be used to quantify sulphate in the extract. The use of X-ray fluorescence for determination of total sulphur in soils gave satisfactory results [16,17]. Elemental analysers are being developed to determine total sulphur in soils and sediments. Their advantage lies in simplicity, speed and convenience. They appear, however, unsatisfactory for research requiring accurate and precise determination of total sulphur in soils or sediments [7,18].

The classical procedures for the determination of reduced and intermediary oxidised sulphur compounds in soils and sediments involve their reduction to H_2S and trapping the evolved H_2S in Zn–acetate solutions. Trapped sulphide is classically determined by colorimetry with methylene blue or by iodometric titration [7]. Instrumental techniques such as high resolution X-ray spectrometry [17], reflectance analysis [19] or a combination of thermogravimetric techniques [20] are being developed to directly determine specific sulphur compounds in the solid sample, but as yet are not largely applied in environmental sulphur analysis.

Accurate determination of the reduced forms of inorganic sulphur is difficult, partly because of the ease with which they can be oxidised on exposure to air, but mainly because of the limitations of current analytical methods [7]. We applied wet chemical methods for the determination of acid-volatile sulphur (AVS), Zn–HCl-reducible sulphur (Zn–HCl S), chromium–reducible sulphur (Cr^{2+}–reducible S), acetone-soluble sulphur and hydroiodic-acid–reducible sulphur (HI–reducible S) on a reduced, contaminated sediment, which was subjected to gradual drying and oxidation such as occurs upon land disposal. The analytical results allow to estimate resulting changes in sulphur compounds that may occur upon land disposal of contaminated dredged materials and are critically evaluated. This may contribute to a better understanding and interpretation of analytical results from sulphur compound analysis and to an improved understanding of the factors that govern the fate and behaviour of pollutants in contaminated dredged materials.

2. Experimental

2.1. Sampling

Sediment was sampled from the confined upland disposal site Geuzenhoek, situated on the left bank of the Gent-Terneuzen canal, Belgium. The canal crosses an industrial area (steel production, thermal power plant, chemical and food industry). The sediment was dredged and disposed 1 year before our sampling. It was characterised by a high carbonate content (15.2%) and a pH (1:5 in H_2O) of 8, and was polluted with heavy metals and organics [21]. It was strongly reduced (− 200 mV versus the standard hydrogen electrode). Organic matter content was 9.5%.

At the time of sampling, 20–50 cm of water covered the sediments. Sediment grab samples were taken in October 1992 and collected in 10 l polyethylene containers. Care was taken to min-

imise the contact time with the air. The sediment was stored covered with canal water.

2.2. Experiment

To assess sulphur fractions affected by gradual drying and oxidation of this reduced sediment, an 8 cm layer of the sediment (dry matter content: 44%) was brought in a rectangular container (50 cm length, 30 cm width and 10 cm height) and kept in the air at an ambient temperature of 20–22°C. No water was allowed to drain: removal of water occurred by evaporation only. Every 2 days, the sediment was stirred using a rinsed polyethylene tube, and 5–10 g were sampled in a plastic bag. The bag was purged with N_2 and sealed, and the sediment was homogenised by kneading. After about 2 weeks, the sediment had dried to the extent (dry matter content: 60%) that aggregates remained upon mixing. These were broken to a diameter size of at most 2 cm.

Total sulphur and various sediment characteristics were determined at the start of the experiment. Calcium carbonate content, organic matter content and sulphur fractions were determined at the start and after 16 and 30 days. Acid-volatile sulphur, extractable sulphate and chromium–reducible sulphur were determined every 2 days.

2.3. Chemical analysis

Organic matter was estimated by ashing during 3 h at 450°C [22]. Carbonate content was determined by back titrating an excess of 0.5 mol l^{-1} HCl added to an amount of sample containing 1 g dry matter with 0.5 mol l^{-1} NaOH [23]. The pH of the sediment was measured potentiometrically in a 1:5 solid:liquid suspension of the sediment in distilled water. Redox potentials were measured by inserting a platinum electrode and a saturated calomel electrode in the sediment paste and waiting for a stable reading. During the experiments, redox measurements were performed in a 1:5 solid:liquid suspension. The values obtained therefore are not actual redox potentials in the undisturbed sediment, but should be considered merely as relative indicators for the progress of oxidation.

2.4. Sulphur determinations

2.4.1. Total sulphur

Total sulphur was determined by dry ashing [7] and sulphate detection using ion-chromatography [24]. Air dry sediment (0.5 g) was ashed with 2.5 g $NaHCO_3$ and 0.1 g Ag_2O during 3 h at 550°C. The ashed residue was boiled in 50 ml of carbonate/bicarbonate buffer (2.6 mmol l^{-1} Na_2CO_3 – 2.4 mmol l^{-1} $NaHCO_3$) during 3 h under reflux to extract sulphates, that were analysed in the filtrate by ion chromatography (Dionex 2000i/SP). Aqueous standard solutions of sulphate (5 and 10 mg l^{-1}), freshly prepared using reagent grade anhydrous sodium sulphate (UCB, Brussels), were used for calibration.

2.4.2. Extractable sulphate

An amount of wet sediment, equivalent to approx. 0.5 g dry matter, was extracted in 50 ml carbonate/bicarbonate buffer (2.6 mmol l^{-1} Na_2CO_3 + 2.4 mmol l^{-1} $NaHCO_3$) in a 250 ml polyethylene centrifuge tube. The extracting solution was previously flushed with N_2-gas. The centrifuge tube was sealed using laboratory film after flushing the head space with N_2-gas. The suspension was mechanically shaken during 1 h [25], centrifuged (1500 × g during 20 min), and the supernatant liquid was analysed for sulphate by ion-chromatography.

2.4.3. Acid-volatile sulphur (AVS)

The following procedures for quantifying sulphur fractions involved the reduction of sulphur to H_2S in an Johnson-Nishita apparatus [26] and trapping the evolved H_2S in Zn–acetate solutions. Acid-volatile, Zn–HCl-reducible, chromium-reducible, acetone-soluble and hydriodic-acid–reducible sulphur were determined as described by Wieder et al. [27] The sample (50 mg for the hydriodic-acid–reducible sulphur and 500 mg for the other fractions) was added to the reaction flask and the system was purged with N_2 at a bubbling rate in the Zn–acetate traps of 1–2 bubbles per s for 10 min before the introduction of reagents.

AVS was determined by introducing 8 ml of 12 mol l^{-1} HCl into the reaction flask. After 10 min,

the suspension was brought to boiling and after 45 min the traps were removed and the sulphides titrated.

2.4.4. Zn–HCl–reducible sulphur (Zn–HCl S)

The procedure for the determination of Zn–HCl S was similar to that for AVS, except that 3 g Zn-metal were added at the same time as the acid. The material was boiled during 1 h before removal of the traps and titration.

2.4.5. Chromium–reducible sulphur (Cr^{2+}–reducible S)

Cr^{2+}–reducible S was determined by percolating a 1 mol l^{-1} solution of $CrCl_3$. $6H_2O$ in 0.5 mol l^{-1} HCl through a Jones reductor column containing Zn amalgamated with Hg [28]. Of the reduced chromium solution, 16 ml were introduced into the reaction flask. After 10 min, heat was applied and the material treated as for Zn–HCl S.

2.4.6. Acetone-soluble sulphur (acetone-soluble S)

To determine acetone-soluble S, 0.5 g sediment were extracted during 16 h with 20 ml of analytical grade acetone. The extraction flask was covered with Parafilm and placed on a horizontal shaker. The mixture was filtered and diluted to 25 ml. The entire filtrate volume was introduced into the reaction flask and subjected to Cr^{2+} – reduction as described above.

2.4.7. Hydriodic-acid–reducible sulphur (HI–reducible S)

For the determination of HI–reducible S, a solution of 50% hypophosphorous acid, 90% formic acid and 57% hydriodic acid in a proportion of 4:2:1 was prepared daily. Instead of 8 ml [27] of that solution, 20 ml were brought in the reaction flasks. After 10 min, the suspension was heated to boil during 90 min.

2.4.8. Sulphide determination

After each of the extraction/distillation procedures, trapped sulphide was determined by iodometric titration [28]. To the sequential wash bottles, 1 mol l^{-1} KIO_3 (8 ml to the first and 2 ml to the second bottle), 1.5 g KI and 4 ml of concentrated HCl (37%) were added. The contents of the wash bottles were pooled in a 500 ml erlenmeyer and titrated with 0.01 mol l^{-1} $Na_2S_2O_3$ using starch as an indicator.

3. Results and discussion

3.1. Total sulphur

Analysis of total sulphur in reference plant material (spruce needles, CRM 101, Community Bureau of Reference, Commission of the European Communities, Brussels) agreed closely with the certified value (Table 1). For the sediment reference sample (CRM 277), we obtained higher results. Sulphur in the sediment reference material, however, was not certified, but indicative only. Reproducibility was excellent for the plant sample, but lower for the sediment samples. During ashing of sediments, as opposed to plant material, the large mineral matrix remaining may be responsible for the lower reproducibility. The higher variability in the analysis of the Geuzenhoek sample as compared with the reference sediment may result from additional random error related with the handling of wet sediments, i.e., increased possibility of sample heterogeneity and more uncertainty about the exact dry weight of the sample.

Table 1
Analysis of total sulphur in reference samples, the Geuzenhoek sediment and spiked sediment samples (g kg^{-1} dry sediment)

	Determined	Reference value
Spruce needles (CRM 101)	1.67 ± 0.05 ($n = 10$)	1.70 ± 0.10[a]
Estuarine sediment (CRM 277)	6.06 ± 0.25 ($n = 10$)	5.17 ± 0.18[b]
Addition		
Geuzenhoek	14.5 ± 0.6 ($n = 15$)

Sulphanylamide	19.3 ± 0.3 ($n = 5$)	19.9 ± 0.6

[a] Certified value.
[b] Indicative value.

Table 2
Determination of sulphur fractions (g kg^{-1} dry sediment)

	Reduced sediment	Oxidised sediment[a]
Total S	14.5 ± 0.6[b]	
AVS	10.4 ± 0.3[c]	0.0
Zn–HCl S	11.6 ± 0.2[c]	2.3
Cr2+–reducible S	12.9 ± 0.2[c]	5.5
Acetone-soluble S	6.9 ± 1.2[c]	—
HI–reducible S	13.9 ± 0.1[c]	14.1
Extractable sulphate	0.08 ± 0.01[c]	6.2

[a] No replicate measurements performed. Estimates on reproducibility may be obtained from replicate determinations on the reduced sediment.
[b] $n = 15$.
[c] $n = 3$.

Spikes of inorganic (potassium sulphate) and organic sulphur (sulphanylamide) were recovered well. Sulphur contents determined were not significantly different from the expected value (*t*-test at the 0.05 level of significance), although the recovery of organic sulphur tended to be somewhat lower. Total sulphur analysis was therefore accurate and reproducible.

3.2. Sulphur fractions

Different sulphur fractions are thought to consist of specific sulphur forms. Sulphur contents in both the reduced and oxidised sediments were determined using various determination procedures (Table 2). The contents of specific sulphur forms may be estimated from the various sulphur determination procedures (Table 3).

Acid-volatile sulphur (AVS) is mostly sulphide S [27,29]. In the reduced sediment, 70% of total sulphur was sulphide S. AVS was quantitatively converted during drying and oxidation of the sediment (Table 2). The formation and accumulation of inorganic sulphur fractions is typical for polluted sediments and is related to a large influx of sulphur compounds, protons and metals [8].

3.3. Zn–HCl sulphur

It has been assumed that Zn–HCl S represents all inorganic sulphur except sulphate [30]. Landers et al. [25] used the Zn–HCl distillation procedure for the determination of inorganic non-sulphate sulphur but warned for incomplete recovery of pyrite when present in reduced soils or sediments. Wieder et al. [27] found the procedure of questionable value because sulphur from S^0, FeS_2 and SO_4^{2-} was only partially recovered.

Zn–HCl S was significantly higher than AVS (Table 2). As extractable sulphates were negligible in the reduced sediment, the difference (1.2 g S^{-1} kg sediment) must be attributed to the presence of FeS_2–S or S^0–S.

In the oxidised sediment, the difference between Zn–HCl S and AVS was 2.3 g as compared with 1.2 g in the reduced sediment. This may result from sulphates in the oxidised sediments, that are partially determined as well. [27]

Wieder et al. [27] determined extraction/distillation efficiencies by analysing pure sulphur compounds with the different methods. They found that 15.5–24.0% of the added sulphate was determined as Zn–HCl S. Assuming a recovery of 20%, then 1.24 g of Zn–HCl S should have originated from sulphates present in the oxidised sediment (6.2 g). The remaining sulphur (1.06 g) agreed with the difference between Zn–HCl S and AVS in the reduced sediment (1.2 g). This may

Table 3
Estimation of sulphur fractions (g kg^{-1} dry sediment)

[a] Estimated from the total content determined at the start of the experiment.

suggest either that the intermediary oxidised sulphur compounds were not affected in the dried, oxidised sediment, or that intermediary oxidised sulphur formed during oxidation was balanced by removal.

3.4. Chromium–reducible sulphur

Chromium–reducible sulphur represents all inorganic reduced and intermediary oxidised sulphur, i.e., iron monosulphides, pyrite (FeS_2) and elemental S [27,31]. The difference between Cr^{2+}–reducible S and AVS was therefore listed as intermediary oxidised sulphur in Table 3.

Intermediary oxidised sulphur was estimated to be 2.5 g kg^{-1} in the reduced sediments. If this was S^0, then 0.25 g kg^{-1} should be extracted in the Zn–HCl-fraction, assuming 10% recovery [27]. If instead it was all FeS_2, then 45% or 1.13 g kg^{-1} should be found in that fraction. The latter value agrees with the observed difference between Zn–HCl S and AVS (1.2 g kg^{-1}) and therefore suggests that intermediary oxidised sulphur in the reduced sediment largely was FeS_2–S.

In the oxidised sediment, 1.06 g out of 2.3 g Zn–HCl S was assumed to originate from intermediary oxidised sulphur (see before). Applying the percent recovery values for FeS_2 in the Zn–HCl and Cr^{2+}-reducible extractions determined by Wieder et al., [27] one can estimate the recovery of this intermediary oxidised sulphur as $1.06 \div 46\% \times 93\% = 2.14$ g S, assuming that it is all FeS_2–S. Otherwise, if this intermediary oxidised sulphur were S^0–S, $1.06 \div 12\% \times 94\% = 8.3$ g sulphur should be extracted in the Cr^{2+}-reducible fraction. The latter value is far in excess of the experimentally found Cr^{2+}-reducible sulphur in the oxidised sediment (5.5 g), while the former value corresponds with the intermediary oxidised sulphur in the reduced sediment (FeS_2–S). It is therefore suggested that FeS_2 was not largely affected during drying and oxidation of the sediment. Other Cr^{2+}–reducible S in the oxidised sediment may include S^0 and perhaps $S_2O_4^{2-}$ and $S_2O_3^{2-}$, formed by oxidation of sulphide S.

It is not likely that new FeS_2 would have been formed during oxidation of the sediment. The formation of pyrite in nature generally is a very slow process, taking months, years, or decades as amorphous iron monosulphides (FeS) react with elemental sulphur (S^0) [32]. It has been shown that pyrite may also form rapidly without iron monosulphides as intermediates, provided soluble sulphides are present and iron monosulphides are undersaturated [32]. These conditions are not likely to have occurred in the sediment studied, as large amounts of FeS were present.

3.5. Acetone-soluble sulphur

The method to determine acetone-soluble S is believed to be specific for S^0 [27]. We found it difficult to obtain reproducible results for acetone-soluble sulphur. Visual detection of the endpoint of the titration was hindered by the presence of a turbidity in the wash bottles. The reproducibility was much lower than for the other sulphur fractions and the results obtained, moreover, were inconsistent with the other fractions.

Acetone-soluble S (6.9 g S kg^{-1} dry sediment) was much higher than intermediary oxidised sulphur, estimated as the difference between Cr^{2+}–reducible S and AVS (2.3 g S kg^{-1} dry sediment). Moreover, the sum of AVS and acetone-soluble S was higher than the total sulphur. It is therefore not possible to obtain an estimate for elemental sulphur from acetone-soluble S. It could be concluded from these high values that intermediary oxidised sulphur largely consisted of elemental sulphur in this sediment, but this is in contradiction with the results obtained for Zn–HCl S and Cr^{2-}–reducible S, as illustrated before.

3.6. HI–reducible sulphur

HI-reduction is commonly used to measure organic ester sulphate S, with the attendant assumption that the procedure liberates sulphur from all inorganic sulphur compounds as well [27]. Ester sulphate S may thus be estimated by the difference between HI–reducible S and the sum of Cr^{2+}–reducible S and sulphate S. Carbon-bonded sulphur is estimated as the difference between total S, inorganic S and ester sulphate S.

The estimation by difference was uncertain because of the large inorganic sulphur pool com-

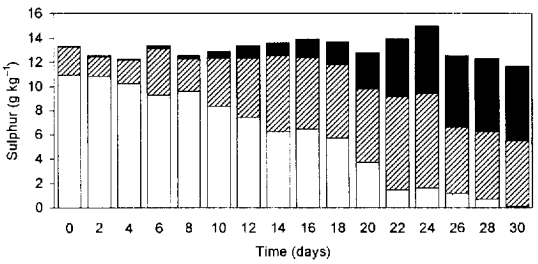

Fig. 1. Sum of chromium-reducible sulphur and sulphate sulphur as a function of time. Sulphide forms were plotted as a fraction of chromium-reducible sulphur.

pared with organic sulphur in our sediment. For comparison, Wieder et al. [27] estimated sulphur fractions in peat soils, containing approx. 0.9 g ester sulphate S and only 0.6 g inorganic S kg^{-1} dry sediment.

3.7. Changes in inorganic sulphur fractions with time

Changes in inorganic sulphur fractions with time are shown in Fig. 1. Sulphides steadily decreased to zero within 30 days. The decrease proceeded faster at day 16 and coincided with the sediment starting to form aggregates upon mixing. A better contact with the air was thus established, resulting in a faster drying and a faster increase in redox potential (Table 4).

The significant decrease in carbonate content shows that a substantial amount of acidity was produced upon oxidation of the sediment. The oxidation of metal sulphides is a major cause of acidification in soils that are drained and aerated [4]. Because of the high carbonate content, the sediment was efficiently buffered, as illustrated by the pH values. Gambrell et al. [33] reported on a carbonate free sediment for which the pH dropped from neutral (7.0) to strongly acidic (3.0) after stirring under air for 8 days.

4. Conclusions

The determination of total sulphur by dry ashing, followed by ion chromatographic detection of sulphate, was reliable. Application of a fractionation scheme allowed to estimate sulphur fractions, but because of the possibility of large relative errors, the estimation of minor fractions may be difficult. Our determination of S^0 by acetone extractable sulphur suffered from a low reproducibility. Values obtained were too high and were

not consistent with results obtained for the other fractions.

Major part of sulphur in the sediment was inorganic. Sulphides were converted partially to sulphate and to intermediary oxidised sulphur compounds upon oxidation of the sediment. The results suggested that an intermediary oxidised sulphur pool in the reduced sediment consisted of pyrite, that was practically not affected within 1 month. No significant changes in organic sulphur were detected.

Abstract

The formation of an inclusion complex between 9-methyl-12*H*-benzo[*a*]phenothiazine (MeBPHT) and 2-hydroxypropyl-β-cyclodextrin (HP-β-CD) was investigated in aqueous medium. A 12-fold fluorescence emission intensity enhancement was found for the complexed relative to the free analyte. MeBPHT forms a 1:1 stoichiometry complex with HP-β-CD. A formation constant of 460 ($\pm$ 100) M^{-1} was calculated using the Benesi-Hildebrand method and fluorimetric data. The limit of detection was 7 ng ml^{-1} for MeBPHT in the presence of HP-β-CD instead of 60 ng ml^{-1} in the absence of HP-β-CD. © 1997 Elsevier Science B.V.

1. Introduction

The most important property of phenothiazines (PHT) is their antidepressant activity [1]. Thereby, they enter in a variety of tranquilizing drug formulations. Also, they possess photochemotherapeutic abilities against carcinoma and they can be used as insecticides [2,3]. Recently, new benzophenothiazines (BPHT) have been synthesized, and their medical and physico-chemical properties have been investigated [4–11]. BPHT are potential anthelmintics and they are endowed with antiviral activity which inhibits multiplication of encephalomyocarditis in tissue culture [4]. The differentiation of three human myelogenous leukemic cell lines into maturing monocytes/macrophage was induced by unsubstituted BPHT and its 5-oxo derivative [3,5,6]. Motohashi et al. [7,8] established a correlation between the π electron density and the antitumoral activity of several BPHT derivatives and found the existence of substituent effects on the T antigen expression of adenovirus infected cells. Among BPHT derivatives, 9-methyl-benzo[*a*]phenothiazine (MeBPHT) (Fig. 1) presents the most potent anticancer activ-

PII S0039-9140(97)00038-6

ity and possesses the highest electronic density on the nitrogen atom [7,8]. On the other hand, the pronounced coloration of BPHT derivatives allows them to be applied in polymer area as polycyclic dyes and pigments [9].

Several analytical methods, including thin layer chromatography (TLC), [12] high performance liquid chromatography (HPLC), [13] flow injection analysis (FIA), [14] and spectrofluorimetry, [15] have been reported for the determination of phenothiazines. Also, in our laboratory, photoinduced fluorescence was used to improve the PHT derivatives detection [16–18]. However, with the exception of Azure A:β-cyclodextrin (CD) complex [19], for which the limit of detection was approximately three times lower than that of the uncomplexed species, the fluorimetric determination of cyclodextrin-complexed PHT or BPHT derivatives has hiterto not been exploited.

In fact, the presence of CD and correctly-sized organic molecule in aqueous solutions results generally in the formation of inclusion complexes [20–22]. It is well documented that even a partial binding to the CD cavity is accompanied by noticeable changes in the photophysical properties of the guest compound. Among other interesting features, fluorescence intensity enhancement [23] and chiral activity induction [24] are obtained upon addition of CD. Accordingly, better enantiometric separations by HPLC, [25,26] TLC [27] or capillary zone electrophoresis, [28] have been reported for various compounds. Also, the spectrofluorimetric determination of procaine [29] and nalidixic acid [30] was improved by the preparation of host:guest complexes.

This paper describes the effect of HP-β-CD on the fluorescence intensity of MeBPHT, and the stoichiometric and thermodynamic characteristics of the inclusion complex. The fluorescence signal enhancement is used to develop a novel cyclodextrin-induced spectrofluorimetric method for the determination of MeBPHT. The possibility of applying this analytical approach to other biomedically-important, structurally-related benzophenothiazines is discussed.

2. Experimental

2.1. Reagents

9 - Methyl - 12*H* - benzo[*a*]phenothiazine (Me - BPHT) was a kind gift of Professor N. Motohashi (Meiji College of Pharmacy, Tokyo, Japan). 2-Hydroxypropyl-β-cyclodextrin (HP-β-CD) was purchased from Aldrich Co., and used without further purification. HP-β-CD was selected for the following reasons: larger solubility in aqueous media (162 g/100 ml in ethanol/H_2O, 50:50, v/v) [20] relative to that of unsubstituted β-CD (1.3 g/100 ml in ethanol/H_2O, 50:50, v/v); [20] convenient size of its cavity for housing MeBPHT, and inexpensive cost relative to other CDs. Solvents used were purified, liquid chromatographic grade water and ethanol (Merck, analytical-grade reagent).

2.2. Apparatus

Fluorescence spectra were recorded on a Perkin-Elmer model LS 50 luminescence spectrometer equipped with a 20 W pulsed xenon lamp, with impulsions of a 8 μs duration. The instrument was connected via an RS-232 interface to an IBM PS\2 80386-SX microcomputer. Data acquisition and analysis were performed with the Perkin-Elmer fluorescence data manager software, version 2.70. Fluorescence spectra were obtained using 15 nm bandwidth excitation and emission slits. The monochromator scan rate was maintained at 240 nm/min. Fluorescence measurements were done at 20°C, using a thermostatically-controlled cell holder and a Selecta Model 382 thermostatically-controlled water bath.

2.3. Procedure

First, 10^{-3} M MeBPHT stock solutions were freshly prepared in ethanol, and kept in the dark to avoid photooxidation and degradation of the analyte. These solutions were used for preparing 10^{-5} M diluted samples for analytical purposes. Also, 0.1 M HP-β-CD aqueous stock solutions were utilized. The general procedure consisted to add a suitable volume of HP-β-CD solution to 0.1 ml of a 10^{-3} M MeBPHT ethanolic solution, and to dilute to the mark in a 10 ml calibrated flask with water. The mixture ratio was 99:1 (water/ethanol, v/v) for all working solutions. At such MeBPHT concentration (10^{-5} M) and solvent composition, the solutions were homogeneous, showing that MeBPHT becomes soluble in this predominantly aqueous medium in the presence of HP-β-CD.

The calculation of the complex formation constant as well as the statistical treatment of analytical data were performed using a software Origin, version 3.5 program.

3. Results and discussion

3.1. Effect of the medium composition

The effects of solvent and of HP-β-CD on the fluorescence spectral properties of MeBPHT were investigated. Fig. 2 shows the excitation and emission fluorescence spectra of MeBPHT in various media: ethanol (curve 1), water/ethanol (99:1, v/v) (WE) mixture (curve 2), and WE mixture with 0.1 M HP-β-CD (WECD) (curve 3). The excitation maxima are located in the 320–340 nm region, and are slightly red shifted ($\Delta\lambda_{exc} \cong 15$ nm) in ethanol and WECD media relative to WE mixture; while one broad emission band occurs at 515 nm and 513 nm in WE and WECD solutions, respectively. The latter value corresponds to a 8 nm red-shift relative to the emission maximum in pure ethanol. This radiative process can be attributed to the π^*, π deactivation transitions belonging to the naphthalene moiety, as previously reported [10,31].

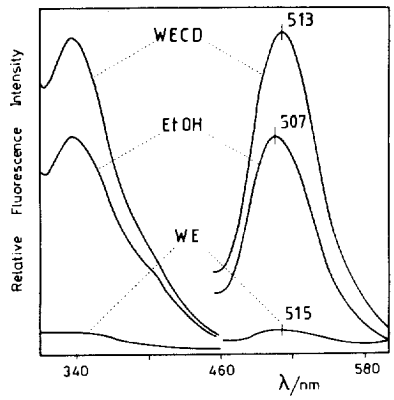

Fig. 2. Excitation and emission fluorescence spectra of 9-methyl-benzo[*a*]phenothiazine (10^{-5} M) in (WE) water/ethanol 1:99 (v/v) mixture; (EtOH) ethanol; (WECD) water/ethanol mixture in the presence of 0.1 M HP-β-CD.

A significant increase of the MeBPHT fluorescence intensity occurs in the presence of HP-β-CD (Fig. 3). Indeed, the emission spectrum of MeBPHT, presents a fluorescence intensity 12 times higher in WECD than in WE. Moreover, the fluorescence signal is approximately 1.5 times higher in HP-β-CD than in an ethanolic solution.

All these spectral features are in agreement with other literature data showing spectrofluorimetric evidence of the complexation with CDs [19,20,30]. Indeed, encapsulation of organic fluorophores in

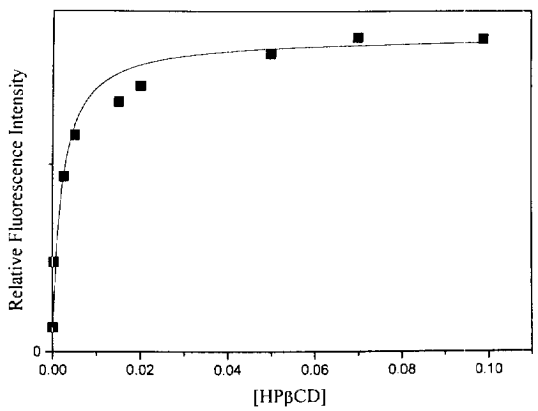

Fig. 3. Influence of HP-β-CD concentration on the fluorescence intensity of a 10^{-5} M MeBPHT solution. The solid line was calculated through the use of Eq. (4), assuming a 1:1 stoichiometry and F_∞ and K_f values obtained by non-linear regression analysis.

cyclodextrins, has generally a minor effect on the ground and excited electronic states energy levels, but it modifies significantly the radiative and radiationless transition rates. This behaviour can be attributed to the restricted mobility of the analyte within the CD cavity, and/or to the shielding of the radiative singlet excited-state from quenching processes by solvent molecules. Also, the hydrophobic effect allows interaction between the apolar CD interior and MeBPHT, which contributes to stabilize the analyte and dissolve it in water. The mechanism of inclusion of MeBPHT in HP-β-CD might be attributed to various hydrophobic/lipophilic processes, as suggested recently [22].

3.2. Effect of HP-β-CD concentration

The HP-β-CD effect was studied quantitatively by adding increasing concentrations of HP-β-CD (from 0 to 0.09 M), to MeBPHT (5×10^{-5} M) solutions, in WE medium. As can be seen in Fig. 3, the increase of HP-β-CD concentration, produces an important enhancement of the complex fluorescence intensity. Indeed, for a HP-β-CD concentration of about 0.02 M, the fluorescence emission intensity reaches a value which is about 12 times that in the absence of HP-β-CD. Higher HP-β-CD concentrations produce only small intensity variations, as shown by the plateau region observed between 0.03 to 0.09 M. This phenomenon can be attributed to completion of the complexation. It is possible to evaluate the molar fraction (f) of complexed MeBPHT, using Eq. (1) proposed by Flamigni [32].

$$f = 1 - \frac{1}{1 + [\mathrm{HP} - \beta - \mathrm{CD}] \cdot K_f} \tag{1}$$

We found f values higher than 0.93, indicating that a majority of the BPHT molecules are complexed by the HP-β-CD host reagents at a concentration of 0.03 M. In Eq. (1), K_f is the formation constant of the inclusion complex. K_f was calculated using the relative fluorescence intensity enhancement data correlated with the HP-β-CD concentrations, as described in the following section.

3.3. Stoichiometry and thermodynamic properties of the inclusion complex

The stoichiometry and the formation constant (K_f) of the HP-β-CD:MeBPHT, host-guest inclusion complexes were determined as previously [19,23]. Assuming a 1:1 stoichiometry ratio, the complex formation constant K_f of the equilibrium (Eq. (2)):

$$[\mathrm{HP} - \beta - \mathrm{CD}] + [\mathrm{MeBPHT}] \rightleftharpoons [\mathrm{HP} - \beta - \mathrm{CD{:}MeBPHT}] \tag{2}$$

will be given by:

$$K_f = \frac{[\mathrm{HP} - \beta - \mathrm{CD{:}MeBPHT}]}{[\mathrm{HP} - \beta - \mathrm{CD}] \cdot [\mathrm{MeBPHT}]} \tag{3}$$

Based on Eq. (1) and Eq. (2), and using the Benesi-Hildebrand method, [33,19] it is possible to express the relation between the fluorescence increment and the HP-β-CD concentration by the following equation:

$$F = F_0 + \frac{(F_\infty - F_0) \cdot K_f \cdot [\mathrm{HP} - \beta - \mathrm{CD}]}{1 + K_f \cdot [\mathrm{HP} - \beta - \mathrm{CD}]} \tag{4}$$

where F_0 and F_∞ denote the fluorescence intensity of MeBPHT, respectively, in the absence and in the presence of 0.1 M HP-β-CD, and F is the observed fluorescence at each HP-β-CD concentration tested.

The data of the above equation, can be represented using either a Scatchard plot, [33] or more conveniently the double-reciprocal plot given by:

$$\frac{1}{F - F_0} = \frac{1}{(F_\infty - F_0) \cdot K_f \cdot [\mathrm{HP} - \beta - \mathrm{CD}]} + \frac{1}{F_\infty - F_0} \tag{5}$$

If the stoichiometry of the complex is supposed to be 2:1, Eq. (6) becomes applicable:

$$\frac{1}{F - F_0} = \frac{1}{(F_\infty - F_0) \cdot K_f \cdot [\mathrm{HP} - \beta - \mathrm{CD}]^2} + \frac{1}{F_\infty - F_0} \tag{6}$$

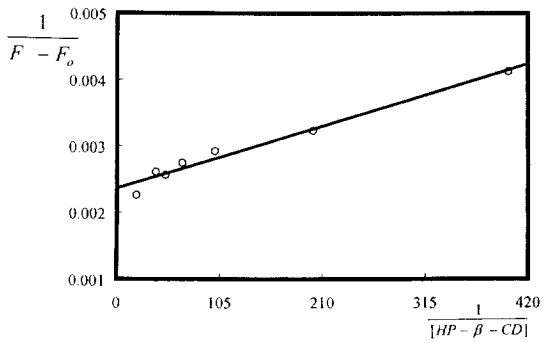

Fig. 4. Double reciprocal plot. A linear relationship is obtained when the data are plotted assuming a 1:1 HP-β-CD:MeBPHT stoichiometry.

Our experimental fluorimetric data fit the mathematical model of Eq. (4), suggesting a stoichiometry 1:1 for the MeBPHT:HP-β-CD complex (Fig. 3). This result is confirmed by the use of the double-reciprocal plot. In Fig. 4, a linear relationship is obtained when $1/F - F_0$ is plotted against $1/[\text{HP-}\beta\text{-CD}]_0$ according to Eq. (5). In contrast, a downward concave curvature is obtained when the data are used according to Eq. (6) (Fig. 5).

The formation constant of the inclusion complex was directly determined by the iterative process of the non-linear least-squares regression analysis, using our data and Eq. (4). The initial parameters needed for the iteration were obtained from the linear plot [33]. The calculated association constant for the MeBPHT:HP-β-CD complex has a value of $460 \pm 100\ M^{-1}$.

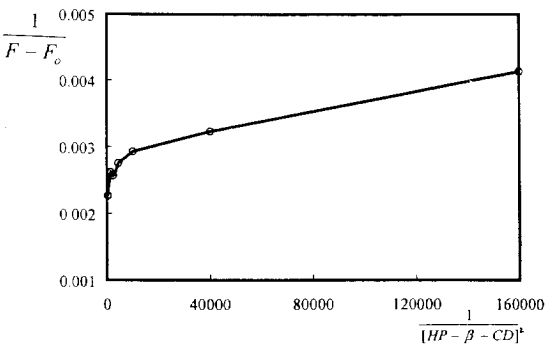

Fig. 5. Double reciprocal plot. Downward concave curvature relationship of $(F - F_0)^{-1}$ vs. $[\text{HP-}\beta\text{-CD}]^{-2}$, using Eq. (6) and assuming a 1:2 $(\text{HP-}\beta\text{-CD})_2$:MeBPHT stoichiometry.

This K_f value is significantly higher than that obtained, under the same conditions, for the complex of unsubstituted benzo[*a*]phenothiazine with HP-β-CD ($K_f = 100 \pm 22\ M^{-1}$) [23]. The formation constant of the Azure A photoproduct:β-CD complex [19] was also $110 \pm 40\ M^{-1}$. Therefore, based on these results, the MeBPHT:HP-β-CD complex seems to be slightly more stable than the others. Our K_f value compares to those of inclusion complexes formed between 2-substituted naphthalene derivatives and β-CD ($560\ M^{-1}$) [34].

3.4. Analytical usefulness

In order to demonstrate the analytical usefulness of the complexation of MeBPHT by HP-β-CD, we compared the analytical figures of merit obtained in the different media under study (Table 1). Linear calibration plots are established over about one order of magnitude, with satisfactory precision, as shown by the correlation coefficient values close to unity. The linear dynamic range is larger in WECD than in ethanol and WE. The slope of the regression equation is more than ten times greater in WECD than in WE, indicating a higher sensitivity of the spectrofluorimetric method in the presence of HP-β-CD. The limit of detection (LOD) of MeBPHT is greatly improved by the formation of the inclusion complex in water solutions. Indeed, the LOD values lay in the low ng/mL range, and are significantly lower for the complexed MeBPHT than in ethanol or WE. A 10-fold decrease is observed for the MeBPHT LOD value in the presence of HP-β-CD relative to WE mixture.

By taking advantage of this HP-β-CD-induced fluorescence enhancement and of the water-solubility improvement, it would be possible to use also this method in combination with an HPLC and/or a FIA technique for increasing the sensitivity and, possibly, the specificity of analysis of other benzophenothiazines. To apply our method to the analysis of BPHT derivatives in biological liquids or in drugs, a separation (or a prepurification) step may be needed to avoid interferences in these complex matrixes.

Table 1

[a] LOD, limit of detection, defined as the amount of analyte giving a signal-to-noise ratio of 3.
[b] R.S.D., relative standard deviation for MeBPHT concentrations ranging between 0.5 and 1 μg ml^{-1} ($n = 7$).
[c] WE, H_2O/EtOH (99:1, v/v) mixture.
[d] WECD, H_2O/EtOH (99:1, v/v) mixture in the presence of 0.1 M HP-β-CD.

4. Conclusion

We have shown that the important increase of the fluorescence intensity of MeBPHT in the presence of HP-β-CD aqueous solution can be attributed to the formation of an inclusion complex of a 1:1 stoichiometry. Its association constant value of 460 ± 100 M^{-1} was calculated using the Benesi-Hildebrand method. The enhancement of the analytical signal allows to develop a sensitive cyclodextrin-induced spectrofluorimetric method for the determination of MeBPHT. Moreover, this approach permits to lower by about 10 times its detection limit in water.

This HP-β-CD-induced fluorescence technique is presently under investigation for analytical application to other biomedically-important BPHT derivatives.

Abstract

An anion exchange HPLC-ICP-MS procedure allowing the simultaneous multielemental speciation analysis of arsenic, selenium, antimony and tellurium has been developed. Four arsenic species (As^{III}, As^{V}, monomethylarsonic acid and dimethylarsinic acid), two selenium species (Se^{IV} and Se^{VI}) may be determined in a single run as well as one antimony (Sb^{V}) and one tellurium species (Te^{VI}). Alternatively Sb and/or Te may be used as internal standards for As and Se speciation studies. Optimisation of ICP-MS conditions led to satisfactory relative (0.01 (Sb^{V}) to 1.8 (Se^{VI}) ng ml^{-1}) and absolute detection limits (1–180 pg). Reproducibility ranged from 3.1 to 5.6% and the linearity was verified in the 0–200 ng ml^{-1} range. © 1997 Elsevier Science B.V.

Keywords: Multielemental speciation; Arsenic; Selenium; HPLC-ICP-MS

1. Introduction

It is now well known that the toxicological and biological properties of most metals depend upon their chemical form. Chemical speciation analysis aims to determine the nature and concentration of the compounds of an element present in a given material. Knowledge of speciation is especially necessary for As, Se, Sb and Te compounds for which oxydated inorganic species are among the most toxic forms, whereas methylated forms such as monomethylarsonic acid (MMA) or dimethylarsinic acid (DMA) are much less toxic. Arsenic is a very common pollutant deserving special attention. Selenium is of particular interest because of its dual role as an essential ultratrace nutrient on one hand and as a toxic when ingested at higher levels on the other hand. Antimony and tellurium have been the object of very few environmental studies.

Several instrumental techniques have been developed that allow selective detection of different species at very low levels. Inductively Coupled Plasma Mass Spectrometry (ICP-MS) is a relatively new technique allowing the total concentration determination of many elements with the

high sensitivity of mass spectrometry. ICP-MS is well suited as a detector for inorganic and organometallic species separated by High Performance Liquid Chromatography (HPLC) [1], comparing favourably with other atomic spectrometric techniques particularly when an aqueous mobile phase is used. Moreover sample pretreatment may be minimized when ICP-MS is used restricting eventual changes in the relative concentration of individual species.

As early as 1986 [2] HPLC-ICP-MS has been applied to As speciation studies. In 1992, a review by McLaren et al. [3] referred four studies about HPLC-ICP-MS arsenic speciation in biological matrices. Some more papers in this field appeared in recent years [4–10] as well as others dealing respectively with sediments [7,11] or natural waters [12,13]. We found few papers dealing with Se speciation using HPLC-ICP-MS [14–16] or HPLC-ICP-AES [17] and only one about Sb [18] to our knowledge. Simultaneous speciation of As and Se compounds has been realised using only emission spectrometry detection [19], eventually preceded by hydridization [20].

The use of ICP-MS as HPLC detector leads to some constraints on the choice of chromatographic conditions concerning the nature and concentration of buffer salts in the chromatographic mobile phase and the presence of organic solvents. Therefore, ion exchange, size exclusion or reversed phase chromatographies are generally preferred and isocratic separations are advisable.

In this work we used an anion exchange PRP-X100 column and a phosphate buffer eluent known from previous optimisation to allow a good separation of four arsenic species (arsenite (As^{III}), arsenate (As^{V}), DMA, MMA), two selenium species (selenite (Se^{IV}) and selenate (Se^{VI})), tellurate (Te^{VI}) and antimonate (Sb^{V}) [21].

The aim of the present study was to optimize the ICP-MS detection in order to develop a fast, sensitive and accurate analytical procedure for the simultaneous speciation of arsenic, selenium, tellurium and antimony. The final objective is the speciation of these elements in soil extracts.

2. Experimental

2.1. Reagents and solutions

Di-arsenic trioxide (As_2O_3, p.a.), di-sodium selenate (Na_2SeO_4, suprapur) and di-sodium selenite (Na_2SeO_3, suprapur) were purchased from Merck. Ammonium hydrogen phosphate ($(NH_4)_2HPO_4$), ammonium hydroxide (NH_4OH), all RPE qualities, methanol (CH_3OH) and acetonitrile (CH_3CN), both HPLC grade, and monomethylarsonic acid (MMA) di-sodium salt (purum) were purchased from Carlo Erba. Dimethylarsinic acid sodium salt trihydrate (DMA, purum), potassium hexahydroxyantimonate(V) (H_6KO_6Sb, analytical reagent), telluric acid ($Te(OH)_6$, analytical reagent) and standard solution (1000 mg As l^{-1}) of arsenate (H_3AsO_4, spectrosol) were obtained from Fluka, Prolabo, Aldrich and BDH, respectively.

Arsenite (As^{III}) standard solution (1000 mg As l^{-1}) was prepared by dissolution of As_2O_3 in 0.2% NaOH solution leading to the formation of sodium arsenite. Other 1000 mg l^{-1} (as element) stock solutions were prepared in deionized water (Milli-RO/Milli-Q system from Millipore, 18 mW). These standards were used without any further purification. All standards (1000 mg l^{-1}) were stored at 4°C in the dark; stability over several months has been confirmed excepted for selenium compounds (1 month). Working standards (10, 1 or 0.1 mg l^{-1}) were obtained daily by dilution in the chromatographic eluent just before use and stored in the dark. Phosphate buffer (12.5 mmol l^{-1}) was prepared by dissolving di-ammonium hydrogen phosphate in deionized water (Millipore) and pH adjustment was obtained by dropwise addition of 30% ammonia. The mobile phase was filtered (0.45 mm) and degassed before use.

2.2. Apparatus

The HPLC system consisted of a Varian 9001 isocratic solvent delivery unit fitted out with a PRP-X100 anion exchange column (Hamilton, Reno, Nevada) (25 cm × 4.1 mm I.D.; spherical 10 μm particles of a styrene–divinylbenzene co-

polymer with trimethylammonium exchange sites; stable between pH 1 and 13; exchange capacity 0.19 meq g^{-1}). In this work a 100 µl loop (Peek, Interchim) was selected in conjunction with a Rheodyne six-port injection valve.

A VG PQ3 ICP-MS (VG Elemental, Winsford, Cheshire, U.K.) was used to detect the compounds in the column effluent. The ICP mass spectrometer was equipped with a Fassel Torch, a Meinhard-type concentric glass nebulizer (Glass Expansion, Pty, Australia) and a doubled pass Scott-type spray chamber with liquid coolant, the temperature of which was maintained at 1°C by a recirculating refrigeration-heating system.

2.3. Method optimization

ICP-MS sensitivity was optimised by varying one instrumental setting at a time during the analysis of standard solutions of the various species studied. A peristaltic pump was used for conventional sample introduction of the analyte solution at 1.5 ml min^{-1} in order to optimize detection conditions or to evaluate either the relative sensitivities of the various analytes or signal enhancement by addition of organic solvents to the mobile phase. Both scanning and peak jumping modes were used. Instrument setting adjusted were the physical positioning of the mass spectrometer relative to the plasma, ion lens voltages, aerosol carrier argon gas flow and R.f. power input to the argon plasma. The optimal conditions were found as differing somewhat from one element to the other. However for multielemental speciation studies only one set of conditions must be chosen. Arsenic being the main centre of interest in this study the instrument settings optimized for this element were retained in all experiments.

Coupling between HPLC column outlet and ICP-MS nebulizer was reduced to a short length (5 cm) of Teflon capillary tubing (0.5 mm I.D.) in order to minimize dead volume and improve peak shape. Isocratic elution was carried out with a 1.5 ml min^{-1} flow rate compatible with the normal sample uptake rate of the ICP- MS device.

Optimised ICP-MS and HPLC settings are summarized in Table 1.

The mass spectrometer was set to sample ion intensities using Time Resolved Acquisition mode (TRA) following mass to charge ratios (m/z) ($^{75}As^+$), ($^{82}Se^+$), ($^{126}Te^+$) and ($^{121}Sb^+$) during the coupling measurements. Those analyte masses were selected taking in account possible interferences caused either by isotopes of other elements or by polyatomic species with the same m/z value as the analyte that are now well known in ICP-MS detection [22]. The problem is relatively simple for As and Sb because of the existence of a single ^{75}As and of only two ^{121}Sb and ^{123}Sb iso-

S, intensity obtained for a 10 ng (as element) ml^{-1} species concentration after direct aspiration in ICP-MS (mean of 3 replicates).
R, ratio of species intensity to the most sensitive one.
N, base-line noise standard deviation for 10 blank replicates.
Mobile phase, $(NH_4)_2HPO_4$ 12.5 mmol l^{-1} + NH_3 to pH 8.5.

topes. ^{121}Sb was retained because it is not subjected to major interferences and is the most abundant. Despite of its lesser abundance ^{82}Se was chosen as free from $Ar–Ar^+$ polyatomic interference and ^{126}Te being not disturbed by the $^{130}Xe^+$ monoatomic interference.

Signal intensities obtained depend on the degree of corrosion of the sampler and skimmer cones in use. Throughout this work, a sampler cone made of platinum was used in order to avoid a rapid degradation by phosphorus ions of the mobile phase.

3. Results and discussion

3.1. Effect of mobile phase composition

Comparison of ICP-MS signal intensities obtained for each species prepared either in water or in the chromatographic eluent without methanol, was made using conventional aspiration at 1.5 ml min^{-1} (Table 2). Ammonium salts are classically used as the counter cation in anion exchange HPLC-ICP-MS studies in order to avoid non-spectroscopic interferences in the presence of alkaline cations such as Na^+ [23]. A phosphate buffer was chosen from previous investigations [21] on a series of buffer solutions tested, it contained 12.5 mmol l^{-1} $(NH_4)_2HPO_4$ adjusted to pH 8.5 by ammonia addition.

Signal intensities obtained for the various species of a single element in a single matrix varied somewhat (Table 2). This was previously noted by Larsen and Stürup [24] in water. Moreover these authors obtained a different order of relative sensitivities for the four arsenic species. Inter-species signal intensities variations reported in this study ($\leq \pm 8\%$ for As or Se species) are quite low compared to those quoted in the literature. It seems that ionization processes differ somewhat from one ICP-MS instrument to the other. Signal intensities obtained for the various species are approximately equivalent in water or mobile phase matrice with only slight signal variations in the presence of the chromatographic eluent (-20 to $+10\%$ at most for all species studied).

However, base-line noise (N) was amplified by a factor of 10 at least by the mobile phase, inducing an equivalent decrease of the signal intensity to noise ratio (S/N). For example we found a 12.8 S/N ratio decrease factor for As^V between water and phosphate buffer. Using a carbonate buffer (0.1 mol l^{-1} $(NH_4)_2CO_3$ at pH 10.3) Larsen and Stürup [24] observed a 1.3 S/N ratio decrease factor only. The difference cannot be explained by the different salt concentrations of the buffers with 1.6 g l^{-1} (this work) and 8.4 g l^{-1} [24]. It appears therefore that the nature of buffer salts may have a significant influence on the HPLC-ICP-MS responses by modifying either plasma chemistry or ionic interactions in the plasma-mass spectrometer interface.

The ICP-MS sensitivity variations depending on species analysed evidence a major problem for the choice of standard solutions in classical ICP-MS total element determination, problem already underlined by Larsen and Stürup [24] for As determination.

3.2. Influence of solvent additions

We have studied the effect of the addition of organic carbon (as methanol or acetonitrile) to the mobile phase on some species signal intensities during direct aspiration at 1.5 ml min^{-1} in ICP-MS. Examples of the ICP-MS responses in a range of 0–7% solvent addition are given in Fig. 1.

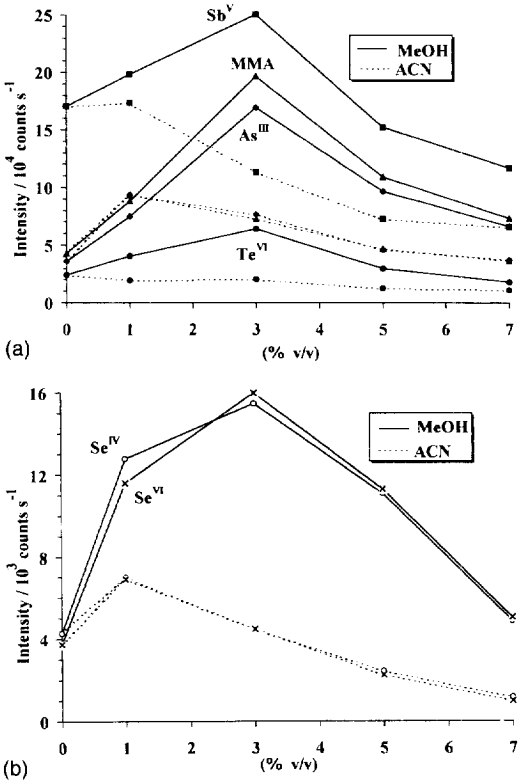

Fig. 1. ICP-MS signal intensities for (a) two arsenic species, one antimony and one tellurium compounds, and (b) two selenium species versus % of methanol or acetonitrile in the mobile phase. Signal intensities are given as count s^{-1} for 10 ng ml^{-1} of each compound.

Table 3
Effects on sensitivity and base-line noise of 3% v/v MeOH addition to phosphate buffer solution

Species	S_r	N_r	S_r/N_r
As^{III}	4.7	2.2	2.2
DMA	4.8	2.2	2.2
MMA	4.6	2.2	2.1
As^{V}	5.1	2.2	2.4
Se^{IV}	3.6	1.8	2.0
Se^{VI}	4.3	1.8	2.4
Sb^{V}	1.5	0.9	1.6
Te^{VI}	2.7	3.3	0.8

S_r, ratio of signal intensities obtained with or without addition of 3% v/v MeOH.
N_r, ratio of base-line noise obtained with or without addition of 3% v/v MeOH.

The loading of organic solvent in the plasma results in energy removal due to pyrolysis and the maximum signal intensity enhancement was obtained for all species of all elements with a 3% v/v addition of methanol. Signal improvements due to the addition of 3% methanol to the phosphate buffer (Table 3) are similar for various species of a same element but differ widely between elements. Similar conclusions were reached by other authors [4,7,12] but with variable optimal percentages of methanol (1–5%) probably due to differences in plasma torch operation conditions. Simultaneously, background level and base line noise amplitude increased more or less depending on the species studied. The signal to noise ratio (S/N) was improved in the presence of 3% methanol for most species (Table 3) but not all. Larsen and Stürup [24] noted already similar effects of methanol addition.

As regards acetonitrile, a 1% v/v addition to the mobile phase led to a maximum signal enhancement. Signal intensities were enhanced by a factor of about 2.2 for As species, 1.5 for selenium species, 1.0 for Te and Sb when base-line noise increased by a factor of 16 for As, slightly for Se (1.5), Sb (1.1) and decrease for Te (0.8), resulting in a slight S/N ratio improvement for Te (1.3), an equivalent S/N ratio for Se and Sb or a degradation of the S/N ratio for all arsenic species. It is difficult to compare in details these results to those of previous studies as either the mobile

phase, direct aspiration flow or plasma conditions differed somewhat [7,12,24]. The general output appears nevertheless clearly in favour of an addition of 3% methanol to the mobile phase for HPLC-ICP-MS studies of these four elements.

3.3. Performances of the coupled HPLC-ICP-MS device

If only As and Se species are present in samples then both Te and Sb could be used as internal standards in order to improve accuracy and reduce analysis time. Sb^{V} as potassium hexahydroxyantimonate was found most convenient for this use. A typical chromatogram of a mixture of all arsenic, tellurium and selenium species together with the internal standard Sb is shown in Fig. 2. Run time was ≈ 17 min. For six replicate injections, the maximum standard deviation (S.D.) obtained for the retention time of any compound was less than 4 s (Table 4). The presence of 3% v/v methanol in the mobile phase caused a slight but significant increase in the retention time (4–50 s) of each species, compared to those obtained without addition of methanol [21]. The increase differs depending on the species considered, effect which may be ascribed to the reduced ionic dissociating power in presence of organic solvent. The elution capacity of the mobile phase is therefore slightly reduced as the more retained species (As^{V}, Se^{VI}) would suffer a larger increase of retention time.

Reproducibility of peak heights was determined from six replicate injections of 5 ng of As and Te species, 20 ng of Se and 1 ng of Sb species (Table 5). Even without using internal standard, the relative standard deviations (R.S.D.) never exceeded 7%. Reproducibility was slightly better when using peak heights rather than peak areas. The linearity of calibration curves plotted with both peak heights and peak areas was satisfactory for all species in the range of concentrations studied (0–200 ng ml^{-1}) (Table 5). Correlation coefficients obtained by using peak height and peak area measurements are excellent and almost identical.

Detection limits (L.O.D.) defined according to IUPAC standard [25] are presented in Table 5. As expected, the limits of detection of Se, Te and Sb species have been improved with about the same factors (S/N ratio) which were obtained by addition of 3% v/v of methanol in the previous signal enhancement study (Table 3). However, detection limits obtained for As species were practically the same as those obtained in a previous study [21] with the same chromatographic conditions but without addition of organic solvent. This could probably be explained by a larger enhancement of the base line noise (N) than expected in the previous signal enhancement study. Anyway L.O.D.

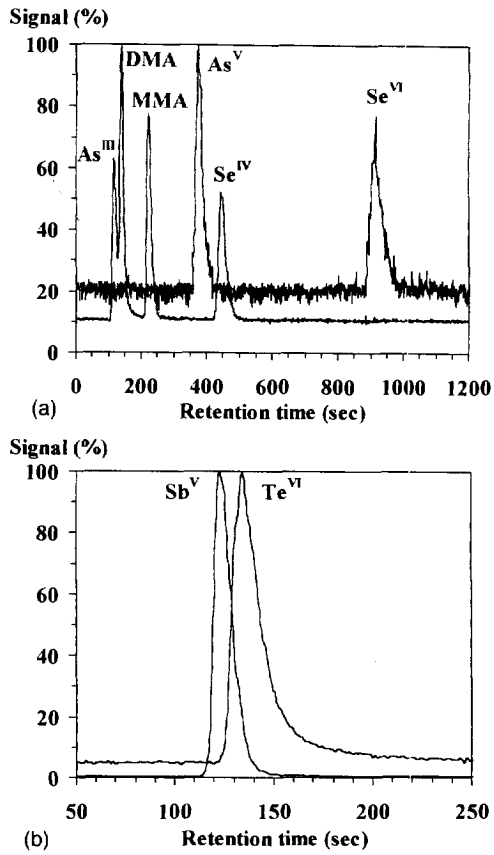

Fig. 2. Typical HPLC-ICP-MS chromatogram of a mixture of 25 ng (as element) ml^{-1} (A) arsenic (As^{III}, DMA, MMA, As^{V}), selenium (Se^{IV}, Se^{VI}), and (B) tellurium (Te^{VI}) species, with antimony (Sb^{V}) 5 ng ml^{-1} as internal standard in a 12.5 mmol l^{-1} phosphate buffer at pH 8.5 with 3% v/v methanol addition. Signal intensities are given as a ratio (%) of species intensity to the most sensitive one for each element. Flow rate: 1.5 ml min^{-1}.

Table 4
HPLC-ICP-MS retention times

Sb^{V}	123 ± 2
Te^{VI}	134 ± 2

[a] Mean of six determinations for each compound.

values for As species obtained in this work (ranging from 10 to 23 pg) still compare well with those reported by Demesmay et al. [7] (10–30 pg), Larsen et al. [4] (80–150 pg) or Thomas and Sniatecki [12] (45–150 pg) who did not use IUPAC definition of L.O.D. however.

3.4. Monitoring the argon chloride interference

Spectral and non-spectral interferences in ICP-MS have been recently considered by Dams et al. [22]. The formation of the polyatomic ion $^{40}Ar^{35}Cl^{+}$ which interferes with the detection of arsenic at m/z 75 has been proved to occur in chloride rich samples such as urine [4,6] or sea water, and the authors have suggested to avoid the formation of the $ArCl^{+}$ ion by addition of a few percent of nitrogen to the argon plasma [6]. Another approach consisted in separating chemically arsenic species from the interfering chloride by formation of volatile arsines [26]. Other studies have shown that chloride present in samples can be chromatographically separated from arsenic species [5,11,27]. The latter approach was tested in the present study and investigated by injecting a 0.9 g l^{-1} sodium chloride solution spiked with arsenic species into the anion exchange HPLC-ICP-MS device and the elution of the chloride ion (monitored as the $^{35}Cl^{16}O^{+}$ ion at m/z 51) occurred as a small peak with a 299-s retention time, completely separated from those of MMA (220 s) and As^{V} (442 s) as shown in Fig. 3.

The formation of $ArCl^{+}$ from the eluting chloride does not consequently interfere in the on line HPLC-ICP-MS analysis of the arsenic containing analytes.

4. Conclusion

The HPLC-ICP-MS method presented allow the simultaneous speciation analysis of four elements (As, Se, Sb, Te). Sensitivity variations between species of a single element and under changes of experimental ICP-MS conditions have been noted and daily individual calibration appear necessary; the use of one of these elements as internal standard may be useful.

Received 2 August 1996; received in revised form 5 November 1996; accepted 9 December 1996

Abstract

The electropolymerization of an enzyme-amphiphilic pyrrole ammonium-laponite nanoparticles mixture preadsorbed on the electrode surface provides the simultaneous immobilization of the enzyme and the hydrophilic laponite-clay-nanoparticles in a functionalized polypyrrole film. The presence of incorporated laponite particles within the electrogenerated polymer induces a strong improvement of the analytical performances (I_{max} and sensitivity) of amperometric biosensors based on polyphenol oxidase. These beneficial effects have been attributed to a marked enhancement of the apparent specific activity of the immobilized enzyme (from 0.21 to 0.85% of the specific activity of the free enzyme), the permeability of the host polymer being unchanged. This strategy of biosensor performance improvement was tested with cholesterol oxidase as an enzyme model. The presence of laponite additive in the poly(amphiphilic pyrrole) host matrix induces a similar enhancement of sensitivity and I_{max} for cholesterol biosensing as well as a large improvement of the storage stability of the polypyrrole-cholesterol oxidase electrode. © 1997 Elsevier Science B.V.

1. Introduction

Enzyme immobilization technology has attracted much attention in connection with the design, fabrication and applications of amperometric biosensors [1–3]. The main conventional approaches for enzyme immobilization on electrodes surfaces include adsorption, cross-linking with glutaralaldehyde, covalent attachment using carbodiimine chemistry and entrapment in polymeric gels or carbon paste. Among these various techniques, the electrochemical polymerization appears as a simple and attractive avenue for fabricating biosensors [4]. This method is based on the enzyme entrapment during the growth of conductive polymers generated by electrochemical oxidation of a suitable monomer from a solution containing enzyme. In particular, the incorpora-

PII S0039-9140(97)00039-8

tion of enzymes in active polypyrrole matrices has been widely used [5] since the first example reported by Foulds et al. in 1986 [6]. Such one-step immobilization procedure allows the facile functionalization of microelectrode surfaces [7], the electrochemical control of the amount of deposited polymeric material [8,9] as well as the electrical wiring of immobilized enzymes [10–12]. However, the electrochemical entrapment of enzymes in polypyrrolic films induces always a strong decrease in the specific activity of the immobilized enzymes [13].

This phenomenon could be due to some internal diffusional limitations of substrates and products but also to the hydrophobic character of these organic matrices [14–16]. A possibility to preserve the activity of entrapped enzymes could be the modification of the enzyme microenvironment by incorporation of hydrophilic additives within the polypyrrole host matrices. Recently Lutz et al. [17] have described the beneficial effect of a number of solid and chemical additives such as sugars, sugar alcohols and cationic polymers on the sensitivity and operationnal stability of tyrosinase carbon paste electrodes. In addition, it has been reported that the incorporation of fumed silica within carbon paste matrices greatly enhanced the sensitivity and the stability of dehydrogenase and glucose oxidase based biosensors [18,19]. Moreover, it has been demonstrated that enzymes and additives such as flavin coenzymes [20] or phospholipidic vesicles [21] can be simultaneously incorporated in polypyrrole films. This coimmobilization induces a marked improvement of the biosensors performances.

With this aim in view, we report here a novel and efficient approach to improve the sensitivity and lifetime of biosensors based on conductive polymers. This procedure is based on the simultaneous adsorption of amphiphilic pyrrole (**1**), enzyme and hydrophilic laponite nanoparticles [22,23] on an electrode surface followed by the electrochemical polymerization of the adsorbed pyrrole derivatives [24]. This induces the entrapment of enzyme and additives within the resulting polypyrrole film.

1 
Thus, the beneficial effect of laponite clay nanoparticles on the analytical performances of the biosensor has been investigated for a polyphenol oxidase (PPO) electrode. In particular, the use of the catechol-PPO electroenzymatic system [25,26] has allowed to distinguish the influence of the synthetic clay additives on the immobilized enzyme activity and on the biomaterial permeability.

2. Experimental

2.1. Instrumentation

The electrochemical instrument consisted of a PAR model 362 potentiostat in conjunction with a Tracelab BD 90 recorder. All electrochemical experiments were carried out using an undivided thermostated three-electrode cell. The working electrode was a glassy carbon disk or a platinum disk (diameter 5 mm) polished with diamond paste. An Ag/AgCl (saturated KCl) reference electrode and a platinum counter electrode were also used. All measurements were carried out at 30°C with PPO or 37°C with cholesterol oxidase (CO).

Spectrophotometric measurements were performed with a Shimazu UV-Vis 2101 PC spectrophotometer.

2.2. Reagents

Polyphenol oxidase (EC 1.14.18.1, from mushroom, 1700 U mg^{-1}) cholesterol oxidase (EC 1.13.6., from *Streptomyces*, 25 U mg^{-1}) and cholesterol were purchased from Sigma. Catechol and phenol were obtained from Fluka and Prolabo respectively. Triton X-100 (TX 100) was purchased from Merck. The amphiphilic pyrrole derivative **1** ((12-pyrrol-1-yldodecyl)triethylammonium tetrafluoroborate) was synthetized as previously reported [27] and laponite is obtained from Laporte Industries.

Supporting electrolytes were 0.1 M $LiClO_4$ (from Janssen) and 0.1 M phosphate buffer (pH 6.5 or pH 7) prepared by mixing $NaH_2PO_4 \cdot 2H_2O$ and $Na_2HPO_4 \cdot 2H_2O$ from Fluka in desionised water.

2.3. Preparation of enzyme electrodes

The poly **1**-PPO electrode and the poly **1**-PPO-laponite electrode were prepared according to the method similar to that previously reported [24]. An aqueous colloidal suspension (5 g l^{-1}) was prepared by dispersing overnight laponite in pure water. Aqueous dispersion of monomer **1** (6 mM) and laponite colloidal suspension were mixed in water to produce a 3 mM aqueous dispersion of **1** containing 0.5 g l^{-1} laponite. Then, 0.3 mg of PPO was dissolved in 30 ml of this latter dispersion. The mixture deposited at the surface of a glassy carbon electrode was dried under vacuum. The polymerization of the dry adsorbed monomer **1**-laponite-enzyme coating was carried out by controlled potential electrolysis for 30 min at 0.78 V in deaerated aqueous 0.1 M $LiClO_4$ solution. Before electrochemical experiments, the electrodes were potentiostated at −0.17 V or 0.7 V for 30 min allowing the background current to decay to a steady state value.

The poly **1**-CO and poly **1**-CO-laponite electrodes were prepared following the same process with a platinum disk electrode. The functioning principle of the cholesterol sensor was based on the amperometric detection of hydrogen peroxide. The amperometric response of the poly **1**-CO and the poly **1**-CO-laponite electrodes have been investigated in 0.1 M phosphate buffer (pH 7) containing Triton X-100 (0.05% v/v) by setting the platinum enzyme electrode at 0.53 V vs. Ag/AgCl.

2.4. Determination of amount and activity of entrapped enzyme

In order to determine the amount of PPO really entrapped in the poly **1** or poly **1**-laponite film, we used a spectrophotometric assay based on the enzymatic oxidation of L-tyrosine by PPO. First the activity of 0.3 mg of free PPO was correlated with our assay: 1 ml of electrolyte containing 0.3 mg of PPO was added to 1 ml of 50 mM phosphate buffer (pH 6.5) and 1 ml of L-tyrosine aqueous solution (1 mM). The L-tyrosine oxidation was monitored at 280 nm by measuring the increase in adsorbance vs. time. The slope of the rectilinear part of the adsorbance versus time dependence was further used as a reference corresponding to 0.3 mg of PPO. The amount of enzyme lost during the electropolymerization step of biosensor construction was evaluated from the enzymatic activity of the electrolyte solution measured following the same procedure. Comparison with the activity of 0.3 mg free enzyme allowed to determine the weight of released enzyme, and then by difference with the amount initially adsorbed, to estimate the amount of PPO really entrapped.

The apparent specific activity of the immobilized PPO was estimated as previously reported [14]. The enzyme electrode was immersed in a 3 ml of stirred phosphate buffer containing 0.3 mM catechol. The increase in concentration of 1,2-benzoquinone enzymatically produced was monitored at 380 nm by measuring the increase of the adsorbance at 1 min intervals. Then, the enzymatic activity is obtained from the slope of the linear part of the adsorbance vs. time dependence. Knowledge of the weight of immobilized PPO (as previously described) allowed to obtain the apparent specific activity of PPO molecules entrapped in the polymer.

3. Results and discussion

Laponite is a synthetic hectorite whose structure and properties have been extensively presented in previous papers [22,23]. Isomorphic substitution of monovalent cation for bivalent cations within the crystalline network is the source of the permanent negative charge of the laponite layers. This excess negative charge is compensated by adsorption of exchangeable cations, Na^+ in laponite. Consequently the laponite cation exchange capacity (cec) is 7.3×10^{-4} mol g^{-1}. When suspended in deionized water, at a concentration less than 10 g l^{-1} a complete delamination process of the elementary laponite layers stacked together occurs leading to a colloidal suspension of negatively charged elementary platelets measuring in size 40 nm × 10 nm × 1 nm on average [28].

On the other hand, the cationic amphiphilic monomer **1** having a very low solubility in water can be ultrasonically dispersed in pure water [27].

These properties allow to prepare a mixed dispersion containing 3 mM of **1** and 0.5 g l^{-1} laponite nanoparticles. Then, the enzyme electrodes are obtained by dissolving PPO into this latter dispersion and the resulting mixture is coated on a glassy carbon electrode surface. The electropolymerization of the adsorbed biological layer yields poly **1**-PPO-laponite electrode or poly **1**-PPO electrode in the absence of laponite in the dispersion.

As previously reported [14], the leakage of PPO during the polymerization step is determined from the enzymatic activity of the electrolyte solution. Thus the quantity of PPO really entrapped in the poly **1** film and the poly **1**-laponite film were evaluated, respectively, as 50% and 40% of the initially adsorbed amount. This slight decrease could be the consequence of electrostatic repulsion between the negatively charged laponite particles and the PPO protein which carries a net negative charge at pH 6.5.

Polyphenol oxidase catalyzes the oxidation of several monohydroxy and *o*-dihydroxybenzene derivatives to *o*-quinones involving molecular oxygen. So, PPO when used in a biosensor configuration, allows to determine a whole group of substrates or inhibitors [14,24,29–31], owing to the electrochemical reduction of the enzymically formed *o*-quinone. As reported previously, the analytical capabilities of the poly **1**-PPO electrode and the poly **1**-PPO-laponite electrode have been investigated in air saturated 0.1 M phosphate buffer by potentiostating the electrodes at −0.17 V. Fig. 1 shows the calibration curve of the poly **1**-PPO electrode and the poly **1**-PPO-laponite electrode obtained with phenol as substrate. The beneficial influence of the incorporated laponite particles is illustrated by the enhancement of the biosensor sensitivity since its value (determined as the slope of the linear range) increases from 36 mA M^{-1} cm^{-2} to 159 mA M^{-1} cm^{-2} in the absence and in the presence of the solid additive in the polypyrrolic matrix. In addition, calibration curves also display a higher maximal current under saturating phenol conditions recorded with the poly **1**-PPO-laponite configuration (I_{max} = 20.4 mA cm^{-2} with laponite and I_{max} = 5.9 mA cm^{-2} without laponite).

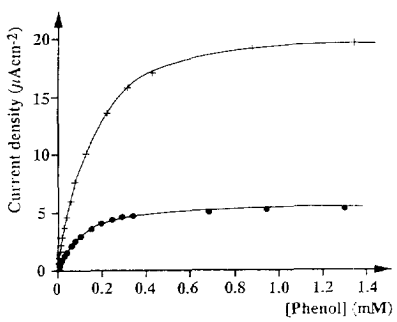

Fig. 1. Calibration curves for phenol obtained at the poly **1**-PPO electrode (●) and at the poly **1**-PPO-laponite electrode (+). Applied potential −0.17 V vs. Ag/AgCl (saturated aqueous KCl), air saturated 0.1 M phosphate buffer (pH 6.5) kept under vigourous stirring at 30°C.

The poly **1**-PPO electrode provides also better limit of detection (based on a signal-to-noise ratio of 3) for phenol, namely 0.1 mM as compared to the 0.6 mM recorded with a poly **1**-PPO electrode. Furthermore, the laponite particles incorporation leads to a slight increase of the electrode response time, since it was of order of 50 s whereas its value reaches 30 s without laponite. These different results could arise from the modification of two parameters induced by the presence of the additive: the activity of the immobilized enzyme, and the biomaterial permeability. In order to estimate the influence of each of these factors, an electrochemical study involving the catechol-PPO system [25,26] has been realized and completed with the determination of the enzymatic activity for the poly **1**-PPO-laponite electrodes.

Indeed, with an amperometric PPO-based electrode, catechol can be detected, on the one hand via the enzymically generated *o*-quinone (Fig. 2B) and on the other hand, via its electrooxidation at 0.7 V whatever the enzyme reactive state, active or inactive (Fig. 2A). Owing to this feature, the various functioning configuration of the PPO-catechol system give informations about the biomaterial permeability as well as the immobilized enzyme activity [25,26]. Fig. 3 shows the calibration curves for catechol obtained at 0.7 V in stirred phosphate buffer with the two kinds of modified electrode after the thermal denaturation of the immobilized PPO. By this way, the current density is connected with the catechol diffusion through the inactivated biomaterial. The response

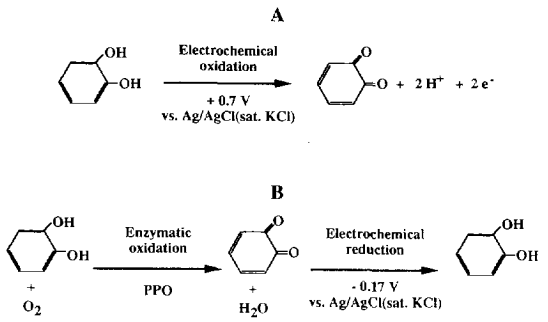

Fig. 2. Schematic description of the catechol electrochemical detection with a PPO electrode. A, bioelectrode potentiostated at 0.7 V, PPO being inactivated; B, bioelectrode potentiostated at −0.17 V.

of a bare glassy carbon electrode has also been reported under the same experimental conditions. In the substrate concentration range investigated, a linear relationship is observed. As expected, the modified electrodes exhibit lower sensitivities than the one obtained on a bare electrode. This behavior simply arises from the presence of the polypyrrolic film which gives additional diffusion barrier where the catechol diffusion coefficient is lower than in the bulk electrolyte. Surprisingly, the curves do not show a marked difference between the poly **1**-PPO and the poly **1**-PPO-laponite electrodes since sensitivities are 486 mA M^{-1} cm^{-2} and 444 mA M^{-1} cm^{-2}, respectively. Consequently, the incorporated laponite particles

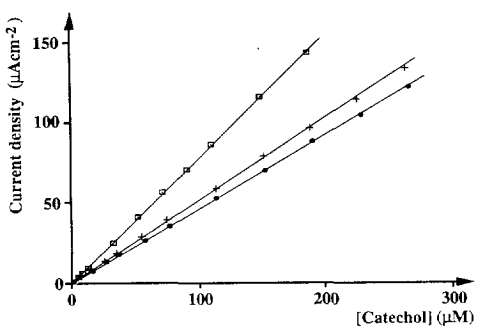

Fig. 3. Calibration curves for catechol obtained at (□) the bare glassy carbon electrode, (+) the poly **1**-PPO electrode, and (●) the poly **1**-PPO-laponite electrode. Immobilized PPO has been previously denaturated and the applied potential was 0.7 V vs. Ag/AgCl (saturated aqueous KCl). Other experimental conditions as in Fig. 1.

lead to only a slight decrease of the biomaterial permeability.

In contrast and as expected, the biosensor sensitivity towards catechol at −0.17 V is greatly enhanced in the presence of laponite. Indeed, in the dynamic range of the biosensors, the amperometric response of the poly **1**-PPO-laponite electrode is nearly two times higher since its value reaches 893 mA M^{-1} cm^{-2} as compared to 539 mAM^{-1} cm^{-2} recorded with the poly **1**-PPO electrode. Since the laponite particles have a slight negative effect onto the biomaterial permeability, the improvement of the biosensor sensitivity could be attributed to a better activity of the immobilized enzyme. Owing to their surface structure characterized by silanol groups and the presence of hydrated sodium counterions [22], the laponite particles can counterbalance the hydrophobic character of the polypyrrole matrix providing a less denaturating microenvironment for the immobilized enzymes. As reported previously for carbon paste matrices [17,32] and poly(amphiphilic pyrroles) matrices [31], the biosensor performances depend on the amount of bound water to PPO. Consequently, the hydration layer of enzymes, necessary for their activity, can be more important and stabilized with the incorporation of the hydrophilic clay particles within the polymeric matrices.

On the other hand, the laponite particles effect on the biosensor response is higher for phenol as a substrate than for catechol: sensitivity is increased by a factor of 4.4 with phenol, wheras this factor is only 1.7 with catechol. Indeed, it is well known that the enzymatic oxidation of phenol requires two successive steps. First the hydroxylation from phenol to catechol followed by its oxidation to *o*-quinone. It has been reported that the first step is preceded by a lag-phase [17,33] slowing down the enzymatic conversion of phenol. Consequently, our results seem to indicate that the laponite-PPO coimmobilization in the poly **1** allows at the one and the same time an higher enzymatic activity and the decrease of the lag-phase. A similar effect has already been reported for chemical additives incorporated within carbon paste matrices [17].

In order to confirm these results, the activity of each PPO electrode has been determined by spectrophotometric measurements (Section 2). Since our method of enzyme immobilization allows us to determine the quantity of PPO really entrapped in the poly **1** film, we were able from these measurements to estimate the apparent specific activity of the immobilized PPO. These apparent specific activities were evaluated in absence and presence of laponite additives, respectively, as 0.21% and 0.85% of the free enzyme. These low values can be explained by the fact that immobilization procedures usually lead to an important lowering of the specific activity because of interactions between the immobilized enzymes and the matrix and subsequent denaturation. In addition, because of diffusion constraints within the biomaterial and development of substrate and cosubstrate concentration gradients, only an apparent specific activity lower than the specific activity can be determined. Nevertheless, it is interesting to notice that the amount of immobilized PPO is practically the same in absence and presence of laponite particles. In contrast, the apparent specific activity is four times higher in the presence of laponite. Taking in mind that the presence of laponite induces a slight decrease of the biomaterial permeability toward catechol, these activity measurements demonstrate that laponite allows to keep a higher specific activity for immobilized PPO. The presence of hydrophilic laponite should confer a favourable microenvironment to PPO by reducing hydrophobic interactions with the long hydrocarbon tails of poly **1** and subsequent denaturation resulting from the protein unfolding [34]. These activity measurements are in good agreement with the improvement of the biosensor performances (higher sensitivity and I_{max}) in the presence of laponite additive.

This interesting strategy can be extended, following our immobilization procedure, to a wide range of enzymes. Thus, we have verified this behavior with cholesterol oxidase (CO), choosen as a model of an important class of enzyme: the oxidases whose substrate molecular recognition is followed by production of hydrogen peroxide. Fig. 4 compares the calibration curves for cholesterol obtained with a poly **1**-CO and a poly **1**-CO-laponite electrode. As previously observed with PPO, a similar enhancement of sensitivity and I_{max} is observed for cholesterol biosensing in the presence of laponite additive. More interestingly we observed that laponite additive markedly enhanced the enzyme electrode stability. Indeed, under the best storage conditions, the poly **1**-CO-laponite electrode retained 74% and 50% of its initial sensitivity after 4 and 20 days, respectively, while the biosensor being totally inactive after 17 days in the absence of laponite. This strong increase of the storage stability confirms again the benefic modification of the enzyme microenvironment induced by the presence of hydrophilic laponite nanoparticles.

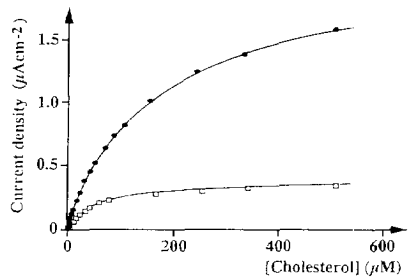

Fig. 4. Calibration curves for cholesterol obtained at the poly **1**-CO electrode (□) and at the poly **1**-CO-laponite electrode (●). Applied potential +0.53 V vs. Ag/AgCl (saturated aqueous KCl), air saturated 0.1 M phosphate buffer (pH 7) containing 0.05% (v/v) Triton X-100 kept under vigorous stirring at 37°C.

In conclusion, this strategy is interesting since by tuning the hydrophilic/hydrophobic character of electrogenerated polymer films, it is possible to counterbalance the negative effect of the hydrophobic microenvironment of the immobilized enzyme and thus to improve its biocompatibility. Following this way the developement of new hydrophilic electropolymerizable organic additives is in progress and comparison with solid additives will be realized.

Abstract

An electroantennographic detector based on the antenna of the Colorado potato beetle (*Leptinotarsa decemlineata* Say, 1824) was used to investigate volatile organic compounds emitted by injured potato plants (*Solanum tuberosum* L., 1753). Samples were collected on charcoal traps using the CLSA method. Analyses were performed with a GC-EAD-FID setup as well as a GC-MS system. The experiments revealed that several groups of compounds are perceptible to the Colorado potato beetle. The ability of the Colorado potato beetle to detect green leaf odours (e.g. (*Z*)-3-hexen-1-ol and (*E*)-2-hexenal), linalool and some terpenes has been noticed before [Visser et al., J. Chem. Ecol. 5 (1979) 13]. In this work the presence of (*Z*)-3-hexen-1-ol, (*E*)-2-hexenal and linalool in the potato odour could be confirmed. Moreover, β-myrcene, benzeneethanol, and several sesquiterpenes (e.g. caryophyllene and germacrene-D) were identified. The GC-EAD experiments reveal that apart from the green leaf odours and linalool prominent reactions of the Colorado bettle antenna are induced by benzeneethanol and the sesquiterpene fraction. © 1997 Elsevier Science B.V.

1. Introduction

Electrical potentials in the hemolymph of insect antennae are influenced by surrounding olfactory receptor cells. The depolarisation of many adjacent receptor cells leads to a slow change in the hemolymph potential called electroantennogram or EAG [2]. The EAG represents a summation of reactions of many receptors with different specificity thus providing unspecific information on the insect's olfactory perception. Yet, when stimulated with an isolated compound the amplitude of the EAG-signal correlates with the strength of the stimulus. Single cell recordings (SSR) of olfactory sensillae [3] may reveal more specific information as compared to EAG but suffer from higher apparative expense and difficulties in quantitative interpretation.

The high sensitivity and selectivity of insect olfactory receptors in combination with a chro-

matographic separation offers a powerful analytical technique [4]. The connection between GC and EAG can be made *indirectly* by collecting fractions of the GC-effluent with subsequent analysis of these samples in an EAG-setup [5]. The *direct* employment of an EAG-setup as a detector in gas chromatography ('electroantennographic detector', EAD) offers extended analytical capacities. However, the coupling of GC with EAG is not as straightforward as physicochemical detectors linked in tandem since the GC-effluent may be very hot and possibly will damage the antenna used as a biological detector. Therefore an interface has to be used which mixes the GC-effluent with cool humidified air. First experiments using an electroantennographic detector in combination with a GC equipped with a packed column were published by Moorhouse [6]. Adaptation and loss of sensitivity of the insect antenna during long-lasting GC-peaks suggested the use of capillary columns. This technique was first published by Arn et al. [7]. A coupling of a device for single-sensillum recordings with a GC was reported by Wadhams [8] as well as Van Der Pers and Löfstedt [9].

The use of GC-EAD-systems is well established in the analysis of pheromones (e.g. [10–14]) but so far has rarely been used for detection of food odours [15–22] of insects. The aim of this report is the employment of a GC-EAD system based on the antenna of the Colorado potato beetle for the analysis of volatiles emitted by the potato plant.

The Colorado potato beetle is able to recognize its host plant by olfactory cues and is attracted by the odour of the potato and other solanaceous plants [23–25]. Visser et al. [1] as well as Mitchell and McCashin [26] examined the volatiles emitted by potato plants and identified several saturated and unsaturated alcohols and aldehydes with 6 carbon atoms. These compounds are found in most green plants and therefore are referred to as green leaf odour (GLO). Moreover, Visser et al. [1] observed linalool and some unidentified terpenes.

The sensitivity of the olfactory receptors of the Colorado potato beetle for GLOs is very high [27] so that it consequently should be able to perceive all green plants emitting these compounds. Visser and Avé [28] hypothesized that the ability to discriminate between host plants and non-host plants is based upon the relative intensities of the GLOs emitted by the plants. The importance of non-GLO substances for the host plant recognition of the Colorado potato beetle so far has not been evaluated.

One possible application of the GC-EAD system is the elucidation of the mechanisms involved in host plant recognition of the potato beetle. Samples for GC-EAD are obtained by closed-loop stripping analysis (CLSA) of plant volatiles. Along with GC-EAD analysis the samples are analysed with a GC-MS system in order to allow identification of the volatiles emitted by the potato plant.

2. Experimental

2.1. Plants and beetles

Experiments were performed with potato plants *Solanum tuberosum* var. Granola, grown in a greenhouse with 16 h light/8 h dark and temperatures ranging from 15 to 25°C.

Colorado potato beetles are reared in a laboratory stock culture under artificial light (16 h light/8 h dark) and temperatures ranging from 20 to 25°C. Beetles are fed with potato plants grown under conditions as described above.

For the experiments female beetles at an age ranging from 7 to 14 days after emerging from pupae were used exclusively. Beetles assigned for experiments are taken from the rearing cages and kept in plastic boxes for 1–2 h without food. In blowflies (*Phormia regina*), an increasing chemoreceptor activity of gustatory receptors was observed after sustained starving [29]. We could not confirm this effect for the olfactory chemoreceptors of the Colorado beetle. Nonetheless, a period of starvation was maintained, allowing the beetles to empty their guts and thus enhancing cleanliness of the preparation. The air in the plastic box is humidified by a filter paper soaked with water in order to prevent desiccation of the beetles. A beetle is fixed with parafilm and dentist's wax before one of it's antennae is cut off

with a pair of microscissors. The time needed for the preparation of an antenna amounts to 15 min. After removal from the body of the beetle the antenna remains operational for 1–2 h.

2.2. Sampling of volatiles

In order to investigate the volatile emissions of potato plants injured by chewing insects, 20 g (fresh weight) of potato leaves were placed in a 500 ml round-bottom flask together with 20 Colorado potato beetles. This procedure provides a continuous source of fresh injuries on the leaves leading to an elevated emission of leaf volatiles. The volatiles were collected on a charcoal trap (CLSA-Filter, Kollbrunn, Switzerland) using the closed-loop stripping technique [30,31]. Air is circulated through the trap by a miniature pump (Fürgut, Aichstetten, Germany) at a flow of 0.8 l min^{-1}. All surfaces getting in touch with the volatiles (pump, capillaries) are either PTFE or stainless steel. The sampling time was varied from 1 to 24 h in order to examine time dependence of the emissions. Adsorbed volatiles are eluted with 50 µl of dichloromethane/methanol (2:1). The solvents used are of analytical quality (Merck, Darmstadt, Germany). The mixture of dichloromethane and methanol provides a solvent capable of eluting the volatiles from the charcoal moistened by the transpiration of the plants. On the other hand, the content of dichloromethane allows dissolving of volatiles with low polarity. After elution, samples are stored in a refrigerator at −25°C. Nonetheless samples were analysed within 24 h after elution.

2.3. GC-MS

A GC-MS system was used to analyse composition of the volatiles collected with the CLSA setup. The system consists of a gas chromatograph HP 5890 Series II and a quadrupole mass spectrometer HP 5989 A (both Hewlett Packard, Palo Alto, USA). The GC is equipped with a capillary column (25 m × 0.2 mm I.D., HP-1) and a KAS-2 cold injection system (Gerstel, Mülheim, Germany). Helium was used as carrier gas at a pressure of 100 kPa (gas flow 0.5 ml min^{-1}, gas vector 28 cm s^{-1} at 70°C). The following temperature programs were employed: GC: start at 70°C, hold for 3 min, rate 10°C min^{-1}, end temperature 250°C, hold for 4 min. KAS: start at 50°C, hold for 1 min, rate 10°C s^{-1}, end temperature 250°C, hold for 3 min.

Within the first min after injection a purge valve prevents excess solvent from entering the column. The loss of substances with high volatility (GLO) in this period was tolerable since the main interest of this work is the identification of compounds with low volatility.

The MS was connected to the GC by a direct coupling interface heated to a temperature of 250°C. The ion source was operated in the EI-mode at an electron energy of 70 eV. The instrument was tuned using the Autotune option of the chemstation-software (HP59944B, ver. B.04.03). Measurements were performed in the scan mode, detecting a mass range from 35 to 250 amu. The operating parameters of the GC and the MS were chosen in order to analyse the compounds of the green leaf odour (molecular weight ~ 100, boiling point ~ 155°C) as well as sesquiterpene hydrocarbons ($C_{15}H_{24}$, mw. 204, bp. ~ 270°C).

2.4. GC-EAD

Experiments were performed with a GC-EAD system consisting of a gas chromatograph (Vega 6300-01, Carlo Erba, Rodano, Italy), an EAD-interface (Syntech, Hilversum, Netherlands), and an EAG-amplifier (Dr. Koch, University of Kaiserslautern). The GC is equipped with a capillary column (30 m × 0.32 mm I.D., DB-1), a flame ionisation detector (FID) and a split-splitless injector. The injector is operated in the splitless-mode. Nitrogen was used as carrier gas at a pressure of 100 kPa (gas flow 2.5 ml min^{-1}, gas vector 50 cm s^{-1} at 50°C).The following temperature program was employed: start at 70°C, rate 10°C min^{-1}, end temperature 200°C.

A split connection at the end of the capillary column allows division of the GC-effluent into two capillaries leading to the FID (length 35 cm, 0.2 mm I.D.) and the EAD (length 45 cm, 0.32 mm I.D.), respectively. This provides a split ratio of 1:5 (FID/EAD). The EAD-interface (Fig. 1) is

under thermostat control and guides the capillary column through the wall of the GC-oven thus preventing condensation of the sample in the cooler segments of the column. The end of the column projects into a small chamber where the effluent is mixed with cold humidified air (400 ml min^{-1}). A PTFE-clad flow tube leads the airflow to the detector cell. The flow tube is provided with an injection port for manual calibration pulses. A PTFE tube guides the tip of an injection needle into the centre of the flow tube. 'Side-port' injection needles (Supelco, Deisenhofen, Germany) allow injection parallel to the air flow. Solutions of (*Z*)-3-hexen-1-ol in paraffin oil (both Merck, Darmstadt, Germany) are used as calibration standard. The calibration syringe contains a filter paper soaked with 50 µl of a standard solution, typically a 10^{-3} dilution of (*Z*)-3-hexen-1-ol in paraffin. The air contained in the syringe thus has a concentration of ca. 4.5 ng (*Z*)-3-hexen-1-ol ml^{-1} of air.

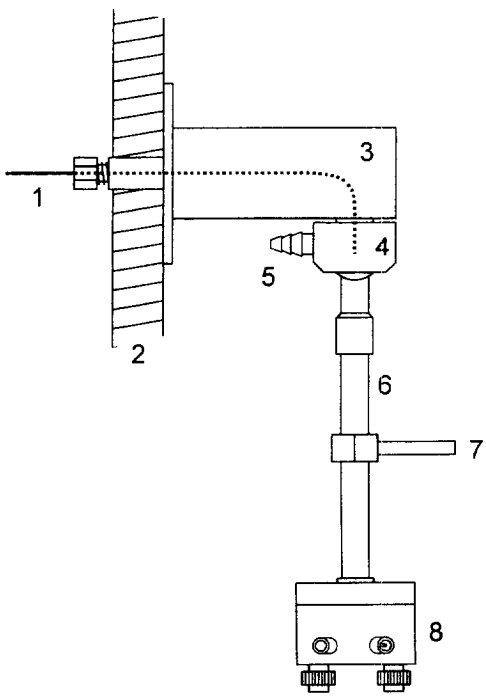

Fig. 1. EAD-interface (schematic). 1, capillary column; 2, wall of GC oven; 3, heated column-guide; 4, mixing chamber; 5, inlet for humidified air; 6, flow tube; 7, inlet for calibration pulses; 8, detector cell

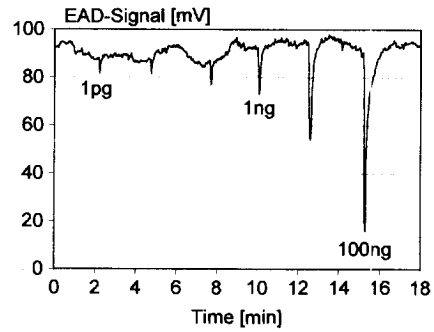

Fig. 2. GC-EAD measurement of a dilution series of (*Z*)-3-hexen-1-ol injected successively in the GC, operated at a constant temperature of 80°C.

The antenna of a Colorado potato beetle is housed in a detector cell designed by Koch [32]. Both ends of the antenna are contacted to Ag/AgCl electrodes via hemolymph Ringer solutions. The Ringer solutions are composed according to Kaissling and Thorson [33]. EAG-potentials of the antenna are amplified by a factor of 100 and recorded with a Chromstar® data acquisition system (Bruker, Bremen, Germany).

3. Results and discussion

3.1. Performance test with standard solutions

In order to evaluate the detection threshold of the GC-EAD system for substances of the green leaf odour measurements were performed with standard solutions of (*Z*)-3-hexen-1-ol in methanol. The GC was operated at a constant column temperature of 80°C. Test solutions containing (*Z*)-3-hexen-1-ol in amounts from 1 to 100 ng were injected successively in 2.5 min intervals. The result of this performance test is depicted in Fig. 2. The solvent methanol leads to broad fluctuations in the EAD signal starting about 1 min before the sharp peaks induced by (*Z*)-3-hexen-1-ol. Apart from the structures caused by methanol the noise of the baseline amounts to approximately 2 mV. One pg of (*Z*)-3-hexen-1-ol elicits an EAD signal of 6.5 mV and thus can be regarded as limit of detection.

The high sensitivity of the Colorado potato beetle for (*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol with detection limits around 20 fg was already noticed by Visser [1]. It was expected that the detection limit in EAD experiments could not match the results obtained from EAG experiments since the compound does not reach the antenna in a short pulse (< 0.5 s in EAG) but is rather stretched over some seconds in the GC column.

The relationship between the EAD signal and the stimulus concentration is depicted in Fig. 3. The EAD signal of an insect antenna may last for some seconds even if the stimulus is very short. If the stimulus lasts for a longer time, the sensitivity of the antenna may decrease during the stimulus (adaptation). With respect to these facts the peak amplitude was chosen as a measure for the EAD response instead of the peak area.

The relationship between the EAD amplitude and the concentration of the sample is not linear. However, it was not possible to describe the obtained data by the model predicted by Beidler [34].

The results observed in the calibration demonstrate that the employed EAD setup is able to detect (*Z*)-3-hexen-1-ol in amounts down to 1 pg. The observed detection limit is comparable to the sensitivity of other selective detectors used in gas chromatography, for example electron capture detectors (detection limit 100 fg for halogen compounds) or the nitrogen-phosphorus-sensitive detector (detection limit ~ 1 pg for compounds containing N or P atoms).

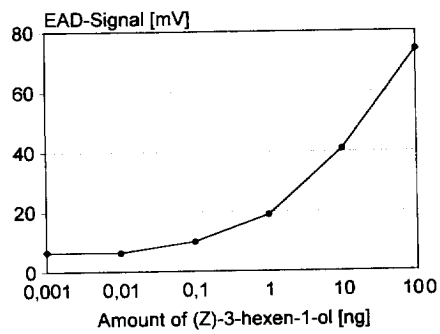

Fig. 3. Dose-response curve for stimulation of an antenna of the Colorado potato beetle with (*Z*)-3-hexen-1-ol in amounts ranging from 1 to 100 ng. The electroantennographic signal is amplified by a factor of 100.

The capability of the EAD of detecting GLOs in high concentrations is limited by saturation of the chemoreceptors and a possible adaptation to the stimulating compound. Saturation only leads to an uncertainty in the quantification of the actually detected compound but adaptation may cause the antenna to overlook compounds eluting from the column shortly after an intense peak. (*Z*)-3-hexen-1-ol in an amount of 1 μg already leads to a strong broadening of the peak so 100 ng are regarded as upper limit for the applicability of the EAD based on the antenna of the Colorado potato beetle. Thus the dynamic range of the used EAD setup covers a range from 10 pg to 100 ng for (*Z*)-3-hexen-1-ol.

Another remarkable feature of the EAD system is the very low sensitivity for methanol and other solvents. In the first measurements immediately after preparation of the antenna usually an olfactory reaction to the solvent methanol is observed. After some injections of methanol, however, no more reaction of the chemoreceptors occurs. This may indicate a selective adaptation of one class of chemoreceptors while the receptors responsible for the detection of green leaf odours are still operational.

Usually an exponential decrease of the sensitivity is observed after the antenna is removed from the head of the beetle. During the first 10–15 min after the preparation the sensitivity is very high but the baseline is quite unstable. After this period a performance test should be undertaken. The amplified EAD signal measured after injection of 3 ml air from a syringe containing a 10^{-3} dilution of (*Z*)-3-hexen-1-ol should amount to 50–100 mV. If this signal is lower than 50 mV the antenna should be rejected. The performance test is repeated before each new GC run.

A drawback of the EAD method is the limited quantitative reproducibility of the signals obtained during the lifetime of one antenna or signals from different antenna preparations. Therefore, an internal calibration should be used in order to test the momentary performance of the antenna employed in the GC-EAD system. Alternatively, calibration can be done by injections in the calibration port.

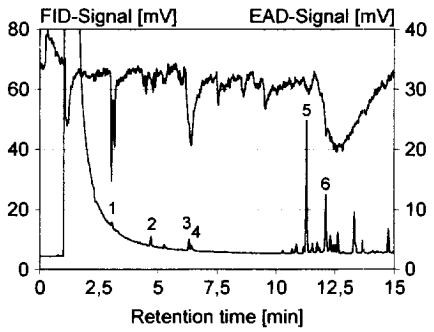

Fig. 4. GC-EAD-FID chromatograms of volatiles sampled 12 h from potato leaves injured by feeding of Colorado potato beetles. The upper line represents the EAD signal, the lower line depicts the FID signal. Peak assignations: 1, green leaf odour ((*E*)-2-hexenal, (*Z*)-3-hexen-1-ol); 2, β-myrcene; 3, linalool; 4, benzeneethanol; 5, caryophyllene; 6, germacrene-D.

3.2. Analysis of volatiles emitted by potato plants

Samples diluted from the charcoal trap after 1, 12 and 24 h sampling time were analysed by GC-MS and GC-EAD. (*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol were found in very low concentrations hardly exceeding the detection threshold of the MS in consideration of the employed mode of operation. Further substances identified in the sample are β-myrcene, linalool, benzeneethanol, caryophyllene, germacrene-D, γ-cadinene, δ-cadinene and some other sesquiterpenes.

The variety and abundance of the emissions reached its maximum in the sample taken after 12 h of exposition to the plant volatiles. The same sample analysed with the GC-EAD setup resulted in the chromatogram depicted in Fig. 4. In order to compensate for the unstable baseline of the EAD, a 2nd order polynomial regression curve was subtracted from the original data.

The solvent (dichloromethane/methanol) elicits a moderate deflection in the EAD signal. The green leaf odours leaving the GC column at retention times (t_R) around 3 min are hardly detectable with the FID whereas the EAD signal reveals a strong reaction of the olfactory receptor cells of the Colorado potato beetle. At retention times between 4 and 5 min several small peaks are visible in the EAD signal probably indicating an olfactory reaction induced by β-myrcene and other terpenes.

Around $t_R = 6$ min the FID is able to detect two peaks corresponding to linalool and benzeneethanol. The olfactory reaction induced by these compounds leads to one broad peak that is not resolved in the EAD signal. The ability of the Colorado potato beetle to perceive linalool and its presence in the odour of the potato plant was already noticed by Visser [1,27]. Experiments with standard solutions revealed that the sensitivity of the Colorado potato beetle for benzeneethanol is about 10–100 times higher as compared to linalool.

An olfactory reaction observed at $t_R = 9.5$ min might be of special interest. The compound inducing this EAD signal was identified as a branched alkane, possibly 5-ethyl-undecane or 6-ethyl-2-methyl-decane. This is not a typical plant volatile and thus could be a hint on a pheromone of the Colorado potato beetle.

At retention times between 10 and 15 min strong peaks are observed both in the EAD and FID signal. The most abundant peak in the FID signal ($t_R = 11.3$ min) corresponds to caryophyllene but its match in the EAD signal is rather small. Instead, a broad peak in the EAD signal starting at $t_R = 12$ min is observed. Using standard solutions containing caryophyllene and germacrene-D it was confirmed that the peak width induced by these compounds amounts to about 1 min. Apparently, the broad structure in the EAD signal is a reaction of the antenna induced by too much of different sesquiterpenes eluting from the GC column in too short intervals.

These results demonstrate that the time resolution of the EAD system is excellent in case of small retention times. The EAD is able to resolve the peaks of (*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol which are only 8 s apart. At higher retention times the peaks in the EAD signal are broadening and the multitude of peaks that is visible in the FID signal cannot be resolved.

3.3. Host plant recognition of the Colorado potato beetle

The sense of smell is of particular importance in host plant recognition of monophagous and oligophagous insects. The first interaction be-

tween the Colorado potato beetle and a potential host plant is mediated by olfactory cues. Only if the odour of a plant is acceptable to the beetle it will approach the plant and proceed with a tactile and gustatory examination. In this respect a detailed knowledge of the olfactory interaction between the Colorado potato beetle and its host plants might be useful for development of new measures in plant protection.

So far it is not fully known which constituents of the potato odour are essential for the host plant recognition of the Colorado potato beetle. Experiments of Visser and Avé [28] indicated that the Colorado potato beetle perceives relative intensities of different compounds and thus can distinguish the potato plant from other plants emitting the same compounds but in other concentrations.

The EAD chromatogram depicted in Fig. 4 indicates that the importance of terpenes and sesquiterpenes in host plant recognition of the Colorado potato beetle might be comparable to that of green leaf odours. Preliminary experiments revealed that the attractivity of potato plants to the Colorado potato beetle is enhanced when they are treated with green leaf odours, linalool or caryophyllene in concentrations simulating the emissions of injured plants. Further experiments are in progress and will be published elsewhere [35].

Acknowledgements

Support by Dr. U. Koch (University of Kaiserslautern, Germany) who provided the detector cell, some holding devices, and a lot of good advice is gratefully acknowledged. We thank Nikola Bitsch for assisting in the first tests of the GC-EAD interface. Professor Dr. W. Boland (University of Karlsruhe, Germany) helped us getting started with the CLSA-technique. We thank Dr. H. Surburg (Haarmann and Reimer GmbH, Holzminden, Germany) for support in identification of the sesquiterpenes emitted by the potato plant. The authors are indebted to the generosity of both the Federal Ministry of Science and Technology, Bonn, and the Ministry of Arts and Sciences of the State of Hesse, Wiesbaden, who jointly provided the generous funds for the quadrupole mass spectrometer used in this study.

Received 5 June 1996; received in revised form 14 February 1997; accepted 25 March 1997

Abstract

The flow field-flow fractionation (FIFFF) technique is a promising method for separating and analysing particles and large size macromolecules from a few nanometers to approximately 50 μm. A new fractionation channel is described featuring well defined flow conditions even for low channel heights with convenient assembling and operations features. The application of the new flow field-flow fractionation channel is proved by the analysis of pigments and other small particles of technical interest in the submicrometer range. The experimental results including multimodal size distributions are presented and discussed. © 1997 Elsevier Science B.V.

Keywords: Particle separation; Flow fractionation

1. Introduction

The separation of particles and macromolecules in a flow field at low Reynolds numbers and under a cross flow field is principally known since the late 1960s [1]. But only in recent years, has this technique received wider attention as an analytical tool for analysing small particles in the submicrometer and micrometer range.

The flow field-flow fractionation (FIFFF) is a complementary technique to the SEC, capillary electrophoresis, capillary injection and centrifuge methods. FIFFF has advantages in the cases where a high selectivity and resolution, gentle, shear free conditions and a broad measurement range from nanometer to over 50 μm is necessary [2,3]. Furthermore, FIFFF allows physical separation of the size fractions of the particle mixture. The technique was recently used for the separation of proteins [4,5], antibody aggregates [6], polymers [7], biological material [8] and calibration particles [9]. For industrial purposes, FIFFF has been applied successfully to analyse pigments and paints [10,11].

This paper describes the newly designed channel and the experimental results gained with selected test particles of technical interest.

2. Basics

In Fig. 1 the FIFFF channel is schematically shown. An appropriate force field is perpendicularly applied to the particle loaden flow field. In the case of FIFFF, the force field is realised by a cross flow over the whole channel length. The width and length of the channel lie typically between 75 and 300 μm and 30 cm, respectively. The measuring set-up of FIFFF is shown schematically in Fig. 2 and Fig. 3 is a photographic representation of the measuring assembly.

2.1. Normal mode

The investigated particle sample is injected at the tip of the channel. Relaxation occurs, which is carried out according to the stop-flow procedure. During the relaxation, the axial flow is deactivated and one to two channel volumes of the carrier fluid are pumped across the channel. Due to the cross flow, the particles are driven toward the membrane covering the bottom frit. However, the diffusion of particles acts in the opposite direction. In consequence, each particle fraction reaches its equilibrium position in the channel, depending on the particular diffusion coefficient. After relaxation is completed, the axial flow is activated and the particle fractions are driven to the channel outlet.

Thus, the parabolic flow velocity profile and the diffusion coefficient related positioning of particles in the channel cause a fractionation of the sample. Applying the Einstein–Stokes equation which couples diameter and diffusion coefficient for small spherical particles, a relationship Eq. (1) for the retention time t_r and the particle diameter d can be derived:

$$t_r = \frac{t^0}{R} = \frac{d\pi\eta w^2 V_c}{2kTV} \quad (1)$$

where t_r is the retention time, t^0 the void time, $R = t^0/t_r$ the retention ratio, d the hydrodynamic particle diameter, η the viscosity of the fluid, w the channel height, k the Boltzmann constant, T the temperature, V_c the volume flow of cross flow, and V the volume flow of channel flow. If the molecular weight M of macromolecules is of interest, the following relation between molecular weight and diameter is generally applied:

$$d = A'M^b \quad (2)$$

where A' and b are constants.

Eq. (1) describes the normal mode of operation. In this mode, small particles are located towards the channel center and bigger ones are closer to the membrane. The channel flow with its parabolic velocity profile, therefore moves the smaller particles faster so the detector at the channel end is passed first. When the FIFFF is operating in the normal mode, it is an absolute method for measuring diffusion coefficients and particle size under certain conditions. Therefore, calibration is not necessary. Where diffusion forces are dominant, particles with small diameters (≤ 1 μm), can be fractionated in this normal mode.

2.2. Steric mode

For particles with $d > 1$ μm, the diffusion motion can generally be neglected. At this point it is solely the particle size that is of importance for the elusion and fractionation. Compared with the normal mode it is the outflow sequence of the particles that reverses and the large particles are detected first. The duration for the analysis is much shorter and instead of Eq. (1) the Eq. (3) applies:

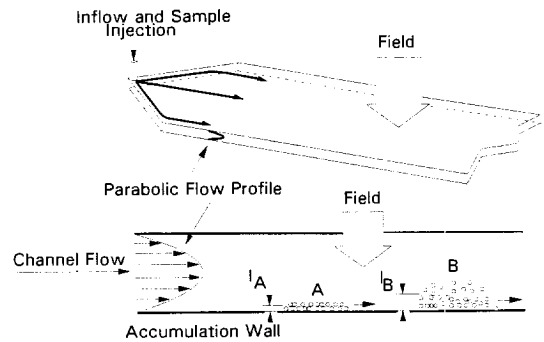

Fig. 1. Principle of field-flow fractionation. A, B, different particle fractions; l_A, l_B, specific distance from the accumulation wall for both fractions.

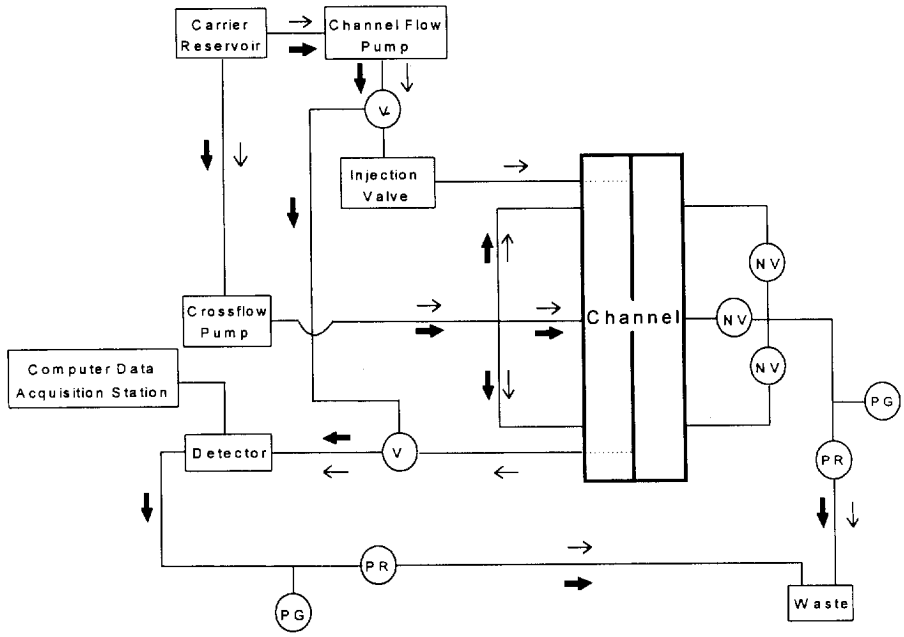

Fig. 2. Schematic diagram of FIFFF setup: V, valve; PR, pressure regulator; PG, pressure gauge; NV, needle valve; full and empty arrows represent the relaxation and elution period, respectively.

$$t_r = \frac{wt^0}{3\gamma d} \tag{3}$$

where γ correction factor $1 \leq \gamma < 2$. Previous calibration using a suspension with known size distribution is mandatory to find the applicable correction factor γ.

2.3. Hyperlayer mode

In the hyperlayer mode, the initial fractionation of large particles is due to the hydraulic lifting force. Again, the larger particles are preferentially driven towards the channel center. Consequently, these particles are detected first. The analysis time is short, whereas Eq. (3) is also used with a correction factor $\gamma \geq 2$. Calibration is mandatory to gain the numerical value of γ for the individual flow conditions.

It is advantageous for routine analysis to work in the steric or hyperlayer mode as the measurement time is short. However, this requires the proper adjustment of the channel height and flow conditions.

2.4. Determination of flow mode

Fig. 4 illustrates schematically the different flow modes, depending on the particle size and its position in the channel.

It is not known a priori which operating mode is applicable for a given sample. In practice, the optimal mode can be found by experiments with latex standards of different sizes. Fig. 5 shows the results gained at specific flow conditions with a channel height of 100 μm [11].

The minimum in the retention ratio versus the diameter separates the modes. Small particles which are diffusion driven follow the normal mode whereas larger ones undergo the hyperlayer or steric mode fractionation. The limit of the modes for the conditions of Fig. 5 lies at a particle diameter of approximately 0.6 μm. This limit depends on the channel height and selected flow conditions and can be to some extend changed.

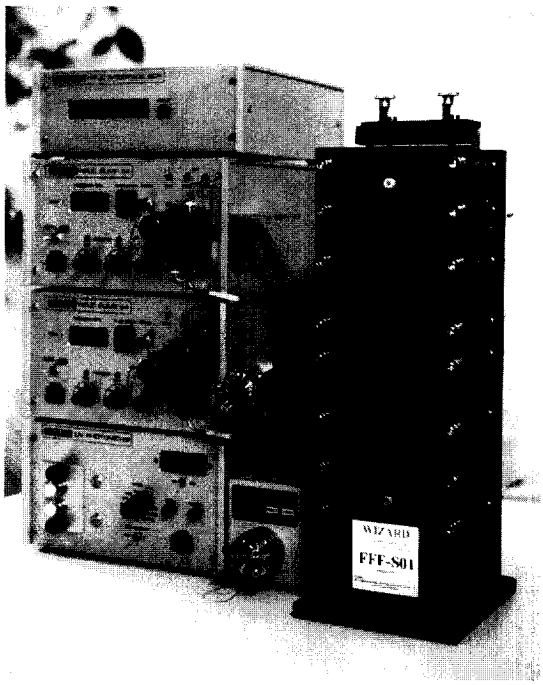

Fig. 3. Photography of the channel setup.

3. Channel design

The channel dimensions like width b, height w and length l are in principle freely selectable. The aspect ratio b/l must be sufficiently low to fulfil the assumption of an indefinitely long channel.

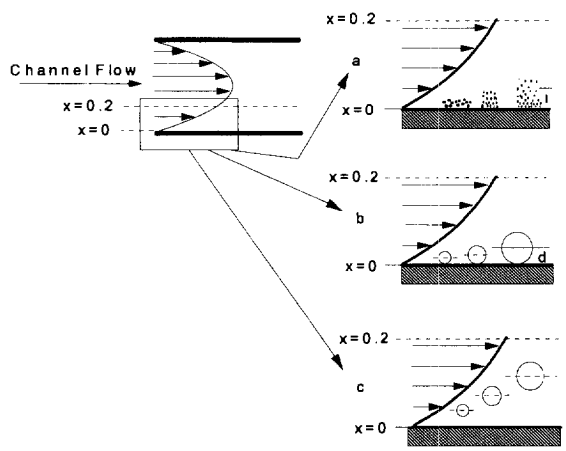

Fig. 4. Illustration of normal (a), steric (b) and hyperlayer (c) mode of operation.

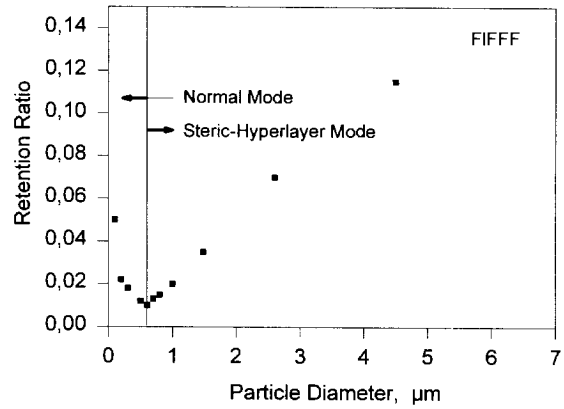

Fig. 5. Determination of flow mode.

The length and height affect via the ratio V_c/V of Eq. (1) the retention time, the flow mode and the separation output. The FIFFF channel under consideration has a length of 300 mm and a width of 20 mm. The channel height was varied between 100 and 250 µm to optimise the resolution and the retention time.

A major feature of the new channel is the division of the hollow compartment under the frit into three separate chambers with an independent pressure control to eliminate pressure drop differences along the channel and to assure a uniform cross flow in the whole channel. As evidenced in [12], the cross flow uniformity in the channel can be adversely influenced by a membrane. Fig. 6 gives an internal view of the separate chambers under the frit.

The handling of the new channel is most simple. Attention is given to a comfort assembling and dissembling of the channel. The change of the spacer or membrane can be done within a short time. The secure replacement and stretching of the delicate membrane is solved by special spring loaded clamping devices [13].

4. Experimental results

The samples were injected into the channel using a 20 µl loop and the stop-flow relaxation was conducted (two void volumes were pumped across the channel by deactivated axial channel

flow). After the relaxation of approximately 30 s, the channel flow was switched on and the fractionated samples were detected with a UV detector.

As submicrometer particles were of interest, only the normal mode was used for the presented data. Because of the simple linear relation between the elution time and the particle diameter in Eq. (1) for the normal mode, the time abscissa can be readily recalculated to the diameter scale. A system peak is typically generated at the UV detector when the valve for the channel flow is activated.

Several test particle samples were investigated. A systematic analysis on the particle shape influence was not made so far. The obtained diameter can be considered as a hydrodynamic one.

Fig. 7 shows a raw data record of intensity versus time for a red iron oxide pigment water suspension. The experimental settings were $V = 1.5$ ml min^{-1}, $V_c = 0.55$ ml min^{-1}, $w = 250$ μm.

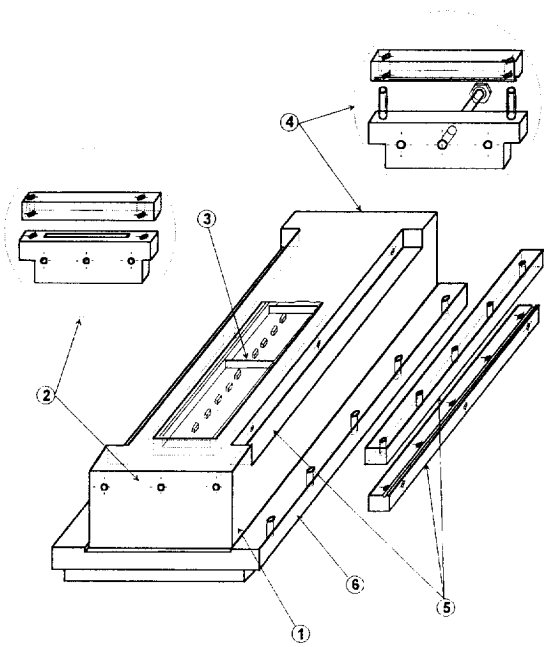

Fig. 6. View of the separated chambers under the frit of the fractionation channel, 1—plexiglass block; 2, 4 and 5—membrane clamping and tensioning device; 3—camber separator; 6—supporting plate.

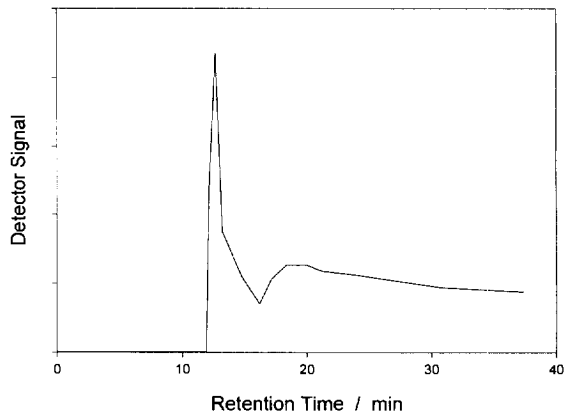

Fig. 7. Printout of the UV detector signal for the iron oxide pigment; flow conditions: $V = 5.5$ ml min^{-1}, $V_c = 0.8$ ml min^{-1}, $w = 210$ μm.

The size distribution has its broad maximum at approximately 20 min which corresponds approximately to a size of 0.1 μm. The broad size distribution is typical for an industrial pigment. The large peak at 12 min is the system peak which is normally equivalent to the void peak and arises when the head of the initiated channel flow arrives at the detector which is approximately the void time (Eqs. (1) and (2)). The system peak, which does not contribute to the measurement results, is omitted in the following data graphs. It can easily be distinguished from the sample and be eliminated by the data acquisition and presentation software. This is a standard procedure.

Fig. 8 represents a detector signal for a bimodal size distribution of a mixture of TiO_2 pigment (Kronos 2057, Kronos) and an acrylic emulsion (Mowilith DM-772, Hoechst AG). Despite that the sizes of both species are rather close together, it was possible to resolve both distributions with the maxima at 0.265 and 0.691 μm. The experimental settings were $V = 5.5$ ml min^{-1}, $V_c = 0.8$ ml min^{-1} and $w = 210$ μm.

Fig. 9 shows again the high resolution of FIFFF. The SiO_2 sample of a narrow distribution was clearly detected with a mean size of 0.496 μm which corresponds within 10% with the manufacturers analysis.

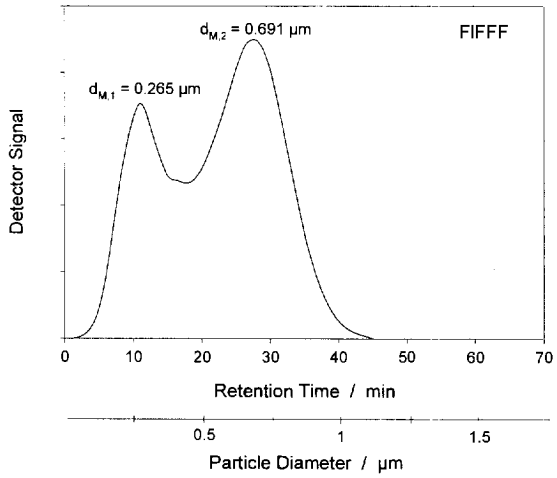

Fig. 8. FIFFF spectrum for a two component sample, consisting of TiO_2 (33 wt.%) and acrylic emulsion (67 wt.%); flow conditions: $V = 5.5$ ml min^{-1}, $V_c = 0.8$ ml min^{-1}, $w = 210$ µm.

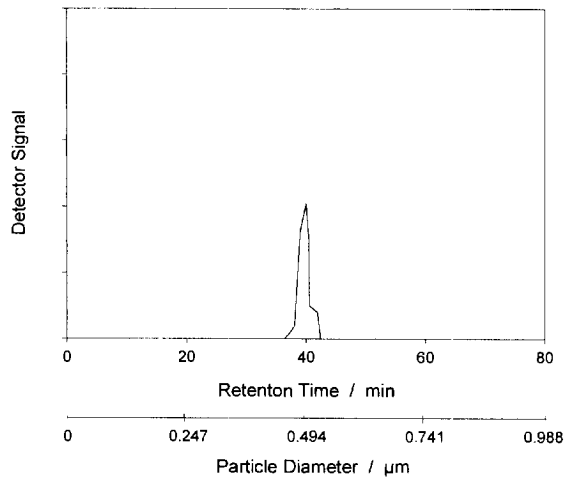

Fig. 9. FIFFF spectrum for SiO_2 sample; flow conditions: $V = 1$ ml min^{-1}, $V_c = 0.2$ ml min^{-1}, $w = 250$ µm.

5. Summary

FIFFF offers an interesting alternative for the fractionation and separation of small particles and the measurement of the molecular weight of macromolecules. Particularly, the broad measuring range from approximately 1 nm to over 50 µm must be mentioned. Of advantage is the possibility to function in different operating modes, i.e. normal, steric and hyperlayer mode. For the two latter modes, the measurement times are remarkably short.

The new FIFFF channel proved its capability to investigate small particles. The design makes the handling easy and fast so that it can be used for standard laboratory applications.

Multicomponent analysis in luminescence spectroscopy[1]

M. Dalibart

LSMC URA 124, Universite Bordeaux I, 351 Cours de la Liberation, 33405 Talence Cedex, France

Received 13 June 1996; received in revised form 2 May 1997; accepted 15 May 1997

Abstract

Multicomponent analysis of absorption spectra (infrared or electronic spectra) by factor analysis is a suitable method to use. The algorithm of factor analysis is now available for luminescence spectroscopy. The first possibility, as in absorption spectroscopy, is to determine pure components emission spectra for a unique set of spectra of mixtures in overdetermined conditions. On the other hand, it is also possible to extract pure components emission and excitation spectra of the only data corresponding to the 3D fluorescent spectrum of a single mixture. The results are evaluated in respect to noise level and concentrations ratio on both simulated and real spectra. © 1997 Elsevier Science B.V.

Keywords: Factor analysis; Simulated spectra; Luminescence; 3D-spectrum

1. Introduction

Multicomponent quantitative analysis allows correlations between the spectra and the concentrations of the calibration set. Numerous methods of least-squares analysis: classical least squares (CLS), inverse least squares (ILS) or bilinear analysis: principal components regression (PCR), partial least squares (PLS) are suitable and can be found in the monograph by Martens and Naes [1]. All these methods require a calibration set of solutions.

On the other hand, factor analysis [2] attempts to predict concentration without the calibration step and can be used when the components are not clearly identified or are not available. In this way, factor analysis appears as a self-calibration method that can be applied to problems concerning mixtures of an unknown number of unknown components.

2. Experimental

The emission, excitation and 3D-spectra were recorded on a SFM25 instrument from KONTRON and processed on a PC computer.

Numerous simulated spectra of mixtures were generated by using experimental spectra of pure components (anthracene and perylene) and adding noise to various level (0–20%).

Our factor analysis programmes were performed on a PC computer for the first method

[1] Presented at the Symposium on Analytical Sciences (SAS) IV, Belgium, 3–5 June, 1996.

PII S0039-9140(97)00221-X

and on a RISC IBM 6000 station for the diagonalisation of the 3D matrix.

3. Theory

The mathematical techniques of factor analysis have been well described in the excellent monographs by Malinowsky [3] and are well covered in the literature [4–12] and we shall restrict our presentation to an abstract.

In absorption spectroscopy the formalism is based on Beer's law:

$$|A| = |K| \cdot |C|$$

where $|A|$ $(p \cdot m)$ is the absorbance matrix; $|K|$ $(p \cdot n)$ represents the product of the absorptivity by the path length; and $|C|$ $(n \cdot m)$ is the concentration matrix $(n \cdot m)$; using n components, a set of m solutions and a set of p absorption wavelengths ($n < m$ and $n < p$).

The first step is to build the covariance matrix:

$$|Z| = |A|^T \cdot |A|$$

where $|Z|$ is a $(m \cdot m)$ small triangular matrix; and $|A|^T$ is the transpose absorbance matrix.

The $|Z|$ matrix is then diagonalised and the number of principal factors is determined, using criteria such the IND indicator [2]. A set of abstract mathematical meaning eigenvector matrices $|R_a|$ and $|C_a|$, but devoid of real physical or chemical meaning, is computed:

$$|A| = |K_a| \cdot |C_a|$$

where $|K_a|$ represents the abstract pure components spectra; and $|C_a|$ is the abstract concentration matrix.

Previously self-modelling method [6–8] or rank annilation method [9–12] were used to convert, in some particular cases, these factors into physically significant matrices.

We have written a more general iterative algorithm to convert these factors using rotation, for two or three factors, and target testing for general cases. In contrast to previous methods, the only assumption is that the computed spectra matrix must only contains positive values [13–15].

Using these computational methods the real spectra $|K_r|$ is obtained. The concentration $|C_r|$ matrix is finally computed by using the CLS method [1]. During these last steps, the extracted matrices $|K_r|$ and $|C_r|$ must be normalised [13–15].

4. Emission spectroscopy

For dilute solutions, the fluorescence intensity is linear versus concentrations and thus the law can be written:

$$|I| = |K| \cdot |C|$$

where $|I|$ is the intensity matrix; $|K|$ represents the product of the absorption coefficient by the path length and by the fluorescence efficiency; and $|C|$ is the concentration matrix; that is to say stickly the formalism used in absorption.

Thus, using a set of emission spectra of mixtures, it is possible to compute both pure components spectra ($|K|$ matrix) and concentration values ($|C|$ matrix).

Fig. 1 presents the comparison of the pure components spectra and the computed spectra of simulated mixtures. The computed spectra are good for reasonable noise level. Factor analysis was performed with noise level from 0 to 20%, the relative error on calculated concentration varies from 0.5 to 1.5% and the quadratic error on computed spectra was estimated (Table 1).

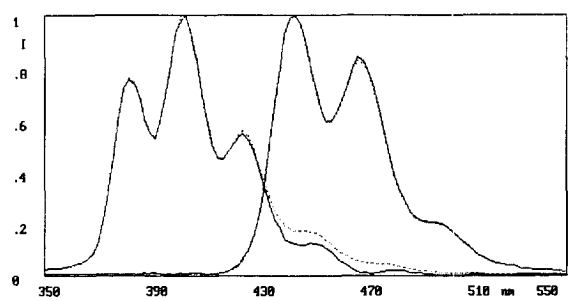

Fig. 1. Comparison of the emission spectra of simulated mixtures of anthracene and perylene. ··· pure components spectra; —— computed spectra.

Table 1
Computation errors on concentrations and spectra vs. noise level for simulated mixtures of anthracene and perylene

% Noise level	% Concentrations error	Quadratic errors on computed emission spectra
0	0.53	0.00002
1	0.55	0.00002
2	0.59	0.00003
5	0.72	0.00004
10	1.50	0.00022
20	1.52	0.00070

5. D-fluorescence data

A 3D-fluorescence spectrum is a set of emission spectra, that is to say intensity versus emission wavelengths, recorded with various excitation wavelengths. A |I| matrix is obtained. The rows represent the emission spectra of the mixture and the columns are the excitation spectra of the mixture [9–12]:

$$|I| = |F| \cdot |E|$$

where |I| $(p \cdot m)$ is the 3D-spectrum; |F| $(p \cdot n)$ represents the emission spectra of the pure components; and |E| $(n \cdot m)$ is the excitation spectra of the pure components; and |E| $(n \cdot m)$ is the excitation spectra of the pure components; using n components, a set of m excitation wavelengths and a set of p emission wavelengths.

The computational methods used for by previous authors [9–12] require wavelengths where only one component emits.

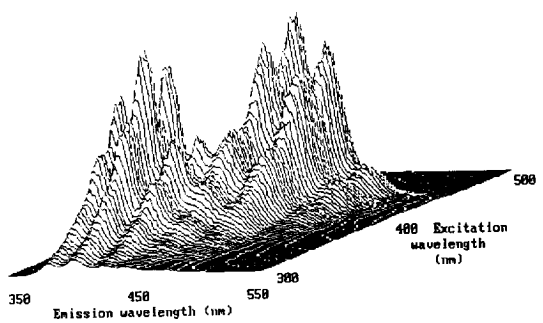

Fig. 2. Simulated 3D-spectrum (anthracene/perylene mixture with 5% noise level).

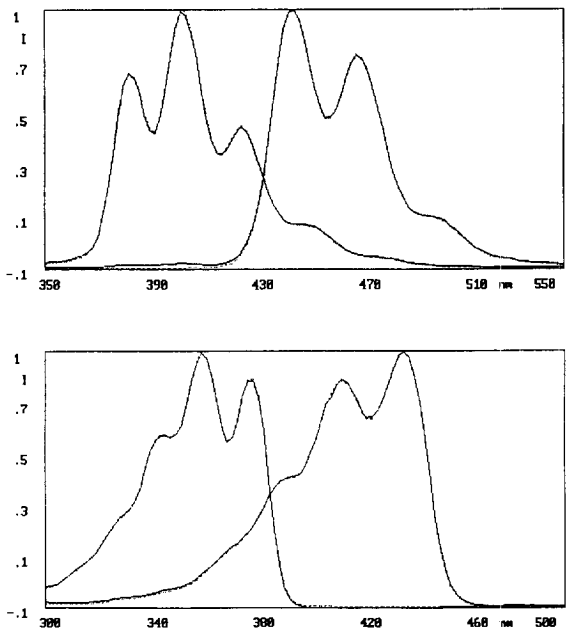

Fig. 3. Emission (a) and excitation (b) spectra computed from a simulated 3D-spectrum (see Fig. 2). ··· pure components spectra; —— computed spectra.

To recover physical meaning, we have used our algorithm described before. The covariance matrix, |Z| is then a $p \cdot p$ matrix, that is to say, for our data, a 101.101 matrix. The diagonalisation is the time consuming step and thus was performed on a RISC station.

Fig. 2 presents a typical 3D-simulated spectrum (anthracene/perylene 1/1). The emission and excitation spectra are displayed on Fig. 3(a, b). The

Table 2
Quadratic errors for computed emission and excitation spectra vs. noise level for 3D simulated spectra (anthracene/perylene)

% Noise level	Quadratic errors on computed spectra	
	Emission	Excitation
0	0.00005	0.00003
1	0.00004	0.00003
2	0.00003	0.00005
5	0.00004	0.00003
10	0.00016	0.00012
20	0.00031	0.00022

Table 3
Quadratic errors for computed emission and excittion spectra vs. concentrations ratio for 3D simulated spectra (anthracene/perylene)

Concentrations ratio A/P	Quadratic errors on computed spectra			
	Emission		Excitation	
	P	A	P	A
1/1	0.00006	0.00002	0.00002	0.00004
1/2	0.00003	0.00003	0.00002	0.00004
1/3	0.00003	0.00007	0.00002	0.00009
1/4	0.00001	0.00043	0.00002	0.00007
1/5	0.00005	0.00055	0.00003	0.00018
1/10	0.00003	0.01150	0.00009	0.00095
1/20	0.00002	0.2650	0.00005	0.00218

accuracy of the prediction is very good although the 3D-spectrum was somewhat noisy. This result shows the great efficacity of the data compression step to extract components spectra from noise. Quadratic errors are of the same order of magnitude for emission and excitation (see Table 2).

Table 3 shows the influence of the relative concentration of the two emitting species, the results are quite good for relative abundances varying from 1/1 to 1/5. Of course, the results are better for the predominant species. But, the table shows also that the results are better for computed excitation spectra than for emission spectra. This result clearly demonstrates that the CLS computation steps are not the main errors source because excitation spectra are computed from emission spectra.

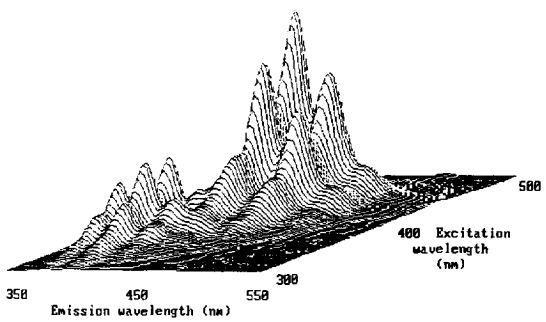

Fig. 4. Experimental 3D-spectrum (anthracene/perylene mixture).

Real experimental results are displayed on Fig. 4 and Fig. 5. The spectra are in very good agreement with those obtained with simulated data, except some inner filter problems, due to concentrations.

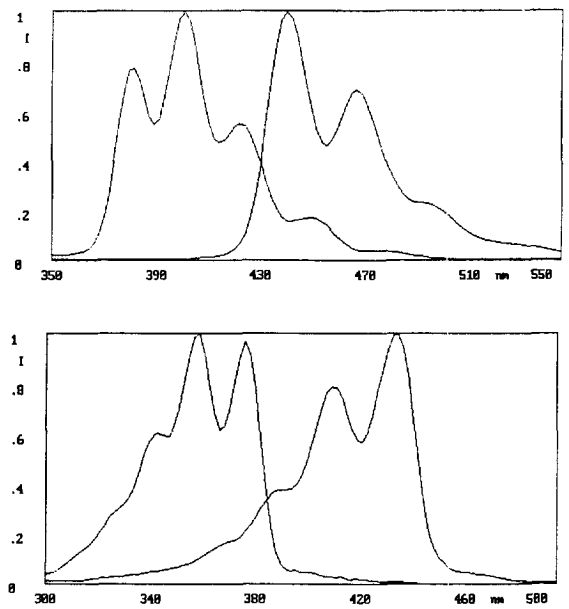

Fig. 5. Emission (a) and excitation (b) spectra computed from an experimental 3D-spectrum (anthracene/perylene mixture).

6. Conclusion

This work demonstrates that factor analysis can now be used to solve multicomponent problems in luminescence spectroscopy, without any assumptions on the pure components spectra.

If a set of mixtures are available, both the pure component spectra and the concentration matrix can be extract from the data by factor analysis.

If the only data is a 3D-spectrum of a unique mixture, the pure emission and excitation spectra are computed, but the concentrations cannot be estimate.

Application of an artificial neural network (ANN) and piezoelectric chemical sensor array for identification of volatile organic compounds[1]

György Barkó, József Hlavay *

Department of Earth and Environmental Science, University of Veszprém, P.O. Box. 158, 8201 Veszprém, Hungary

Received 24 July 1996; received in revised form 26 May 1997; accepted 27 May 1997

Abstract

A piezoelectric chemical sensor array was developed using four quartz crystals. Gas chromatographic stationary phases were used as sensing materials and the array was connected to an artificial neural network (ANN). The application of the ANN method proved to be particularly advantageous if the measured property (mass, concentration, etc.) should not be connected exactly to the signal of the transducers of the piezoelectric sensor. The optimum structure of neural network was determined by a trial and error method. Different structures were tried with several neurons in the hidden layer and the total error was calculated. The optimum values of primary weight factors, learning rate ($\eta = 0.15$), momentum term ($\mu = 0.9$), and the sigmoid parameter ($\beta = 1$) were determined. Finally, three hidden neurons and 900 training cycles were applied. After the teaching process the network was used for identification of taught analytes (acetone, benzene, chloroform, pentane). Mixtures of organic compounds were also analysed and the ANN method proved to be a reliable way of differentiating the sensing materials and identifying the volatile compounds. © 1997 Elsevier Science B.V.

1. Introduction

Chemical sensor systems and detector arrays are widely applied for determination of organic vapors, gases and odors in the atmosphere. A piezoelectric quartz crystal can be used as a chemical sensor that is able to measure the chemical concentration reversibly. There are two fundamental methods to develop a chemical sensor from quartz crystal; the crystal can be used for preparing either surface acoustic wave (SAW) or piezoelectric quartz microbalance (PQM) sensors. Due to Sauerbrey's fundamental equation (Eq. (1)), the change of frequency is proportional to the change of loaded mass [1].

$$\Delta F = -2.3 \times 10^6 \times F^2 \times \frac{\Delta M}{A} \quad (1)$$

* Corresponding author.

[1] Presented at the Symposium on Analytical Sciences (SAS) IV, Belgium, 3–5 June, 1996.

PII S0039-9140(97)00168-9

where ΔF is the change of frequency (Hz); F is the basic frequency of the quartz crystal (MHz); ΔM is the change of mass (g); A is area coated (cm^2).

From this simple mass balance a sensitive and selective chemical sensor can be developed by coating the surface with different organic and/or inorganic compounds as sensing materials. The fundamental experiments with the first PQM sensor were carried out by King [2]. The quartz crystal was coated by stationary phases used in gas chromatography and the trace amount of organic compounds could be determined. This simple sensor device was not able to differentiate and could not be used directly to measure the concentration of analytes, it showed a low selectivity on the organic compounds.

The requirements for a reliable piezoelectric chemical sensor are the sensitivity, selectivity and reversibility towards the analyte to be determined. However, to find an entirely selective material for only one analyte is almost unrealizable. On the other hand, application of the chemical sensor in the environmental analysis is hampered by the fact that several compounds are in the matrix and generally only one has to be detected. Mathematical algorithms have to be developed for the data processing, and chemometric methods are necessary to explain the behavior of non-selective chemical sensors. Principal component analysis (PCA), cluster analysis, pattern recognition (PARC) and artificial neural network (ANN) methods can be applied to perform the data evaluation. The artificial neural network approach based upon the biological neuron model is an up-to-date tool for extraction of the main information from the signals. Although, the human nervous system contains about 10^{10} biological neurons, the common back propagation algorithms are computed by only 10^1 to 10^4 artificial neurons [3,4]. The biological odor sensors—like the olfactory neurons—have excellent sensitivity (ppm or ppb, depending upon the analytes), but does not have any specificity.

In the food and drug industry, several metal-oxide semiconductors, piezoelectric, surface acoustic, amperometric, optical and thermal detectors were applied for identification and determination of the gases and odors. Smells of coffee, wine, beans, whisky, beer, meat, fish and perfumes were analysed using an 'artificial nose' [5]. Fraser et al. [6] made a sensor system for detection of ammonia and other inorganic air pollutants. A chemical sensor with five piezoelectric quartz crystals was developed by Klinkhachorn et al. [7] and inorganic compounds were measured in nanogram levels. Signal processing based upon the pattern recognition algorithm was applied for data handling. Schmautz [8] has built a piezoelectric sensor system for determination of anesthetic gas mixtures. Quartz crystals were coated by different sensitive layers and pattern recognition was used for investigation of the mixing ratio. Chang et al. [9] developed an odor recognition device using quartz crystals coated by lipids for measurements of odor components. A few common odors (i.e. fragrance of rose, wine) were investigated and different adsorption coefficients were found on the lipids. A computer program based upon the artificial neural network was developed. A sensor system with nine piezoelectric chemical detectors has been developed by Carey et al. [10] for determination mixtures of analytes using partial least-squares and multiple linear regression methods. As an industrial application, discrimination of liquor aromas was achieved by Aishima [11] using gas sensor array and chemometric methods. The complex aroma materials were discriminated and the beverages were classified. Principal component analysis and cluster analysis were successfully applied.

2. ANN based on the back propagation method

The back propagation method is part of the parallel distributed processing system [12]. One-layer networks like Hopfield and Kohonen structure, and multilayer systems like counter propagation and back propagation of errors, can be used for chemical applications. In these cases the processing unit is a so-called *neuron*. Two neurons are linked by a connection. Every connection has a weight factor (W), the input values $I_j(t)$ correcting by the weight factor are summarized (see Eq. (2)). The i and j neurons are connected by $W(i,j)$.

$$I_j(t) = \sum_i W_{i,j}(t) O_i(t) \quad (2)$$

First, the system has to be taught. The output values ($O(t)$) go through the connections between the neurons. The neuron unit (N) has an activity level (A) in every time step t. The output value (O) depends on the activity A of the neuron, this is an output function (see Eq. (3)).

$$O(t) = f(A(t)) \quad (3)$$

The status of the active neuron can be written with an activity function (F):

$$A(t) = F(A,I)(t) \quad (4)$$

During the learning process the weights are changed time by time with a ΔW value. The change of the weight among the t and $t+1$ time steps depends upon the difference between the measured and taught values. F is used to determine the activity level (A) of a neuron. The activity level may be a discrete or continuous value. For example, if the input of the neuron is smaller than the threshold limit, $A = 0$. If the input is higher than the threshold, the activity may even be a value between 0 and 1, or equal to 1. Below the threshold value the neuron has no output, while above the threshold limit the neuron has an answer proportional to the activity. The strength of the effect of a neuron on the other neuron depends on the weight of the connections between the two neurons. The higher weights cause a higher effect of input data on the receiver neuron. If $W < 0$, the effect is similar to the inhibition, if $W = 0$, the connection has no role in the network.

In multilayered neural networks, the neurons are arranged in layers. During the teaching process, the strengths of the connections are changed. In most cases Hebb's law of selection is used for computing the modification of the weight factors. The rule can simply be written (Eq. (5)), where $O(t)$ is the output signal of the i-th neuron (see Eq. (3)) and η is the learning rate. Generally, the higher the learning rate the faster the adaptation of the model.

$$\Delta W_{i,j}(t) = \eta \cdot A_j(t) \cdot O_i(t) \quad (5)$$

Other form is the delta-rule or generalized perception rule, where $T(t)$ is the teaching level of the neuron:

$$\Delta W_{i,j}(t) = \eta \cdot (T_j(t) - A_j(t)) \cdot O_i(t) \quad (6)$$

The detailed processes can be applied in different computational methods, not only in chemical data handling. Before the artificial neural networks had been developed, the simple pattern recognition method was utilized. It can be used for classification of species by generating patterns, if the groups of the analytes have characteristic features. The neural network with back propagation of error method is an advanced development for data processing. The delta rule (Eq. (6)) can be composed as a square error function to determine the accurate error of the determination ($E^{(p)}$). During the teaching, the aim of the computing is to minimize the difference between the O_j^p output values and T_j^p taught values.

$$E^{(p)} = \tfrac{1}{2} \sum_j (T_j^{(p)} - O_j^{(p)})^2 \quad (7)$$

The rule says if there are two active neurons and the first unit sends data to the second one, the connection will be more powerful, proportional to the activity of the processing neurons [13].

In this work the identification of volatile organic compounds (i.e. acetone, benzene, chloroform, pentane) is carried out by a non-selective and differently sensitive piezoelectric gas sensor array using the ANN method.

3. Experimental

3.1. The sensor system

Four AT-cut quartz crystals with 9 MHz fundamental frequencies were used (Gamma Co., Hungary). The crystals were arranged in an array and coated by gas chromatographic stationary phases like OV1 (poly-dimethyl siloxane, Supelco), OV275 (poly-cyanoakryl organosilane, Supelco), ASI50 (poly-methyl-phenyl siloxane, Applied Science Laboratories Inc.), and polyphenyl-ether (Carlo Erba), respectively. The appropriate stationary phases were found using

experimental and theoretical means based upon a principal component analysis [14]. The thin film of the coating was formed by solvent evaporation. The coated surface was 0.2 cm^2 and the frequency of the quartz crystals decreased usually by about 8 kHz. Nitrogen (T 45, Messer Griesheim, Hungary) was used as carrier gas and 20 l h^{-1} mass flow was maintained by a GFM17 $3\frac{1}{2}$ digit flow controller (AALBORG). The nitrogen contained 30 ppm water vapor and it was dried by a CRS 202268 packed GC column (Chromatography Research Supplies, USA) to remove the traces of water. The analyte was injected by a syringe. A NAFION drying unit (DM-060-24, Perma Pure Inc., USA) was set into the carrier line for declining the interference of the trace amount of moisture. A data handling card was built and a computer program was developed to measure the frequency changes. The computer program compared the measured frequency to that of the clock of the computer. The detailed set-up of the system was published in Ref.[15].

3.2. The connection of the neural network to the sensor array

The ANN model based on the back propagation of error method can be used to handle the frequency signals of the piezoelectric quartz crystal sensors. All neurons are active in any time, so the activity function has not been applied. There are no threshold limits for the neurons. During the teaching period only the weights of the connections are changed. The second (hidden) and the third (output) layers are linked by connections to the layer above the current one. The layers are fully connected, since every neuron in the current layer is connected to all neurons in the previous layer.

The detector array has four crystals and there are three layers in the neural network. The first (input) layer consists of four neurons, equal to the number of chemical sensors (Fig. 1). This first layer is used only to share the information. The input data are the four lowest output frequencies (X_{pm}) of the four detectors measured during one teaching experiment. The ratio of the measured frequencies was characteristic, and can be used to discriminate the analytes. The effect of the unstable concentration of the compounds was investigated, and frequency signal normalization was applied (see details in Ref. [15]). The same frequency ratio was found in the 100–700 vppm range. Only a limited effect was observed on the repeatability of the analyte's pattern in the mentioned concentration range [15]. However, the teaching experiments were carried out at 600 vppm in all cases because qualitative measurements were performed. Quantitative determination could also be established by ANN [16], but it was not the aim of the current development.

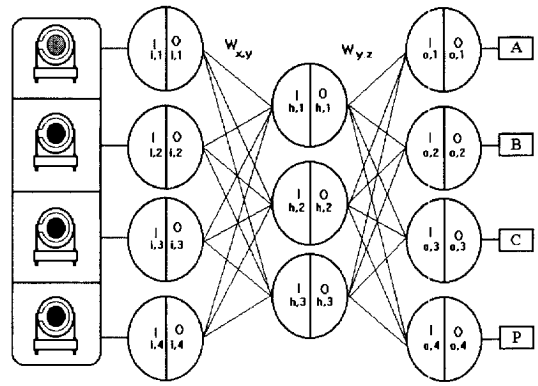

Fig. 1. The sensor system and the artificial neural network.

When an experiment was performed, the four frequency values were read by the computer program and were used as input $I(1)$–$I(4)$ (see Table 1 and Fig. 1). The amount of the analytes was

Table 1
The frequency values in the first 10 training sets of acetone (Hz)

Training set	$I(1)$	$I(2)$	$I(3)$	$I(4)$
1	−250	−110	−260	−390
2	−252	−112	−262	−392
3	−250	−110	−260	−392
4	−253	−110	−260	−391
5	−252	−111	−262	−390
6	−252	−113	−263	−390
7	−250	−110	−261	−391
8	−252	−111	−260	−392
9	−250	−113	−263	−390
10	−250	−110	−260	−393

generated by a vapor generator device and the reproducibility of the generation was determined. The generator performance was validated by gas chromatography [17]. The number of the teaching experiments—and the data sets as well—is p. Every data set consists of four frequency values, extracted from the curves of the measured analytes. One training set is formed by the lowest frequencies of the curves of benzene, acetone, pentane and chloroform. The signals which correspond to the four analytes will be arranged in four columns. To perform the $I(1)$–$I(4)$ input data from the measured signals, X_{pm} training set values are extracted as X_{p1} is the lowest frequency value which has been measured on the quartz crystal coated by OV1, X_{p2} is that coated by ASI50, X_{p3} is that coated by OV275, and finally, X_{p4} is that coated by polyphenyl-ether, respectively, in the p-th sample set. The input layer has four neurons ($m = 4$) with a simple identical output function:

$$O_{i,x}(t) \equiv X_{i,x}(t) \tag{8}$$

The qualitative information can be transformed into real numbers. The simplest way is to use a teaching value 0 for the output neurons where the current analyte answers are not expected, and 1 where the analyte is predicted. In our experiments, 0.9 as a target value of the analyte and 0.1 as a target value of the unexpected answer were used for computing of the back propagation of error algorithm. The taught values are added to the output layer during the teaching process. T_{pn} is the taught sample set and it consists of four values between of 0.05 and 0.95. These values are fed on the output neurons during the teaching process in every time step t. The output layer has four neurons ($n = 4$) connected to the four taught analytes. T_{p1} is the value between 0.8 and 0.95 on the first neuron in the output layer of the p-th sample set. If in our experiment the taught compound is benzene, T_{p2}, T_{p3} and T_{p4} are in the range of 0.05 and 0.2. In Fig. 1 the benzene is assigned to the answer box B. If T_{p2} is between 0.8 and 0.95 on the second neuron in the output layer, the taught compound is acetone, and T_{p1}, T_{p3}, T_{p4} are in the range of 0.05 and 0.2 (Fig. 1, A). T_{p3} is the value between 0.8 and 0.95 on the third neuron in the output layer and this refers to the chloroform. T_{p1}, T_{p2} and T_{p4} are also in the range of 0.05 and 0.2 (Fig. 1, C). If T_{p4} is between 0.8 and 0.95 on the fourth neuron in the output layer, the taught compound is pentane (Fig. 1, P), and T_{p1}, T_{p2}, T_{p3} are in the range of 0.05 and 0.2.

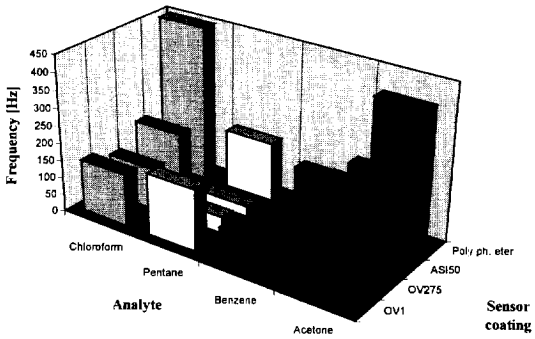

Fig. 2. The frequencies of the chemical sensors for pure analytes.

There are two phases of the application of the ANN. First, the system has to be taught. This means that the compounds are directly introduced into the sensor-array and the output values of the network are calculated. The analytical information is transformed to mathematical values. The four most characteristic frequency values of the four sensing compounds are transferred into the input layer. The frequencies measured on the four sensors are used as the input neurons (Fig. 2). The 600 ppm of organic compounds injected was always kept constant to avoid disturbance of the different concentrations. For example, using acetone as an analyte, signals of the sensor were measured, the output values of the neurons were calculated, and sent to the next layer via connections. Depending upon the weight factors of the connections, the values had more or less effect on the neurons in the layer above the current one.

The frequency values are given to the input layer (Eq. (8)). The output values are computed from layer to layer; first in the input layer, then in the hidden one, and at last in the output layer (Fig. 1). Depending on the weight of connections, the input of the hidden neurons (Eq. (9)), the output of the hidden neurons (Eq. (10)), the input of the output neurons (Eq. (11)) and the output of the output neurons (Eq. (12)) can be calculated:

$$I_{h,y}(t) = \sum_{x=1}^{4} W_{x,y}(t) \cdot O_{i,x}(t) \quad y = 1..3 \tag{9}$$

$$O_{h,y}(t) = \frac{1}{1 + e^{-\beta \cdot I_{h,y}(t)}} \quad y = 1..3 \tag{10}$$

$$I_{o,z}(t) = \sum_{y=1}^{3} W_{y,z}(t) \cdot O_{h,y}(t) \quad z = 1..4 \tag{11}$$

$$O_{o,z}(t) = \frac{1}{1 + e^{-\beta \cdot I_{o,z}(t)}} \quad z = 1..4, k = 0.6 \tag{12}$$

After computing, four output values are available for the correction of the weight factors of the neural network. The difference between the calculated and taught data set is decreased using the delta rule. The teaching process means that the weights of the connections are changed according to the difference between the calculated output of the network (O) and the taught values (T). First, the weights between the output and hidden layers, then that of between the hidden and input layers are calculated (Eq. (13)).

$$W_{y,z}(t+1) = W_{y,z}(t) + \delta_p \cdot \eta \cdot O_{o,z}(t) \tag{13}$$

The proper learning rate, h can be determined by a trial and error method. The error pointer of the p-th training data set $\delta_{p,z}$ is calculated by different way in the two weight matrices. One training set ($T_{p,z}$) is used to determine the δ error pointer between the output and hidden layer (Eq. (14)).

$$\delta_{p,z} = n \cdot O_{o,z}(t) \cdot [1 - O_{o,z}(t)] \cdot [T_{p,z} - O_{o,z}(t)] \tag{14}$$

where n is the number of the neurons in the output layer ($n = 4$).

The error pointer of these weight factors (Eq. (14)) is used to compute the error between the hidden and input layers (Eq. (15)).

$$\delta_{p,y} = n \cdot O_{h,y}(t) \cdot [1 - O_{h,y}(t)] \cdot \sum_{n=1}^{4} \delta_{p,z} \cdot W_{y,z}(t+1) \tag{15}$$

A new training experiment should be performed after computing the weight changes until the error pointer (Eq. (7)) has been decreased to an appropriate level. Considering this theory, new weights were first computed between the last and the middle layers, and then between the middle and the first layers. During the calculation the error was calculated back to the network layer by layer. Experiments should be carried out until the proper learning level has been reached, and the error of recognition would be the lowest value.

4. Results and discussion

Since the number of the input neurons was equal to the number of sensors, and the number of the output neurons was equal to the number of the analytes (Fig. 1), the estimation of the optimum number of hidden neurons was necessary. The optimum structure of the neural network can be determined by a trial and error method. Four different structures were tried with 3, 4, 6, and 8 neurons in the hidden layer. The error ($E_{(p)}$) was calculated and primary parameters of η, μ and β, respectively, suggested by Zupan and Gasteiger [18] were used. It was found that, with increasing number of the neurons in the middle layer, the error of the estimation did not decrease considerably. Instead of further declining the error, calculation of the best computing parameters (η, μ and β) proved to be a better technique to reach the optimal computing performance.

Depending upon the proper primary weight values, the speed of adaptation during the teaching process can be increased. However, local interruption of the computing might also be caused by unsuitable primary weight factors and an inappreciable answer for the network can be achieved after the teaching process. The optimum primary weight factors can be determined by experiments. First, the weight matrices were filled with randomly generated values between -1 and $+1$. The minimum of the total error could be calculated by the algorithm, hence, the trapping of the calculation in a local minimum has to be avoided. The speed of the convergence depends not only upon the structure but the number of the iteration, as well.

The speed of the changing of weight was determined by the learning rate (η). This factor was applied to control the effect of the new weight factor. However, the momentum term (μ) was utilized to determine the interference of the previous weight factor on the new weight value. Theoretically, the error will be decreased during the

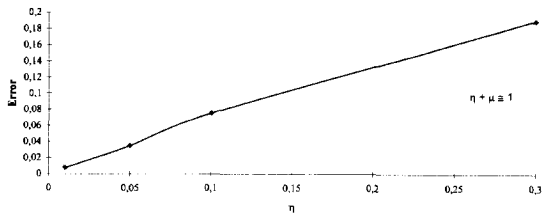

Fig. 3. The effect of learning rate on the total error.

analysis. Naturally, sometimes disturbances of the algorithm could be accomplished and oscillation of the error could occur. The sum of the learning rate and the momentum term was generally 1 [18]. The neural network with 3 hidden neurons was applied, and the optimum η and μ values were searched (Fig. 3). The higher the learning rate, the shorter the time of teaching. However, irrelevantly high η and μ values make the computing almost impossible. The optimum learning rate ($\eta = 0.15$) and the momentum term ($\mu = 0.9$) were successfully determined by experiments. Not only the optimum values of primary weight factors, learning rate, and momentum term, but the sigmoid parameter (β) could also be determined by experiments. It was found that using $\beta = 1$ the total error of the calculation was at a minimum. The value $\beta = 1$ was also suggested from other findings [12,13,18].

To avoid overtraining of the network, the optimum number of teaching experiments has to be estimated using the back propagation method [13,18]. Several teaching experiments were performed, and a decrease of error was expected. The effect of overtraining was observed after about 1000 iteration steps (Fig. 4), while the error slowly increased. Masters [19] suggested that using too

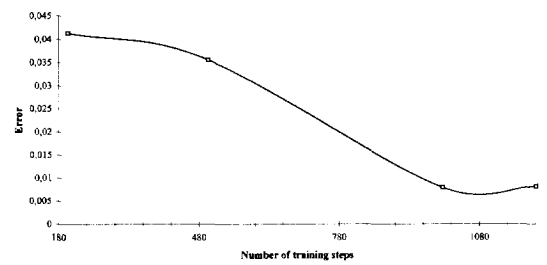

Fig. 4. The effect of overtraining on the total error.

many hidden neurons, the overfitting effect could easily be observed. So, a new network structure was tried. With increasing number of the neurons in the hidden layer, the error will not decrease to any measure and the possibility of overfitting will also be higher. Finally, in our experiments, 3 hidden neurons and 900 training cycles were applied.

4.1. Identification of pure analytes and mixtures

After the teaching process had been completed, the ANN has been able to give a response on the output layer for the taught analytes. Of course, the analytes, that had not been taught yet, could also be investigated, but all of the output neurons gave almost the same value. Only the previously investigated and taught analytes were determined by the ANN successfully. The unknown analyte has not been classified by the network, since the discrimination can be carried out by the existing training set. For example, if a taught analyte was injected—depending upon the compound—only one output neuron gave a value of 0.9, and all of the other output neurons produced a value of 0.1. If an unknown analyte was injected, every neuron in the output layer showed a value between 0.20 and 0.24.

The performance of the identification can be characterized by the number of hits of the taught analyte. For example, with the trained network, 100 analyses were performed. The analyte was correctly found in 99 cases, but in one case a wrong analyte was assigned to the output neuron. Thus, the error of the estimation proved to be 1%. The error calculated by Eq. (7) is often used to estimate the quality of the identification. After 900 teaching steps, it was found that the four investigated compounds could be identified. The differences between the taught and calculated values are summarized in Table 2. As can be seen, the identification has been completed for all analytes investigated. The unknown analyte was also injected and an output value of 0.2333 was obtained.

Three kinds of two-component mixtures with a 1:1 mixing ratio in 150 ppm was also taught (Fig. 5). The aim of this research was to discriminate

Table 2
The predicted values (O_j) for the pure compounds after 900 training steps

	Output				Error (see Eq. (3))
	Neuron 1	Neuron 2	Neuron 3	Neuron 4	
Benzene	0.8967	0.1188	0.1189	0.1214	0.0006
Pentane	0.1214	0.8970	0.1188	0.1188	0.0006
Acetone	0.1188	0.1214	0.8967	0.1190	0.0006
Chloroform	0.1189	0.1188	0.1214	0.8968	0.0006
Taught value of the target neuron (T_j)	0.9000	0.9000	0.9000	0.9000	
Absolute error ($T_j - O_j$)	0.0033	0.0030	0.0033	0.0032	

the mixtures from each other, and the selection of the components in one mixture has not been performed yet. On the other hand, the piezoelectric sensor coated by sensing materials as gas chromatographic stationary phases is not an additive sensor in the applied concentration range. For classification of the compounds in mixtures the system should be retrained. This simple model has been applied to test the sensor-array and to try the classification ability of the ANN. In the food industry, several examples could be found for discrimination of similar alcoholic beverages (e.g. Ref. [11]).

In this examination, different analytes were selected to perform a set of experiments with the mixtures. Considerable differences in frequency values of the sensing compounds were observed. The ANN was used for data evaluation similar to the identification of the pure analytes. All mixtures were successfully differentiated. The error of the identification was slightly higher than that of pure compounds (Fig. 6). Further experiments are needed for the investigation of the effect of different concentration ranges and mixture ratios on the pattern.

The performance of the developed method was compared to the previously used PARC without ANN [15] and PCA [14] methods, and the accomplishment of other similar systems described in the literature [20–23]. The former PARC method could be used for classification of compounds using the stored patterns of the analytes with 80% probability. The new ANN technique was successfully applied for identification of organic compounds with higher efficiency. The error of the identification was insignificant (Table 2), and after 15 determinations had been made no error was observed. These findings are similar to the results described in Ref. [20], and even superior to the recognition probability in Refs. [21,22]. Ema et al. [22] reported that the recognition probability was found to be 67–73% depending upon the structure and the training of the network. The results

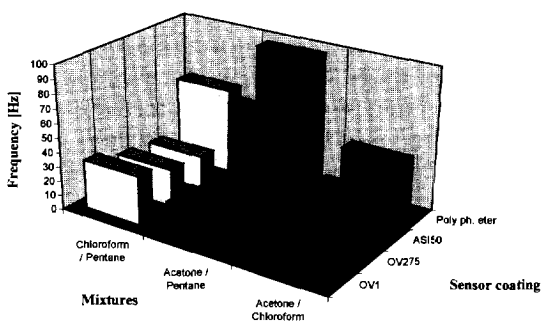

Fig. 5. The frequencies of sensors for different mixtures of volatile organic compounds.

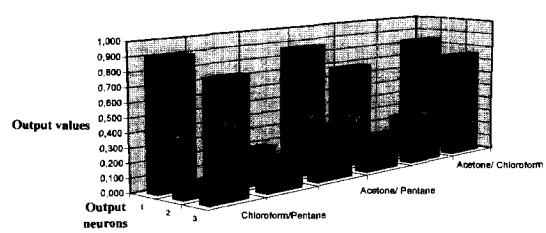

Fig. 6. Identification of the mixtures using the values of output neurons.

were compared to discrimination analysis (DA). The comparison has shown the advantages of the ANN: the recognition probability was 67% (ANN with 6 hidden neurons), 73% (ANN with 8 hidden neurons), and 64% (DA). Chang et al. [21] reported a 70% probability only. The application of the improved sensor arrays and software tools proved to be better than the earlier systems. After 5000 training steps, 14 entirely successful analyses were made by Nanto et al. [20]. Comparison of the developed ANN and pattern recognition methods using supervised (i.e. principal component analysis, discrimination analysis, template matching/partial least-squares, back propagation/artificial neural network, learning vector quantization) and unsupervised (i.e. Euclidean and other cluster analysis, Kohonen network) can be found in Ref. [23].

5. Conclusions

The application of the ANN method proved to be remarkably advantageous if the measured property (mass, concentration, etc.) should not be connected exactly to the signal of the transducers of a chemical sensor. The frequency values of the compounds were taught by a computer program. The optimum structure of neural network was determined by a trial and error method. Four different structures were tried with several neurons in the hidden layer, and the total error was calculated. It was found that the calculation of the best computing parameters (η, μ and β) proved to be an appropriate technique to reach the optimal computing performance. The optimum values of primary weight factors, learning rate ($\eta = 0.15$), momentum term ($\mu = 0.9$), and the sigmoid parameter ($\beta = 1$) were determined by experiment. Three hidden neurons and 900 training cycles were applied. Mixtures of organic compounds were also analysed and the ANN method proved to be a reliable way to differentiate the sensing materials and to identify the volatile compounds.

Editorial

It was a pleasure for the Editors of Talanta to arrange this special issue, proposed by Professor Vasile Cosofret, honoring Professor George Baiulescu on the occasion of his 65th birthday. The great diversity of the research fields presented in this issue actually reflects the broad activity of Professor Baiulescu covered during his career in Analytical Chemistry. Professor Baiulescu has significantly contributed in separation sciences, spectroscopy and electrochemistry by the quality of his publications. We are particularly thankful to Professor V. Cosofret for having solicited numerous experts and friends of Professor Baiulescu for contributing to this issue.
