Review

Microcells for voltammetry and stripping voltammetry

Ya. I. Tur'yan

National Physical Laboratory of Israel, Danciger "A" Bldg., The Hebrew University, Givat Ram, Jerusalem 91904, Israel

Received 12 February 1996; revised 19 June 1996; accepted 24 June 1996

Abstract

The designs and applications of "non-flow" microcells in voltammetry and stripping voltammetry for samples with volumes from sub-microliters to 5 ml are reviewed. The analysis of microcell designs was carried out on the basis of their classification: (i) microcells with a static sample, including thin-layer microcells with a static sample; (ii) microcells with forced convection of the sample; and (iii) microcells for batch injection of samples. Two working electrode types (the usual state and inverted state) are discussed. The use of working micro- and mercury-film electrodes and of the accelerated removal of dissolved oxygen are also considered in detail.

Keywords: Microcells; Review; Sample batch injection; Stripping voltammetry; Voltammetry.

1. Introduction

Electrochemical methods of anlysis, including voltammetry and stripping voltammetry, are widely used [1–3] in microanalysis with small volumes of samples. Voltammetry and stripping voltammetry can be used for the analysis of small volumes of samples after their preconcentraion by different methods [4], for the automation of anlaysis [5–10] and for the anlaysis of the limited volume materials in biology, medicine and the environment, such as biological fluids [11,12], brain slices [13], products of enzymatic reactions [9], catecholamines [14] and human cerebrospinal fluid [15].

The possibilities of voltammetric and stripping voltammetric microanalysis essentially depend on the design of the microcell where the measuring process takes place. We define the "microcell" as the complex of following elements: the working, auxillary and reference electrodes, the electrode compartments and electrolytic diaphragms and the devices for sample inlet and outlet, for removal of dissolved oxygen and for sample forced convection.

The term "micro" is not related to the cell size but to the sample volume, which we conditionally accepted up to 5 ml: 0.5–5 ml [16–23], 20–300 μl [5–13,24–27] and $\leqslant$10 μl [10,14,15,25,28–53].

There are flow-through and "non-flow" microcells. In flow-through microcells, sample is introduced in to the cell with a continuously moving carrier solution and leaves the cell together with it. In "non-flow" microcells, sample is introduced to the cell directly and discretely with a pipette or some mechanical closer. After analysis it is re-

PII S0039-9140(96)02040-1

moved from the cell or from the measuring zone with the same device or by the rotation of the mixer or working electrode or by displacement by the next sample of the electrolyte.

Flow-through microcells are intended mainly for detection in liquid chromatography and flow injection analysis. These cells have been considered in detail in reviews by Kissinger [54], Gunasingham and Fleet [55], Berisci et al. [1] and for stripping voltammetry by Lunque de Castro and Izquierdo [56]. Therefore, the novel aspects of this review are the analysis of designs and application of "non-flow" microcells in which a sample is introduced directly and discretely with a pipette. These microcells are widely used in voltammetry and stripping volammetry. Some microcells that were developed for other electrochemical methods of analysis are also included in this review since they are suitable in principle for the voltammetry and stripping voltammetry.

Designs of "non-flow" microcells can be classfied depending on the sample state in the cell:

(i) microcells with a static (motionless) sample;

(ii) microcells with forced convection of the sample;

(iii) microcells for bath injection of samples. These cells are designed for the analysis of groups of samples during a relatively short time. In such a microcell a sample during analysis can be in either the static state or in the forced-convection state. Therefore, such a cell can be classified as (iii) and (i) or (ii) types simultaneously.

2. Designs of microcells and their applications

2.1. Types of electrodes

We consider here only working electrodes and among them such important kinds as micro-, mercury-film and modified electrodes. Others electrodes will be considered in the analysis of cell design.

2.1.1. Working microelectrodes

Wightman and co-workers [57–59] pioneering work was the basis for the use of working micro- and submicroelectrodes in microcells [45–53]. The surface area of these microelectrodes is ~ 0.1 mm^2 but often it is 10^{-4}–10^{-3} mm^2. Microelectrodes have been fabricated from carbon paste [35, 60], carbon fiber of diameter 8–10 μm [45–47, 52], cylindrical graphite fiber of diameter 8 μm [50], Pt wire of diameter 10 μm [47], Au film of surface area 0.12–5.7 mm^2 [48], Pt film of surface area 4×10^{-3} mm^2 [53] and 0.1 mm^2 [49] and Cu, Ag and Pt wire of diameter of 25 μm [51]. Working solid microelectrodes can be plated with a mercury film (see below).

Advantages of the working microelectrodes are following [45–53]: (1) possiblility of the use of the extremely small sample volumes, down to the sub-microliter level; (2) decrease in the current capacity and the possibility of potential rapid scanning; (3) rapid reaching of the steady-state current; (4) high current density compared with that of the usual rotating disk electrode, which together with the better reproducibility and the simpler design of the microcell, allow the same or a shorter preconcentration time to be achieved in stripping voltammetric analysis as with a rotating disk electrode; (5) insignficant iR distortion allows the use of non-aqueous solvents and low concentrations of the supporting electrolyte, and as a consequence the effect of contamination is decreased, which is of particular importance in the stripping voltammetry; and (6) there is a possibility of combining the functions of auxiliary and reference electrodes in one electrode and electrolytic diaphragms can be excluded.

The drawback of working microelectrodes is the necessity to amplify a very small current. Therefore, the ratio of the analytical signal to noise is decreased and the detection limit is increased correspondingly. In order to decrease or to eliminate this drawback completely, the application of a microelectrode array is reasonable. The microelectrode array increases the analytical signal proportionally to the number of microelectrodes (with a sufficient distance between them). Although we do not know of the use of such kinds of microelectrodes in microcells, the recent development [61] of an iridium-based ultramicroelectrode array (without or plated with mercury) by microlithography is very promising for microcells.

2.1.2. *Working mercury-film electrodes*

There are two directions in the development of these electrodes: (1) the development of mercury-film electrodes for voltammetry that are ecologically sounder than the classical dropping mercury electrode (DME), while the advantages of the DME such as a high hydrogen overpotential and excellent reproductibilty have been retained and (2) the development of mercury-film electrodes for stripping voltammetry.

Mercury films that have been used in voltammetry (first direction) have a greater thickness. It has been shown that only in mercury films with thickness $\geqslant 10-25\ \mu m$ do the electrochemical properties of the film correspond to those of metallic mercury [62,63]. A mercury-film has been electrochemicaly plated and dissolved on a Pt microelectrode in the automatic regime imitating the DME [63].

In stripping voltammerty (second direction), very thin mercury films with a thickness of $\leqslant 1\ \mu m$ have been used. The films for stripping voltammetry are obtained either by preliminary electrochemical plating or in situ [64]. In stripping voltammetry on mercury-film electrodes including microcells [8,28,30,36,37,43,47,51], a lower detection limit and better reproducibility are achieved. In microcells, mercury-film working macroelectrodes have been prepared by the electrochemical plating of mercury on glassy carbon [8,28,30,43] and impregnated graphite [26,27,36,37] and for microelectrodes on carbon fiber [47], Cu, Au and Pt [51].

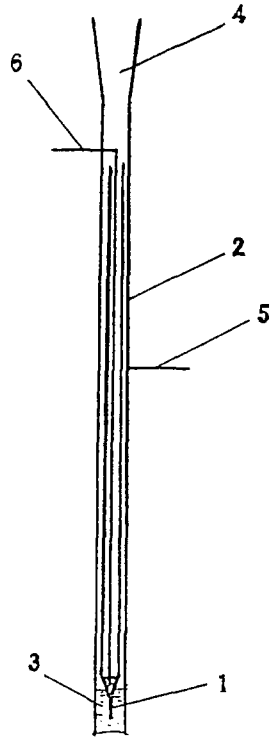

Fig. 1. Capillary microcell.

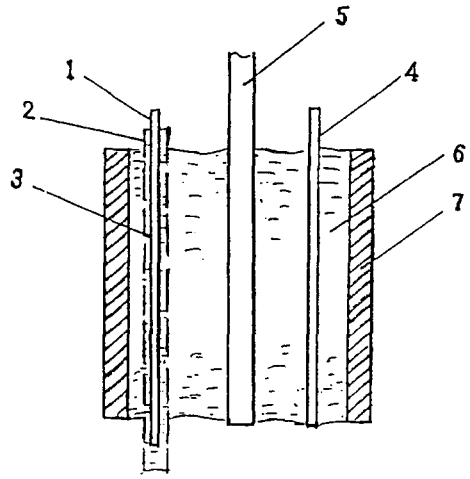

Fig. 2. Microcell with Nafion membrane.

Methods of preparation of mercury films have been considered in detail in many publications [2, 3, 65], so here newer work in this field is considered. The problem of the mercury-film regeneration to obtain a film in situ has been considered in connection with the formation of Hg_2Cl_2 [66]. To resolve this problem, the use of a supporting electrolyte containing a high concentration of NaSCN has been proposed [67]. The other technique for improving the regeneration of a mercury film in situ was developed by Lovrić and co-workers [68,69]. They first used a mercury film in situ, then the analysis was continued in situ but in a solution with an Hg^{2+} concentration ~ 100 times smaller. Frenzel [70] has shown that better adhesion of the mercury film takes place on the rough surface of a carbon electrode. Brainina et al. [71] proposed to add to the supporting electrolyte Zn^{2+} ions, which form adatoms on the electrode surface that improve the adhesion of the mercury film on the carbon

electrode. Ping Wu [72] showed that rapid scanning of the potential at the anodic stripping stage worsens the mercury-film structure.

2.1.3. Working modified electrodes

Modification of the working electrode surface can accelerate the electrode process and make it more selective. Application of physical, physicochemical and chemical activation of the working electrode surface has often been used in macrocells [73,74]. For microcells only a few examples of modification of the working electrode, by enzyme glutamate dehydrogenase [9], 7,7,8,8-tetracyanoquiodimethane [33], poly(vinylferrocene) [49,52] and poly(vinylpyridine) [52], are known.

2.2. Removal of dissolved oxygen

This aspect concerns all microcell types ((i–iii); see Introduction). In many cases, especially when using voltammetry with mercury and mercury-film working electrodes, the dissolved oxygen inferferes with the analysis. To accelerate the removal of the dissovled oxygen in voltammetry, Yarnitzky [75] sprayed the sample into the nitrogen compartment. In another study [22] a thin sample film was poured down the wall of a capillary tube in which nitrogen flows at the center. Baranski and co-workers [45,51] proposed to put the microcell in a special chamber through which an inert gas, saturated by the vapor of the corresponding solvent, passes. The time of the oxygen removal is ~5 min.

In anodic stripping voltammetry, the problem connected with dissolved oxygen is simplified since the dissolved oxygen does not influence the stage of metal preconcentration although it influences the anodic stripping stage [76,77]. For exclusion of this influence, an increase in the scanning rate during the anodic stripping stage was proposed by Wojciechowscki and Balcerzak [77]. The expedience of this approach is confirmed by the results of stripping voltammetric analysis in microcells [8,36,37,47,50]. At the same time, for greater accuracy, Baranski [47] took into account the background current in the presence of oxygen.

2.3. Microcells with static sample

The advantages of the use of a static sample are the possibility of decreasing the sample volume and applying a relatively simple design of microcell. The higher limit of detection [78] in comparision with that reached with microcells with forced convection of the sample [36,37] is a drawback to the static sample approach.

Two different working electrodes (in the usual and inverted states) are used in these cells.

2.3.1. Working electrode in the usual state

The working electrode in the usual state, that is, set from top to bottom, has been used in a number of microcells, e.g. Fig. 1 [50]. As the working electrodes, hanging mercury drop [16,17,22,31] and solid macro [15,18,19,30,44] and micro [35,50,60] electrodes have been applied.

The microcell [50] (Fig. 1) is sufficiently simple and is based on a two-electrode system. In Fig. 1, (1) is the cylindrical graphite fiber working microelectrode, (2) is the reference/auxiliary stainless-steel needle, (3) is the sample, (4) is the hole

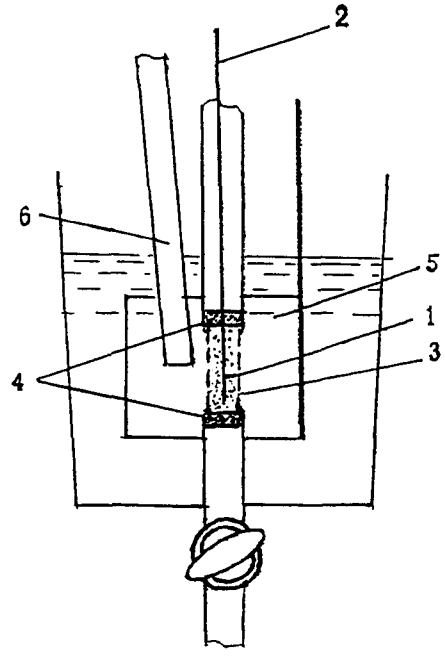

Fig. 3. Microcell with the packed graphite working electrode.

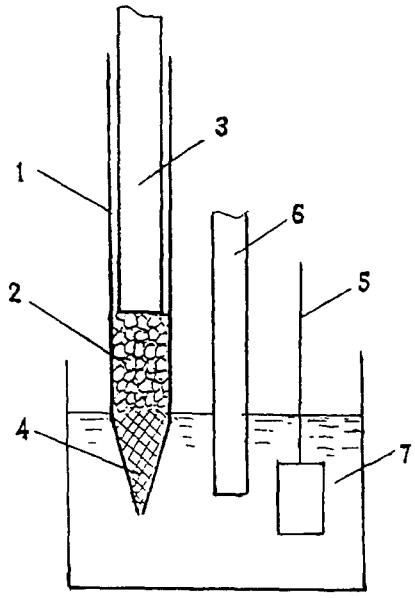

Fig. 4. Microcell with capillary packed-bed working electrode.

for the micropipette for aspirating/dislodging a sample, (5) is the reference/auxiliary electrode contact and (6) is the working electrode contact. In the case of the anodic stripping voltammetry, it has been recommended [50] to preplate the reference/auxiliary stainless-steel needle (2), with mercury. A two-electrode system of the catheter type has also been used in a microcell [60] but the electrodes were immersed in a supporting electrolyte in the outer compartment and this caused the undesirable dilution of a sample.

The possibility of using a very small sample volume ($\leqslant 1$ μl) in a microcell [44] (Fig. 2) has been

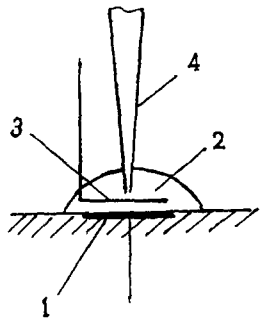

Fig. 5. Microcell with inverted working electrode.

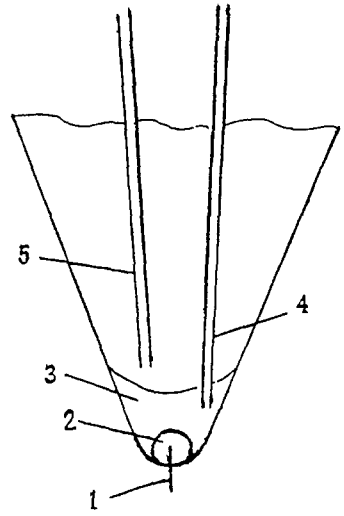

Fig. 6. Microcell with working mercury-drop electrode.

reported with the working microelectrode placed in a Nafion membrane tube. In Fig. 2 (1) is the working microelectrode (Au wire), (2) is the Nafion membrane tube, (3) is the sample, (4) is the auxiliary electrode (Au wire), (5) is the reference electrode, (6) is the supporting electrolyte and (7) is a Teflon tube. Sample (4) and supporting electrolyte (6) enter the microcell by the capillary action. Since cations diffuse through the Nafion membrane, only anions can be determined in the sample.

Microcells with the working solid electrode in the form of a packed bed [15, 18, 19] have been developed. In the cell (Fig. 3) [19], (1) is the packed-bed electrode in the form of powdered graphite, (2) is pencil lead for contact, (3) is a Vycor porous glass tube, (4) are cotton plugs, (5) is the platinum auxiliary electrode and (6) is the reference electrode. The sample and solvent for washing of

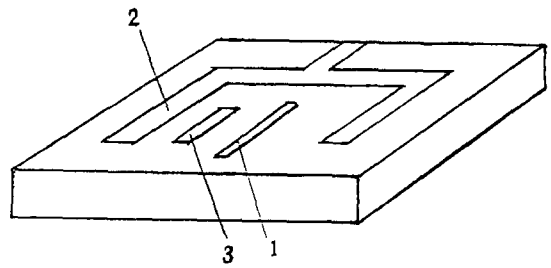

Fig. 7. Microcell with inverted microlithographicallly fabricated microelectrodes.

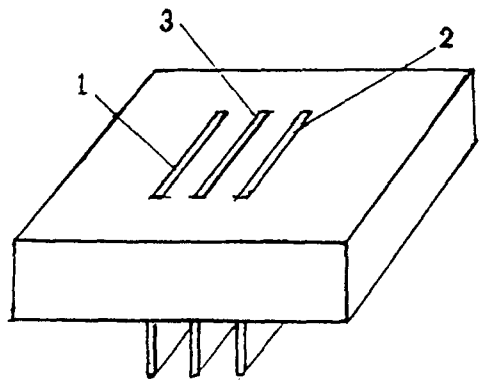

Fig. 8. Microcell with inverted metal foil microelectrodes in a multi-decker sandwich heat-sealing film.

tube (3) are removed by an aspirator. It is more efficient to use a microcell [15] with a packed-bed working electrode also but having a simpler design (Fig. 4). In Fig. 4, (1) is a glass capillary tube for the sample (10–40 μl), (2) is granular glassy carbon, (3) is pencil lead for contact, (4) is glass wool, (5) is the platinum auxiliary electrode, (6) is the reference electrode and (7) is the supporting electrolyte. The filling of the microcell with a sample was carried out by immersion of the tip in a sample solution. For emptying, the tip is touched to a tissue.

2.3.2. Working electrode in inverted state

This kind of solid working electrode, which is set from bottom to top, is illustrated in Fig. 5 [24]. The analogous state of the mercury working electrode is shown in Fig. 6 [42]. Working electrodes in the inverted state have been used in microcells more often than working electrodes in the usual state because of the possibility of applying a sample of smaller volume. Both macro [12,13,24,29,34,43] and micro [45–49,51,53] working electrodes in the inverted state have been used in microcells.

The first development of the working electrode in the inverted state by Iwamoto et al. [24] was based on the use of a Pt plate (Fig. 5). On the surface of the Pt plate (1), the sample drop (50 μl) (2) is placed. The Pt wire auxiliary electrode is in the form of a ring (3) and the tip (4) of the electrolytic bridge of the reference electrode is immersed in the sample drop. In the microcell (Fig. 5), a capillary with mercury as the working electrode that is directed upwards has also been used [24].

The cone form of the microcell with the mercury drop working electrode on the bottom of the cell is shown in Fig. 6 [42]. In Fig. 6, (1) is the Pt contact, (2) is the mercury drop of 5 μl volume, (3) is the sample of 10 μl volume, (4) is the capillary of the electrolytic bridge of the auxiliary and simultaneously of the reference electrode and (5) is the capillary for the inlet of nitrogen. In the microcell (Fig. 6), deaeration of the sample is carried out simultaneously with the pre-electrolysis (stripping voltammetry), but nitrogen is admitted higher than the sample level.

In microcells [48, 49, 53], all three electrodes (working, auxiliary and reference) have been inverted, which allowed a decrease in sample volume, e.g. down to sub-microliter levels [53]. In the microcells shown in (Fig. 7) [48, 49], the three-electrode system was fabricated by microlithography. In Fig. 7, (1) is the working microelectrode (Au [48], Pt [49]), (2) is the auxiliary microelectrode (Au [48], Pt [49]) and (3) is the reference microelectrode (Au [48], Ag/AgCl [49]). The sample volume is ~ 2 μl [48,49].

The microcell shown in (Fig. 8) [53] consists of three strips of metal foil in a multi-decker sandwich heat-sealing film. In Fig. 8, (1) is the working microelectrode (4 μm Pt foil) and (2) is the auxiliary microelectrode (100 μm Ag foil). This micro

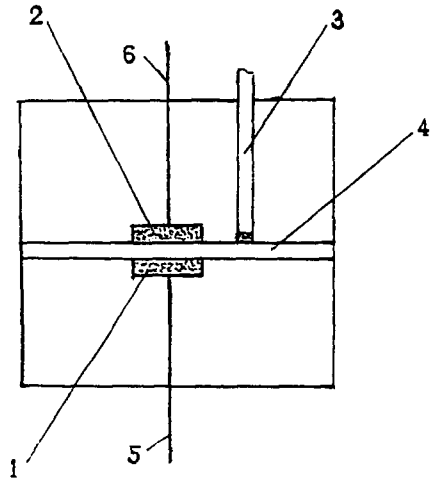

Fig. 9. Kissinger-type microcell for a static sample.

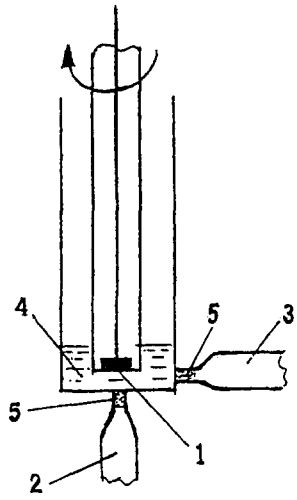

Fig. 10. Microcell with a working rotating disk electrode.

cell has a sample volume of 0.05–1.0 μl.

The use of a very small current in the microcells shown in Fig. 7 and 8 obviated the need to separate the electrode compartments by diaphragms.

2.3.3. Thin-layer microcells

In thin-layer electrochemical cells [79,80] which will be discussed below, both types of working electrodes (usual and inverted states) have been applied. In such microcells the sample is usually in the form of a very thin layer between the working and auxiliary electrodes. Although thin-layer microcells are applied for flow-through systems more often [54,55], there are also some thin-layer microcells [11,14,26,27,32,38,40,41] for a static sample that are of interest. There are thin-layer microcells [11,32] that are suitable for both flow and static samples which is advantgeous. A microcell similar to the Kissinger type [54] has been used [32] for static samples (Fig. 9). In Fig. 9, (1) is the carbon paste working electrode, (2) is the carbon paste auxiliary electrode, (3) is the electrolytic capillary of the reference electrode (Ag/AgCl), (4) is the sample layer (2–5 μl, but a 100 μl volume was used to wash and fill the microcell), (5) is the working electrode contact and (6) is the auxiliary electrode contact.

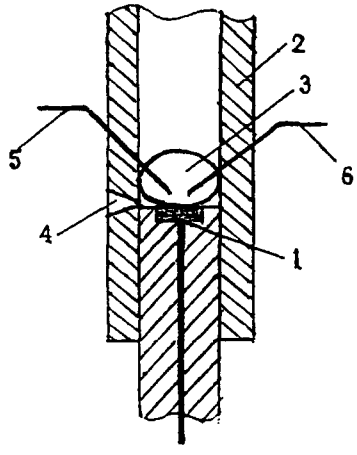

Fig. 11. Capillary microcell for the batch injection analysis.

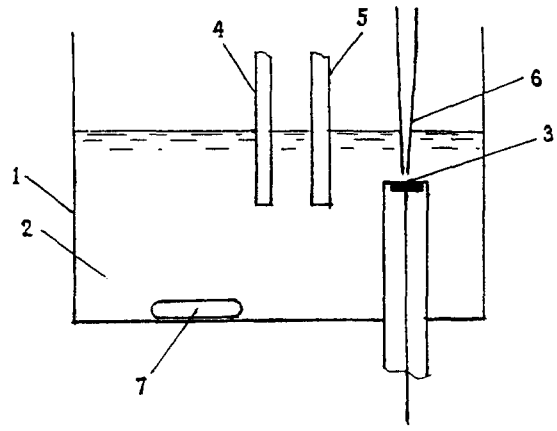

Fig. 12. Microcell with static working disk electrode for batch injection analysis

2.4. Microcells with forced convection of sample

In comparison with the static sample, in the case of forced-convection of the sample the diffusion of the analyte to the working electrode surface is accelerated and hence the analytical signal is increased and the detection limit decreased by about an order of magnitude [36,37]. In stripping voltammetry under the same conditions, the use of forced convection of a sample decreases the times of pre-electrolysis and of analysis.

Usually in non-flow microcells, forced convection was carried out in one of the following ways: rotation of the working electrode [5,20,21,28,36,

37], stirring of the sample by a magnetic stirrer [23], vibration pump [81] or rotation of the cell [82, 83]. In the case of the vibration pump [81], the fall of the mercury drop used as the working static merucry electrode was eliminated.

As the rotating working electrode, a disk electrode is usually used [84]. The rotating disk in microcells has been made from the one of following materials: glassy carbon without [5] and with a mercury film [28], Au [20], Pt [20,21] and impregnated graphite with a mercury film [36,37]. The sample volume is 0.5–4.0 ml [20,21,23] but the sample volume can be also decreased to 200 μl [28,36,37].

A microcell with a rotating disk working electrode is shown in Fig. 10 [28]: (1) is the rotating disk working electrode, (2) is the auxiliary electrode, (3) is the reference electrode and (4) is the sample. The auxiliary and reference electrodes are separated by electrolytic plugs (5) of porous ceramics.

It should be noted that forced convection has been successfully combined with hydrodynamic modulation [85–93]. Although this effect was applied in macrocells, it can also be used in microcells to decrease the influence of the current which is not connected with the diffusion of the analyte

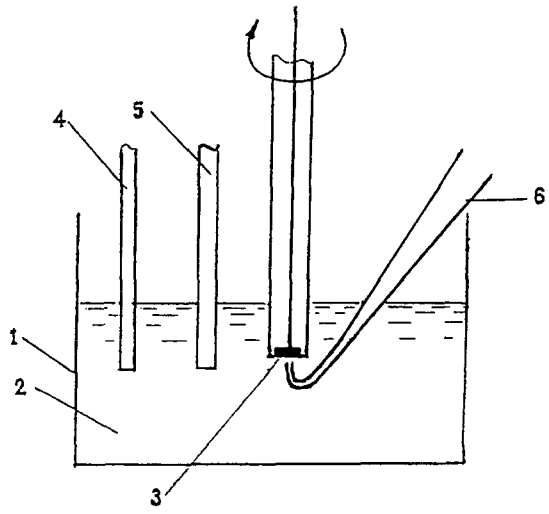

Fig. 13. Microcell with working rotating disk electrode for batch injection analysis.

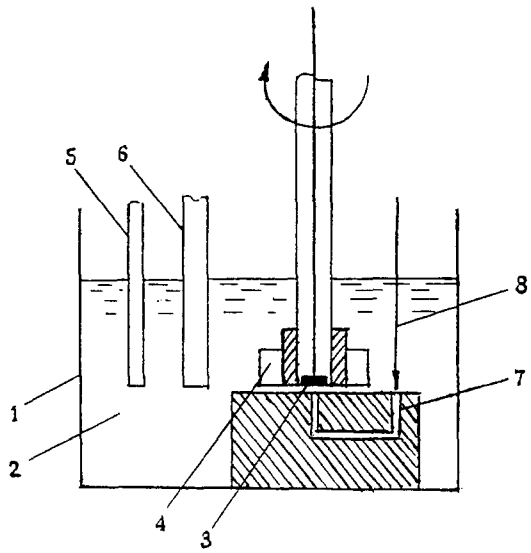

Fig. 14. Microcell with working rotating disk electrode with impeller for batch injection analysis.

to the working electrode surface. Hence it allows the detection limit to be decreased.

2.5. Microcells for batch injection of sample

In these microcells the working electrode can be in the usual state [5, 36, 37], but more often it is in the inverted state [6–10, 25, 94, 95].

The first microcell for voltammetric batch-injected analysis was proposed by Karolczak et al. [25]. This cell (Fig. 11) is distinguished by its exceptional simplicity. In Fig. 11, the working carbon paste electrode (1) in a Teflon sheath is put in a Teflon capillary (2). The sample (3) does not wet the Teflon and the carbon paste. The injection port (4) serves as an inlet for the sample (1–300 μl) by a micropipette and for sample removal by an aspirator without washing. The residuals are negligible (< 1%). The auxiliary electrode (5) is a platinum wire and (6) is the reference electrode in the form of a silver wire.

A different approach to batch injection analyses was developed by Wang and co-workers [5–8], Amine et al. [9] and Brett and co-workers [10,94,95]. The principle of the flow large-volume wall-jet cell developed by Gunasingham and co-workers [96–98] for liquid chromatography and

flow injection analysis has been used in microcells [5–10, 94, 95] for batch injection analysis. An example of such a microcell is shown in Fig. 12: (1) is a large compartment, (2) is a large volume of supporting electrolyte, (3) is the static working electrode (glassy carbon [8, 95], carbon paste [6] and modified carbon paste [9], Pt disk [9, 10, 94] and ion-selective electrodes [6, 7] have been used), (4) is the auxiliary electrode, (5) is the reference electrode, (6) is the micropipette tip for the inlet of a sample (10–100 μl) (for maximum sensitivity, the minimum sample volume of 14 μl is required at a fixed distance of the tip from the center of the working electrode (2–3 mm) [94]) and (7) is a magnetic stirring bar. The important advantage of this design and of the design with rotating working electrodes (see below) is the possibility of automatic removal of the sample. The latter, after contact with the surface of the working electrode, is washed by the large-volume of supporting electrolyte in compartment (1). Since considerable dilution of the sample takes place in this case, a large number of analyses can be carried out without replacing the supporting electrolyte in compartment (1). In the case of anodic stripping voltammetry [8], the magnetic stirring is switched off before the inlet of a sample and carrying out the pre-electrolysis and stripping stage. After the stripping stage the magnetic stirring is switched on again for cleaning of the working electrode.

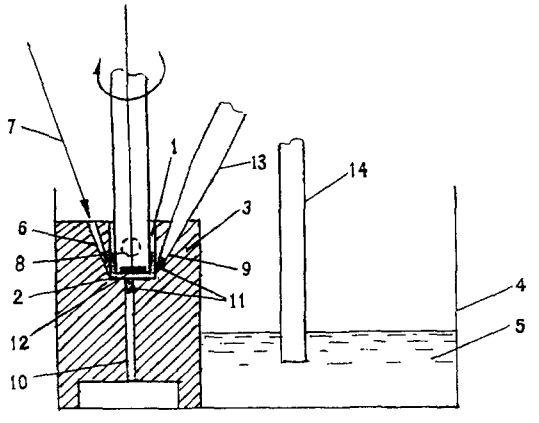

Fig. 15. Microcell with working rotating disk electrode for batch injection analysis.

A microcell with a rotating working electrode [5] has been used for batch injection voltammetric analysis. In this cell (Fig. 13), (1) is a large compartment, (2) is the large-volume supporting electrolyte, (3) is the rotating disk working electrode (glassy carbon), (4) is the auxiliary electrode, (5) is the reference electrode and (6) is the plastic tip for sample injection by micropipette.

A cell [99] with a rotating disk working electrode (Fig. 14) was used for macrosamples but it can also be applied for batch injection voltammetric microanalysis. In Fig. 14, (1) is the compartment, (2) is the supporting electrolyte, (3) is the rotating disk working electrode (glassy carbon), (4) is the impeller fixed to the shaft of the rotating electrode and rotating together with it, (5) is the auxiliary electrode, (6) is the reference electrode, (7) is the channel for internal circulation of electrolyte, and (8) is the micropipette for inserting the sample in channel (7). In the case of a working rotating disk electrode with an impeller, additional internal circulation of electrolyte occurs. The inlet sample is first moved down in channel (7) and then up to the working electrode surface. On contact of the sample with the electrode surface the analytical signal is generated. Such a system is analogous to the usual system for detection in flow injection analysis. However, the system [99] is different from the others in its simplicity and compactness. In comparison with the microcell in Fig. 13, in the microcell in Fig. 14 steadier movement of the sample to the working electrode surface and a more intensive hydrodynamic effect have been achieved [99].

We have seen that the microcell with a static working electrode (Fig. 12) was used for batch injection in anodic stripping voltammetry and this design did not allow the use of a rotating working electrode for stripping voltammetric analysis. At the same time, the design in Fig. 15 [36, 37] with the rotating disk working electrode in the microcell for batch injection in anodic stripping voltammetry decreased the detection limit by approximately an order of magnitude. In Fig. 15, (1) is the inner microcompartment, (2) is the sample (200–300 μl), (3) is the body of the microcompartment, (4) is the outer large compartment, (5) is the supporting electrolyte, (6) is the channel

Table 1
Use of microcells in analysis

Analyte	Sample volume, (μl)	Method	Ref.
Microcells with static sample and working electrode in the usual state			
Dopamine	10–40	Voltammetry	[15]
p-Nitrophenol, hydroquinone, *p*-phenylenediamine	2000	Chronopotentiometry	[19]
Acetaminophen, chlorpromazine, ascorbic acid	50	Voltammetry	[60]
Catecholamine epinephrine	10	Voltammetry	[50]
Pb(II), Cd(II)	10	Stripping voltammetry	[50]
Pb(II)	50–100	Stripping voltammetry	[31]
$Fe(CN)_6^{3+}$	0.25–1	Voltammetry	[44]
Microcells with static sample and working electrode in the inverted state			
Brain ascorbate	100	Chronoamperometry	[13]
Dopmaine, chlorpromazine, ferrocynaide	50	Voltammetry	[29]
Methyl viologen, thionine	250	Voltammetry	[34]
Ascorbic acid	25	Voltammetry	[49]
Ferrocene, *p*-nitrotoluene, anthraquione, ferri/ferrocynaide	0.05–1	Voltammetry	[53]
I, Zn(II)	50	Chronopotentiomentry	[24]
Hg(II), Pb(II)	5	Stripping voltammetry	[43]
Cu(II), Pb(II), Cd(II)	5	Stripping voltammetry	[45]
Pb(II), Cd(II)	5	Stripping voltammetry and potentiometry	[46, 47]
Br^-, S^{2-}, cysteineanion	10	Stripping voltammetry	[51]
Thin-layer microcells with static sample			
Chlorpromazine	23	Voltammetry	[11]
Adrenaline, noradrenaline, dopamine, dopa	1	Voltammetry	[14]

for inlet of the sample, (7) is the micropipette for the injection of the sample, (8) is a channel for displacement of the sample and washing solution into the outer large compartment, (9) is a channel for the auxiliary electrode, (10) is a channel for electrolytic contact with the reference electrode, (11) are electrolyte plugs made of hardened ashless filter-paper or porous ceramic, (12) is the rotating disk working electrode, (13) is the auxiliary electrode and (14) is the reference electrode. The inner microcompartment is replaced with another that enables one to work with different volumes of samples and working electrode sizes.

Recently, Brett et al. [95] have shown that the detection limit in anodic stripping voltammetry using microcells with batch injection analysis can be significantly decreased with employment of a static working electrode also. The microcell of the type in Fig. 12 was used but instead of a manual micropipette a programmable motorized electronic micropipette was applied [95] (see also [94]). The choice of the optimal sample dispensing rate allowed the maximum hydrodynamic well-jet effect to be obtained [94,95,100] and hence a significant increase in the analytical signal. This also ensured the complete displacement of the analyte sample with a new sample without the use of a mixer (Fig. 12).

The application of all the microcells considered above is surveyed in Table 1. Microcells have been used for the analysis of both organic and inorganic substances. Microcells with a static sample and the working electrode in the inverted state have a number advantages in the simplicity of design and the very low sample volume. In this respect, such microcells with microeletrodes fabricated by microlithography are especially promising. Microcells for batch injection analysis accelerate the analysis (to 30–60 and more samples per hour) and facilitate complete automation. These microcells with forced-convection of the sample (rotating working electrode [36,37] or wall-jet effect [95]) have permitted the batch injection stripping voltammetric anaysis of metal traces with nanomolar detection limits.

Received 8 January 1996; revised 9 April 1996; accepted 10 April 1996

Abstract

The immobilization of formylsalicylic acid compounds on the surface of amino group-containing silica gel phases is described. The resulting phases were tested for the extraction of iron(III) and showed an exchange capacity of 0.95–0.96 mmol g^{-1}. The other metal ions tested showed lower metal capacity values than iron(III). The selectivity of the phases tested for the extraction of iron(III) from a mixture containing several other metal ions was evaluated using atomic absorption spectrometry. A method for the recycling of immobilized silica gel after metal extraction is described for practical applications.

Keywords: Iron(III) extraction; Silica-immobilized formylsalicylic acid

1. Introduction

Immobilization and cross-linking of organic compounds with certain functional groups on the surface of silica gel has gained importance in different research and industrial fields [1–13]. However, irreversible binding of the metal ions and lack of selectivity are the main disadvantages of some of the silica gel-bound ligands reported [9,14]. The development of highly selective and high-affinity chelating phases is based on the selection of donor atoms employed in selective metal ion binding. Examples of such immobilized phases are the use of crown ether derivatives for the selective extraction and preconcentration of some cations such as alkali and alkaline earth metal ions [15,16]. Another example is the selection and immobilization of thioaniline derivatives on the surface of silica gel for application as a selective sorbent for the separation and preconcentration of Pd(II) from large quantities of Rh(II) and Ir(II) [17]. Iron is an essential metal and is used for the treatment of anaemia, but excessive intake or overdosing requires a selective analytical method or medication for metal treatment. Deferrioxamine B is a naturally occurring trihydroxamic acid which shows a high affinity and selectivity for iron(III), leading to its use in the treatment of iron overload in Couley's anaemia [18,19].

PII S0039-9140(96)01960-1

Formylsalicylic acid derivatives have been reported to form stable metal complexes with different metal ions in the solid state [20,21]. Moreover, the iron(III)–salicylic acid complex formed in solution showed higher sensitivity than other iron(III) complexes with phenolic compounds [22]. The immobilization of formylsalicylic acid has not been reported previously, and in this work we immobilized 3- and 5-formylsalicylic acid ($C_8H_6O_4$) on the surface of silica gel by a direct chemical reaction of the amino group-containing silica gel phase and the aldehyde group of formylsalicylic acid, in order to evaluate their performance in the extraction of different metal ions, and with the anticipation of such a phase being selective for the extraction and preconcentration of iron(III).

2. Experimental

2.1. Materials and solvents

The silica gel used was of TLC grade with a 70–230 mesh size and 60 Å pore diameter, purchased from Woelm Pharma (Eschwege, Germany). 3-Aminopropyltrimethoxysilane, 3-chloropropyltrimethoxysilane and ethylenediamine were purchased from Aldrich (Milwaukee, WI, USA). Organic solvents were dried according to literature methods. 3-Formylsalicylic acid and 5-formylsalicylic acid were synthesized according to the literature [23,24].

2.2. Synthesis of silica gel-bound amines

For the synthesis of silica gel-bound amines, the silica gel particles were first activated by refluxing with concentrated hydrochloric acid for 4 h, filtered off and washed with doubly distilled water several times until acid-free and dried in an oven for 6 h. A 20 g amount of the dry silica gel was transferred into a round-bottomed flask, then 150 ml of dry toluene were added followed by 20 ml of 3-aminopropyltrimethoxysilane (or 3-chloropropyltrimethoxysilane) and refluxed overnight. The silica gel-bound amino or chloro derivative was filtered off, washed with toluene, ethanol and diethyl ether and dried at 60°C for 6 h. The product was silica gel-bound 3-aminopropyl phase (SGBAP) or 3-chloropropyl phase (SGBCP). A 20 g amount of SGBCP was suspended in 100 ml of dry toluene and 20 ml of ethylenediamine were added to the suspension and refluxed for 12 h. The amine derivative was filtered off, washed with toluene, ethanol and diethyl ether and dried in an oven at 60°C for 6 h. The product was silica gel-bound ethylenediamine (SGBEDA).

2.3. Synthesis of silica gel-bound formylsalicylic acid (SGBFSA)

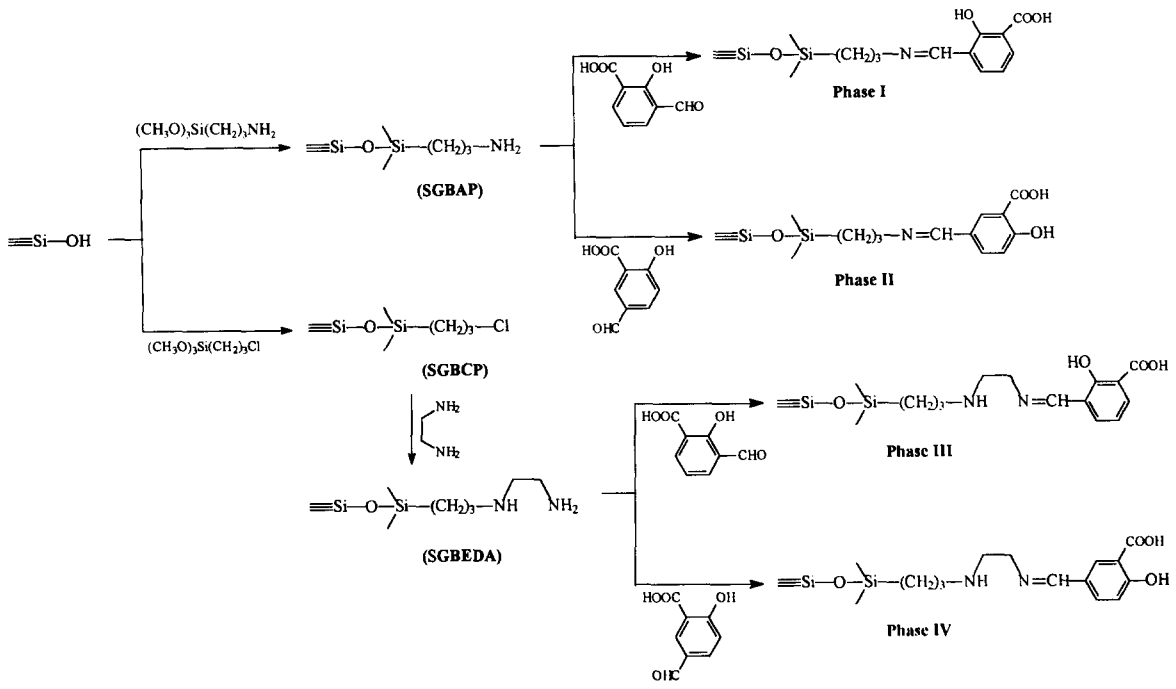
For the synthesis of silica gel-bound formylsalicylic acid, 1.8 g of 3- or 5-formylsalicylic acid was dissolved by heating in 150 ml of dry toluene, then 10 g of SGBAP or SGBEDA were added to the solution. The mixture was reflexed for 2 h, left to cool, filtered, washed with toluene, ethanol and diethyl ether and dried under vacuum at 80°C for 5 h. The synthetic route to the silica gel-immobilized formylsalicylic acid phases is illustrated in Scheme 1.

2.4. Metal capacity of bonded phases

The capacity of the modified phases for the extraction of different metal ions from aqueous solution was determined in triplicate by the batch equilibrium technique. Typically, 100 mg of the silica gel phase were equilibrated with 1.0 ml of 0.1 M metal ion solution and 9 ml of acetate buffer solution in a 50 ml volumetric flask and automatically shaken for 30 min at room temperature. After equilibration, the mixture was filtered and washed with 50 ml of doubly distilled water and the unextracted metal ion was determined by EDTA titration using the buffer and indicator appropriate for each ion.

2.5. Iron selectivity measurement

To 100 mg of the immobilized silica gel phases, 10 ml of bufferd mixture (pH 5.5) containing eight metal ions, viz. Fe(III), Mg(II), Mn(II), Co(II), Ni(II), Cu(II), Zn(II) and Cd(II), approximately 500 ppm each, were added and automati-



Scheme 1. Synthetic routes to phases I–IV.

cally shaken for 30 min. After equilibration, the extracted metal ions on the surface of silica gel were filtered off and washed with 20 ml of doubly distilled water. The filtrate and washings were quantitatively transferred into a 50 ml volumetric flask and diluted to volume with doubly distilled water. A standard solution containing the same metal ions were also prepared for quantitative evaluation. The sample mixtures and the standard solution were subjected to atomic absorption spectrometry at the wavelength appropriate for the metal ion under investigation.

2.6. Recycling procedure

Recycling of the immobilized phases after first use for metal extraction was carried out by treatment of the phase–Fe(III) complex with an excess (100 ml) of 0.1 M EDTA solution [25]. The mixture was automatically shaken for 30 min, filtered, washed with 25 ml of 0.1 M EDTA and 100 ml of doubly distilled water and dried in an oven at 80°C and used for a second metal ion extraction.

2.7. Apparatus

IR spectra of the immobilized phases were obtained from KBr pellets by using a Perkin-Elmer Model 1430 ratio-recording spectrometer. pH measurements were carried out by using a Schott Geräte pH meter, which was calibrated against two standard buffer solutions of pH 4.0 and 9.2. Atomic absorption spectrometry was performed with a Perkin-Elmer Model 2380 atomic absorption spectrometer at the appropriate wavelength for each metal ion tested.

3. Results and discussion

3.1. Characterization of the bonded phases

The immobilization of formylsalicylic acid on the surface of silica gel modified with two amine derivatives was confirmed by IR analysis. Comparison of the band assignments listed in Table 1 indicates that formylsalicylic acid is covalently

bonded to the silica gel amino group through Schiff base bond formation, characterized by the presence of a new band at 1530–1580 cm^{-1} corresponding to $\nu_{C=N}$ of all the phases studied. In addition, the ν_{NH_2} band present in silica gel-modified amine derivatives is absent in the IR spectra of phases I–IV owing to the participation of the amino group in the Schiff base formation. The characteristic $\nu_{C=O}$ band at 1600–1700 cm^{-1} in the four phases I–IV is further evidence of the presence of a carbonyl group in the structure of the immobilized phases I–IV, which is direct evidence for the presence of a carboxylic moiety. The total amount of formylsalicylic acid immobilized on the silica surface was determined according to the iron(III) probe method [26,27] and found to be 0.95 ± 0.01 mmol g^{-1} of the synthesized phases I–IV.

Table 1
Infrared spectral data for the immobilized phases

Bonded phase	IR band (cm^{-1})	Band assignment
SGBAP	3410, 3390	$\nu(NH_2)$
	2890	ν(C–H) aliphatic
	<1400	ν(Si–O)
SGBEDA	3455	ν(N–H)
	3415, 3385	$\nu(NH_2)$
	2890	ν(C–H) aliphatic
	<1400	ν(Si–O)
I	3650	ν(O–H)
	1653	ν(C=O)
	1560	ν(C=N)
	<1400	ν(Si–O)
II	3655	ν(O–H)
	1652	ν(C=O)
	1577	ν(C=N)
	<1400	ν(Si–O)
III	3660	ν(O–H)
	3453	ν(N–H)
	1645	ν(C=O)
	1534	ν(C=N)
	<1400	ν(Si–O)
IV	3667	ν(O–H)
	3431	ν(N–H)
	1645	ν(C=O)
	1534	ν(C=N)
	<1400	ν(Si–O)

3.2. Metal capacity in different buffer solutions

The metal capacity values, expressed in mmol g^{-1} of phases I–IV and determined in different buffer solutions, are given in Table 2. These values are the averages of three measurements and the relative standard deviations were found to be in the range 0.00–0.05% for $n = 3$. The Mg(II) metal capacity values are low at lower pH solutions, but slightly increase with increase in the pH of the metal ion solution. The maximum Mg(II) metal capacity value was found to be in the range 0.10–0.22 mmol g^{-1} in buffer solutions of pH 5–6. Zn(II) was found to behave similarly, the maximum capacity for Zn(II) being in the same range as for Mg(II) under the same buffering conditions. One can conclude from the metal capacity values of both Mg(II) and Zn(II) that phases I–IV have little affinity for these metal ions.

Cd(II) and Pb(II) were also found to show little tendency towards extraction and binding by immobilized phases I–IV. The metal capacity values for these ions lie in the range 0.12–0.20 mmol g^{-1}, determined in higher pH solution. In the same manner, Co(II) and Ni(II) showed metal capacity values in the range 0.12–0.29 mmol g^{-1}. The difference between Co(II) and Ni(II) is that the higher metal capacity value for Co(II) is determined in low pH solutions (pH 3–4), whereas that of Ni(II) is determined in higher pH solution (pH 5–6).

There is no or little contribution of the ethylenediamine moiety in phases III and IV, which may be attributed to the position of the active chelating sites on the surface (OH and COOH) if compared with the position of the ethylenediamine moiety away from the surface.

The maximum metal capacity value of Cu(II) showed a dramatic increase from 0.45 mmol g^{-1} for phase II to a maximum of 0.78 mmol g^{-1} for phase I (Table 2). The basic difference between these two phases is the position of the nitrogen atom, which is in the *ortho* position in the case of phase I and in the *para* position in the case of phase II. This situation may assist the chelation of Cu(II) by the nitrogen atom [21] in phase I, leading to an increase in the metal capacity. The

same trend is also evident when comparing phases III and IV. This assumption of nitrogen participation in Cu(II) binding may help in designing new selective phases for Cu(II) extraction and preconcentration.

Finally, Fe(III) was found to be the only metal ion highly extracted by all four immobilized phases I–IV. The metal capacity values of Fe(III) are all above 0.95 mmol g^{-1}, which is indicative of the higher selectivity of these phases towards Fe(III). The reason for such high selectivity is mainly based on the presence of two chelating oxygen atoms, one of which is a carboxylic [22] in all phases tesed. Comparison of the metal capac-

[a] Values in parantheses are the percentage extraction relative to the values at 30 min.

ity values of Fe(III) in Table 2 with those found in the literature [6,8,17] reveals a superior selectivity for the extraction of Fe(III) by the immobilized silica gel phases containing 3- or 5-formylsalicylic acid.

3.3. Metal capacity at different shaking times

The shaking time is an important factor in determining the possibility of application of the immobilized phases I–IV for the selective extraction of Fe(III) from a mixture containing several metal ions. Table 3 gives the effect of shaking time on the extraction of each metal ion at the selected optimum pH found in the previous section. The percentage extraction compared with the maximum metal capacity value in the case of Fe(III) is also included in Table 3. It is notable from Table 3 that Fe(III) is rapidly extracted, giving a metal capacity value of 0.62 mmol g^{-1} after only 2 min of shaking, corresponding to about 65% extraction of the Fe(III) present in the solution. This minimum value of the metal capacity determined after shaking for 2 min is higher

than almost any other metal ion capacity value even after 30 min of shaking, except for one value for Cu(II)–phase I. These trends in the variation of metal capacity values with shaking time are useful in the evaluation of the immobilized phases I–IV as highly selective for Fe(III) extraction.

3.4. Selective extraction of Fe(III)

The results of Fe(III) metal capacity determination as a function of either shaking time or pH prompted us to perform selective extraction studies of Fe(III) by the immobilized phases I–IV from mixtures containing other metal ions. A mixture of metal ions was prepared with similar ppm concentrations of Fe(III), Mg(II), Mn(II), Co(II), Ni(II), Cu(II), Zn(II) and Cd(II). However, Pb(II) precipitated in this mixture of metal ions and was therefore excluded from selectivity investigation. The mixture of metal ions was extracted with the four immobilized phases I–IV under the same experimental conditions of buffer, shaking time and dilution steps. A standard solution containing the same eight metal ions was also prepared for quantitative determination of the percentage extraction of each metal ion. The results of the atomic absorption analysis of the four phases and the standard are given in Table 4. Interpretation of selectivity is always based on the separation factor, α, which is a direct measure of the concentration or distribution ratios of the two solutes between the two phases. However, the data in Table 4 are expressed in mmol l^{-1} and percentage extraction values for simplicity. These values clearly demonstrate that only Fe(III) was isolated by the four phases tested, the values being in the range 93.4–97.1%, which is an excellent match with the metal capacity values previously described. On the other hand, the remaining seven metal ions were found to be less than 4% extracted by the immobilized phases, except for Cu(II), with extraction in the range 5.6–8.5%. Comparison of the percentage extractions obtained for Fe(III) and Cu(II) shows the great affinity of phases I–IV to Fe(III), but with some noticeable interference by Cu(II) ion. The interference of Cu(II) in selective extraction of Fe(III) by phases I–IV is mainly attributed to the high metal

Table 5
Comparison of metal capacities (mmol g^{-1}) of the original and recycled phases

Metal ion	Metal capacity							
	Phase I		Phase II		Phase III		Phase IV	
	Original	Recycled	Original	Recycled	Original	Recycled	Original	Recycled
Fe(III)	0.96	0.90	0.95	0.92	0.95	0.89	0.96	0.90
Cu(II)	0.78	0.70	0.45	0.39	0.44	0.42	0.25	0.20
Pb(II)	0.15	0.16	0.18	0.14	0.20	0.17	0.16	0.16

capacity value expected under the experimental conditions of the selectivity test. Therefore, optimization of the selective extraction of Fe(III) in the presence of Cu(II) can be accomplished by selection of the appropriate experimental conditions, such as the pH of the solution, which favour the elimination of Cu(II) interference.

3.5. Recycling of Fe(III)–phase I–IV complex

Selection of the Fe(III)–phase I–IV complex for recycling was based on the higher affinity of the metal ion to different silica gel phases. EDTA was used as the recycling reagent because of its high capability for back-extraction of metal ions from the complexes formed [25,28] and elution from the surface of immobilized silica gel. The recycled phases were subjected to a second metal ion extraction from a solution containing Fe(III), Cu(II) and Pb(II), and the results of this study are shown in Table 5. The values of the metal capacity of recycled phases (Table 5) indicate the possibility of using EDTA as a good recycling agent based on the similarity of the values of the metal capacity in the second extraction to those of the initial metal extraction given in Table 2.

Abstract

A chemically modified electrode (CME) was constructed and evaluated for use as an end-point indicator in the automatic titration of Ni(II) with EDTA. The CME consisted of a graphite paste prepared by mixing a strong acid ion exchanger containing 4-(3,5-dichloro-2-pyridylazo)-1,3-diaminobenzene and graphite powder–Nujol paste. This mixture showed high mechanical resistance in strongly acidic and alkaline solutions (6 M HCl–pH 12). The CME did not require any special conditioning prior to use. It could be used over long periods (5–6 months) of continuous work without renewing either the electroactive surface or paste. In buffered solutions (pH 3–4.5), automatic direct potentiometric titrations could be carried out over a wide interval of Ni(II) concentrations, ranging from 3 to 6000 ppm, with satisfactory accuracy and precision. For practical analysis, the electrode was applied to the determination of nickel in two certified composition alloys. Interferent ions were previously separated by applying an ion-exchange procedure.

Keywords: Chemically modified electrode; Graphite paste electrode; Nickel; Potentiometric titrations

1. Introduction

In parallel with the development of new ion-selective electrodes for the direct potentiometric determination of ions or substances in solution, from the analytical viewpoint research on chemically modified electrodes (CME) for end-point detection in automatic potentiometric titrations is also of interest. Generally, for sufficiently high concentrations, potentiometric titrations give good accuracy, they are not strongly dependent on the exact interpretation of small changes in voltage and are not limited by the accuracy of the electrode response to changes in solution concentrations. However, the development of suitable end-point sensors is not very simple. Thus, in addition to the often severe chemical limitations inherent to the titrimetric procedures (e.g. interferences, side-reactions, pH

* Corresponding author.

PII S0039-9140(96)01961-3

effects, suitability of reagents), there are other factors relating to the electrode behaviour, e.g. response times, slope of titration curves and overall voltage changes. In general, fundamentally high rates of potential change (especially at low concentration levels) are needed to ensure that the end-point and equivalence point are as close as possible.

In an earlier paper [1], we reported the construction of a simple electrode of 4-(3,5-dichloro-2-pyridylazo)-1,3-diaminobenzene (3,5-Cl2-PADAB)-modified graphite paste. This electrode was shown to be reliable as an end-point indicator in the automatic potentiometric titration of Zn(II) with EDTA, but owing to the relatively high reactive solubility in acidic solutions (pH < 4), its use was restricted only to neutral or alkaline solutions. We report here the construction and performance of a chemically modified electrode system consisting of a conventional graphite paste mixed with a strong acid ion exchanger which contains absorbed 3,5-Cl2PADAB. Both macroporous resin and ion exchangers modified with selective complexing agents have been widely used for the preconcentration or separation of metal ions [2–16]. This kind of ligand immobilized substances, so-called chelating agents resins, have also been incorporated into a conventional graphite power–Nujol oil pastes for the developement of CMEs. Most of these electrodes were not potentiometric sensors; the modified substance was incorporated in order to preconcentrate the analyte from dilute solution. Then, once the analyte had been extracted into the electrode surface, the analytical measurements were made in some other medium by using voltammetric method [17–26]. The successful developement of carbon paste electrodes should involve, at least, a permanently immobilized and stable species. In addition, such a modifier must be insoluble enough to avoid a continuous flow of the modifier from the electrode to the working solution (from the electrode response viewpoint, the dissolution of any component of the modified substance yields a continuous potential drift and a stable potential is not attained). Initial experiment carried out with the pure 3,5-Cl2PADAB-modified resin showed that it was almost insoluble in water over a wide range of pH. No disolution of 3,5-Cl2PADAB was observed after several days of exposure to these solutions. We also found that the electrode developed in this work possessed high mechanical stability in both strongly acidic and alkaline solutions. Although it proved to be sensitive to changes in Co(II), Zn(II), Cu(II) and Ni(II) concentrations, it was used as an end-point sensor for the automatic potentiometric titration of Ni(II) with EDTA.

2. Experimental

2.1. Apparatus

All potentiometric titrations were made with an Orion Automatic Titrator (Model 960 Autochemistry System, Orion Research, Cambridge, MA, USA), by using ion exchanger modified-graphite paste electrodes in conjunction with a double-junction Ag/AgCl electrode (Orion 90-02). The titrator was programmed to record millivolt readings during the analysis when the electrode response reached a pre-set stability. All titrations were started when the electrode responses became stable (± 1 mV min^{-1}) after immersion in sample solutions. Typically, such stability was attained in not more than 0.5–1 min in stirred solutions. Measured increments of titrant were automatically added from the titrator's burete. During the course of a titration, each new pre-set titrant volume was added after the potential had become stable to ± 1 mV or less. Near the end-point, the electrode response was slower than at the start of the titrations. In general, in these regions $\pm$ mV min^{-1} stability was attained 2–3 min after addition of each titrant volume. When the Ni(II) concentrations were higher than 2000 ppm, pre-dose volumes of titrant were added to reduce the time of titrations. The end-points were taken by applying either the first- or second-derivative technique to the data generated during the titrations.

2.2. Reagents

2.2.1. Standard nickel solution (ca. 0.1 M)

Ni(II) standard solution was prepared by dissolving the required amount of metal (99.95% pure) in 50 ml of 1 + 1 hydrochloric acid. The solution was diluted with distilled water in a 1000 ml volumetric flask.

2.2.2. Standard EDTA solution (ca. 0.1 M)

The disodium salt was dissolved in distilled water and standardised by potentiometric titration with a Zn(II) solution prepared from 99.99% pure metal.

2.2.3. 3,5-Cl2PADAB reagent

The reagent was synthesized and purified in our laboratory as described previously [27].

2.2.4. Formic acid–formate buffers

Several stock buffers were prepared by adjusting 1 M formic acid solutions (500 ml each) to the required pH with concentrated sodium hydroxide solution. All reagents were of analytical grade. All solutions were prepared in doubly distilled water and diluted further as required.

2.3. Electrode preparation

The electrode body was constructed as described previously [1].

2.3.1. Preparation of 3,5-Cl2PADAB-modified resin

Dowex 50W-X12 H^+ form resin (200–400 mesh) was cleaned before being used by boiling for 2 h with methanol. The resin was packed into a glass tube (200 mm × 6 mm i.d.) to give a bed about 2 cm high. The column was first washed with 50 ml 5% (v/v) HCl and then with a large volume of distilled water to remove acid from the column. A 0.05% (w/v) solution of 3,5-Cl2-PADAB in 95% ethanol was passed through the column at a 10 ml min^{-1} flow rate until the effluents became strongly coloured. At this point, to ensure complete resin "saturation", an additional 50 ml of reactive solution was passed through the bed at a 0.5 ml min^{-1} flow rate. Then both the inner tube walls and column were carefully washed with several portions of pure ethanol (100 ml in total). Finally, the modified resin was dried overnight at 90°C and stored in a tightly stoppered 2 ml vial. The final product was not appreciably hygroscopic.

2.3.2. Preparation of modified carbon pastes

The pastes were prepared by mixing a weighed amount of modified resin and the required weight of carbon (spectroscopically pure graphite powder, 400 mesh). Before mixing, the resin was wetted with a few drops of Nujol oil and then thoroughly mixed with a spatula. When necessary, more Nujol was added, drop by drop, until the entire mixture appeared uniformly wetted. The modified pastes were packed firmly into the cavity of the electrode body, then the surfaces of pastes were smoothed off by rubbing the electrode across a flat piece of glass, Finally, the excess paste was scraped off with a glass spatula.

2.4. General procedure for Ni(II) titrations

Pipette a sample volume containing between 0.15 and 300 mg of Ni into a 100 ml beaker. If necessary, dilute to 50 ml with distilled water and neutralize to litmus paper with dilute sodium hydroxide or hydrochloric acid solution. Add 1 ml of pH 3 sodium formate–formic acid buffer (ca. 1 M); connect both the working and reference electrodes, stir the solution continuously with a magnetic stirrer and start the titration when a stable potential (±1 mV) is attained.

2.5. Recommended procedure for Ni(II) separation

2.5.1 Preparation of resin column

Slurry an adequate amount of resin (Dowex 1-X10 type, 200–400 mesh, Cl^- form) with water and pour into 25 ml burette containing a small plug of glass-wool at the bottom, to form a 20 cm bed. Allow the resin to settle and then wash it with hot dilute acetone (1 + 1) until the effluent is colourless. Rinse with 100 ml of dis-

tilled water, then wash the resin with 9 M HCl (50 ml) to displace water, adjusting the burette tap so that the flow rate is ca. 10 ml min^{-1}. Just before use, allow the solution to flow from the burette until the surface is ca. 1 cm below the top of the resin level. After samples have passed through column, to displace iron(III), regenerate the resin by passing 0.1 M HCl solution (about 150 ml) until Fe(III) is not detectable with 5% KSCN solution.

2.5.2. Ni(II) separation

With a clean, dry pipette, pour 5 ml of the solution to be analysed on the top of column and let it flow in slowly until the liquid surface is ca. 1 cm below the top of the resin level, discarding the first few millilitres of effluent. Change the receiver to a 50 ml Pt dish and elute Ni(II) with two portions of 5 ml each of 9 M HCl. Evaporate the solution to near 0.5 ml on a sand-bath and allow it to cool. Dilute the residue with 5 ml of water, and quantitatively transfer the solution into a 100 ml beaker. Wash the dish with three 10 ml portions of water. Add 1 ml of 1 M formic acid–formate buffer (pH 3.5), mix well and titrate with EDTA when the potential is stable (± 1 mV min^{-1}).

2.5.3. Preparation of samples

IPT standard No. 24 samples (about 100 mg) were dissolved in 20 ml of concentrated hydrochloric acid and the solutions were evaporated until almost dry. The residues were taken up in 25 ml of 9 M HCl, quantitatively transferred into a 100 ml volumetric flask and finally diluted to volume with 9 M HCl. Portions of 5 ml of each of these solutions were loaded on to the column.

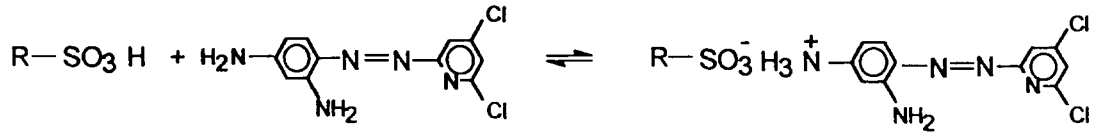
When the chromium content was low, as in IPT standard No. 45, it was most convenient to dissolve samples (about 3 g) in 50 ml of dilute (1 + 1) HNO_3. The resultant solutions were evaporated carefully just to dryness and allowed to cool. The residues were then dissolved in 10 ml of 9 M HCl and auantitatively transferred into a 100 ml volumetric flask with the aid of several portions of 9 M HCl. Finally, 9 M HCl was added to reach the 100 ml mark. Portions of 5 ml each of these last solutions were loaded on to the column for Ni(II) separation.

Results and discussion

We found that an electrode prepared with plain carbon–Nujol paste, that is, a paste containing neither 3,5-Cl2PADAB nor 3,5-Cl2PADAB-modified strong acid ion-exchange resin, was not sensitive to Ni(II) or another ions in the pH range 0–12. However, when the electrode was filled with a graphite–Nujol paste mixed with 3,5-Cl2PADAB-saturated resin, it showed a well defined response to concentration changes of ions such as Ni(II), Co(II), Cu(II) and Zn(II). In aqueous solution, 3,5-Cl2PADAB reacts with the above ions (pH 2–11) to form coloured complexes which have been used as the basis for development of several spectrophotometric [27–31] and titrimetric [1,32] procedures. The reagent could also be absorbed by a strong acid ion-exchange resin, and once absorbed it maintained the ability to react with these ions. In these cases, apparently the reactions did not occur in solution but in the grains of the ion exchanger. For example, it was clearly observed that when the modified resin was immersed in a solution containing an excess of Cu(II), after a few seconds of contact with liquid, the deep red colour of resin changed to the characteristic red–purple colour of the Cu(II)–Cl2PADAB complex. The complex formed in this way was also strongly retained by the resin and was more stable than the same complex formed in solution. Thus, the red–purple Cu(II)–3,5-Cl2PADAB complex formed in solution at pH 2–5.5 was rapidly destroyed by increasing the acidity of the medium to pH < 2 by addition of HCl. Otherwise, the same complex formed with the reagent retained by the resin was not destroyed even if the HCl concentration was increased to 6 M. The complex was partially desorbed or destroyed by HCl at concentrations higher than 6 M, by (1 + 1) 6 M HCl–ethanol mixtures and by EDTA solution at pH > 2.

The absorption of 3,5-Cl2PADAB and the reactions of the modified resin with the above metallic ions can be understood by considering that (1) 3,5-Cl2PADAB possesses two amino groups located in *ortho* and *para* positions with respect to the azo group, and (2) that in the complexation reactions with metallic ions only the *o*-amino and azo nitrogen atoms participate [28].

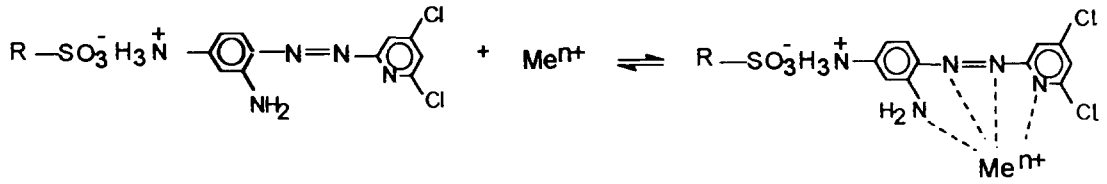
Furthermore, if an interaction with the ion exchanger occurs through the *p*-amino group as follows:



Solid (pale yellow) Solution (red) Solid (dark red)

Form 1

the resultant product will keep both the *o*-amino and azo groups free to react with the metallic ions according to



Solid Solution Solid

Form 2

The above assumption is in good agreement with the experimental results.

The calibration of the electrode as a direct potentiometric sensor was attempted at pH 3, 3.5 and 4 with pure Ni(II) solutions for concentrations down to 10^{-3} M and with Ni(II)–EDTA and Ni(II)–CDTA buffer [33,34] solutions for concentrations lower than 10^{-5} M. These solutions covered the pa_{Ni} range from ca. 3 to 12. For the calculations, the Ni(II)–formate complexes were neglected. The ionic strength in all solutions was adjusted to 0.1 by addition of the calculated amount of KNO_3. The results obtained indicated that the electrode response was not linear in either $-\log a_{Ni(II)}$ or $-\log_{[Ni(II)]}$. However, some initial titrations of the metallic ion carried out with EDTA as the titrant showed that the electrode should be suitable as an end-point indicator for these titrations. Therefore, the studies were orientated in that sense.

3.1. Paste composition

The electrode response was strongly affected by the paste composition. Several modified graphite pastes containing different amounts of 3,5-Cl2PADAB (from 1% to 80% (w/w), relative to the weight of graphite powder) were prepared and assayed. Below 40%, the behaviour of the electrode was poor, showing a slow response and smooth potential jump at the end-point, while ion-exchanger contents higher than 60% yielded pastes without mechanical resistance. The ion-exchanger grains of electrodes containing more than 60% were rapidly removed from the paste when they were immersed in solutions. However, with 40–60% pastes, the CME showed the best response and suitable mechanical resistance. Usually, 50% modified pastes were used in subsequent studies.

3.2. Electrode conditioning

The CME did not need any conditioning before use. We found that previous exposure to Ni(II) solutions as a conditioning process was not necessary for the electrode to work. However, the first

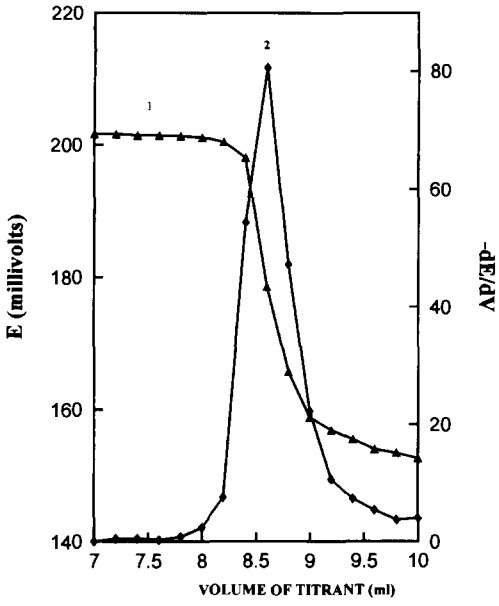


Fig. 1. Typical electrode response in the titration of Ni(II) at pH 3.5. (1) Titration of 50 ml of 244 ppm Ni(II) (7 ml pre-dose volume). (2) Curve obtained by applying the first derivative method to the data for curve 1.

titrations carried out with all recently prepared electrodes gave curves that showed inflection points not coincident with the theoretical end-point. Typically, exact results were obtained after carrying out two or three titrations of standard Ni(II) solutions. Once working, a large number of determinations could be made at various concentration levels, over a period of almost 6 months of continuous work, without the need to renew the electrode surface or paste.

Table 1
Some typical results obtained in EDTA potentiometric titrations of Ni(II) using a graphite paste electrode containing, 3,5-Cl2PADAB absorbed by a strong acid ion exchanger.

6001.00	5976.70	0.60	20

[a] Mean of 20 titrations.

3.3. Ni(II) titrations. Influence of pH

The influence of pH on the Ni(II) titrations was studied by carrying out titrations of buffered (formic acid–sodium formate or acetic acid–sodium acetate buffers) 10^{-3} M Ni(II) solutions in the pH range 2–6. In the pH range 3–4.5 the accuracy and repeatability obtained were insensitive to variations of pH. However, with a gradually more acidic or alkaline medium (up to pH 2 and pH 6, respectively), although the potential jump at the end-point became small,

Table 2
Maximum concentrations of foreign ions tolerated in Ni(II) determination by the proposed method.

Ion	Maximum concentration tolerated (ppm)	Ion	Maximum concentration tolerated (ppm)
Fe(III)	23	Thiosulphate	9600
Cu(II)	20	Nitrate	12400
Zn(II)	20	Phosphate	47500
Pb(II)	63	Fluoride	3800
Co(II)	24	Chloride	35500
Ca(II)	20000	Thiocyanate	29000
Mg(II)	12000		
Cr(III)	156		
Mn(II)	55		
Mo(VI)	96		

Table 3
Compositions of certified samples and results obtained for the determination of Ni

Sample Composition (% w/w)		Ni found (% w/w)	Error (%)	Standard deviation (ppm)
IPT No. 45 (nodular)	C (total) 2.95, C (graphitic) 2.66, Si 2.82, Mn 0.425, P 0.017, S 0.011, Cu 0.194, Cr 0.221, Ti 0.004, Mg 0.0031			
	Ni 0.196	0.195	0.51	0.005
IPT No. 24 (AISI 316)	C (total) 0.044, Si 0.528, Mn 1.500, P 0.039, S 0.004, Cu 0.030, Cr 17.81, Mo 2.640, Co 0.045, Fe 67.42			
	Ni 9.930	9.98	0.57	0.04

Ni(II) could be titrated with lower accuracy but with good precision. Therefore, in all subsequent work, a pH value of 3.5 was employed for the titrations. Fig. 1 illustrates a typical titration of Ni(II) at pH 3.5.

3.4. Accuracy and precision. Range of determinable Ni(II) concentrations

At pH 3.5 and with formic acid–formate buffered solutions, direct Ni(II) potentiometric titrations could be carried out in the range from nearly 3 to 6000 ppm with an accuracy of better than 0.5% (relative error) and a repeatibility lower than 0.71 (relative standard deviation). Some typical results obtained are shown in Table 1.

3.5.Interferences

The influence of foreign ions on the Ni(II) determination by the proposed method was studied for several cations, principally those which were expected to be interferents (e.g. Cu(II), Zn(II), Co(II), and Fe(III)). The cations tested were added as their chlorides or nitrates because these anions, as well as perchlorate, sulphate, acetate and formate, did not interfere at concentrations up to 1 M. An ion was considered to interfere when it produced an error greater than 0.6% (relative error) in the nickel determination. Table 2 shows the results obtained.

The greatest limitations were brought by the metallic ions mentioned above, and interference could not be controlled either by masking or by reducing them to another oxidation state. Previous separations proved to be the best way to avoid their interference. For that purpose, and to extend the method's application to samples containing large amounts of iron, cobalt, zinc, chromium and molybdenum, several separation procedures were tried. The ion-exchange method suggested by Kraus [35,36] was the simplest and most convenient manner for nickel separation from samples containing high proportions of other metals.

3.6. Applications

To evaluate the electrode performance in practical analytical work, two alloy samples certified by the Instituto de Pesquisas Tecnológicas (IPT), of San Pablo state, Brazil (IPT Nos. 24 and 45) were analysed for their nickel content. The sample compositions and the results obtained are shown in Table 3. In both cases, six determinations were carried out on three portions of each sample.

4. Conclusions

The method developed in this work showed good accuracy and precision in direct automatic potentiometric titrations of Ni(II) with EDTA. The CME was constructed by using easily available and inexpensive materials. The 3,5-Cl2PADAB-modified ion exchanger and the modified resin–carbon paste were very easily prepared and rapidly incorporated into the electrode body or replaced. They could be stored for long periods without loss or reactivity. For example, no difference in the electrode behaviour was found on comparing the results obtained from a freshly prepared modified paste with those for the same paste after 10 months of storage in a stoppered vessel, protected against direct sunlight. The electrode did not need any special conditioning to work correctly. All electrodes used in this work were ready to use immediately after their preparation. At pH 3–4.5 they gave excellent results for automatic Ni(II) titrations over a wide range of concentration (3–6000 ppm). This was especially attractive because it should allow application of the method to samples with high nickel contents without carrying out extensive dilutions before titrations. Only inexpensive and easily available reagents were required for the titrations. Furthermore, no external standards for instrument calibration were required. The only calibration necessary was standardization of the EDTA solution. In the above pH range, the titration curves were symmetrical, with the inflection points coincident with the theoretical end-points. Typically, overall potential jumps of 80–100 mV were obtained at the end-points.

Although the method showed several interferences, which could only be avoided by applying a simple separation procedure, the above findings suggest the resin–carbon paste electrodes could be advantageously employed for Ni(II) determinations in a wide variety of materials, such as minerals, soils and some industrial effluents.

Application of SQUAD to the refinement of formal potentials from coulometric steady-state and spectrophotometric measurements

Ma. Teresa Ramírez *, Alberto Rojas-Hernández, Ignacio González

Departmento de Química, Universidad Autónoma Metropolitana-Iztapalapa, Apdo Postal 55-534, C.P. 09340, México, D.F. Mexico

Received 20 November 1995; revised 24 May 1996; accepted 31 May 1996

Abstract

The application of SQUAD to the refinement of formal potentials from potentiometric or coulometric steady-state and spectrophotometric measurements was tested. The formal potential thus obtained for the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple in 0.5 M H_2SO_4 agreed with published data. This method was found to be satisfactory for the determination of typical standard potentials and it is suggested that it may be advantageous when dealing with multi-component systems.

Keywords: Coulometry; Formal potentials; Potentiometry; Spectrophotometry; SQUAD

1. Introduction

Several studies have been published using spectrophotometric, potentiometric and coulometric data to determine experimental standard potentials [1,2]. Most of these have used the cell potential (E) and absorbance values in a specific wavelength to determine the standard potential through graphical methods. In this way, it is only possible to determine standard potentials with a 100 mV/n separation in simple systems with few components (two or three). When the system is multi-component, it could be convenient to solve multiple regression with computer programs such as SQUAD [3–8], SCOGS [7,8], LETAGROP-SPEFO [8] and DALSFEK [9]. However, these programs have been designed for systems where oxidation state changes do not exist.

Sillén [10] suggested the use of an equilibrium constant for the redox couple. We evaluate the capability of using the SQUAD program with potentiometric or coulometric measurements and spectrophotometric data to refine these equilibrium constants and their standard potentials. In order to demonstrate the methodology used to achieve this task, we

PII S0039-9140(96)02005-X

selected a simple system, the $Fe(CN)_6^{3-}$ / $Fe(CN)_6^{4-}$ couple in 0.5 M H_2SO_4 over a Pt electrode, as a typical example for the redox couple.

2. Theory

SQUAD [3–8] is a program with the capability of refining the stability constant of a general complex, $M_m M'_l H_k L_n L'_q$, where m, l, n, $q \gg 0$ and k is positive (for protons) and negative (hydroxide ions), employing a non-linear least-squares approach.

The data fed to SQUAD are absorption spectra, chemical composition (total concentration of M, M'L, L' and pH) and a chemical model to describe the system. The residual sum (U) is calculated from the following equation [6]:

$$U = \sum_{1}^{I} \sum_{1}^{NW} (A_{i,k}^{\text{calc.}} - A_{i,k}^{\text{obs}})^2 \quad (1)$$

where the absorbance values $A_{i,k}$, for each spectrum, give a total of I for each wavelength and a grand total of NW.

In order to use the SQUAD program to refine standard potentials for several redox couples, we proposed to following the stability constant defined by Sillén [10] for a redox couple:

$$\text{Ox} + ne^- \rightleftharpoons \text{Red} \quad (2)$$

The Nernst law is

$$E = E^\circ + 2.303 \frac{RT}{nF} \log \frac{|\text{Ox}|}{|\text{Red}|} \quad (3)$$

The product of $F/2.303RT$ on both sides of Eq. (2) gives

$$pe = \frac{1}{n} \log K + \frac{1}{n} \log \frac{|\text{Ox}|}{|\text{Red}|} \quad (4)$$

where

$$pe \equiv \frac{F}{2.303RT} E \quad \text{and}$$

$$\frac{1}{n} \log K \equiv \frac{F}{2.303RT} E^\circ \quad (5)$$

Eq. (4) is of the Henderson–Hasselbalch type and demonstrates that [e] and pe can be introduced in the place of [H] or pH in the input data of SQUAD to refine this kind of cumulative constant for the redox couple (and then E°).

The same idea has been used in other approaches in different electrochemical studies [11].

3. Experimental

3.1. Reagents and instrumentation

All the reagents were of analytical grade from Baker and Merck and aqueous solutions were prepared using deionized water (Millipore, 18 $\mu\Omega^{-1}$).

Solutions of Fe(III) and Fe(II) were separately prepared by weighing both salts, $K_3Fe(CN)_6$ and $K_4Fe(CN)_6 \cdot 3H_2O$, and dissolving them in 0.5 M H_2SO_4.

A Radiometer–Tacussel Model LPH4430T potentiometer was used for the potentiometric studies. The reference electrode (saturated calomel electrode (SCE), Tacussel) and the working electrode (platinum electrode) were introduced into the electrochemical cell for potentiometric measurements.

3.2. Procedure

The solutions, 1.095×10^{-3} M $K_3Fe(CN)_6$ and 1.023×10^{-3} M $K_4Fe(CN)_6 \cdot 3H_2O$, were placed in 10 or 25 ml burets as required, different aliquots were transferred to the beaker of the cell and the measurement of the equilibrium potential was taken (e.g. 24 ml of Fe(III) and 1 ml of Fe(II) solution).

For controlled-potential coulometry, a Model 377A PAR coulometry cell system was used. A three-electrode glass cell was used under a nitrogen atmosphere, a platinum-gauze working electrode was used for the oxidation and reduction systems and the reference electrode (SCE) was introduced by means of a Luggin capillary. The counter-electrode was a platinum mesh. The study was performed using a DEA 332 Digital Electorchemical Analyzer with IMT 101 electrochemical interface from Radiometer–Tacussel, with Voltamaster II software.

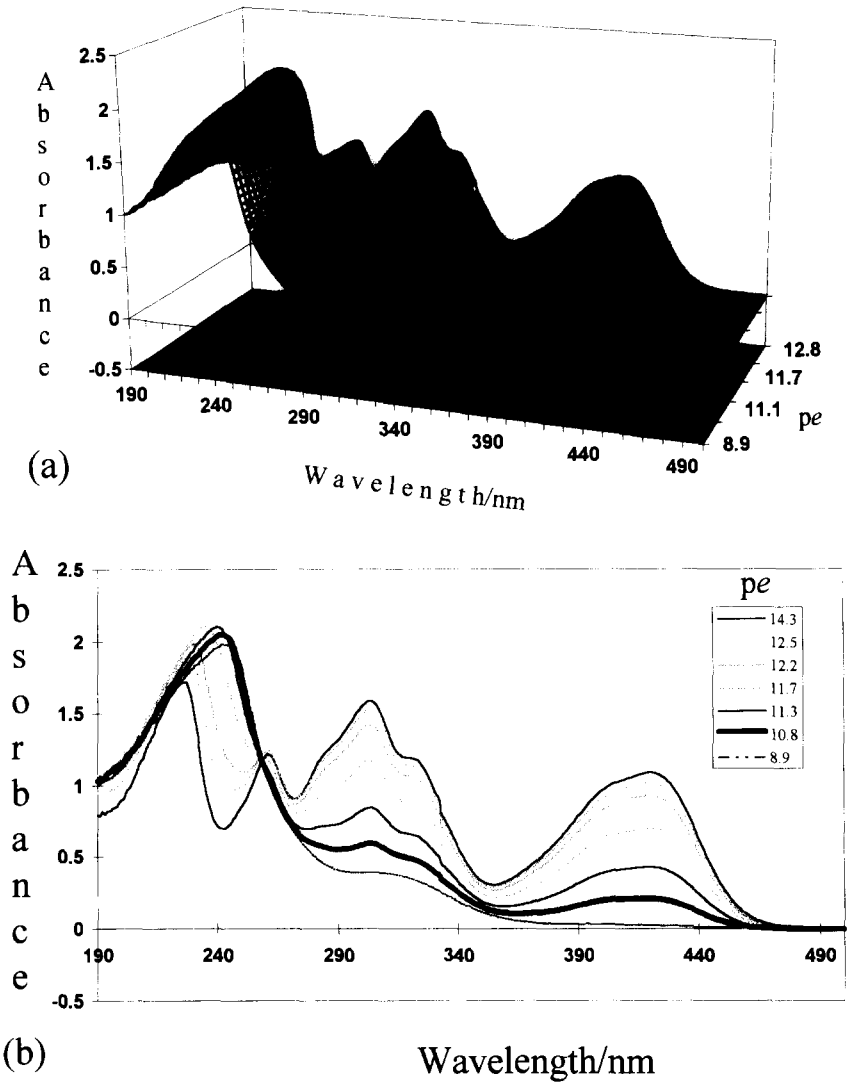

Fig. 1. Absorption spectra for solutions containing different $Fe(CN)_6^{3-}/Fe(CN)_6^{2-}$ ratios in 0.5 M H_2SO_4 volumetrically mixed. (a) Three-dimensional representation. (b) Typical absorption spectra for several *pe* values. In both cases *pe* is calculated following Sillén's suggestion, from potentiometric measurements.

For the spectrophotometric study, a Perkin-Elmer Lambda 17 double-beam UV-visible spectrophotometer with 1 cm quartz cells was utilized.

4. Results and discussion

4.1. Potentiometric study

The experimental E vs. $\log\{[Fe(CN)_6^{3-}]/[Fe(CN)_6^{4-}]\}$ plot is linear following the equation $E\,(mV) = 676.5\ (\pm 0.1)\ mV + 59.8\ (\pm 0.4)\ [mV^{-1}]\log\{[Fe(CN)_6^{3-}]/[Fe(CN)_6^{4-}]\}$ ($r^2 = 0.9999$) in agreement with the Nernst law. A slight blue coloration appeared when $[Fe(CN)_6^{4-}] \gg [Fe(CN)_6^{3-}]$, which was probably due to the formation of Prussian Blue by to the slow degradation of $Fe(CN)_6^{3-}$ in the acidic medium.

Representative absorption spectra obtained for different $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ ratios as a function

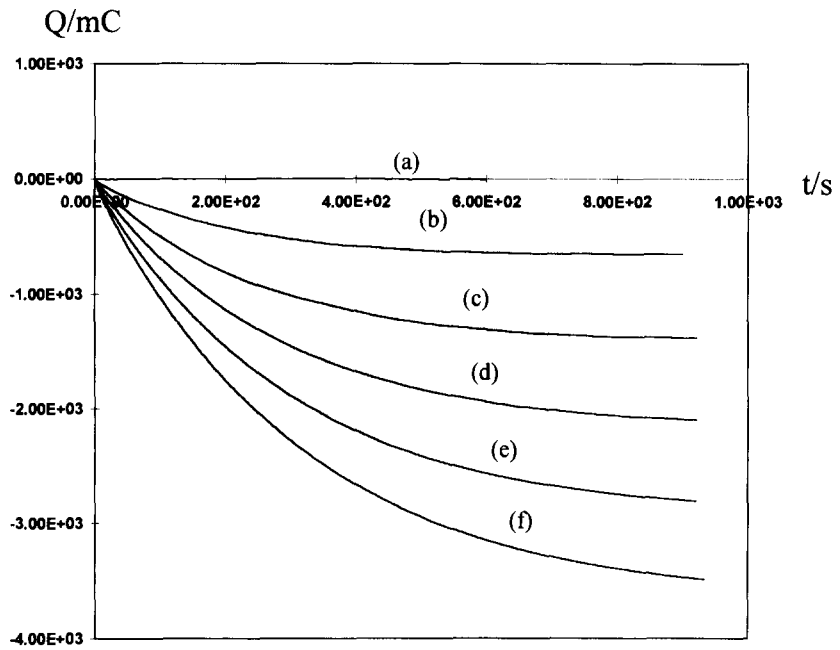

Fig. 2. Time dependence of charge involved in controlled-potential coulometry at 470 mV vs. NHE for different amounts of $K_3Fe(CN)_6$ dissolved in 0.5 M H_2SO_4: (a) 0, (b) 8.13×10^{-3}, (c) 1.63×10^{-2}, (d) 2.44×10^{-2}, (e) 3.25×10^{-2} and (f) 4.06×10^{-2} mmol.

of *pe* are shown in Fig. 1. In this case *pe* was calculated from the potential measurement with a platinum electrode immersed in the solution and using Eqs. (4) and (5).

4.2. Coulometric study

In order to analyze the $K_3Fe(CN)_6$ behavior under the above conditions, a coulometric study was carried out. The charge (Q) vs. time plots obtained in this process are shown in Fig. 2. From these curves and for long times, a Q vs. $[K_3Fe(CN)_6]$ plot was constructed for 470 mV vs. SHE. The charge varied linearly with the number of moles of $K_3Fe(CN)_6$ in solution (correlation coefficient = 0.9999) and the function was Q (mC) = -66 (± 435) mC + 91052 (± 9026) [mC mmol^{-1}] mmol $K_3Fe(CN)_6$. Considering that the slope of this function is equal to the product nF, the number of electrons involved in the reaction is 0.9 ± 0.1. This indicates that the $Fe(CN)_6^{3-}$ has been transformed into $Fe(CN)_6^{4-}$.

Solutions containing 15 ml of 8.17×10^{-4} M $K_3Fe(CN)_6$ were electrolyzed, imposing different potentials in the range 780–520 mV vs. SHE for 800 s. Solutions containing 15 ml of 8.57×10^{-4} M $K_4Fe(CN)_6 \cdot 3H_2O$ were similarly electrolyzed, imposing different potentials in the range 520–850 mV vs. SHE for 800 s.

For a liquid junction between two different electolytes, E_j may be estimated on the basis of the Henderson equation. In this case, $E_j = 14$ mV for $KCl-H_2SO_4$ solutions [12], and the potentials obtained in potentiometric and coulometric methods are corrected taking this E_j value into account.

Fig. 3 shows representative spectra obtained from steady-state solutions in coulometric experiments at several imposed potentials. The spectra are also represented as functions of *pe*. In this case *pe* is calculated from the potential imposed at the working electrode.

4.3. SQUAD results

The spectral behavior of the potentiometric and

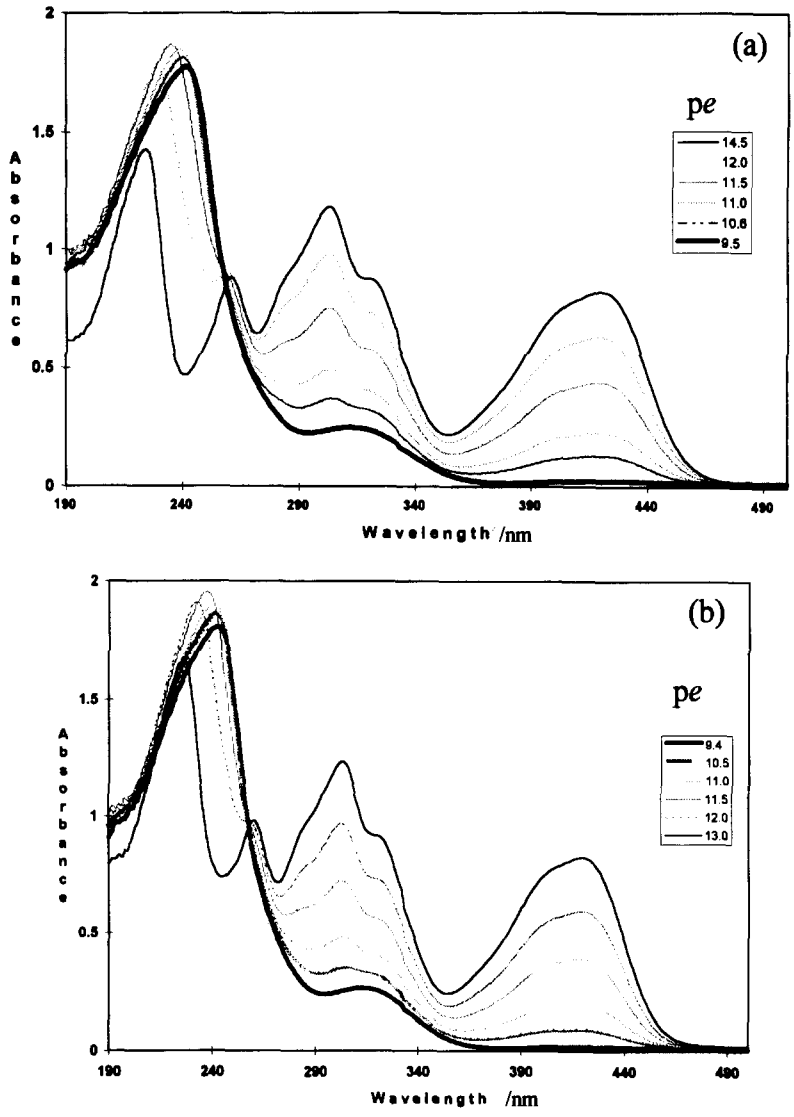

Fig. 3. Typical absorption steady-state spectra for different imposed potentials in coulometric experiments from solutions initially in 0.5 M H_2SO_4 containing (a) 8.17×10^{-4} M $Fe(CN)_6^{3-}$ and (b) 8.57×10^{-4} M $Fe(CN)_6^{4-}$. The imposed potentials are shown as *pe* values.

coulometric methods is similar. Only one isosbestic point is observed in all cases ($\lambda = 258$ nm). This can be associated with the presence of only one redox couple over the potential range considered.

In Table 1, the values of the equilibrium constants (and standard potentials) obtained from refinement achieved with SQUAD by assuming only one redox couple with the exchange of one electron are reported.

The statistical data (Table 1) are within the range of experimental error expected in all cases.

The difference between $E°$ obtained from electrolysis of $Fe(CN)_6^{3-}$ or $Fe(CN)_6^{4-}$ (approximately 10 mV) could indicate a hysteresis of the electron exchange in the redox couple, probably due to kinetic complications (see below). On the other hand, the difference between $E°$ obtained from electrolysis of $Fe(CN)_6^{3-}$ and the potentiometric

Table 1

Coulometric Fe(III) → Fe(II)	11.4601×0.0166	677.98	2.3662×10^{-2}	0.3354
Coulometric Fe(III) → Fe(II)	11.6733×0.0173	690.59	4.5156×10^{-2}	1.4661

[a] σ_A represents a global standard deviation of refinement of absorbance data.
[b] U represents the sum of squares of residuals, Eq. (1).

method could be due to the slight degradation of $Fe(CN)_6^{3-}$ in acidic media in the latter case.

In order to verify the quality of these data, several $E°$ values reported in the literature were compared with those obtained in this study (Table 2). Our results agreed with the published values.

The difference between the formal potentials in H_2SO_4, HCl and $HClO_4$ media and the standard potential may be explained by the protonation of hexacyanoferrate (II) [10]. Fig. 4 shows the Pourbaix-type diagram for the redox couple. For the construction of this diagram it was assumed that $Fe(CN)_6^{3-}$ and $H_iFe(CN)_6^{i-4}$ complexes are kinetically inert [13]. From this diagram it is evident that the protonation of hexacyanoferrate (II) increases the formal potential with respect to the standard potential.

Under the experimental conditions of this study, the redox couple involved was

$$2H^+ + Fe(CN)_6^{3-} + e^- \rightleftharpoons H_2Fe(CN)_6^{2-} \quad (6)$$

The protons included in the coordination sphere in hexacyanoferrate (II) indicate chemical reactions coupled to electron exchange. This could explain the hysteresis observed in the coulometric experiments.

5. Conclusions

From the above results, it is possible to propose the refinement of formal potentials by the SQUAD program, using the log K proposed by Sillén for redox couples.

The data can be obtained from potentiometric and spectrophotometric measurements. In addition, we showed that refinement of the formal potential from coulometric steady-state and spectrophotometric measurements is also possible. The application of this methodology to redox systems with several couple electron exchanges and chemical reactions will contribute to the understanding of the electrochemical behavior of complex systems. Interpretation of the data must be done carefully, such as in this case for $Fe(CN)_6^{3-}/Fe(CN)_6^{2-}$ in 0.5 M H_2SO_4, since spectrophotometric changes may result from a chemical reaction irrelevant to the

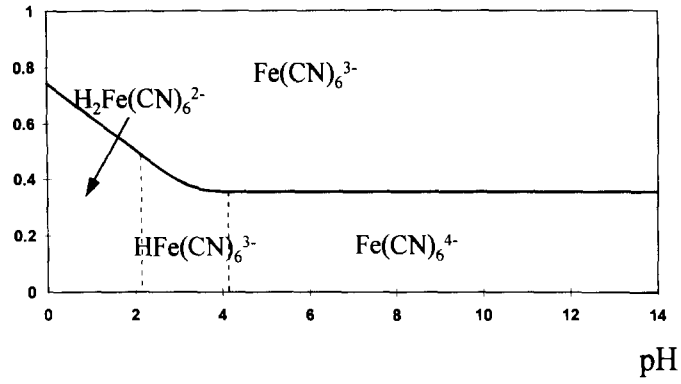

Fig. 4. Pourbaix diagram for the $Fe(CN)_6^{3-}/Fe(CN)_6^{2-}$ couple. Data taken from Sillén [10]. It is assumed that $Fe(CN)_6^{3-}$ and $H_iFe(CN)_6^{i-4}$ are inert complexes [13].

potential being measured. The application of the methodology to complex systems will be demonstrated in future studies.

Received 14 March 1996; revised 23 May 1996; accepted 23 May 1996

Abstract

A capacitively coupled microwave plasma (CMP) operating at 800 W was examined for the direct determination of cadmium in solids. The laboratory-constructed system contained a tungsten cup electrode capable of holding microsample quantities. A low-powered plasma was used to heat the sample, while at higher powers the plasma was used for sample vaporization and excitation. This plasma enabled thermal vaporization (TV) sample introduction to be accomplished in situ as the plasma formed directly around the sample. Thus, the need for sample preparation, procedural steps and sample transport was eliminated. This technique was capable of the direct determination of trace elements in solid samples in less than 5 min. The effects of experimental parameters such as gas flow rate, atomization power and electrode position were investigated. Detection limits obtained for Cd by TV–CMP-AES were in the picogram range with a relative standard deviation of $<20\%$. The accuracy and precision of the method were also evaluated by measuring Cd in several NIST Standard Reference Materials.

Keywords: Atomic emission spectrometry; Cadmium; Capacitively coupled microwave plasma; Solids

1. Introduction

The direct analysis of solids is important for several reasons. Because many samples occur naturally in solid form, pretreatment is usually needed to convert the sample into a liquid for analysis. Dissolution of the solid prior to analysis is often time consuming and requires the use of hazardous chemicals. Contamination from the added reagents can also occur [1]. Dilution errors and sample transfer losses arising from sample handling steps are possible and can lead to poor detection limits [2]. Also, some digestion procedures may result in the loss of some volatile elements [3]. In addition, the resultant solution can contain a high salt content with the potential for clogging nebulizers [4]. The plasma perfor-

PII S0039-9140(96)02006-1

mance as an excitation and atomization source can be degraded from the introduction of the solvent [5]. These problems can be avoided by the direct analysis of solids, as this would allow the sample to be analyzed in its natural state [2]. However, direct introduction of solids into plasmas does suffer from some disadvantages. Poorer precision is observed than with solution nebulization techniques [6]. Sample heterogeneity becomes more of a concern owing to the small sample sizes required of this method [2]. Furthermore, calibration curves are more difficult to determine as compared with solution analysis, where aqueous standards are used directly [7]. Even so, direct analysis of solids offers a means of rapidly quantifying the elemental content of a sample before it is subjected to extensive pretreatment.

Several methods have been used for the direct introduction of solids into an inductively coupled plasma (ICP). These include direct sample insertion (DSI) [2,8,9], electrothermal vaporization (ETV) [7,10,11], arcs [12], sparks [13], laser ablation [2] and slurry nebulization [14]. However, these techniques have some difficulties, including transport losses of analyte, background shifts, the need for matrix modifiers, the difficulty with availability of standards and tedious sample preparation and/or sample introduction procedures. Some of these problems can be alleviated by performing direct solid introduction into a capacitively coupled microwave plasma (CMP). The CMP allows for the analysis of an analyte in situ as the plasma forms directly around the sample. Thus, the need for sample preparation and procedural steps is eliminated. Also, this method allows for discrete sampling without any resultant sample dilution or losses.

Until recently, no work has been reported on methods of direct solid sampling without employing some means of analyte vapor transport into microwave plasmas. Ali et al. [4] developed a method for the rapid screening of solids using CMP-AES. The solid powder samples were placed in a graphite cup electrode and then the electrode was heated to initiate vaporization and atomization of the analyte. This method was evaluated using samples of tomato leaves (NIST SRM 1573a) and coal fly ash (SRM 1633a). Limits of detection were observed in the nanogram range.

Masamba et al. [5] used this same technique for the direct analysis of steel samples. Metal samples are conducting, easily machined into different shapes, resistant to sputtering and relatively homogeneous. For these reasons, metals are amenable to direct analysis. The steel samples were machined into cylinders which could fit snugly into the top of a hollow graphite holder. Power was supplied to the holder to create a plasma for vaporization and atomization of the analyte. Detection of constituents in steel was possible from less than 1 $\mu g\ g^{-1}$ to the per cent range.

In this work, a CMP with a tungsten cup was used for the determination of cadmium. Samples of graphite powder, to which Cd has been added, and a variety of NIST of Standard Reference Materials (SRMs) were evaluated. A mixture of helium and hydrogen was used as the plasma gas. The effects of experimental parameters were examined. The detection limit for solid Cd was in the picogram range. The results were compared with those previously obtained for Cd in solution [15]. The accuracy and precision of this method of direct analysis were also investigated.

2. Experimental

2.1. Instrumentation

The laboratory-constructed CMP system consisted of a high-voltage power supply which transferred energy to a 2450 MHz magnetron. The actual microwave power output of the magnetron could not be measured, thus the power used represented the amount of power supplied to the magnetron. The energy propagated as a standing wave through a brass waveguide with the plasma forming at the surface of the electrode. The tungsten cup electrode supported by a graphite holder sits in the center tube of a two concentric tube quartz torch and is shown in Fig. 1. The tungsten cup was capable of holding a volume of up to 10 μl. The plasma gas was introduced through the bottom of the torch.

Emission was detected by a 1 m Jobin-Yvon spectrometer which contained a photodiode array (PDA) detector. The design of this CMP system was described in greater detail elsewhere [15].

2.2. Sample preparation

The Cd solid standards used for analysis were prepared from cadmium chloride salt obtained from Fisher Scientific (Fairlawn, NJ, USA). The Cd salt was added to a 10 g quantity of high-purity graphite powder (grade SP2X, lot 721, Union Carbide, New York, USA) and thoroughly mixed in plastic vials using a ball-mill. This solid standard was quantitatively diluted with additional spectroscopic-grade graphite powder to prepare the remaining concentrations. It was necessary to use coarse graphite powder for the standards because fine powder caused atomization difficulties.

The SRMs studied were obtained from the National Institute of Standards and Technology (NIST). These solid samples included coal fly ash (1633a), tomato leaves (1573a), Montana soil (2711), bovine liver (1577b) and oyster tissue (1566a). No pretreatment or dilution steps were performed on these samples prior to analysis.

2.3. Procedure

The solid samples were deposited into the tungsten cup using a micropipettor (Model 225, Drummond Scientific, Broomall, PA, USA) with glass capillary tips, which was originally designed for liquid introduction. The pipettor was set to 1 μl and the end of the capillary was inserted into the solid sample. The pipettor was repeatedly moved back and forth until the tip was filled. Any sample adhering to the outside walls of the capillary was wiped off before deposition into the tungsten cup. The amount of sample dispensed was determined by calibration. The calibration was performed by weighing 20 loads of the graphite standard with a microbalance. It was determined that for a 1 μl load, 0.6 mg of Cd solid in graphite was introduced with about an 8% relative standard deviation (RSD).

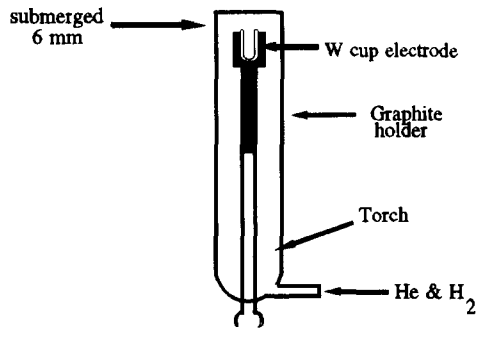

Fig. 1. Exaggerated view of tungsten cup design. The inner diameter is 3 mm, the outer diameter is 4 mm and the depth is 2 mm.

Once deposited in the electrode cup, the sample was subjected to a preatomization step which used a low-powered plasma to heat the sample. Preatomization was performed at a microwave power of 124 W for 3 s. After this step, the gas flow rates were set to the appropriate levels. The power was then rapidly increased to the atomization power, while simultaneously starting the computer for data acquisition. The emission signal was integrated for 1.0 s intervals for a 3 s time period. The electrode was submerged 6 mm below the top of the torch as shown in Fig. 1. The emission signal was observed at 5 mm above the electrode cup. All experimental parameters were optimized for the best signal-to-background ratios.

After each sample had been measured, it was necessary to clean the electrode cup. This was accomplished using a laboratory-constructed "vacuum cleaner". A Pasteur pipet was connected to a side-arm flask with a rubber hose. The top of the flask was attached to a ceiling vent. The pipet was placed inside the tungsten cup and the suction from the vent was used to remove any residue. This method proved satisfactory for sample removal as it was quick and easy to use.

2.4. Detection limits

Peak heights were used in the analysis of the data. The peak height was obtained from the maximum signal over a 3 s time interval to vaporize and excite the analyte. The peak height from this spectrum was corrected for the blank signal. The blank was graphite powder which had also been subjected to mixing with a ball-mill. The

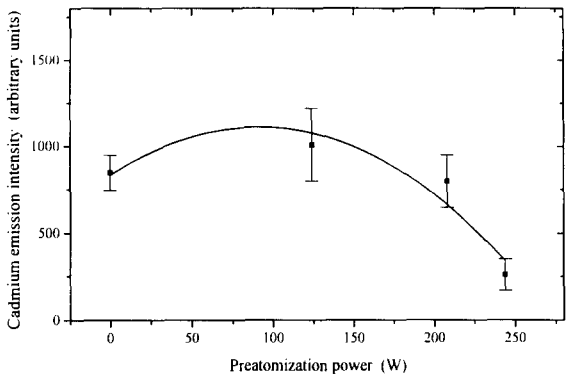

Fig. 2. Effect of preatomization power on solid Cd signal.

signals were background corrected by the computer software. All signals are reported as the mean of the three measurements with error bars representing one standard deviation from the mean. The calibration curve was obtained using the optimal experimental conditions determined from solid Cd. The optimization studies for each parameter were performed individually while all other experimental conditions were held constant. The optimal conditions were defined as those which produced a maximum signal-to-background ratio. The detection limit was determined as three times the standard deviation in the blank. The blank standard deviation was calculated from 10 measurements of the blank signal at a wavelength of 228.802 nm.

3. Results and discussion

3.1. Preatomization stage

The preatomization stage was necessary for the analysis of the solid Cd samples by thermal vaporization introduction into the CMP. It was found that elimination of this step produced an initial instability of the plasma which led to atomization difficulties. Also, the sample would sputter out of the electrode, contributing to irreproducible signals. However, it was found that preatomization at high powers results in signal losses of Cd as shown in Fig. 2. These losses were attributed to the volatile nature of this analyte. Similar results were found by previous researchers [4,16]. It was determined that a preatomization power of 124 W was sufficient for solid Cd measurements.

Optimization of the duration of the preatomization stage was also necessary. The preatomization time is the difference between the time the plasma was ignited and the time when the power was increased for atomization. It was found that the Cd signal was relatively constant with increasing preatomization times up to 60 s.

3.2. Temporal profile

The emission signals obtained were transient, which is an inherent characteristic of the thermal vaporization technique. The temporal profile of 180 pg of Cd in graphite powder is displayed in Fig. 3. For Cd in graphite, the signal lasted approximately 3 s. These results were similar to those observed for aqueous Cd [15].

3.3. Electrode position

The vertical distribution of the Cd emission for Cd in graphite is shown in Fig. 4. The observation height is the position above the electrode in the plasma where the signal is observed. A 0 mm observation height corresponds to the electrode surface being even with the center of the entrance slit of the spectrometer. The maximum signal-to-background ratio, and therefore the optimal emission signal, were observed to occur at 5–6 mm observation height; this low height was attributed to the volatile nature of Cd. Similarly to aqueous Cd [15], the background level also increased at 5–6 mm. In addition, the emission intensity began to decrease at observation heights greater than 7 mm.

The horizontal distribution of the emission of Cd (in graphite) across the plasma was also examined. A cylindrical-shaped plasma was used for the measurements and produced a uniform emission intensity for Cd (in graphite samples) over a width of 1 mm. These results are similar to those obtained for cylindrical plasmas with aqueous analytes [15]. The emission intensity across the plasma was asymmetric.

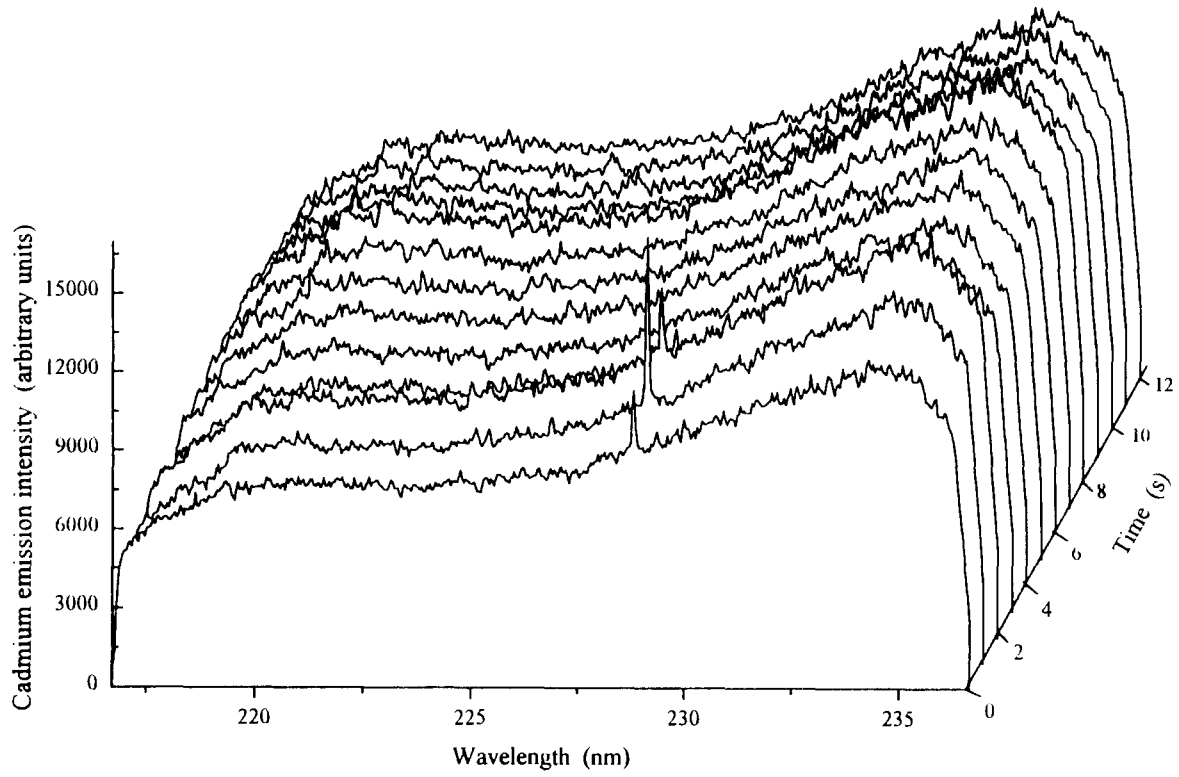

Fig. 3. Temporal profie of 180 pg of the emission signal Cd (in graphite powder) at 228.802 nm.

3.4. Atomization power

It was found that the emission intensity for Cd in graphite increased with increasing atomization power to a maximum; the maximum occurred when 800 W of power was supplied (see Fig. 5). Further increase in the atomization power led to a decrease in the intensity. These observations differ from those reported for Cd in aqueous samples [15]. The higher atomization power required here was probably due to the solid nature of the matrix.

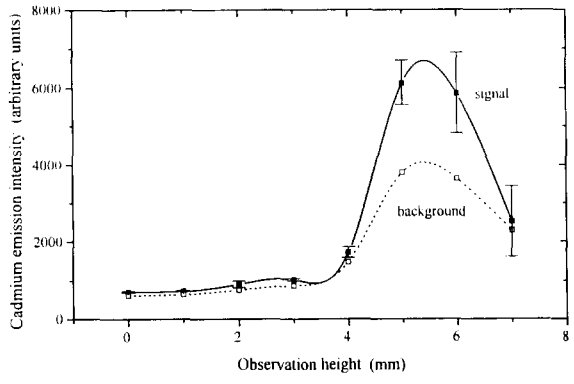

Fig. 4. Vertical distribution of solid Cd signal and background.

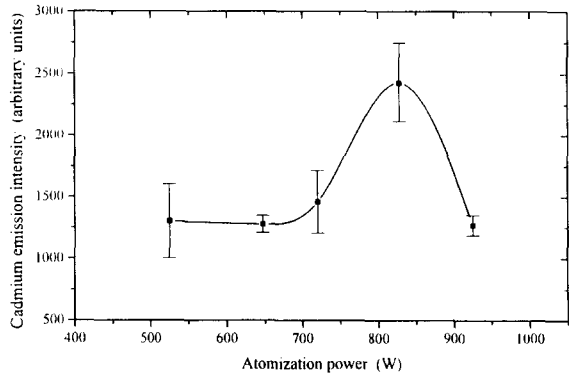

Fig. 5. Effect of atomization power on the emission signal for Cd in graphite.

Table 1
Comparison of optimal conditions selected for solid and aqueous [15] Cd

Parameter	Solid	Aqueous
Wavelength (nm)	228.802	228.802
Observation height (mm)	5	4
Displacement (mm)	0	0
He flow rate (l min^{-1})	7	5
H_2 flow rate (cm^3 min^{-1})	380	460
Preatomization/drying power (W)	124	90
Preatomization/drying time (s)	20	45
Atomization power (W)	828	525–630

3.5. Plasma gas flow rate

The helium flow rate did not have a significant effect on the Cd signal (in graphite). However, the emission intensity did experience a twofold increase at 7 l min^{-1}. The reason for this increase is unknown. Further investigation of solids with a CMP needs to be performed before definite conclusions can be drawn. The plasma was observed to be cylindrical in shape at this flow rate. These findings are similar to those for Cd in aqueous samples [15].

Just as for Cd in pollution samples [15,17–19], a small addition (of ca. 400 cm^3 min^{-1}) results in the maximum. The signal was not detectable unless at least 100 cm^3 min^{-1} of H_2 was introduced. If flow rates higher than 400 cm^3 min^{-1} were used, the emission signal decreased slightly, probably as a result of the decrease in the excitation temperature of the plasma with increase in hydrogen addition. [18].

3.6. Trace Cd determination

The operating conditions used for evaluating the analytical performance of TV–CMP-AES for solid Cd were based upon the optimization studies just described. The optimal conditions were selected as those which produced a maximum signal-to-background ratio while all other parameters were held constant. These conditions are given in Table 1. The conditions for both matrices were similar, with the main difference being the atomization power required for analysis. The higher power necessary for the solid analyses is probably due to the nature of the matrix. The analytical calibration curve for Cd in graphite was linear and had a log–log slope of 1.0 over the region from the detection limit to at least two orders of magnitude higher. The absolute detection limit obtained for Cd in graphite was 40 pg and the concentration detection limit was 70 ng g^{-1}. These absolute and relative detection limits are also compared with those obtained for Cd in solid samples by analogous methods [4,20] in Table 2.

When comparing the results obtained for Cd in both an aqueous and a solid matrix, many similarities are observed (Table 1). As mentioned previously, many of the operating conditions chosen to be optimal for the Cd measurement closely agree. Likewise, the trends observed for most of the experimental parameters agree. However, it was still discovered that the determination of Cd was not independent of the matrix studied. This was demonstrated by the fact that there was a threefold difference in the slopes of the calibration curves obtained for these matrices. This difference was largely a result of the dissimilar trend in the atomization power required for analysis. The solid matrix required a higher power for Cd measurement, and above this power the emission intensity decreased. In an aqueous matrix, the atomization power increased to a maximum and then reached a steady state. Further studies of the behavior of solids in a CMP should be investigated before any more conclusions can be drawn.

Table 2
Comparison of detection limits for Cd

Technique	LOD	
	pg	ng g^{-1}

Table 3
Determination of Cd in solid SRMs

Sample	SRM	Measured concentration[a] ($\mu g\ g^{-1}$)	Certified concentration ($\mu g\ g^{-1}$)	Bias (%)
Montana soil	2711	38 ± 11	41.70 ± 0.25	−9
Tomato leaves	1573a	1.4 ± 0.4	1.52 ± 0.04	−8
Bovine liver	1577b	0.6 ± 0.3	0.50 ± 0.03	20

[a] The ± values represent confidence intervals for the three measurements at the 95% level.

3.7. Standard reference materials

The accuracy and precision of the method developed for the determination of Cd in solids using CMP-AES were examined. Analyses were performed using a variety of SRMs obtained from NIST without any prior sample preparation. The operating conditions used were those listed in Table 1. The results observed for Cd measurment are displayed in Table 3 compared with the certified concentrations provided by NIST. The listed concentration ranges are within one standard deviation of the mean of three measurements. These values were obtained based upon the calibration of Cd in graphite powder. The observed concentrations closely agree with the certified values for each of the SRMs Montana soil, tomato leaves and bovine liver, showing less than 10% bias for the first two and 20% for the third. The accuracy may possibly be improved by performing the calibration by the method of standard additions, thus eliminating any errors caused by matrix effects. Even so, the precision of the measurments was less than about 20%. The precision was limited by sampling precision and data processing precision (selection of temporal peak). Current work involves the measurement of the peak area, which should minimize the latter.

4. Conclusions

The method developed for the determination of Cd in solid samples using TV–CMP-AES is capable of measurement at trace levels. A detection limit of 40 pg was possible with an RSD of <20%. The experimental conditions were found to agree closely with those obtained for the determination of Cd in aqueous solution. The main difference in the operating conditions between these two matrices was the atomization power, which at present makes the current method matrix dependent. Even so, this technique provided reasonable accuracy when applied to solid standard reference materials and compared favorably with other atomic methods of analysis. In addition, this preliminary investigation demonstrated the promise of TV–CMP for the direct analysis of solid samples.

Received 17 October 1995; revised 20 May 1996; accepted 30 May 1996

Abstract

A method for the analysis of tungsten alloy to determine selected elements using inductively coupled plasma atomic emission spectroscopy is described, with emphasis on line selection and spectral interference. The spectral interference coefficients were calculated for the spectral lines of selected major and trace elements. These values were used to select analytical lines and to calibrate concentrtions of the analytes. The detection limits of the elements for this method were determined and compared with those obtained by flame atomic absorption spectrometry and direct current carbon arc emission spectrometry. The results indicated that the detection limits for all of the elements determined by the proposed method are significantly better than those obtained by other techniques. In this study, the analytical reliability of the proposed method was estimated by comparison of the analytical data for the two types of tungsten alloys produced by the Korean Tungsten Company with those obtained by the matrix matching method and the results indicated that the accuracy of multi-element analysis is satisfactory.

Keywords: Inductively coupled plasma atomic emission spectrometry; Interference correction; Line selection; Tungsten alloy

1. Introduction

Tungsten alloys are of great importance in various branches of industry. They are mainly employed for radiation shields, balance weights and inertial navigation systems [1]. A detailed knowledge of the levels of the major and trace elements in metal alloys is essential since they may have either a deleterious or beneficial effect upon the mechanical and physical properties of alloys [2–5]. Trace element analysis of metal alloys can be a problem owing to the difficulty of dissolution and the instability of the sample solutions. Inductively coupled plasma atomic emission spectroscopy (ICP-AES) is a popular tool in the determination of trace elements [6–22], but a current limitation is the spectral interferences observed with elements that emit line-rich spectra. In order to

* Corresponding author. Fax: (82) 53-950-6330.

PII S0039-9140(96)02007-3

overcome this problem, a number of studies have been carried out to develop methods for isolating elements from complex matrices, including coprecipitation [9–11], complex formation [12,13] hydride conversion [14], adsorption [15], ion exchange [16] and chromatography [17–19]. However, these methods are concomitant with the risk of contamination from the chemicals and tedius time-consuming procedures.

In this study, the interfering spectral lines for nearly all of the elements in tungsten alloy that can be determined by ICP-AES were investigated. Spectral interferences, which arise from the incomplete isolation of the net signal at the analysis line, seriously affect the analytical results, particularly when high concentrations of matrix constituents are present. For the analytical lines of elements of interest we calculated the spectral interference correction coefficient (K_{ij}), which is defined by the ratio of the spurious concentration observed for element i and the actual concentration of interference j to evaluate quantitatively the amount of spectral interference on the individual lines. The corrected concentrations of the elements for the real samples were obtained using the K_{ij} values and the results were compared with those obtained by other analytical methods such as flame atomic absorption spectrometry (FAAS) and direct current carbon arc atomic emission spectrometry (d.c. arc AES). The detection limits for the analytes were also evaluated for the procedure suggested in this paper.

2. Experimental

2.1. Instrumentation

For ICP-AES, a JY 38 Plus ICP system (Jobin-Yvon, Longjumeau, France) was employed. Argon was used to purge the optical path and the monochromator for wavelengths in the range 180–195 nm. Since solutions containing hydrofluoric acid were employed in the present study, a hydrofluoric acid-resistant sample introduction system was used. This system consists of a platinum–iridium concentric nebulizer (Jobin-Yvon; Cat. No. 20925080), a PTFE nozzle, a Scott-type coaxial plastic spray chamber (Jobin-Yvon; Cat. No. 11285268), a plastic sheathing tube and a sapphire sample introduction tube. A force-fed Miniplus II peristaltic pump (Jobin-Yvon; Cat. No. 21357000) was used to deliver sample solution at a rate of 1.5 ml min^{-1}. The other operating conditions for ICP-AES are listed in Table 1. For FAAS a Model 3030B atomic absorption spectrometer (Perkin-Elmer, Norwalk, CT, USA) was used, and for d.c. arc AES a Model 70-000 system (Thermo Jarrell Ash, Franklin, MA, USA) with a 3.4 m focal length monochromator with a ruled grating was employed.

2.2. Samples and reagents

Two types of tungsten alloys (Grades P and T) used for real sample analysis were supplied by the Korea Tungsten Company (Kyungpook, Korea). Water was purified with a Milli-Q system (Millipore, Bedford, MA, USA). Concentrated hydrofluoric acid and nitric acid were of analytical-reagent grade. Metal standard solutions for ICP measurements were prepared by diluting 1000 ppm stock solutions obtained from Spex Industries, (Edison, NJ, USA). Internal standard and buffer materials used for d.c. arc AES were silver chloride (Zeebac; reagent grade) and Specpure graphite powder (Bay Carbon; spectrographic grade), respectively.

acids, adding 3 ml of each acid slowly to 1 g of sample. The mixture was then heated in a microwave digestion system (CEM; Model MDS-81D) until dissolution was achieved. The system was operated at 90% power (576 W) for 3 min, 0% for 3 min and 50% (320 W) for 3 min in sequence. The resulting solution was diluted with deionized water to give a final volume of 100 ml. In order to determine minor components in samples using the matrix matching method, standard solutions were prepared using aqueous solutions containing the same percentage of major constituents as those in the real samples.

2.3.2. D.c. arc AES

For d.c. arc AES, the sample was mixed with buffer (2 parts sample + 3 parts buffer) with a Wig-L-Bug shaker for 60 s. The composition of buffer used was 1 part silver chloride (Zeebac; reagent grade) and 2 parts Specpure graphite powder (Bay Carbon; spectrographic grade). The mixture of 75 mg was then loaded into graphite cups (Bay Carbon; Model S-12). Trace element analysis was carried out with a current of 10 A and an arcing period of 40 s. The signal at the 244.793 nm line of Ag was used as an internal standard.

3. Results and discussion

3.1. Line selection

Line selection was performed for the major and trace elements using a solution containing 10 g l^{-1} of each of the major components. Spectral interferences of spectral lines of the elements to be determined were studied by scanning the spectra of the interfering elements using the profiling mode of the analysis program. For the simultaneous determination of elements of interest in tungsten alloy, the most sensitive line for each element cannot always be used owing to the possible interferences of spectral lines of major components.

In order to evaluate quantitatively the amount of spectral interferences, the interference ocrrection coefficients (K_{ij}) for all of the lines of the elements were calculated. K_{ij} is defined by Eq. (1) and the values are listed in Table 2 [23–25].

$$K_{ij} = \frac{\text{spurious concentration observed for element } i \text{ (ng ml}^{-1}\text{)}}{\text{actual concentration of interferent } j \text{ (}\mu\text{g ml}^{-1}\text{)}} \quad (1)$$

A K_{ij} value of 0.01 means that a spurious concentration of 100 ppb was observed for the element i

Table 3
Detection limits (ppm) for elemental analysis of tungsten alloy by ICP-AES

Elements	Wavelength (nm)	K_{ij} method	FAAS	D.c. Arc AES
Al	396.152	0.010	0.091	0.07

in the matrix solution of 1.00% (w/v). Therefore, it is recommended to select the wavelength at which the sum of K_{ij} values of the interferent elements are the lowest. The corrected concentrations using the K_{ij} values were calculated from the equation

$$C_i' = C_i - \sum K_{ij} C_j \quad (2)$$

where C_i', C_i and C_j are the corrected, measured and matrix concentration, respectively. Thus the corrected concentrations should provide more reliable

[a] Errors are standard deviations for five measurements.

data in the determination of trace elements in a tungsten matrix.

3.2. Detection limit

The detection limits for 10 elements are listed in Table 3. These detection limits are the concentrations required to give a signal three times greater than the standard deviation of the background fluctuation. The relative standard deviation of the background was determined for each selected analytical line for 10 replicates measured with a 0.5 s integration time. The average value of the standard deviation was found to be about 1% for the matrix solution. This value does not significantly differ from that found for pure waer. On the other hand, the signal-to-background ratios were substantially decreased in the presence of matrix, which explains the difference between the detection limits measured in water and with matrix. In comparison with the detection limits in aqueous solution, the ICP-AES detection limits in the matrix solution were decreased by factors varying from 1 to 20. The values of the detection limits for the elements determined by the present technique are also compared with those obtained by FAAS and d.c. arc AES in Table 3. The results indicate that the detection limits for all the elements except V, Ta and Ni determined by the proposed method are better than those obtained by the other techniques.

3.3. Analysis of tungsten alloys

Determinations of major and trace elements in two types of tungsten alloys obtained from the Korea Tungsten Company were performed by the K_{ij} correction method. The results are presented in Table 4. The certified values listed in Table 4 were obtained by collaborative trials. The concentrations of major elements obtained by the K_{ij} correction method are in good agreement with the certified values and those obtained by the matrix matching technique. The analytical data for the trace elements were also found to agree with those obtained by the matrix matching method.

Ion-association method for the spectrophotometric determination of the antitussive drug noscapine

Bahruddin Saad[1], Salah M. Sultan, Fakhr Eldin O. Suliman*

Department of Chemistry, King Fahd University of Petroleum and Minerals, P.O. Box 2026, Dhahran 31261, Saudi Arabia

Received 31 October 1995; revised 22 May 1996; accepted 24 May 1996

Abstract

A simple, sensitive and fairly rapid method for the determination of noscapine is described, based on the measurement of the absorbance of the organic soluble ion-association complex formed between the noscapine monocation and a bulky counter anion. Methyl Orange, Bromothymol Blue and Bromocresol Green (BCG) were examined as counter ions. The effect of few solvents, the counter-ion concentration and pH on the extraction were also investigated. The most suitable system was based on BCG (pH 3.0) with chloroform as the extraction solvent. The use of the other counter ions, in conjuction with their respective solvents, was found to be less sensitive. The BCG system exhibits negligible or no interference when used for the determination of 38 ppm of noscapine in the presence of several drug excipients, thus lending itself as a possible procedure for the determination of this alkaloid in pharmaceutical preparations.

Keywords: Bromoscresol Green; Drug formulations; Extraction; Ion association; Noscapine

1. Introduction

Noscapine (**I**) is an important naturally occurring opium alkaloid, and is present in amounts of 6–11% of the raw material depending on season and locality [1,2]. Unlike morphine and codeine, it has no analgesic activity or abuse potential. Its major pharmaceutical action is its anti-tussive activity, which has been reported to be equivalent to that of codeine [1].

Noscapine and its metabolites in plasma have been determined using high-performance liquid chromatography (HPLC) [3–7]. Frequently, the use of a coupled-column arrangement was mandatory for the analytes to be separated first into two fractions on a polar precolumn [6,7]. Each fraction was next transferred to an analytical column for the final separation. HPLC procedures for the determination of noscapine in cough syrups [8] and capsules [9] have also been reported. In the former work, noscapine was oxidized by bromine generated on-line prior to detection.

The British Pharmacopoeia (BP) procedures [10,11] for the determination of noscapine in pharmaceutical preparations include an absorption method, which lacks specificity, and an acid–base titrimetric method in a non-aqueous medium with potentiometric end-point detection. Neither method is suitable for the determination of low levels of the alkaloid.

Simpler alternative methods that use inexpensive instruments are clearly needed for the determination of this pharmaceutically important anti-tussive drug. The use of bulky dyes for the formation of ion-association complexes that form the basis of extractive spectrophotometric methods for the determination of drugs in pharmaceutical preparations has been reported [12,13]. A method for the determination of anti-inflammatory agents using Methylene Violet was reported [12], and some phenotiazines were determined spectrophotmetrically by monitoring their ion-association complexes with Brilliant Blue and Orange-II [13]. In this work, the use of three bulky dyes as anionic counter ions for the formation of noscapine ion-association complexes whose absorbance can be monitored upon extraction was investigated. The systems were further optimized with respect to pH, choice of solvent, counter ion concentration and shaking time. Key analytical characteristics of the complexes were compared. Determinations of noscapine in the presence of common drug excipients were also performed.

2. Experimental

2.1. Apparatus

All absorbance measurements were made on a Perkin-Elmer Lambda 5 UV–visible spectrophotometer with matched quartz cuvettes of 1 cm path length. pH measurements of the aqueous phase were performed using a Corning combination glass electrode (Catalog No. 476530) in conjunction with a Corning Model 21 pH meter.

2.2. Reagents and solutions

All chemicals were of analytical-reagent grade, except noscapine hydrochloride, which was a gift from Dumex (Amsterdam, The Netherlands). Chloroform-stabilized ethanol and toluene were purchased from Fluka, methyl isobutyl ketone from Baker and dichloromethane from Winlab. These solvents were claimed to have purities of at least 99.9%. The counter ions were obtained from the following sources: Bromothylmol Blue (BTB) from Fisher Scientific, Methyl Orange (MO) from BDH and Bromocresol Green (BCG), sodium salt, from Allied Chemical. Demineralized, distilled water was used throughout.

2.2.1. Standard solutions

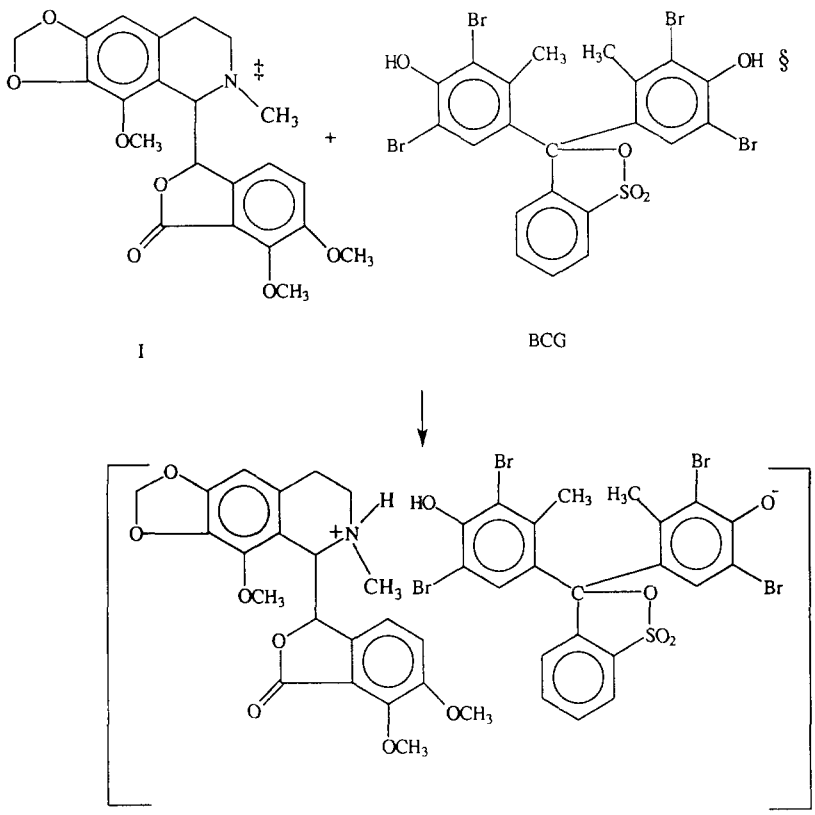
The masses of reagents used to prepare 10^{-2} M stock standard solutions in 50 ml volumetric flasks were BCG 0.3600 g, MO 0.1637 g and noscapine hydrochloride 0.2067 g. A BTB stock standard solution was prepared by dissolving 0.3232 g of the reagent in 5 ml of ethanol and diluting to the mark with water. Working standard solutions were prepared by dilution of the stock standard solutions as required.

2.2.2. Noscapine tablet solutions

A standard solution was prepared by crushing five tablets (Longatin; Dumex, Copenhagen, Denmark) and dissolving an amount of the powder equivalent to 100 mg of noscapine in 50 ml of water. The mixture was warmed at 70°C in a water-bath for 10 min, agitated by an electrical shaker for 10 min and filtered through an ordinary filter-paper. After washing several times with hot water, the filtrate plus washings were cooled to room temperature and the final volume was made up to 100 ml.

2.2.3. Buffer solutions

Buffer solutions were prepared in 200 ml volumetric flasks, as follows: acetate buffer (pH 3.0), dissolve 0.80 g of anhydrous sodium acetate, add glacial acetic acid to adjust the pH to 3.0 and dilute to the mark; acetate buffer (pH 3.5), dissolve 100.0 g of ammonium acetate, adjust the pH to 3.5 with 7 M hydrochloric acid and dilute to



I BCG

Drug-dye complex

‡ $pK_a = 7.8$

§ $pK_a = 4.9$

the mark; phosphate buffer (pH 4.5), dissolve 3.4025 g of potassium dihydrogenorthophosphate, adjust the pH to 4.5 with 0.1 M HCl and dilute to the mark; and phosphate buffers (pH 5.5–8.0), mix 50 ml of 0.2 M potassium dihydrogen-orthophosphate solution, adjust to the required pH by addition of 0.2 M sodium hydroxide and dilute to the mark.

2.3. General procedure for extraction-spectrophotometry

Volumes of 1 ml each of counter ion and buffer solution were transferred into a series of 125 ml separating funnels then, aliquots of 1.0 mM alkaloid solution were added. The total volume of the aqueous phase was adjusted to 5 ml by the addition of distilled water. Finally, 10 ml of extraction solvent were added to each funnel and the contents were shaken vigorously for 60 s and then allowed to stand for a few minutes until the two phases had completely separated. The absorbance of the separated organic layer was measured at the respective λ_{max} against a reagent blank (see Table 2). At least duplicate measurements were made in all cases.

Table 1
Physical properties of background extracts of counter ions in different extraction solvents

Extraction solvent	Counter ion		
	MO	BTB	BCG
Chloroform	Colorless	Intense yellow	Slight yellow
Toluene	Colorless	Slight yellow	Colorless
Methyl isobutyl ketone	Slight yellow	Intense yellow	Intense yellow
Dichloromethane	Colorless	Intense yellow	Colorless

3. Results and discussion

3.1. Background absorption

A preliminary investigation of the background absorption of 1 ml of 10^{-3} M counter ion solution (without noscapine) was conducted. The characteristics of the extracts are shown in Table 1 and reveals that the BTB system has a high background absorption, especially when chloroform, methyl isobutyl ketone or dichloromethane was used as the extracting solvent. For systems that are highly coloured, no further investigations were conducted.

3.2. Choice of organic solvent

Chloroform, methyl isobutyl ketone, toluene and dichloromethane were used as solvents in the extraction. The absorbances for 38 ppm of noscapine, corrected for the corresponding blanks, for the MO and BCG system are shown in Figs. 1 and 2, respectively. It is evident that the most suitable solvent for the MO-based complex is dichloromethane, whereas for the BCG system dichloromethane and chloroform seem to be promising solvents. For BTB, the only suitable solvent that merits further study was toluene. The respective solvents were in further studies.

3.3. Effect of pH

The pH of the aqueous phase is an extremely important factor for ion-pair extractions [13–15]. Here the influence of pH on the extraction was evaluated by measuring the absorbance of the complex when 38 ppm of noscapine was used, and that of the corresponding blanks over the pH range 3–8, by the addition of the appropriate buffers. In general, it was found that negligible or no extraction occurred at pH > 6 for all systems.

For the BTB system, it was found that the optimum pH was 4.0 when toluene was used as the solvent and the most suitable pH for the MO- and BCG-based complexes was 3.0. These pH values were adopted in further studies.

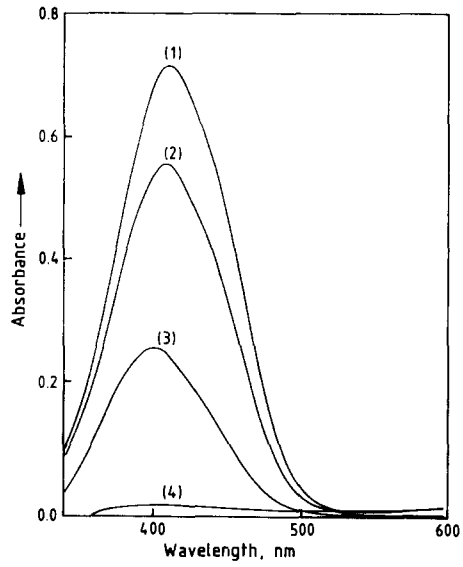


Fig. 1. Typical absorption of noscapine–MO complex n different solvents: (1) dichloromethane; (2) chloroform; (3) methyl isobutyl ketone; and (4) toluene. Conditions: noscapine, 38 ppm; MO, 10^{-3} M; pH, 3.0; reference, blanks in respective solvent.

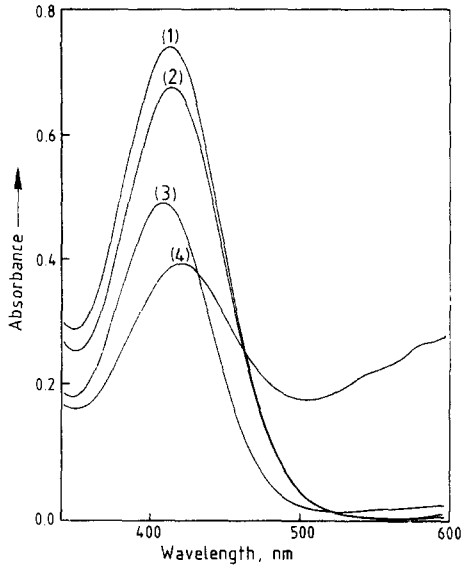

Fig. 2. Typical absorption of noscapine–BCG complex in different solvents: (1) dichloromethane; (2) chloroform; (3) toluene; and (4) methyl isobutyl ketone. Conditions: noscapine, 38 ppm; BCG, 10^{-3} M; pH, 3.0; reference, blanks in respective solvent.

3.4. Counter-ion concentration

The influence of the respective counter-ion concentrations on the absorbance of the extracted ion pair was studied by fixing the alkaloid concentration at 38 ppm and varying the counter-ion concentration from 0.1 to 1.2 mM. The results are plotted in Fig. 3, which shows that the signal remains constant at counter-ion concentrations >0.80 mM for the BCG and BTB systems and >1.0 mM for the MO system. A fixed concentration of 1.0 mM counter-ion was subsequently used for all systems in order to minimize the blank absorbance; also, no further improvement in precision was observed for concentrations of counter ion higher than 1.0 mM.

3.5. Effect of shaking time

The extraction was studied by manual shaking and varying the shaking time from 30 to 300 s for the complexes based on 38 ppm of alkaloid. It was found that the absorbance remained constant over this time period for all complexes. A shaking time of 60 s was adopted for all extractions. It was further observed that the yellow extracts remained stable for at least 2 days.

3.6. Calibration

The most suitable extraction conditions were as follows: MO, extraction solvent dichloromethane, pH 3.0; BTB, extraction solvent toluene, pH 4.0; and BCG, extraction solvent chloroform or dichloromethane, pH 3.0. In all instances, a shaking time of 60 s and counter-ion concentration of 1 mM were adopted.

The calibration graphs were generated by using 8–10 points, each point being repeated at least twice. The day-to-day variation in the calibration graph was found to be within acceptable limits, as well as the repetitive determination of standard solutions carried out over a period of several

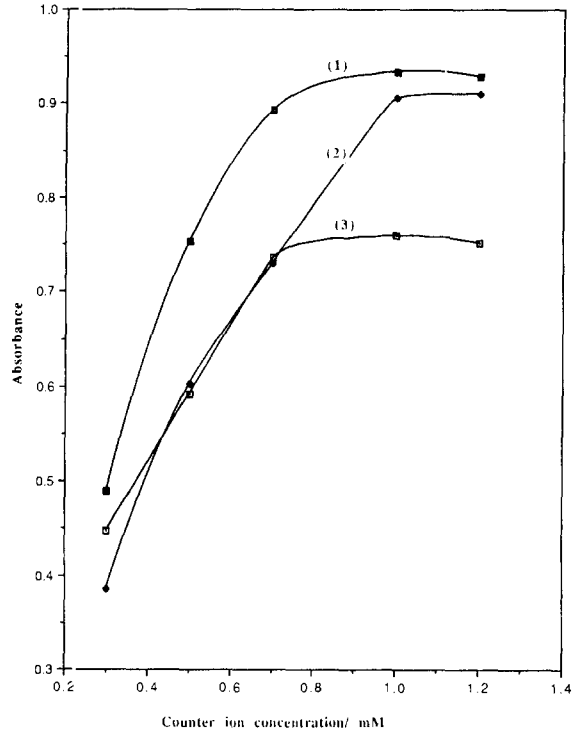

Fig. 3. Effect of counter ion concentration: (1) BCG; (2) MO; (3) BTB. Conditions: noscapine, 38 ppm. For BTB: solvent, toluene; pH, 4.0. For BCG: solvent, chloroform, pH, 3.0. For MO: solvent, dichloromethane; pH, 3.0. Absorbance measured at the respective λ_{max}.

Table 2
Analytical characteristics of noscapine–counter ion complex

Counter ion	Extraction solvent	λ_{max} (nm)	Molar absorptivity ($l\ mol^{-1}\ cm^{-1}$)	Detection limit (ppm)	Dynamic linear range (ppm)	Calibration equation		
						Slope	Intercept	Correlation coefficient, r
BTB	Toluene	403	7800	1.9	6–60	0.0192	0.1214	0.997
MO	Dichloromethane	426	7300	2.0	6–70	0.0179	0.2571	0.998
BCG	Chloroform	413	9100	1.6	5–60	0.0222	0.0765	0.999
BCG	Dichloromethane	412	9300	1.5	4–60	0.0228	0.2217	0.999

days, where a relative standard deviation (RSD) of not more than 1.0% was obtained. The linearity of the calibration graphs was studied under the above conditions for the respective counter ions. The analytical characteristics of the extraction are summarized in Table 2. The detection limit was calculated as described earlier [16] using the equation $3s/S$, where s is the standard deviation of the blank and S is the corresponding slope of the calibration graph. The upper and lower limits of the dynamic linear range of concentration were estimated from the calibration graph, noting when the points started to deviate from the straight line. The molar absorptivity of the ion-association systems obtained are comparable to those based on phenothiazine derivatives [12] and anti-inflammatory drugs [12] described earlier. Table 2 reveals that the most sensitive counter ion is BCG. The use of chloroform or dichloromethane yields almost comparable characteristics. However, chloroform was chosen as the extraction solvent owing to its lower volatility for application studies. The BCG-based ion-association complex is not only the most sensitive but also exhibits the lowest detection limit and the widest dynamic linear concentration range (Table 2).

The choice of counter ions was based on the guidelines suggested by Toei [17], where it is desirable for ion-association reagents to be univalent and bulky and for the charge to be distributed over the whole ion. It was further suggested [17] tha the use of plane-type cationic or anionic ion-association reagents will yield sensitive spectrophotometric systems. The interaction of aromatic surfaces is also believed to play a significant role in ion association and is termed aromatic stacking. Although the forces that drive aromatic–aromatic interactions are not yet clear, it has been suggested that both dispersion forces and interactions between partial charges within adjacent rings are responsible for these attractions; another component that is believed to add to these interactions was thought to arise from the hydrophobic nature of hydrocarbon aromatics [18]. The fact that the BCG and the BTB systems are more sensitive than the MO systems is probably due to their bulkiness. The ability of BCG to form ion-association complexes with alkaloids has been reported earlier [19].

3.7. Determination of noscapine in drug formulation

Interferences from some common drug excipients were examined and the results are given in Table 3. It was found that these compounds exhibit minimum interference, even when present at 50 times the level of noscapine. Determination of 38 ppm of noscapine in a mixture containing 380 ppm each of ascorbic acid, citric acid, glucose, magnesium sulfate and starch are also satisfactory, with an RSD of 0.6% and a recovery of 96%. The RSD of five determinations of 38 ppm noscapine standard solution was 0.50%.

The method was successfully applied to the determination of the drug in proprietary Longatin tablets (Dumex), claimed to contain 25 mg noscapine, and a recovery of 00.9% was obtained with an RSD of not more than 0.8%, indicating that the method is suitable for the determination of noscapine in drug formulations without interferences from excipients such as starch and glu-

[b] 380 ppm each of the compounds in the first column.

cose. The same batches were analyzed by the BP[10] method and the results obtained were compared statistically utilizing Student's t-test. The present method showed almost the same degree of accuracy as the BP method, as was inferred from the value of t at the 95% confidence level ($t_{\text{experimental}} = 1.6$ and $t_{\text{theoretical}} = 2.78$, $n = 5$). Noscapine is a controlled drug in Saudi Arabia and the only proprietary drug obtained was Longatin. The proposed method has the advantage of being virtually free from interferences (see Table 2) as well as having moderately low detection limits, and it may therefore be suitable for the determination of this drug in biological fluids. A few metabolites of noscapine have been identified in urine and rat liver microsomes [6], e.g. narcotoline and cotarnine. Also, it has been reported that *N*-demethylated noscapine and *N*-demethylated narcotoline or cotarnine are other possible metabolites of noscapine [6]. Both narcotoline and cotarnine preserve the isoquinoline part of the parent compound and are therefore able to form ionpairs with the BCG counter ion and could pose a major interference to the determination of noscapine in biological fluids by this method. Related drugs such as codeine are of the same nature as noscapine and are considered determinable by the same procedure and could be thoroughly studied in future work.

4. Conclusion

An extractive spectrophotometric procedure for the determination of noscapine was developed based on BCG with chloroform as the extraction solvent. The proposed procedure is fairly rapid, simple, sensitive and accurate and promises good prospects for the determination of noscapine in pharmaceutical preparations. Additionally, the method uses cheaper instrumentation than HPLC.

Acknowledgements

B. Saad is indebted to KFUPM for a postdoctoral fellowship and also to the Universiti Sains Malaysia, Penang, for leave of absence. The authors thank Dumex (Copenhagen, Denmark) for the gift of a noscapine sample.

Received 15 January 1996; revised 24 May 1996; accepted 6 June 1996

Abstract

A specific spectrophotometric method was developed for the determination of *p*-aminophenol and acetaminophen. The method is based on the reaction of *p*-aminophenol at ambient temperature with sodium sulphide in presence of an oxidant to produce a methylene blue-like dye. Different oxidizing agents were tried, e.g. Ce(IV) and Fe(III). The colour developed within 10 min and remained stable for at least 3 h. The method was applied successfully to the determination of *p*-aminophenol in the presence of acetaminophen without prior separation. The method was also applied to the analysis of various commercially available acetaminophen dosage forms and excellent recoveries were obtained comparable to those obtained by official procedures. The reaction product was isolated and a possible reaction mechanism was suggested.

Keywords: Acetaminophen; *p*-Aminophenol, Pharmaceutical analysis; Spectrophotometry

Introduction

Acetaminophen (*N*-acetyl-*p*-aminophenol or paracetamol) is an effective analgesic and antipyretic agent. *p*-Aminophenol is the hydrolytic product of acetaminophen and is reported to have significant nephrotoxicity and teratogenic effects and has been detected in acetaminophen as an impurity or synthetic intermediate [1].

Numerous methods have been reported for the determination of *p*-aminophenol and acetaminophen in pure form, pharmaceutical preparations and biological fluids, including gravimetric [1], titrimetric [2–4], UV[5], derivative [6–8] and differential [9] spectroscopic methods. Spectrophotometric [10–14], fluorimetric [15–17], chromatographic [18–23] and electrochemical procedures [24] have also been reported. Many of these procedures suffer from interferences from other active ingredients or additives especially those carrying phenolic or amine functional groups, and chromatographic separation is usually required.

PII S0039-9140(96)02013-9

Aromatic diamines have been used before for the determination of sulphide and sulphide-producing compounds in the presence of Fe(III) through the formation of methylene blue dye [25]. In this work, the applicability of the principle of this reaction for the determination of acetaminophen and *p*-aminophenol was investigated using sodium sulphide and Fe(III) or Ce(IV) as reagents. As a result of this investigation, a rapid, sensitive and selective spectrophotometric method for the determination of acetaminophen and *p*-aminophenol was developed. Advantages are that the reaction occurs at room temperature and using distilled water as a solvent.

2. Experimental

2.1. Apparatus

A Varian Model DMS100 UV–visible spectophotometer connected to a Varian Model DS15 data station and a Hewlet–Packard Model 82905B printer was used.

A Model 1500 Fourier transform IR spectrophotometer, equipped with a data station, Model PPI printer–plotter and 1502 central processing unit was obtained from Perkin-Elmer.

Elemental microanalyses were performed with Perkin-Elmer Model 2400, CHNO Elemental Analyser.

2.2. Materials and reagents

Pharmaceutical-grade acetaminophen (Riedel-de Haën, Seelze-Hannover, Germany) and *p*-aminophenol (BDH, Poole, UK) were used as working standards without further treatment. Various commercially available dosage forms were purchased from the local market. All other chemicals and solvents were of analytical grade. Distilled water was used throughout.

2.3. Reagent solutions

Sodium sulphide was used as a 0.025% aqueous solution.

Fe(III) solution was prepared as 0.5% ammonium iron (III) sulphate in 0.03 M sulphuric acid and Ce(IV) solution as 0.08% cerium(IV) sulphate in 0.03 M sulphuric acid.

2.4. Preparation of standard solution

p-Aminophenol: prepare accurately a 50 μg ml^{-1} *p*-aminophenol aqueous solution.

Intact acetaminophen: prepare accurately a 1 mg ml^{-1} acetaminophen aqueous solution.

Hydrolysed acetaminophen: transfer accurately 0.1 g of acetaminophen into a 100 ml volumetric flask, add 20 ml of 5 M H_2SO_4, Heat in a boiling water-bath for 30 mins, cool and dilute to volume. Dilute quantitatively in order to obtain a concentration of 50 μg ml^{-1}.

2.5. Preparation of samples

2.5.1. Tablets

Weigh and finely powder 20 tablets. Transfer an accurately weighed amount of powder equivalent to 100 mg of acetaminophen into a 100 ml volumetric flask, add 20 ml of 5 M H_2SO_4, mix well and place in a boiling water-bath for 30 min, then cool and dilute to volume with distilled water. Filter through a Whatman 41 filter-paper. Discard the first portion of the filtrate. Use the clear solution as a stock solution.

2.5.2. Liquid preparations (Syrups, suspension and drops)

Measure accurately a volume of either syrup, suspension or drop samples equivalent to 100 mg of acetaminophen and transfer it to a 100 ml calibrated flask. Add 20 ml of 5 M H_2SO_4 and proceed as for tablets for suspensions and omitting the filtration step for syrups and drops.

2.6. General assay procedure

Transfer 10 ml of either *p*-aminophenol or hydrolysed acetaminophen standard or sample solution into a 50 ml volumetric flask. Add 5 ml of sodium sulphide reagent followed by 5 ml of Fe(III) or Ce(IV) solution. Stopper the flask and

shake for about 30 s, then allow it to stand for 15 min in the case of Fe(III) and 10 min in the case of Ce(IV). Dilute to volume with distilled water, allow to stand for a further 10 min, then measure the absorbance at 550 nm against the corresponding reagent blank.

2.7. Preparation and identification of chromogen

Prepare about 500 ml of the coloured product of *p*-aminophenol with sodium sulphide and Fe(III). To this solution add portionwise a saturated aqueous solution of picric or perchloric acid and stir the mixture vigorously. Keep the mixture in a refrigerator for 24 h. Filter the precipitate picrate salt and wash with water several times. Recrystallize from aqueous ethanol. Dry in vacuum desiccator over calcium chloride and subject to microanalysis and IR identification.

2.8. Microanalysis data

The microanalysis data for the compounds studied are given in Table 1.

3. Results and discussion

3.1. Absorption spectra

p-aminophenol was allowed to react with sodium sulphide in the presence of an oxidant to produce a bluish violet colour ($\lambda_{max} = 550$ nm). The absorption spectra of the reaction product using Fe(III) or Ce(IV) as oxidants are shown in Fig. 1. Colourless reagent blanks were obtained for both oxidants. *N*-Bromosuccinimide was tried as an oxidant but low absorption intensities were obtained.

3.2. Effect of sodium sulphide concentration

The effect of changing the sulphide concentration on the absorbances of solutions containing 10 μg ml^{-1} *p*-aminophenol was studied. From Fig. 2, it is evident that the absorbance increase with increase in sulphide concentration reached a maximum on using 0.025% (w/v) sodium sulphide for both oxidants. Therefore, 0.025% (w/v) sodium sulphide was used in all subsequent work.

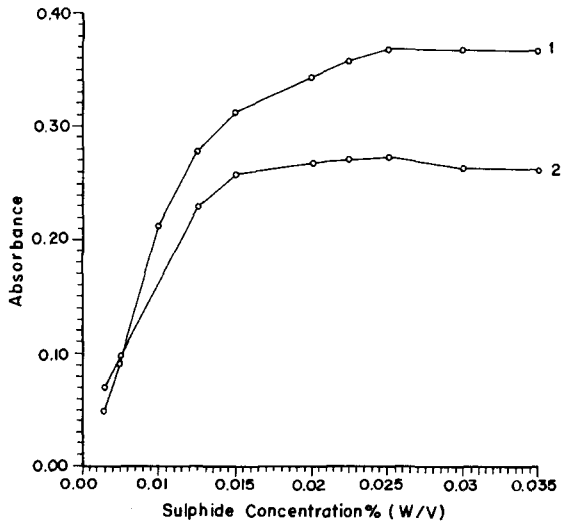

Fig. 2. Effect of variation of sodium sulphide concentration on the absorption intensitiy of the reaction products of 10 μg ml^{-1} *p*aminophenol with (1) Fe(III) and (2) Ce(IV) and Na_2S reagents.

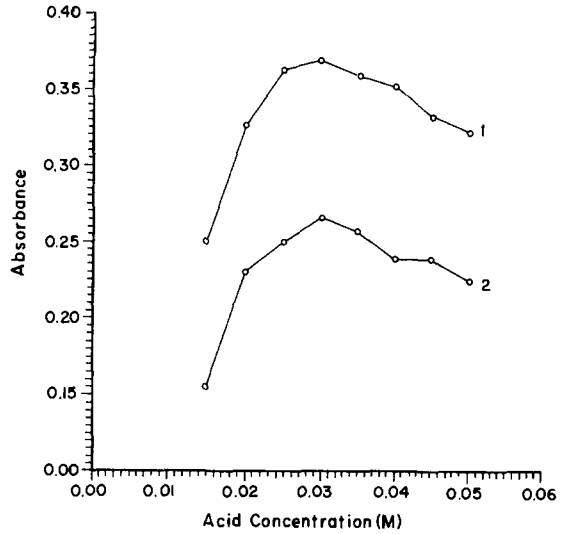

Fig. 3. Effect of variation of sulphuric acid concentration on the absorption intensity of the reaction product of 10 μg ml^{-1} *p*-aminophenol with (1) Fe(III) and (2) Ce(IV) and Na_2S reagents.

3.3. Effect of sulphuric acid concentration

Various concentrations of sulphuric acid, ranging from 0.01 to 0.05 M, were tried to dissolve the oxidant. Fig. 3 indicates that 0.03 M is necessary for maximum colour intensity for both oxidants.

3.4. Effect of oxidant concentration

In order to study the influence of oxidant concentration, the reaction was carried out in a series of 50 ml calibrated flasks containing 10 μg ml^{-1} *p*-aminophenol solution and 5 ml of 0.025% sodium sulphide solution. This was followed by 5 ml of different oxidant concentrations ranging from 0.1 to 0.8% (w/v) in the case of Fe(III) or from 0.03 to 0.15% in the case of Ce(IV) solution. Figs. 4 and 5 indicate that the highest intensities and most reproducible results are obtained on using 5 ml of 0.5% Fe(III) or 5 ml of 0.08% Ce(IV) dissolved in 0.03 M sulphuric acid.

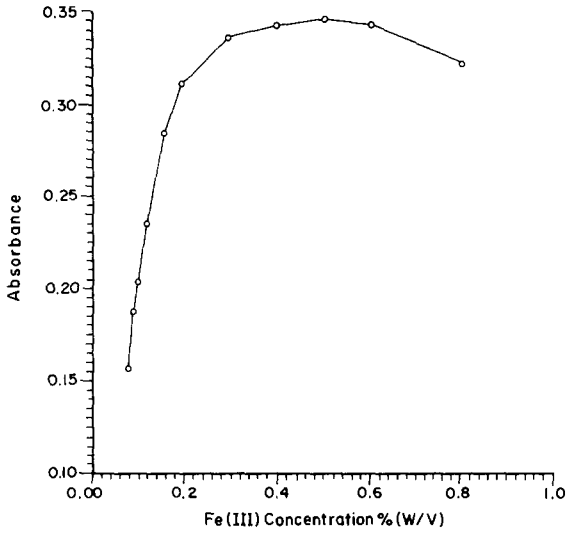

Fig. 4. Effect of variation of Fe(III) concentration on the absorption intensity of the reaction product of 10 μg ml^{-1} *p*-aminophenol with Fe(III) and Na_2S reagents.

3.5. Order of reagent addition

The order of reagent addition was very important as the sulphide solution has to be added to the sample and finally the oxidant. Changing the order produced low results.

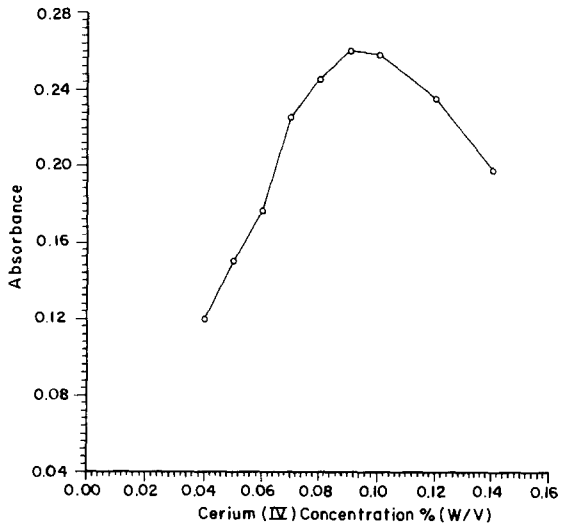

Fig. 5. Effect of variation of Ce(IV) concentration on the absorption intensity of the reaction product of 10 μg ml^{-1} *p*-aminophenol with Ce(IV) and Na_2S reagents.

Table 2
Effect of dilution solvents on the absorption intensity for the interaction product of 10 μg ml^{-1} *p*-aminophenol with sodium sulphide and Fe(III) or cerium (IV) reagents

Solvent	Fe(III)		Ce(IV)	
	λ_{max} (nm)	A^a	λ_{max} (nm)	A^a
Distilled water	550.0	0.300	550.0	0.285
Ethanol	550.0	0.323	551.3	0.245
Methanol	548.0	0.286	546.0	0.239
Dimethyl sulphoxide	553.3	0.257	553.9	0.265
Propan-2-ol	549.3	0.295	550.0	0.267
Acetone	548.6	0.287	548.3	0.290
Dioxane	550.3.	0.294	548.6	0.305

3.6. Effect of temperature and reaction time

The reaction time was determined by following the colour development at room temperature and in a thermostatically controlled water-bath at different temperatures. The flasks were removed after different periods ranging from 5 to 50 min. The absorbance was measured at 5 min intervals against a reagent blank treated similarly. It was observed that at higher temperatures, absorption was maximum after few seconds then decreased rapidly with increasing heating time, probably due to loss of H_2S at higher temperatures. At room temperature the absorbance increased gradually and reached a maximum after 15 and 10 min using Fe(III) and Ce(IV) respectively. Hence these reaction times at room temperatures were chosen for colour development.

3.7. Effect of solvent variation

Dilution of the coloured reaction product with different solvents showed no effect on λ_{max} whereas the absorption intensity was influenced slightly (Table 2). However, distilled water was used as solvent throughout this study.

3.8. Colour stability

After dilution of the coloured solutions with distilled water, a gradual increase in absorption

[d] Recovery using Ce(IV).

intensity was observed throughout the first 10 – min and it then remained constant for more than 3 h. Therefore, absorption measurements were carried out 10 min after dilution with distilled water.

3.9. Quantification

Under the proposed experimental conditions, a linear response between the absorbance and concentration was observed over the concentration

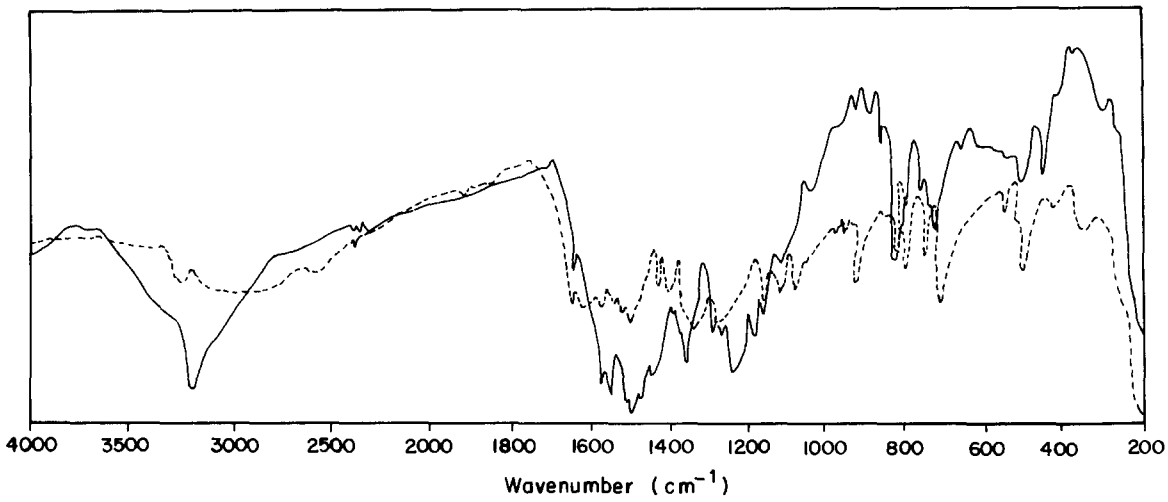

Fig. 6. IR spectra for (–) perchlorate and (---) picrate salts of the dye resulting from the reaction of *p*-aminophenol with Na_2S and Fe(III) reagents.

ranges given in Table 3. Correlation coefficients, intercepts and calibration data are listed in the table.

3.10. Applications

3.10.1. Determination of acetaminophen

Under the proposed experimental conditions, no colour was observed with the intact acetaminophen solution. Only the hydrolysed acetaminophen solution gave an intense colour. Hence the proposed method was applied to the determination of acetaminophen in pure form and in pharmaceutical formulations after its hydrolysis to *p*-aminophenol. Several commercially available acetaminophen formulations, including tablets, drops, syrups and suspension, were analysed for their content of acetaminophen without further treatment. The same samples were analysed using the official method [5]. The official BP procedure depends on UV measurements for paracetamol tablets whereas for solutions and suspensions a liquid chromatographic method is used.

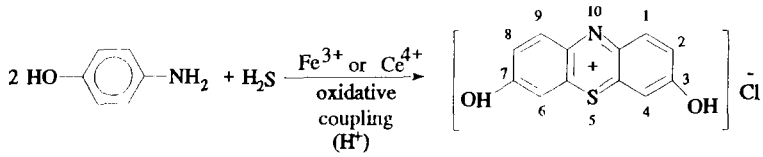
On applying the proposed procedures, good recoveries were obtained with tablets, capsules, solutions, syrups and suspensions without interference from frequently encountered excipients and additives. Moreover, compounds which are usually dispensed with paracetamol, such as acetylsalicylic acid, codeine, caffeine, chlorpheniramine and ascorbic acid, did not interfere. As shown in Table 4, the results are in good agreement with those given by the offical BP method.

3.10.2. Determination of p-aminophenol in the presence of acetaminophen

p-Aminophenol, which is reported to have significant toxicity such as teratogenic effects and nephrotoxicity, has been detected in acetaminophen as an impurity which can either be a synthetic intermediate or a degradation product [1]. The proposed method was applied to the determination of *p*-aminophenol in pure form and in the presence of acetaminophen. The method allowed the determination of *p*-aminophenol in the presence of acetaminophen without prior separation. The results obtained are accurate and precise. Average recoveries of 100.4 ± 0.8 and 100 ± 1 were obtained using Fe(III) and Ce (IV) as oxidants, respectively.

3.11. Investigation of reaction mechanism

The reaction product could be isolated as picrate and perchlorate salts and subjected to microanalysis, UV–Vis and IR identification tests.



Scheme. 1. Suggested mechanism for the reaction *p*-aminophenol with Na_2S and Fe(III) to form a methylene blue-like dye.

A λ_{max} of 550 nm was obtained. On the other hand, the IR spectrum of both picrate and perchlorate salts of the isolated reaction product of *p*-aminophenol with sodium sulphide (Fig. 6) shows a significant difference from that of the pure compound in region of 3500–3100 cm^{-1}. The disappearance of the doublet peaks that are characteristic of a primary amino group indicates that the nitrogen is the possible reaction site. In addition, analogous structures have been reported before for methylene blue [25] and methylene blue–like structure [26]. From the microanalysis data and IR spectra, a mechanism for the reaction could be suggested (Scheme 1).

4. Conclusion

The proposed method offers several advantages over previously reported procedures. With the proposed method any UV-absorbing material, e.g. caffeine, pheniramine and acetylsalicylic acid, should not interfere when present in the quantities encountered in pharmaceutical preparations. The proposed method could be used in the detection of *p*-aminophenol in the presence of acetaminophen. In addition, it could be used for determination of acetaminophen in biological fluids, which will be our target in the future.

Lability of heavy metal species in aquatic humic substances characterized by ion exchange with cellulose phosphate

J.C. Rocha[a,*], I.A.S. Toscano[a], P. Burba[b]

[a] *Analytical Chemistry Department, Institute of Chemistry of Araraquara, UNESP 14800-900, CP 355, Araraquara, SP, Brazil*
[b] *Institute for Spectrochemistry and Applied Spectroscopy (ISAS), 44139 Dortmund, Germany*

Received 21 February 1996; revised 4 June 1996; accepted 12 June 1996

Abstract

Labile metal species in aquatic humic substances (HSs) were characterized by ion exchange on cellulose phosphate (CellPhos) by applying an optimized batch procedure. The HSs investigated were pre-extracted from humic-rich waters by ultrafiltration and a resin XAD 8 procedure. The HS–metal species studied were formed by complexation with Cd(II), Ni(II), Cu(II), Mn(II) and Pb(II) as a function of time and the ratio ions to HSs. The kinetics and reaction order of this exchange process were studied. At the beginning (<3 min), the labile metal fractions are separated relatively quickly. After 3 min, the separation of the metal ions proceeds with uniform half-lives of about 12–14 min, revealing rather slow first-order kinetics. The metal exchange between HSs and CellPhos exhibited the following order of metal lability with the studied HSs: Cu > Pb > Mn > Ni > Cd. The required metal determinations were carried out by atomic absorption spectrometry.

Keywords: Aquatic humic substances; Cellulose phosphate; Heavy metal species; Ion exchange; Lability

1. Introduction

The main mass of organic carbon distributed in natural aquatic environments and soils is concentrated in humic substances (HSs). In general, HSs, final products of microbial degradation processes of plant remnants in soils and waters, are complex mixtures of organic macromolecules of varying molecular-weight distributions, substructures and functionalities [1]. They can be transported into natural waters by the leaching process or formed directly in aquatic environments by the decomposition of plants and aquatic organisms. Despite their great variety and heterogeneity, HSs mostly exhibit comparable functional groups of phenolic and carboxylic types and are characterized by their exceptional complexation capabilities towards metal ions, as studied during the last decade [2–6].

* Corresponding author Fax: (+55) 162-22-7932.

PII S0039-9140(96)02017-6

Due to their complexation properties HSs are important natural buffers in the environment, binding strongly both inorganic and organic pollutants. The thermodynamic and kinetic stability of the HS–pollutant species formed influences directly their transport, accumulation and bioavailability in the biosphere [7,8]. In aquatic systems, the concentrations of dissolved metal ions and HSs and their ratio can vary considerably and hence might influence the formation of HS–metal species as well as their distribution between liquid and solid phases (e.g. suspended matter, sediment). Therefore, investigations of exchange processes between HSs and metal ion are of great interest when studying the hydrogeochemical turnover of metal in soil and natural waters [9], especially under the influence of acid rain caused by the increasing pollution of the atmosphere by man-made nitrogen and sulfur oxides [10].

From this point of view, analytical information on the lability of HS–metal species and their possible transformation into species of either higher or lower stability is of increasing relevance. For this purpose, a variety of methods have been proposed, such as electrochemical and chromatography techniques, in order to study the complexing capacity of HSs, the HS–metal equilibrium and the dynamics of complexes [11,12]. The advantageous application of immobilized chelators for the differentiation of labile and inert metal species in HSs by ligand exchange has been described in other reports [13–15]. In the previous papers, both the kinetics and the degree of metal exchange have been used for the operational characterization of metal labilities in aquatic HSs. In the present study, the lability of metal fractions complexed with dissolved HS was characterized by ion exchange on cellulose phosphate (CellPhos), which has been shown recently to be a collector of high efficiency and with fast kinetics for traces of heavy metals dissolved in aqueous salt solutions [16]. Applying an optimized batch procedure based on the usage of CellPhos, a number of important parameters (such as pH, HS concentration, complexation time) which influence the lability of environmentally relevant metal ions (e.g., Cd, Ni, Mn, Cu and Pb) in HSs were evaluated [17].

2. Experimental

2.1. Sampling of aquatic HSs

Humic-rich water was sampled (100 l) from a reservation bog lake (Venner Moor (VM 4); 8 mg l^{-1} dissolved oxygen content (DOC), pH 3.7) located in Münster, Germany and recently described elsewhere [18,19]. After filtration through a 0.45 μm membrane, 50 l of the sample was concentrated by ultrafiltration (UF) to 0.5 l (maintaining the original pH of 4.5) using a Millipore Pellicon system in tangential flow mode (0.42 m^2 membrane area, nominal molecular weight cut-off 1000 Da, 30 ml min^{-1} penetration rate). The UF concentrate (VM 4-UF with 90% recovery of HSs) contained 3.5 mg ml^{-1} DOC, exhibiting a complexing capacity of 3.3 mmol Cu(II) g^{-1} DOC (referred to DOC of HS), which was determined by a Cu(II)-selective electrode.

2.2. CellPhos and cellulose HYPHAN sorbents

The cellulose sorbent CellPhos used in this study for the separation of labile metal fractions in HSs was functionalized according to Ref. [20]. It is comparable to the commercial Chelex P (Bio-Rad, USA). This collector has a surface area of 1.94 ± 0.06 m^2 g^{-1} and 1.3 ± 0.09 mol g^{-1} of immobilized phosphate groups.

Cellulose HYPHAN (functional group: 1-(2-hydroxyphenylazo)-2-naphthol, supplied by Riedel-de Haën AG, Hannover, Germany) used for the removal of heavy metals from HS concentrates was applied according to recommendations given in Ref. [14].

2.3. Preparation of standardized HS solutions

In order to remove the metals naturally contained in the HS concentrate (50 ml VM 4-UF) it was magnetically stirred for 72 h with 1 g of cellulose HYPHAN. The pH value was maintained at 8.0. After filtering and adjusting the pH to 4–5 the purified HS solution was stored in polyethylene bottles for defined periods of time in a refrigerator at 4°C.

Stardardized HSs loaded with heavy metal ions under defined conditions were prepared in the following way. First, the HS concentrate was diluted to the desired HS concentration (e.g. 10 mg ml^{-1} HS, 10 ml sample) by adding high-purity water (Milli-Q system, Millipore) and then spiked with a multimetal standard solution (e.g. 0.5 μg ml^{-1} Cd, 2.0 μg ml^{-1} Cu, 1.0 μg ml^{-1} Mn, 2.0 μg ml^{-1} Ni, 2.0 μg ml^{-1} Pb), adjusting the pH to the desired values with dilute solutions of NaOH and HCl. After defined periods of time (complexation time) these standardized HS samples were used in subsequent batch experiments.

2.4. Batch procedure

Distribution coefficients, K_d, of metal ions between the chosen adsorbent (CellPhos) and dissolved HS were evaluated by a batch procedure. 10.0 ml of standardized HS, preloaded with metal ions for a complexation time of 24 h, and 80.0 mg of CellPhos were stirred for 24 h. The collector was filtered through a filter paper (2 cm diameter) previously precleaned with 1.0 M HCl p.a. Then the resin, together with the filter paper, was eluted with 3.0 ml of 2.0 M HCl suprapur. After centrifugation of the eluate the metals contained were determined by flame atomic absorption spectrometry (AAS).

2.5. Metal determinations by AAS

Trace metals concentrated in the eluate were determined according to the operating instructions of the manufacturer (Spectrometer Varian-Intralab-AA 1475). Synthetic metal standards having the same acid concentration (2.0 M HCl) as the experimental samples were used for calibration.

3. Results and discussion

Efficient multielement preconcentration by an ion-exchange batch process requires collectors with high distribution coefficients, K_d, preferably $>10^4$, as calculated by the following equation:

$$K_d = C_{col}/C_{sol}(ml\ g^{-1})$$

where C_{col} is the concentration of metals in the collector (mg g^{-1}) and C_{sol} is the concentration of metals in solution (mg ml^{-1}). When using the ion exchanger CellPhos as collector for the labile metal fraction in the HS solution, K_d values of 10^2–10^3 (ml g^{-1}) were obtained in the pH range 3.0–11.0. As shown in Fig. 1, all metals exhibit curves with a maximum in neutral solutions and a small reduction in slightly acidic and alkaline solutions. Therefore, metal ions complexed by HSs are easily exchanged by the phosphate groups of the collector. At pH < 3 metal ions are increasingly remobilized from both HS molecules and phosphate groups of the collector.

Chelating ion exchangers based on cellulose often exhibit high distribution coefficients of the order of 10^4 for metal ions such as Cu, Ni, Co, Pb, Mn and Zn in salt solutions [13,14,21]. Moreover, the separation of the metal ions from aqueous solutions by cellulose collectors (but in the absence of HS) can be characterized by a relatively short half-life, $t_{1/2}$, in the range of 8–20

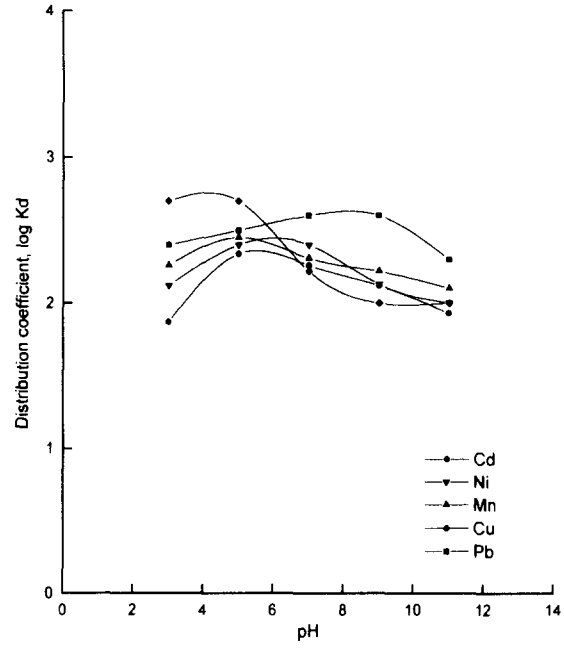

Fig. 1. Metal distribution coefficient K_d on CellPhos in the presence of HSs as a function of pH (1.0 mg ml^{-1} HS VM-4 UF, 24 h equilibrium, 10 ml sample, 80.0 mg CellPhos).

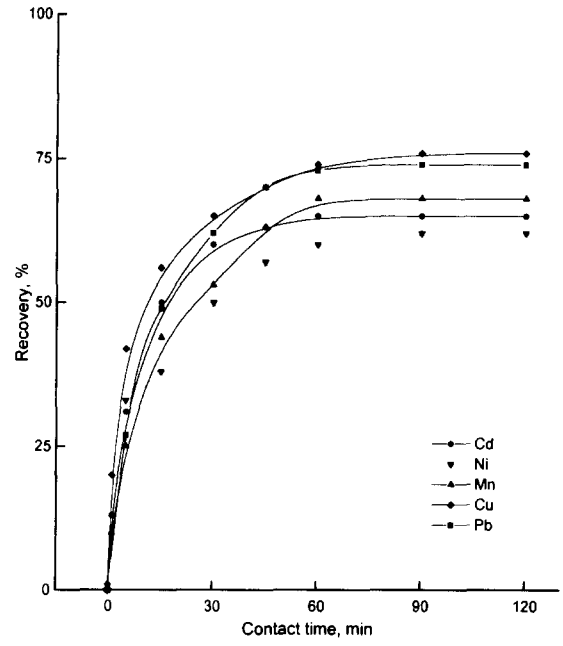
s as recently shown in Ref. [14]. The equilibrium between collector and solution phase is established within a matter of minutes. In a recent paper [13] it was shown, however, that the separation kinetics of metal ions complexed by HSs can be delayed by orders of magnitude. Both effects, the delayed kinetics and the reduced recovery rates of HS-bound metal fractions, have been utilized for the operation characterization of their lability. The following order was reported: Mn > Zn > Cu > Ni > Fe [14].

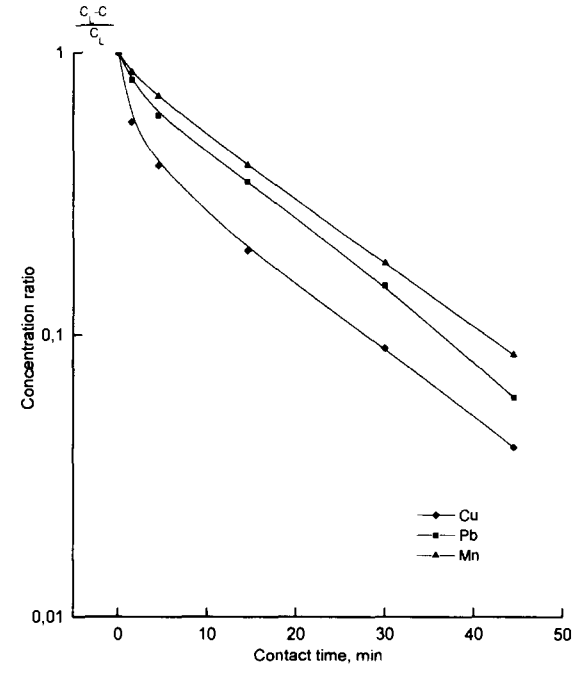
The collector HYPHAN applied for the evaluation of this lability order [14], however, suffered from the drawback of a relatively high working pH (8.0) necessary for quantitative metal separation by a batch operation, in contrast to the CellPhos usage proposed in the present study. Similar labilities of aquatic HS–metal species could be shown as well by means of an analogous flow procedure based on a strongly chelating collector of EDTA-type [21].

The separation of metal ions complexed to HS (1.0 mg ml^{-1}, VM 4-UF, 0.1 μmol ml^{-1} sum of Cd, Cu, Mn, Ni and Pb) by means of CellPhos is shown in Fig. 2a as a function of the contact time. Accordingly, a contact time of >60 min is required to attain the exchange equilibria as shown in reaction (1) and to obtain a final recovery of 65–75% metal by CellPhos, depending on the element.

The kinetics and reaction order of this ion-exchange process can be derived from Fig. 2b, which exhibits the separation of the exchange-labile Cu, Mn and Pb (concentration C_L) logarithmically plotted as a function of the contact time. At the very beginning (3), merely 50% of the HS-bound Cu(II) and about 20% of the Mn and Pb are separated relatively quickly. After 3 min, the separation of the HS-bound metal ions proceeds with uniform $t_{1/2}$ values of about 12–14 min, revealing rather slow first order kinetics compared to metal exchange by CellPhos from aqueous salt solutions ($t_{1/2}$ in the range 10–25 s [17]). These first-order kinetics indicate that either slow dissociation of the HS–metal complexes may occur or else delayed transport of the macromolecular HS–metal complexes within the narrow pore system of the cellulose collector may take place.



(a)



(b)

Fig. 2. (a) Batch separation of HS-bound metal ions as a function of the contact time (1.0 mg ml^{-1} HS VM-4 UF, 2.0 μg ml^{-1} of each trace metal, pH 5.0, 24 h equilibrium, 80.0 mg CellPhos). (b) Separation of exchange-labile metal fractions (concentration C_L) from HSs as a function of the contact time (for conditions, see Fig. 2a).

In principle, the exchange of metal ions between resins and labile macromolecular metal complexes such as HS–M can be described by the following equilibrium:

$$\underset{\text{solution}}{\text{HS–M}} \overset{K_{HS}}{\rightleftharpoons} \text{HS} + \text{M} + \text{EX} \overset{K_{Ex}}{\rightleftharpoons} \underset{\text{exchanger}}{\text{M–Ex}} \quad (1)$$

where HS–M indicates species formed between metal and HSs, Ex indicates ion exchanger, solid phase, and M–Ex indicates species formed between metal and collector. Thus, the concentrations of species HS–M and M–Ex, governed by the equilibrium constants K_{HS} and K_{Ex}, are shifted towards HS–M as the concentration of HSs increases. The influence of increasing HS concentration on the metal distribution on the collector CellPhos is shown in Fig. 3. An eightfold increase in the HS concentration (e.g 4.0 mg ml^{-1} HS) lowers the metal distribution coefficients K_d by about a factor of five to about 10^2 ml g^{-1}. Consequently, in the case of very high HS concentrations only a multistage flow procedure using CellPhos-filled columns can be used for quantitative separation of labile metals fractions in HSs.

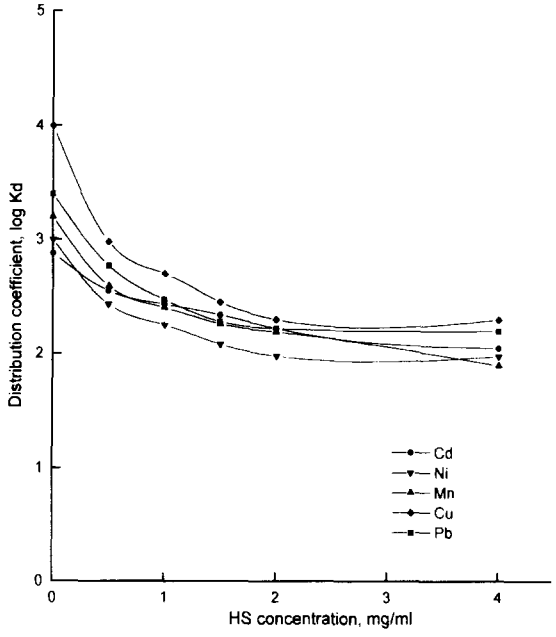


Fig. 3. Metal distribution coefficients K_d as a function of the HS concentration (HS VM-4 UF, 2.0 μg ml^{-1} of each trace metal, pH 5.0, 24 h equilibrium, 80.0 mg CellPhos).

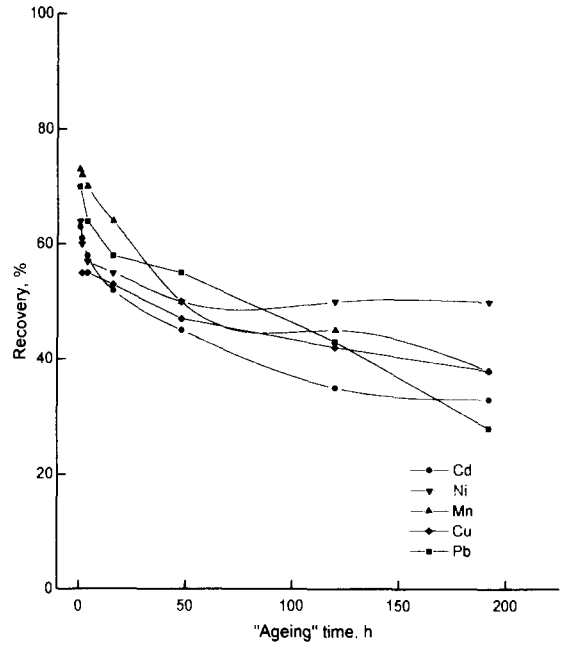

Fig. 4. Lability of heavy metals in HSs as a function of "ageing" (batch procedure, 1 mg ml^{-1}) HS VM-4 UF complexed with 2.0 μg ml^{-1} of each trace metal, pH 5.0, 80.0 mg CellPhos).

Another important parameter strongly influencing the lability of metals bound in HSs is the time of complexation ("ageing") of the HS–M species formed, as has recently been shown in a paper dealing with the exchange process between HS–metal species and chelating collectors [14]. A similar transformation effect (as shown in Fig. 4) may be observed in the case of metal exchange between dissolved HSs and CellPhos. For instance, after a complexation period of 8 days the Cu(II) recovery is reduced form $\approx$55% to $\approx$20%. A similar decrease in metal lability in HSs can be observed for several other metal ions.

4. Conclusions

The thermodynamic and kinetic stabilities of HS–metal species depends on a variety of environmental parameters, in particular the pH values, the metal and HS concentrations and their ratio, the complexation capability of the HSs and

potential transformation processes which are still poorly characterized. Thus, the stability of HS–metal species in aquatic environments cannot be described solely by conventional thermodynamic stability functions measured for HS–metal complexes freshly formed "in vitro". There is a special demand for analytical methods applicable for the evaluation of the lability of HS–metal species and their changes due to potential ageing processes.

Our investigations using the collector CellPhos for the characterization of labile metal fractions in aquatic HSs are an additional confirmation of the utility of the ion-exchange method. Both the kinetics and the degree of separation can be used for the operational evaluation of the metal lability in HSs as a function of different parameters (e.g. pH, ratio of metal: HS, complexation time). In particular, the influence of the complexation time of HS–metal species on their lability shows that the " reactivity" of such species depends not only on their thermodynamic stability but also on typical transformation processes. The operational character of such ion-exchange procedures, however, only allows the description of a relative order of metals labilities in dissolved HSs under standardized conditions.

Spectrophotometric determination of lithium with Quinizarin in drugs and serum

Laura Gámiz Gracia, Luis Cuadros Rodríguez*, Manuel Román Ceba

Department of Analytical Chemistry, Faculty of Sciences, University of Granada, c/ Fuentenueva s.n., E-18071 Granada, Spain

Received 4 October 1995; revised 15 May 1996; accepted 17 June 1996

Abstract

A very sensitive analytical method is proposed for the determination of lithium based on the reaction of Li^+ ion wiht 1,4-dihydroxyanthraquinone (Quinizarin). In dimethylsulfoxide medium (90%) and in the presence of sodium hydroxide and sodium carbonate, a bluish-violet color ($\lambda_{max} = 601$ nm) develops and is stable over a period of 30 min to 2.5 h. The NaOH and Quinizarin concentrations were optimized simultaneously using the response surface methodology from sequential experimental Doehlert designs. Beer's law is obeyed in the concentration range 14–250 ppb Li^+ in aqueous and serum matrices, and the errors (RSD) in the determination of 100 ppb Li^+ are 4.0% and 3.9% respectively. The proposed procedure was satisfactorily applied to the determination of lithium in drugs and human serum (no deproteinization is required).

Keywords: Doehlert experimental design; Lithium; Quinizarin; Visible-spectrophotometry

1. Introduction

Lithium, like other alkali metals, shows relatively poor chemical coordination. However, its high charge density provides greater affinity to ligands with donor oxygen atoms than the rest of the alkali metals and therefore lithium forms stable chelates in solution more easily [1,2]. Therefore, few organic reagents which form colored chelates with alkali metals are known.

Several chromogenic organic reagents with two aromatic rings linked by an azo group (–N=N–) with ortho substituents –OH in one ring and –COOH, $-PO(OH)_2$ or $-AsO(OH)_2$ in the second ring have been used as complexing agents of Li^+ (Thoron, Quinazolinazo, Nitroantranylazo, Phosphonazo R, Arsenazo III) in photometric determinations [3]. Among these, Thoron (*o*-(2-hydroxy-3,6-disulfo-1-naphthylazo)benzenearsonic acid) has been the most used. Proposed by Kuznetsov [4], it gives, together with Li^+ ion, an orange color in a strong basic medium. The spectrophotometric method using this reagent, developed by Thomason [5], has been used for the determination of lithium in high-purity beryllium and beryllium oxide [6], sea water [7], mollusc shells [8] and blood serum [9].

PII S0039-9140(96)02018-8

Multidentate ligands derived from 3-fenilformazano ($NH{=}N{-}C(Ph){=}N{-}NH_2$) have also been suggested as spectrophotometric reagents for Li^+ [10–14].

Recently, with the development of macrocyclic ligands such as crown and aza-crown ethers, cryptands and spherands, new spectrophotometric methods for the determination of lithium in drugs, serum and urine samples have been proposed. These methods show good selectivity against other alkali metals but due to the low solubility of this type of ligand anhydrous media [15], extraction processes [16,17] or the use of a water–micellar medium is required for solubilization [18].

Quinizarin (1,4-dihydroxyanthraquinone) is a chromogenic and fluorogenic agent of metallic ions that shows high selectivity in its reactions since the O-donors are blocked by two strong intramolecular hydrogen bondings [19]; therefore, few spectrophotometric methods using this reagent are known. This reagent has been applied for the determination of Mg^{2+} [20] and UO_2^{2+} [21] and for the simultaneous determination of Lu^{3+} and Pr^{3+} [22] and Tm and Nd [23]. Other similar reagents have also been used occasionally such as Quinizarin-sulfonic acid (1,4-dihydroxy-anthra quinone-2-sulfonic acid) for Be^{2+} [24] and Al^+ [25]; Leucoquinizarin(1,4,9,10-tetrahydroxyanthracene) for Mg^{2+} [26] and Be^{2+} [27], and naphthazarin (*5,8-dihydroxy-1,4-naphthoquinone*) for Th^{4+} [28], and Th^{4+} and UO_2^{2+} simultaneously [29].

Response surface methodology (RSM) [30] is a group of mathematical and statistical techniques used for analyzing and modeling a problem where a particular response is a function of several variables, and where the aim is to optimize this response. RSM obtains an appropriate estimate of the real functional relationship between the instrumental response and the experimental factors under study. A quadratic function is the best solution as it is a simple model which can describe a great variety of surfaces [31], allows the prediction of the existence of curvature in the system and permits the computation of the maximum coordinates. In addition, this type of function can be simply obtained with a three-level experimental design.

In this paper, a sensitive method for the spectrophotometric determination of lithium in dimethylsulfoxide: water medium in the range 14–250 ppb lithium is proposed. The method is suitable for the clinical assay of lithium.

2. Experimental

2.1. Instrument

A Perkin-Elmer Lambda 5 UV–Vis spectrophotometer with two matched 1 cm quartz cells, thermostatically controlled at 25.0 ± 0.5°C with a water-bath circulator (Frigiterm S-382, J.P. Selecta), and a Corning 410 Flame Photometer were used.

A Casio FX-850 P pocket micro-computer with scientific library was used to calculate *P* values os statistic tests. All the calculations for optimization were carried out using the STATGRAPHICS data analysis package [32].

2.2. Reagents and materials

All materials, solvents and reagents were of analytical grade and were used without further purification. Doubly-distilled water was used throughout.

2.2.1. Lithium solution

A stock solution of Li^+ (500 ppm) was prepared by dissolving 1.24 g of lithium nitrate (Merck) in 250 ml of water. Working solutions were prepared by appropriate dilution of the stock solution.

2.2.2. Quinizarin solution

A 10^{-3} M solution was prepared by dissolving 60 mg of 1,4-dihydroxyanthaquinone (Merck) in 250 ml of dimethylsulfoxide.

2.2.3. Sodium hydroxide solution

A 1 M stock solution was prepared by dissolving 10 g of NaOH (Merck) in water. Working solutions were prepared daily by appropriate dilution of the stock solution.

2.2.4. Sodium carbonate solution

A 2.5 M stock solution was prepared by dissolving 66.237 g of sodium carbonate (Merck) in 250 ml of water. Working solutions were prepared by appropriate dilution.

2.3. Drug and serum

In order to verify the applicability of the proposed analytical method, the determination of lithium in the following real samples was validated

2.3.1. Otogén (Rimafar Laboratory S.A., Madrid, Spain)

Tablet containing lithium carbonate, potassium bromide, potassium iodide, thiamine and excipient. Mean weight of tablet: 319 mg.

2.3.2. Plenun (Lasa Laboratory, Barcelona, Spain)

Tablet containing lithium carbonate and exicipient. Mean weight of tablet: 516 mg.

2.3.3. Glucosor-Litio (Soria Natural, S.A., Soira, Spain)

Solution containing lithium gluconate, glucose and distilled water.

2.3.4. Serum

Blood serum from healthy individuals who had not been treated with lithium salts was centrifuged for 5 min at 4000 rev min^{-1} [33] and the supernatant liquid was separated and kept frozen at −15°C until the analysis. Once thawed, analyis must be done within 7 days [34]. Serum samples required no deproteinization.

2.4. General procedure for drugs

Using a micropipet, the indicated amount of standard or sample preparation was added to a test tube, followed by 50 μl of 0.1 M NaOH, 40 μl of 0.25 M Na_2CO_3 and water to make up to 1 ml. 250 μl of this solution was pipeted into another test tube, followed by 2.15 ml of dimethylsulfoxide and 100 μl of 10^{-3} M Quinizarin. The tubes were kept at 25°C in a thermostatic bath for 30 min. The absorbance of the solution was measured at 601 nm against a reagent blank prepared similarly. The calibration was made under identical conditions.

2.4.1. Otogen

Exactly 319 mg, obtained from 10 tablets previously powdered, was placed in a 100 ml glass beaker. 10 ml of 1 M hydrochloric acid was added and the solution was digested close to dryness. The residue was extracted with 10 ml of hot water, filtered, washed, transferred to a 100 ml volumetric flask and made up to volume with water. 40 μl of this solution was used for the analysis of lithium as described in section 2.4.

2.4.2. Plenur

The same procedure was followed, starting with 516 mg of the sample, transferring the final filtrate into a 250 ml volumetric flask and making up to volume with water. This solution was diluted 1:10 with water taking 50 μl for the subsequent analysis as described in section 2.4.

2.4.3. Glucosor-Litio

1 ml of sample was pipeted into a 10 ml volumetric flask and made up to volume with water. 100 μl of this solution was used, as described in section 2.4.

2.5. Procedure for serum

Accurately pipeted amounts (40, 50 and 70 μl) of standard lithium solution (50 ppm) were added to 500 μl of centrifuged serum and these solutions were diluted with water to make up to 1 ml. 100 μl portions of each of these spiked serum soltutions were pipeted into a test tube, followed by 100 μl of 0.1 M NaOH, 10 μl of 0.25 M Na_2CO_3, 40 μl of water, 2.15 ml of dimethylsulfoxide and 100 μl of 10^{-3} M Quinizarin. The procedure was completed as described in section 2.4. The calibration was made with lithium standards of increasing concentration, containing 100 μl of centrifuged pooled serum (obtained by mixing serum of 10 individuals) diluted 1:1 with water, and operating under the conditions described above.

3. Results and discussion

All the abosorbance measurements for optimization, calibration and interference experiments were performed against a corresponding solvent blank prepared under identical conditions.

3.1. Effect of dimethylsulfoxide: water ratio

The maximum absorption wavelengths and the absorbance difference between chelate and reagent are strongly dependent on the solvent. All the described spectrophotometric methods require a polar, water-miscible solvent and so water, methanol, ethanol, ethyline glycol, 2-propanol, acetone, acetonitrile, *N,N*-dimethylformamide, hexamethylphosphotriamide, dimethylsulfoxide, 1,4-dioxan and pyridine were tested in order to find the maximum absorbance difference. The results of this experiment are shown in Table 1. Dimethylsulfoxide was selected because it showed the maximum difference and the maximum hipsochromic displacement between the two spectra.

Table 1
Experimental values of wavelengths and absorbance for the system lithium–Quinizarin in different solvent/water mixtures (9/1, v/v) (Experimental conditions: $[Li^+] = 1.2 \times 10^{-4}$ M; $[NaOH] = 5 \times 10^{-3}$ M; $[Quinizarin] = 4.8 \times 10^{-5}$ M)

Solvent	λ_b[a]	λ_b[c]	$\Delta\lambda$[c]	$A^d{}_{max}(\lambda_d)$[e]
Water	550	550	0	0.023

[g] Dimethylsulfoxide.

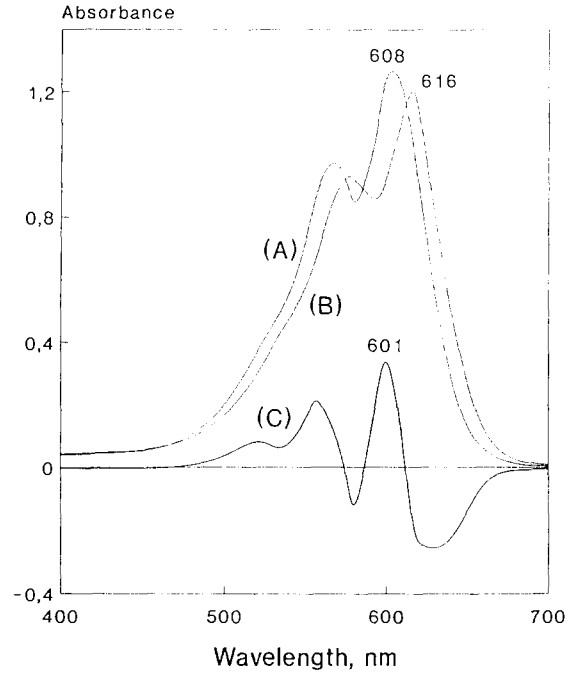

Fig. 1. Absorption spectra in 90% dimethylsulfoxide: (A) chelate; (B) ligand blank; (C) difference. ($[Li^+] = 1.2 \times 10^{-3}$ M, $[Quinizarin] = 4.8 \times 10^{-4}$ M, $[NaOH] = 5 \times 10^{-3}$ M)

As the proportion of water was increased, the absorbance of the chelate, measured against a reagent blank, decreased. Thus a proportion of 10% of water was selected as this provided sufficient aqueous phase for the preparation of the samples.

3.2. Absorption spectra

Fig. 1 shows absorption spectra of chelate and ligand blank against the solvent in 90% dimethylsulfoxide. Both curves show a maximum difference at 601 nm.

3.3. Effects of the Quinizarin and sodium hydroxide concentrations

Sodium hydroxide was selected (instead of KaOH or an organic base) in order to give an homogeneous background for the serum analysis. Molecular spectroscopic methods for the determination of lithium show a great interfering effect

from the other ions in solution, of which Na^+ is the principal one in a serum matrix, so in order to prevent possible interference from Na^+, NaOH was selected.

The NaOH and Quinizarin concentrations were optimized using the RSM from sequential experimental Doehlert designs [35] (Fig. 2), proposed by Bosque Sendra et al. [36,37], in order to obtain the maximum absorbance while simultaneously varying these two parameters for a constant lithium concentration of 1.2×10^{-4} M. These designs have never been used in optimization of experimental variables in analytical methods by molecular absorption spectrophotometry in solution.

As the central point, the values $-\log[\text{NaOH}] = 2.0$ and $10^5 \times [\text{Quinizarin}] = 2.0$ M were chosen for the first experimental design. Table 2 (Design I) shows the proposed Doehlert design and the experimental results obtained for the chelate absorbance measured against a reagent blank. Since

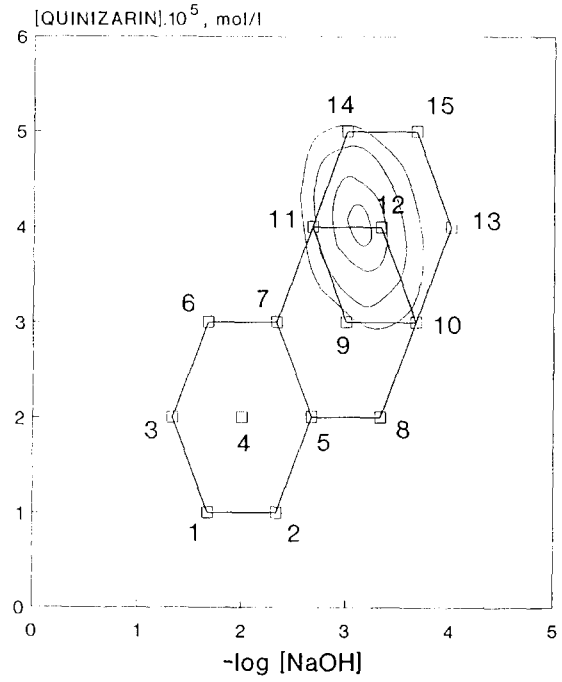

Fig. 2. Representation of the Doehlert designs I, II and III used for the simultaneous optimization of the Quinizarin and NaOH concentrations. Contour diagram of the response surface obtained from design III (the curves indicate 0.4, 0.5, 0.6 and 0.64 units of absorbance).

one of the factors is at five levels and the other at three levels, it is preferable to choose the variable with the stronger effect as the first factor. In this case, the five-level factors was chosen for $-\log[\text{NaOH}]$. The experimental data obtained fitted the function

$$A = 544.86 - 277.33Y - 372.38X + 115.15XY + 33.13Y^2 + 76.85X^2$$

where A = absorbance, $X = -\log[\text{NaOH}]$ and $Y = 10^5 \times [\text{Quinizarin}]$ (concentrations in moles per liter). The application of Lagrange's criterion ($\partial^2 A/\partial X^2 = 153.8, \partial^2 A/\partial Y^2 = 66.2, H(X, Y) = -3089.5$) indicated the presence of a saddle point. As no maximum was found, the absorbance maximum variation directions at points 5 and 7 (Fig. 2) were calculated, since this appeared to be the direction of increase in the response. The maximum variation directions of response found for each point were 29.77° and 31.2°. Because the two directions are almost parallel, a new experimental design is carried out in the referred direction (Fig. 2).

The proposed Doehlert design II was centred on the point $X = 3.0$, $Y = 3.0$, and the new experimental results obtained are shown in Table 2 (Design II). The equation which fits the new experimental values is

$$A = -1049.59 - 283.82Y + 11.4076X + 25.76XY + 49.59Y^2 - 198.25X^2$$

The application of Lagrange's criterion indicated the presence of a saddle point ($\partial A^2/\partial X^2 = -396.5$, $\partial A^2/\partial Y^2 = 99.2$, $H(X, Y) = 39\,991.9$). The absorbance maximum variation directions at the (11) and (12) points were calculated (Fig. 2). The maximum variation directions of responses found for each point were 44.47° and −68.91°. The lines drawn from the points, with the calulated directions, intersected at a coordinate point $X = 3.15$ and $Y = 4.47$.

Table 2 (Design III) shows the proposed Doehlert design III, centred on $X = 3.33$ and $Y = 4.00$, and the experimental results obtained. The contour diagram of the response surface is shown in Fig. 2. The new equation fitted to the experimental values is

Table 2
Experimental values used in the simultaneous optimization of Quinizarin and NaOH concentrations (mol l^{-1}), from Doehlert designs I, II and III ($[Li^+] = 1.2 \times 10^{-3}$ M)

Doehlert design	Experiment	$10^5 \times$ [Quinizarin]	−log[NaOH]	Absorbance
(I)	1	1.0	1.67	0.075
	2	1.0	2.33	0.129
	3	2.0	1.33	0.80
	4	2.0	2.00	01.46
	5	2.0	2.67	0.281
	6	3.0	1.67	0.170
	7	3.0	2.33	0.376
(II)	8	2.0	3.33	0.423
	9	3.0	3.00	0.415
	10	3.0	3.67	0.276
	11	4.0	2.67	0.446
	12	4.0	3.33	0.622
(III)	13	4.0	4.00	0.179
	14	5.0	3.00	0.490
	15	5.0	3.67	0.031

$$A = -13\,029.40 + 2669.22Y + 5318.84X - 238.81XY - 239.41Y^2 - 696.71X^2$$

The application of Lagrange's criterion indicated the presence of a maximum ($\partial A^2/\partial X^2 = -1393.4$, $\partial A^2/\partial Y^2 = -478.8$, $H(X, Y) = 610\,172.6$), which is the required optimum and corresponded to 4.0×10^{-5} M Quinizarin and 7.4×10^{-4} M NaOH.

The pK_1 and pK_2 values of Quinizarin in water are 9.35 and 11.78 respectively [38] while in 9:1 dimethylsulfoxide:water they should be slightly higher due to the lower value of the dielectric constant (46.5) of this proton-donor solvent with respect to that of water (78.3) [39]. The optimum working value of apparent pH found ($\approx$10.9) shows that only the first acid disociation occurs and the corresponding mono-anion is the reactive species.

3.4. Effect of concentrations of salts

The effect of increasing concentrations (10^{-4}–0.1 M) of different salts (Na_2CO_3, NaCl, KCl) on the abosorbance of the chelate, measured at 601 nm against a reagent blank, was studied. A maximum absorbance was obtained for a 10^{-3} M concentration of Na_2CO_3.

3.5. Effect of temperature

When the solution was thermostated between 10 and 50°C the absorbance of the chelate showed a linear decrease (temperature coefficient = -8.1×10^{-3} absorbance units $°C^{-1}$), while the absorbance of the reagent blank appeared to be constant. A working temperature of 25°C was chosen.

3.6. Other variables

The effect of the order of addition was studied, and found to be insignificant. Measurements were stable 30 min to 2.5 h after the preparation.

2.5. Calibration curve (Beer's law)

Experiments indicated that the Beer's law was obeyed for lithium concentrations up to 250 ppb, while higher concentrations yielded a non-linear response. New factorial designs (2^2) were performed in order to check the optimized NaOH

Table 3
Statistics and performance characteristics of the analytical methods from the calibration data set in aqueous and serum matrices

Parameter	Matrix	
	Water	Serum
Statistics		
Residual standard deviation (a.u.)[a]	3.909	2.883
Intercept (a.u.)	-2.51×10^{-3}	1.55×10^{-3}
Slope (a.u. per ppb Li)	0.63×10^{-3}	0.36×10^{-3}
% Lack-of-fit P value	39.9	62.4
Performance[b]		
Linearity (%)	98.3	98.3
Analytical sensitivity (ppb Li)	6.2	8.0
Detection limit (ppb Li)	13.2	13.3
Determination limit (ppb Li)	44.1	44.3
Precision (relative standard deviation, %):		
50 ppb Li	9.0	7.4
100 ppb Li	4.0	3.9
150 ppb Li	2.6	2.6
200 ppb Li	2.0	2.0
250 ppb Li	1.8	1.8

[a] a.u.: absorbance units.
[b] Calculated as indicated in Ref. [41].

and Quinizarin concentrations given above for a lithium concentration of 250 ppb. The result indicated that both values were suitable for calibration.

The calibration linearity was tested by "lack-of-fit" statistical F-test [40]. Three replicates for the aqueous matrix and five for serum of 0, 50, 100, 150, 200 and 250 ppb lithium standard solution were taken in order to set up the calibrations.

3.8. Analtyical performance characteristics

The main statistical and performance characteristics, calculated from the calibration data set [41], are shown in Table 3. The IUPAC detection limits [42], calculated from 10 replicates of the reagent blank, were 17.6 ppb and 14.5 ppb for aqueous medium and serum respectively.

The ruggedness [43] of the new analytical method for the determination of 100 ppb Li^+, for variations of $\pm 10\%$ in procedure temperature and concentrations of Quinizarin, NaOH and Na_2CO_3 and for a variation of $\pm 5\%$ in the proportion of water, was studied using a 2^{7-4} saturated factorial design with two dummies. The method was rugged for every variable and no interactions between tested variables were found.

3.9. Effect of diverse ions

The effect of various ions on the determination of 50 ppb Li^+ in aqueous medium was studied, setting the tolerance limit at an error of $\pm ts_R$ [44] over the predicted value for the absorbance of the chelate measured against a reagent blank (t = one-tail Student t value for n-2 degrees of freedom and an α value of 0.05; S_R, standard deviation of the analytical response, predicted for the tested analyte concentration, obtained from the calibration data set). The tolerance limits of various ions are shown in Table 4. Note that the tolerance limits of some ions are low. Thus, in the case of a complex matrix, and as blood serum, a new calibration is required.

Table 4
Tolerance concentrations of several ions in the determination of 50 ppb Li^+

Anion[a]	Tolerance (ppb)	Cation[b]	Tolerance (ppb)
Cl^-	>50 000	K^+	500
I^-	10 000	Mg^{2+}	50
SO_4^{2-}	5000	Zn^{2+}	5
Br^-, NO_3^-	1000	Fe^{3+}	2.5
SiO_3^{2-}	500	Cu^{2+}, Ca^{2+}, Pb^{2+}	1
F^-, PO_4^{3-}	100		
$C_2O_4^{2-}$	10		

[a] All the test solutions were prepared from the sodium salts. (The tolerance concentration of Na^+ ion, calculated from the tolerance concentration of the Cl^- ion, is >32 000 ppb.)
[b] All the test solutions were prepared from the corresponding nitrates.

3.10. Application of the proposed method to real samples

3.10.1. Drugs

The basic method, as described, was applied for the determination of lithium in various pharmaceutical preparations, using flame photometry as the reference method. Results in Table 5 show the values found from both methods and the *P* value of the corresponding Welch *t*-test [45].

3.10.2. Blood serum

An accurate volume of standard was added to three different samples of serum, so that the final concentration of Li^+ was of the order of the therapeutic levels (approximately 4–8 ppm). Table 6 shows the recovery of the added lithium. The pooled recovery was 96.7%.

Table 6
Recovery of added Li^+ in different serum samples

Serum	Added (ppm)	Found (ppm)	% Recovery
1	4.00	3.24	81.0
	4.00	3.24	81.0
	4.00	2.69	67.3
	4.00	3.93	98.3
	4.00	3.79	94.8
2	5.00	5.32	106.3
	5.00	5.45	109.1
	5.00	5.59	111.8
	5.00	5.18	103.5
	5.00	5.45	109.1
3	7.00	8.21	117.4
	7.00	7.52	107.5
	7.00	6.70	95.7
	7.00	7.52	107.4
	7.00	7.38	105.4

A *t*-test, which compares the mean value against a reference value, was carried out in order to check if this value was significantly different from 100%. The statistic used, $t = (\bar{\Re} - 100)\sqrt{n}/s_{\Re}$ ($\bar{\Re}$, pooled recovery; $s_{\Re}$, recovery standard deviation), was obtained from the statistic for the comparison of the means of paired samples [46]. The following data were obtained: $\bar{\Re} = 99.4$; $s_{\Re} =$

Table 5
Determination of lithium in various drugs using flame photometry as the reference method and the proposed spectrophotometric method

Drug	Flame photometry		Proposed method		% *P* value[b]
	$c \pm s_c$[a]	n[b]	$c \pm s_c$[a]	n[a]	
Otogén (mg Li_2CO_3 per tablet)	18.0 ± 0.1	9	18.4 ± 0.3	9	1.1
Plenur (mg Li_2CO_3 per tablet)	335 ± 4	9	340 ± 7	8	8.7
Glucosor-Litio (mg Li gluconate per ml)	3.28 ± 0.02	3	3.2 ± 0.1	3	31.1

[a] Mean and standard deviation of *n* determinations.
[b] *P* value for Welch's *t*-test.

15.783; $t = 1.605$; d.o.f. = 14, P value = 93.1. The high P value shows that the difference between the pooled recovery and 100 is solely due to random error, and therefore the method does not show systematic error.

Complexing influence of cobalt and nickel ions on the electrochemical reduction of pterin and related compounds at a mercury drop

Urszula Kucharska

Institute of General Food Chemistry, Technical University of Lodz, Stefanowskiego 4/10, 90-924 Lodz, Poland

Received 22 November 1995; revised 20 May 1996; accepted 17 June 1996

Abstract

The effect of Co^{2+} and Ni^{2+} ions on the electrochemical reduction of pterin and its derivatives, pteroic and pteroylmonoglutamic acids, has been studied. The measurements were carried out in aqueous solutions at fixed pH (7.5 ± 0.2), temperature (298 ± 0.2 K) and ionic strength ($\mu = 1.00$; $NaClO_4$) using polarographic techniques. By employing cyclic voltammetry and differential pulse polarography displacements were determined of the half-wave potentials $E_{1/2}$ of ligands of the reducible organic compounds at a dropping mercury electrode. The recorded polarograms and inherent potential differences were then utilized to calculate conditional stability constants of the complexes. The Casassas–Eek method was employed for the interpretation of the potential differences of the free and complexed ligands. The log β_1 values of the stability constants revealed moderate stability of the complexes. The donor atoms of the ligands in the coordination compounds have also been identified.

Keywords: Complexes; Cobalt; Nickel; Pterin derivatives; Stability constants

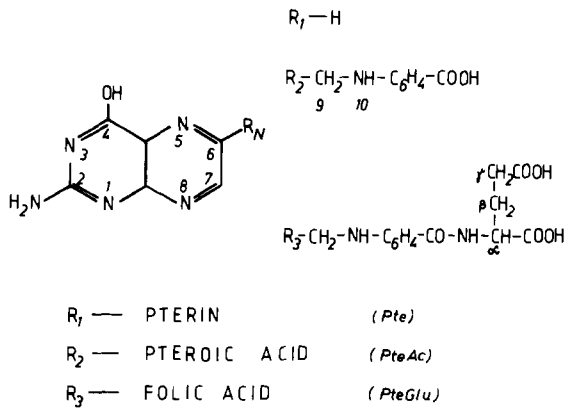
1. Introduction

The polarographic behaviour of pterin (Pte) as a function of pH has been studied by Komenda and co-workers [1,2]. Similar studies have also been reported by Kretzschmar and Jaenicke [3] with pteroylmonoglutamic acid, which is also known by the trivial names folic acid or vitamin $B_9(B_c)$. Earlier studies [4–9] revealed the formation of coordination compounds between folic acid and metal ions. The present work has focused on transformations taking place in aqueous solutions during electrochemical reduction of Pte and pteroic (PteAc) and pteroylmonoglutamic (PteGlu) acids (Scheme 1) in the presence Co^{2+} and Ni^{2+} ions.During these investigations, carried out with model solutions at fixed pH, temperature and ionic strength, variations of the half-wave potentials of reduction of the ligands (R_1, R_2, R_3; Scheme 1) with varying concentrations of either metal (M) or ligand (L) were expected. The variation of the half-wave potential of an organic

PII S0039-9140(96)02019-X

compound in the presence of a metal ion may be due to a chemical reaction (e.g. complexation) occurring in the solution. The magnitude of the half-wave potential of the free and complexed ligand has a direct bearing on the form being complexed. A chemical reaction occuring in solution results in a variation in the concentrations of the oxidized and reduced forms of the depolarizer, thus shifting the equilibrium potential according to the Nernst equation. When the oxidized form is involved in the reaction, its concentration drops and the equilibrium potential is displaced towards negative values, whereas involvement of the reduced form shifts the potential towards positive values [10].

Previous electrochemical studies of the complexes were restricted by certain limitations, such as the reversibility of the electrode reaction of the metal ion and the formation of a single complex in solution at large ligand excess [11–13]. The restrictions of the De Ford–Hume method have been highlighted by some authors [14,15] in particular in relation to the accuracy required for measuring the half-wave potential. A comprehensive analysis of errors in the determination of the stability constants from polarographic measurements has been presented by Klatt and Rouseff [14]. They also accounted for the conditions for detection of consecutive complexes occurring in solutions analyzed by polarography. Slopes of the current–voltage curves at large ligand excess have already been analyzed by many authors [16–19].



Scheme 1. Chemical formulae of Pte, PteAc and PteGlu.

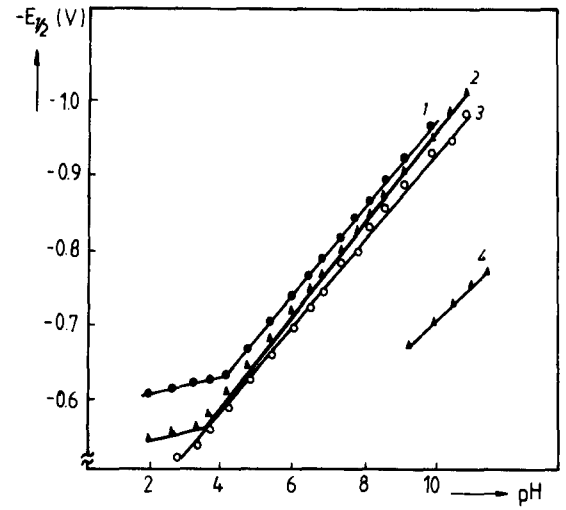


Fig. 1. Variations of the half-wave potential of the ligand, $E_{1/2}$, with pH for solutions of Pte (3), PteAc (1) and PteGlu (2) and (4) in Britton–Robinson buffer solutions at 298 K.

Casassas and Eek [20], as well as Naideker [21], have modified the De Ford–Hume method and adapted it to systems containing electroreducible organic compounds as complexons. Using an excess of the metal ion has been suggested for these systems, in order to create conditions for competition for each ligand molecule. These conditions enabled full identification of complexes with the lowest stability constant, i.e. of the M:L = 1:1 type. Also, the consecutive complexes could be analyzed in this way. In some cases, however, the stability constants of these species were determined with large errors. The errors were analyzed by Casassas and co-workers [22–24] in many systems. The main feature of the Casassas–Eek method is the inclusion and analysis of the hydrogen ion concentration which plays a crucial role in the reduction processes of organic compounds. In the De Ford–Hume method, only the reduction of hydrated metal ions has been studied over certain concentration and potential ranges. Furthermore, De Ford and Hume [13] assumed that the ligand is an electrochemically inert species, making the method inapplicable in some instances.

Complexation reactions of the 3d″ metal ions by folic acid were previously studied using poten-

tiometric and spectrophotometric methods [9,25]. Relevant stability constants have now been verified by the polarographic method, although the primary objective of this study was investigation of the influence of the Co^{2+} and Ni^{2+} ions in the electrochemical reduction of folic acid. Furthermore, it was also interesting to examine the interaction of some fragments of pteroylmonoglutamic acid with the ions. Results of the previous papers [9,25] suggested unambiguously that the Casassas–Eek method should be applied in as much as the solutions metal its restictions. The ligands are reversibly reducible at the dropping mercury electrode (DME) at potentials more positive than those of uncomplexed ions. The reduction of a ligand at the mercury electrode can be described by the following general equation:

$$L + nH^+ + ze^- \rightleftarrows H_nL \quad (1)$$

and the redox potential of the electrode is given by

$$E = E_o - \frac{RT}{zF} \ln \frac{(c^\circ)_{HnL}(v^\circ)_{HnL}}{(c_L)(c_H^\circ)^n(v_L)(v_H)^n} \quad (2)$$

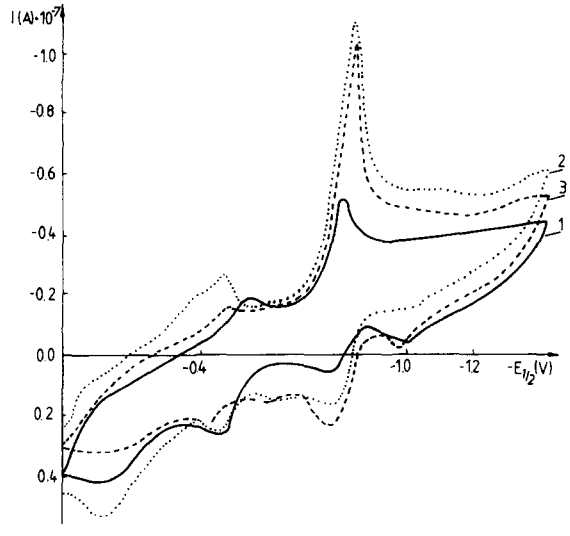

Fig. 2. Cyclic voltammograms of the ligands: (1) 1.03×10^{-5} M folic acid; (2) 1.04×10^{-5} M PteAc; (3) 1.04×10^{-5} M Pte in the system DME–SCE–Pt electrode. Potential scan rate 20 m V s^{-1}; pH 7.5; $T = 298$ K.

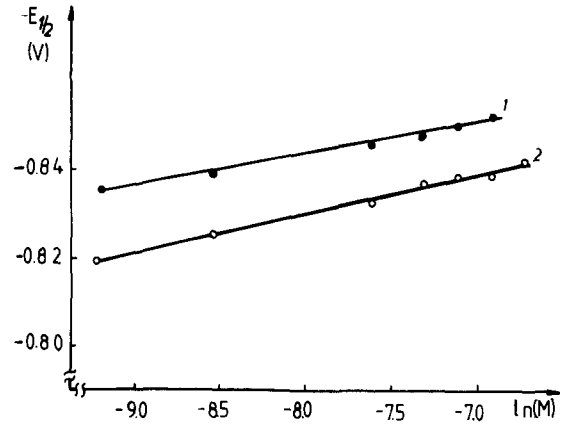

Fig. 3. Variations of the half-wave potential, $E_{1/2}$, of 5×10^{-5} M aqueous solutions of PteGlu in the presence of (1) Ni^{2+} and (2) Co^{2+} ions with the natural logarithm of the metal ion concentration. pH 7.5; $T = 298$ K; $\mu = 1.0$ ($NaClO_4$).

where E_o is the standard potential of the L–H_nL couple, c is the concentration, v is the activity coefficient of the oxidized (c_L, v_L, L) and reduced (c_{HnL}, v_{HnL}, H_nL) forms, c_H is the hydrated ion concentration, and v_H is its activity coefficient. The complexation process can thus be given by

$$L + pM^{n+} \rightleftarrows L(M^{n+})_p \quad (3)$$

where $p = 1, 1/2, 1/3, \ldots, 1/N$. Bearing in mind all the considerations described in Refs [20,21] we can obtain Eq. (4), which links the half-wave potential differences of the free and complexed ligand, $(E_{1/2})_c$, with the calculated stability constants:

$$F_o[M] = \exp\left[\frac{zF}{RT}\right]\Delta E_{1/2} + \ln\frac{I_L}{I_{exp}} = v_L \sum_1^P (\beta_p c_M^{1/p} v_{LM_p}) \quad (4)$$

At a large excess of the metal ion, favouring the formation of a 1:1 complex, only one type of complex predominates in the solution at 298 K and Eq. (4) can be simplified to yield:

$$\Delta E_{1/2} = 0.059/z(1 + \beta_1[M^{n+}]) \quad (5)$$

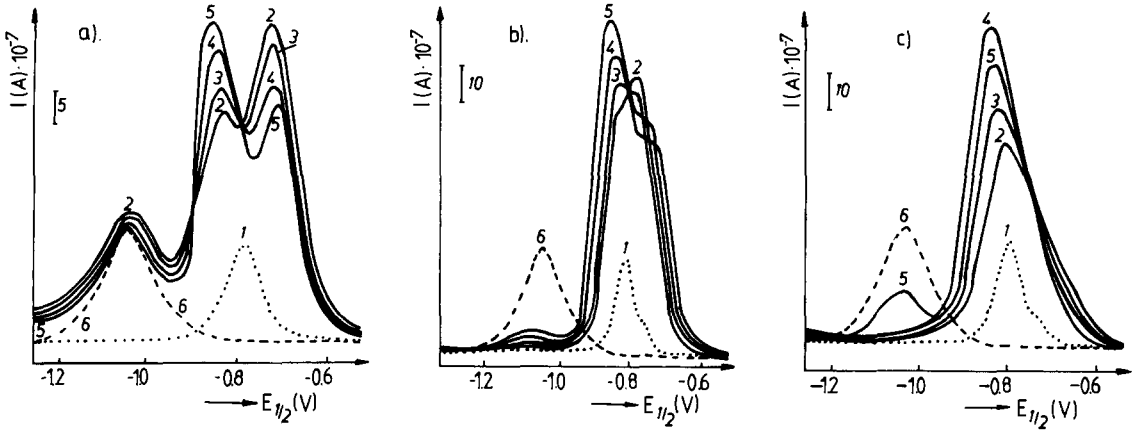

Fig. 4. Experimental DPP curves of the ligands: (a) Pte ($c = 1 \times 10^{-5}$ M); (b) PteAc ($c = 1.5 \times 10^{-5}$ M); (c) PteGlu ($c = 5 \times 10^{-5}$ M) in the presence of Ni^{2+} ions (1) in the absence of metal ions; (2) 5×10^{-4}; (3) 8×10^{-4}; (4) 1.0×10^{-3}; (5) 5.0×10^{-3}; (6) 8.0×10^{-3} M $Ni(ClO_4)_2$ solution without ligand. Potential scan rate 20 mV s^{-1}; pH 7.5; $T = 298$ K; $\mu = 1.0$ ($NaClO_4$).

Biernat and Korita [26] introduced a correction adequate for entirely irreversible processes by which Eq. (4) assumes the shape

$$F_o[M] = \exp\left[\frac{\alpha z F}{RT}\right]\Delta E_{1/2} + \ln\frac{I_L}{I_{exp}} = \nu_L \sum_1^P (\beta_p c_M^{1/p} \nu_{LM_p}) \quad (6)$$

where α is the so-called transfer coefficient of the electrode reaction which accounts for the deviation from the reversibility of the process.

2. Experimental

2.1. Chemicals

Water used for the preparation of solutions was demineralized by ion exchange and then distilled over $KMnO_4$. Pte, PteGlu and PteAc solutions from 1×10^{-3} to 1×10^{-6} M were prepared from analytical-grade reagents (Sigma). The solutions were freshly prepared and protected from light. During measurements the samples were kept in light-protected cells. Stock solutions of $Co(ClO_4)_2$ and $Ni(ClO_4)_2$ were prepared by the procedure of Ulmgren and Wahlberg [27]. The metal concentrations in the solutions were determined complexometrically [28] and spectrophotometrically [29,30]. The ionic strength of the solutions was maintained by aqueous $NaClO_4$ solutions prepared from analytical-grade $NaClO_4 \cdot H_2O$ crystals (Reachim). The pH was adjusted by standardized $HClO_4$ (p.a., VEB Jenapharm) and NaOH (p.a., POCh, Gliwice, Poland) solutions [31]. The pH-meters were calibrated against standard solutions (Radelkis) and Britton–Robinson buffers were used for adjusting the pH over the range 2.0–11.0 [32].

2.2. Equipment

The pH measurements were run on an automatic titrimeter OP-506 (Radelkis) equipped with a combination electrode (OP-0808P) and an automatic MEKB 6.25075 flask-burette. The temperature was held constant by means of a U-10 thermostat. Absorption spectra were taken on Specord UV–Vis and Specol-20 (Carl Zeiss, Jena, Germany) spectrophotometers. The differential pulse polarograms were recorded on a PA-4 (Lab. Praha) precision polarographic analyzer fitted with a static mercury drop electrode (SMDE) and a XY 4106 recorder. A DME served as the cathode and a platinum plate (surface area 1.5 cm^2) was the counter electrode. A saturated calomel electrode (SCE) served as a reference electrode and was mounted close to the working

electrode over a Luggin capillary filled with a NH_4NO_3 solution. All polarographic measurements were carried out in a 25 ml light-protected glass vessel equipped with a double jacket enabling the access of argon and mounting of the electrode system.

2.3. Procedure

Before running each series of polarographic measurements, the performance of the measuring system was thoroughly checked by taking polarograms with a 5.0×10^{-4} M $CdCl_2$ solution in 0.1 M KCl. The half-wave potential of this system was $-0.640(\pm 0.002)$ V. Analyzed solutions were prepared in 25 ml flasks and 10 ml aliquots were transferred from them to the polarographic cell. The solutions were purged with oxygen-free argon for 15 min and then a polarogram was recorded. Throughout the measurement process the rate of potential variation of 20 mV s^{-1}, the amplitude of 50 mV and the drop lifetime of 2 s were held constant. In the series of measurements aimed at recording potential variations of the reduction of the ligands (R_1, R_2, R_3) as a function of pH, Britton–Robinson buffers of pH 2.5–11.0 were used. The measurements were run in Pte, PteAc and PteGlu solutions of concentrations ranging from 1×10^{-7} M–10×10^{-4} M. In another series of measurements, variations in the positions of polarographic waves of the reduced ligands due to complexation were measured. In these solutions the ligand concentration was held constant and the metal ion concentration was raised from a 10-fold to a 20-fold excess at constant pH (7.5 ± 0.2), temperature (298 ± 0.2 K) and ionic strength ($\mu = 1.00$; $NaClO_4$). Differential pulse polarograms were recorded repeatedly in these solutions.

3. Results and discussion

The differential pulse polarograms of 5×10^{-5} M Pte, PteAc and PteGlu solutions at various pHs exhibited three peaks due to free folic acid (PteGlu). A similar pattern was observed in systems containing Pte and PteAc without the metal ions [1–3]. In the presence of metal ions the peak at $E_{1/2} = -0.808$ V at pH 7.5 is shifted due to reduction at the N(5) and N(8) nitrogen atoms of the rigid Pte framework. The remaining peaks are unaffected. The $E_{1/2} = -0.808$ V peak is due to a reversible two-electron transformation accompanied by the transfer of two electrons onto the pyrazine ring [33]. A plot of the potential vs. pH is shown in Fig 1. Using the cyclic voltammetry technique it was possible to prove the reversibility of electroreduction processes at the DME based on the separation of the cathodic $(E_{1/2})_c$ and anodic $(E_{1/2})_a$ peaks. Support for this statement is provided by the separation of the cathodic and anodic peaks as illustrated in Fig. 2. These results show that $E_{1/2}$ satisfies quite well the relation $(E_{1/2})_a - (E_{1/2})_c = 0.059/n$ V. The two remaining conditions for the reversibility of the process, namely $I_{pc} = I_{pa}$ and $E_{1/2} = 1/2\ (E_{pc} - E_{pa})$, have also been roughly satisfied [33]. The reversibility of the system has previously been reported by Dryhurst [33] and by Dillard and Hanck [35] by calculation of the half-wave potential on the basis of differential pulse polarography (DPP). Further, it was shown that the limiting current d.c. polarography increased linearly with the square root of the height of mercury, thus revealing the process to be diffusion-controlled. Inspection of potential variations of the PteGlu peaks in the presence of Co^{2+} and Ni^{2+} reveals that a chemical reaction proceeds in these systems. A plot of the metal concentration vs. peak potential is a rising curve (Fig. 3). It can thus be concluded that complexation takes place in these solutions under the adopted experimental conditions. Variations in the peak potential of the reduction of PteGlu due to this process displace the equilibrium potential towards negative values, revealing complexation of the oxidized form of PteGlu by the metal ions. The complexation of PteAc and Pte by the ions takes a different course as illustrated by the polarograms shown in Fig. 4. With Pte, the peak for the reduction of this molecule is displaced towards both positive and negative values, indicating complexation of both the oxidized and reduced forms. In the Co^{2+} and Ni^{2+} concentration range from 8×10^{-4}–3.5×10^{-3} M, peaks of higher currents at more positive potentials and those of lower currents at more negative poten-

tials than the peak of Pte itself are recorded. Further, an increase in the peak currents at more negative potentials is noted upon raising the metal ion concentration. At the same time, the peak currents decreases at more positive potentials than the peak of Pte reduction. These results show that the contribution of complexed oxidized Pte species increases with increasing Ni^{2+} and Co^{2+} ion concentrations. A similar picture is seen with PteAc, although the contribution of the reduced forms to the complexatin process is much smaller than that of the reduced forms of Pte at equal metal ion concentrations. This is supported by the peak heights of PteAc at more negative potentials (strong currents) and by the PteAc peaks at more positive potentials (weak currents) than the reduction peak of the free ligand. The differences can be attributed to the presence and the structure of the R_N substituent at C(6) in the Pte molecule.

The presence of R_2 or R_3 at C(6) facilitates the complexation of the Co^{2+} and Ni^{2+} ions. At the same time, the unsubstituted Pte molecule undergoes more readily reduction at the DME and more readily binds the Co^{2+} and Ni^{2+} ions than do its reduced forms (PteAc and PteGlu). This is evidenced by missing peaks at more positive potentials in systems containing PteGlu and by a smaller number of peaks of weak currents at more positive potentials in the PteAc systems as compared with those containing Pte (Fig. 4). Based on the potential variations of the peak obtained by DPP, stability constants of the complexes were calculated by the Casassas–Eek method [20]. The values of peak currents and potential differences related to the free and complexed ligands were substituted into Eq. (4). The obtained F_o values were plotted against metal concentration, [M] (Fig. 5). From this relation, both the form and composition of the complexes were calculated.

The results of polarographic investigation of the systems comprising Pte, PteAc and the Co^{2+} and Ni^{2+} ions are summarized in Tables 1 and 2. The variations of the polarographic peak currents of Pte, PteAc and PteGlu vs. natural logarithms of the Ni^{2+} ion concentration are shown in Fig. 6 and plots of the potential variations of the complexed PteAc and Pte vs. natural logarithms of the Ni^{2+} ion concentration are presented in Fig. 7.

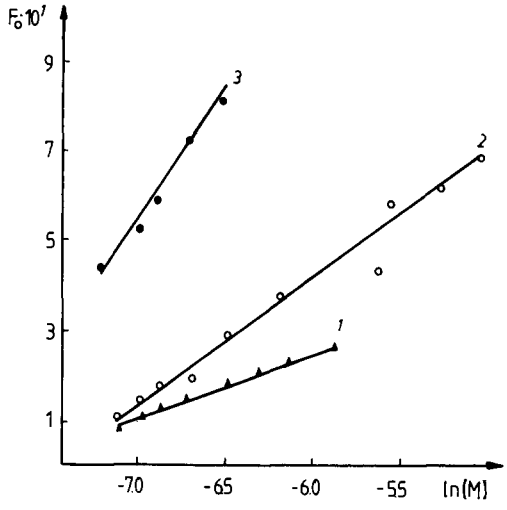

Fig. 5. Graphical presentation of the calculated F_o values as a function of the natural logarithm of the Ni^{2+} ion concentration: (1) Pte; (2) PteAc; (3) PteGlu.

The data of Tables 1 and 2 indicate that the complexation reaction practically ceases to proceed over the higher concentration range because there is no displacement of ligand reduction peaks upon raising the metal ion concentration. In po-

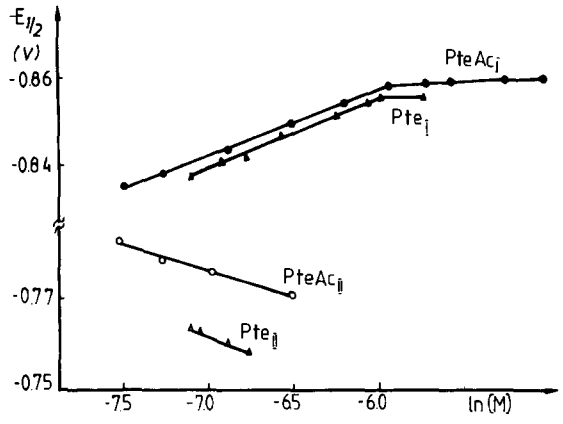

Fig. 7. Variations of the half-wave potential, $E_{1/2}$, for Pte and PteAc as a function of the natural logarithm of the Ni^{2+} ion concentration pH 7.5; $T = 298$ K; $\mu = 1.0$ ($NaClO_4$).

larograms recorded at higher Co^{2+} ion concentrations, a new peak appears at $E_{1/2} = -1.080$ V, while in Ni^{2+} solutions the peak appears at $E_{1/2} = -1.100$ V (Fig. 4). According to the instructions of Galus [36] the peaks can be assigned to hydrated ions, $[Ni(H_2O)_p]^{2+}$ and $[Co(H_2O)_p]^{2+}$, occurring in excess of ions in the solutions. Generally, electrochemical reduction of the hydrated ions can be described by the following equation:

$$[Ni(H_2O)_p]^{2+} + 2e^- \rightarrow Ni^0(Hg) + pH_2O \qquad (7)$$

This particular case of electrochemical reduction is attributed to variations in the water activity in solution [36]. The calculated stability constants of the complexes are summarized in Table 3 together with those determined by other methods under the same conditions [9,25,37].

The properties of the Co^{2+} and Ni^{2+} complexes with Pte, PteAc and PteGlu were investigated in order to identify the complexed species under identical experimental conditions. Another purpose was to identify the coordination sites of the ligand molecules. It can be hypothesized that when the same donor atoms are involved in the coordination of the metal ions, the stability constants determined under identical conditions should be comparable.

Bearing in mind the results reported by Pullman and Pullman [38], dealing with the reactivity of particular atoms in the folic acid molecule and related compounds (Pte, PteAc), an assumption has been made that the N(5) and N(10) atoms are the most readily coordinated. According to Pullman and Pullman just these atoms exhibit the highest free valency, which is a measure of the atomic polarizability under the influence of metal ions. Consequently, these centres carry the largest partial charges and the activation energy required for electrophilic or radical addition is relatively low. Indeed, the determined stability constants of the Co^{2+} and Ni^{2+} complexes with Pte, PteAc and PteGlu are very close to one another (Table 3). Small differences between these stability constants can be attributed to the presence of various subtituents at the C(6) atom of the Pte framework. The theoretically predicted reactivities of the atoms in the ligand molecules and coordination sites at N(5) and N(10), on the basis of the literature evidence, seem to be confirmed by the results of the present study. The good agreement between the stability constants suggests that the lone pair of electrons of the atoms acts as an electron donor in the coordination bonds. Somewhat higher values of log β_1 for the folate complexes, as compared to those for the pteroate and pterate complexes, show that the chain length of the substituent R_N and the presence of the glutamate residue in this molecule stabilize the compound.

A computer-assisted (POTECOM program) inspection of various ionic and neutral forms reveals complexation through the deprotonated form [9,25]. The established composition of the folate complexes (M:L = 1:1) also reveals the possibility of coordination through the oxygen atom of the C_γ carbonyl group of glutamic acid. The preferred geometry of the Co^{2+} and Ni^{2+} complexes is an octahedral or square-planar one where the central atom is surrounded by six or four donor atoms respectively [39]. The Co^{2+} and Ni^{2+} complexes obtained from the deprotonated anion of the trinuclear ligand, PteGlu (H_2L^-), are likely to have octahedral or pseudo-tetrahedral symmetry about the central ion respectively [40].

It should also be assumed that the PteAc and Pte molecules from octahedral species with the Co(II) and Ni(II) ions. The coordination bond is

likely to have a certain contribution to the ionic bond due to the difference in electronegativites of the cation and the donor atom of the ligand. Since the N(5) atom is incorporated in the ring with conjugate double bonds, its lone pair of electrons participates in delocalization of π electrons of the pyrazine ring of the Pte framework. Owing to this displacement, the nitrogen atom loses part of its electrons, thus lowering the effective charge. Houghton's [41] concept of the σ-donor strength of a ligand is a quantitative measure of the capacity of various ligands to impart covalent character to the σ-bond formed in a complex. The σ-donor strength depicts the tendency of a ligand to lower the positive charge on the central atom by increasing the electron density on this atom. A change in the nature and sequence of substituents R_N or an increase in the length of the glutamate chain (the tendency observed with PteGlu in natural systems [42,43]) can affect the σ-donor strength of the ligands. The chemical nature of these substituents leads to a change in electron density on the coordinating nitrogen and oxygen atoms of the ligand through the influence of the mesomeric and inductive effects.

An octahedral structure of the Ni(II) and Co(II) complexes with organic compounds containing the ethylenediamine moiety has been established by magnetic susceptibility measurements [39,41]. The oxygen–Ni(II) (or –Co(II)) bonds in these complexes have been found to be ionic, whereas for the nitrogen–Ni(II)(or –Co(II)) bonds a partial positive charge on the nitrogen atom was detected. By analogy, it can be assumed that the ligands studied here can coordinate the Co^{2+} and Ni^{2+} ions through the N(5) atom of the rigid Pte framework and through the oxygen atom at C(4). With PteAc and PteGlu, the R_2 and R_3 substituents respectively at C(6) introduce a highly reactive N(10) atom. Consequently, the neighbouring atoms N(5), C(6), C(9) and N(10) in PteAc and PteGlu jointly form an ethylenediamine framework. The capacity for the formation of coordination bonds with the Co^{2+} and Ni^{2+} ions by this framework has already been widely discussed in the literature [33,39–41]. Also in this case such complexation appears to be highly probable. The presence of glutamate in PteGlu enables the participation of the oxygen atom of the C_γ carbonyl group in bonding to the central ion. Less probable, however, is coordination through the carboxyl group at C_α, owing to the large distance from the assumed coordination centre. Obviously, the presence of the water molecules in the coordination sphere of the complex cannot be ruled out.

It seems quite likely that the nature and distribution of functional groups in the molecules of the Co(II) and Ni(II) complexes of Pte, PteAc and PteGlu markedly affect their physical and chemical properties [37,44–47]. The electronic spectra of the PteGlu complexes with these ions reported earlier [9,25] seem to be supported by the results of the present study. The bands at 280 and 300

nm for Ni(II) and Co(II) respectively also indicate the complexation within the Pte framework. The observed bathochromic shifts of these maxima are probably due to the effect accompanying bond formation of weakening of the ligand field strength [48] due to the change of conformation and the formation of a chelate. The electronic spectrum of folic acid exhibits three bands (at 255, 282 and 365 nm) in the UV region. The 255 and 365 nm bands are assigned to electron transitions in the Pte fragment of the molecule, whereas the 282 nm band is assigned to a transition in the *p*-aminobenzoate fragment [49–51]. In the spectra of folic acid solutions containing Co^{2+} and Ni^{2+} ions the 255 nm band is missing and the 365 mn band is displaced [9,25]. Further, a distinct increase in the intensity of the 280 nm band is noted on raising the Ni^{2+} ion concentration (the 300 nm band also increases on intensity with the addition of Co^{2+} ions). This finding supports the assumption of the ion binding to the rigid Pte framework. It seems highly probable that the nondisplaceable 282 nm band or the slightly shifted 280 nm band in systems with the Ni^{2+} ions (300 nm with Co^{2+}) is responsible for the variations in steric accommodation of the *p*-aminobenzoic acid residue. These variations are probably due to the formation of new bonds with the metal ions. The electronic spectra of the Co^{2+} and Ni^{2+} complexes of PteGlu, PteAc and Pte display some other bands assignable to metal–ligand electron transitions and to those within the molecule of the coordinated ligand [9,25,37].

The results of this work are complementary with the earlier ones and both sets of results strengthen the suggestion made as to the mode of binding of the metal ions with the ligands.

Bearing in mind the total effort devoted to the study of the complexing effect of the Co^{2+} and Ni^{2+} ions on the electrochemical reduction of the ligands should be emphasized. The first distinctsign of the influence is the variation of the reduction potential of the pterins on variation of the Co^{2+} and Ni^{2+} concentrations in solution. Further, distinct differences have been noted in the variations of the peak currents of reduction of the ligands as the metal ion concentrations were varied. Thus, complexation has a distinct influence on the rate of formation of the reduced forms of the compounds.

This study enables the identification of those forms of Pte, PteAc and PteGlu which complex the Co^{2+} and Ni^{2+} ions in aqueous solutions. Good agreement should also be emphasized between the stability constants determined by three independent methods [9,25,37].

The results of this study reveal the important role played by the Co^{2+} and Ni^{2+} ions in formation of unique conformations of the ligands which are likely to control their bioactivity in living organisms.

Received 21 September 1995; revised 24 June 1996; accepted 26 June 1996

Abstract

Mixed-ligand chelate extraction of trivalent lanthanides such as Nd(III), Eu(III) and Lu(III) into benzene with mixtures of 4,4,4-trifluoro-1-phenyl-1,3-butanedione (HBFA) and bis-2-ethylhexyl sulphoxide (B2EHSO) or triphenylphosphine oxide (TPhPO) from thiocyanate solutions was investigated. The results demonsrate that these metal ions are extracted as $Ln(BFA)_3$ with HBFA alone and in the presence of a neutral oxo-donor, B2EHSO or TPhPO(S), as $Ln(BFA)_3 \cdot S$ and $Ln(BFA)_3 \cdot 2S$. The equilibrium constants of the above species increase monotonically with decreasing ionic radii of these metals ions. The addition of a neutral donor to the metal chelate system not only enhances the extraction efficiency but also improves the selectivity among these trivalent lanthanides. Hence this mixed-ligand system may be useful for the extraction and separation of individual lanthanides and also for the separation of lanthanides as a group from other metal ions.

Keywords: Mixed-ligand chelate extraction; Trivalent lanthanides

1. Introduction

Mixed-ligand chelate extraction of trivalent lanthanides by mixtures of a chelating agent and a neutral oxo-donor has been studied extensively by several workers and the relevant data are covered in reviews on synergistic extraction [1,2]. Several models have been proposed to explain the synergism observed in these systems. However, the role of each of the factors involved in such models is not fully understood. To clarify the roles of dehydration and of expansion of metal ion coordination number, calorimetric studies were conducted on the reaction between thenoyltrifluoroacetone (HTTA) complexes of UO_2^{2+}, Th^{4+} and Nd^{3+} cations with tributyl phosphate (TBP) and tri-*n*-octylphosphine oxide (TOPO) neutral adducts [3]. These studies were conducted in organic solvents and it was confirmed that the major role of the neutral adduct is to increase the organophilicity of the complex when the adduct displaces some or

all of the hydration of the binary β-diketonate complexes.

Many studies have been carried out on the synergistic extraction of trivalent lanthanides using a mixture of HTTA and a neutral organophosphorus reagent such as TBP or TOPO or *n*-octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) [4–6]. Compared with these, the systematic study of synergistic extraction systems involving 4,4,4-trifluoro-1-phenyl-1,3-butanedione (HBFA) and a neutral oxodonor is sparse [7]. Shigematsu et al. [7] studied the extraction of selected lanthanides with mixtures of HBFA and TBP or TOPO. HBFA has been found to extract metal ions from more acidic solutions than HTTA ($pK_a = 6.25$) owing to its lower pK_a value (6.03). However, no studies relevant to the extraction of trivalent lanthanides with HBFA in the presence of bis-2-ethylhexyl sulphoxide (B2EHSO) as a neutral donor have been reported. B2EHSO, a sterically hindered branched-chain extractant, has recently been explored in our laboratory as a synergist in the extraction of trivalent lanthanides and actinides with various β-diketones such as HTTA and 4-acylpyrazolones [8–10]. A very high synergistic enhancement of the order of 10^3 has been observed in the above mixed-ligand systems. Further, a few systems have also shown improved selectivites either among the trivalent lanthanides or between the trivalent lanthanides and actinides. This prompted us to initiate a systematic study on the extraction of trivalent lanthanides using B2EHSO as a synergist in the presence of HBFA as a chelating agent, with a view to elucidating the nature of the complexes extracted into the organic phase and also to investigate the selectivity of this mixed-ligand system. For comparison, studies were also carried out with HBFA in the presence of triphenylphosphine oxide as a neutral oxodonor.

2. Experimental

HBFA and TPhPO were purchased from Aldrich Chemical (USA). B2EHSO was obtained from Fairfield Chemical (USA) and purified by the method reported in the literature [11]. Tracer solutions of ^{147}Nd, $^{152,154}Eu$ and ^{177}Lu were supplied by the Board of Radiation and Isotope Technology (BRIT), (India). All other chemicals were of reagent grade.

The solvent extraction procedure and the experimental details were as described previously [8,9]. All the computer programs were written in FORTRAN 77 and executed on a 32 bit mini-computer (HCL Horizon III).

3. Results and discussion

3.1. Theoretical

Lanthanide ions in the aqueous phase adopt a variety of complex forms in the presence of thiocyanate ions, but under the present experimental conditions it is sufficient to consider only the first two complexes as defined by

$$Ln^{3+} + i SCN^- \overset{\beta_i}{\rightleftharpoons} Ln(SCN)_i^{(3-i)+} \quad (1)$$

where Ln = Nd(III) or Eu(III) or Lu(III) and $i = 1$ and 2. Then the total concentration of Ln(III) in the aqueous phase $[Ln_t]$ is given by

$$[Ln_t] = [Ln^{3+}]\,(1 + \beta_1[SCN^-] + \beta_2[SCN^-]^2) \quad (2)$$

The values of the stability constants β_1 and β_2 were obtained from the literature [12] (β_1, Nd = 6.47; β_2, Nd = 1.30; β_1, Eu = 5.05; β_2, Eu = 1.35; β_1, Lu = 2.82).

The extaction of a trivalent lanthanide ion, Ln^{3+}, with a chelating extractant, HA, can be expressed as follows:

$$Ln_{aq}^{3+} + 3HA_{org} \overset{K_{ex}}{\rightleftharpoons} LnA_{3org} + 3H_{aq}^{+} \quad (3)$$

where k_{ex} is the extraction constant. The distribution ratio of the metal, D_0, can be written as

$$D_0 = \frac{[LnA_3]}{Ln^{3+} + \Sigma[LnA_n^{3-n}] + \Sigma[Ln(SCN)_i^{3-i}]} = \left(\frac{P_{HA}}{K_{HA}}\right)^3 K_{ex}\left(\frac{[A^-]^3}{1 + \Sigma\beta_i[SCN^-]^i + \Sigma\alpha_n[A^-]^n}\right) \quad (4)$$

where P_{HA} and K_{HA} are the partition and acid dissociation constant of HA, respectively, α_n is the stability constant of MA_n^{3-n} in the aqueous

phase and A^- is the chelating anion in the aqueous phase. In the lower concentration region of A; $\alpha_n[A^-]^n$ is negligibly small; hence $D_0(1+\beta_1[SCN]+\beta_2[SCN]_2)$ depends on the third power of $[A^-]$.

The mechanism of extraction of trivalent lanthanide, Ln^{3+}, with a chelating agent in the presence of neutral oxo-donor (S) may be expressed as follows:

$$Ln_{aq}^{3+} + 3HA_{org} + mS_{org} \xrightleftharpoons{K_{syn,m}} LnA_3 \cdot mS_{org} + 3H^+_{aq} \quad (5)$$

where $m = 0$, 1 and 2. The the distribution ratio, D can be written as

$$D = \frac{[HA]^3}{[H^+]^3}\left(K_{ex} + \sum_{m=1}^{2} K_{syn,m}[S]^m \times \frac{1}{1+\alpha_n[A^-]^n+\beta_i[SCN]^i}\right) \quad (6)$$

As is well known, chelating agents are weak acids and the neutral donors are bases; the chelating agent and the neutral oxo-donor will interact in the organic phase, leading to reduced concentrations of the free chelating agent and neutral donor. This reaction can be written as

$$HA_{org} + S_{org} \xrightleftharpoons{K_I} HA{\cdot}S_{org} \quad (7)$$

The constants $K_{syn,m}$ and K_I are deduced by non-linear regression analysis using the following procedure.

(1) Assume values of $K_{syn,m}$ and K_I.

(2) The equilibrium concentration of the species occuring in Eq. (6) were determined with the knowledge of the initial concentrations [HA] and [S], P_{HA}, K_{HA} and the assumed values of K_I by solving a quadratic equation and a linear equation.

(3) The values of the assumed equilibrium constants which lead to the minimum root mean square fractional error, y, where

$$y = \sqrt{\frac{1}{N}\sum_{j=1}^{N}\left(\frac{D_{calc.i} - D_{expt.i}}{D_{expt.i}}\right)^2}$$

for all the experimental data were taken to be equilibrium constants for the system under consideration.

The adduct formation reaction in the organic phase and the stability constants, β_m, are given by

$$LnA_{3org} + mS_{org} \xrightleftharpoons{\beta_m} LnA_3{\cdot}mS_{org} \quad (8)$$

$$\beta_m = K_{syn,m}/K_{ex}$$

where $m = 1$ or 2.

3.2. Extraction of trivalent lanthanides with HBFA alone

The extraction of Nd(III), Eu(III) and Lu(III) from 0.1 mol dm^{-3} ammonium thiocyanate solution of pH 3.0 with HBFA (0.1–0.6 mol dm^{-3}) in benzene was studied. The plots of $\log\{D(1+\beta_1[SCN]+\beta_2[SCN]^2)\}$ against the logarithim of the equilibrium concentration of the BFA- anion in the aqueous phase are shown in Fig. 1. The equilibrium concentration of BFA^- in the aqueous phase was calculated from its partition and dissociation constants, using the equation

$$[BFA^-] = \frac{C_{HA}}{(P_{HA}+1)[H^+]/K_{HA}+1}$$

where C_{HA} denotes the initial concentration of HBFA. The literature values of $pK_{HA} = 6.03$ and $\log P_{HA} = 2.61$ were used [13]. The slope of the

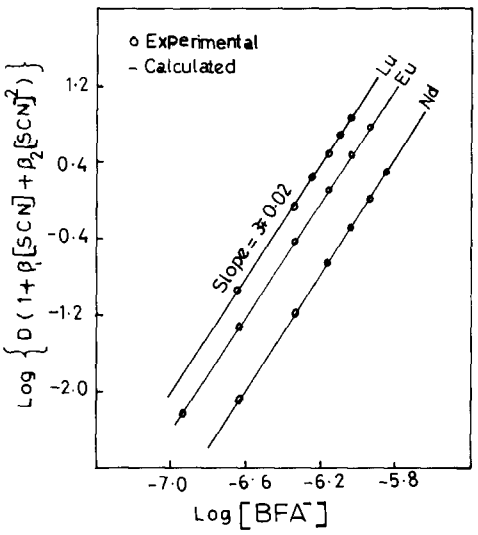

Fig. 1. Effect of HBFA concentration on the extraction of Nd(III), Eu(III) and Lu(III). Aqueous phase 0. 1 mol dm^{-3} thiocyanate pH 3 $[Ln]^{3+} = 1.0 \times 10^{-6}$.

Table 1
Two-phase equilibrium constants of trivalent Nd, Eu and Lu–HBFA–neutral oxo-donor–benzene systems

Complex	Log (equilibrium constant)		
	Nd(III)	Eu(III)	Lu(III)
$Ln(BFA)_3$	-8.09 ± 0.01	-7.33 ± 0.01	-6.97 ± 0.02
$Ln(BFA)_3 \cdot B2EHSO$	-5.62 ± 0.01	-3.21 ± 00.01	-2.65 ± 0.02
$Ln(BFA)_3 \cdot 2B2HSO$	-3.30 ± 0.01	-1.15 ± 0.01	–
$Ln(BFA)_3 \cdot TPhPO$	–	-1.71 ± 0.01	-1.02 ± 0.01
$Ln(BFA)_3 \cdot 2TPhPO$	-0.53 ± 0.01	1.98 ± 0.02	–
HBFA·B2EhSO	1.07 ± 0.01	$1.07. \pm 0.01$	1.07 ± 0.01
HBFA·TPhPO	1.27 ± 0.02	1.27 ± 0.02	1.27 ± 0.02

plot (Fig. 1) is 3 ± 0.02, indicating the extraction of simple metal chelates, $Ln(BFA)_3$, for all the metal ions studied here. This was further confirmed by analysing the data in Fig. 1 using Eq. (4). The best fit between the experimental and calculated D values was obtained only when the formation of simple metal chelate species, $Ln(BFA)_3$, was assumed. The extraction constants (K_{BFA}) for the above species were determined by non-linear regression analysis and are shown in Table 1. It is clear that the K_{BFA} value increases with decreasing ionic radius of the ln^{3+} ion. A similar type of behaviour has also been observed for the K_{TTA} values for the extraction of trivalent lanthanides with HTTA from thiocyanate solutions [9].

3.3. Extraction with a mixture of HBFA and B2EHSO or TPhPO

The extraction of Nd(III), Eu(III) and Lu(III) from 0.1 mol dm^{-3} ammonium thiocyanate solution (pH 3.0) with mixtures of HBFA (0.1–0.5 mol dm^{-3}) + B2EHSO (0.0002–0.07 mol dm^{-3}) in benzene was studied and the results are shown in Figs. 2 and 3. It was found that these metal ions are not extracted in practice by B2EHSO alone into xylene from thiocyanate solutions. However, with mixtures of HBFA + B2EHSO, about 5–20-fold enhancement in the extraction of Nd(III) and 20–200-fold enhancement in the extraction of Eu(III) and Lu(III) were observed.

It can be seen from Fig. 2 of the plot of log $\{D[H+]^3(1+\beta_1[SCN^-]+\beta_2[SCN^-]^2)/1+[B2EHSO](K_{syn.1}/K_{BFA}+K_{syn.2}/K_{BFA})[B2EHSO])\}$ vs. log [HBFA] at constant B2EHSO that only three HBFA moieties are attached to the synergistic species for all the metal ions studied here. The plots of $\log\{D[H^+]^3(1+\beta_1[SCN^-]+\beta_2[SCN^-]^2)/([HBFA]^3-K_{BFA})\}$ vs. log [B2EHSO] at constant HBFA concentration yields a slope of 1 ± 0.01 in the case of Lu(III) and non-integral values in the case of Nd(III) and Eu(III),

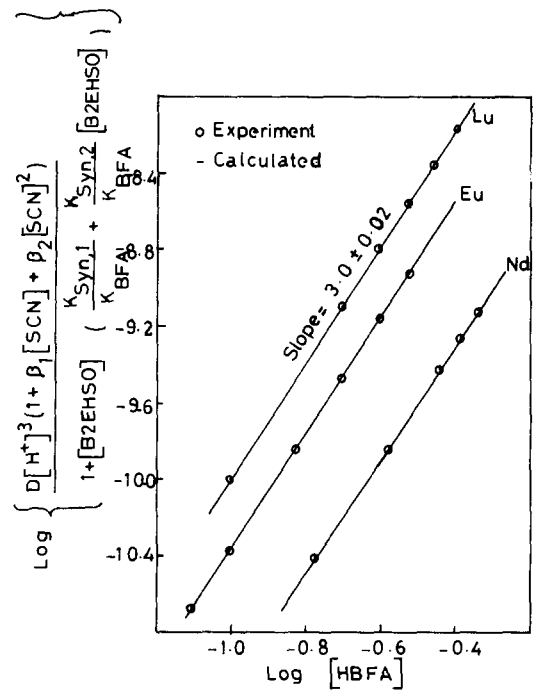

Fig. 2. Effect of HBFA concentration on the extraction of Nd(III), Eu(III) and Lu(III) at fixed B2EHSO concentration. Aqueous phase, 0.1 mol dm^{-3} thiocyanate (pH 3); $Ln^{3+} = 1 \times 10^{-6}$ mol dm^{-3}.

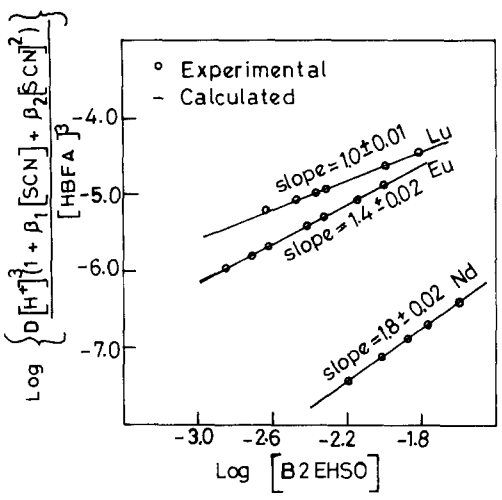

Fig. 3. Effect of B2EHSO concentration on the extraction of trivalent Nd(III), Eu(III) and Lu(III) at fixed HBFA concentration. Aqueous phase, 0.1 mol dm^{-3} thiocyanate (pH 3); $[Ln^{3+}] = 1 \times 10^{-6}$ mol dm^{-3}.

indicating the extraction of the species $Ln(BFA)_3 \cdot m$B2EHSO, where $m = 1$ or 2 for Nd(III) and Eu(III) and $m = 1$ for Lu(III). This was further confirmed by analysing the equilibrium data presented in Figs. 2 and 3 using Eq. (6). The best fit between the experimental and calculated D values was obtained only when the formation of the species $Nd(BFA)_3 \cdot$B2EHSO/2B2EHSO, $Eu(BFA)_3 \cdot$B2EHSO/2B2EHSO and $Lu(BFA)_3 \cdot$B2EHSO was assumed. The synergistic extraction constants for the above species and interaction constant (K_1) were deduced by non-linear regression analysis and are given in Table 1.

The extraction of Nd(III), Eu(III) and Lu(III) from 0.1 mol dm^{-3} ammonium thiocyanate solution (pH 3.0) with HBFA (0.1–0.6 mol dm^{-3}) in the presence of TPhPO (0.0001–0.007 mol dm^{-3}) in benzene was also investigated and the results are shown in Figs 4 and 5. It was found that the extraction of these metal ions is negligible with TPhPO alone under the present experimental conditions. However, with mixtures of HBFA + TPhPO about 5–80-fold enhancement in the extraction of Nd(III) and 10–140-fold synergistic enhancement in the extraction of Eu(III) and Lu(III) were observed. The plots (Fig. 4) of $\log \{D[H^+]^3(1 + \beta_1[SCN^-] + \beta_2[SCN^-]^2)/(1 + [TPhPO](K_{syn,1}/K_{BFA}) + (K_{syn,2}/K_{BFA})[TPhPO])\}$ at constant concentration of TPhPO are linear with slopes of 3 ± 0.02 for all the metal ions, indicating that three molecules of HBFA are involved in the respective extractable complexes. It can be seen from Fig. 5 that the slope of the plot $\log\{(D[H^+]^3(1 + \beta_1[SCN] + \beta_2[SCN]^2)/[HBFA]^3 - K_{BFA}\}$ vs. log [TPhPO]) is equal to 2 ± 0.02 for Nd(III) and 1.0 ± 0.02 for Lu(III) and is a non-integral value (1.3 ± 0.02) for Eu(III), indicating the extraction of the species $Nd(BFA)_3 \cdot 2TPhPO$, $Eu(BFA)_3 \cdot TPhPO/2TPhPO$ and $Lu(BFA)_3 \cdot TPhPO$. This was further confirmed by analysing the data using Eq. (6). The synergistic extraction constants and interaction constants were obtained by non-linear regression analysis and are given in Table 1.

It can be clearly seen from Table 1 that the synergistic extraction constants for both systems studied here with increase with decreasing ionic radii of these trivalent metal ions. Further, the values of $K_{syn,1}$, $K_{syn,2}$ and K_1 for the TPhPO

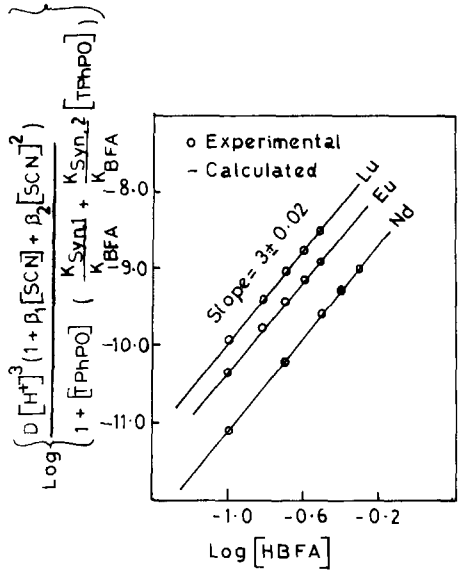

Fig. 4. Effect of HBFA concentration on the extraction of Nd(III), Eu(III) and Lu(III) at fixed TPhPO concentration. Aqueous phase, 0.1 mol dm^{-3} thiocyanate (pH 3); $[Ln^{3+}] = 1 \times 10^{-6}$ mol dm^{-3}.

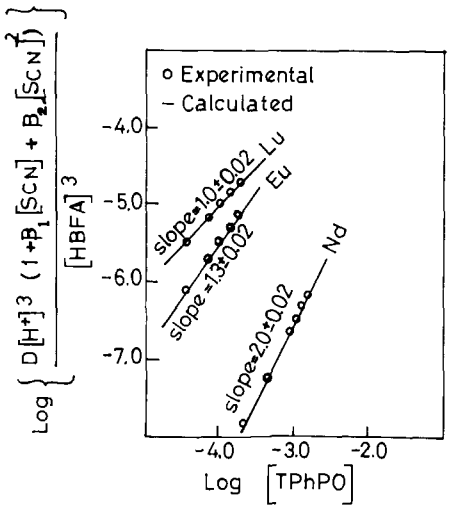

Fig. 5. Effect of TPhPO concentration on the extraction of Nd(III), Eu(III) and Lu(III) at fixed HBFA concentration. Aqueous phase, 0.1 mol dm^{-3} thiocyanate (pH 3); $[Ln^{3+}] = 1 \times 10^{-6}$ mol dm^{-3}.

system are higher than those for B2EHSO system, which is in the order of basicity of these neutral oxo-donors.

The stability constants (β_1 and β_2) for the organic phase synergistic reaction of the trivalent lanthanide–HBFA chelate with neutral oxo-donors were calculated according to Eq. (8) and are given in Table 2. These stability constants for both systems increase with decreasing ionic radii of the trivalent lanthanides. Comparing the log β_1 and β_2 values of Eu–HBFA–S (where S = B2EHSO, TBP, TPhPO and TOPO) of various oxo-donors given in Table 3, it can be concluded that the stability of these adducts follow the order B2EHSO < TBP < TPhPO < TOPO, which is also

Table 2
Equilibrium constants for the organic phase synergistic reactions of trivalent Nd, Eu and Lu–HBFA chelates with B2EHSO or TPhPO in benzene

Ln(III)	Mixture	Log β_1	Log β_2
Nd	HBFA + B2EHSO	2.47 ± 0.01	4.79 ± 0.01
Eu		4.12 ± 0.02	6.19 ± 0.02
Lu		4.32 ± 0.01	–
Nd	HBFA + TPhPO	–	7.56 ± 0.01
Eu		5.62 ± 0.02	9.31 ± 0.01
Lu		5.95 ± 0.01	–

Table 3
Log β_1 and log β_2 values for the formation of $Eu(BFA)_3 \cdot S$ and $Eu(BFA)_3 \cdot 2S$ adducts

S	Log β_1	Log β_2	Ref.
B2EHSO	4.12	6.19	This work
TBP	4.60	7.80	[7]
TPhPO	5.62	9.31	This work
TOPO	6.93	11.86	[7]

the order of basicity of these neutral oxo-donors [8,14].

It can be concluded from the above study that in the extraction of Nd(III) with HBFA in the presence of B2EHSO or TPhPO, the predominant species extracted into the organic phase is $Nd(BFA)_3 \cdot 2B2EHSO$ or $Nd(BFA)_3 \cdot 2TPhPO$. In the cases of Eu(111), two types of species, $Eu(BFA)_3 \cdot B2EHSO/2B2EHSO$ or $Eu(BFA)_3 \cdot TPhPO/2TPhPO$, are extracted into the organic phase. However, in the case of Lu(III), the only species extracted into the organic phase is $Lu(BFA)_3 \cdot B2EHSO$ or $Lu(BFA)_3 \cdot TPhPO$. This is possibly because of the smaller ionic radius of Lu compared with Nd and Eu, causing steric hindrance during the attachment of the second molecule of the neutral oxo-donor.

Table 4 gives the separation factors between these trivalent lanthanides, defined as the ratio of the respective distribution ratios with HBFA (0.3 mol dm^{-3}), (0.3 mol dm^{-3} HBFA + 0.005 mol dm^{-3} B2EHSO) and (0.3 mol dm^{-3} HBFA + 0.0001 mol dm^{-3}) TPhPO systems. It is interesting to note that the addition of B2EHSO or TPhPO to the metal chelate system significantly improves separation factors between these trivalent metal ions.

Table 4
Separation factors for Nd(III), Eu(III) and Lu(III) with HBFA and HBFA + B2EHSO or TPhPO systems

Extractant	Separation factor	
	Eu/Nd	Lu/Eu
HBFA (0.3 mol dm^{-3})	6.2	2.8
HBFA (0.3 mol dm^{-3}) + B2EHSO (0.005 mol dm^{-3})	52.8	3.8
HBFA (0.3 mol dm^{-3}) + TPhPO/ (0.0001 mol dm^{-3})	48.9	5.0

4. Conclusion

The extraction equilibria of trivalent lanthanides with HBFA and also with mixtures of HBFA + B2EHSO or TPhPO has been investigated. The mechanism of extraction can be explained by a simple chemically based model presented in this paper. The results demonstrated that not only enhanced extraction but also better selectivities can be achieved with these mixed-ligand systems. Hence such a system would be of practical values in the extraction and separation of individual lanthanides and also for their separation as a group from other metal ions.

Simultaneous determination of Amaranth and Sunset Yellow by ratio derivative voltammetry

Yongnian Ni*, Jieling Bai

Department of Chemistry, Nanchang University, Nanchang 330047, China

Received 28 December 1995; revised 18 June 1996; accepted 26 June 1996

Abstract

A ratio derivative voltammetric method for resolving overlapping voltammograms without a pre-separation is described. The method is based on the use of the first derivative of ratios of the voltammograms of binary mixtures. The voltammogram of the mixture is obtained and the amplitudes of the current at appropriate potentials are divided by the corresponding amplitudes in the voltammogram of a standard solution of one of the components, and the first derivative of the ratio voltammogram is obtained. The concentration of the other component is then determined from a calibration graph. The method has been successfully applied for resolving binary mixtures of Amaranth and Sunset Yellow, which have overlapped adsorptive voltammograms in pH 6.0 McIlvane buffers.

Keywords: Amaranth; Dyes; Ratio derivative voltammetry; Sunset yellow

1. Introduction

The electrochemical behaviour of a variety of azo compounds has been investigated over the years, and the mechanism of the polarographic reduction of azo compounds has been known for some time [1,2]. Fogg and co-workers [3–12] studied a series of applications of the use of polarography and voltammetry in the determination of these colouring matters. The addition of tetraphenylphosphonium chloride (TPPC) was found to be advantageous in some instances in improving the selectivity as the reduction potentials of some colouring matters, such as Tartrazine, were shifted to more negative potentials, and procedures were given for the determination of Tartrazine–Sunset Yellow, Tartrazine–Green S, Amaranth-Green S and Chocolate Brown–Tartrazine–Green S in soft drinks by differential-pulse polarography (DPP) without prior separation of the colouring matters from the samples [3–5]. Dominguez et al. [13] reported a polarographic method for the determination of Sunset Yellow and Tartrazine in the presence of polyvinyl-pyrrolidone. With this method, it was possible to determine Sunset Yellow in the presence of up to 10 times as much Tartrazine at pH 10.0. However, the determination of Tartrazine in the presence of Sunset Yellow was only possible

PII S0039-9140(96)02028-0

when the Sunset Yellow interferent/Tartrazine ratio was less than 1, and also a different medium of pH 1.6 should be used.

In this paper, a mathematical method which is based on the use of the first derivative of the ratio voltammogram, for the voltammetric analysis of binary mixtures of colouring matters with overlapping voltammetric waves is proposed.

2. Theory

Salinas et al. [14] developed a new spectrophotometric method, named the "ratio derivative spectrum" for resolving binary mixtures. This method has been widely used to solve spectrophotometric problems [15–20]. In this paper, this method is extended to resolve voltammetric problems.

For a binary mixture containing components A and B, the voltammogram of the mixture can be defined by the equation

$$I_i = a_{A,i}C_A + a_{B,i}C_B + I_{i0} \quad (1)$$

where I_i is the voltammetric curent of the mixture at potential E_i, C_A and C_B are the concentrations of A and B, $a_{A,i}$ and $a_{B,i}$ are the proportional coefficients of A and B at potential E_i and I_{i0} is the residual current at E_i, which can be simply denoted as $I_{i0} = k_0 + kE_i$ (k_0 and k are constants here) in a limited potential region.

If Eq. (1) is divided by the proportional coefficient of one of the components (e.g. $a_{A,i}$), the following equation can be obtained:

$$I_i/a_{A,i} = C_A + C_B(a_{B,i}/a_{A,i}) + (k_0 + kE_i)/a_{A,i} \quad (2)$$

By using the first-derivative approach, the following equation can be written:

$$d(I_i/a_{A,i})/dE = C_B d(a_{B,i}/a_{A,i})/dE + k/a_{A,i} \quad (3)$$

where $k/a_{A,i}$ is a constant. Eq. (3) indicates that the amplitude of the "ratio derivative voltammogram" of the mixture at any given potential is dependent only on the value of C_B and is independent on the value of C_A in the mixtures.

A calibration graph is obtained by recording and storing the voltammograms of solutions of pure B at different concentrations. The amplitudes for B are then divided, potential by potential, by the corresponding amplitudes of unit concentration for A. The "ratio voltammograms" thus obtained are then differentiated with respect to potential and the derivative values for a given potential are plotted against C_B to give a calibration graph. Application of the method to a sample containing both A and B, and use of the calibration graph, will then give the value of C_B in the mixture. Component A can be determined by an analogous procedure if it is also overlapped by B.

3. Experimental

3.1. Apparatus

The voltammograms were obtained with a BAS 100A electroanalyser equipped with an electrolytic cell stand (PARC 303A, EG&G). A three-electrode cell containing a mecury drop electrode (the function of a hanging mercury drop electrode (HMDE) was used in this work) as the working electrode, an Ag–AgCl (3 M KCl) electrode as the reference electrode and a Platinum wire as the counter electrode was used. The pH of the solution was measured with a pH meter (Orion SA720). All experiments were performed at 20 °C.

3.2. Reagents

Stock solutions of 10 μg ml^{-1} of Amaranth and Sunset Yellow were prepared by dissolving the crystalline dyes in deionized water. McIlvane buffers (pH 6.0; $I = 0.5$ mol l^{-1}) were prepared from potassium phosphate, citric acid and potassium chloride [21]. All reagents were of analytical-reagent grade.

3.3. Procedure

A suitable amount of Amaranth or Sunset Yellow or their binary mixtures, together with 5.0 ml of buffer solution, was placed in a cell and made up to 10.0 ml with deionized water. The solution was purged with purified nitrogen for 300 s and then electrolysed for 240 s at an HMDE with an accumulative potential of -100 mV. After a 10 s

quiet time, the potential was scanned from −100 to −1100 mV versus the Ag–AgCl reference electrode at a scan rate of 100 mV s^{-1}. The voltammograms were recorded by using a DMP-40 plotter (Houston Instruments) and stored in an IBM 386 computer with an interval of 2 mV. Fig. 1 shows the voltammetric waves of Amaranth and Sunset Yellow.

For the determination of Amaranth, the stored voltammograms of the mixtures were divided by a standard voltammogram (divisor) of Sunset Yellow. The ratio voltammograms thus obtained were smoothed through the use of seven experimental points and the first derivatives were calculated with $\Delta E = 4$ mV [22]. The concentration of the Amaranth was proportional to the amplitude of the minimum at −465 mV (see Fig. 3).

Generally, both components with seriously overlapped voltammograms in binary mixture can be evaluated by the proposed ratio derivative voltammetric method. In this work, however, Sunset Yellow can be determined directly at its peak potential, −500 mV, because there is no influence from Amaranth at this potential (see Fig. 1).

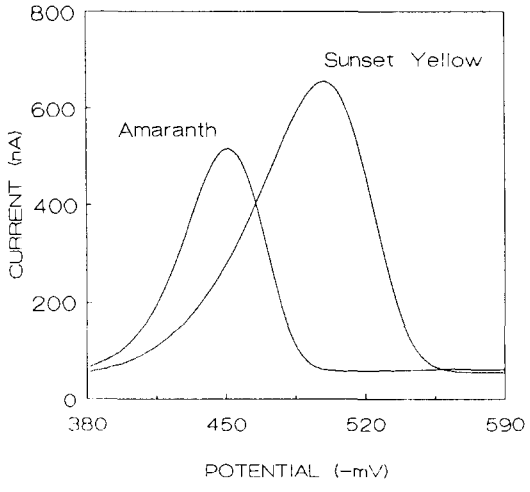

Fig. 1. Voltammetric waves of Amaranth (0.15 μg ml^{-1}) and Sunset Yellow (0.15 μg ml^{-1}).

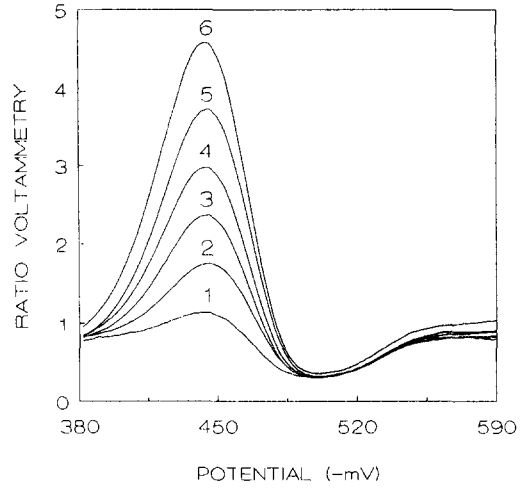

Fig. 2. Ratio voltammograms for different concentrations of Amaranth (0.03 μg ml^{-1} Sunset Yellow as divisor): (1) 0.03; (2) 0.06; (3) 0.09; (4) 0.12; (5) 0.15; (6) 0.18 μg ml^{-1}.

4. Results and discussion

4.1. Selection of the standard solution for divisor

In this work, if the voltammogram of component A with known concentration C_A^0 is used to replace the proportional coefficient (i.e. the voltammogram of unit concentration) as divisor. Eq. (3) will then become

$$d(I_i/a_{A,i}C_A^0)/dE = (C_B/C_A^0)d(a_{B,i}/a_{A,i})/dE + k/(a_{A,i}C_A^0) \quad (4)$$

This is valid for the determination of B. Hence in pratical experiments, a solution with suitable concentration was chosen as a standard factor (divisor). In this work, 0.03 μg mg^{-1} Sunset Yellow was used as a standard factor for the determination of Amaranth. The term $k/(a_{A,i}C_A^0)$ represents the effect of the residual current, and in most cases it can be eliminated.

4.2. Determination of Amaranth and Sunset Yellow in synthetic mixtures

Figs 2 and 3 are the ratio voltammograms and their ratio derivative voltammograms of Amaranth with different concentrations (the voltam-

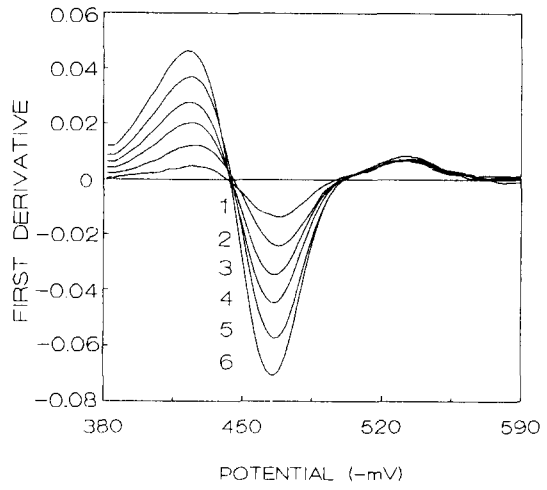

Fig. 3. First derivatives of ratio voltammograms for different concentrations of Amaranth (0.03 μg ml^{-1} Sunset Yellow as divisor); (1) 0.03; (2) 0.06; (3) 0.09; (4) 0.12; (5) 0.15; (6) 0.18 μg ml^{-1}.

mogram of 0.03 μg ml^{-1} Sunset Yellow as divisor). The amplitudes of the derivative voltammogram at the peak potential, −465 mV, were selected as the measurement potential. The calibration graph for Amaranth is represented by $D_1 = -9.53 \times 10^{-4} - 0.379\ C$ ($r = 0.9985$).

The calibration graph at −500 mV for the determination of Sunset Yellow can easily be obtained as $I = 18.4 + 3.88 \times 10^3\ C$ ($r = 0.9997$).

Table 2
Determination of Amaranth and Sunset Yellow in drinks

Samples	Found (μg ml^{-1})[a]	
	Amaranth	Sunset Yellow
Orange juice	1.1 (0.1)	32.4 (0.8)
Fruit juice	4.1 (0.4)	8.9 (0.5)
Merida orangeade	2.1 (0.4)	49.9 (1.5)

[a]Values in parentheses are standard deviations ($n = 3$).

In this work, ten synthetic mixtures of Amaranth and Sunset Yellow were analysed by the proposed method. The results are given in Table 1.

4.3. Determination of Armaranth and Sunset Yellow in drink

The proposed method was also applied to the determination of these two colouring matters in several soft drinks produced in China. The samples were dissolved in a certain volume of deionized water, gently warmed to dissolve completely and filtered. Measurements were carried out directly as described above using an HMDE. The results are given in Table 2 and are in agreement with the manufacturer's specifications.

Table 1
Resolution of Amaranth and Sunset Yellow mixtures by the proposed method

Sample No.	Added (μg ml^{-1})		Found (μg ml^{-1})		Recovery (%)	
	Amaranth	Sunset Yellow	Amaranth	Sunset Yellow	Amaranth	Sunset Yellow
1	0.030	0.160	0.025	0.171	83.3	106.9
2	0.030	0.100	0.024	0.110	80.0	110.0
3	0.030	0.040	0.032	0.040	106.7	100.0
4	0.160	0.160	0.138	0.140	86.3	87.5
5	0.160	0.100	0.150	0.096	93.8	96.0
6	0.160	0.040	0.169	0.042	105.6	105.0
7	0.100	0.160	0.084	0.147	84.0	91.9
8	0.100	0.100	0.097	0.108	97.0	108.0
9	0.100	0.040	0.101	0.043	101.0	107.5
10	0.080	0.080	0.074	0.076	92.5	95.0

5. Conclusion

The results show that the proposed method is effective for resolving binary mixtures and suitable for the simultaneous voltammetric determination of Amaranth and Sunset Yellow in the concentration range 0.03–0.16 $\mu g\ ml^{-1}$, which is much more sensitive than spectrophotometric approaches [19]. This work indicates that some voltammetric problems can benefit from the mathematical methods often used in spectrophotometry.

Control samples for the determination of pH in low ionic strength waters: consensus values from interlaboratory tests

M.J. Gardner[a,*], J.E. Ravenscroft[a], C. Ackers[b]

[a] *WRC, Henley Road Medmenham, Marlow SL7 2HD, UK*
[b] *Central Regional Council, St. Ninians Road, Stirling FK8 2HB, UK*

Received 19 February 1996; revised 17 April 1996; accepted 4 July 1996

Abstract

The results of a series of interlaboratory tests using low ionic strength buffer solutions are reported. The test data and other background information are presented as the basis for more realistic quality control materials for pH determination in low ionic strength waters. The effect of atmospheric carbon dioxide on the pH of low ionic strength reference samples is discussed. Several control samples are recommended for routine use.

Keywords: pH determination; Quality control; Waters

1. Introduction

In an earlier paper [1], we identified four desirable characteristics for an analytical quality control (AQC) sample for pH determination in low ionic strength waters: (a) it should be of known pH value, to allow systematic error to be assessed; (b) it should have a similar susceptibility to the main sources of measurement error as real samples; (c) it should be adequately stable to allow its use in an extended series of batches of analysis; and (d) it should be a similar pH (and ionic strength; see (b)) to unknown samples. Subsequently, Peck and Metcalf [2] identified the need to make separate checks on sample handling and on the measurement stage of analysis. In their view, this necessitated two types of control sample. The first would be adequately stable (not susceptible to change by exchange of carbon dioxide (CO_2)), of well characterized pH and appropriate ionic strength. This sample would be used to validate the measurement process. The second sample would be subject to the sources of potential sample instability, as a check on sample handling. In a well argued paper, they went on to use computer modelling of chemical equilibria to compare calculated pH values with the results of careful measurement and interlaboratory tests. They recommended two solutions/test samples which would be used as more realistic AQC solu-

PII S0039-9140(96)02042-5

tions (than high ionic strength buffers) for the determination of the pH value of environmental samples.

The most common practice for the day to day determination of pH, in environmental and water laboratories, is to use a buffer solution as an AQC sample. Such solutions are of relatively high ionic strength in comparison with the natural waters that are examined routinely. The use of a high ionic strength buffer solution satisfies few (none apart from (a)) of the key quality control criteria above.

This paper is intended to extend the process of defining a range of more relevant (i.e. than high ionic strength buffers) control samples for pH determination. The two solutions recommended by Peck and Metcalf [2] are of very low ionic strength (ca. 10^{-4} M). These are appropriate to monitoring of very soft upland waters, those which are most susceptible to acidification. The samples discussed here are more applicable to determinations of pH in a wider range of surface and potable waters (ionic strength ca. 10^{-3} M). The aim of this paper is to present the results of a series of interlaboratory tests for pH determination in water samples. The test samples used and the measured values for pH are presented as an illustration of the types of solution which might be employed as more realistic, routine quality control test samples. The group of laboratories carried out a rigorous programme of internal performance testing. This helps to provide consensus estimates of pH which can be regarded as reliable reference values for future use. The role of atmospheric CO_2 in determining the reference pH value of low ionic strength check samples is also discussed.

2. Interlaboratory tests

SADWSS (the Scottish Association of Directors of Water and Sewerage Services) coordinates AQC activity between Scottish Regional Council laboratories in order to achieve and to demonstrate adequate standards of accuracy in chemical analysis. Principal areas of activity for the SADWSS AQC Group are drinking water quality monitoring and the control of effluents discharged to rivers and estuaries. Laboratories of the Department of the Environment (Northern Ireland) Water Executive are also involved in the AQC programme. WRc has acted on behalf of SADWSS to design within- and between-laboratory AQC test programmes and to conduct and interpret a series of within-laboratory and interlaboratory tests for a wide range of determinands. This work has been carried out over a period of 6 years, beginning in 1990.

The accuracy of chemical analysis can often fall short of that required for its intended purpose. A stepwise approach to testing different components of the analytical system has been devised [3] and applied in water analysis in the UK for a number of years. Applications have included the determination of pH [4,5]. This approach was used by the laboratories involved in SADWSS programme.

For pH determination, the work programme involved: (a) adoption of a best practice approach to pH determination as recommended by Covington et al. [6]; (b) within-laboratory tests of precision; and (c) confirmation that adequate accuracy has been achieved by means of an interlaboratory test. The within-laboratory tests can be summarized as follows. In each of 11 batches of analysis, each laboratory made duplicate determinations on the solutions, including a NIST postassium hydrogenphthalate (0.05 M) buffer, a 1×10^{-4} M solution of hydrochloric acid, a 1×10^{-5} M solution of hydrochloric acid and two samples of drinking water. The results of these tests were subjected to an analysis of variance and the overall (total) standard deviation [7] of results was estimated for each laboratory–sample combination. The maximum acceptable value for total standard deviation was set at 0.05 pH units. Laboratories which failed to achieved this standard of precision took action to improve and repeated the tests as a demonstration of satisfactory control over random error.

3. Experimental

Each test involved the distribution of 1 l portions of five test solutions. Samples were prepared

in 50 l portions which were homogenized and distributed by overnight carrier in fully filled low-density polyethylene bottles. Participants were advised that pH determinations should be carried out within 3 days of sample receipt. Test samples were chosen to be of pH value relevant to participants' routine work. Interest centred on the pH region of 5–6 for the control of aluminium flocculation in water treatment processes and of higher pH values, in the range 7–9, for potable waters supplied to the water distribution system. Participants were asked to carry out four pH determinations on each sample, in two separate batches of analysis. The pH values of the samples were determined at WRc before distribution and 3 and 6 days afterwards. Samples were found not to change by more than 0.05 pH units (except hydrogencarbonate buffers, see below). The target for comparability of pH measurement was that laboratories' mean results should not differ from the reference value by more than 0.1 pH unit. Reference values were established by the coordinating laboratory (WRc) by measurement using two pH systems, each incorporating free flowing junctions (Orion "Ross" pH electrode and separate reference calomel (or "Ross" reference) electrodes).

An essential confirmatory check on the reference pH values and on sample stability for the interlaboratory tests was provided by comparison between the consensus mean pH (after rejection of data from laboratories which showed a consistent bias of greater than 0.1 pH units for several solutions in a given test) and the WRc value. Since the laboratories operated a rigorous programme of within-laboratory quality control, the incidence of rejection was low, not more than two rejections per test.

4. Results

Data from the interlaboratory tests reported here were obtained over a period of 4 years. Table 1 shows the results of the series of interlaboratory test for pH determination. Each test involved analysis of five solutions. Of these, several were intended as candidates for routine quality control samples. The compositions of these solutions and the relevant results are shown, together with the consensus mean values and WRc reference values. In each case the range of participants' results is shown. The number of laboratories taking part in each test (and hence contributing to the consensus value) was 11 at the start of the series of tests (1990). The results of these laboratories have been reported in Table 1 for the whole series of tests.

5. Discussion

The 'true pH value' is the key to be addressed for all check samples/buffers. pH values may be assigned in a number of ways. Primary reference values and pH scales are set for standard buffers with respect to a number of conventions (see, for example, Ref. [8]). The observed pH of most measurements is relative to the pH of these primary buffer values. The question here, in relation to the routine quality control (QC) check solutions used in these interlaboratory tests, is one of deciding on an accepted value for routine QC use, rather than assigning a primary reference value. The values given in Table 1 are those observed in a series of interlaboratory tests. We propose that these values can act as a guide to the reference value, against which bias can be evaluated, for routine control purposes.

For the dilute acid samples and the succinate buffers, the difference between the WRc values and the consensus mean values is 0.04 units pH or less. Nevertheless, the laboratory mean value is often negatively biased with respect to the WRc value. A principal source of error for pH determination in lower ionic strength sample is negative bias caused by liquid junction potential effects. This probably accounts for much of the observed bias. The tendency towards negative bias is clearer (although not necessarily larger) in the case of the phosphate buffers, particularly for the lower ionic strength samples. The largest difference is −0.04 pH units, for the lowest ionic strength samples (a test carried out at the start of the series of tests (12/90) was excluded; after this test, many laboratories took steps to minimize liquid junction errors by ensuring a more freely flowing junction, either by applying pressure to the reference cell or

Measurements were made at 20 ± 1°C; calculated values are for 20°C.
[a] With CO_2 refers to full equilibration with atmospheric CO_2; loss or gain can occur.

by using a newer electrode (with a less blocked junction)). Given this and acknowledging that it is not possible to justify either value as completely unbiased, we propose that analysts using the solutions as control samples should expect to obtain long-term mean pH values which are in the range limited by the WRc value and the laboratory mean. Measured mean pH values less than the lower limit of this range might be considered as evidence of negative bias (i.e. sources such as calibration or liquid junction errors should be investigated). Values higher than the upper limit of the range might be taken to be evidence of positive bias (perhaps arising from calibration errors or lack of electrode equilibration). The results for hydrogencarbonate buffers (see Ref. [2]) are not reliable for reasons discussed below.

The results of these tests can be compared with those from the interlaboratory tests carried out by Koch and Marinenko [9]. They obtained a very small between-laboratory range of results (less than 0.1 pH unit) for a dilute acid standard solution. This study illustrates a wider range of 0.1–0.36 pH unit for similar samples. The relatively high precision demonstrated by Koch and Marinenko related to closely defined procedures used in relatively specialist laboratories whose main interest was surface water acidification. The wider range shown relates to routine measurements in water utility laboratories. The standard of accuracy achieved in this study met the requirements defined for drinking water quality monitoring by the UK Water Supply Regulations (Department of the Environment, 1990) in most cases.

5.1. Effect of CO_2 on pH for low ionic strength buffers

The measured pH values in Table 1 are compared with two values calculated using the MINTEQ chemical equilibrium model [10]. The first is arrived at on the assumption that atmospheric CO_2 does not interact with the sample; the second assumes equilibration with a partial pressure of 315 ppm with respect to the volume of CO_2. The former assumption is the one usually made for standard buffers. This is consistent with the practical approach of establishing the pH of these solutions in the absence of CO_2 and the fact the effect of exposure to atmospheric CO_2 has relatively little effect on the pH of solutions of high buffer capacity (and high ionic strength). However, as the molarity of buffer solutions is decreased, it becomes increasingly difficult to justify the assumption the CO_2 has no effect under normal measurement conditions. We have to ask the question, "how much does CO_2 change the pH of a buffer of ionic strength nearer to that of real samples?" Samples of pH <6 are unlikely to be affected by CO_2. For the solutions of higher pH, it cannot be immediately assumed that the sample in question achieves full equilibration with the atmosphere.

Covington et al. [11] have undertaken primary reference pH determination for a diluted version of the standard NIST phosphate buffer. They chose a 10-fold dilution. Their value was based on use of a platinum-hydrogen electrode system with exclusion of atmospheric CO_2 (the normal convention for reference buffers). Peck and Metcalf [2] established an empirical value for a 200-fold dilution of the same standard NIST buffer; this was backed up by model calculations (assuming equilibration with atmospheric CO_2). Our results for a 50-fold dilution of the same standard buffer and other samples are given in Table 1.

The results suggest that caution is required in using equilibrium computer modelling to calculate the reference pH value for low ionic strength buffers, which may be sensitive to atmospheric CO_2. In such models, it is sensible, at first sight, to include the influence of a normal partial pressure of CO_2. It is also tempting to assume that the modelled value is the pH when the buffer is in equilibrium with a normal laboratory atmosphere. However, this is not the case. The modelled value is a true equilibrium value. True equilibrium may only be achieved after a considerable time and may involve the exchange (absorption or loss) of a substantial quantity of CO_2, more than might be available in practice. The data in Table 1 suggest that full equilibrium may not be achieved under the normal conditions of measurement, either for the buffer samples or for real waters. Even for samples such as the 50-fold dilution of

Table 2
Recommended AQC samples

Buffer composition	Ionic strength (M)	Nominal pH value
5×10^{-4} M $KH_2PO_4 + 5 \times 10^{-4}$ M Na_2HPO_4	2×10^{-3}	7.14 (7.11–7.15)
0.01 M borax	3×10^{-2}	9.23 (9.22–9.25)
0.6×10^{-3} M NaH succinate + 1.8×10^{-3} M Na_2 succinate	6×10^{-3}	5.58 (5.57–5.59)
2.5×10^{-5} M HCl	2.5×10^{-5}	4.61 (4.60–4.62)

the NIST phosphate buffer, which are not very sensitive to CO_2, it appears that the modelled value which does not take account of atmospheric CO_2 is a closer estimate of the consensus/reference value than a fully equilibrated value.

In the case of the hydrogencarbonate sample, the stability of the sample is so poor that neither the "no CO_2" nor the "full CO_2" value is appropriate. These samples are probably only suitable to be used as check samples if special precautions are taken to ensure adequate equilibration. The modelled equilibrium values for hydrogencarbonate buffers involve a substanial loss of CO_2. This appears not to reach completion under normal laboratory measurement conditions.

6. Conclusions and recommendations

The determination of pH is often regarded as "trivial", something which may be entrusted to non-analysts or even to poorly trained personnel. pH remains the most fundamental measure of water quality, one which controls the fate and behaviour of a wide range of key quality parameters. Accurate pH determination is far from straightforward; the production of useful pH data requires an awareness of potential sources of error and validation by the application and documentation of soundly based AQC procedures.

The determination of pH in natural waters can be subject to at least three critical sources of error which are not addressed by checks using buffer samples: ionic strength-based, liquid junction potential errors, bias due to lack of glass electrode equilibration and CO_2 exchange effects. Although the principles of analytical quality control are now appreciated and at least partially implemented in the majority of water laboratories, routine AQC practice can still fail to provide a reliable check on accuracy. There is a need for more relevant control analyses, measurements which are subject to the same potential sources of error as those which can affect routine analyses. The use of more sophisticated control materials is an important step in the development of improved approaches to routine AQC for the determination of pH and a wide range of other determinands.

The samples summarised in Table 2 are recommended as routine AQC samples, which might be used for pH determination in natural waters.

The use of such QC buffers provides a more realistic assessment of measurement error for pH. The effect of poor sample handling remains a challenge; reliable techniques for the evaluation of the effect of CO_2 exchange still need to be developed.

Received 30 October 1995; revised 10 May 1996; accepted 6 June 1996

Abstract

A widely-used method for the spectrophotometric determination of procyanidins in wines has been adapted to wine vinegar samples. Reagent concentrations have been established and the analytical method tested for possible matrix effects. The recovery of catechin was approximately 98% and the limit of reliable measurement was 0.48 mg l^{-1}. The within-day and between-day precisions were evaluated and according to the two-tailed *F*-test the precisions were statistically equivalent. Application to wine vinegars obtained by traditional and quick acetification methods showed differences in concentration between the two groups.

Keywords: Procyanidins; Spectrophotometry; Wine vinegars

1. Introduction

Phenols encompass heterogeneous groups naturally occurring in plant products. Their occurrence in grapes and wines [1] has been exhaustively reviewed. Among the wine and vinegar constituents, flavanoids represent an important kind of phenol [2]. Grape anthocyanins are particularly interesting as they are responsible for wine colour development. During the maturation of wines, anthocyanins slowly undergo numerous chemical processes involving colourless flavanoids that were originally present in the grape to produce procyanidins, whose presence in wines is an indicator of the extent of contact of musts (unfermented grape juices) with grape seeds and, to a lesser extent, with grape skins. Accordingly, analytical procedures for determination of procyanidins in wines and vinegars were developed. Today, HPLC methods are well suited for these purposes as well as for pattern recognition [3–8], but they are also expensive and time-consuming. Here we are interested in procedures for the rapid estimation of the global procyanidin content using simple instrumentation.

Procyanidins containing the phloroglucinol group can be spectrophotometrically quantitated by reaction with vanillin (or other similar aldehydes) to yield a quinoid product whose colour can vary from a pale to a deep pink. The product has an absorption maximum at 500 nm. This procedure was proposed in 1959 by Swain and Hillis [9] for the "catechins assay in wines" and has remained, practically unchanged. However, when the method is applied to vinegars, excessively scattered results are obtained [10]. The aim of the present paper is a deeper study of the variables that influence the reaction development and their corresponding optimization for wine vinegars, as well as the improvement of the procedure in terms of sensitivity and reliability.

2. Experimental

2.1. Reagents

D-catechin (Fluka), vanillin, concentrated hydrochloric acid, methanol and ethanol (Merck) were used as received. Glass-distilled water was used throughout. Vanillin solutions can be kept for longer than 4 months if stored in an amber bottle in a refrigerator. D-catechin stock solution and alcoholic hydrochloric acid solutions should be prepared daily.

2.2. Apparatus

Absorbance measurements were carried out using a Milton Roy Spectronic 3000 photodiode array spectrophotometer fitted with matched silica cuvettes of 10 mm pathlength.

2.3. Samples

20 commercial wine vinegars were studied: 10 of them were obtained from quick acetification processes and the other 10 were obtained by the dynamic solera system (slow acetification of sherry vinegars).

3. Results and discussion

3.1. Study of influencing variables

In order to attain optimal conditions for reaction development, a preliminary study of the influence of the variables or factors substantially involved in the chemical process was done. The starting point was the reaction scheme of Broadhurst and Jones [11], who established the optimum addition order. Thus, we have taken from these authors the following procedure. To a 25 ml volumetric flask containing 2.5ml of catechin solution (or a sample containing catechin), add 7.5 ml of vanillin reagent and then, add hydrochloric acid solution to the mark. Mix well and allow to stand for about 25 min. Measure the absorbance at 500 nm. Note that protection from direct light is needed. The solvent used for preparing the vanillin reagent (alcohol) is the same solvent used for the hydrochloric acid solution. Accordingly, we have chosen to vary the following factors: the nature of the alcoholic solvent, the concentration of hydrochloric acid and the vanillin concentration. The catechin probe was a solution of 100 mg l^{-1}. The original reagents used were 8 M HCl in ethanol and 1% vanillin in ethanol.

3.1.1. Effect of the nature of alcohol

Methanol and ethanol were used as solvents in order to compare their influence on the measured absorbance. The effect of substituting ethanol for methanol (all other conditions were fixed with the original reagents and a catechin concentration of 100 mg l^{-1}), is in all cases, an enhancement of the absorbance. This indicates that methanol is the better choice for the development of the reaction. This effect can be explained according to the high polarity of methanol which may cause a hyperchromic effect on the $n-\pi^*$ transition responsible for the colour intensity.

3.1.2. Effect of the concentration of hydrochloric acid

Different methanolic hydrochloric acid solutions ranging from 2 to 10 M in HCl were prepared by taking the required volume of

concentrated hydrochloric acid in a volumetric flask and then adding methanol to the mark. The development of the reaction was monitored at fixed concentrations of 1% vanillin in methanol and 100 mg l^{-1} catechin. As can be observed in Fig. 1, the measured absorbance increases with the concentration of hydrochloric acid. However, for HCl concentrations greater than 7.2 M, vanillin-containing blanks seem to undergo some condensation process leading to green-yellowish products. So, in order to avoid this undesirable behavior of the blanks, a fixed concentration of 7.2 M HCl was selected for further experiments. The corresponding absorbance vs. hydrochloric acid concentration plot for blanks is also presented in Fig. 1.

3.1.3. *Effect of the vanillin concentration*

The reaction was performed using several vanillin solutions whose concentrations ranged from 1% to 16% in methanol. The fixed conditions were 100 mg l^{-1} catechin and 7.2 M HCl in methanol. The more the vanillin concetration increases, the more the reaction displays its sensitivity. Saturation was attained at about 12% of

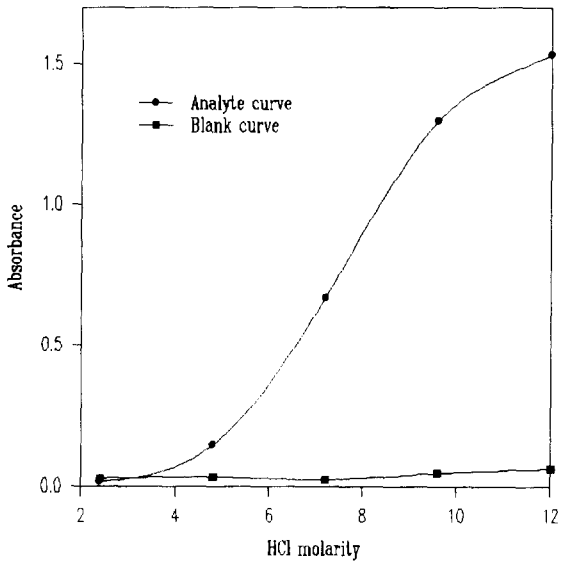

Fig. 1. Effect of the concentration of hydrocloric acid on the colour development of the vanillin reaction for a catechin probe and for a blank as indicated in the text.

vanillin. Accordingly, the analytical optimized procedure for catechin determination is as follows. To a 25 ml volumetric flask add 2.5 ml of vinegar sample containing not more than 100 mg l^{-1} catechin, 7.5 ml of 12% vanillin reagent and 7.2 M HCl in methanol to the mark. Mix well and measure the absorbance at 500 nm after 25 min. Readings are stable for at least 10 min.

3.2. *Evaluation of the analytical procedure*

3.2.1. *Accuracy: Constant and proportional bias*

For preventing possible matrix effects of vinegar samples, the Method of Standard Additions (MOSA) was applied in conjunction with the conventional external calibration (EC) [12] using catechin aqueous standards. Assuming the non-existence of direct matrix effects, the determination of the Total Youden Blank (TYB) is a prior step in the application of MOSA. Cardone [13] had pinpointed the difference between the typical analytical blank and the TYB, namely that the analytical blank cannot be subtracted from the analytical signal, because it comes from a treated solution of free-matrix sample analyte. The Youden plot [14] consists of plotting the analytical signal against increasing amounts of test portion (TP). The value obtained from extrapolation to TP = 0 is the TYB, directly involved in the occurrence of constant bias in calibration. Accordingly, in order to remove possible constant bias in our case, a Youden plot was performed for all vinegar samples by taking different sample volumes of vinegar (six points) and then measuring the absorbance after the application of the proposed analytical assay. For all vinegars TYBs are within the range 0.0098–0.0091. According to the Student t-test (at a 5% confidence level), these intercepts have no statistical significance [15] and consequently there is no constant bias in all the studied vinegar samples.

MOSA and EC were then carried out for the study of possible proportional bias in calibration. MOSA slopes for all vinegar samples were averaged to the value $b_{MOSA} = 0.044 \pm 0.002$, whereas the EC slope was taken as $b_{EC} = 0.045 \pm 0.003$. The difference between these slopes is statistically

Table 1
Total procyanidines, expressed as catechin (mg l^{-1}) of different vinegar samples

Vinegars from quick acetification methods (sample number)	Catechin concentration (mg l^{-1})[a]	Vinegars from sherry (sample number)	Catechin concentration (mg l^{-1})
1	154.0	1	10.5
2	217.0	2	4.1
3	92.2	3	6.1
4	61.8	4	20.6
5	59.9	5	9.8
6	217.3	6	18.1
7	364.2	7	32.7
8	106.0	8	14.1
9	408.2	9	13.6
10	414.4	10	14.2

[a]Data are means of triplicate determinations.

non-significant and, therefore, the neglection of proportional bias is acceptable. This ensures that conventional EC may be used for the quantization of catechin in vinegars. The recoveries calculated from the quotient b_{MOSA}/b_{EC} were about 98%, indicating the suitability and reliability of the assay. Accordingly, the linear dynamic range for the EC straight line was 0–10 mg l^{-1} catechin. By taking the sensitivity as the slope of the EC curve, the proposed procedure is somewhat more sensitive than the conventional one according to the optimization performed as described above. The limit of reliable measurements (LRM) is calculated from EC data following the method proposed by the AOAC [16]. The averaged value from the LRMs obtained from 11 between-days calibration graphs is 0.48 mg l^{-1} catechin. For validation purposes, a further assesment for accuracy was performed with spiked vinegar samples by calculating the recovery as the mean value of the recoveries found at each fortification level. In all cases recoveries were close to 100% and, accordingly, the method is suitably validated.

3.2.2. Precision

For the study of precision, target samples of 40 mg l^{-1} catechin were analyzed according to the proposed procedure. The within-day precision or repeatability expressed as the percent RSD is 2.7% (10 replicates). The between-days precision or reproducibility is 5.6% (six randomized determinations over 1 month using the same materials, appartatus and stock reagent solutions). The two-tailed F-test indicated that within the frame of our experiments both precision measurements are statistically equivalent.

3.2.3. Application to vinegar samples

The proposed procedure was applied to the determination of total procyanidins expressed as catechin in 20 vinegar samples as indicated above. Vinegars containing more than 100 mg l^{-1} procyanidins were suitably diluted with water. Results obtained from EC graphs (mean of triplicate determinations) are presented in Table 1. As can be observed, the procyanidin contents of quick acetification vinegars range from 414.4–59.9 mg l^{-1} whereas procyanidin concentrations of sherry vinegars are 4.1–32.7 mg l^{-1}, noticeably lower. This is statistically proved using the non-parametric Tuckey quick test [17]. From these results, the total procyanidin content can be considered as a good descriptor for pattern recognition of different wine vinegars. Moreover, the determination of total procyanidins in wine vinegars may be of interest in order to elucidate the quality of the substrate employed for the acetification. If the substrate wine is of overpressure basis (where the musts are processed at high pressure) the procyanidin content may presumably be higher than with a quality wine substrate.

In order to compare the results obtained from the proposed procedure with those obtained from the "traditional" method of Swain and Hillis [9], this latter was applied to the same vinegar samples presented in Table 1. However, in all cases, the catechin content cannot be reliably calculated because of the dramatic fading of the absorbance measurement, which leads to data so strongly dispersed as to make comparison impossible. This behaviour is in agreement with the results reported by Gil and Gómez-Cordovés [10] and indicates that the Swain and Hillis method for determination of procyanidins in wines cannot be applied to vinegars without adaptation.

4. Conclusions

The traditional method for spectrophotometric determination of total procyanidins by reaction with vanillin has been optimized. EC graphs suffice for reliable determinations of catechins in vinegar samples. Quick acetification vinegars exhibit greater procyanidin contents than sherry vinegars.

Abstract

Reactive Violet 5 and its hydrolysis product, which is produced as a side product in the dyeing process, can be determined in an admixture at sub-ppb levels by cathodic stripping voltammetry because the potentials of their azo reduction peaks are separated sufficiently. For both dyes, at intermediate pH values the azo peak is preceded by a complexed -copper reduction peak at a less negative potential, which aids the identification of the dyes. The use of pH 6 EDTA buffer removes the complexed-copper peak, as does the use of an acidic buffer (pH < 3). This unusual use of EDTA as a pH buffer facilitates the determination of mixtures of the dye and its hydrolysis product.

Keywords: EDTA; Hydrolysis product; Reactive Violet 5; Stripping voltammetry

1. Introduction

There is a need for methods of determining dyes, and particularly reactive dyes which form a major part of the dye market, at concentration levels below those which can be determined by visible and UV spectroscopy. In the case of the most efficient reactive dyes about 80% of the dye becomes covalently bonded to cotton [1]. Much of the rest of the dye becomes hydrolysed and has to be washed out of the fabric. This residual dye has to be removed from the effluent before discharge. Visible observation of the effluent is used to indicate satisfactory removal of the colour. However, it would be useful to be able to determine the exact concentration of dye, below that which can be observed visibly, in the discharge. Such low-concentration determinations would be useful in developing methods of removing dyes from effluent, e.g. in assessing the effectiveness of zeolites for this purpose. Further, for health reasons there is a need to monitor any unhydrolysed reactive dyes that are discharged as their half-lives in near neutral solution are long and they will react with proteins, etc. in the ecosystem. Finally, in the development of new reactive dyes there is a need for methods capable of monitoring the dyes

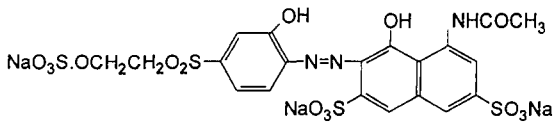
PII S0039-9140(96)02014-0

and their products in dyeing and dyeing simulation (e.g. by reaction with methanol) reactions.

In addition to visible observation, HPLC with UV–Visible detection is used to monitor reactive dyes and their reaction products, but there are difficulties in distinguishing (i.e. in obtaining sufficiently different retention times) between the dyes and their products and, in some situations, the detection limit is not adequate [2,3]. Electrolytes in effluent are a further problem in applying HPLC [3].

In previous publications from this laboratory the ability to determine reactive dyes down to sub-ppb levels by cathodic stripping voltammetry (CSV) has been demonstrated [4–7]. Chromophores, such as azo and anthraquinone groups, are reducible at the hanging mercury drop electrode (HMDE), although the differential pulse signal of the anthraquinone group has been shown to be absent in the case of very fast reduction processes owing to the nature of the differential pulse technique [4]. The chloro- and dichloro-triazine groups are also reducible. The hydrolysis and methanolysis reactions of Procion Blue MX-R and Cibacron Blue 3GA were followed by differential pulse CSV by observing the loss of the chlorotriazine peak or the appearance of the anthraquinone peak: the latter peak is present in the case of the hydrolysed dyes [4]. The differential pulse CSV peaks of these reactive dyes are also present for solutions of the dyes in borate buffer, owing to the complexation of the aminoanthraquinone group by boron, which apparently slows the rate of reduction [4]. The hydrolysis of several azo reactive dyes having the same basic structure but different potential leaving groups has been followed by observing the loss of the peak due to the leaving group [7].

In this present study the CSV of Reactive Violet 5 (**I**)



(I)

and its hydrolysis product are reported. This is the first report of the CSV of a copper-complexed reactive dye and further illustrates the dual use of EDTA as a pH buffer and as a complexant.

2. Experimental

2.1. Apparatus and reagents

CSV was carried out with a Metrohm 646/647 VA Processor, using a multi-mode electrode in the HMDE mode. The three-electrode system was completed by means of a glassy carbon auxiliary electrode and an Ag/AgCl (3 M KCl) reference electrode. All potentials are quoted relative to this reference electrode. Differential pulse voltammetry was carried out with a pulse amplitude of 50 mV, a scan rate of 10 mV s^{-1} and a pulse interval of 1 s.

A sample of Reactive Violet 5 was kindly provided by Zeneca Specialities. Standard solutions were made by dissolving weighed amounts of the dye in water before making up to volume.

Britton–Robinson buffer, 0.02 M in acetic, *o*-phosphoric and boric acids, was adjusted to the required pH with dilute sodium hydroxide solution. The pH 6 EDTA buffer was 0.04 M in EDTA.

The general procedure used to obtain cathodic stripping voltammograms was as follows. A 20 ml aliquot of buffer solution was placed in a voltammetric cell and the required volumes of dye and copper(II) solutions were added using a micropipette. The stirrer was switched on and the solution was purged with nitrogen gas for 5 min. After forming a new HMDE, accumulation was effected for the required time at the appropriate potential whilst stirring the solution. A medium drop size ($\approx$0.40 mm^2) was used. At the end of the accumulation time the stirrer was switched off, and after 10 s had elapsed to allow the solution to become quiescent, the negative-going potential scan was initiated. When further volumes of dye or copper(II) solution were added to the cell, the solution was deoxygenated with nitrogen gas for 1 min before carrying out further voltammetry.

Standard solutions of hydrolysed Reactive Violet 5 were prepared by dissolving weighed

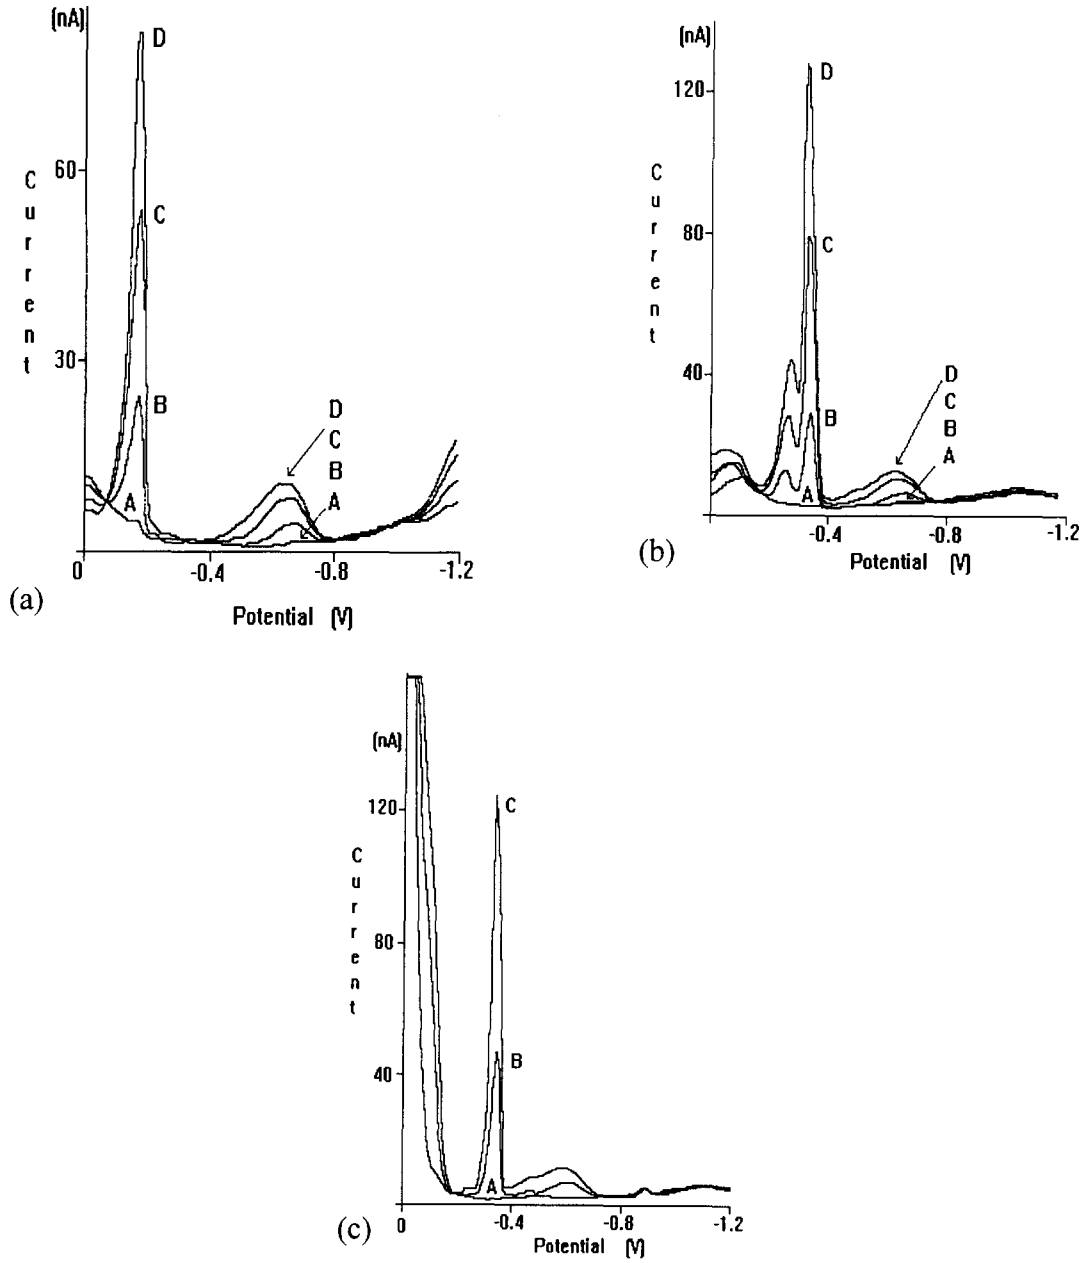


Fig. 1. Cathodic stripping voltammograms of Reactive Violet 5 in various buffers: (a) Britton–Robinson buffer pH 3; (b) Britton–Robinson buffer pH 6; (c) EDTA buffer pH 6. Reactive Violet 5 concentration: (a,b) A,0; B,1; C,3; D,5 $\times 10^{-7}$ M; (c) A,0; B,2; C,5 $\times 10^{-7}$ M.

amounts of Reactive Violet 5 in 5 ml of 0.1 M sodium hydroxide solution, heating for 4 h, cooling, neutralising with 0.1 M hydrochloric acid solution, and diluting with water to the required volume.

3. Results

Typical cathodic stripping voltammograms of Reactive Violet 5 at the 1×10^{-7}–5×10^{-7} level in Britton–Robinson and EDTA buffers are

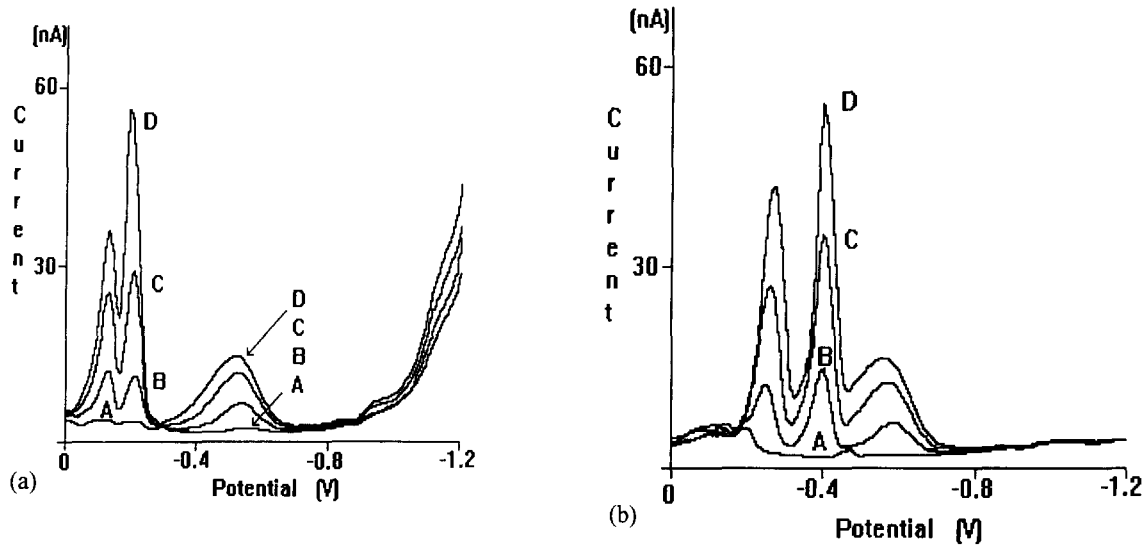

Fig. 2. Cathodic stripping voltammograms of hydrolysed Reactive Violet 5 in various buffers: (a) Britton–Robinson buffer pH 3; (b) Britton–Robinson buffer pH 6. Hydrolysed Reactive Violet 5 concentration: A,0; B,1; C,3; D,5 × 10^{-7} M.

shown in Fig. 1. In pH 3 Britton–Robinson buffer (Fig. 1a) the azo peak is clearly seen at −0.17 V without the complexed-copper peak, but in pH 6 Britton Robinson buffer (Fig. 1b) the complexed-copper peak is clearly seen at −0.29 V and is incompletely resolved from the azo peak at −0.36 V. In pH 6 EDTA buffer (Fig. 1c) the complexed-copper peak is absent. With accumulation at 0 V the slope of a large peak at a less negative potential due to reduction of the mercury EDTA complex is apparent, but the azo peak is completely resolved from this at −0.36 V.

In the case of hydrolysed Reactive Violet 5 the azo peak appears at −0.23 V in pH 3 Britton–Robinson buffer and the complexed-copper peak is also present at −0.17 V (Fig. 2a), in contrast to the situation with the reactive dye. The complexed-copper peak at −0.31 V is better resolved from the azo peak at −0.45 V in pH 6 Britton–Robinson buffer (Fig. 2b). As with the reactive dye the complexed-copper peak is absent in pH 6 EDTA buffer (not shown).

In pH 6 EDTA buffer the azo peaks of Reactive Violet 5 and its hydrolysis product are resolved. Typical cathodic stripping voltammograms showing this are given in Fig. 3: here accumulation is effected at −0.20 V which avoids the appearance of the mercury EDTA peak. Preliminary experiments have been carried out showing that the hydrolysis of Reactive Violet 5 down to concentrations of about 1 × 10^{-9} M can be followed very conveniently in this buffer.

4. Discussion

EDTA, a tetrabasic acid with pK_a values of 2.0, 2.67, 6.16 and 10.26, is used extensively as a complexing agent. Indeed it is the best known complexant in general use. Its complexing properties seem to have overshadowed its acid–base characteristics, except as a means of making its reactions with metals more selective as indicated in numerous texts on classical analytical chemistry. Its use solely as a pH buffer seems to have been largely neglected, although its use as a complexing agent in other pH buffers over a wide range of pH values is clearly well established. In previous publications concerned with the determination of sulfonamides we have shown that interferences in CSV due to copper(II), and in

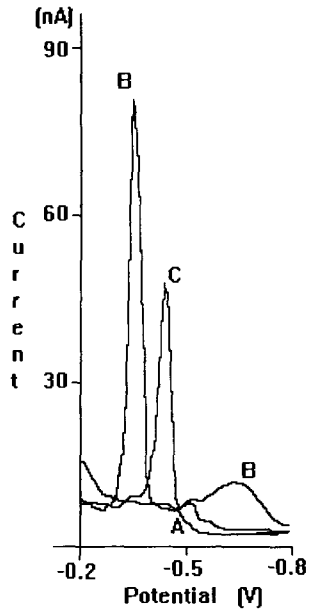

Fig. 3. Cathodic stripping voltammograms showing that Reactive Violet 5 and hydrolysed Reactive Violet 5 can be determined in an admixture in EDTA buffer pH 6. A, buffer only; B, Reactive Violet 5 concentration = 3×10^{-7} M; C, hydrolysed Reactive Violet 5 concentration = 3×10^{-7} M.

particular due to unwanted accumulation of copper(I) salts leading to the appearance of unwanted copper (I) reduction peaks, can be avoided by the use of EDTA buffers [8,9].

In the present case of Reactive Violet 5 the appearance of the complexed-copper peak serves to help identify the dye, but the use of the EDTA pH buffer makes its determination easier. Indeed, because the azo peaks of Reactive Violet 5 and its hydrolysis product are sufficiently well separated, the use of the EDTA pH buffer allows the hydrolysis of the reactive dye to be monitored effectively.

Further work is in progress to study the CSV of reactive dyes with various reactive groups, and on the use of CSV in dye pollution studies.

Short communication

Determination of L-phenylalanine in serum by flow-injection analysis using immobilized phenylalanine dehydrogenase and fluorimetric detection

Nobutoshi Kiba*, Akiko Itagaki, Motohisa Furusawa

Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

Received 25 March 1996; revised 7 June 1996; accepted 12 June 1996

Abstract

A flow-injection system with an immobilized enzyme reactor is proposed for the determination of L-phenylalanine. Phenylalanine dehydrogenase from *Rhodoccus* sp. M4 was immobilized on tresylated poly (vinyl alcohol) beads (13 μm) and packed into a stainless-steel column (5 cm × 4 mm i.d.). Serum sample was deproteinized with tungstic acid and filtered through an ultrafiltration membrane. The sample solution (30 μl) was injected into the carrier stream (water). The NADH formed was detected at 465 nm (excitation at 340 nm). The calibration graph was linear for 0.9–600 μm L-phenylalanine; the detection limit was 0.3 μm. The sample throughout was 25 h^{-1} without carryover. The half-life period of the immobilized enzyme was 23 days.

Keywords: Flow-injection analysis; Fluorescence detection; Immobilized enzyme reactor; L-phenylalanine; Serum

1. Introduction

The measurement of L-phenylalanine (Phe) is of clinical importance in the diagnosis and therapy of phenylketonuria. Enzymatic methods have been developed for the selective determination of Phe based on the conversion of Phe in to phenylpyruvate with concomitant reduction of nicotineamide adenine dinucleotide (NAD^+) to reduced nicotineamide adenine dinucleotide (NADH) with phenylalanine dehydrogenase (EC 1.4.1.–., PheDH) [1–8]. PheDH has been immobilized on a nylon coil and applied in a bioluminescence continuous-flow system for the determination of Phe in serum [9]. The PheDHs used were purified from *Thermoactinomyces* sp. [1], *Brevibacterium* sp. [2], *Rhodococcus* sp. [3–8] and *Bacillus badius* [9]. Among them, the enzymes from *Rhodococcus* sp. are more specific for Phe and are stable in the presence of glycerol [10,11]. The PheDH from *Rhodococcus* sp. M4 has been immobilized on aminopropyl-substituted controlled-pore glass (CPG) and used as a reactor in

PII S0039-9140(96)02016-4

the fluorimetric flow-injection system for the determination of Phe in serum [12,13]. The method is not very sensitive because the reactor was used in the neutral buffer (pH 7.1) to prolong the lifetime of the reactor; the optimum pH for the PheDH is 10.0 [10,11] and CPG is unstable in alkaline solution [14].

This paper describes a flow-injection system for the enzymatic determination of Phe with PheDH immobilized on poly(vinyl alcohol) beads contained in a packed-bed reactor. The enzyme from *Rhodococcus* sp. M4 was used. The enzymatic reaction was performed in a basic buffer (pH 10.0). The NADH produced in the reactor was monitored fluorimetrically. The flow-injection method was applied to the determination of Phe in serum.

2. Experimental

2.1. Materials and reagents

PheDH from *Rhodococcus* sp. M4 was obtained from Calbiochem (San Diego, CA, USA) with an activity of 12 U ml^{-1}. The activity was measured with Phe as substrate at pH 10.0 at 30°C. NAD^+ (free acid, 96%) and NADH (disodium salt, 99.5%) were purchased from Kohjin (Tokyo, Japan) and Boehringer Mannheim (Mannheim, Germany), respectively. L-Amino acids were purchased from Sigma (St. Louis, MO, USA). Poly(vinyl alcohol) beads (GS-520, 13 μm diameter) were obtained from Showa Denko (Tokyo, Japan). All other chemicals, which were purchased from Nacalai Tesque (Tokyo, Japan), were of analytical-reagent grade.

A glycine buffer (pH 10.0) consisting of 0.2 M glycine–0.2 M sodium chloride–0.2 M sodium hydroxide–2% (v/v) glycerol was used. NAD^+ solution (8 mM NAD^+ in water) was prepared fresh daily. The carrier solution was water.

2.2. Preparation of the immobilized enzyme reactor

PheDH was immobilized on the poly(vinyl alcohol) beads. The beads (1 g) were washed with dry acetone (20 ml). The beads were suspended in 20 ml of a mixture of dry acetone and pyridine (1:1 v/v). With vigorous magnetic stirring, 1 ml of 2,2,2-trifluoroethanesulphonyl chloride (tresyl chloride) was added dropwise to the suspension during 5 min. The reaction was continued for 5 min. The beads were washed with acetone (10 ml) and 1 mM HCl (20 ml). The beads were packed into a stainless-steel column (5 cm × 4mm i.d.) by the slurry-packing method. Enzyme solution (PheDH 26 U in 10 ml of 2% (v/v) glycerol in 10 mM phosphate buffer) was circulated through the column at 0.2 ml min^{-1} for 6 h at 10°C. During the process the enzyme solution was kept at 2–5°C. The reactor was washed with 10% glycerol in 0.1 M phosphate buffer (pH 7.0) and stored in a refrigerator when not in use. The coupling yield was evaluated by measuring the decrease in the activity of PheDH in the enzyme solution after the process. The PheDH was immobilized with a 95% yield. Also, epoxy-activated beads (epoxy-beads) and glutaraldehyde-activated beads (glutar-beads) were used for the coupling of PheDH; the preparation methods for the activated beads were similar to those described previously [15] and coupling conditions were identical with those described above. The yields for epoxy-beads and glutar-beads were 5% and 24%, respectively.

2.3. Flow system and procedure

A schematic diagram of the flow system is shown in Fig. 1. The system consisted of three piston

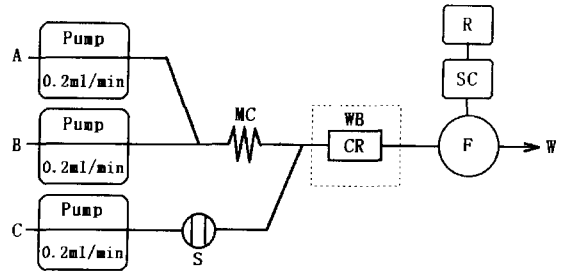

Fig. 1. Schematic diagram of the flow-injection system for the determination of L-phenylalanine with an immobilized phenylalanine dehydrogenase reactor. A, 8 mM NAD^+ solution; B, 2% (v/v) glycerol in 0.2 M glycine buffer; C, carrier solution (water); S, injector with a 30 μl loop; MC, mixing coil (100 cm × 0.5 mm i.d.); WB, water-bath thermostated at 20°C; CR, enzyme column reactor (5 cm × 4 mm i.d.); F, spectrofluorimeter with a flow-through cell (15 μl); SC, signal cleaner; R, recorder; W, waste. All connecting tubing (0.5 mm i.d.) was made of PTFE.

pumps (Hitachi L-6000), an injection valve (Sanuki SVI-6M2) equipped with a 30 μl loop, a reactor, a spectrofluorimeter (Jasco FP-210) with a flow-through cell (15 μl) connected to a signal cleaner (SIC SC77) and a recorder (TOA FBR-251A). The reactor was maintained at 20°C.

Serum (50 μl) was deproteinized by adding 10% (w/v) sodium tungstate solution (100 μl) and 0.06 M sulphuric acid (100 μl). The mixture was filtered through an ultrafiltration membrane (Advantec Q0100, nominal molecular weight cut-off 10 000) and the filtrate (30 μl) was injected into the carrier stream (water). The time taken to prepare the sample solution was about 3 min.

The present method was compared with liquid chromatography (amino acid analyser, Kyowa Seimitsu K-201; column, TSKgel SCX, 150 × 6.0 mm i.d.; mobile phase, citrate buffer; solvent gradient, post-column derivatization with ninhydrin).

3. Results and discussion

3.1. Reactor performance

The effect of pH on the activity of the reactor was studied in the pH range 9.0–11.0 using glycine buffer. The optimum pH was about 10.0. The peak height in the glycine buffer was about 1.2 times that in carbonate buffer at the same pH. Borate buffer consisting of 0.2 M borax–0.1 M NaOH (pH 9.5–11.0) inhibited the enzymatic reaction completely. The temperature dependence of the reactor was investigated over the range 15–30°C. The reactor exhibited maximum activity at 20°C.

The effect of NAD^+ concentration on the activity was studied over the range 1–12 mM at the 600 μM Phe level. The response increased with increasing concentration, first rapidly and then gradually. Above 6 mM, the response was almost constant. A concentration of 8 mM NAD^+ was chosen to prevent interference of phenylpyruvate and ammonium ions, which are products of the enzymatic reaction; at this concentration, the NAD^+ concentration in the reactor is 2.7 mM.

The peak height was measured by changing the flow-rates of the glycine buffer, the NAD^+ solution and the carrier solution (water), keeping the flow-rate ratio of these solutions at 1:1:1. The peak height decreased linearly as the total flow-rate increased from 0.3 to 0.9 ml min^{-1}. The peak height at 0.3 ml min^{-1} was about 2.4 times that at 0.9 ml min^{-1}. A total flow-rate of 0.6 ml min^{-1} was selected as a compromise between sensitivity and sample throughput; at this flow-rate, the sample throughput was 25 h^{-1}.

Under the conditions of 8 mM NAD^+ at pH 10.0 and 20°C, the conversion efficiency of the reactor was 90% immediately after the preparation of the reactor. The efficiency was measured by using NADH. Under the same conditions, the response for Phe (10 μM) was not affected by the presence of 30 μM phenylpyruvate and 100μM ammonium ion. Also, no interferences was recorded with 1 mM L-ascorbic acid, 2 mM uric acid and 50 mM glucose.

Amino acids normally found in proteins, other than Phe, did not give any response.

The operational stability of the reactor was evaluated over 4 weeks. The reactor was used for analyses of 50 samples (20 μM Phe) for 2 h per day and then washed with 10% (v/v) glycerol in 0.1 M phosphate buffer (pH 10.0) and stored 4°C when not in used. The decrease in activity obeyed first-order kinetics. The kinetic constant was 2.9×10^{-2} day^{-1}; the half-life period of the reactor was 23 days.

3.2. Calibration

The calibration graph of peak height against Phe concentration was linear over the range 0.9–600 μM with a correlation coefficient of 0.999 (12 data points) under the same conditions as described in section 2.3; since the serum sample was diluted five fold, this method can be applied to the assay of samples containing 5 μM–3 mM Phe. Below a concentration of 0.9 μM a concave graph was obtained and above a concentration of 600 μM the graph was convex. The relative standard deviation (RSD) for seven replicate injections of 10.0 μM Phe was 0.65% with a reactor having a conversion efficiency of 88%. By the use of a reactor having a conversion efficiency of 50%, the RSD for the same runs was 1.3%. To obtain precise results, the reactor must be used within a

Table 1
Recovery of phenylalanine added to pooled serum[a]

Added (μM)	Recovered (μM)[b]	Recovery (%)
5.00	4.87	97
10.0	10.3	103
50.0	49.0	98
100	101	101
500	500	100
1000	998	100
2500	2520	101

[a] Values corrected for Phe (63.6 μM) already present in serum.
[b] All values are means ($n = 5$).

coversion efficiency of 50%. The limit of detection (signal-to-noise ratio = 3) with a reactor having a conversion efficiency of 80% was 0.3 μM (2 ng in a 30 μl injection) with RSD 5.6%.

3.3. Application

This method was applied to the determination of Phe in serum.

Pooled human serum was repeatedly analysed for 30 day with the reactor. The reactor was used for analyses of 50 samples in a day and standards were measured at 25-sample intervals, in order to correct the variation of the conversion efficiency. The reactor was renewed every 10 days (about 500 injections) because more precise results were obtained. The method gave satisfactorily precise and reproducible results; for serum containing 62.7 μM Phe, the within-day RSD was 0.88% and the day-to-day RSD was 1.2%.

Serum of known Phe concentration was supplemented with Phe to give final concentrations of 0.073–2.50 mM. The recoveries were in the range range 97–103%, as shown in Table 1.

The results ($n = 21$, from 51 to 849 μM) were compared with those obtained by liquid chromatrography. The calculated linear regression and correlation coefficient were $y = 0.997x + 1.58$ and $r = 0.998$, respecively.

4. Conclusion

The flow-injection system with immobilized PheDH reactor and fluorescence detection is useful for the sensitive and reliable measurement of Phe and can easily be used for the analysis of serum. The PheDH immobilized on polymer beads is stable enough to permit the measurement of more than 500 samples.

Received 16 April 1996; revised 29 May 1996; accepted 30 May 1996

Abstract

The solubility of 49 metal-containing compounds and 15 "free" ligands in supercritical fluid carbon dioxide is reviewed. Solubilities were found to range over eight orders of magnitude, with the highest value of solubility being 56 g l^{-1}. Metals complexed with fluorine substituted ligands were found to be the most soluble, and metals complexed with phenyl-substituted ligands the least soluble. A general trend for increasing solubility with increasing oxidation state is observed and this is correlated with the increased number of coordinating ligands protecting the metal center from interaction with the supercritical fluid and also due to the increased number of solvation interactions with the increased number of ligand groups.

Keywords: Carbon dioxide; Chelating agents; Metal-containing compounds; Solubility; Supercritical fluids

1. Introduction

Interest in supercritical fluids (SFs), particularly carbon dioxide as a solvent for use in extraction processes, has been driven by increased environmental legislation restricting the use of conventional solvents [1]. This has resulted in the development of both analytical and large-scale techniques for organic waste extraction from contaminated matrices [2]. Extensive data are available for the solubility of organic compounds in SF CO_2 and means of solubility prediction have been proposed [3,4]. Solubility is one key aspect to achieving quantitative extractions in a reasonable time using the minimum of extraction fluid and an extraction system which can be constructed on a practical scale.

Recently, the use of SFs modified by the addition of complexing agents has been utilized in the

PII S0039-9140(96)02008-5

extraction of metal ions from various solid and liquid matrices [5,6]. This was first demonstrated by Laintz et al. [7], with the extraction of Cu^{2+} via in situ chelation and extraction into SF CO_2. This has opened up a whole new area of research into the use of SFs in environmentally acceptable technology, as an analytical preconcentration technique and as an extractive system for large-scale metallurgical purification [8]. Initially, metal extraction using SFs has been considered not to be feasible owing to the charge neutralization requirements. By addition of a complexing agent to the SF phase, the charge on the metal ion can be neturalized and lipophilic groups introduced to the metal–complex system. Solubilization of the metal complexes into the SF is then possible [9]. Wide ranges of solubilities have been observed for metal complexes, the solvation of which is influenced by several parameters, including pressure and temperature of SFs, modifier effect in SF, ligand used, the identity of the metal, the oxidation state of metal and the complexant functional group [10].

In this paper, solubility data relevant to metal extraction are reviewed with a view to assessment of present data and identification of the most promising areas for future work. The major aim of this review is to ensure that currently available data in this rapidly expanding area are compiled and assessed, to allow focusing of future research efforts such that the technique can be developed to its full potential.

The data presented are split into three areas: ligand solubility, metal complex solubility and organometallic solubility. Where sufficient data are available, correlation with a solubility model is made [11]. The relevance of the available literature to the area of metal extraction using SFs is discussed. Abbreviations used for the ligand and metal complex names are given in Section 7.

2. Data correlation model

This review is correlated using a model based on the relationship between ln(solubility) and ln(density) [11]. Although limited in scope, this model does not require additional physical parameters of the solutes such as critical constants for equation of state approaches or molar volumes and solid activities as in the Hildebrand solubility parameter approach [12].

This model relates the solubility of a solute to solvent density and absolute temperature:

$$\ln S = k \ln D + C \quad (1)$$

where S = solubility of the solute (g l^{-1}), D is the density of the SF (g l^{-1}), k is a constant for the solute–solvent system and is an indication of the solvation of the solute in the SF and C is a constant which varies with temperature, is independent of density and is related to the volatility of the solute. The solvation process is therefore closely related to the vapor pressure of the solute and the intermolecular interactions between the solute and solvent. The vapor pressure of a given solute depends mainly on temperature, whereas the solvent strength of a supercritical fluid depends on the density of the fluid. Other properties such as viscosity, diffusivity and polarity can also change with temperature and pressure and may affect solubility. Therefore, a knowledge of k and C for the temperatures studied will allow the solubilities to be determined over an extended range of densities. Eq. (1) predicts a linear relationship between $\ln S$ and $\ln D$ with a slope proportional to k and intercept C.

All data presented in this review are represented as a function of g l^{-1} for both the solute concentration and SF concentration (density) unless stated otherwise.

3. Solubility of 'Free' Ligands in SF CO_2

The ligands that have been investigated in SF CO_2, β-diketones, dithiocarbamates and organophosphate systems [13–16]. The relevance of ligand solubility to metal extraction capability is obvious, in that a reasonable quantity of ligand must be solubilized to be able to access the metal ions in the various matrices.

Table 1
Solubility of triazolocrown ethers in SF CO_2 [13]

Compound	MW	P(atm)	T	D	Fluid	S
Crown 1	418.5	200	60	733	CO_2	5.43×10^{-3}
Crown 2	406.5	200	60	733	CO_2	4.06×10^{-3}
Crown 3	518.0	200	60	733	CO_2	0.223
Crown 1	418.0	200	60	772	CO_2 + 5% MeOH	0.0878
Crown 2	406.0	200	60	772	CO_2 + 5% MeOH	0.0812
Crown 3	518.0	200	60	772	CO_2 + 5% MeOH	0.673

3.1. Macrocyclic ligands

The only ligands from the macrocyclic class that have been investigated for the extraction of metals are the crown ethers [13]. The crown ethers are a class of selective ligands which form stable complexes with metal ions based primarily on the ionic radius–cavity size compatibility concept. Modification of crown structure by attaching negatively charged functional groups to the host can eliminate the need for counter ions, which are conventionally required for the transport of charged complexes into an organic phase.

Solubility data available for triazolocrown ether systems are given in Table 1. The triazolocrown systems are a group of macrocyclic compounds containing two triazolo subcyclic units, which are suitable for complexation with divalent metal ions [17]. The solubility significantly increases on modifying the CO_2 with 5% MeOH [13]. The increase in solubility for each crown ether system is one order of magnitude on going from pure CO_2 to 5% MeOH-modified CO_2. This correlated with the extraction data for Hg^{2+} and Au^{3+} from both solid (cellulose-based) and aqueous materials, where the extractions in the MeOH-modified solutions are greatly enhanced compared with pure CO_2.

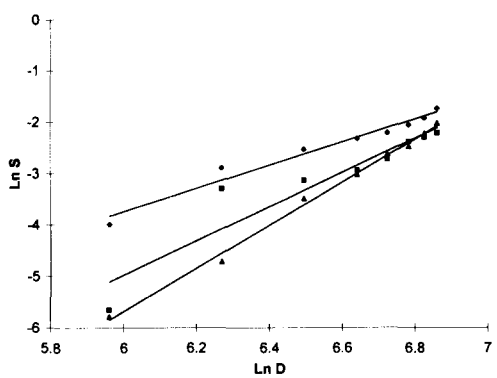

Fig. 1. Ln(solubility) of (◆) F6 crown, (■) F2 crown and (▲) H crown in SF CO_2 at 50°C as a function of ln(density).

Elsewhere the solubility of carboxylic acid substituted crown ether systems have been presented [18]. This data are illustrated in Fig. 1 and the correlation parameters obtained are shown in Table 2. At all densities, the solubility of the fluorine-substituted ligands is greater than that of the non-fluorinated ligand. Increasing the amount of fluorine substitution also increases solubility. At higher densities of CO_2, the difference between the fluorinated and non-fluorinated systems decreases.

3.2. β-Diketones

No solubility data are available for β-diketone systems in SF CO_2. The most commonly studied systems are acetylacetone (acac), trifluoroacetylacetone (tfa), hexafluoroacetylacetone (hfa) and thenoyltrifluoroacetylacetone (tta) [5,10,14,15]. Of these ligands, only tta is a solid, the others being liquids at room temperature. Under supercritical fluid extraction (SFE) conditions, all these ligands show high miscibility with CO_2. For example, substituting two CF_3 groups into the acac molecule significantly increases the acidity of the ligand by four orders of magnitude (e.g. acac $pK_a = 8.67$, hfa $pK_a = 4.46$), and this enables hfa to extract metals from much more acidic media [19]. This reduction in the basic strength of the

Table 2

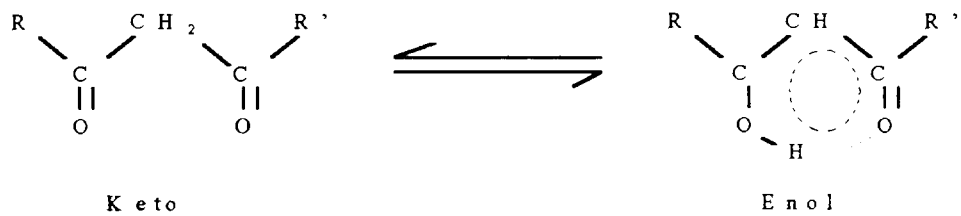
fluorinated ligand can be advantageous as water (which is generally required in the SF process to obtain extractions) in contact with SF CO_2 is strongly acidic [13].

The β-diketone ligands are used almost exclusively in protonated forms. The β-diketones are rendered acidic by the tautomeric equilibrium established between the enol and keto forms:



Form 1.

The fluorinated ligands have been found to be almost exclusively in the enol form under the high pressures and temperatures relevant to SFE [20]. The non-fluorinated ligand (acac) is found to be partly in each form in the SF phase [21]. The acidity of the ligand originates from the enol form and the deprotonated β-diketone involved in the metal complexation process. Elsewhere it has been shown that the presence of electron-withdrawing fluorine substituents can significantly increase ligand acidity [22].

3.3. Dithiocarbamates

The dithiocarbamates studied in SFE work are commonly used as salts (Na^+ and NH_4^+) of the ligand rather than in the acidic form [6,7]. The first work on metal extraction in SF CO_2 was demonstrated using the fluorinated ligand sodium bis(trifluoroethyl)dithiocarbamate (NaFDDC). This ligand was found to have greatly enhanced solubility compared with the non-fluorinated analogue (Table 3) in SF CO_2. For non-fluorinated dithiocarbamates, the alkylammonium salts serve as a suitable means for solubilization of the ligands for analytical extractions (Table 3) [23]. Increasing the alkyl chain length of the alkylammonium salts by two carbon units increased the solubility of the ligand by an order of magnitude.

Elsewhere, these ligands have been assessed for the extraction of toxic heavy metals using liquid CO_2 as the extraction fluid [24]. No data are available regarding ligand solubility in this medium.

3.4. Organophosphorus reagents

Organophosphorus reagents such as tributyl

Table 3

phosphate (TBP) and phosphine oxides such as tributylphosphine oxide (TBPO), tri-*n*-octylphosphine oxide (TOPO) and triphenylphosphine oxide (TPPO) have long been established for use as extractive ligands for actinide elements [25]. Recently, these compounds have been used in an SF environment for the extraction of U and Th from solid and liquid matrices [26]. Such reagents have found great technological importance within the nuclear industry; in particular, TBP is extensively used in the extraction and separation of U and Pu in the Purex process [27].

TBP is a viscous liquid at room temperature. The phase behavior of TBP in SF CO_2 has been described in detail by Page et al. [28] and this is shown in Table 4. Elsewhere 2% TBP-modified CO_2 has been shown to have a large influence on organic compound solubilities in the SF phase, as reported by Lemert and Johnson et al. [29].

The solubility of triphenyl phosphate (TPP) has been measured by Schmitt et al. [30]. These data are illustrated in Fig. 2, using the correlation method described earlier, and the constants k and C generated are given in Table 2. Temperature had no significant effect on the solubility of TPP at constant density between 37 and 47°C. The solubilities of different phosphine oxides have been measured by both Schmitt and Reid [30] and Lin et al. [26]. The TOPO ligand shows solubilities approximately one order of magntiude higher than those of the TPP ligand. High solubilities have been observed for TOPO and TBPO as shown in Table 5. A much lower solubility is observed for the phenyl-substituted phosphine oxide TPPO. This correlates with the qualitative observation that aromatic substituent groups such as phenyl have a negative effect on the SF solubility of organic compounds [31].

3.5. Amines

Although no SFE data are available for the extraction of metals using amines as extractants,

they are known to extract metals under conventional solvent extraction conditions [32]. Limited solubility data are available for amines from the work of Schmitt and Reid [30] and this is shown in Fig. 2. The amines investigated in this study included triphenylamine (TPA), di-*n*-dodecylamine (DnDA), trihexylamine (THA) and trioctylamine (TOA). The correlation coefficients k and C are given on Table 2. Trihexylamine is the most suitable, forming a completely miscible phase with CO_2 at approximately 150 bar. Similarly to the case of the phosphine oxides, the phenyl-subsituted ligands show the lowest SF solubility from the amine range of compounds, for which data are available.

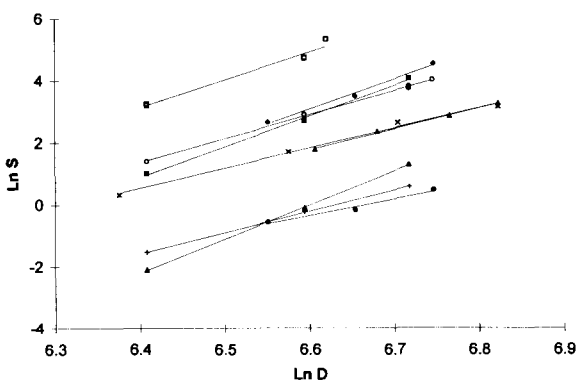

Fig. 2. Ln (solubility) of organic ligands in SF CO_2 as a function of ln(density): (◆) TOPO, 37°C; (■) TOPO, 47°C; (▲) TPP, 37°C; (×) TPP, 47°C; (△) TPA, 47°C; (●) DnDA, 37°C; (+) DnDA, 47°C; (□) THA, 47°C; (○) TOA, 47°C.

3.6. Other extractive reagents

Yazdi and Beckman [33] have measured the solubilities of a range of fluorinated polymeric ethers with picolylamine, bis(picolylamine), dithiol and dithiocarbamate functionalities. The molecular weights of these compounds were between 2500 and 7500. Although very high solubilities of the ligands are observed in weight per cent terms (ca. 5%), the solubilities in terms of molar concentration are very low.

3.7. Prediction techniques for ligand solubilities

Harrington et al. [34] have recently shown that the solubility of many organic compounds

Table 5

TPPO	278	200	60	0.7318	2.127

can be estimated to within 30% accuracy using an equation of state approach. Critical to this approach is the determination of the van de Waals interaction parameter k_{12}. This parameter describes the forces involved in the interaction between solute and solvent. The k_{12} parameter is usually determined by correlation of experimentally determined solubility values with the Peng–Robinson equation of state. Once the k_{12} value is known, then solubilities at a range of conditions can be estimated. Harrington et al. [34] demonstrated that the k_{12} parameter can be predicted via a group contribution approach. Here the various contributions of individual functional groups to the k_{12} parameter are assumed to be additive. The functional groups for which sufficient data are available to make reaslistic predictions are given in Table 6. This approach gives a fast method to assess the likely solubility of ligands for which no experimental solubility data are available.

4. Solubility of metal complexes in SF CO_2

The metal complexes that have been studied in terms of solubility in SF CO_2 cover a range of systems including most of the ligand types given above. Unfortunately few systematic investigations have been carried out, thus limiting the ability to model such data. The correlation procedures discussed above are utilized where possible.

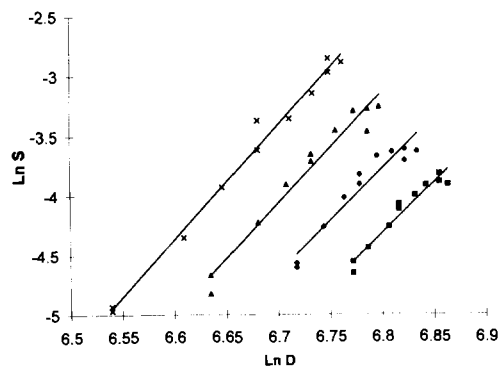

Fig. 3. Ln (solubility) of [({5,7,12,14-tetramethyl}-2,3:9,10-dibenzo[*b,i*]tetraazocyclotetradecine)nickel(II)] in SF CO_2 + 10% (v/v) methanol as a function of ln(density): (■) 40°C; (◆) 50°C; (▲) 60°C; (×) 70°C.

4.1. Macrocyclic systems

The solubilities of metal crown ether systems have not yet been investigated, probably owing to the nature of the complexes that are formed, usually ion pairs which are difficult to obtain in a purified crystal form.

Cowey et al. [35] have reported the solubility of a nickel cyclam complex, [({5,7,12,14-tetra-methyl} -2,3:9, 10-dibenzo[*b,i*]tetraazocyclotetradecine)-nickel (II)] (referred to subsequently as Ni cylam in this paper), in SF CO_2 modified with 10% (N/N) methanol. Ni cyclam had very poor solubility in pure CO_2 such that it could not be

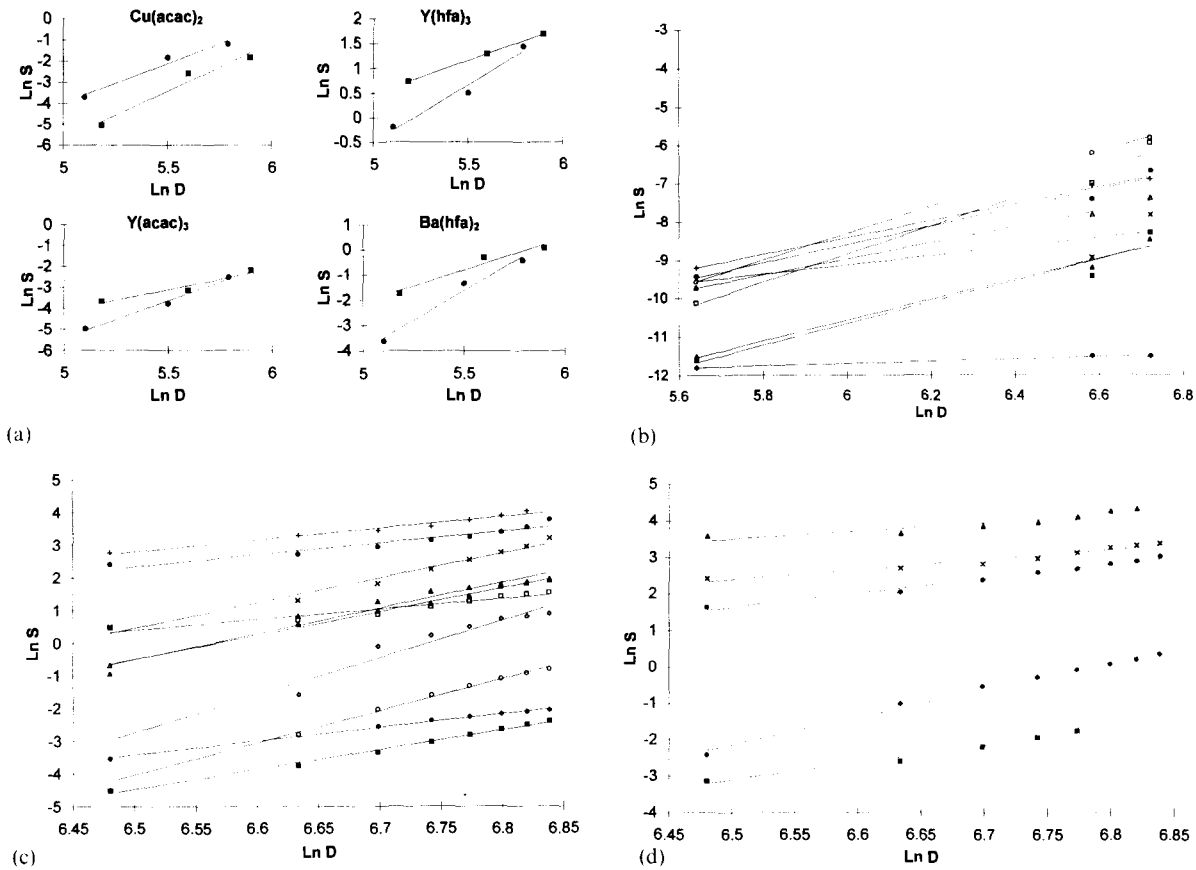

Fig. 4. Ln(solubility) of metal β-diketone complexes in SF CO_2 as a function of ln(density). (a) (i) $Cu(acac)_2$, (■) 150°C, (●) 170°C; (ii) $Y(hfa)_3$, (■) 150°C, (●) 170°C; (iii) $Y(acac)_3$, (■) 150°C, (●) 170°C; (iv) $Ba(hfa)_2$, (■) 150°C, (●) 170°C.

quantified by the technique used by these workers. The Ni cyclam complex is a nearly planar system and the effect of adding methanol as a modifier was interpreted as involving the formation of an octahedral MXL_2 system with the methanol solvating the two *trans* sites of the complex and reducing the polarity. The actual solubility of the nickel cyclam complex is still low, however, as shown in Fig. 3. For a given density of SF, it was observed that the solubility increased significantly with increase in temperature. The correlation constants are shown in Table 7. In the case of Ni cyclam, a range of data at differing temperatures and densities are available. The highest solubilities were observed at the highest temperatures and pressures studied, which indicates that the solubility of the Ni cyclam complex is significantly influenced by the complex volatility, even at temperatures as low as 70°C. It is observed that the effect of increasing density on the solubility of the Ni cyclam complex is almost independent of the temperature, i.e. as the temperature increases, the relative changes in solubility are equivalent for a given SF density change.

Brauer et al. [36] have studied the solubility of a range of fluorinated metal porphyrin complexes. The solubility of these complexes is low, but they do show measurable solubility in pure CO_2. Al-

though the above systems are of interest for extraction, the main interest in SF solubility has been the possibility of using these as catalytic systems [37]. Hence, in such cases, low solubility may not be critical as in the area of extraction.

4.2. Metal β-diketone systems

Three major systematic studies of the solubility of metal β-diketone complexes in SF CO_2, have been carried out [38–40]. The metal β-diketone systems are by far the most extensively studied system for solubility in SF CO_2. The various correlation parameters for the β-diketone complexes are given in Table 7.

Hamdi et al. [38] have studied the solubilities of a range of different metal acetylacetone and metal hexafluoroacetylacetone complexes in SF CO_2. The data obtained are shown in Fig. 4(a). The solubilities of the acetylacetone were determined at high temperatures (150–170°C) in this study. At such temperatures, the density of CO_2 is low (e.g. 160–360 g l^{-1}) and the major contributing factor to the solubility is likely to be the metal complex volatility. It is therefore surprising that for the hexafluoroacetylacetone complexes it is observed that solubility decreases with increasing temperature, indicating a decrease in solvating effects even at temperatures as high as 150–170°C. The effect of fluorination of the complex on solubility can be observed from the data presented for the yttrium system. With fluorination of the methyl groups of the acetylacetone ligand, increases in solubility of between three and four orders of magnitude are observed.

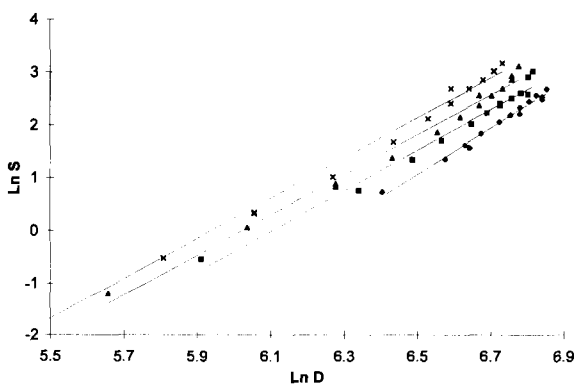

Fig. 5. Ln(solubility) of ferrocene in SF CO_2 as a function of ln(density): (◆) 40°C; (■) 50°C; (▲) 60°C; (×) 70°C.

Saito et al. [39] have studied acetylacetone complexes of different metals at temperatures lower than those of Hamdi et al. [38] (60°C compared with 150°C) and these data are shown in Fig. 4(b). At these milder temperatures, the solubility of the metal complexes is much lower than those observed at >150°C. The poorest solubility was observed for the Li complex, which can be interpreted in terms of the inability of the single acac ligand to shield the ionic Li center from the SF CO_2. The highest solubility was observed for In and Ga, which can be correlated with their behavior, lying between metallic and non-metallic systems. For elements which exist in the oxidation states 2+ and 3+ (Mn and Co), it was observed that the higher oxidation state complex shows an enhanced solubility. This can be correlated with a more complete shielding of the 3+ metal ion center with a greater number of ligands so that the solvation of the resulting complex is enhanced owing to the increase in solute–solvent interactions between the SF CO_2 and the complex.

Lagalante et al. [40] have studied the solubility of copper and chromium β-diketone systems, with nine different ligand types being studied. The data obtained are illustrated in Fig. 4(c) and (d). In this work, a direct correlation was observed between the metal complex solubility and the Hildebrand solubility parameter of the uncomplex ligand. This illustrates that for a given metal system, the nature of the ligand side-chains influences the solubility of the metal complex in accordance with 'regular' solution theory. Lagalante et al. [40] observed that the fluorinated ligand systems showed the highest solubility, with the hexafluoroacetylacetone complexes having the highest values. The lowest solubility was observed for the benzyl-substituted β-diketone sysem, correlating with the general observation for organic compounds where aromatic substituted systems showed the lowest solubilities. Similar trends were observed for the Cr β-diketone complexes to those for the Cu β-diketone complexes in terms of the effects of different ligand substituents on the

solubility. The high solubility of $Cu(hfa)_2$ complexes correlates with vapor pressure data for the Cu β-diketone complexes, where the $Cu(hfa)_2$ has a vapor pressure an order of magnitude greater than that of the non-fluorinated $Cu(acac)_2$ complex [41].

However, in all cases where the same ligand was used for Cu and Cr, the Cr complexes showed higher solubilities [40]. This may be due to the greater protection of the metal ion center from the SF CO_2 and to the enhanced solvation effects for the 'extra' ligand, as discussed previously. Molecular weight does not seem to influence the solubility of the metal complexes, since although that of Cr (52.0) is slightly lower than Cu (63.6), the requirement of Cr for three ligands to satisfy valency requirements, compared with two ligands for Cu, means that the overall complex molecular weight is always higher for the Cr system.

One interesting complex is hexafluoroacetylacetonecopper(I)trimethylphosphine ($hfaCuPme_3$), which shows SF CO_2 solubilities of the order of 0.1 M [42]. This complex is of interest in metal deposition technology, forming copper films upon spraying from an SF on to a hot surface via a disproportional reaction of the Cu(I) complex [43].

4.3. Metal dithiocarbamates

A range of metal dithiocarbamate metal complex solubilities have been investigated. Laintz et al. [7] showed that fluorination of the end methyl groups of diethyldithiocarbamate ligands resulted in greatly enhanced solubilities of the metal complexed systems in SF CO_2. This is illustrated in Table 3. Solubility enhancement in the range of 300-fold were observed for the fluorinated complexes. The lowest enhancements in solubility were observed for the sodium complexes, indicating that in this system, it is the interaction between the sodium ion and the SF that strongly influences the solubility value. The effect of methanol modification of the SF is illustrated for the Hg–dithiocarbamate complexes, where modification with 5% methanol increases the observed solubility by nearly one order of magnitude [16]. Laintz et al. [7] have studied the solubility of $Cu(FDDC)_2$ complexes in SF CO_2 at various densities. The correlation parameters are shown in Table 7. The solubility is observed to increase significantly with increase in density.

Wang and Marshall [23] studied dithiocarbamate complexes with various hydrocarbon tail groups, observing the highest solubility for butyl-substituted ligands. The solubilities of the butyl-substituted dithiocarbamates approach those of the fluorinated systems, but are still slightly lower.

4.4. Organophosphorus reagents

No data have been reported for the solubility of metal organophosphorus complexes in CO_2. Similarly to the crown ethers, metal organophosphorus complexes involve ion-pair extraction via a coordination complex. Such systems are difficult to obtain as purified crystal systems.

5. Organometallic systems

5.1. Ferrocene

Only one organometallic compound, ferrocene, has been extensively studied with regard to solubility in SF CO_2 [34]. Ferrocene shows high solubility, as illustrated in Fig. 5. The effect of increasing density on solubility is almost independent of temperature. The high solubility of ferrocene was interpreted as being due to the nature of the bonding in the ferrocene compound. Ferrocene is a system in which the metal 3d, p and s orbitals are filled such that no free coordination sites are available for interaction with the solvating CO_2, resulting in ferrocene having properties resembling those of an aromatic compound.

5.2. Other organometallics

The catalytically active compound $RuCl_2[P(CH_3)_3]$ has been shown to be soluble in SF CO_2, but only qualitative measurements have been carried out [44]. A number of studies of the behavior of organometallic systems in SF CO_2 have been carried out, with particular reference to reactivity

and catalysis [45,46]. These studies indicate that a wide range of organometallic systems show high SF solubility, although rarely is a direct measurement of this parameter made.

A wide range of toxic environmental contaminants have been shown to be soluble in SF CO_2, as evidenced by determination by SF chromatography or by extraction using SF CO_2 [5,8,13,16].

6. Relevance to metal extraction

From the data presented above, it can be seen that, in general, many ligands show relatively high SF CO_2 solubilities or are completely miscible [30]. Even ligands containing fairly polar functional groups, such as amines, show high SF solubilities, such that their potential as an extractive reagent is not likely to be limited by solubility. In general, it appears that the most favorable configuration for high SF solubility is a fluorine-substituted ligand system [5,7,15]. For analytical applications, the fluoroine-substituted systems are clearly the most suitable. However, the high costs of fluorine-substituted ligands will probably limit their use to the analytical scale. For hydrocarbon-based ligands, aliphatic substituted systems show high solubilities approaching those of the fluorine-substituted systems and these may have potential for larger scale application [23]. Phenyl-substituted ligands showed the lowest solubilities and are not likely to find many SF applications [26,30].

In parallel with the 'free' ligands, metal complexed systems show the highest solubility for fluorine-substituted systems, then aliphatic substituted systems and the lowest for phenyl-substituted systems [40].

The maximum metal complex solubilities observed in an SF CO_2 system are in the range 30–60 g l^{-1} for both non-fluorinated and fluorinated systems [35,40]. This is equivalent to dissolution of between 5 and 10 g l^{-1} of metal into the SF system. For analytical purposes, it is unlikely that this level of metal ion loading of the SF would be required; however, for larger scale applications this may limit some processes.

The fluorinated complexes show the highest solubilities [40]. In general, increasing ligand hydrocarbon tail lengths increase the solubility [40]. Also, a general trend exists for trivalent complexes to be more soluble than divalent complexes, which in turn are more soluble than monovalent complexes [39].

The use of both β-diketones and dithiocarbamates as extractive reagents is of great interest, since for natural aqueous samples these ligands are effective in the pH range 2–5 [32]. SF CO_2 has recently been shown to establish a pH in aqueous systems of approximately 2.9, via the formation of a carbonic acid solution [47]. Hence the pH of unbuffered aqueous systems will approach closely that favored for efficient extraction.

The organophosphorus reagents have been found to be effective for extractions from acidic media such as concentrated nitric acid solution [26]. This is particularly relevant to the nuclear industry, where these reagents are used in the purification of actinide elements. Unfortunately, no data are available for the solubility of these metal complex systems in SF CO_2, since reasonable solvent loading of the SF phase will be essential to achieving industrial-scale extractions. Experimental data in this area would thus be of great interest.

From Tables 2 and 7 it is observed that, in many cases, the values of k are lower for the fluorinated than aliphatic substituted systems. This indicates that the solvation effects are lower for the fluorinated systems. Consequently, at higher SF pressures, the enhanced solubility of fluorine-substituted systems may not be significant.

Spectrophotometric determination of a nanomolar amount of ascorbic acid using its catalytic effect on copper(II) porphyrin formation[1]

Masaaki Tabata*, Hirofumi Morita

Department of Chemistry, Faculty of Science and Engineering, Saga University, 1 Honjo-machi, Saga 840, Japan

Received 1 May 1996; revised 6 June 1996; accepted 7 June 1996

Abstract

A simple, fast and sensitive flow-injection method is proposed for the determination of nanomolar amounts of ascorbic acid in tea, urine and blood. The procedure is based on the accelerating effect of a nanomolar level of ascorbic acid on the reaction of cooper(II) with 5,10,15,20-tetrakis(1-methylpyridinium-4-yl)porphyrin, H_2tmpyp^{4+}. Ascorbic acid reduces Cu(II) to Cu(I) which catalyzes the incorporation of Cu(II) into H_2tmpyp^{4+} to form $Cu^{II}(tmpyp)^{4+}$. In this method two solutions, one containing ascorbic acid and H_2tmpyp^{4+} and the other containing copper(II) and acetate buffer (pH 5.0), were injected into two flowing streams of water through two sample injectors of 120 μl sample volume. The mixture was allowed to react in a 2 m reaction coil and the colored solution of $Cu^{II}(tmpyp)^{4+}$ was monitored at 550 nm ($\varepsilon = 2.01 \times 10^4$ M^{-1} cm^{-1}). The present method was applied to the determination of ascorbic acid in tea, urea and blood. Reducing agents such as sugars and vitamins B_1, B_2, B_6 and B_{12} did not give serious errors at a concentration of 10^{-6} M for the determination of 1.0×10^{-8} M ascorbic acid. The relative standard deviation of the present method was 2.8% for the determination of 1.0×10^{-8} M ascorbic acid. The reaction mechanism was clarified from the kinetic results of the formation of $Cu^{II}(tmpyp)^{4+}$ in the presence of various concentrations of ascorbic acid, copper(II) and hydrogen ion.

Keywords: Ascorbic acid; Blood; Catalytic determination; Cu(II) porphyrin; Tea; Urine

1. Introduction

Ascorbic acid is an essential vitamin and participates in many different biological processes. It occurs naturally in most fruit juices and vegetables. Often, it is added during the manufacture of juices or soft drinks to improve their nutritional value, to attract consumers or to prevent the autoxidation of commerical products. Owing to the wide use of ascorbic acid in canned fruits,

I^-	10^{-4}	101	Glucose	10^{-6}	98

vegetables and drugs, and because of its importance in human physiology, numerous methods have been reported for the determination of ascorbic acid, including titrimetric [1,2] spectrophotometric [3–6], fluorometric [7], chemiluminescence [8] and kinetic [9] methods. A highly sensitive and rapid analytical method is required for the analysis of a sample, such as blood, which contains a low concentration of ascorbic acid in a small volume of sample. In addition, the method must take into account the instability of ascorbic acid in air.

A catalytic method is a suitable method for sensitive analysis. Since catalytic measurements require both reproducibility of the mixing of the analyte with reagents and a definite reaction time, a flow-injection (FI) method is considered to be very appropriate for the catalytic method of analysis, as it has been used in routine analysis, [10,11].

This paper describes an FI spectrophotometric method based on the accelerating effect of ascorbic acid on the formation rate of 5, 10,15,20-tetrakis(1-methylpyridine-4-yl)porphyrinatocopper(II), $Cu^{II}(tmpyp)^{4+}$, and the increase in absorbance of the Cu(II) porphyrin. The procedure is simple, precise, sensitive and selective for the accurate determination of ascorbic acid in tea, urine and blood even at nanomolar level of ascorbic acid. Other compounds normally present along with ascorbic acid, such as metal ion, anions, vitamins and sugars, did not interfere with the determination of ascorbic acid at a 100-fold excess.

2. Experimental

2.1. Reagents

H_2tmpyp^{4+} tosylate, (Fig. 1) was purchased from Dojindo Chemical Institute (Kumamoto, Japan). The concentration of the porphyrin solution was determined spectrophotometrically using copper(II). A copper(II) solution was prepared by dissovling copper(II) nitrate in water and its concentration was determined by ethylenediaminetetraacetic acid (EDTA) titration using 4-(2-thi-azolylazo)resorcinol as an indicator. Sodium nitrate was recrystallized from distilled water. Ascorbic acid was used without further purification and its solution was prepared freshly before measurement. A small amount of a complexing agent such as *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetric acid (DCTA) or EDTA was added to the sample solution to prevent the catalytic decomposition of ascorbic acid by contamination with metal ions such as iron(III). Buffer solutions were prepared by mixing acetic acid and sodium acetate solutions.

2.2. Apparatus and measurements for kinetic study

All kinetic experiments were carried out under anaerobic conditions and the temperature was controlled to within ±0.1°C. Most measurements were performed at 25°C. The ionic strength was maintained at 0.10 M with sodium nitrate. Absorption spectra were recorded on a Shimadzu UV-2100 spectrophotometer. The spectral changes during the course of the reaction were the disappearance of the characteristic absorption bands of H_2tmpyp^{4+} (*Q* bands at 520, 558 and 647 nm) and the growth of the characteristic band of $Cu^{II}(tmpyp)^{4+}$ (*Q* band at 550 nm). The isosbestic points were observed at 490, 534 and 577 nm. The change in absorbance at 550 nm was monitored with a thermostated 10 mm cell as a function of time at a given temperature by a Neslab small refrigerated thermostat, type RTE-100. The reaction was stated by mixing two solutions, i.e. one containing sodium nitrate (0.1 M), copper(II) nitrate and buffer, and the other containing sodium nitrate (0.1 M), H_2tmpyp^{4+}, ascorbic acid and buffer. The mixing was carried out with a sample-mixing device (Type MX7, Ohtsuka Denshi) under a nitrogen atmosphere. The pH was measured by a Radiometer 85 ion analyzer with a combined electrode (GK2401C). A 1.000×10^{-2} M nitric acid solution containing 0.09 M sodium nitrate was employed as the standard hydrogen ion concentration ($-\log [H^+] = 2.000$; $I = 0.1$.

Table 2
Determination of ascorbic acid in tea, urine and blood using the present method

Sample	Volume taken[a]	Ascorbic acid found (M)
Tea	2 ml[b]	$(1.94 \pm 0.06) \times 10^{-7}$ [b]
Human urine	10 μl	$(6.9 \pm 1.7) \times 10^{-5}$
Human blood	100 μl	$(1.31 \pm 0.29) \times 10^{-6}$

[a] The sample was taken in a 25 ml volumetric flask.
[b] The sample was diluted 12 500 times and the known concentration of ascorbic acid in the sample is 2.04×10^{-7} M.

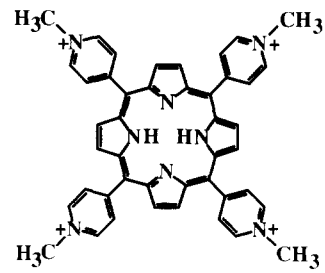

Fig. 1. 5,10,15,20-Tetrakis(1-methylpyridinium-4-yl)porphyrin (H_2tmpyp^{4+}).

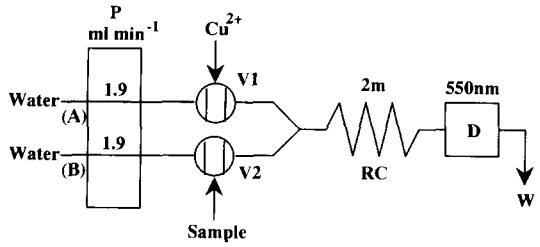
2.3. FI manifolds and experimental conditions

A schematic diagram of the FI manifold is shown in Fig. 2. The system consists of a two-channel manifold with two plunger pumps (Jasco RP-4F, FIU high pressure reciprocal pumps) operating at a flow rate of 1.9 ml min^{-1} and two six-way valve injectors of 120 μl sample volume were placed in each line. Two solutions were injected into each stream. One solution contained copper(II) nitrate (4.000×10^{-4} M), acetate buffer (pH 5.0, 10^{-2} M), DCTA (1.0×10^{-4} M), and sodium nitrate (0.1 M), and the other contained ascorbic acid (10^{-9}–10^{-7} M), H_2tmpyp^{4-} (2.5×10^{-5} M), acetate buffer (pH 5.0; 10^{-2} M), DCTA (1.0×10^{-4} M), and sodium nitrate (0.1 M). The two solutions were mixed in a reaction coil. The absorbance at 550 nm was measured by a Jussco UVIDEC-100 VI spectrophotometer with an 8 μl flow cell and recorded on a Graphtec Servocorder SR 6211, and the peak heights were measured. The FI experiment was thermostated at room temperature (25 ± 0.5°C).

3. Results and discussion

3.1. Kinetics and mechanism of formation of $Cu^{II}(tmpyp)^{4+}$ in the presence of ascorbic acid

The rate of metalloporphyrin formation is 10^{-6}–10^{-8} times slower than that of complex formation with open-chain ligands [12,13]. Several methods have been proposed for the enhancement of the incorporation of metal ion into porphyrin [14]. The slow reaction rate is a result of difficulty



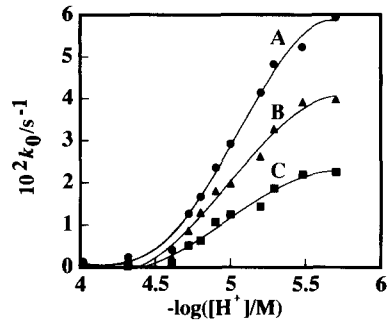


Fig. 2. Manifold used for determination of ascorbic acid: A and B, water streams; P, plunger pump; V1 and V2, six-way loop injector valves of 120 μl sample volume; RC, reaction coil (5 mm i.d.); D, spectrophotometer; W, waste. All flow lines were made from Teflon tubing (0.5 mm i.d.).

in deforming the porphyrin ring. Interestingly, large metal ions such as mercury(II), cadmium(II) and lead(II), which cannot be incorporated into the porphyrin core and just sit on the top of the porphyrin plane due to their large ionic radii, deform the porphyrin core and accelerate the incorporation of other medium-sized metal ions such as copper(II) [13,14]. Copper(I) has an ionic radius comparable to that of cadmium(II). Therefore, it is expected that copper(I) will accelerate metalloporphyrin formation in a similar way to cadmium(II) [15].

The present FI method is based on ascorbic acid reducing copper(II) ion to copper(I), which catalyzes the formation of $Cu^{II}(tmpyp)^{4+}$, and measuring the increase in absorbance of the Cu(II) porphyrin at a definite time after the start of the reaction. This reaction gave a straight line in a first-order kinetic plot. Hence, the kinetic equation for the reaction is described by Eq. (1), where k_0 is the conditional rate constant involving concentrations of ascorbic acid, hydrogen ion and copper(II):

$$-d[H_2tmpyp^{4+}]/dt = d[Cu^{II}(tmpyp)^{4+}]/dt = k_0[H_2tmpyp^{4+}] \quad (1)$$

3.2 Effect of hydrogen ion

The reaction of copper (II) with H_2tmpyp^{4+} was investigated in the presence of ascorbic acid at pH 4–5.6. Fig. 3 shows the effect of hydrogen ion in the presence and absence of ascorbic acid. The rate of formation of $Cu^{II}(tmpyp)^{4+}$ increased with pH. The rapid increase in the rate constant above pH 4.5 can be ascribed to the deprotonation of acetic acid and acsorbic acid ($pK_a = 4.56$ (acetic acid), 4.25 (ascorbic acid) [16]) and to the release of proton from H_2tmpyp^{4+} followed by the formation of $Cu^{I}(tmpyp)^{5+}$ (*vide infra*).

3.3 Effect of ascorbic acid and copper (II)

The formation of $Cu^{II}(tmpyp)^{4+}$ was dramatically accelerated in the presence of ascorbic acid even at nanomolar levels. The observed rate constant was linearly correlated with the total concentration of ascorbic acid (Fig. 4a) and increased significantly with copper(II) concentration, reaching a plateau at the highest concentration of Cu(II) at each temperature (Fig. 4b). The reduction of Cu(II) to Cu(I) was completed within 1 min

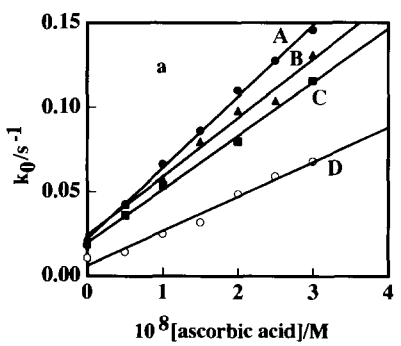

Fig. 3. Effect of pH on the reaction of H_2tmpyp^{4+} with copper(II) in the presence and absence of ascorbic acid: (A) 1.00×10^{-8}; (B) 5.00×10^{-9}; (C) 0 M $[Cu^{2+}] = 1.02 \times 10^{-4}$, $[H_2tmpyp^{4+}] = 1.54 \times 10^{-5}$ and $[DCTA] = 7.5 \times 10^{-6}$ M.

under the present experimental conditions ($[Cu^{2+}] = 1.0 \times 10^{-4}$ M, pH 5.0, $I = 0.1$ $NaNO_3$) [17,18]. The copper(I) formed catalyzes the rate of incorporation of copper(II) into the porphyrin core by deforming the porphyrin plane favorably for the attack of copper(II) from underneath. The mechanism is similar to the effect of large metal ions such as mercury(II), cadmium(II) and lead(II) [14,15,19]. Thus, the reaction mechanism for the accelerating effect of ascorbic acid is expressed by the following reaction scheme:

$$Cu^{2+} + HA^- \xrightarrow{\text{fast}} Cu^+ + HA^{\bullet}; \quad Cu^{2+} + A^{\bullet -} \xrightarrow{\text{fast}} Cu^+ + A$$

$$Cu^+ + H_2tmpyp^{4+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cu^{I}(tmpyp)^{5+} + 2H^+ \quad (2)$$

$$Cu^{I}(tmpyp)^{5+} + Cu^{2+} \xrightarrow{k_2} Cu^{II}(tmpyp)^{4+} + Cu^+ \quad (3)$$

The Cu^+ formed in reaction (3) contributes repeatedly to reaction (2) i.e., Cu^+ plays a role as a catalyst for the formation of $Cu^{II}(tmpyp)^{4+}$. Applying the steady state-approximation for $Cu^{I}(tmpyp)^{5+}$, the observed rate constant for the catalytic reaction is given by

$$k_0 = \frac{k_1 k_2 [Cu^+][Cu^{2+}]}{(k_{-1}[H^+]^2 + k_2[Cu^{2+}])} \quad (4)$$

From this equation, it can be deduced that the catalytic effect of Cu^+ becomes independent of $[Cu^{2+}]$ at high concentration ($k_{-2}[H^+]^2 \ll [Cu^{2+}]$). Thus, Eq. (4) is reduced to $k_0 = k_2[Cu^+]$ at high concentrations of copper(II) as shown in Fig. 4b.

3.4. Optimization of FI method

Ascorbic acid was found to enhance the formation of $Cu(tmpyp)^{4+}$, and the reaction was adapted in order to develop an FI method for the determination of ascorbic acid. A schematic diagram of the FI manifold is shown in Fig. 2. The absorbance of $Cu(tmpyp)^{4+}$ was measured at 550 nm (λ_{max} of $Cu(tmpyp)^{4+}$) and the peak height was also measured. The presence of ascorbic acid caused an increase in the peak height proportional to the ascorbic acid concentration. Flow rate, coil length, temperature and other chemical variables were optimized for the proposed FI method. This study was carried out by altering each variable in turn while keeping the others constant. The effect of the reactor coil length on the peak height was studied in the range 0.3–5 m (0.5 mm i.d.) in the presence of various concentrations of ascorbic acid. The absorbance increased with reactor coil length, reached a maximum at around 2 m, and then gradually decreased above 2 m (Fig. 5). Thus, a 2 m reactor coil was selected.

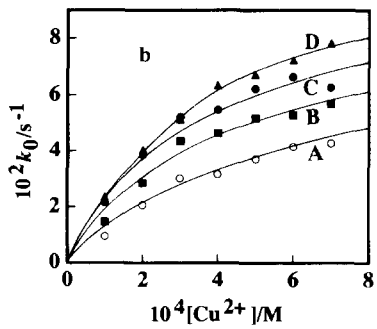

Fig. 4. Effect of ascorbic acid (a) and copper(II) (b) on the formation of $Cu(tmpyp)^{4+}$. (a) $[Cu^{2+}] = 1.02 \times 10^{-4}$; $[H_2tmpyp^{4+}] = 1.54 \times 10^{-5}$; $[DCTA] = 7.5 \times 10^{-6}$ M; pH 5.70 (A); 5.50 (B); 5.29 (C); 5.10 (D). (b) $[H_2tmpyp^{4+}] = 1.52 \times 10^{-5}$; $[DCTA] = 1.00 \times 10^{-5}$; [ascorbic acid] $= 5.00 \times 10^{-9}$ M; pH 4.80; T (°C) = 16.2 (A); 20.7 (B); 25.0 (C); 29.9 (D).

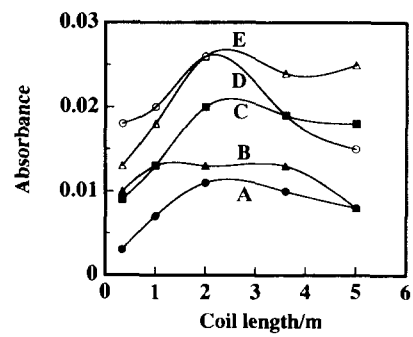

Fig. 5. Effect of reaction coil length on the determination of ascorbic acid using the present FI method. [Ascorbic acid] (10^{-8} M) = 2.00 (A); 4.00 (B); 6.00 (C); 8.00 (D); 10.00 (E).

3.5. Determination of ascorbic acid

With the manifold described above and under the selected experimental conditions, namely pump rate = 1.9 ml min^{-1}, sample volume = 120 μl, reactor coil length = 2.0 m, two solutions were injected simultaneously using two sample injectors with a six-way valve. One solution contained 0.1 M $NaNO_3$, acetate buffer (pH 5.0, $[CH_3COOH] + [CH_3COONa] = 0.01$ M), 1.0×10^{-4} M DCTA and 4×10^{-4} M Cu^{2+} in a 25 ml volumetric flask and the other contained 0.1 M $NaNO_3$, acetate buffer (pH 5.0, $[CH_3COOH] + [CH_3COONa] = 0.01$ M), DCTA = 1.0×10^{-4} M, sample solution (ascorbic acid = 10^{-9}–10^{-7} M) and H_2tmpyp^{4+} (1.80×10^{-5} M). A linear calibration graph was obtained by plotting the peak height (or absorbance) vs. the concentration of ascorbic acid in the range $5.0 \times 10^{-7} - 1.2 \times 10^{-7}$ M ascorbic acid. The regression equation was: absorbance = 4.94×10^5 [ascorbic acid] + 0.0283, with a correlation factor (r) of 0.9949. The relative standard deviation was 2.8% for the determination of 1.0×10^{-8} M ascorbic acid.

3.6. Interference studies

The effect of foreign ions on the present FI method was studied for frequently encountered reducing agents and inorganic ions, in addition to the effect of other vitamins that are likely to be present along with ascorbic acid in foods. The results are summarized in Table 1. Since ascorbic acid is easily decomposed in the presence of trace amounts of iron(III), DCTA was added to the sample solution to mask iron(III). EDTA also showed the same masking effect for the foreign ions as DCTA. Since the stability constant of Fe(DCTA) is larger than that of Fe(EDTA), and the difference between the Fe(III) and Cu(II) stability constants of DCTA is higher than that of EDTA [20], DCTA was used in this method. The present method is based on the ability of ascorbic acid to reduce Cu(II) to Cu(I). Hence, chemical species that can bring about reduction would be expected to interfere with the determination of ascorbic acid. Among the agents listed in Table 1, thiosulfate interfered significantly, but the effects of other reducing agents of sugars were negligible at the 10^{-6} M level. Vitamins B1, B2, B6 and B12 did not produce serious errors in the determination of 10^{-8} M ascorbic acid.

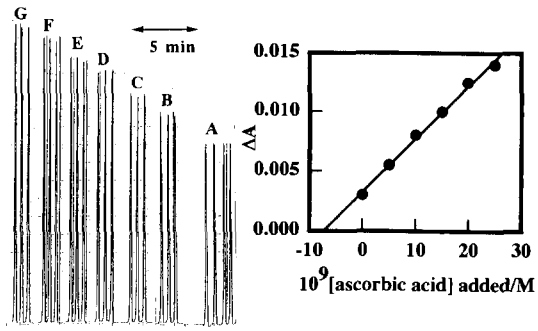

Fig. 6. Typical recorder signals for the determination of ascorbic acid in diluted tea samples after addition of a given concentration of ascorbic acid: (A) blank; (B) 0; (C) 5.0×10^{-9}; (D) 1.00×10^{-8}; (E) 1.50×10^{-8}; (F) 2.0×10^{-8}; (G) 2.5×10^{-8} M.

3.7. Application

In order to check the applicability of the present method to real samples, it was used for the determination of ascorbic acid in samples of tea, human urine and blood. Since the concentrations of ascorbic acid in these samples were too high for the present method, the samples were diluted 312 500, 5000, and 100 times for tea, urine and blood respectively. Typical FI signals and a calibration graph using the standard addition method are shown in Fig. 6 for the determination of ascorbic acid in a diluted tea sample. The blood sample was centrifuged for 5 min at 5000 rev min^{-1} and a 500 μl sample was taken into a 25 ml volumetric flask and diluted with water. It was anticipated that many materials in urine and blood would interfere with the determination of ascorbic acid. However, the interference of these species was greatly reduced due to the marked dilution of the sample before the determination of ascorbic acid. The analytical results for tea, urine and blood are summarized in Table 2. The accuracy and precision of the present method were tested by comparison of the results for the diluted (12 500 times) tea sample with the known concen-

tration of ascorbic acid in the tea sample and by a standard addition method respectively. Satisfactory results were obtained.

4. Conclusion

The proposed method for the determination of ascorbic acid is highly sensitive, selective, simple and precise. The method can be easily adapted for handling large numbers of samples by an FI method and has the potential for automatic routine clinical analysis. The high sensitivity of the proposed method provides rapid analysis of a nanomolar level of ascorbic acid in urine and blood without serious errors from sugars and vitamins.

Received 4 December 1995; revised 18 June 1996; accepted 26 June 1996

Abstract

The application of the second-derivative UV spectrophotometry for determining the stability of 3-bromo-*N*-bromo-*N*-(3,4-dimethyl-5-isoxazolyl-4-amine)-1,2-naphthoquinone in ethanolic solutions is described. The validity of this method was evaluated using synthetic mixtures of the intact drug and its degradation products and by statistical analysis of the calibration data. In order to verify the usefulness of this method for stability studies, recovery experiments by the standard addition method were also carried out.

Keywords: 3-bromo-*N*-bromo-*N*-(3,4-dimethyl-5-isoxzxolyl-4-amine)-1,2-naphthoquinone; Degradation kinetics; Second-derivative UV spectrophotometry

1. Introduction

The stability of halogenated isoxazolylnaphthoquinones in ethanolic solutions is affected by factors such as temperature and daylight [1–3]. Previously, we have demonstrated that 3-bromo-*N* - bromo - *N* - (3,4 - dimethyl-5-isoxazolyl-4-amine)-1,2-naphthoquinone (**1**) [4], a potential tripanocidal agent [5], decomposes in ethanolic solutions, at 35–50°C under daylight and dark conditions giving two main degradation products: 3 - bromo - 2 - hydroxy - *N* - (3,4 - dimethyl - 5 - isoxazolyl) -1, 4 - naphtho-quinon-4-imine (**2**) and 3-bromo - *N* - bromo - 4 - ethoxy - *N* - (3,4 - dimethyl - 5 - isoxazolyl - 4 - amine) - 1,2 -

Derivative UV spectrophotometry has proved to be particularly useful in assays of single components in the presence of excipients or degradation products with very similar structures [1,3,6–9]. This paper describes the applicability of second-derivative spectrophotometry for determining the disappearance kinetics of **1** in the presence of its degradation products. The method was validated using synthetic mixtures of **1** with its degradation products and by statistical analysis of the calibration data. In order to verify its usefulness in stability studies of **1**, recovery experiments were performed by the standard addition method [10].

2. Experimental

2.1. Apparatus

UV spectrophotometric studies were carried out on a Shimadzu UV-260 spectrophotometer using 1 cm quartz cuvettes. A Chromatotron Model 7924 T was used for preparative radial chromatography (PRC). The coating rotors were prepared with silica gel 60 PF-254 (Merck). For kinetic measurements, the constant-temperature bath was regulated by a Haake D8 thermostat with ± 0.1°C precision.

2.2. Materials

All chemicals and reagents were of analytical grade. Ethanol was treated with sulfanilic acid and potassium hydroxide/Zn [11]. Compounds **1**–**3** were obtained as reported previously [2,4]. Compounds **1** and **3** are freely soluble in dichloromethane and sparingly soluble in ethanol, therefore dichloromethane was used as the solvent to prepare their stock solutions.

2.3. Second-derivative UV spectrophotometric analysis

Zero-order and second-derivative absorption spectra of standard and sample solutions were recorded at 220–350 nm against ethanol as a blank. Suitable settings were a slit width 1 nm and a fast scan speed. The recorder scale expansion was also optimized to facilitate reading on the recorder tracing. The peak-to-baseline measurements h (mm) were performed at 258.0 nm in duplicate scans of the same solution and normalized (H) [1,3,6]. All transfers and dilutions were carried out in the dark.

2.4. Calibration graph

Five solutions of **1** were prepared in duplicate by diluting aliquots taken from two stock solutions (1.37×10^{-3} M in dichloromethane) with ethanol to obtain final concentrations in the range $(1.37–4.11) \times 10^{-5}$ M. The peak heights h (mm) at 258.0 nm were measured and normalized [1,3,6]. The system obeys Beer's law in the range examined.

2.5. Recovery assays

Dichloromethane stock solutions of **1** (1.47×10^{-3} M) and **3** (1.22×10^{-3} M) were prepared. A stock solution of **2** was prepared in ethanol (1.20×10^{-3} M). Aliquots were transferred into 25 ml volumetric flasks and diluted to volume with ethanol to obtain final concentrations in the ranges $(3.56–1.01) \times 10^{-5}$ M for **1**, $(0.49–2.40) \times 10^{-5}$ M for **2** and $(0.49–2.44) \times 10^{-5}$ M for **3**. The second-derivative spectra for different mixtures of **1** with **2** and **3** were recorded in duplicate and the h values at 258.0 nm were measured, normalized and compared with the corresponding calibration graph run (Table 1).

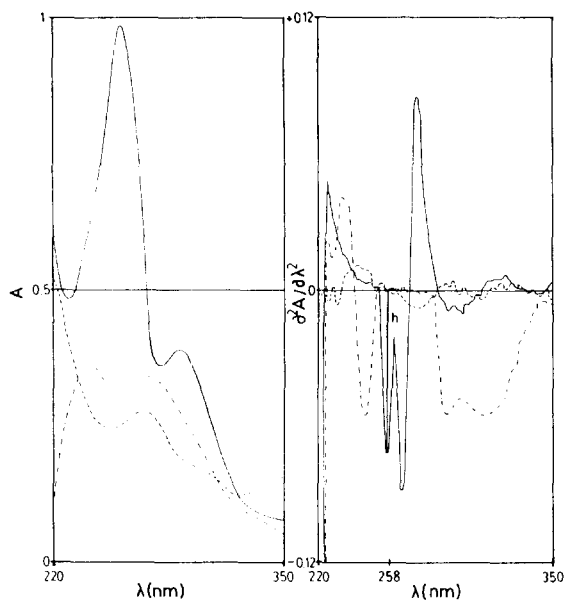

Fig. 1. Zero-order absorption spectra (left) and second-derivate spectra (right) for 3.50×10^{-5} M of **1**, **2** and **3** in 95% ethanol; *h* is the peak-to-baseline distance in mm. (—) **1**; (– · – · –) **2**; (– – –)**3**.

2.5.1. Standard addition method

A stock solution of **1** was prepared in dichloromethane (1.47×10^{-3} M). An aliquot of 6.0 ml was transferred into a 250 ml volumetric flask and diluted to volume with ethanol to obtain a final concentration of 3.53×10^{-5} M. The flask was sealed and then stored at 50°C in a constant-temperature bath for 26 min under daylight. It was then withdrawn and immediately cooled in an ice-bath. Aliquots (15 ml) of this degraded solution were taken and transferred into 25 ml volumetric flasks. Aliquots (0.10–0.60 ml) from the stock solution of **1** were added and then diluted to volume with ethanol. The second-derivative spectra of these solutions were recorded in duplicate. The *h* (mm) values at 258.0 nm were measured, normalized and compound **1** was quantified by the ratio of the intercept on the ordinate and the slope of the calibration line (Table 2) [10]. This assay was performed in quintuplicate.

2.6. Repeatability assay

A solution of 3.53×10^{-5} M of **1** was measured by replicate analysis ($n = 10$) on the same day.

2.7. Kinetic studies

Aliquots were taken from a dichloromethane stock solution of **1** (1.37×10^{-3} M) and diluted with 95% ethanol to produce a final concentration of 3.53×10^{-5} M. The sample solutions were transferred into 5 ml glass ampoules and 5 ml amber-glass ampoules, flame sealed and then stored at the appropriate temperature in a constant-temperature bath. The "zero time" samples were immediately maintained at −20°C. Ampoules were withdrawn at suitable time intervals, immediately cooled in an ice-bath and stored at −20°C in a freezer. Upon removal of the last samples, the stored solutions were allowed to warm to room temperature and then all samples were analysed. These kinetic studies were carried out in duplicate.

3. Results and discussion

The structural similarities between **1** and its degradation products **2** and **3** make it necessary to choose a specific method of analysis. Second-derivative spectrophotometry was found to be

Table 1
Recovery of **1** in the presence of its degradation products **2** and **3** using the second-derivate method

		Mean ± SD:	100.9 ± 0.7

[a] Mean of five determinations.

the best method for determining the residual concentration of **1** under the experimental conditions of this study owing to the lack of interference from the signals of **2** and **3**.

3.1. Spectrophotometric measurements

Fig. 1 (left) shows the zero-order absorption spectra of **1** and its degradation products **2** and **3** in the range 220–350 nm. Owing to the extensive spectral overlap of the absorption bands of these compounds, their second-derivative spectra were recorded, revealing a good selectivity for determining **1** in mixtures of **2** and **3**, as shown in Fig. 1 (right).

The peak-to-base line distance (h) at 258.0 nm for the determination of the remaining concentration of **1** was selected, since at this working wavelength no interference from **2** and **3** was observed.

3.2. Calibration graphs and statistical analysis

The ordinate values of the regression line (H) were calculated from the h (mm) measurements and were proportional to the concentration of pure **1** in the range $(1.37–4.11) \times 10^{-5}$ M. The linear regression equation for **1** [$H = (8.21 \pm 15.1) \times 10^{-4} + (2.24 \pm 0.05) \times 10^{3}c$ (M)], the correlation coefficient ($r = 0.9992$), the standard deviation (1.13×10^{-3}), the limit of detection (LOD: 1.51×10^{-6} M) and the limit of quantitation (LOQ: 5.03×10^{-6} M) were estimated from the calibration data at the $p = 0.05$ level of significance for $n = 5$ standard specimens [10,12].

The good sensitivity of the method is indicated by the slope of the calibration graph. The linearity of the regression line and the negligible scatter of the experimental points are clearly evidenced by the correlation coefficient and the standard deviation. A test of significance for the intercept of the regression line was performed as described previously [1,3,6] to verify whether the intercept a is significantly different from zero. The calculated value of $t = 0.54$ was compared with tabulated data for the t distribution ($t = 3.18$; $n = 5$), and as it does not exceed the 95% criterion, the calculated intercept is not significantly different from zero.

	Mean $\pm$ SD: 100.6 $\pm$ 0.9	

[a] Value obtained by standard addition method $\pm$SD ($n = 5$).

The absolute error (S_c) in the determination of a given concentration of **1** was calculated by statistical analysis of the regression equation [6,10]. As the errors are minimal in the range $(2.06–3.50) \times 10^{-5}$ M, the last concentration was chosen for degradation studies.

The validity of the second-derivative spectrophotometric method was tested by successive determinations of **1** in synthetic mixtures with **2** and **3**. The concentrations of the intact drug in these mixtures were in the range $(3.56–1.20) \times 10^{-5}$ M, in the presence of various concentrations of **2** [$(0.49–2.40) \times 10^{-5}$ M] and **3** [$(0.49–2.44) \times 10^{-5}$ M], to reproduce the stability studies conditions. The results are presented in Table 1 and indicate that the recoveries of **1** are in good agreement with the theoretical amounts of the compound.

Even though the recovery experiments demonstrated the applicability of the method, they are not sufficient to prove its specifity owing to intermediates and minor products that may be formed during the degradation reactions. Therefore, a recovery assay was performed using degraded samples of **1** by the standard addition method [10]. It can be seen from Table 2 that the results obtained do not differ significantly from 100%, confirming the accuracy of the method for measuring the kinetic disappearance of **1**.

The precision of the results was determined by using a standard solution (3.53×10^{-5} M; $n = 10$).

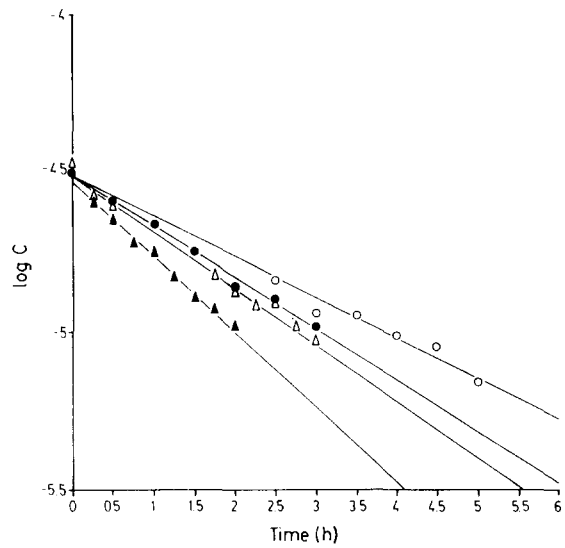

Fig. 2. Effect of temperature on the pseudo-first order rate constants for the degradation of **1** in 95% ethanol in daylight. (○) 35°C, $k_{obs} = 0.293\ h^{-1}$; (●) 40°C, $k_{obs} = 0.368\ h^{-1}$; (△) 45°C, $k_{obs} = 0.442\ h^{-1}$; (▲) 50°C, $k_{obs} = 0.546\ h^{-1}$.

The value obtained of $100.2 \pm 0.10\%$ (found $\pm$ SD) shows that the method has a satisfactory precision.

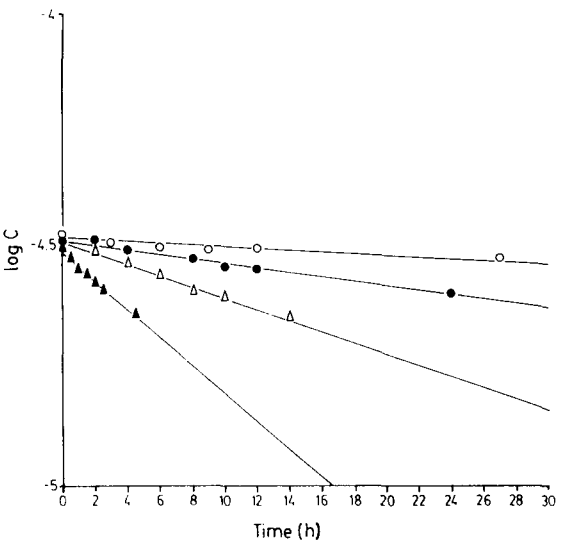

Fig. 3. Effect of temperature on the pseudo-first-order rate consants for the degradation of **1** in 95% ethanol in the dark. (○) 35°C, $k_{obs} = 0.00412\ h^{-1}$; (●) 40°C, $k_{obs} = 0.0105\ h^{-1}$; (△) 45°C, $k_{obs} = 0.0268\ h^{-1}$; (▲) 50°C, $k_{obs} = 0.0682\ h^{-1}$.

3.3. Kinetic studies

Figs. 2 and 3 show the residual concentration of **1** vs. time at different temperatures, exhibiting good linearity ($r > 0.99$). From these plots, the pseudo-first-order degradation rate constants of **1** were calculated [2] and it can be seen that the rate constants under daylight conditions are faster than those in the dark.

4. Conclusions

The advantages of second-derivative UV spectrophotometry, such as simplicity, lack of sample pretreatment and expensive solvents and reagents and the good selectivity, accuracy and precision achieved in the assays make it suitable for stability evaluation of ethanolic solutions of **1** under different experimental conditions.

Received 14 December 1995; revised 18 June 1996; accepted 22 June 1996

Abstract

The use of 85% phosphoric acid in borosilicate conical flasks for the dissolution of ilmenites at $230 \pm 10°C$ is reported. The samples were quantitatively dissolved in less than 13 min. Titanium was determined by both spectrophotometry and inductively coupled plasma atomic emission spectrometry ICP-AES. Vanadium and iron were determined by ICP-AES. In several samples of ilmenites analyzed, the TiO_2 concentration was in the range 10.6–57.5% and those of FeO and V_2O_5 were in the ranges 31.6–51.4% and 0.39–1.32%, respectively. In the spectrophotometric method, vanadium interference occurs only when the Ti/V concentration ratio is <4. In all samples analyzed this ratio was around 12, resulting in no interferences due to vanadium. Hence the ilmenite dissolution procedure using phosphoric acid was compatible with titanium quantification by both spectrophotometry and ICP-AES.

Keywords: Inductively coupled plasma atomic emission spectrometry; Ilmenites; Phosphoric acid dissolution; Spectrophotometry; Titanium

1. Introduction

Titanium occurs in nature as the minerals rutile, brookite and anatase, and also occurs as titanates, ilmenite and perovskite. Industrially, ilmenite is of greatest importance. The decomposition of ilmenites is a very time-consuming operation, and involves fusion with pyrosulfate and/or the use of several mineral acids. Besides the time-consuming dissolution, the acids are usually volatilized into the atmosphere with consequent contamination problems. It is desirable to develop decomposition methods for solid samples that would allow a rapid and clean analysis [1–3].

PII S0039-9140(96)02026-7

Phosphoric acid has been used successfully to decompose solid samples. Therefore, usually special glassware apparatus [4–11] or platinum crucibles have been required [12,13]. The use of phosphoric acid in determinations which involve atomic absorption spectrometric measurements [12] has been limited owing to nebulizer clogging as a result of solutions with high viscosity. Additionally, the determination of titanium in ilmenites by spectrophotometry using hydrogen peroxide [14] has limitations due to the interferences caused by the high iron concentrations and by vanadium, even at lower concentrations.

In the present work, the use of phosphoric acid in borosilicate conical flasks in the decomposition of ilmenites followed by titanium quantification by spectrophotometry using hydrogen peroxide and inductively coupled plasma atomic emission spectrometry ICP-AES was investigated. Iron and vanadium were quantified by ICP-AES.

2. Experimental

2.1. Reagents

All reagents were of ACS reagent grade. Deionized water (18.0 MΩ cm) was used throughout.

2.2. Apparatus

The absorbance measurements were made in a Varian DMS 80 spectrophotometer using 1.0 cm pathlength silica cells at 404 nm. The ICP-AES determinations were made using an ARL Fisons Model 3410 instrument. The working parameters were incident power 650 W, reflected power <10 W, slit width 20 μm, Meinhard concentric nebulizer and quartz mini-torch. The wavelengths used were Fe 259.9, Ti 334.9 and V 292.4 nm. The gas flow-rates were cooling 7.5 l min^{-1}, intermediate 0.8 l min^{-1}, aerosol carrier 0.8 l min^{-1} and peristaltic pump 2.3 ml min^{-1}.

2.3. Sample preparation

After drying (120°C), ca. 0.1000 g of the sample was placed in conical flasks and 2–3 ml of deionized water were added to disperse it. Then 17 ml of 85% phosphoric acid were added and the system was heated at ca. 230°C to promote the sample dissolution (on average 12 min). The hotplate was thermostatically controlled and it was previously calibrated with a glass thermometer (0–600 ± 1°C). The dissolved sample was placed in a 100 ml volumetric flask and diluted to volume with deionized water.

2.4. Spectrophotometric procedure

Aliquots of 10 ml were transferred into 50 ml volumetric flasks to which were added 4.5 ml of H_2SO_4 (1:1) and 5 ml of 30% H_2O_2 [14] and the volume was completed with deionized water.

2.5. ICP-AES procedure

The determinations were performed after sample dissolution (17 ml of 85% phosphoric acid) and dilution to 100 ml with deionized water, which resulted in a solution containing 15% of phosphoric acid. The standards were also adjusted to contain 15% of phosphoric acid in order for the sample and standard solutions to have the same viscosity. Phosphoric acid concentrations $>30\%$ must be avoided because they can result in nebulizer clogging.

3. Results and discussion

On heating, phosphoric acid undergoes a series of condensation reactions, giving mainly pyrophosphoric acid ($H_4P_2O_7$) and metaphosphoric acid [$(HPO_3)_n$] [1,2]. Fig. 1 shows the temperature profile when 30 ml of phosphoric acid are heated continuously with 0.25 g of ilmenite. The first transition, at ca. 160°C, corresponds to the formation of pyrophosphoric acid. The second, at 280°C, corresponds to the formation of metaphosphoric acid. The formation and decomposition of the $H_4P_2O_7$ were observed by qualitative tests [15]. Hence, as the complete dissolution of the ilmenite occurs in less than 15 min, we can consider that the species responsible for the ore decomposition are pyrophosphoric acid at the beginning and later metaphosphoric acid.

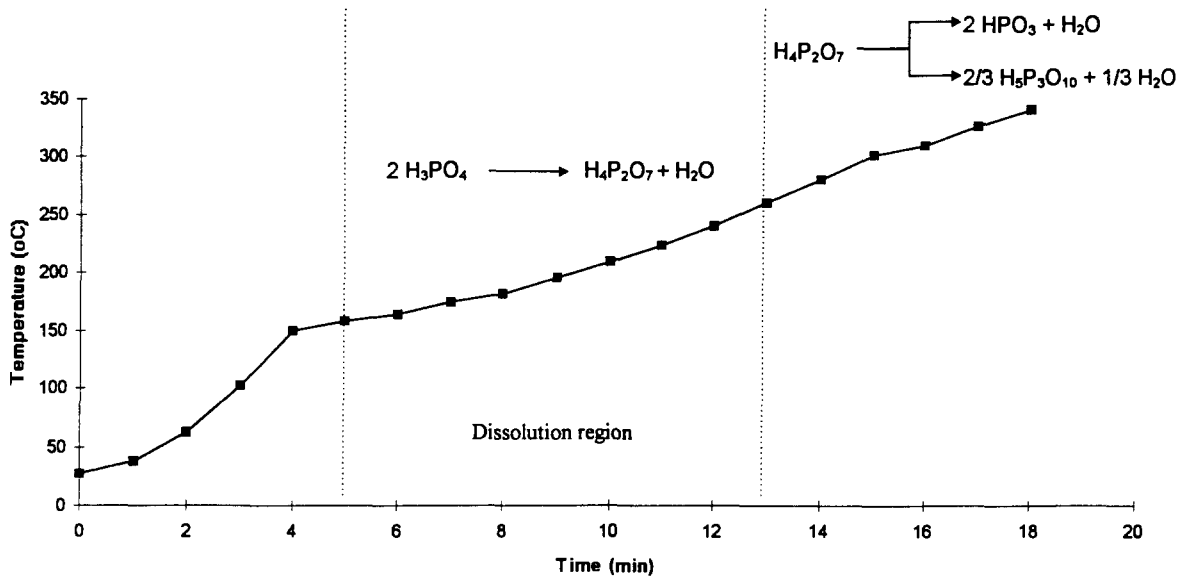

Fig. 1. Temperature profile when 30 ml of phosphoric acid are heated continuously with 0.25 g of ilmenite.

In spectrophotometric titanium determinations, iron in the presence of phosphoric acid forms a strong complex which does not absorb at 404 nm [14]. Therefore, our results demonstrate that the vanadium interference depends on the Ti/V ratio. Table 1 gives the absorbance values measured for seven different solutions containing hydrogen peroxide, 4.8 μg ml^{-1} of titanium and vanadium concentrations in the range 0–4.34 μg ml^{-1}. Vanadium interference, increasing the absorbance value by 6.3% (Table 1), occurred only when its concentration was at least 1.45 μg ml^{-1}, corresponding to a Ti/V concentration ratio of <4. For all samples analyzed this ratio was around 12, resulting in no interference due to vanadium.

Table 1
Absorbance measured in solutions containing titanium at 4.8 μg ml^{-1} and various vanadium concentrations

Ti (μg ml^{-1})	V (μg ml^{-1})	Absorbance	Ti/V
4.80	0	0.16	–
4.80	0.14	0.16	34.3
4.80	0.36	0.16	13.3
4.80	0.72	0.16	6.67
4.80	1.45	0.17	3.3
4.80	2.17	0.17	2.2
4.80	4.34	0.19	1.11

The data for the calibration curves (five points) for TiO_2 concentration in the range 0–160 μg ml^{-1} are given in Table 2.

Method validation was performed with six different aliquots of one sample analyzed both at CEPED (Research and Development Center, Bahia State) using their routine procedures [16] and by the present methodology in which the ore was decomposed with phosphoric acid and titanium was determined by both spectrophotometry and ICP-AES. The results are shown in Table 3.

The application of the $t_{95\%}$ test to the results obtained at CEPED and in this work (Table 3) did not show significant differences. In the sample

Table 2
Calibration curves for UV spectrophotometric and ICP-AES determination of titanium ($A = aC + b$) [a]

Method	a	b	r^2
UV	0.0092	−0.0066	0.9996
ICP-AES	0.0489	−0.0483	0.9994

[a] A = absorbance; C = concentration (g/l^{-1}); a = slope; b = intercept; r = correlation coefficient.

Table 3
Concentrations (%) of TiO_2 in an ilmenite sample determined at CEPED and using the procedures described in this paper

This work [a]		CEPED[b]
UV	ICP-AES	
12.27 (±0.009)	12.14 (±0.096)	12.30

[a] Mean of six different determinations in six independent samples; the ilmenite sample contained 38.2% FeO and 1.0% V_2O_5. Numbers in parentheses are mean relative standard deviations.
[b] CEPED (Research and Development Center, Bahia State) is a State reference bureau. They used a routine analytical procedure [16].

analyzed the concentrations of FeO and V_2O_5 were 38.2% and 1.0%, respectively. Owing to the high complexant activity of the phosphate ion, interferences of iron and vanadium in the spectrophotometric determinations were avoided.

The titanium concentrations determined by spectrophotometry and by ICP-AES were in good agreement when phosphoric acid was used to decompose several samples of ilmenites in which the TiO_2 concentrations were in the range 10.6–57.5% and those of FeO and V_2O_5 were, in the ranges 31.6–51.4% and 0.39–1.32%, respectively.

In conclusion, the ilmenite dissolution procedure using phosphoric acid was compatible with titanium quantification by both spectrophotometry and ICP-AES. One chemist, in a working day of 8 h, can determine titanium spectrophotometrically in at least 20 samples of ilmenite. The method is rapid, inexpensive and clean because it does not emit gases (e.g. SO_2 and/or NO_x) into the atmosphere.

Abstract

Studies on the determination of trace metallic impurities in nuclear materials such as uranium, thorium and plutonium are described. The bulk of the matrix is separated by batch extraction from their nitric acid solutions using 2-ethylhexyl hydrogen 2-ethylhexyl phosphonate (KSM-17, equivalent to PC88-A). The final aqueous phase containing the metallic impurities is fed to a high-temperature source inductively coupled plasma and the analysis is carried out employing a computer-controlled multichannel direct-reading spectrometer. The studies also included the recovery of impurities at various acidities and spectral interferences of the above matrices over the analyte elements. Based on the above studies, methods were standardized for the determination of 19 elements, viz. Al, B, Be, Ca, Cd, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Si, Zn, Ce, Dy, Eu, Gd and Sm, in U/Th/Pu solutions. The relative standard deviation for various elements is in the range 1–5%.

Keywords: Impurities; Inductively coupled plasma atomic emission spectrometry; Plutonium; Thorium; Uranium

1. Introduction

Uranium and plutonium find application as fuels in different types of nuclear reactors. Thorium is an important fertile material whose irradiation in a reactor yields ^{233}U. These materials are required to meet stringent specifications before use in the nuclear fuel cycle [1,2]. The performance of these nuclear materials depends on several factors, of which purity is particularly important. The presence of impurities beyond specified limits will affect the neutron economy and metallurgical characteristics of the fuel and hence it is necessary to characterize them.

Several techniques have been employed for the determination of trace metals, among which spectrochemical methods are the most common since many elements can be estimated simultaneously in a short time using small quantities of samples.

* Corresponding author.

PII S0039-9140(96)02027-9

The great improvements in excitation sources such as inductively coupled plasma (ICP) and detection with photomultiplier tubes have considerably improved the range, precision and sensitivity of spectrochemical methods.

Direct analysis of these nuclear materials for trace metals is not possible since uranium, thorium and plutonium have very complex spectra with thousands of lines spread over the entire range of 200–500 nm. These lines severely interfere with the analytical lines of the elements of interest. Hence it is desirable either to separate the major matrix or to suppress its excitation. Although the d.c. arc–carrier distillation technique [3] is normally employed, this method is mainly applicable to volatile impurities and has poor reproducibility. Solvent extraction employing various extractants or alternatively the ion-exchange techniques [4–8] have been utilized, wherein the major matrix is first separated from the impurity elements and the aqueous fraction thus obtained is analysed by ICP atomic emission spectrometry (ICP-AES). 2-Ethylhexyl hydrogen 2-ethylhexyl phosphonate (KSM-17, equivalent to PC-88A) has been utilized for the extraction of several metal ions [9]. This extractant has also been used in extraction studies of uranium and plutonium at trace concentrations [10]. This paper describes studies on the extraction and separation of U, Th and Pu from impurity elements using 20% KSM-17 in dodecane or xylene. The aqueous portions are analysed for trace metals using a computer-controlled direct-reading spectrometer.

2. Experimental

2.1. Apparatus

The spectrometer system, consisting of a 48-channel polychromator and computer-controlled scanning monochromator, was aligned with an inductively coupled argon plasma located in a glove-box [11]. With added electronics, the polychromator could be used in the $n+1$ mode along with a scanning monochromator facilitating simultaneous measurements. The instrumental parameters and operating conditions are listed in Table 1.

2.2. Reagents

All acids and water used were quartz distilled. Specpure chemicals were obtained from Johnson Matthey (Royston, UK). The extractant KSM-17, of solvent extraction grade, was supplied by Uranium and Rare Earth Extraction Division of Bhabha Atomic Research Centre. Dodecane was obtained from Transware Chemica (Hamburg, Germany). Xylene was supplied by Merck (India).

2.3. Preparation of standards

Individual elements in metal or compound form (Specpure) were used to prepare stock solutions of 1 g l^{-1} concentration in HNO_3–HCl medium. Taking appropriate aliquots, a composite standard containing 21 elements (Table 2) at different concentration levels ranging between 5 and 25 μg ml^{-1} was prepared and designated the High stan-

dard. Doubly quartz distilled water was used as the low standard. A composite test standard of 1 μg ml^{-1} of each element was used as a check standard for the calculation of precision.

Specpure uranium and thorium oxides were used to prepare stock solutions with metal concentrations of 100 g l^{-1} in HNO_3. Ion-exchange purified and coulometrically certified plutomium nitrate solution was used to prepare the Pu stock solution of 5 g l^{-1}. These solutions were used with appropriate dilutions and acidity adjustments in various studies.

2.4. Preparation of blank

A 10 ml volume of 1 M HNO_3 was contacted three times with 10 ml of 20% KSM-17 in dodecane. The equilibration in this and all other experiments was carried out for 5 min. The aqueous fraction collected at the end of third contact was used as the blank during the analysis of both uranium and plutonium samples. In all the experiments using thorium, xylene was used instead of dodecane as the diluent to avoid third-phase formation problems during extraction. The blank solution for thorium was prepared in the same manner as above.

2.5. Preparation of samples

Uranium oxide or metal samples (1 g of uranium) were dissolved in concentrated. HNO_3 and made up to 10 ml after adjusting the acidity to 1 M HNO_3. A thorium oxide sample, amounting 1 g of Th, was dissolved in a platinum dish using concentrated HNO_3 and HF as described in Ref. [8]. The solution was made up to 10 ml using 1 M HNO_3. The same procedure was adopted for the dissolution of a PuO_2 sample amounting to 50 mg of Pu and the acidity was adjusted to 1 M HNO_3.

Eu	393.0	0.10	2.0
Gd	335.0	0.15	3.0
Sm	332.1	0.25	5.0

2.6. Interference studies

Spectral interferences due to uranium for analyte elements were studied using uranium solutions of different concentrations such as 1, 5, 10, 25 and 50 $\mu g\ ml^{-1}$. These solutions were fed into the ICP system without separating uranium and the resultant concentrations due to uranium in different analytical channels were recorded. Similar interference studies were carried out using thorium and plutonium solutions of different concentrations.

2.7. Recovery of impurities

A composite solution containing 21 impurity elements at different concentration levels was prepared. An appropriate aliquot of this composite solution was added to pure uranium solution and made up to 10 ml after adjusting the acidity to 0.5 M HNO_3. This synthetic mixture, containing a total of 1 g of uranium and trace level impurities, was given three contacts with 20% KSM-17 in dodecane. The aqueous fraction was then fed to the ICP system and the analysis was carried out using direct-reading spectrometer. The same extration procedure was followed for pure uranium solution (1 g in 10 ml) and the aqueous fraction collected was used as the blank during these experiments.

Recovery experiments with Th and Pu matrices were conducted in a similar manner, except that in the case of Pu solution, 10 ml contained 50 mg of Pu along with all the impurities.

The recovery studies were also repeated by preparing synthetic mixtures containing impurities in a U/Th/Pu matrix at different acidities such as 1, 2 and 4 M HNO_3.

2.8. Analysis

The aqueous phase obtained after extraction of U/Th/Pu in KSM-17 was analysed using a two-point calibration procedure with a composite standard as the high and doubly distilled water as the low standard. An analytical program incorporating "blank subtraction" mode was written utilizing the source program JY-70 Plasma V-2.3 (Pascal) supplied by Jobin Yvon (France). As mentioned earlier, the ICP source is optically

aligned with both spectrometers and this arrangement, combined with suitable software, allowed the simultaneous operation of both spectrometers. Uranium was monitored simultaneously on the sequential spectrometer using the spectral line at 385.9 nm. Similarly, when analysing the aqueous fractions of Th and Pu samples, the spectral lines at 401.9 and 453.6 nm were used for measuring the concentrations of Th and Pu, respectively.

3. Results and discussion

Table 2 lists the wavelengths and detection limits for the various elements as found by ICP-AES utilizing a multichannel direct-reading spectrometer. The limits given were obtained after processing 1 g uranium or thorium or 50 mg plutonium samples. It may be noted that the direction limits achieved in the present method meet the required specification limits for all the elements except boron and a few rare earths. The detection limits for these elements can be improved by increasing the quantity of sample taken for extraction.

It is well know that prior separation of the major matrices helps in achieving lower detection limits. The present extraction studies showed nearly complete removal of the major matrix, thus leaving an aqueous fraction containing U/Th/Pu only at trace levels (<1 μg ml^{-1}) after three contacts with KSM-17. The extent of extraction of the major matrix from 1 M HNO_3 by KSM-17 is given in Table 3. Also, the kinetics of KSM-17 extraction are fast and therefore the time required for separation is considerably reduced. In order to establish the magnitude of spectral interferences, the gross peak intensities (I_g) for 1 M HNO_3 and Specpure uranium solutions (1–50 μg ml^{-1}) were measured at various elemental channels. Similarly, intensities due to doubly distilled water (I_b) were also measured at the peak positions

Table 5
Comparison of the present method with other methods

Ref.	Method of separation	Matrix	Quantity processed	No. of elements determined
This work	Three-stage liquid–liquid extraction of 5 min duration each using 20% KSM-17 in dodecane	U/Th/Pu	1 g/1 g/ 50 mg	19
[4]	Column extraction chromatography using tri(2-ethyl-hexyl) phosphate (TEHP) and di-*n*-hexyl *N*,*N*-diethylcarbamyl methylene phosphonate (DHDECMP)	U	0.2–0.4 g	36
[5]	AGMP-1 anion-exchange resin (50–100 mesh) in HCl	Pu	0.3–0.8 g	32
[6]	Two-step liquid–liquid extraction using 30% TBP in CCl_4 (three contacts) and 0.2 M TOPO–CCl_4 (one contact)	U	10 g	8
[8]	Liquid–liquid extraction using TOPO–xylene and HDEHP–xylene in HNO_3 and HCl with 8–10 contacts	Th	1 g	13

and the ratio I_g/I_b was evaluated; this represents graphically the magnitude of interferences due to uranium for different elements. Since there was a large variation in the magnitude of interferences for different elements, the ratio mode was adopted to show the interferences for the analyte elements simultaneously. Fig. 1 shows a typical graphical representation of the magnitude of spectral interferences at different concentration levels of uranium for those elements whose spectral lines are within a distance of about ± 0.035 nm from the interfering uranium lines [12]. It can be clearly seen that I_g/I_b is practically the same for both 1 M HNO_3 and 1 μg U ml^{-1}, indicating the absence of uranium spectral interference at 1 μg U ml^{-1} and below for the elements shown. For other elements which are not included in Fig. 1, the interference effect is not noticeable even up to 50 μg U ml^{-1} in the aqueous fraction. This suggests that there is no direct spectral interference for these analyte elements at the trace levels of uranium studied. Similarly, no spectral interferences were observed with Th and Pu matrices at levels of 1 μg ml^{-1} and below for the analyte elements studied.

The data obtained during the recovery experiments for 21 elements in the case of U are summarized in Table 4. It can be seen that the recoveries for all the elements at all the acidities studied are in the range 90–110%, except for Dy, Mo, Zr and Fe at all the acidities studied. The recovery improves for Dy at 1 M acidity and above and is almost quantitative; for Mo and Zr it decreases as the acidity increases. For Fe, the recovery is between 98 and 97% at acidities of 0.5–1 M and decreases sharply at 2 and 4 M HNO_3. For the best results, it was decided to maintain an acidity of 1 M for analysis of the samples. Since the recoveries for Mo and Zr are very poor, these elements cannot be determined using the present method.

Sm	0.313	0.25	–	0.10	0.25	1.99	5.0

The above-mentioned recovery studies were repeated with Th and Pu and the results were similar to those obtained with uranium.

Stripping of Th and Pu from the organic phase could be achieved using 0.3 M oxalic acid containing 0.05 M HNO_3. However, in the case of uranium, back-extraction was possible only with 8 M HCl, where several contacts were necessary for nearly complete recovery.

Huff [4,5] employed column extraction chromatography and anion-exchange separation techniques followed by ICP-AES for the characterization of uranium and plutonium fuels, respectively. Biswas et al. [6] separated uranium by two-step liquid–liquid extraction and determined the rare earths by ICP-AES. Characterization of thorium oxide fuel was carried out by Porwal et al. [13] using a carrier distillation and direct reader technique for common elements, whereas the Bangia et al. [8] determined rare earths in thorium oxide by solvent extraction followed by d.c. arc/photographic detection. A comparison of the salient features of the present procedure along with those cited in the literature is given in Table 5. The greatest advantage of the present method is that a single extractant can be used for the nearly complete separation of all three matrices (U/Th/Pu), thereby permitting the determination of a number of elements simultaneously, including the rare earths.

The detection limits in the present method are compared with those of other methods in Table 6. It can be seen that for uranium and plutonium the detection limits are comparable to those reported in Refs. [4] and [5], respectively, for most of the elements. For thorium, the detection limits for rare earths are comparable to those reported in Ref. [8], whereas those obtained for all the other elements except boron are lower than the values given in Ref. [13]. Hence the present procedure for the extraction of the major matrix and determination of metallic impurities is superior than those used earlier.

4. Conclusion

The separation of major matrices such as ura-

nium, thorium and plutonium from trace metals using KSM-17 and subsequent analysis of the aqueous fraction for trace impurities by ICP-AES has several advantages. Since the kinetics of KSM-17 extraction are fast, the time required for separation is considerably reduced. Analysis by computer-controlled ICP-AES not only yields highly reproducible results but also increases the analytical throughput manyfold. The acidity adjustment is not critical for most of the impurity elements. Uranium, thorium and plutonium can easily be extracted in KSM-17 over a wide range of HNO_3 concentrations. The methods standarized here can be effectively employed for the routine determination of the trace metal constituents in these nuclear materials.

Acknowlegements

The authors are grateful to Shri. N. Venkataraman, Head, Fuel Reprocessing Division, for his keen interest and encouragement during the course of this work.

Received 15 October 1996; revised 24 June 1996; accepted 26 June 1996

Abstract

A spectrophotometric method was developed for the determination of ferbam (iron(III) dimethyldithiocarbamate) by converting it into an iron–phenanthroline complex, which was then absorbed on microcystalline naphthalene in the presence of tetraphenylborate, and the absorbance was measured at 515 nm against a reagent blank. The molar absorptivity of the complex was 1.2×10^4 l mol^{-1} cm^{-1}. Ten replicate analyses of a sample solution containing 150 μg of ferbam gave a relative standard deviation of 0.84%. Beer's law was obeyed over the concentration range 22.4–372.9 μg of ferbam. The effects of various factors such as reagent concentration and naphthalene, shaking time and diverse ions were studied in detail. The method is sensitive and selective and can be applied to the direct determination of ferbam in commercial samples and in mixtures containing various other dithiocarbamates (e.g. ziram, zineb and maneb) in foodstuffs.

Keywords: Ferbam determination; Iron(III) dimethyldithiocarbamate; Spectrophotometry

1. Introduction

Ferbam (iron(III) dimethyldithiocarbamate) is widely used as a protective fungicide in agriculture. Most of the methods for the determination of ferbam, like other dithiocarbamates, is based on its decomposition by hot mineral acid to the amine and carbon disulphide [1,2]. Dithiocarbamates have also been determined in vegetable foodstuffs using high-performance liquid chromatography [3], extraction voltammetry [4] and titrimetry [5]. Ferbam is determined by converting it into molybdenum [6] and copper [7] complexes in an acidic medium and into a selenium [8] complex by extraction into chloroform. The extraction of the molybdenum complex is slow and requires about 5 min of shaking. Ferbam can also be determined by its decomposition and extraction of the diphenylcarbazone complex [9] of iron into isobutyl methyl ketone. Dithiocarbamate fungicides have also been determined by headspace gas chromatography [10] of the CS_2 evolved under controlled conditions from foodstuffs, atomic absorption spectrometry [11] and

similar methods as given by the Analytical Methods Committee [12]. Here we present a relatively simple, rapid, sensitive and selective method by converting ferbam into iron–1,10-phenanthroline and adsorption on microcrystalline naphthalene in the presence of tetraphenylborate.

2. Experimental

2.1. Reagents

2.1.1. Ferbam solution

All reagents were of analytical-reagent grade. Ferbam was prepared by the reported method [13] and its purity was checked by elemental analysis. The iron content was checked by decomposing it with concentrated nitric acid and determining the iron by EDTA titration using Variamine Blue B as indicator [14]. A stock solution of ferbam (0.1%) was prepared by dissolving 100 mg in 100 ml of acetonitrile.

2.1.2. 1,10-Phenanthroline (phen) solution (1.0%)

Prepared by dissolving 1.0 g of phen in 100 ml of distilled water with warming.

2.1.3. Hydroxylamine hydrochloride (5%)

Prepared by dissolving 5 g in 100 ml of distilled water.

2.1.4. Sodium tetraphenylborate solution

A 2% solution in water was prepared.

2.1.5. Naphthalene solution

A 20% solution in acetone was prepared.

2.1.6. Buffer solution

Acetate buffer was prepared by dissolving 68 g of sodium acetate trihydrate in 400 ml of distilled water, adjusting the pH to 4.25 by adding 25–30 ml of glacial acetic acid and diluting to 500 ml.

2.1.7. Stock solutions for the study of interferences

Stock solutions of different salts were prepared by dissolving them in water. Disodium ethylenebis(dithiocarbamate) (nabam), zinc dimethyldithiocarbamate (ziram), zinc ethylenebis(dithiocarbamate) (zineb), managanese ethylenebis(dithiocarbamate) (maneb) and tetramethylthiuram disulphide (thiram) were obtained from Wilson Laboratories (Bombay, India). Sodium monomethyldithiocarbamate (vapam), sodium dimethyldithicarbamate (dibam), sodium *N*-methylanilinecarbodithioate and potassium morpholinecarbodithoate [15] and xanthates [16] (ethyl, isopropyl and butyl) used in the interference study were prepared in the laboratory by reacting amine/alcohol, carbon disulphide and sodium/potassium hydroxide at a low temperature (below 4°C) using an ice-salt mixture. The solids (except dibam, which is a liquid) were separated by filtration, washed with diethyl ether and recrystallized. Solutions of dithiocarbamates were prepared by dissolution in distilled water or, for the more insoluble preparations, in organic solvents: ziram and thiram in acetonitrile (Merck Pure) and zineb and maneb in dimethyl sulphoxide. Synthetic samples were prepared by mixing the solutions of the constituents to give the required composition.

2.2. Equipment

The spectral measurements were made on a Bausch and Lomb Spectronic 20 spectrophotometer and an Elico pH meter was used for the pH measurements.

2.3. General procedure for determination of ferbam

To a known volume of solution ($\leqslant 3$ ml) containing 22.4–372.9 μg of ferbam taken in a 100 ml Erlenmeyer flask were added 1.0 ml of phen, 1.5 ml of hydroxylamine hydrochloride, 1.5 ml of acetate buffer (pH 4.25) and 1.0 ml of sodium tetraphenylborate, and the volume was made up to 40 ml with distilled water. This solution was mixed and allowed to stand for 5 min, following which 1.0 ml of naphthalene solution was added and shaken vigorously for 1 min. The naphthalene containing the complex was separated by filtration, air dried in the folds of the filter-paper, dissolved in dimethylformamide (DMF) and diluted to 10 ml with DMF. A preliminary study

	150	148.6	2.4	140.0	2.4

[a] Average of ten experiments.

confirmed that the adsorption was complete in one step. Therefore, the absorbance of the DMF solution was measured at 515 nm against a reagent blank prepared under similar conditions.

2.4. Formulation analysis

The method was applied to the determination of ferbam in different commerical samples: Fermacarb containing 75% ferbam, Ferbam 75% WP and Ferbam 85% WP. The formulated products were dissolved directly in acetonitrile, filtered and analysed by the general procedure. Table 1 shows the results of the determinations. The results obtained by the present method were compared with those obtained by the method of Rangaswamy et al. [7].

2.5. Determination of ferbam in crops

A known amount of ferbam in acetonitrile was mixed with 5 g of grain (rice or wheat) and shaken mechanically with 10 ml of chloroform for 5 min. The mixtures were filtered and the residue in the funnels were washed with three 5 ml portions of chloroform. The extracts were evaporated to 2.0 ml on a water-bath and the remaining solvent was removed by blowing a current of dry air at room temperature. The residues were dissolved in acetonitrile and the ferbam content was determined by the general procedure. Untreated samples were taken as a reference. The results of the determinations are given in Table 2.

2.6. Determination of ferbam in synthetic samples

Ferbam was deterimined by the general procedure in synthetic samples prepared by mixing solutions of the constituents. The results are given in Table 3.

3. Results and discussion

The absorption spectra of the iron–phen–TPB complex collected on microcrystalline naphthalene was recorded against the reagent blank prepared under similar conditions. The complex shows maximum absorbance at 515 nm. The absorbances of the reagent and reagent blank were

negligible at this wavelength. The reaction conditions were examined for 150 μg of ferbam. The optimum pH for the determination of ferbam (Fig. 1) was 2.0–6.5, and pH 4.25 was selected. It was observed that 1.0 ml of 1,10-phenanthroline, 1.5 ml of hydroxylamine hydrochloride and 1.0 ml of sodium tetraphenylborate were sufficient for the determination of ferbam. Adsorption on naphthalene was quantitative when 0.5 ml of 20% naphthalene solution was used with shaking for 30 s. However, for better results, 1.0 ml of naphthalene solution was used and the solution was

shaken vigorously for 1 min. The effect of the aqueous phase on the absorbance was studied by varying the aqueous phase volume between 40 and 2500 ml and applying the general procedure. It was observed that the absorbance remained constant up to 2000 ml but then decreased with increase in the aqueous phase volume. Hence 40 ml of the aqueous phase was maintained.

The method was repeated for the determination for ferbam in the filtrate and negligible absorbance was observed, indicating complete adsorption in the first step.

3.1. Beer's law and sensitivity

The calibration graph for ferbam under the optimum conditions was linear over the concentration range 22.4–372.9 μg of ferbam in dimethylformamide. Ten replicate determinations on sample solutions containing 150 μg of ferbam gave a relative standard deviation of 0.84%. The molar absorptivity was calculated to be 1.2×10^4 l mol^{-1} cm^{-1} at 515 nm.

3.2. Composition of the complex

The Job, mole ratio and logarithmic methods indicated the adsorption of a 1:3:2 (Fe:phen:TPB) complex under these conditions (Fig. 2).

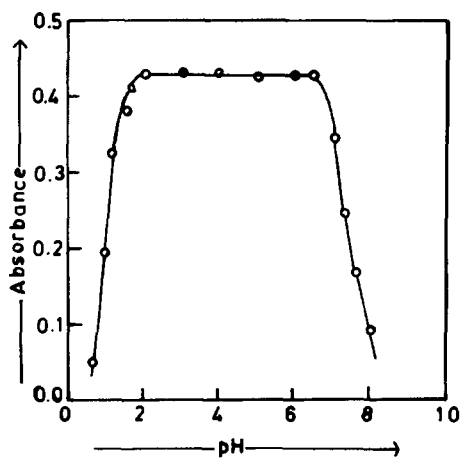

Fig. 1. Effect of pH. Ferbam, 150 μg; wavelength, 515 nm; 1% 1,10-phenanthroline, 1.0 ml; 2% sodium tetraphenylborate, 1.0 ml; 20% naphthalene, 1.0 ml; shaking time, 1 min; reference, reagent blank.

3.3. Interferences

The procedure was applied to the determination of 150 μg of ferbam in the presence of diverse ions. The following foreign ions (mol l^{-1}) did not interfere in the determination of ferbam: bromide

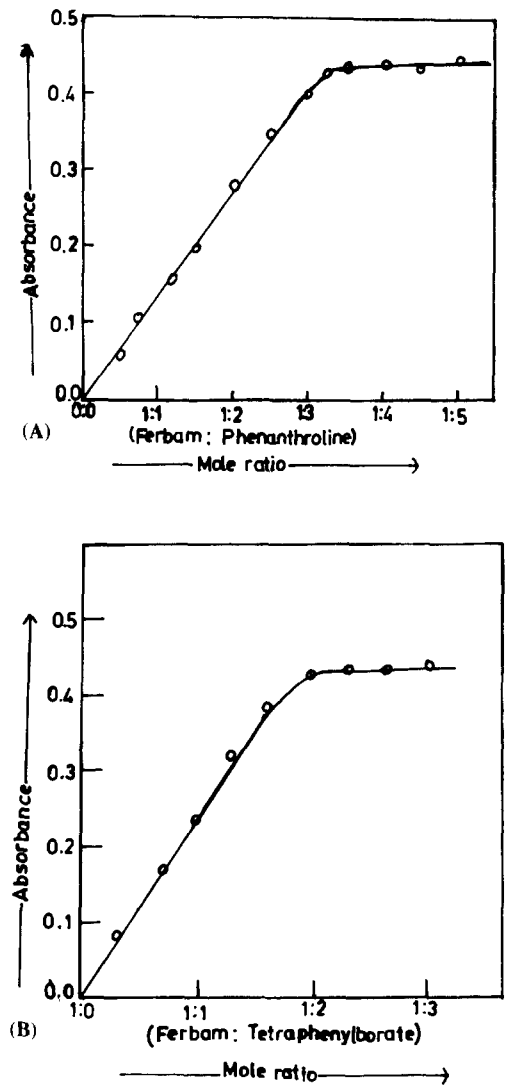

Fig. 2(a). Mole ratio method (comparison with respect to 1,10-phenanththroline). Ferbam, 0.36×10^{-4} M; tetraphenylborate, 0.72×10^{-4} M pH, 4.25; other conditions as in Fig. 1. (b) Mole ratio method (composition with respect to tetraphenylborate). Ferbam 0.36×10^{-4} M; 1,10-phenanthroline, 1.08×10^{-4} M; pH, 4.25; other conditions as in Fig. 1.

Table 4
Comparison of molar absorptivity with other methods

Molar absorptivity (l mol^{-1} cm^{-1})	Method	Comment	Reference
1.33×10^4	Molybdenum	Requires acidic medium (4 N H_2SO_4) and a shaking time of 5 min	[6]
1.46×10^4	Selenite	Not selective for ferbam	[8]
5.3×10^4	Diphenylcarbazone	Interference due to maneb, ziram, zineb, etc., can only be avoided by using masking agents	[9]
1.2×10^4	1,10-Phenanthroline	Highly selective for ferbam	This work

(0.31), chloride (0.71), sulphate (0.26), perchlorate (0.25), acetate (0.42), iodide (0.20), nitrate (0.40), oxalate (0.42) orthophosphate (0.13), citrate (0.13×10^{-2}) and EDTA (0.2×10^{-3}). Of the metal ions examined, Pb^{II} (0.36×10^{-4}) Zn^{II} (0.15×10^{-4}) Cu^{II} (0.57×10^{-4}) Bi^{III} (0.53×10^{-4}) and Cd^{II} (0.49×10^{-4} mol l^{-1}) could be tolerated. Fe^{II} and Fe^{III}, if present along with ferbam, interfere, but this interference can be avoided by pre-extraction of ferbam into chloroform, where Fe^{II} and Fe^{III} remain in the aqueous phase and ferbam can be determined by the general procedure after evaporation of the chloroform to dryness. Of the dithiocarbamates and xanthates examined vapam (0.39×10^{-3}), dibam (0.34×10^{-3}), thiram (0.2×10^{-3}), nabam (0.18×10^{-3}), zineb (0.18×10^{-3}), maneb (0.19×10^{-3}), potassium morpholinecarbodithioate (0.25×10^{-3}), sodium *N*-methylanilinecarbodithioate (0.24×10^{-3}), butyl xanthate (0.35×10^{-3}), isopropyl xanthate (0.32×10^{-3}) and butyl xanthate (0.3×10^{-3}), each tested upto the concentration given in the parentheses (mol l^{-1}), did not interfere in the determination of 150 μg of ferbam in 10 ml of final solution, because they do not undergo complex formation with 1,10-phenanthroline under these conditions.

4. Conclusion

Ferbam, if present with nabam, ziram, zineb, maneb, vapam, sodium dimethyldithiocarbamate, sodium diethyldithiocarbamate and potassium morpholinecarbodithioate, can be determined safely and without any interference by the proposed method. This is not possible with other published methods. The present method is more sensitive than the CS_2 evolution methods, as described by Cullen [17], Chmiel [18] and others, where a minimum 20 μg of CS_2 evolved equivalent to 36.46 μg of ferbam can be determined. It is more sensitive than the direct methods reported by Rangaswamy et al. [7] (0.8 μg ml^{-1}), Verma et al [19] (0.6 μg ml^{-1}), Rao and co-workers (1.0 μg ml^{-1} [8] and 0.8 μg ml^{-1} [9]). With the present method it is possible to determine 0.56 μg ml^{-1} of ferbam, equivalent to 0.31 μg ml^{-1} of evolved CS_2. A comparison of molar absorptivity with some earlier methods is given in Table 4. The wide applicability, simplicity and selectivity of this method makes is preferable to others.

Received 13 December 1995; revised 24 June 1996; accepted 26 June 1996

Abstract

The determination of traces of Zn, Pb and Cu in rum samples by anodic stripping voltammetry without previous treatment or addition of a supporting electrolyte, using a hanging mercury drop electrode, is described. The choice of an appropriate stripping voltammetric method and deposition potential minimizes the influence of the organic content and ensures good reproductibility of the measurements. The reliability of the method was tested by comparing the results with those given by absorption spectrometry, the differences being about 10%. The method allows heavy metal ions to be determined in the $\mu g\ l^{-1}$ concentration range.

Keywords: Anodic stripping voltammetry; Copper; Lead; Rum; Zinc

1. Introduction

Rum is an alcoholic distillate from fermented sugar cane molasses, having an alcoholic content of about 40% (v/v) and can be consumed pure or matured. It is a widely consumed alcoholic beverage and the control of its heavy metal content is fundamental both from a toxicological point of view and with regard to its acceptance as an alcoholic beverage.

The application of voltammetric techniques, such as polarography and stripping analysis, for heavy metal determinaiton in distilled beverages has only occasionally been reported [1–7], despite their high precision and sensitivity. The procedures requires a previous treatment of the sample for the elimination of organic species, which can be adsorbed on the working electrode surface and suppress the reduction waves. Despite these phenomena, it has been demonstrated that the direct determination of heavy metals in alcoholic beverages, such as Brazilian sugar cane spirits [8], tar and ginger cognacs [9], is possible.

This paper reports the determination of traces of heavy metals in rum samples, pure and oak cask matured, by anodic stripping voltammetry (ASV) with a hanging mercury drop electrode without previous treatment and in the absence of

PII S0039-9140(96)02030-9

a supporting electrolyte. The results were compared with those obtained by atomic absorption spectrometry (AAS).

2. Experimental

2.1. Apparatus and reagents

The instrument used for the ASV analysis was an IBM-PC interfaced instrument consisting of a BASIC program [10], a converter interface and a Metrohm Model E506 polarograph coupled with Metrohm Model 663VA stand. The polarographic cell contained a working electrode (Metrohm Model 6.1246.020 multi-mode electrode), a carbon rod (Metrohm model 6.123.345) as auxiliary electrode and an $Ag/AgCl/KCl_{sat}$ reference electrode.

The AAS measurements were carried out in an atomic absorption/flame emission spectrophotometer (Shimadzu Model AA-680), equipped with an air–acetylene burner of 10 cm slot burner head and metal cathode-hollow lamps (Zn, Pb and Cu). The optimum instrumental conditions for each elements were fixed automatically by the equipment [11].

Triply distilled mercury and stock standard solutions (500 mg L^{-1} each for Zn, Pb and Cu) were prepared by dissolving the metal in nitric acid and diluting as required. The water used was distilled and deionized.

2.2. Analytical procedure

Each mixture and series of standard solutions was analysed by ASV and the peak current was plotted as a function of the metal content. Three measurements were carried out for each sample and the statistical treatment of the data was performed according to Miller and Miller [12,13].

The AAS measurements were carried out by introducing the samples directly into the flame and the absorbances were obtained after a prespray time of 3 s and an integration time of 5 s. The absorbance values were plotted as a function of the standard concentration added. Triplicate measurements were carried out and the data were treated as earlier.

3. Results and discussion

The ASV analysis is subject to the influence of surface-active agents, such as organic species, which can adsorb strongly on the electrode surface, affecting either the metal depostion or the stripping process [14]. This problem is generally circumvented by subjecting the sample to a previous treatment to eliminate the organic species, which can result in losses of analytes and contamination. However, depending on the conductivity of the sample, the analysis can be carried out without such treatment, even in the presence of organic substances, where a suitable deposition potential allows the metallic ions to be deposited on the electrode surface, avoiding the adsorption–desorption phenomena caused by the surface-active species present in the sample [15].

Despite the complex composition of rum, owing to the different organic compounds present in the raw materials (e.g. organic acids, phenolic compounds, esters and higher alcohols), a deposition potential of about −1.3 V vs. Ag/AgCl, allows the metallic ions to be deposited on the electrode surface, minimizing the adsorption of the surface-active species present in the samples.

In order to elucidate the influence of the organic content on the stripping response, different anodic stripping methods were tested, viz. linear-sweep, differential-pulse and square-wave modes. Fig. 1 shows that the voltammograms obtained with the linear-sweep mode gave better resolution of the Zn, Pb and Cu waves than the square-wave and differential-pulse modes, in agreement with results for Brazilian sugar cane spirits [8]. Despite their high sensitivity, high-frequency voltammetric techniques, such as differential-pulse and square-wave methods, are more sensitive to small changes in the rate of the electrode reaction and give rise to organic adsorption–desorption peaks, obscuring or not permitting a good resolution of the metal stripping peaks [15]. On the other hand, the lower sensitivity of linear-sweep voltammetry permitted a good resolution of the metal stripping waves, mainly for Cu. As the Zn, Pb and Cu contents are of the same order of magnitude, the determinations of these ions were performed simultaneously, which was not possible for the

Brazilian sugar cane spirits because its higher copper content (approximately 1 mg l^{-1}) and lower lead content (approximately 10 μg l^{-1}).

The best operating conditions obtained for the determination of traces of Zn, Pb and Cu in rum samples by linear-sweep ASV were Hg drop size 0.52 mm^2, deposition potential −1.3 V vs. $Ag/AgCl_{sat}$, deposition time 600 s, conditioning time 20 s and anodic scan rate 50 mV s^{-1}.

In contrast to Brazilian sugar cane spirits, in rum determinations faster scan rates (50 instead of 5 mV s^{-1}) and larger drop sizes (0.52 instead of 0.25 mm^2) can be used to obtain well defined stripping waves. This difference is due to the presence of different organic species in the beverages that adsorb on the electrode surface, causing distinct interferences on the stripping waves.

Fig. 2 shows the resulting voltammograms obtained after the successive standard additions. The sucessive addition of 25 μL of standard did not cause any significant potential peak shifts or any other alterations to the voltammograms, except for an increase in peak current.

In order to verify the behaviour of different organic matrices, the method was tested with four rum samples of two different types: pure (R1 and R2) and oak-cask matured (R3 and R4). Fig. 3 shows typical linear-sweep stripping voltammograms obtained for the determination of heavy metal ions directly in different samples of rum.

The metal ion contents obtained by ASV and AAS are given in Table 1. As can be seen, the

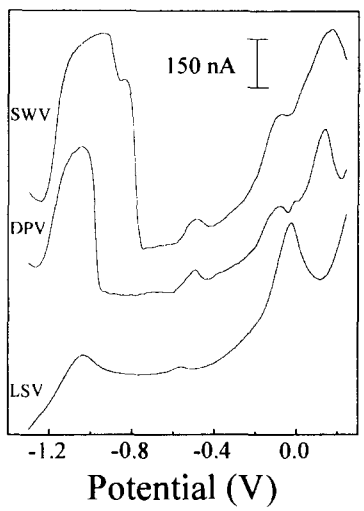

Fig. 1. Voltammograms obtained for rum sample R2 with different anodic stripping techniques: SWV square-wave; DPV, differential-pulse LSV, linear-sweep voltammetry. Operating conditions: SWV, frequency 50 Hz and pulse amplitude +50 mV; DPV, scan rate 10 mV s^{-1} and pulse amplitude +50 mV; LSV, scan rate 50 mV s^{-1}.

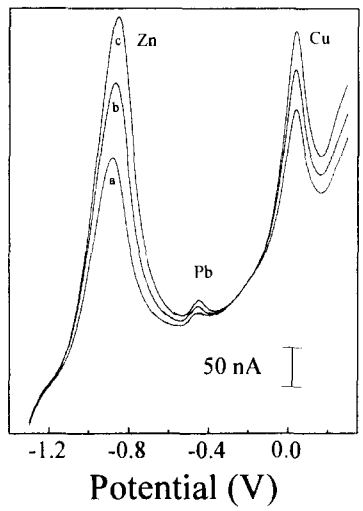

Fig. 2. Linear-sweep anodic stripping voltammograms after successive standard additions for a 5 ml rum sample (R2): (a) 0; (b) 25 and (c) 50 μl. Standard concentrations: Zn, 20; Pb, 20; Cu, 10 mg l^{-1}.

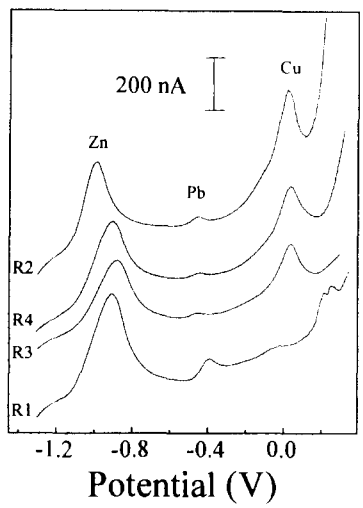

Fig. 3. Linear-sweep anodic stripping voltammograms for different samples of rum (R1 and R2, pure; R3 and R4, oak-cask matured).

Table 1
Concentrations ($\mu g\ l^{-1}$) of Zn, Pb and Cu ions in rum samples

Sample	Element	ASV	AAS
R1	Zn	64 ± 4	70 ± 15
	Pb	65 ± 4	Not detected
	Cu	3 ± 1	Not detected
R2	Zn	44 ± 3	48 ± 11
	Pb	32 ± 3	Not detected
	Cu	14 ± 2	Not detected
R3	Zn	69 ± 3	62 ± 14
	Pb	52 ± 2	Not detected
	Cu	45 ± 3	Not detected
R4	Zn	59 ± 6	68 ± 17
	Pb	23 ± 6	Not detected
	Cu	20 ± 2	Not detected

results obtained by ASV are in agreement with the AAS results with discrepancies of about 10%. The relative errors of the stripping measurements were similar to those for AAS (4%).

The stripping method has the important advantage over AAS of a lower detection limit. For AAS the detection limits are 0.02, 0.2 and 0.09 mg l^{-1} for Zn, Pb and Cu respectively [11], which explains the inability to measure Pb and Cu in all samples. For ASV, these limits can be improved, if necessary, by increasing the deposition times. A further advantage is the simultaneous determination of the three ions, provided that they are present at similar concentrations, and the method is suitable for application in routine analysis.

Development of reference materials for the analysis of acid-extractable metals in sludge

Stuart J. Nagourney, Nicholas J. Tummillo, Jr., John Birri, Kenneth Peist, Jean S. Kane

State of New Jersey Department of Environmental Protection, Laboratories and Quality Assurance, CN 411, Trenton, NJ 08625-0411, USA

Received 3 April 1996; revised 24 June 1996; accepted 25 June 1996

Abstract

The development of reference materials to verify the determination of metals in sludge is described. Effluents from domestic and industrial treatment facilities were dried, size-reduced and homogenized. Multiple aliquots of each material were analyzed in two different government laboratories to determine reference values for the acid-extractable concentrations of more than 15 metals. These acid-extractable concentrations are distinct from total metal values. Different sample preparation and instrumental methods, along with internal quality assurance protocols, were used to confirm the results. The data show good agreement for most metals in the domestic material. Reference values for the leachable concentrations of several toxic metals and major constituents will become part of the Certificate of Analysis for Standard Reference Material (SRM) 2781 issued by the National Institute of Standards and Technology (NIST). Data for the candidate industrial sludge reference material are also presented and discussed.

Keywords: Acid-extractable metals; Atomic absorption spectrometry; Inductively coupled plasma atomic emission spectrometry; Microwave digestion; Reference materials; Sludge

1. Introduction

New Jersey Department of Environmental Protection (NJDEP) regulations require sewage treatment plants to limit the levels of toxic substances in their sludge effluents. Once maximum contaminant levels are established, they become part of the facility's operating permit. When chemical analyses indicate that these permit levels are being exceeded, the NJDEP has statutory authority to assess significant monetary penalties.

Treatment plants process influents from a variety of domestic and industrial sources, resulting in sludges of widely varying physical and chemical composition. Pre- and post-treatment residual management practices also generate sludges of widely varying compositions from liquids containing less than 0.5% suspended solids, through multi-phase samples with several organic and inorganic components, to cakes with solids contents

PII S0039-9140(96)02031-0

exceeding 50%. Metal levels in sludge can vary from near the limit of detection of the analytical method for some analytes to concentrations of more than 25% (m/v) for other analytes. The NJDEP's permit limits for metals are based on the amount of material that leaches during mineral acid digestion. Decisions such as whether permit conditions are being met, how the material is to be disposed of or whether the sludge can be beneficially used all require accurate analytical data. In as much as sludge is a complex and variable matrix, concurrent analyses of reference materials that approximate the sludge matrix and have defined metal levels with defined uncertainties are essential to insuring the quality of the data being generated.

The NJDEP has authorized the use of a specific analytical method, NJDEP 100 [1] for the determination of a limited number of metals in sludge. The method was developed in the early 1980s by a task force comprised of professional from government, acadame and the private sectors. NJDEP 100 treats sludges with less than 10% total residue as wastewaters [2] and sludges with greater than 10% total residue as solid wastes [3]. This dichotomy is consistent with other analytical protocols developed by the United States Environmental Protection Agency (USEPA) for the determination of metals in various types of water by inductively coupled optical plasma emission spectrometry (ICPOES) [4]. While there are reference materials, performance evaluation samples and laboratory certification programs for wastewaters, no quality assurance materials or certification programs are available from the US government for materials such as sludge with higher than 10% solids content. Sludges from domestic sources typically have lower metals and higher nutrient and organic contents than sludges where industrial sources are a significant component of the influent stream. It is therefore desirable to have separate solid sludge reference materials for these two sources.

NIST certifies the chemical composition of a wide variety of Standard Reference Materials (SRMs) to insure the quality of physical and chemical measurements. SRM certified concentrations are generally provided only for total constituent values [5]. Environmental professionals, including soil scientists and geochemists, often require information about labile or extractable concentrations of metals to address issues such as ionic mobility and vegetative uptake. To provide such information, NIST has begun to provide data on the acid-extractable levels of metals in selected new solid sample environmental SRMs [6].

This paper describes a collaborative project among the NJDEP, USEPA, Region II Technical Support Branch and NISTs Standard Reference Materials Program (SRMP) to develop sludge reference materials from domestic and industrial sources having reference values for their acid-extractable metals content as determined by NJDEP Method 100 and USEPA Method 3050, in addition to certified total concentrations.

2. Experimental

2.1. Reference samples

The candiate domestic sludge reference material SRM 2781 was prepared from more than 100 kg of source product from a Denver, CO, publicly owned treatment work (POTW). The source product was shipped to NIST. Contractors freezedried, radiation sterilized and homogenized the material using crushing, blending and sieving procedures similar to those used for preparing United States Geological Survey and NIST geological reference materials [7]. The candidate industrial sludge reference material SRM 2782, based on a similar amount of electroplating waste supplied by AT&T Bell Laboratories, Murray Hill, NJ, was prepared similarly by contractors for NIST.

Samples were placed in 125 ml polyethylene bottles and supplied to the NJDEP Bureau of Radiation and Inorganic Analytical Services and USEPA, Region II, Technical Support Branch laboratories for chemical analysis.

2.2. Experimental reagents

The NJDEP and USEPA loboratories used Class A glassware and calibrated microliter pipettes to perform all volumetric dilutions. ACS reagent grade chemical, doubly distilled water and redistilled acids were employed for sample preparation and digestions. Individual NIST aqueous SRMs were used for spike recovery studies.

2.3. Sample preparation

The NJDEP used open-vessel hot-plate digestion (NJDEP Method 100) for all of their acid digestions. The USEPA used open-vessel hot-plate digestion (USEPA Method 3050) for the industrial product and Method 3050 and closed-vessel microwave digestion techniques (USEPA Method 3051) to prepare the domestic product for measurement. The digestion conditions for the various preparation methods are shown in Table 1.

The USEPA and NJDEP independently analyzed three aliquots from each of five bottles of the industrial material (SRM 2782) and six bottles of the domestic material (SRM 2781) supplied to each laboratory.

Table 1
Sample preparation methods for sludge reference materials

	EPA Method 3050	EPA Method 3051	DEP Method 100
Sample amount	1 g	1 g	1.0 g
Acid(s)	5 ml HNO_3	10 ml HNO_3 2.5 ml 1:1 HCl	5 ml 1:1 HNO_3 6 ml HNO_3
H_2O_2	3 ml at first; up to 10 ml total	None	2 ml at first; up to 11 ml total
Heating time	15 min at Reflux	100% power 70 psi 20 min	Gentle Reflux
Evaporation	To 5 ml	Not Applicable	To 3 ml

2.4. Instrumentation

The NJDEP used a Perkin-Elmer (PE) Model 5000 atomic absorption spectrometer (AAS) for its flame atomic absorption (FAAS) metal measurements. A similar unit, equipped with a PE Model 500 furnace and a PE AS-50 autosampler, was used for the graphite furnace atomic absorption (GFAAS) measurements. The NJDEP also employed a Thermo-Jarrell Ash Model 25 sequential inductively coupled plasma emission spectrometer (ICPOES) for some of its metal determinations. The USEPA used a CEM Model 81D microwave digestion system for some sample preparations and a Thermo Jarrell-Ash Model 61 Simultaneous ICPOES and a PE 5100 GFAAs, equipped with a Model AS-600 furnace and AS-60 autosampler for its metal determinations. The USEPA performed the metals measurements by either simultaneous ICPOES or GFAAS, using one technique per metal. The NJDEP used FAAS, sequential ICPOES and GFAAS and, where possible, employed more than one technique to measure most of the metals.

Calibration standards were prepared by serial dilution from commercial concentrates; working level concentrations were prepared daily. A minimum correlation coefficient of 0.999 for the linear calibration curve was required. Continuing calibration check samples were analyzed at a frequency of one every 10 determinations. Aqueous quality assurance samples, with known analyte values and from sources other than those used for the calibration solutions, were analyzed at a frequency of one every 10 determinations. Blank solutions, consisting of the reagents used in the sample digestion procedure(s), were prepared and analyzed at a frequency of one every 10 samples. All values were corrected for any blank concentration. The instrumental conditions were identical with the manufacturer's nominal values.

3. Results and discussion

The process of providing values for certification places greater demands on the precision and accuracy of the results than do data ob-

tained for such purposes as environmental surveillance or ambient monitoring. The goal of certification or other reference analyses is to obtain the best estimate of the "true value", which is the actual amount of analyte present in the sample. The overall uncertainty of a certified value includes both random error of measurement and any systematic bias which migh be inherent in the method(s) employed to estimate the true value. Issues such as the method of measurement, the complexity and composition of the sample matrix and the concentration and heterogeneity of the analytes all contribute to the overall uncertainty. For example, isotope dilution, when properly applied, is a method believed to be free from systematic errors and capable of achieving random errors of less than 0.2% relative. When uncertainties at the 95% confidence interval of 1–2% are needed, isotope dilution is often the method of choice for certification measurements. Only if the concentration being measured is at or very near regulatory limits are these narrow uncertainty limits necessary for routine measurements as well as for the certified values used to assure their validity. While wider uncertainties are expected when commonly applied analytical methods such as FAAS, GFAAS and IPCOES are used, reference values based on these methods are useful to confirm results of environmental monitoring such as sludge effluents from treatment plants.

It is difficult to select, homogenize, prepare, analyze and certify the chemical composition of natural non-aqueous environmental samples. NIST has historically focused on the certifying of the total metals content in non-aqueous environmental samples, while the USEPA has required the environmental testing community to use analytical methods that report only the amount of metal leachable by acid digestion test protocols. The amount of metal liberated from a non-aqueous environmental sample varies with the matrix and metal; for some elements in some samples, nearly 100% of the total metal content is released by an extraction such as USEPA Method 3050. For other metals in other sample types, the amount found in an acid leach may only be 30–40% of the total content. The significance of developing reference values for leachable metals content in a non-aqueous environmental sample is that these values can be used to quality assure the results submitted for regulatory purposes such as those required by NJDEP and USEPA.

The experience of NIST, NJDEP and USEPA analysts and NIST SRMP program managers is that ranges of 20–30% are typical for the determination of metals in environmental samples when conducted in separate laboratories. These between-laboratory discrepancies indicate the presence of bias but, at concentrations far removed from regulatory thresholds, have little pratical significance. Similarly, quality control sections of many analytical methods require that recoveries of between 80% and 120% for spike additions be demonstrated. This is viewed as indicative of the absence of significant bias caused by matrix interferences in the routine measurement process.

However, when relative between-method or between-laboratory differences exceed the pooled relative standard deviations, analysis of variance (ANOVA) show that these differences are statistically significant. Spike recovery data can then be used to evaluate method bias.

3.1. Domestic sludge reference material SRM 2781

The precision of replicate analyses of domestic sludge material SRM 2781 was calculated from 18 independent measurements (three aliquots from each of the six bottles) performed at both the NJDEP and USEPA laboratories (Table 2). The difference between the NJDEP results obtained by FAAS and ICPOES is less than 10% relative for 9 of 17 elements. When comparing the means of data obtained by the NJDEP and the USEPA laboratories the between-method differences of the means are greater than 10% only for Ba, Be, Ca, K and Pb. Similarly, the differences between the means of leach results for Methods 3050 and 3051 performed at USEPA are less than 10% relative with the single exception of Al, and less than 5% relative for nine elements. There are insufficient collaborative data to make any statements about Mo, P, Si and Ti.

Table 3 compares the mean values of spike recoveries from the two laboratories for the

domestic material SRM 2781. The NJDEP's mean spike recovery by FAAs is 97.3%; by sequential ICPOES the mean is also 97.3%. The USEPA's mean spike recovery using plate digestion and simultaneous ICPOES is 102.8%; using microwave digestion the mean value is 105.3%. Where the spiking level was less than twice the actual leachable concentration, the results were not reported. These data show acceptable agreement between the added and recovered spike values, and provide evidence of minimal bias or matrix interferences in the measurements of the acid-extractable metals in sludge.

ANOVA can be used to evaluate whether two means from different sets of data are statistically significant [8]. F is the ratio of variance between two sets of data to the variance of data within a set of data. By comparing the calculated value of F with statistical tables for known degrees of freedom, the statistical significance of the means can be assessed. P is a measure of the probability that the actual sample data fall within hypothetical frequencies for infinitely large data populations. The ANOVA analysis for the domestic sludge material (Table 4) illustrates the impact of within-method uncertainties on the significance of laboratory bias despite the routine acceptability of the data. For example, as listed in Table 2, the copper data obtained by the NJDEP differ by only 2% between FAAS and ICPOES, whereas the vanadium data differ by 4%. The vanadium method differences are not statistically significant, since the within-method relative standard deviation (RSD) is 4.7% for each of the two methods. However, the smaller copper method differences are significant, based on the 1.3% and 1.4% RSDs. The USEPA Methods 3050 and 3051 difference of 3% for cobalt is not significant be-

[a]Dashes indicate spike amounts less than twice the actual analyte concentration.

cause the within-method RSDs are larger, at 3.7% and 3.4%.

Having considered between-method differences for each laboratory, the data can next be compared between laboratories. For example, no significant differences for leachable Ag, Cu, Fe and V are found between the NJDEP and USEPA when laboratory, rather than method, is used as the classification variable. For Ag and Cu, the uncertainty of the interlaboratory means, based upon all data and expressed as the 95% confidence interval, are less than 4% relative. For Fe and V, the uncertainties are slightly larger, but less than 6%. This overall uncertainty level compares very favorable with many certifications for total concentrations of inorganic environmental SRMs whose certificates are based primarily on NIST laboratory analyses. While significant between-laboratory differences are found for leachable Ca, Mg, Mn and Zn, there is less than a 6% range in the 95% confidence interval of the interlaboratory means.

Reference values for these seven elements in the domestic sludge SRM 2781 have been derived. At less than 6%, the confidence intervals of the interlaboratory means are 4–5 times less than the between-laboratory differences of 20–30% experienced in most laboratories. The levels are also well above regulatory criteria. Reference values are also proposed for the following six other elements measured in this study where the interlaboratory means is greater than 6% but less than 10%: Al, Ba, Cr, Mg, Ni and Pb. Only Ca, Cd and Na have 95% confidence intervals that exceed 10%. These values will be included in an addendum to the SRM certificate. Further work is under way to narrow the range and to work on other elements of environmental interest such as

As, Be, Hg, Mo, P, Se and Ti in order to provide reference values for these elements also.

3.2. Industrial sludge reference material SRM 2782

For the industrial sludge SRM 2782, the situation is different. The complex composition of this material presented a considerable challenge to the preparation and measurement steps of the analytical process. The iron content of the sludge is very high, greater than 25% mass fraction as the element. Factors such as the difficulty of small amounts of mineral acid to dissociate large amounts of Fe-containing inorganic and organo-metallic complexes could affect the extent and reproducibility of extraction of less abundant elements. The high amount of Fe also makes it difficult to select interference-free analytical lines for plasma spectrometry for most analytes. These factors are reflected in the data obtained thus far for the leachable content of the industrial sludge material SRM 2782. As shown in Table 5, 12 of the 18 elements where between-laboratory comparisons are made show differences of greater than 10%, with eight elements exceeding 20%. The differences were less than 5% only for Pb. Because data were available from just two of the three leach protocols, the extensive comparisons applied to the domestic material were not possible. Further study and additional measurements are under way that it is hoped will enable NIST to generate reference values for metals in the industrial sludge. The available data presented here are intended to provide some guidance for laboratories in the quality assurance of their industrial sludge measurements until better defined reference values are established.

4. Conclusions and recommendations

Even with a complex sample matrix such as sludge, reference values can be derived for the leachable concentration of many metals. Both open-vessel hot-plate acid digestion (NJDEP Method 1000 or USEPA Method 3050) or microwave digestion (USEPA Method 3051) are appropriate methods for sample preparation of these materials and may be measured by either FAAS or sequential or simultaneous ICPOES. Matrix interferences, both physical and chemical, must be addressed for the analysis of sludges containing high levels of dissolved matrix components.

Sludge Standard Reference Materials, with reference values for their acid-extractable metals content, can now support the quality assurance of sludge metal measurements. In the future, quality assurance analyses of the domestic sludge SRM should be required of POTW's compliance data submitted to regulatory agencies such as the USEPA and NJDEP. It is also recommended that these materials become part of any future laboratory certification program for sludge effluents.

Acknowledgements

The authors thank the NJDEP's Bureau of Pretreatment and Residuals for providing the funding for this study and Mary Jo Aiello and Tony Pilawski of that Bureau for many helpful discussions. Thomas LaFisca and Gail Suozzo are NJDEP chemist who conducted some of the chemical analyses. Robert Markow of AT&T Bell Laboratories supplied the industrial sludge source material.

Spectrofluorimetric determination of trace amounts of aluminium with 5-bromo-salicylaldehyde salicyloylhydrazone

Chongqiu Jiang*, Bo Tang, Rongying Wang, Jianchong Yen

Department of Chemistry, Shandong Normal University, Jinan, 250014, Shandong, Peiople's Republic of China

Received 8 November 1995; revised 7 June 1996; accepted 25 June 1996

Abstract

The fluorescent reagent 5-bromo-salicylaldehyde salicyloylhydrazone (5-Br-SASH) was synthesized and its ionization constants were established spectrophotometrically. The fluorescent reaction of this reagent with aluminium was studied. Based on this chelation reaction, a spectrofluorimetric method was developed for the determination of aluminium in acetic acid–ammonium acetate buffer solution of pH 5.4. Under these conditions, the Al–5-Br-SASH complex has excitation and emission maxima at 370 and 460 nm, respectively. The linear range of the method is from 0 to 120 ppb and the detection limit is 1.1 ppb of aluminium. The molar ratio of aluminium to the reagent is 1:3. Interferences of other ions were studied. The method was successfully applied to the determination of aluminium in glucose injection and common beverages.

Keywords: Aluminium determination; 5-Bromo-salicylaldehyde salicylolhydrazone; Spectrofluorimetry

1. Introduction

Hydrazones have been widely used in the spectrophotometric determination of metal ions [1] but only in recent years have they found application as fluorescent reagents in this field [2]. Aluminium is a harmful element for humans [3], when it is taken in excess. For this reason, several methods have been developed for the determination of aluminium including the use of hydrazones [4–10].

In this work, 5-bromo-salicylaldehyde salicylolhydrazone (5-Br-SASH) was synthesized and its complex with aluminium was studied. The fluorescence intensity of the complex was increased by the coplanar effect owing to the presence of aromatic rings at both ends of the reagent's structure. Based on this complexation, a spectrofluorimetric method with high sensitivity was developed for the determination of aluminium, without any organic solvents or surfactants. The detection limit is 1.1 ppb of aluminium. The procedure is easily performed and affords good precision and accuracy. This method has been successfully applied to the determination of aluminium in glucose injec-

tion and common drinks by the standard additions method.

2. Experimental

2.1. Apparatus

All fluorescent measurements were carried out on an RF-540 recording spectrofluorimeter (Shimadzu, Kyoto, Japan), equipped with a xenon lamp source and 1.0 cm quartz cells. A UV-265 recording spectrophotometer (Shimadzu) equipped with 1.0 cm quartz cells was used for UV scanning. All pH measurements were made with a pHS-3C digital pH meter (Shanghai Leici Device Works, Shanghai, China) with a combined glass–calomel electrode.

2.2. Solutions

All chemicals used were of analytical or higher grades. Deionized water was used for the preparation of all solutions. A stock standard solution of

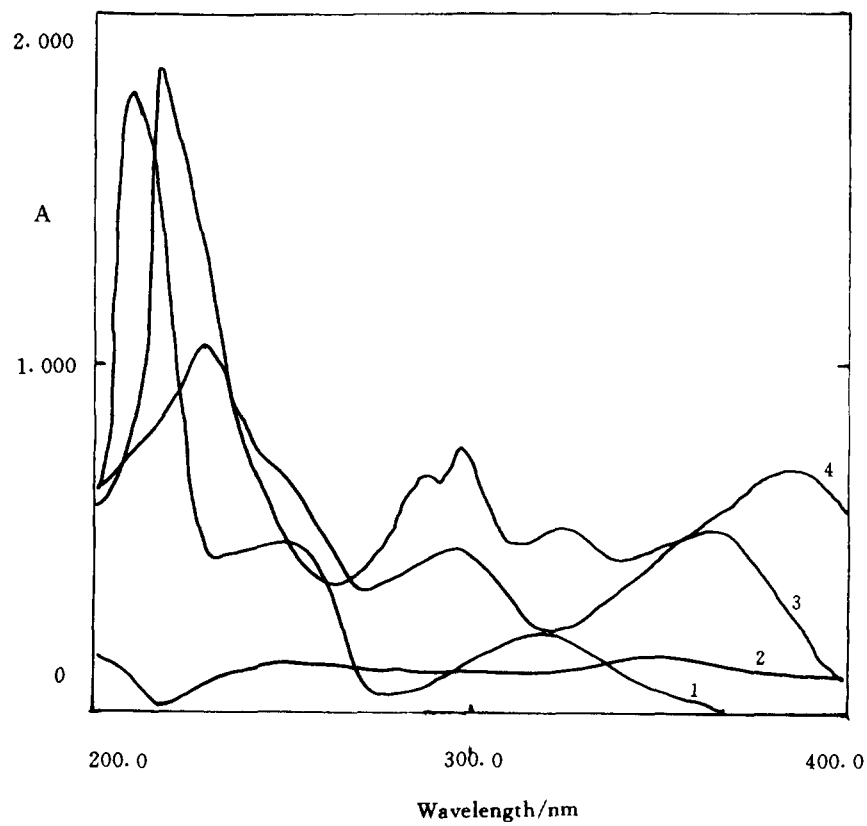

Fig. 1. UV absorption spectra of 5-Br-SASH reagent (4.5×10^{-4} mol dm^{-3}). pH: 1, 0.0; 2, 3.05; 3, 7.60; 4, 12.40.

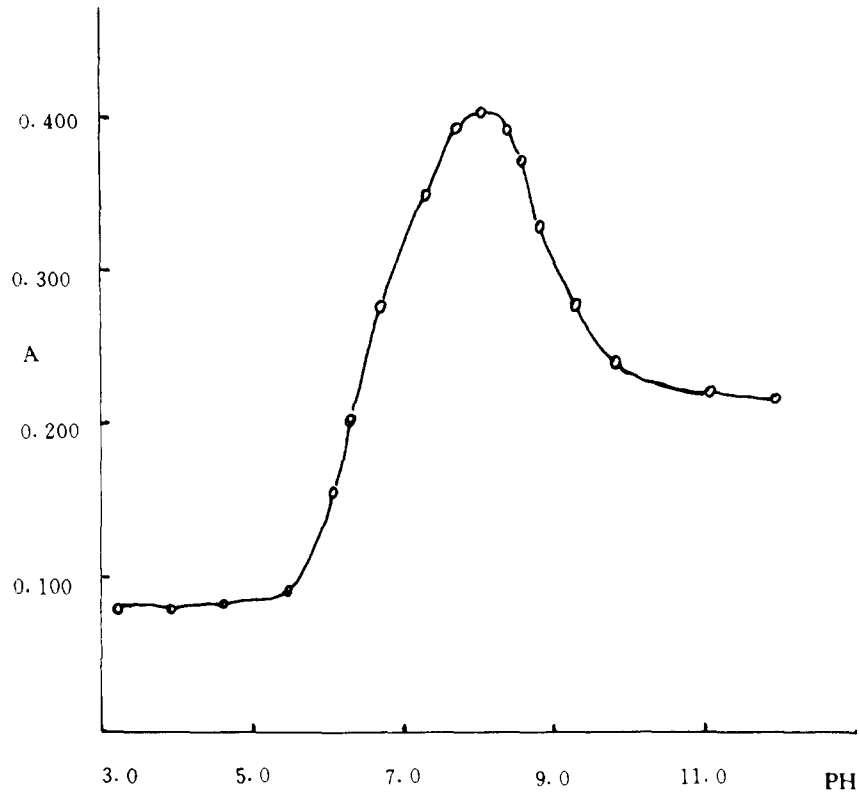

Fig. 2. Effect of pH on UV absorbance of 5-Br-SASH reagent (4.5×10^{-4} mol dm^{-3} at 296.8 nm)

aluminium (100 ppm) was prepared from aluminium metal and working standard solutions were prepared by dilution. An acetic acid–ammonium acetate buffer solution (0.4 mol dm^{-1}, pH 5.4) was used.

5-Br-SASH solution (4.5×10^{-4} mol dm^{-3}) was prepared by dissolving 0.1503 g of the reagent in 1000 ml of absolute ethanol.

2.3. Synthesis and properties of 5-Br-SASH reagent

A 2.3 g amount (about 0.01 mol) of 5- bromo salicylic hydrazide (synthesized by ourselves) was dissolved in 20 ml of 95% ethanol then, a mixed solution of 1.10 ml of salicylaldehyde and 10 ml of 50% ethanol was added slowly and the mixture was refluxed at 85 °C for 2 h. The reaction is shown in Scheme 1. The mixture was then cooled to room temperature, filtered and recrystallized from ethanol. A yellowish white powder was obtained (yield 65%).

The melting point of 5-Br-SASH is 212 °C. Element analysis gave a composition of C 50.60, H 3.31, N 8.34%, which is in good agreement with the theoretical composition of 5-Br-SASH, C 50.17 H 3.26, N 8.36%.

The infrared spectrum of 5-Br-SASH (KBr discs) was obtained and the bands were assigned as follows: OH (3254.9 cm^{-1}), C–OH (1201.4 cm^{-1}), C=O (1639.6 cm^{-1}), C=N (1287.3 cm^{-1}), C–H (3063.7 cm^{-1}) and C=C (1454.2 cm^{-1}) of the aromatic ring.

5-Br-SASH is slightly soluble in water but soluble in ethanol. The ultraviolet spectra of an aqueous solution of the reagent in various pH media show different absorbance maxima (Fig. 1) 5-Br-SASH behaves as a dibasic substance. The

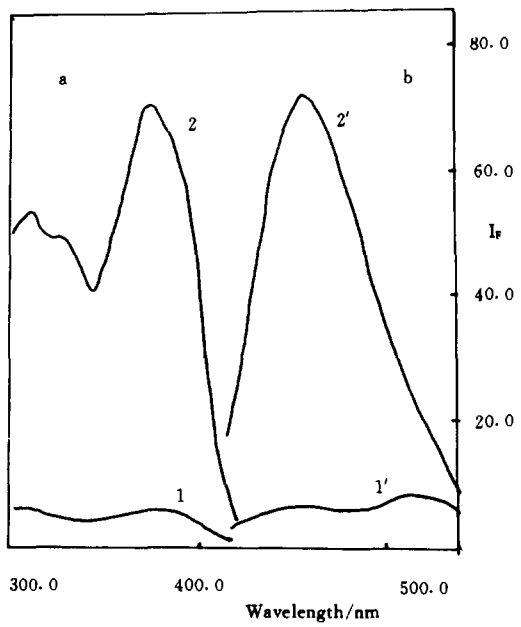

Fig. 3. (a) Excitation and (b) emission spectra of Al–5-Br-SASH complex. 1 and 1′, reagent blank (2.25×10^{-5} mol dm^{-3} 5-Br-SASH, pH 5.4); 2 and 2′, Al–5-Br-SASH complex (100 ppb Al^{3+}, 2.25×10^{-5} mol dm^{-3} 5-Br-SASH, pH 5.4).

ionization constants, determined by a spectrophotometric method [11], are $pK_{a1} = 6.58 \pm 0.06$ and $pK_{a2} = 8.92 \pm 0.08$ (at 0.1 mol dm^{-3} KCl, 25 ± 1 °C) (see Fig 2).

2.4. Fluorimetric determination of aluminium

In a 10 ml colour comparison tube were placed 1.0 ml of 0.5 μg ml^{-1} aluminium solution, 2.0 ml of acetate buffer (pH 5.4) and 0.5 ml of 4.5×10^{-4} mol dm^{-3} 5-Br-SASH and water was then added to the mark. The solution was mixed and equilibrated at room temperature for 30 min, then the fluorescent intensity was measured at 460 nm with excitation at 370 nm againt a reagent blank. A calibration graph was prepared under the same conditions for the determination of aluminium. A suitable amount of masking agent can be added if there are interfering metal ions present in the sample. The standard additions method was used in the determination of aluminium in glucose injection and common drinks.

3. Results and discussion

3.1. Excitation and emission spectra

In order to determine the optimum working wavelength, the spectral characteristics of the Al(III)–5-Br-SASH complex were studied at various pH values. The corrected excitation and emission spectra (Fig. 3) show that the wavelengths of maximum excitation and emission of the Al(III)–5-Br-SASH complex are 370 and 460 nm, respectively. The fluorescence intensity of reagent blank is very low.

3.2. Effect of pH

The pH of the medium had a great effect on the fluorescence intensity of the Al(III)–5-Br-SASH complex. The experimental results show that the optimum pH range for complex formation is between 5.2 and 5.6. Therefore, a pH of 5.4 was fixed with the use of acetate buffer. As the volume of the buffer (from 1.5 to 2.5 ml) had little effect on the fluorescence intensity, 2.0 ml was adopted in subsequent experiments.

3.3. Effect of temperature and time

Heating can be used to speed up the attainment of the maximum fluorescence intensity, but temperature has little effect on the fluorescence intensity of the Al(III)–5-Br-SASH complex. The experimental results show that room temperature can be selected, so the experimental procedure is simple. At room temperature, the fluorescence intensity of the complex reached a maximum after 25 min and remained constant for at least 4 h.

3.4. Effect of amount of 5-Br-SASH

The influence of the amount of 5-Br-SASH on the fluorescence intensities of solution containing 50 ppb of aluminium was studied under the conditions established above. The fluorescence intensity increased with increase in the amount of 5-Br-SASH up to 0.4 ml (4.5×10^{-4} mol dm^{-3}), remained constant between 0.4 and 0.6 ml and decreased slowly thereafter. Thus, 0.5 ml was se-

Mango juice drink	0.418 ± 0.04	3.85	0.39
Average of three determinations			

lected to ensure a sufficient excess of the reagent throughout the experimental work.

3.5. Effect of foreign ions

A systematic study of the interferences of foreign ions in the determination of Al^{3+} (100 ppb) was carried out. For this study, different ions were first added to give a 2000-fold of (m/m) excess over aluminium. If interference occurred, the ratio was gradually reduced until the interference ceased. The criterion for interference was fixed as a ± 5.0% variation of the average fluorescence intensity calculated for the established level of aluminium. The results are shown in Table 1.

3.6. Stoichiometry of the complex

The stoichiometry of the complex was studied under the established experimental conditions by the molar ratio and continuous variation method. [12] The two methods showed that the composition of the complex is 1:3.

3.7. Analytical characteristics

Under the experimental conditions, there is a linear relationship between fluorescence intensity and Al^{3+} concentration in the range 0–120 ppb with a correlation coefficient (r) of 0.9957. The regression equation is $\Delta I_F = 63.69C$ (μg/10 ml) + 5.01. The detection limit as defined by IUPAC [13], was determined to be 1.1 ng ml^{-1} when the K value was taken as 3 and the standard deviation was 0.23 ng ml^{-1} obtained from a series of 11 blank solutions. The relative standard deviation was 1.45% obtained from a series of 11 standards each containing 100 ppb of aluminium.

3.8. Determination of aluminium in glucose injection and common beverages

The developed method was applied to the determination of aluminium in samples of glucose injection and common drinks. The standard additions method [14] was used in all analyses. The results are shown in Table 2 and compared

with those obtained by atomic absoption spectometry (AAS) with a graphite furnace.

To 1.0 ml of sample solution of glucose injection, various amounts of aluminium were added, which were then determined fluormetrically by the procedure established above.

For the assay of aluminium in drinks, 10.0 ml of the drink sample was transferred into a crucible and heated to dryness on an electric furnace and then in a muffle furnace for 30 min at 500–550 °C. The residue was dissolved in 1 mol dm^{-3} NaOH. The solution was filtered and washed with 0.1 mol dm^{-3} NaOH. The solution was then transferred into a 50 ml volumetric flask, adjusted to pH 5.0 with dilute H_2SO_4 and diluted to the mark with water. To 1.0 ml of this sample solution, various amounts of standard aluminium were added, which were then determined fluorimetrically by the method developed above.

The proposed method was compared with other common fluorimetric procedures (Table 3).

Received 11 December 1995; revised 18 June 1996; accepted 24 June 1996

Abstract

Quantitative structure–activity/property relationships (QSAR/QSPR) studies have been exploited extensively in the designs of drugs and pesticides, but few such studies have been applied to the design of colour reagents. In this work, the topological indices A_{x1}–A_{x3} suggested in this laboratory were applied to multivariate analysis in structure–property studies. The topological indices of 43 phosphone bisazo derivatives of chromotropic acid were calculated. The structure–property relationships between colour reagents and their colour reactions with cerium were studied using A_{x1} A_{x3} indices with satisfactory results. The purpose of this work was to establish whether QSAR can be used to predict the contrasts of colour reactions and in the longer term to be a helpful tool in colour reagent design.

Keywords: Cerium; Colour reagents; Quantitative structure–property relationships; Neural networks

1. Introduction

Rare earth elements are used widely in the metallurgical and ceramics industries and in the processing of electronic and luminescent materials because they possess special physico-chemical properties. For these reasons, studies of the rare earth elements have become important in recent years. Many methods have been developed for the determination of rare earth elements, the most important being spectrophotometric methods [1–4]. A key step in a spectrophotometric method is the selection of a sensitive, highly selective colour reagent and suitable analytical conditions. Spectorphotometric methods provides sensitive, precise and accurate measurements and they can offer practical and economical advantages over other methods. Many colour reagents, such as asymmetrical phosphone biaszo derivatives of chromotropic acid, owing to their high sensitivity and selectivity, have been synthesized and used for the determination of the rare earth elements in China.

Correlations between the structures of colour reagents and their reactivities and physico-chemical properties are important because they can be used to guide the design of colour reagents.

The method of topological indexing of molecular structures has also been used widely in recent years in connection with quantitative structure–activity/property relationships (QSAR/QSPR) studies. The topological index is a numerical quantity that is mathematically derived from the structure graph of a molecule. Many topological indices, such as the Wiener index, W [5], Randic index, ID [6], Hosoya index, Z [7], Balaban index, J [8], and the general a_N index [9], have been proposed to convert chemical structures into numerical values. In recent years, topological indices have gained substantial attention in explaining the biological activities and physical and chemical properties of organic compounds. The topological indices A_{x1}–A_{x3} based on the augmented distance matrices, devised recently in our laboratory, have been successfully employed in studies on structure–activity relationships for compounds such as alkanes, alcohols and barbiturates [10]. In this study, we further applied these indices to the structure–property relationships between colour reagent and their colour reactions with cerium.

2. Neural network algorithms

Computational neural networks are mathematical algorithms, inspired by the current understanding of neurophysiology, that try to model the human brain and its ability to learn. A neural network can be considered as a group of interconnected nodes (neurons) forming a net, where every node receives a weighted input signal, through its inputs (synapses), from everynode connected to it. The efficiency of signal transmission depends on the weights, which correspond to the strength of the synapses joining dendrites. The summation of all the input signals to the node (neuron body) excites it and up to a threshold makes the nodes (neurons) produce an output signal through its output (axon). There are three types of neurons contained in a network: input neurons which accept the input data characterizing each observation, output neurons which provide the predicted value, and hidden neurons which neither receive inputs directly nor provide output values directly. The input signals are weighed as they are transmitted to the nodes of the second layer, the hidden layer. The hidden layer neurons process the data and send a signal to the neurons of the output layer. The output layer provides the predicted value, i.e. the contrasts of the colour reactions in this work. A neural network is trained to relate certain inputs (descriptor values) to target outputs (contrasts). To accomplish this, a variety of neural-network learning algorithms can be used. In this study, back-propagation (BP) and quasi-Newton methods were used. We found that the quasi-Newton method required fewer training cycles than did the back-propagaion algorithm.

2.1. The back-propagation training algorithm

A neuron in the hidden or output layer computes the weighted sum of inputs, net $_j$, given by

$$\text{net}_j = \sum w_{ij} X_i + \theta_j \quad (1)$$

where w_{ij} denotes the connection weight between node i in the previous layer and node j in the current layer, X_i is the ith output from the previous layer node i and θ_j is the bias for node j. The output of node j is calculated using a sigmoidal function:

$$\theta_j = 1/(1 + e^{-\text{net}_j}) \quad (2)$$

For training, the BP algorithm computes the sum-squared error between the network output and the target values:

$$E = \sum (t_p - o_p)^2 \quad (3)$$

where p is an index for training observations. The target value for pattern p is t_p and the computed value is o_p.

The connection weights and biases in the network are adjusted sequentially to reduce the error. This adjustment is made from the output layer to the hidden layer using a gradient descent method. In this method, the partial derivative of the error function is used to determine each weight adjustment, ΔW_{ij}. If the neuron of interest is contained in the output layer, then the error is calculated from the difference between the output value and the target value multiplied by the derivative of the

output value. The error terms for the hidden-layer neurons are more complicated because the target values do not exist and must be calculated recursively from neurons already modified. To improve the training time of the BP algorithm and avoid the hazards of oscillating or becoming trapped in local minima, a momentum term is added to the weight adjustment equation. The full details of BP training have been published previously [11,12].

2.2. Quasi-Newton (BFGS) training algorithm

The BFGS (Broyden–Fletcher–Goldfarb–Shanno [13–18]) quasi-Newton optimization method is an alternative way to minimize the sum-squared error of Eq. (3). The advantages of using the BFGS method over the BP method are that specifying progresses much more rapidly.

The basis of all quasi-Newton methods is that in cycle $K+1$ of the optimization, the error E and gradient $\mathbf{g}_{K+1}$ are assumed to be expressible as truncated Taylor series in the parameters $\mathbf{X}$:

$$E(\mathbf{X}_{K+1}) \approx E(\mathbf{X}_K) + \mathbf{g}_K{}^T\Delta\mathbf{X}_K + 1/2\Delta\mathbf{X}_K{}^T\mathbf{H}_K\Delta\mathbf{X}_K \quad (4)$$

$$\mathbf{g}_{K+1} \approx \mathbf{g}_K + \mathbf{H}_K\Delta\mathbf{X}_K \quad (5)$$

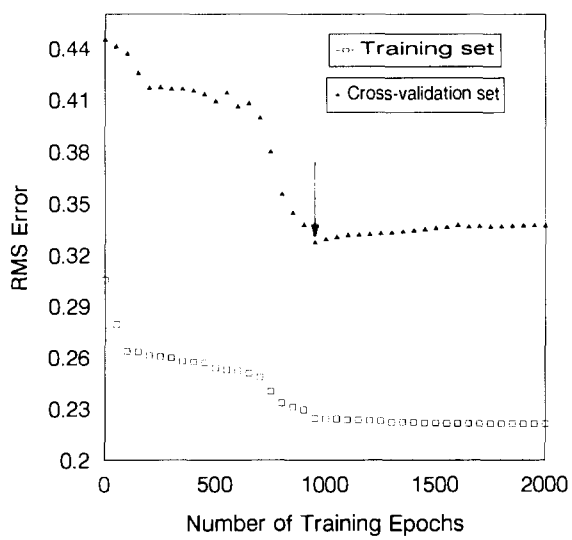

Fig. 1. Plot of RMS error vs. training cycles for quasi-Newton neural network.

where $\Delta\mathbf{X}_K = \mathbf{X}_{K+1} - \mathbf{X}_K$ is the change in the parameters from cycle K to cycle $K+1$ and $\mathbf{H}_K$ is the Hessian matrix of cycle K. The Hessian is defined as the matrix of the second derivatives of the error function with respect to the parameters. For a neural network, the parameters are just the weights and biases.

If $\mathbf{X}_{K+1}$ is to correspond to a minimum of the error functional, then $\mathbf{g}_{K+1} = 0$. This leads to the "Newton" step equation

$$\Delta\mathbf{X}_K = -\mathbf{H}_K{}^{-1}\mathbf{g}_K \quad (6)$$

In the quasi-Newton method, the inverse Hessian matrix $\mathbf{H}_K{}^{-1}$ is never computed directly. Instead, it is iteratively estimated and updated as the optimization proceeds. The initial estimate of the inverse Hesssian matrix $\mathbf{G}$ is obtained from the gradient for two different sets of weights and biases. After computing $\mathbf{g}$ for one set of weights and biases, each weight and bias is changed by a small amount and the gradient is computed a second time. The corresponding change in $\mathbf{g}$ is used to estimate the diagonal elements of $\mathbf{G}$:

$$\mathbf{G}_{ii} \approx \Delta\mathbf{W}_{ij}/\Delta\mathbf{g}_i \quad (7)$$

With an estimate $\mathbf{G}_K$ of the inverse Hessian matrix, the steps in a BFGS cycle are as follows:

(1) Choose search direction d_K according to $\mathbf{d}_K = -\mathbf{G}_k\mathbf{g}_k$.
(2) Determine the scaler α_K to minimize $E(\mathbf{X}_K + \alpha\,\mathbf{d}_K)$.
(3) Let $\mathbf{X}_{K+1} = \mathbf{X}_K + \alpha\,\mathbf{d}_K$.
(4) Compute the gradient $\mathbf{g}_{K+1}$ corresponding to the parameters $\mathbf{X}_{K+1}$.
(5) Update the inverse Hessian matrix $\mathbf{G}$ by the BFGS method.
(6) Iterate.

The line minimization parameter α_K can be estimated using a parabolic fit of the error along $\mathbf{d}_K$:

$$E(\mathbf{X}_K + \alpha\,\mathbf{d}_K) \approx E(\mathbf{X}_K) + \mathbf{a}\alpha + \mathbf{b}\alpha^2 \quad (8)$$

Two pieces of data are needed to find the constants a and b. Satisfactory results are obtained by using (a) the slope, $\partial E/\partial\alpha$ at $\mathbf{X}_K$, which is given by $\mathbf{d}_K{}^T\mathbf{g}_K$, and (b) the error $E(\mathbf{X}_K + \mathbf{S}\mathbf{d}_K)$, where s is an appropriately chosen step size. The minimum of this curve occurs when $\alpha = -a/(2b)$.

When using any iterative training procedure, a criterion must be available for deciding when to stop the iterations. Three approaches were used in this study: (a) the weights were adjusted for each observation until the sum-squared-error reached an acceptable value for the entire training set; (b) the number of training cycles was limited, and training was stopped after a fixed number of training cycles had been reached; and (c) training was stopped when the minimum cross-validation set error was achieved.

3. Topological indices

On the basis of distance matrix indices, A_{x1}–A_{x3} were derived in our laboratory. To facilitate understanding of A_{X1}–A_{x3}, the method is briefly introduced here. The three topological indices are generated from path matrices A, B and C, respectively. These three matrices are defined as follows:

$$A=(a_{ij}),\ a_{ij}=\begin{cases}1 & \text{path}=1\\ 0 & \text{others}\end{cases}\quad (i,j=1,2,\ldots,n)$$

$$B=(b_{ij}),\ b_{ij}=\begin{cases}2 & \text{path}=2\\ 0 & \text{others}\end{cases}\quad (i,j=1,2,\ldots,n)$$

$$C=(c_{ij}),\ c_{ij}=\begin{cases}3 & \text{path}=3\\ 0 & \text{others}\end{cases}\quad (i,j=1,2,\ldots,n)$$

Augmented path matrices G_1–G_3 are obtained by adding two columns into matrices A, B and C, respectively. The elements in the first column of matrices G_1–G_3 are square roots of vertex degrees, and the elements in the second column represent the square roots of the van der Waals radii atoms. From matrices G_1–G_3, we can obtain matrices Z_1–Z_3.

$$Z_1=G_1\cdot G_1';\ Z_2=G_2\cdot G_2';\ Z_3=G_3\cdot G_3'$$

where G_1'–G_3' are the transpose matrices of G_1–G_3. The three new topological indices are defined as

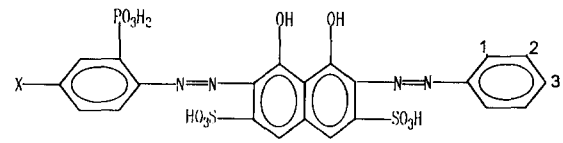
$$A_1=\lambda_{\max 1}2;\quad A_{x2}=\lambda_{\max 2}/2;\quad A_{x3}=\lambda_{\max 3}/3$$

where $\lambda_{\max}$–$\lambda_{\max 3}$ are the largest eigenvalues of matrices Z_1–Z_3.

4. Experimental

The neural network software included two modules: BP and quasi-Newton neural networks, which were written in FORTRAN 77 and installed on a micro VAX II. All computations were performed using multivariate statistic analysis programs (MSAP), which consists of multiple regression analysis, pattern recognition and calculations of topological indices, etc.

The structures of asymmetric phosphone bisazo derivatives of chromotropic acid are shown.



The experimental conditions employed and colour reactions with cerium are listed in Table 1.

5. Results and discussion

5.1. Calculation of descriptors

The topological indices A_{x1}–A_{x3} of 43 asymmetric phosphate bisazo derivatives of chromotropic acid were calculated acid were calculated. A total of three topological indices were generated for each colour reagent.

5.2. Structure-selective factors

From the colour reaction experiment, we know that the different positions of the auxochrome in asymmetric phosphone bisazo derivatives of chromotropic acid play important roles in analytical reactivities. In order to reflect the influences of auxochrome positions on colour reactions, structure-selective factors were introduced:

$$K\begin{cases}0.1\ (ortho)\\ 0.8\ (meta)\\ 0.7\ (para)\end{cases}$$

5.3. Objective feature selection

In order to determine which set of descriptors was important in computed topological indices, multiple stepwise regression analysis was necessary to refine the topological indices in order to reduce the possibility of chance correlations andto weed out the less useful topological indices. A model possessing a high multiple correlation value, a small standard deviation of regression and as few topological indices as possible was considered. Thus, ${}^{1/2}A_{x2}$, ${}^{1/2}A_{x3}$, ${}^{1/2}A_{x3}$ and K were selected and taken as the variables in the subsequent sections.

5.4. Results with neural network

To obtain the best network performance, the optimal network architecture must be chosen. Studies of the network structure include the selection of the number of layers and the number of neurons in each layer. The architecture of the neural network in this paper is as follows.

The number of layers is three, i.e. layer input, hidden and output. The number of input neurons is three (one for each descriptor), and there is one output neuron. The number of neurons used in the hidden layer was determined by trial and error.

The input neurons are ${}^{1/2}A_{x2}$, ${}^{1/2}A_{x3}$ and K. Usually, the value of each neuron is defined between 0 and 1, thus the input data should be scaled within the defined region. Note that if the value of a neuron in input layer is zero, the connections from this neuron are always zero, i.e. the information form that neuron cannot be propagated to the following layers. To avoid this situation, the values were set between 0.05 to 0.95 in this work.

The major difference betweeen BFGS and BP learning algorithms is how the weights are adjusted. In BP, the weight adjustments depend on a predetermined learning rate. BFGS networks, on the other hand, utilize variable-step size when individual weights are being adjusted.

The weights are the adjustable parameters altered by training. During the learning procedure,

[a] Member of cross-validation set.

a series of input patterns with their corresponding expected output values are presented to the network in an iterative adaption of weights when a given input expects a certain output. To obtain the best model, the set of random starting weights needs to be determined. This is a very time-consuming procedure and requires training the network several times using different sets of starting

weights and biases.

The number of output neuron is one. There are two ways to express the output neurons. Typically, single output neuron networks are usually used to predict continuous values. In this manner, the neural network is shown to be analogous to nonlinear regression analysis. Therefore, single output neural networks were used.

The total number of weights including biases should be as few as possible. Finding a compromise between the performance and the training time of the work, the optimum number of neurons in the hidden layer for this application was found to be three. Therefore, a hidden layer with three neurons was used in all the studies, yielding an overall network architecture of 3:3:1.

By stopping the training before the neural network reaches equilibrium one can prevent it from fitting the details of the training data set (to model random noise specific to the calibration data) and to exploit the full potential of all its weights. Another way to avoid overfitting is through the choice of a lean network topology with only a minimum of element. This reduces the number of weights to be trained accordingly. In this experiment, we chose the cross-validation set as a monitor to control the training processing. As long as the cross-validation set results improve, training continues. However, when the cross-validation set ceases to improve, the training must also cease in spite of the continued improvement in the training set results.

Fig. 1 shows a plot of the mean root square error as a function of the number of training epochs for both the training and cross-validation set. The results at epoch 951 is highlighted with an arrow in Fig. 1. The model corresponding to epoch 951 was chosen because the minimum cross-validation set error can be obtained.

The 43 colour reagents were randomly divided into two groups: a training set containing 35 colour reagents and a cross-validation set containing eight (colour reagents labelled footnote a in Table 2). The calculated results by the best model obtained using the network are listed in Table 2, last column. The RMS values for the training set and cross-validation set are 0.2243 and 0.3271, respectively.

6. Conclusion

The topological indices $A_{x1}-A_{x3}$ have been successfully used to model the structure–property relationships between colour reagents and their colour reactions with cerium. The experiments with computational neural networks reveal that the network architecture, initial conditions and the data organization are all important factors affecting the prediction. The performance of the network was enhanced by using the cross-validation set to monitor the training process. After the neural network had been fully trained, it was capable of forming reliable generalizations to predict the contrasts of colour reactions. The study demonstrates convincingly that $A_{x1}-A_{x3}$ are useful topological indices.

Acknowledgments

We thank Professor P.C. Jurs (Department of Chemistry, Pennsylvannia State University, USA) for providing us with the neural network program. The financial support of the National Natural Science Foundation of China is gratefully acknowledged.

Received 25 October 1995; revised 21 June 1996; accepted 24 June 1996

Abstract

Surface-enhanced Raman scattering (SERS) spectrometry of the diuretic drug triamterene is discussed. The SERS-active substrate used is a silver foil etched with nitric acid. The influence of solvent and sample doping method on sensivity, intercept and shape of the calibration graphs is discussed.

Keywords: Diuretic drugs; Human urine; Laser spectroscopy; Organic analysis; Raman spectrometry; Surface-enhanced Raman spectrometry; Triamterene

1. Introduction

The surface-enhanced Raman scattering (SERS) effect has been tested on various forms of metal surfaces. The enhancement depends critically on the creation of surface roughness [1]. One of the earlier types of substrate is the metal electrode [2–4], for which the required surface roughness is achieved by repeated oxidation–reduction cycles. Other procedures are available to produce the required roughness in the substrate, some of them involving elaborate laboratory practices [5,6]. For chemical characterization, colloidal silver [7–10] seems to be the most amenable substrate in terms of production, storage and sample handling, although difficulties with the reproducibility of SERS intensities have been reported [11]. Other procedures producing suitable rough surfaces include matrix-isolated metal clusters [12], iodine-roughened silver in an ultra-high vacuum [13], tunnel junction structures [14], metal-capped polymer posts [15], holographic gratings [16], vacuum depositing calcium fluoride on a glass slide and subsequently evaporating metal on to the surface [17,18], metal-coated filter-paper [19,20] and acid-etched metal foils [21–26].

In most previous work involving SERS-active solid substrates the sample was spotted on the substrate, allowed to dry and then subjected to measurement. The development of easily fabri-

cated SERS-active optical sensors that can be used in solution is important for the application of SERS to in situ analysis. Acid-etched silver foils [26], silver island films [27] and TiO_2-based substrates [28] have been used for this purpose. Simplicity, low cost, speed and availability are outstanding features of these sensing devices.

In the present paper, the use of a silver sensor for surface-enhanced Raman detection of triamterene is discussed. The sensor is used either by applying a sample and drying before Raman examination or by dipping the substrate into the solution where the Raman analysis is performed. The analytical figures of merit, including sensitivity, shape of calibration graphs and limit of detection, are discussed.

2. Experimental

2.1. Instrumentation

The excitation source consisted of an argon ion laser (Coherent Innova 70) tuned at 488 nm, releasing about 40 mW at the sample, and focused with a biconvex glass lens (30 cm focal length). Silver-foil rectangles of 0.8×1 cm^2 were used as the substrate for SERS. Raman scattering was collected at right-angles dispersed with a double spectrometer (Spex Model 1680B) and detected with a thermoelectrically cooled photomultiplier tube (Hamamatsu Model R928) and a photon-counting system (Stanford Research Model SR400). Operation of the photon counter was controlled by an AT personal computer with Stanford Research SR465 software. The acquisition time per spectral element was 1 s and each spectrum consisted of 300 data points. All spectra reported represent single scans and are provided without spectral smoothing (except Figs. 4 and 5, with spectral smoothing of five points (Savitzky–Golay algorithm). The spectrometer resolution was generally set to 14 cm^{-1}. Frequencies were accurate to within 3 cm^{-1} for the bands studied. Spectral data were generated in binary code and converted in ASCII for processing in standard graphics software.

2.2. Chemicals and procedure

All chemicals were of analytical-reagent grade or equivalent and were used without further purification. Chromatography-grade methanol was used throughout. A 0.025 mm thick silver foil was immersed in vigorously stirred nitric acid (diluted 8:20 with water) at room temperature. Stirring was continued for about 2–3 min until the foil showed a milky surface. After etching, the silver foils were thoroughly rinsed with distilled water and dried in air.

2.3. The SERS sensor

The SERS sensor designed and constructed in our laboratory has been described in a previous paper [26]. It basically consisted in a 4 cm long and 2.5 cm wide metallic body with a folding portion in the bottom for holding the substrate. The silver substrate was place in this fold and kept in place with a turning plate to permit easy insertion.

2.4. Sample doping method

The dry-state method appeared to provide good SERS spectra for absorbates that could be dissolved in volatile solvents. In this method, coating of the substrate with the molecules of interest was accomplished by one of two techniques: (1) dipping the silver roughened with HNO_3 in the absorbate solution approximately 30 s, or (2) placing several drops of bulk solution on substrate. As reported earlier [29], the first technique results in a fairly uniform coverage of the absorbate, controlled by the concentration of the absorbate solution. In both cases the substrate was allowed to dry and was then subjected to Raman measurement. In the in situ method, the sensor was immersed in the analyte solution filling a standard 1 cm path glass cuvette for Raman examination.

3. Results and discussion

3.1. Sample doping dependence

The SERS spectrum of a substance results from adsorption of molecular species on a suitably

roughened substrate. For multi-component samples, selective molecular adsorption on substrate surfaces has been demonstrated [30]. The situation may be of relevance when an organic solvent is used. In this case, the organic solvent may behave as a competing adsorbate for the silver surface [31], resulting in large variations in the ability of the analyte to produce a well defined SERS spectrum (SERS activity). This is clearly shown in Fig. 1. Two spectra using the dry-state method corresponding to a triamterene–methanol solution (top) and to methanol (bottom) are plotted. The top spectrum shows the characteristic vibrational modes of triamterene at 1170, 1284, 1349 and 1526 cm^{-1}, superimposed on non-lasing plasma lines of the argon ion laser at 1131, 1168, 1323 and 1506 cm^{-1}; only these bands are observed in the spectrum of methanol. The effect of the substrate in SERS was also studied. For this purpose, the triamterene–methanol spectrum was compared with its equivalent when using colloidal silver as a substrate. Some differences have been observed mainly due to the dynamic behavior of colloids with time. As is known, several bands can change its shape or even appear and disappear, depending on the aggregation state of the colloid. Following the evolution with time of the color change of the colloidal dispersion is a very simple and effective method. Very good long-term stability of the vibrational structure and intensity of the SERS spectrum of triamterene has been observed when an etched silver foil was used.

Fig. 2 shows the SERS spectrum of triamterene in methanol (top) and the SERS and Raman spectra of methanol (center), with the use of in situ method. The conventional Raman spectrum (bottom) shows a broad band centered at 1480 cm^{-1}; this band also appears in the SERS spectrum of methanol when an etched silver foil is inserted directly in solution, superimposed on the scattering spectrum of the substrate (peaks at 1131, 1169 and 1323 cm^{-1}). In the SERS spectrum of triamterene dissolved in methanol (top), the following features can be observed: the peaks corresponding to non-lasing plasma lines of the argon ion laser, the strong band of methanol at 1480 cm^{-1} and the characteristic band of triamterene at 1349 cm^{-1}. It is thus apparent that the solvent plays a major role in the SERS activity of triamterene. The observed effect will depend on the volume of solvent and on the adsorbate concentration.

3.2. Spectral analysis of mixtures

For clinical application, triamterene is used in association with other diuretics. It is known [32] that the relative intensities of SERS features arising from several components in a mixture depend not only on their solution concentration, but also on their relative adsorptivities on the substrate.

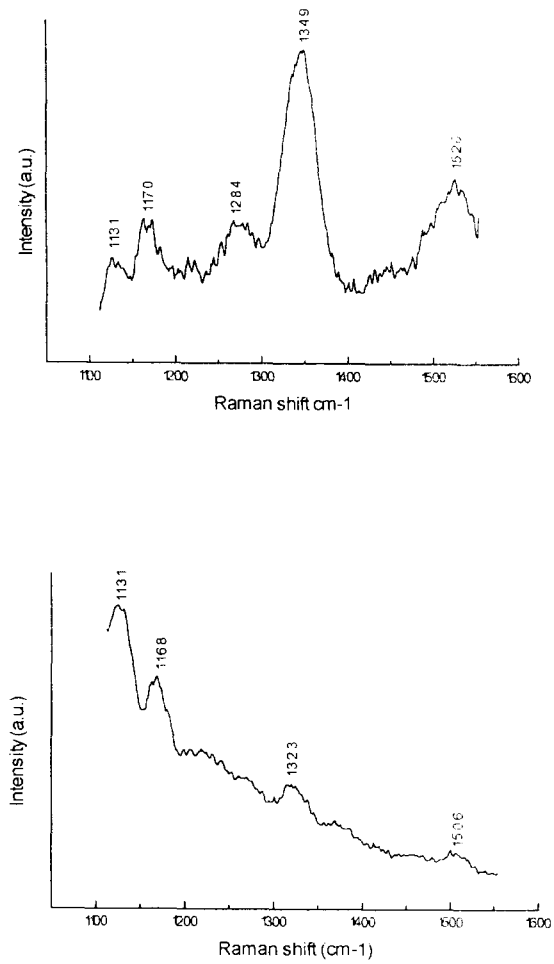

Fig. 1. SERS spectrum of triamterene in methanol (1 μg ml^{-1}) (top) and SERS spectrum of methanol (bottom). Sample volume, 5 μl.

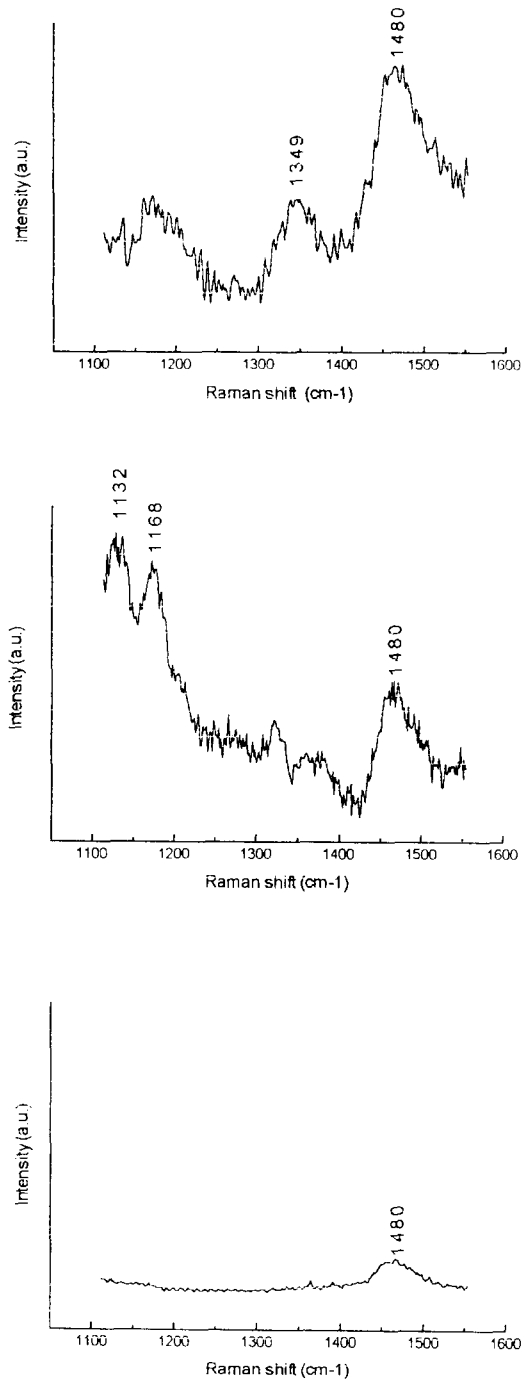

Fig. 2. SERS spectra of a solution of triamterene in methanol (top) and solvent blank (bottom). Drug concentration, 1 μg ml^{-1}. The Raman spectrum of methanol is shown as the lower trace.

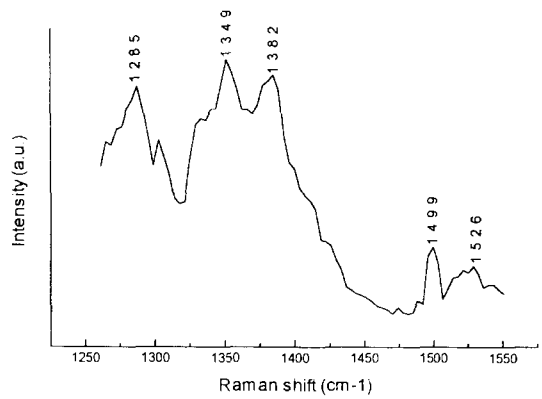

Fig. 3. SERS spectrum of a mixture of triamterene and amiloride in methanol. Triamterene:amiloride concentration ratio, 1:10; drug concentration, 10^{-4} M; sample volume, 5 μl.

When similar concentrations of compounds are used, the extent of the aggregation process depends on the chemical structure of the adsorbed compound [33]. The intensity in the spectrum of a mixture is modulated by the intensity distribution of the species that is most readily adsorbed [34]. For similar adsorptivities, the spectral features of various compounds can be additive and the spectrum of one component can be subtracted from the spectrum of the mixture with the features of the others left intact [34].

In general, diuretics show only moderate SERS activity. Of 10 diuretics investigated on colloidal silver [10], acetazolamide, bendroflumethiazide, ethacrynic acid and xipamide provide no surface-enhanced spectra; pre-aggregation of colloidal dispersions by external agents is required for the large Raman signals of spironolactone, furosemide, bumetamide and chlorthalidone. Amiloride and triamterene show well defined spectra. Amiloride has been extensively studied [35] on colloidal silver using water as solvent and analyzed directly in human urine samples. On colloidal silver, the SERS signal of triamterene show poor reproducibility, probably owing to changes occurring in the colloidal dispersion, easily followed by simple visual observation during data acquisition. Fig. 3 shows the SERS spectrum of a mixture of triamterene and amiloride on a silver substrate prepared by the nitric acid etching method. Triamterene is readily adsorbed, causing displacement of amiloride from the surface when a mixture

[c] In situ method.

of two compounds is examined. The SERS spectrum of triamterene is dominant even at triamterene:amiloride concentration ratios of 1:10, with no noticeable changes in spectral features. Triamterene is recognized by the characteristic band at 1349 cm^{-1} and peaks centered at 1285 and 1527 cm^{-1}, whereas amiloride is recognized by reproducible bands at 1382 and 1499 cm^{-1} [10].

3.3. Effect of solvent

To evaluate possible matrix effects on the SERS response of the analyte, the analytical figures of merit of the SERS method were evaluated using methanol and urine as solvents for the drug. The spectrum recorded by the in situ method is characterized by a strong signal background which may be due to elastic scattering from suspended material or to luminescent components. No characteristic bands are detected. Fig. 4 shows the spectra of filtered urine under several experimental conditions when 10 μl where spotted on an etched silver foil. Fig. 4(a) corresponds to the spectrum obtained with a freshly prepared sample. Non-lasing emission lines of the argon ion laser were present superimposed on the background, but no characteristic vibrational modes of urine with observed. Fig. 4(b) shows the SERS spectrum after 30 min of continuous irradiation with the laser beam. The baseline increases and the spectrum is flat. The SERS spectrum of urine obtained 10 min after sample preparation is shown in Fig. 4(c). Two medium bands at 1236 and 1253 cm^{-1} can be attributed to urine [7]. Fig. 4(d) shows the same sample after exposure for 15 min to laser radiation; the vibrational structure is partially lost, but the band at 1236 cm^{-1} is observed.

Fig. 5 shows the SERS spectrum of urine sample spiked with 5 µl of triamterene on a freshly prepared sensor substrate (bottom) and after 5 min of continuous irradiation (top). The characteristic peaks of the drug at 1349 and 1526 cm^{-1} are clearly distinguishable, while the band at 1284 cm^{-1} is not observed, presumably owing to the strong background of the solvent in this zone. After 15 min, some of the absorbate activity is changed, as manifested by an increase in the ratio of the triamterene activity at 1349 and 1526 cm^{-1}.

The SERS spectrum of urine sample from a patient receiving combined triamterene–furosemide medication (triamterene:furosemide concentration ratio 25:77) is presented in Fig. 6. Triamterene, used clinically to treat hypertension, is normally excreted in urine as 15–25% of the administered dose in the native form [36]. The spectrum was recorded after filtering the urine sample through a 0.45 μm membrane filter. As shown, triamterene can be recognized by the band at 1349 cm^{-1} and the weak peaks at 1283 and 1526 cm^{-1}. The peak at 1466 cm^{-1} may be due to furosemide [10]. The peak at 1254 cm^{-1} corresponds to urine. Although these data have not been compared with those from another analytical technique, they indicate that the detection of triamterene in human urine by SERS on a silver substrate prepared by the nitric acid etching method is feasible.

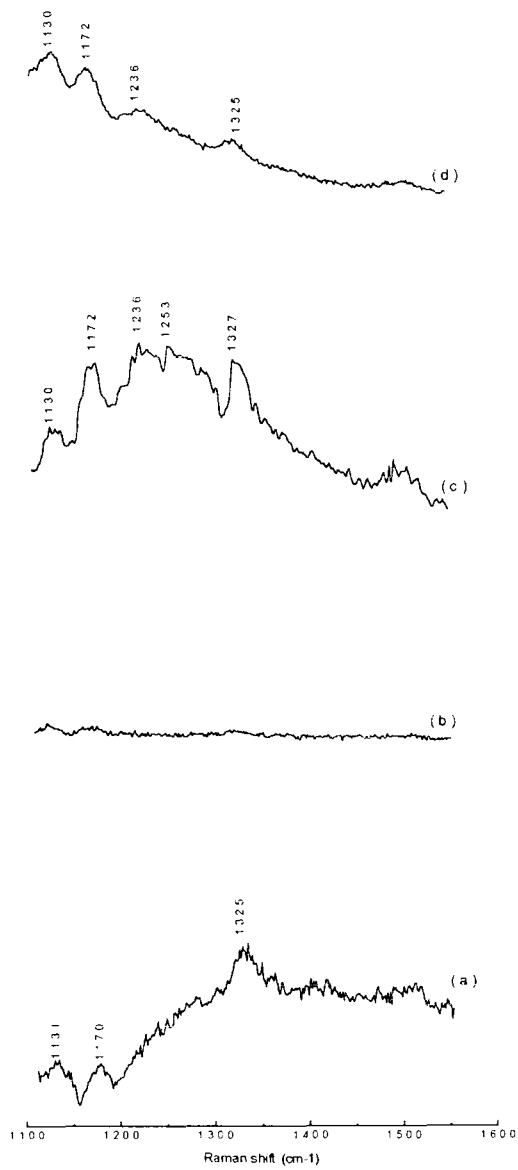

Fig. 4. (a) SERS spectrum of human urine in a freshly prepared substrate; (b) SERS spectrum after 30 min of continuous irradiation; (c) SERS spectrum of urine blank obtained 15 min after spotting; (d) SERS spectrum of the same sample after 15 min of continuous irradiation. Sample volume, 10 μl.

3.4. Quantitative study

The spectral capability of the etched silver foil for the quantitative analysis of human urine spiked with triamterene was evaluated by comparing the results obtained with the silver sensor and colloidal silver. Calculation of the limits of detection (LODs) was described in a previous paper [25]. Table 1 summarizes the analytical figures of merit. Etched silver foils and urine cause a strong signal background [7,27], which results in a higher intercept on the calibration graph. The LODs observed with colloidal silver were worse than those obtained with etched silver foil using the dry method. Large differences between the two methods in the slope of the calibration graph were observed. The slope for the in situ method was similar to that in col-

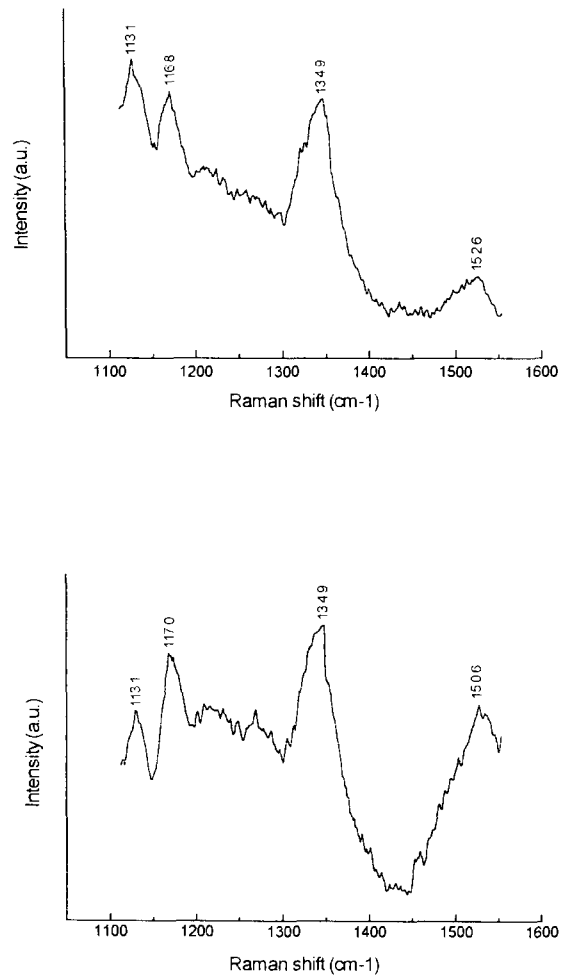

Fig. 5. SERS spectra of triamterene in human urine obtained at 0 min (bottom) and after 15 min of continuous irradiation of the sample (top). Drug concentration, 5 μg ml^{-1}; sample volume, 5 μl.

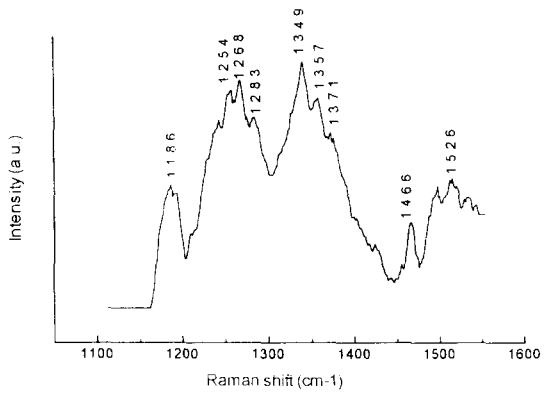

Fig. 6. SERS spectrum of a urine sample from a patient receiving continuous triamterene–furosemide medication (triamterene:furosemide concentration ratio, 25:77).

loidal silver. The correlation coefficients on silver foils are better than 0.99, and the upper limits of the linear part of the calibration graph estimated by polynomial interpolation, are 3.6 and 3.9 μg ml^{-1} for the dry method on a methanol and urine matrix respectively, 7.4 μg ml^{-1} for the in situ method and 14.7 μg ml^{-1} using colloidal silver as substrate. The larger (better) correlation coefficient provided by the etched silver foils may be due to the improved stability under laser irradiation and upon aging of triamterene in this substrate.

4. Conclusions

Strongly enhanced Raman spectra for triamterene can be obtained from acid-roughened silver foils using a simple and inexpensive sensor. The spontaneous adsorption of the analyte from solution directly on the substrate is an advantage of the sensor. The results reported here demonstrate that the detection of triamterene in human urine by SERS on etched silver foils is feasible. Good stability under laser irradiation and upon aging was observed. The main drawback is related to the large background signal observed when urine is used as solvent. The results reported here are important steps in the direction of bringing SERS under experimental control for analytical applications.

Investigation of HfO^+ interference in the determination of platinum in a catalytic converter (cordierite) by inductively coupled plasma mass spectrometry

M. Parent*, H. Vanhoe, L. Moens, R. Dams

Laboratory of Analytical Chemistry, Institute for Nuclear Sciences, Ghent University, Proeftuinstraat 86, B-9000 Ghent, Belgium

Received 1 February 1996; revised 24 May 1996; accepted 24 June 1996

Abstract

The determination of Pt in cordierite is subject to strong interference by spectral overlap from HfO^+ ions with all Pt isotopes. Two mathematical correction methods based on the HfO^+/Hf^+ ratio and a method for the chemical separation of Hf based on adsorption chromatography and isotope dilution were investigated to correct for this interference. Flow infection was used to prevent clogging of the cone orifice. To enhance the sensitivity and thus lower the detection limit, thermospray nebulization was used for sample introduction and the method was compared with pneumatic nebulization. In addition, the memory effects were evaulated for both systems. Analysis of artificial solutions (1 ng Pt ml^{-1}) yielded results within 3% of the true value. The Pt content (ca. 50 ng g^{-1}) of a cordierite sample, previously exposed to exhaust gases, could be determined with precisions of about 10–25% and the results agreed with earlier determinations by other workers.

Keywords: Cordierite; Inductively coupled plasma mass spectrometry; Isotope dilution; Platinum

1. Introduction

Awareness of the importance of Pt determination for environmental purposes began to develop with the introduction of catalytic converters in motorized vehicles. The possible enhancement of Pt levels in the environment, due to automotive emission of Pt, has motivated the development of analytical methods to determine Pt in environmental samples [1–5]. The Pt concentrations in, e.g., street dust, soil and grass near motorways are, however, still extremely low. Owing to its very low detection limits (ca. 10 ng l^{-1}), inductively coupled plasma mass spectrometry (ICP-MS) is a powerful technique for determining Pt at low levels. With more efficient sample introduction systems, the detection limit can be further improved. In many cases, separation and/or preconcentration methods also allow limits of detection to be improved [6,7]. However, ICP-MS suffers from problems of non-spectral and spectral interferences, which have been reviewed by

PII S0039-9140(96)02037-1

Evans and Giglio [8]. Many problems arise when solutions containing high concentrations of dissolved solids have to be analyzed. The latter may cause clogging of the nebulizer and the sampling orifices and salt deposition on the torch or even a salt build-up on the ion lens stack. Some of these effects can be corrected for by the use of an internal standard [9,10]. Hutton and Eaton [11] found that when analyzing a matrix containing refractory compounds such as alumina, plugging of the interface occurred, leading to a signal reduction of about 85% over a period of 1 h.

In this work, Pt was determined in cordierite (Mg–Fe–Al silicate), used as a catalyst body. Since cordierite contains Al, Zr and Ce as some of its major components, analogous problems can be expected. Associated with the Zr, some Hf is also present. It was found that the sample contains about 8 $\mu g\ g^{-1}$ Hf, which can interfere with the determination of Pt owing to spectral overlap from HfO^+ ions with Pt [5]. Although the contribution of the oxide species can to some extent be minimized by instrumental settings [12], addition of N_2 to the plasma [13], or the use of an efficient desolvation system [13–15], it is not possible to reduce the interference sufficiently. Another method consists in using sample introduction techniques with preliminary evaporation of the solvent, such as electrothermal vaporization [16]. Thirdly, mathematical correction can be applied to separate the signal of the analyte from that of the overlapping oxide [17,18].

Besides HfO^+ interference, memory effects and insufficiently low detection limits also hamper analyses for Pt. In previous experiments [19,20], it was shown that the application of thermospray nebulization (TN) for sample introduction in ICP-MS leads to an increase in the sensitivity by a factor of 10 compared with pneumatic nebulization (PN), while the oxide levels are reduced by a factor of 2.5, even for the elements with the highest MO bond strengths [20].

This paper deals with the optimization of the ICP-MS procedure for determining Pt in cordierite. This was achieved by investigating two methods of interference correction for HfO^+, using the HfO^+/Hf^+ ratio experimentally determined either in a separate experiment or deduced from standard addition of Hf to the sample. A third method applied consisted in the complete removal of Hf by chemical separation and included the application of isotope dilution as a calibration method. Furthermore, the use of thermospray nebulization and flow injection to enhance the performance of the sample introduction system is discussed. All three correction procedures were applied with both PN and TN, in combination with and without flow injection. The memory effects were evaluated for PN and TN. The accuracy and precision of the correction and separation procedures were demonstrated by the analysis of cordierite that had been exposed to the exhaust gases of an engine equipped with a catalyst [21].

2. Experimental

2.1 ICP-MS instrumentation

The instrument used for all the experiments was a VG PlasmaQuad PQI ICP mass spectrometer (VG Fisons, Loughborough UK). The interface in the standard configuration was replaced with a "high-performance interface" supplied by VG Fisons. The operating conditions are summarized in Table 1.

2.2. Pneumatic nebulization system

The instrument is equipped with a Meinhard-type (Tr-30-A3) concentric glass nebulizer and a double-pass Scott-type spray chamber with surrounding liquid jacket, the temperature of which was controlled to within 1 °C with a recirculating refrigeration-heating system.

2.3. Thermospray nebulization system

A laboratory-made thermospray system (TN), consisting of an LC pump and a stainless-steel capillary (i.d. 180 μm), was used in combination with a desolvating unit consisting of a conical flask followed by a heated tube and a modified Friedrichs condenser. More details of the system are given elsewhere [20].

Table 1
VG PlasmaQuad operating conditions

Plasma	R.f. power	Forward: 1350 W Reflected: <5 W
Ion sampling	Sampling cone Skimmer cone	Nickel, 1.0 mm orifice Nickel, 0.75 mm orifice
Vacuum	Expansion stage Intermediate stage Analyzer stage	1.8 mbar 1×10^{-4} mbar 3×10^{-6} mbar
Sample introduction	Ar flow rate	Plasma: 13.5 l min^{-1} Auxillary: 1 l min^{-1} Nebulizer: 0.7 l min^{-1}
Pneumatic nebulization	Sample uptake rate	0.9 ml min^{-1} 1.5 ml min^{-1} (flow injection)
	Spray chamber	Scott-type double bypass, water cooled
	Nebulizer	Meinhard concentric type
Thermospray nebulization	Temperature of aerosol Temperature of cooling water Carrier gas flow rate Sample uptake rate	120 °C 1 °C 830 ml min^{-1} 1.33 ml min^{-1}

A flow injection valve (six-port) with a 200 μl sample loop made of PTFE was connected to the sample introduction system. Semi-continuous measurements were performed using a large sample loop of 5 ml.

2.4. Reagents

Working standard solutions were obtained by successive dilution of 1 g l^{-1} commercial AAS standard solutions (Alfa Products, Germany and Janssen Chimica, Belgium) with 0.14 M HNO_3. The standard solution for isotope dilution was obtained by dissolving 1 mg of isotopically enriched (^{194}Pt: 97.41%) Pt sponge (Campro Scientific, The Netherlands) in aqua regia and subsequent dilution to the required concentration. The glassware used for the enriched isotope solution was kept apart from the rest in order to avoid any cross-contamination. HNO_3(14 M), HCl (10 M) (both purified by sub-boiling distillation of reagent-grade acid from quartz apparatus) and Millipore Milli-Q water were used.

The polystyrene–divinylbenzene resin used was Amberlite XAD-4 with 0.3–0.9 mm particle size (Merck, Germany). The resin was purified by Soxhlet extraction with methanol for 8 h, then dried, ground and sieved [7]. The procedure described by Plantz et al. [6] for synthesizing the bis(carboxymethyl) dithiocarbamate (CMDTC) was applied. $SnCl_2$ solution was prepared by dissolving 0.3 g of $SnCl_2$ (Merck) in 0.5 ml of HCl and subsequently diluting to 1 ml with water.

All other reagents were of analytical grade.

2.5. Sample preparation

Two digestion methods for cordierite were applied: open acid digestion and digestion with a high-pressure asher (HPA), (Kürner, Germany). The open acid digestion was performed because it allows larger sample amounts (several grams) to be handled. In this way, the same solution could be used for Pt determination with PN and TN. For HPA the amount of sample is restricted to ca. 100 mg when glassy carbon vessels of 20 ml are used. The open digestion was applied in experi-

ments in which a mathematical correction for the HfO^+ interference was tested. HPA digestion was applied in combination with the elimination of Hf by chemical separation.

2.5.1. Open acid digestion

Approximately 400 mg of cordierite were weighed into a PTFE beaker and heated with 10 ml of HNO_3 at about 70 °C for ca. 3 h then 5 ml of $HClO_4$ were added, the temperature was raised to 120 °C and the solution was heated overnight. Subsequently, 10 ml of HNO_3, 5 ml of HF and 5 ml of HCl were added, followed by heating for 24 h at 70 °C and evaporation to near dryness. The residue was dissolved by adding 5 ml of HNO_3, 5 ml of HCl and 5 ml of HF, followed by heating at 70 °C for 24 h. Finally, the solution was evaporated to near dryness several times to remove HF and HCl (redissolution with HNO_3). HCl was removed because it attacks the capillary material of the thermospray system. A clear solution was obtained. The contents of the vessels were transferred quantitatively into a volumetric flask and diluted to 10 ml with 0.14 M HNO_3. Next, the solutions were divided in two equal portions and further diluted until the concentration was 20 g l^{-1} for PN and 10 g l^{-1} for TN.

2.5.2. HPA digestion

About 100 mg of cordierte were weighted into a glassy carbon vessel. After adding 1 ml of HF, 1 ml of HCl and 200 μl of ^{194}Pt-enriched spike (for isotope dilution), the samples were decomposed in the HPA at the following temperatures and with a maximum pressure of 130 bar: step 1 temperature ramp from 25 to 120 °C (15 min); step 2, 120 min at 220 °C. After cooling, dilute aqua regia was added and the samples were heated to ensure that all Pt was in the quadrivalent state and to remove HF. Further heating and addition of HCl completely removed the excess of HNO_3, which otherwise would disturb the subsequent adsorption chromatography. The contents of the vessels were transferred quantitatively into a glass vessel and 10 M HCl was added to obtain a concentration of 1 M HCl.

2.6. Adsorption chromatorgraphy

Pt was preconcentrated as the bis(carboxymethyl)dithiocarbamate chelate on a microcolumn packed with XAD-4 [7], and eluted in a small volume of EtOH. Adsorption occurred from strong HCl medium after reduction with $SnCl_2$. The EtOH was evaporated and the residue was dissolved in 0.14 M HNO_3, to avoid problems with the determination of Pt in organic solutions by ICP-MS. Accurate measurement of Pt in samples after isolation through enrichment via adsorption chromatography is only possible by isotope dilution mass spectrometry, as this method allows a correction for the variable yields. The Pt spike was added to the sample before digestion. The Pt concentration was calculated using the $^{194}Pt/^{195}Pt$ ratio.

3. Results and discussion

3.1. Spectral interferences due to HfO^+

Since Hf is present in cordierite, the level of oxides formed by Hf was investigated with both Pn and Tn. HfO^+ species interfere with all Pt isotopes (Table 2) and it is therefore necessary to assess the importance of this interference. Hence an Hf standard solution (50 μg l^{-1}) was introduced via both PN and TN. For PN the level of oxides varied between 0.3% and 0.7%, which is in agreement with the results obtained by Vanhaecke et al. [12]. After careful optimization of the measurement of Hf with TN (see below), the level of oxides was reduced to 0.2–0.3%, owing to the better desolvation system used with TN. It was found that when measuring ^{194}Pt, the apparent Pt concentration due to 50 μg l^{-1} Hf can amount to 450 ng l^{-1} with PN and 250 ng l^{-1} with TN (see Table 3). Table 3 also shows that the formation of oxides and hence the apparent Pt concentration vary from day to day, because the operating conditions change [17]. The other isotopes are also to a large extent interfered with by HfO^+ ions.

3.2. *Study of memory effects*

Memory effects, as encountered for Hg [22,23] and Au [24], are insidious in isotope dilution,

Table 2
Abundance of Hf and Pt nuclides and possible interferences on Pt

Hf and other isotopes	Abundance (%)	Possible interference	Pt isotopes	Abundance (%)
^{174}Hf	0.18	$^{174}Hf^{16}O$	^{190}Pt	0.013
^{176}Hf	5.20	$^{176}Hf^{16}O$	^{192}Pt	0.78
^{177}Hf	18.5			
^{178}Hf	27.2	$^{178}Hf^{16}O$ $^{177}Hf^{16}O^{1}H$	^{194}Pt	32.9
^{179}Hf	13.8	$^{179}Hf^{16}O$ $^{178}Hf^{16}O^{1}H$	^{198}Pt	33.8
^{180}Hf	35.1	$^{180}Hf^{16}O$ $^{179}Hf^{16}O^{1}H$	^{196}Pt	25.3
^{180}W	0.13	$^{180}W^{16}O$		
^{196}Hf	0.15	^{196}Hg		
^{182}W	26.3	$^{182}W^{16}O$	^{198}Pt	7.23
^{181}Ta	99.9	$^{181}Ta^{16}O^{1}H$		
^{198}Hg	10.2	^{198}Hg		

where the isotope ratios in subsequently measured solutions may be very different. A flow injection system with a sample loop of 5 ml was used in this study. In Fig. 1(a) the ^{195}Pt signal observed before, during and after the injection of 10 $\mu g\ l^{-1}$ is plotted. PN was used for sample introduction and 0.14 M HNO_3 as the rinsing solution. It can be seen that the background level is not reached even after 5 min of rinsing. Rinsing with H_2O, 1.4 M HNO_3, 0.1 M HCl and 1% aqua regia was also not successful. Rinsing with 0.1 M HCl seemed to lead to an acceptable level of the background signal, but this was only the result of a suppression of the Pt signal. Only rinsing with 0.1% and 1% Triton X-100 for 2–3 min resulted in nearly complete removal of the Pt signal. Apparently Triton effectively wets the walls of the delivery tubing and the spray chamber, thus facilitating the washing out of Pt. Additional experiments showed that all parts of the sample introduction system contribute to the memory effect, as was mentioned by other workers [25–27].

The memory effects for TN, situated in the capillary and especially in the desolvation unit, were larger than for PN, as can be seen in Fig. 1(b). Also in this case rinsing with Triton X-100 decreased the memory effect significantly. When using flow injection (200 μl loop), the Pt signal also drops quickly to the background level [19].

Table 3
Apparent concentration of Pt due to spectral overlap with HfO^+ (50 $\mu g\ l^{-1}$ Hf) with pneumatic (PN) and thermospray (TN) nebulization

Pt isotope	Interfering polyatomic ion	Apparent Pt concentration ($ng\ l^{-1}$)	
		PN	TN
^{194}Pt	^{178}-$Hf^{16}O$ $^{177}Hf^{16}O^{1}H$	260–450	80–250
^{195}Pt	$^{179}Hf^{16}O$ $^{178}Hf^{16}O^{1}H$	150–250	50–120

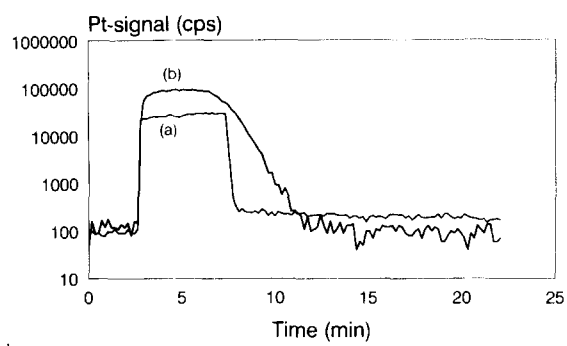

Fig. 1. Memory effect after introduction of 10 $\mu g\ l^{-1}$ Pt with (a) pneumatic nebulization and (b) thermospray nebulization.

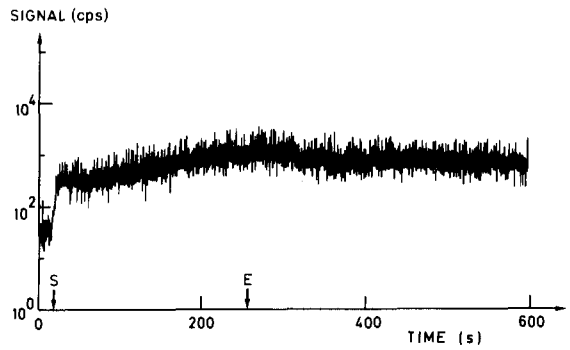

Fig. 2. Memory effect observed for 10 μg l^{-1} Hf with thermospray nebulization.

Persistent memory effects occur on introducing a 10 μg l^{-1} Hf solution in TN (Fig. 2). These are caused by the deposition of HfO_2 near the end of the heated capillary [28]. The Hf oxide precipitation probably occurs because the traces of HF present in the Hf solution evaporate in the heated capillary. The oxide is then only slowly removed by the carrier solution (0.14 M HNO_3). Decreasing the power applied to the capillary or adding HF decreased and prevented, respectively, Hf oxide precipitation (see Fig. 3(a)and (b)). In order to confirm this experiment, solutions of other elements requiring HF for the stability of their solutions (e.g. Zr, Nb, Ta and W) were injected and were found to cause a similar memory effect to Hf.

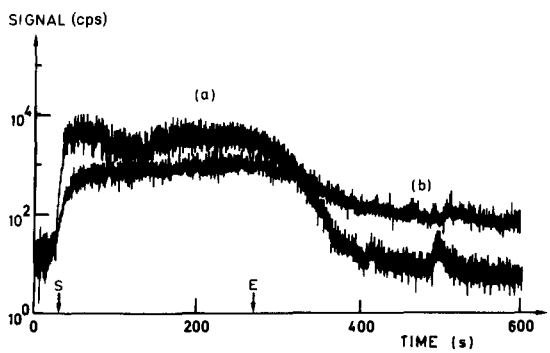

Fig. 3. Memory effect observed for 10 μg l^{-1} Hf with thermospray nebulization (a) in 0.1% HF and (b) with decreased power applied to the capillary.

3.3. *Analysis of artificial solutions*

Fig. 4 shows that with the present instrumental set-up, the maximum ion signal intensities for Hf^+, Pt^+ and HfO^+ were found at the same nebulizer gas flow rate, so that optimisation of the gas flow rate, as applied successfully by Vanhaecke et al. [12] cannot be used to reduce the interference. Therefore, two mathematical correction methods, using the HfO^+/Hf^+ ratio from a standard solution or from standard addition of the interferent Hf to the sample, were applied to correct for the HfO^+ interference. Addition of the interferent has already been applied by Munro et al. [29] for correction for ClO^+ interference and originally suggested by Henshaw et al. [30]. Both mathematical correction methods require a linear dependence of the HfO^+ signal on the Hf concentration. In Fig. 5 the measured HfO^+ signal is plotted versus the Hf concentration. A linear dependence over two orders of magnitude can be observed (correlation coefficient of 0.998). The same conclusions are valid for thermospray nebulization. In all cases the $^{195}Pt^+$ isotope was used for calculations, because the interference is less severe, as can be seen in Table 3. The signals, represented by I, were normalized with the internal standard (TI signal) and were blank subtracted.

3.3.1. *Correction for the HfO^+ interference via the HfO^+/Hf^+ ratio*

The HfO^+/Hf^+ signal ratio was determined in a standard solution containing 50 μg l^{-1} Hf and used to correct for the HfO^+ interference observed in the sample solution. The following equation was used:

$$I_{Pt} = I_{Pt,s} - (I_{Hf,s} R_{HfO}) \quad (1)$$

where I_{Pt} = the corrected Pt signal, $I_{Pt,s}$ = the Pt signal measured for the sample solution, $I_{Hf,s}$ = the signal for Hf in the sample solution and R_{HfO} = the previously determined HfO^+/Hf^+ signal ratio.

3.3.2. *Correction for the HfO^+ interference via standard addition of Hf*

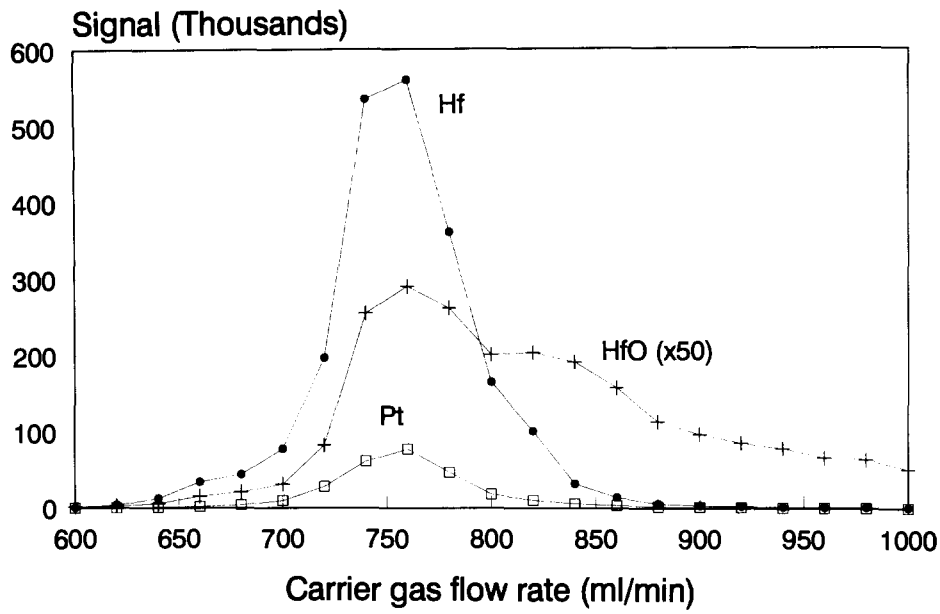

Fig. 4. Dependence of the signal intensity for Pt^+, Hf^+ and HfO^+ on the nebulizer gas flow rate.

A known amount of the Hf interferent was added to the sample solution. From the difference between the intensities of the Pt signals measured in the Hf spiked and unspiked sample solutions, the interference originating from the added amount of Hf can be calculated. After determination of the concentration of Hf in the sample, the contribution of HfO^+ can be subtracted according to the following equation:

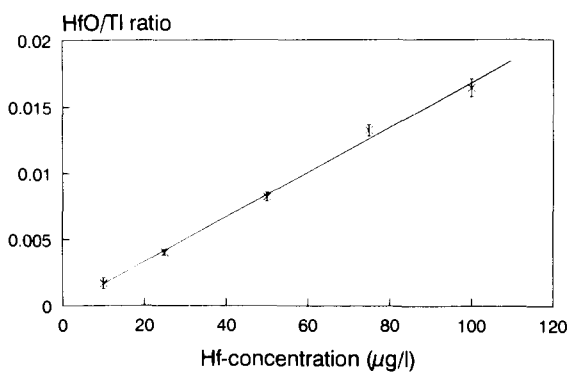

Fig. 5. Dependence of the HfO^+ signal on the Hf concentration.

$$I_{Pt} = I_{Pt,s} - \frac{C_{Hf,s}(I_{Pt+Hf,s} - I_{Pt,s})}{C_{Hf,a}} \quad (2)$$

where $I_{Pt+Hf,s}$ = the signal intensity for Pt in the sample solution to which Hf was added, $C_{Hf,s}$ = the concentration of Hf in the sample solution and $C_{Hf,a}$ = the Hf concentration corresponding to the amount of Hf added to the sample solution.

3.3.3. *Removal of Hf by chemical separation and application of isotope dilution*

Another method consists in separating Hf from the sample solution. Therefore, the adsorption chromatographic procedure proposed by Lee et al. [7] for the enrichment of Pt was applied. Under the conditions described in previous work [31], most of the matrix elements encountered are not strongly retained on the microcolumn used and can thus be separated from Pt. Because the Pt recovery is not quantitative and not reproducible, isotope dilution was used in this work. Isotope dilution requires that the measured isotope ratios reflect the isotopic composition of the sample, mixture or spike and that they are not influenced by interferences. By analyzing a standard solu-

Table 4
Determination of Pt in a solution containing 1 $\mu g\ l^{-1}$ Pt and 50 $\mu g\ l^{-1}$ Hf: comparison of results obtained with pneumatic (PN) and thermospray (TN) nebulization and using differen methods to correct for the HfO^+ interference on Pt^+

Correction method	Pt found ($\mu g\ l^{-1}$)[a]	
	PN	TN
Via the HfO^+/Hf^+ ratio	1.00 ± 0.02	0.99 ± 0.04
Via standard addition of Hf	1.00 ± 0.03	1.03 ± 0.05
Separation of Hf	0.99 ± 0.05	1.01 ± 0.05

[a]With 95% confidence interval.

tion, containing 50 $\mu g\ l^{-1}$ Hf, it could be demonstrated that Hf is separated with 99.9% efficiency.

To check the accuracy of the proposed method, an artificial solution, containing 50 $\mu g\ l^{-1}$ and 1 $\mu g\ l^{-1}$ Pt was analyzed and the results are shown in Table 4. The concentrations of Pt obtained with both sample introduction systems, after correction for HfO^+ or separation of Hf, are in good agreement with the expected concentration. The deviations are smaller than 3% and within the confidence limits.

3.4. Analysis of cordierite

The same correction procedures as used for the artificial solutions were applied. However, the signal intensity ratios for oxide species and their parent atomic ions are known to change with variations in matrix [29,32] composition (e.g. the acids used for destruction), operating conditions [17] and even aging of the interface [29,33]. Corrections based on this ratio can be improved by the use of the oxide ratio of a reference element to correct for possible changes in the HfO^+/Hf^+ ratio [33]. In this work, therefore, an oxide-forming element, with approximately the same MO bond strength as HfO^+, was used [34]; Zr (MO bond strength 182 kcal mol^{-1} [35]), present in cordierite, was chosen. The ZrO^+/Zr^+ ratio measured for the sample solution versus this ratio in the standard solution was used to correct for the matric dependence of the HfO^+/Hf^+ ratio. The scanning region was set from 92 to 207 u. $^{94}Zr^+$ and $^{94}Zr^{16}O^+$ were measured and $^{115}In^+$ was used as an internal standard.

The mathematical correction procedure using the HfO^+/Hf^+ ratio was therefore slightly modified and Eq. (1) was adapted to become

$$I_{Pt} = I_{Pt,s} - \left(I_{Hf,s} R_{HfO} \frac{R_{ZrO,s}}{R_{ZrO}} \right) \quad (3)$$

where $R_{ZrO,s}$ = the ZrO^+/Zr^+ ratio for the sample solution and R_{ZrO} = the ZrO^+/Zr^+ ratio for the standard solution.

The results obtained after correction are summarized in Table 5. It was observed that the MO^+/M^+ oxide ratio varied from sample to sample and was very different from that obtained with a standard solution (a factor of up to 2.5 was observed), as was predicted by other workers [17,29,32,33]. This effect could be readily corrected for by the use of Zr. TN was not used for sample introduction because too severe matrix effects, including obstruction of the interface, occurred.

To alleviate the effects of clogging of the sampling device [36,37], flow injection (FI) was also applied. Because a large mass region (92–207 u)

Table 5
Comparison of results for the determination of Pt in codierite, obtained with pneumatic (PN) and thermospray (TN) nebulization using continuous nebulization (CN) or flow injection (FI), and correction for the HfO^+ interference on $^{195}Pt^+$ with different methods

Correction method	Pt found ($ng\ g^{-1}$)	
	PN	TN
via the HfO^+/Hf^+ ratio:		
CN	32 ± 21	–
FI	47 ± 17	–
Via standard addition of Hf:		
CN	36 ± 20	–
FI	34 ± 9	38 ± 14
Separation of Hf:		
CN	37 ± 3	38 ± 4
FI	37 ± 8	36 ± 3

The values ($\pm$ 95% confidence intervals) are the means for five samples (three in the case of separation of Hf), each measured five times (CN), or four injections (FI). Indicative value: 50 (SD30) ng g^{-1} [21].

had to be scanned when Zr was measured simultaneously with Hf and Pt, the mass region between 120 and 174 u was skipped. Applying FI, no clogging of the cone and skimmer occurred, and the sample could also be measured with TN.

Finally, the Hf was separated by adsorption chromatography and both PN and TN were used in combination with continuous nebulization (CN) and with FI. The results are summarized in Table 5. Most obvious is the much better precision obtained after Hf separation than with mathematical correction procedures. In fact, repeatabilties of about 10% can be achieved. When comparing the two mathematical correction methods, preference should be given to the standard addition of Hf to correct for the interference by HfO^+. FI seems generally to yield slightly more precise results than CN. Our results obtained with different correction and sample introduction methods are in good agreement with each other and suggest a value of 34–38 ng g^{-1}. To evaluate the accuracy, comparison with the indicative value derived by Wegscheider and Zischka [21] from the results of a round robin study on the same sample gives some indication. The large uncertainty, 50 (SD 30)ng g^{-1}, in this indicative value reflects the difficulty of the determination. An alternative comparison can be made with values reported by Alt and Tölg [38] as obtained by ICP-MS (42.0 ng g^{-1}) and by GFAAS (46.1 ng g^{-1}) for the same cordierite sample.

4. Conclusions

The optimization study of the procedure and the determination of Pt in cordierite has shown the superiority of a chemical separation of Hf to avoid the interference of HfO^+. Adsorption chromatography yields a nearly quantitative separation of Hf and Pt losses during the procedure can be corrected for by applying isotope dilution. Mathematical correction yields less precise but for Hf/Pt ratios up to 50 also accurate results, especially when the interference is calculated from an addition of Hf interferent to the sample.

Without chemical separation, flow injection is to be preferred in order to avoid severe matrix effects including clogging of the sampling device and the interface, especially when thermospray nebulization is applied.

Care has to be taken to avoid problems associated with memory effects of Pt and precipitation of Hf oxide. These effects can be avoided by rinsing between solutions with 0.1% Triton X-100 by addition of 0.1% HF to the sample solution.

Acknowledgements

This research was supported by a specialization grant from the Flemish Institute for the Promotion of Scientific and Technological Research in Industry (IWT). Professor, Dr. W. Wegscheider (Austria) kindly provided the cordierite sample.

Collection of trace heavy metals complexed with ammonium pyrrolidinedithiocarbamate on surfactant-coated alumina sorbents

Masataka Hiraide*, Junichi Iwasawa, Hiroshi Kawaguchi

Department of Materials Science and Engineering, Nagoya University Chikusa-ku, Nagoya 464, Japan

Received 7 March 1996; revised 26 June 1996; accepted 27 June 1996

Abstract

Surfactant aggregates were formed on alumina surfaces by mixing 100 mg of sodium dodecyl sulfate (SDS) and 1.5 g of γ-alumina in 50 ml of water. The SDS-coated alumina incorporated water-insoluble metal–ammonium pyrrolidinedithiocarbamate complexes over the pH range 2–8 with a recovery of >97%. The metals were quantitatively desorbed from the alumina with 4 mol l^{-1} nitric acid, leaving >99% of SDS on the solid phase. They were determined by inductively coupled plasma mass spectrometry or graphite furnace atomic absorption spectrometry. The proposed method was successfully applied to the determination of traces of iron, cobalt, nickel, copper, cadmium and lead in high-purity alumina.

Keywords: Alumina analysis; Inductively coupled plasma mass spectrometry; Sorption; Surfactant micelles

1. Introduction

Ionic or nonionic surfactant molecules form self-aggregate structures called "micelles" in aqueous solutions above the critical micelle concentration. The hydrocarbon cores of the micelles give them the ability to solubilize hydrophobic organic compounds. Similar surfactant aggregates can be formed on solid surfaces such as alumina [1,2] and hydrated iron(III) oxide [3]. They are called "hemi-micelles" or "ad-micelles", whose interior tends to incorporate sparingly soluble organic substances (e.g. pentachlorophenol, toluene, *p*-xylene and trichloroethylene).

Previously, we studied the potential and utility of hemi- and ad-micelles in inorganic trace analysis [4,5]. Hydrophobic chelating agents were introduced into the micelles for the separation and preconcentration of trace elements. For example, dithizone was immobilized on alumina by mixing alumina with an ammoniacal dithizone solution (containing sodium dodecyl sulfate (SDS)) and acidifying the mixture. During the acidification, the SDS was sorbed on the alumina to form surfactant aggregates, into which water-insoluble

* Corresponding author. Tel.: 052-789-3579; fax: 052-789-3241; e-mail: hiraide@emerald.numse.nagoya-u.ac.jp

PII S0039-9140(96)02038-3

dithizone was incorporated. The color of the alumina changed from white to gray–blue. The dithizone-coated alumina was useful for the collection of many trace metals from water [6]. One of the problems is the blank value for copper. In the preparation of the sorbent, copper impurities in SDS were complexed with dithizone and introduced into the alumina. Incomplete desorption (e.g. for cobalt) was another problem.

In the present work, surfactant aggregates were first formed on alumina surfaces by coulombic attraction. Then water-insoluble metal–ammonium pyrrolidinedithiocarbamate (APDC) complexes were trapped in the aggregates. This procedure was simple and effective in eliminating the copper blank. Complete desorption of heavy metals was achieved with dilute nitric acid. The SDS-coated alumina functioned well even in solutions containing large amounts of aluminum ions. Compared with conventional liquid–liquid extraction with APDC, the proposed sorption method can directly be combined with inductively coupled plasma mass spectrometry (ICP-MS) or atomic emission spectrometry (ICP-AES), where the organic extractants can cause plasma instability. Sorption and desorption and also the preparation of the sorbent do not require any toxic organic solvents, which is an advantage from the viewpoint of discharge of solvents to the environment. The proposed method was applied to the determination of metals impurities at the sub-μg g^{-1} level in high-purity alumina.

2. Experimental

2.1. Apparatus

A Seiko SPQ-6500 ICP-mass spectrometer was used for the determination of $^{59}Co^{+}$, $^{58}Ni^{+}$, $^{63}Cu^{+}$, $^{114}Cd^{+}$ and $^{208}Pb^{+}$ under the following plasma conditions: r.f. power 1.2 kW; and argon flow rates 16 l min^{-1} for outer, 0.7 l min^{-1} for intermediate and 1.0 l min^{-1} for carrier.

A Seiko I&E SAS-760 atomic absorption spectrometer equipped with an SAS-715 graphite furnace atomizer was employed for the determination of iron. The graphite tube was heated for 20 s to 150°C, held for 15 s and then heated for 5 s to 900°C and held for 10 s; the tube was further heated at a final atomization temperature of 2400°C for 2 s; the clean-up stage was carried out at 2500°C for 3 s. The wavelength and hollow-cathode lamp current were 248.3 nm and 10 mA, respectively.

A Tokyo Rikakikai AU-60C ultrasonic cleaning bath (28 kHz, 210 W) was used for the purification of alumina particles. A Tokyo Rika NTS-1300S shaker was employed for mixing alumina with SDS at a shaking rate of 160 min^{-1}.

All separation procedures were carried out in a Hitachi ECV-843 BY clean bench.

2.2. Reagents

γ-alumina (10–50 μm particles, chromatographic grade, Katayama Chemicals) was ultrasonically washed in 5 mol l^{-1} nitric acid for 3 min and rinsed thoroughly with water three times.

SDS (special grade for water analysis, Nacalai Tesque) was used without further purification.

An APDC solution (0.1%, w/v) was prepared by dissolving APDC (special grade for AAS, Nacalai Tesque) in water.

Metal standard solutions (1 μg ml^{-1} in 0.1 mol l^{-1} nitric acid) were prepared from commercial standard solutions and diluted to appropriate concentrations with 0.1 mol l^{-1} nitric acid immediately before use.

An aluminum solution (10 mg ml^{-1}) was prepared by dissolving aluminum sulfate in 0.1 mol l^{-1} hydrochloric acid and purifying by extraction with APDC and chloroform [7,8]. The aluminum solution was used for the preparation of synthetic samples, which were employed to study the separation of trace metals from large amounts of aluminum ions.

All reagents were of analytical grade (Nacalai Tesque) unless stated otherwise. Water was purified by distillation and ion exchange and then passed through a Millipore Milli-Q purification system.

Table 1
Effect of quantity of SDS on a flow rate of 50 ml of water

SDS sorbed on alumina	(mg)	1	10	25	50	75	100
Flow rate[a]	(ml min^{-1})	7.5	7.9	8.4	9.2	10.0	12.9

[a] Average of three experiments.

2.3. Preparation of SDS-coated alumina column

Purified alumina particles (1.5 g) were suspended in 50 ml of water and mixed with 100 mg of SDS. The suspension was acidified to pH 2 with 4 mol l^{-1} nitric acid and mixed for 15 min with a mechanical shaker. After discarding the supernatant solution, the SDS-coated alumina was transferred to a Millipore filter holder (column size: 15 mm in diameter × 7 mm height). A 0.4 μm Nuclepore polycarbonate membrane filter (25 mm in diameter) was placed on the sintered-glass disk to prevent the disk from clogging with alumina.

2.4. Recommended procedure for the analysis of high-purity alumina

Place a 700 mg alumina sample in a 30 ml Teflon pressure decomposition vessel and add 20 ml of 4 mol l^{-1} sulfuric acid. Heat the vessel at 220°C for 18 h to decompose the sample completely. After cooling the solution to room temperature, dilute it to 100 ml with water. Transfer a one-fifth aliquot into a 30 ml beaker and adjust the pH to 2.5–3 with 15 and 5 mol l^{-1} aqueous ammonia. After adding 1 ml of APDC solution and mixing for 30 s, pass the solution through the SDS-coated alumina column to collect the metal–APDC complexes. Wash the column with 20 ml of 0.005 mol l^{-1} nitric acid. Desorb the desired trace metals with 1 ml of 4 mol l^{-1} nitric acid and collect in a 10 ml volumetric flask. Repeat the desorption twice more with 1 ml each of 4 mol l^{-1} nitric acid and finally wash the column with 5 ml of water. Adjust the combined solution to 10 ml with water and, after dilution (if necessary), determine the desired metals by ICP-MS (for Co, Ni, Cu, Cd and Pb) and GFAAS (for Fe).

Construct the calibration graphs by taking nanogram quantities of heavy metals and 3 ml of 4 mol l^{-1} nitric acid in a 10 ml volumetric flask and diluting to the mark with water.

3. Results and discussion

3.1. Preparation of SDS-coated alumina

The anionic surfactant SDS is effectively sorbed on the positively charged alumina surfaces to form SDS aggregates [1,2,4]. A clear difference in the sorption was observed on two types of alumina particles [6]. γ-Alumina sorbed the surfactant completely over a wide pH range (1–6), whereas α-alumina sorbed very little SDS because of the chemically inert surface. Therefore, γ-alumina is essential for the preparation of surfactant-coated sorbents.

By shaking 1.5 g of γ-alumina and 100 mg of SDS in a slightly acidic solution, tiny alumina particles were coagulated to form bulky flocs. All SDS was sorbed on the alumina, which was confirmed by the toluidine blue titration method [6,9]. After packing the SDS-coated alumina into a column, 50 ml of water were passed to examine the effect of SDS on the flow rate. As shown in Table 1, the flow rate increased with increase in the amount of SDS. The SDS aggregates did not clog the alumina column but improved in the flow rate of samples. This is favorable for practical use.

3.2. Sorption of metal–APDC complexes on SDS-coated alumina

Previously, we prepared SDS-coated alumina sorbents containing dithizone [4,6] and 1-nitroso-2-naphthol [5]. The dithizone–alumina, however, often caused 30–50 ng copper blanks (originating

from 100 mg of SDS). Incomplete desorption (e.g. 40–50% for cobalt) was another problem. The 1-nitroso-2-naphthol-immobilized alumina cannot be used for multi-element separation.

In the present work, SDS aggregates were formed on alumina in the absence of chelating agents, into which water-insoluble metal complexes were incorporated. By this procedure, the blank value of copper was reduced to less than 1 ng. APDC [7,8,10] was selected as the chelating agent because it reacts with many elements to give sparingly soluble complexes in water. Further, it is more stable than sodium diethyldithiocarbamate (DDTC) in acidic solutions.

Incorporation of APDC complexes in SDS aggregates is illustrated in Fig. 1. The formation of hemi- and ad-micelles may depend on the concentration of SDS. The collection of APDC complexes was first examined in a batch experiment. Copper was complexed with APDC and stirred with the SDS-coated alumina for 15 min. By analyzing the supernatant solution, it was found that nearly complete recovery was obtained for the copper.

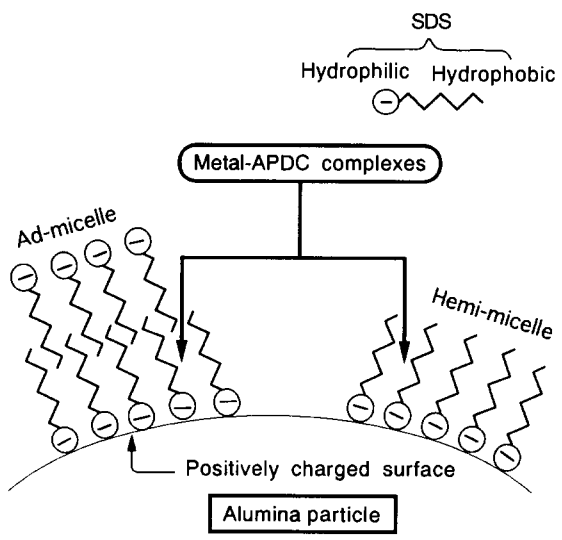

Fig. 1. Incorporation of metal–APDC complexes in surfactant aggregates formed on alumina.

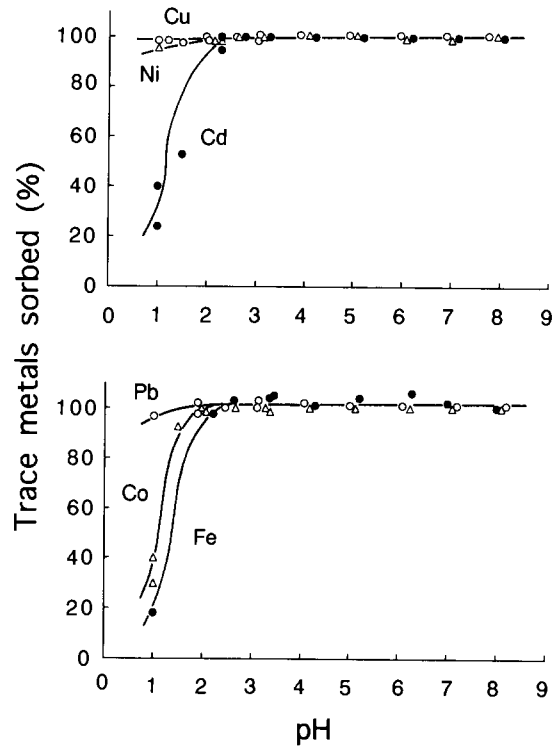

Fig. 2. Sorption of Fe(III), Co(II), Ni(II), Cu(II), Cd(II) and Pb(II) on SDS-coated alumina.

Next, freshly prepared SDS-coated alumina was packed into a column and sorption recoveries were measured for different trace metals. Aqueous sample solutions (20 ml, pH 1) containing trace metals (30 ng ml^{-1} each of Fe, Co, Ni, Cu, Cd

and Pb) were adjusted to different pH values with 1 and 0.1 mol l^{-1} aqueous ammonia. After adding 1 ml of APDC solution and stirring for 30 s, the solution was passed through the SDS-coated alumina column to sorb the APDC complexes. The effluent from the column was acidified to pH 1 and analyzed by ICP-MS to obtain the sorption recovery. However, the ICP-MS determination of iron at the ng ml^{-1} level was difficult because of an overlap of two spectra ($^{56}Fe^{+}$ and $^{40}Ar^{16}O^{+}$). Therefore, iron was determined by GFAAS.

Fig. 2 shows the percentage of trace metals sorbed as a function of the pH of the solution. All trace metals were recovered in >97% yields over a wide pH range (2–8). At basic pH, some metals (e.g. Fe and Cu) may exist as hydroxide colloids, but these species can also be collected on the column.

3.3. Desorption of trace metals from SDS-coated alumina

Trace heavy metals at the 30 ng ml^{-1} level in 20 ml of water were sorbed on the SDS-coated alumina column at pH 2.5–3 and then desorbed with 3 ml of 4 mol l^{-1} nitric acid. As shown in Table 2, more than 93% of the metals were recovered when three portions of 1 ml of nitric acid were used for the desorption. When 3 ml of nitric acid were added at a time, part of the metals still remained on the column.

Compared with conventional liquid–liquid extraction with APDC and chloroform [7,8,10], the proposed sorption method was directly combined with ICP-MS, because the final nitric acid solution was suitable for the plasma.

3.4. Separation of trace metals from aluminum matrix

Because APDC does not react with aluminum ions [7,8,10], the sorption method was applied to the analysis of high-purity alumina. The recovery of trace heavy metals was studied by using synthetic aluminum solutions. Because commercial aluminum sulfate contained appreciable amounts of metal impurities (nominally <30 $\mu g\ g^{-1}$), the reagent was purified by extraction with APDC and chloroform. When APDC solution was added to the aluminum solution, the solution immediately turned brown. Extraction with chloroform was therefore repeated three times.

Aluminum ions precipitated as hydroxide above ca. pH 4, hence the sorption was carried out at pH 2.5–3. Trace metals at the 30 ng ml^{-1} level in 20 ml of aluminum solution (containing 50–150 mg of aluminum) were sorbed, desorbed and determined by the recommended procedure. Table 3 shows that the SDS-coated alumina is useful for quantitative separation from the aluminum matrix. The amount of aluminum accompanying the desired trace metals was 2–3 mg when a sample containing 100 mg of aluminum was treated by the recommended procedure.

Further, a large volume of aluminum solution (200 ml; containing 1.0 g of aluminum and trace metals at the 30 ng ml^{-1} level) was introduced on to the SDS-coated alumina column and desorption and determination were carried out. Nearly complete recoveries were obtained for the trace metals examined.

Because 100 mg of SDS was used for the preparation of the alumina sorbent, the behavior of SDS in the desorption should be checked. The

[b] Not detected.

SDS in the final solution was determined by the toluidine blue method [6,9] and found to be 0.4–0.9 mg. In other words, more than 99% of SDS was still strongly sorbed on the alumina. Therefore, no interference occurred in the determination by ICP-MS and GFAAS.

3.5. Analysis of high-purity alumina

Generally, it is difficult or impossible to determine impurities at sub-$\mu g\ g^{-1}$ levels in alumina. For example, direct analysis by ICP-AES after sample decomposition [11,12] caused a decrease in the signal intensity and an increase in the background. Fusion followed by coprecipitation with zirconium hydroxide [13] resulted in high blanks and an increase in the background in ICP-AES. Extraction with dithizone and APDC [14] required large amounts of ammonium tartrate to mask the hydrolysis of aluminum, which can cause appreciable contamination. Analysis of an alumina suspension by AAS [15] needed accurate background correction and tedious preparation of a standard alumina suspension.

Although ICP-MS offers a highly sensitive multi-element determination technique, the mass analyzer is seriously contaminated if large amounts of matrix element are introduced. Therefore, trace elements should be separated from the aluminum prior to the determination. Table 4 shows the analytical results for two samples of high-purity alumina obtained by the recommended procedure. Trace metals at low $\mu g\ g^{-1}$–$ng\ g^{-1}$ levels were determined with relative standard deviations of $<10\%$. It is interesting that the contents of metals sought in sample No. 1 (99.9%, α-alumina) were almost same as or lower than those in sample No. 2 (99.995%, corundum). For accurate evaluation of the purity of alumina, the determination of other elements (especially boron, sodium, silicon and calcium) may be required. Unfortunately, these elements cannot be determined because they do not react with APDC. However, considering the well established APDC chemistry, we hope that the SDS-coated alumina could easily be employed for the separation and preconcentration of trace heavy metals in a wide range of applications.

Received 21 February 1996; revised 25 June 1996; accepted 26 June 1996

Abstract

A simple and low-cost amperometric sensor for amines has been developed using a cobalt wire electrode working in alkaline solution. The sensor may be used as a detector for high-performance liquid chromatography (HPLC) that avoids the need for derivatization or post-column reaction. Experimental conditions for flow injection analysis (FIA) and HPLC separation, including the applied potential, pH and concentrations of organic modifier and carrier solution, were optimized. A cobalt wire electrode, in the constant potential amperometric mode, gives an excellent response toward amines in ion-exclusion chromatography in unbuffered solution. The sensitivities of the detection and separation of amines on the column are affected by flow rate, the concentration of the mobile phase and the concentration of organic solvent in the mobile phase, whereas the applied potential only affects the sensitivity of the detector. A cobalt electrode is more sensitive than a copper electrode, and comparable in sensitivity to a UV detector for most amines tested. The detection sensitivity is comparable to that obtained with GC methods, but the procedures are far simpler. The detection limits of the order of nanomoles obtained under the chromatographic conditions used offer an alternative for the determination of amines in a variety of matrices, such as in environmental, biomedical and pharmaceutical samples.

Keywords: Amines; Amperometric detection; Cobalt electrodes; Ion-moderated partition chromatography

1. Introduction

The determination of amines by gas chromatography, when effective, is a sensitive technique [1], but derivatization is required for non-volatile amines and the polar nature of amines may cause severe tailing of peaks [2]. In the last decade, several electrochemical approaches have been explored to detect amines after separation by high-performance liquid chromatography (HPLC). HPLC methods for the separation of biogenic amines tend to use reversed-phase sorbents with pre-or post-column derivatization and UV detection. However, this

* Corresponding author.Fax: (61)2-9385-6141.

PII S0039-9140(96)02039-5

procedure adds complexity and may lead to problems associated with side-reactions of the derivatizing compound. HPLC on ion-moderated partition columns with sodium hydroxide as eluent has been reported to separate up to 10 volatile and non-volatile amines [3]. Electrochemical detection has employed polarography, square-wave voltammetry, pulsed amperometry and biosensors. The last method used avocado, mushroom and potato tissue on a Clarke oxygen electrode [4]. However, the most favourable electrochemical detectors for these compounds are limited to carbon-based electrodes [5–7]. Drawbacks of electrochemical detectors are a high overpotential for the oxidation of amines, which leads to poor selectivity, and the use of derivatization procedures or post-column reactions, which also complicates the method [5–7].

Metal or oxidized metal electrodes are preferred to carbon-based electrodes in many respects. They are simpler in construction, robust and have lower oxidation potentials for many redox compounds, and therefore have greater sensitivity and selectivity. As a consequence, there has been extensive exploration of metal/metal oxide electrodes for the constant-potential amperometric detection of organic compunds, including Pt, Au, Cu, Ni, Ag, Pd, Rh, Ir, Fe and W [8–15].

Cobalt, as the phthalocyanine, has also been used as a material for the construction of chemically modified carbon-paste electrodes for many compounds, including amines [16–18]. However, there has been no report on the use of cobalt wire for the constant-potential amperometric detection of these compounds. As metallic wire electrodes respond to complexing agents only in alkaline solution ($pH \gtrsim 6$) [12,19,20,21], our attempts were focused on the use of an alkaline solution as carrier. We report here the performance of cobalt wire as a simple and low-cost amperometric detector for the determination of amines after HPLC separation using an ion-exchange column (Aminex HPX-72-O) with sodium hydroxide as eluent. Its action is compared with that of a copper electrode.

2. Experimental

2.1. Apparatus

The cyclic voltammetric study was performed with a BAS-100B potentiostat equipped with Ag/AgCl (3 M NaCl) reference and platinum wire auxiliary electrodes. An EG&G Princeton Applied Research Polarograph, type 174, was used for constant-potential amperometric detection with a single-line flow injection analysis (FIA) manifold and HPLC systems. The output was recorded and processed by a Macintosh II VX microcomputer.

The flow cell used in both FIA and HPLC detection was made from a Perspex block (5 × 3 × 1 cm) with a 1.2 mm channel allowing the analyte first to contact the working electrode (1 mm diameter wire) along a 1 cm length and then flow away past auxiliary and reference electrodes [22]. The Ag/AgCl reference electrode, prepared by electrolysis at a silver wire electrode in 1.0 M KCl, was coated with 1.0 M KCl in 4% agar gel and was located out of the flowing stream. Each electrode was polished with emery paper and rinsed with deionized water before use. After pretreatment (see below), the potential was kept fixed at the optimum level. Only after a stable baseline current had been obtained in the supporting electrolyte were analytes added and their peak currents determined.

The separation of amines was performed using a Model 510 HPLC pump, U6K injection valve, and Model 484 tunable absorbance detector, all from Waters (Milford, MA, USA) with a resin-based, modified partition column (Aminex HPX-72-0,300 mm × 7.8 mm i.d. × 11 mm o.d.) purchased from Bio-Rad Laboratories (Sydney, Australia).

2.2. Chemicals and solutions

All chemicals were of analytical grade and were used without further purification. Methylamine (me), *n*-propylamine (pro), *n*-butylamine (but), trimethylamine (tma), cysteamine hydrochloride (cys) and benzylamine (ben) were purchased from Sigma Chemical (St. Louis, MO, USA). Stock solutions of the amines 10 mM were prepared in

Milli-Q water and diluted to the required concentrations before use. The solutions were filtered through a Millipore 0.45 μm membrane filter and degassed in an ultrasonic bath prior to use. All water was distilled and passed through a Milli-Q water purification system.

2.3. Procedure

Cyclic voltammetric studies (10 cycles) were performed with a potential scan rate of 50 mV s^{-1}. In the flow injection system, the carrier solution was continuously pumped through the detector cell at a constant flow rate until a stable baseline current was obtained. All experiments were performed at room temperature with sodium hydroxide solution as a carrier. The hydrodynamic voltammograms were obtained in the flow-through cell, point-by-point, allowing for stabilization of the current.

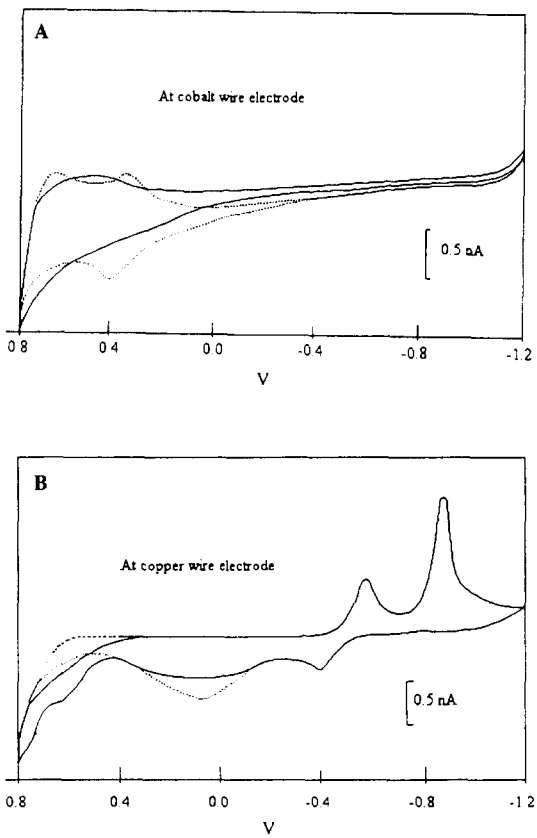

Fig. 1. Cyclic voltammograms at (A) cobalt and (B) copper wire electrodes in 0.1 M NaOH (dotted line) and after addition of 1 mM methylamine (solid line). Sweep rate, 50 mV s^{-1}.

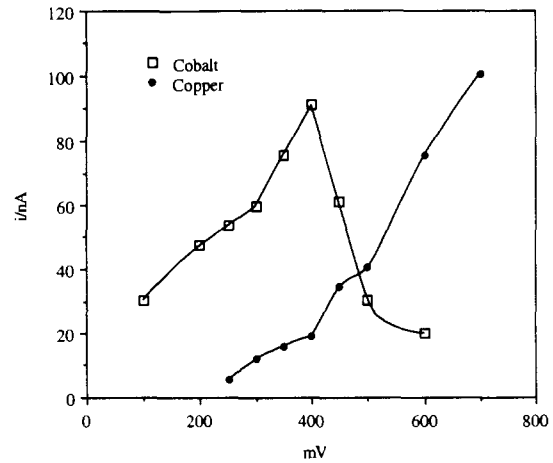

Fig. 2. FIA peak height of 25 nmol (cobalt electrode) and 20 nmol (copper electrode) of methylamine as function of applied potential. Carrier solution, 0.1 M NaOH; flow rate, 0.75 ml min^{-1}.

In HPLC, the effects of eluent concentration, electrode pretreatment, addition of organic solvent and flow rate on the electrode response were investigated by applying each parameter at various levels. The electrochemical detector performance of a cobalt electrode was compared with that of a copper electrode and UV detection. The wavelength used for UV detection recommended by Bio-Rad (210 nm) [23] was chosen with a

sensitivity setting of 0.1 a.u.f.s. (absorbance units full-scale). All experiments were performed at room temperature with 0.075 M sodium hydroxide solution as the mobile phase. The injection volume was 20 μl.

3. Results and discussion

3.1. Principles of electrode response

The effect of amines on the electrochemistry at a cobalt surface is twofold. At more positive potentials at which Co^{III} is formed (> 0.5 V vs. Ag/AgCl, 0.075 M NaOH), a so-called catalytic oxidation may occur, in which the amine is oxidized by Co^{III}, which is regenerated electrochemically [8–11,14–17]. Schematically the reactions are

$$Co^{III} + \text{amine} \rightarrow Co^{II} + \text{amine oxidation products} \quad (1)$$

$$Co^{II} \rightarrow Co^{III} + e \quad (2)$$

The species present at the surface include oxides and hydroxy compounds such as CoO, $Co(OH)_2$ and CoO(OH) [24,25]. Nickel has been shown recently to participate in these types of reaction [9]. The cyclic voltammograms in Fig. 1 demonstrate this effect for both cobalt and copper in the presence of methylamine, above +0.5 V.

In constrast to the above mechanism, amines may absorb at potentials below that at which they are oxidized, blocking the surface and leading to a reduction in the oxidation current of the metal. As an example of this behaviour, Luo et al. [11] reported that the addition of glucose and lactic acid reduced the oxidation current of copper wire electrodes. Hui and Huber [26] also reported that the oxidation current of a nickel electrode was reduced by 100 nA after addition of 1.0 mM glycine at an optimum potential of 0.55 V. Similarly to the published cyclic voltammograms of glucose, lactic acid and glycine at copper electrodes [11,26], our results show that the oxidation currents of cobalt and copper wire in 0.1 M NaOH (dotted lines, Fig. 1), were diminished at low potentials (< +0.5 V) with the addition of 1 mM of methylamine (solid lines, Fig. 1). The broad oxidation peak of cobalt at +0.4 V was significantly reduced when 1.0 mM of methylamine was added. A similar trend was observed at a copper electrode with significant depression at the maximum in the oxidation current (+0.05 V).

There is a difference between the dynamic nature of cyclic voltammetry and constant-potential amperometry. However, a similar trend was obtained at a constant potential, with a decrease in the current as the amines were introduced into the system at a cobalt wire held at +0.4 V, and an increase in current at a copper wire held at +0.7 V. The behaviour is consistent, and we note that for cobalt at +0.4 V the baseline was maintained constant over many hours of operation.

3.2. Selection of working potential

Flow-injection studies were carried out to determine whether cobalt and copper electrodes could be used with ion-exclusion chromatography. Methylamine standards were injected into a single-line FIA system using NaOH as the carrier solution and the FIA conditions were optimized for high sensitivity with acceptable precision. First the current was recorded as a function of the applied potential to determine the working potential giving the highest response. Amounts of 25 nmol (cobalt electrode) and 20 nmol (copper electrode) of methylamine were injected into the flow system at applied potentials between 0.0 and +0.7 V.

The results (Fig. 2) show consistency between FIA and cyclic voltammetry, but the changes in current were greater in the flow system. The greatest reduction in current due to injection of methylamine at a cobalt wire occured at +0.40 V. At a copper electrode the FIA peaks steadily increased with increase in applied potential. They were poorly reproducible and the baseline noise was high, giving poor precision when used to calibrate for amines. Subsequent work was therefore concentrated on the use of a cobalt electrode for practical analysis of amines.

3.3. Electrode pretreatment and position

Stitz and Buchberger [9] reported that the sensitivity of a nickel electrode for the detection of carbohydrates and related compounds is strongly influenced by the pretreatment of the electrode surface. Procedures affecting the amount of oxide on the electrode are likely to affect the sensitivity. In this experiment, after polishing with emery paper and rinsing with dionized water, the electrodes were pretreated with four different procedures as follows: (1) the potential was kept fixed at the optimum working level: (2) the electrodes were cycled initially in the blank solution over the desired potential range (−0.4 to 1.1 V), for 10 cycles; (3) a potential of +2 V was applied for 2 min; (4) a potential of +2 V was applied for 10 min.

Table 1 shows that the highest sensitivity was achieved by applying the optimum potential directly after polishing with emery paper and rinsing with deionized water. The same sensitivity was shown when the electrode was cycled 10 times.

Table 3
Effect of organic modifier (methanol) on the peak height and the resolution of the most overlapping peaks (methylamine and propylamine)

Methanol concentration (%)	Peak height (nA)		Resolution
	Methylamine	Propylamine	
0	15	3.4	0.73
0.25	7.4	2.0	1.07
0.5	4.6	1.3	1.08

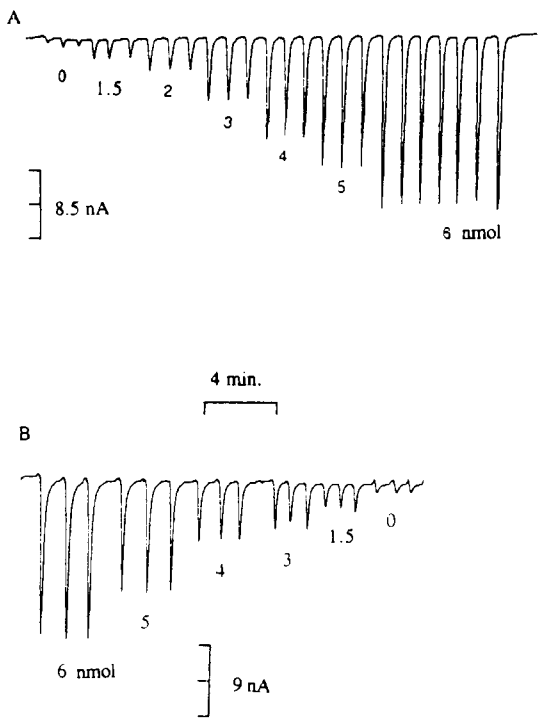

Fig. 3. Typical FIA peaks of the methylamine standards detected at (A) cobalt and (B) copper electrodes. Carrier solution, 0.075 M NaOH; flow rate, 0.75 ml min^{-1}; potential, 0.4 V (cobalt) and 0.5 V (copper).

The sensitivity was reduced significantly when the electrode was pretreated by oxidation at 2 V. The longer the oxidation at a cobalt electrode, the lower was the sensitivity. Completing a thick layer of oxide by this treatment would leave little to be affected by an absorbed amine.

3.4. Concentration of NaOH in the mobile phase

The effect of the concentration of the mobile phase on the detection response was examined to obtain a compromise between maximum sensitivity and solute retention on the chromatographic column. Since only two amines were overlapped (methylamine and propylamine), we focused on the separation of these two compounds.

Table 2 shows the effect of the concentration of NaOH in the range 0.025–0.100 M on the resolution of selected amines. The retention times of

compounds increased slightly as the concentration of sodium hydroxide increased, which improved the resolution. The best overall resolution of six compounds was achieved by using 0.075 M sodium hydroxide as the mobile phase. The resolution of methylamine and propylamine increased from 0.68 to 1.35 on increasing the NaOH concentration 0.025 to 0.10 M (Table 2). Similar observations have been reported where the concentration of ion-interaction reagent in the mobile phase increased, leading to a corresponding increase in solute retention [3,13].

An optimum concentration of alkaline medium is essential to develop the oxide film on the surface of the electrodes to respond sensitively to amines. Detailed studies by UV–visible reflectance spectroscopy and FTIR spectrometry at a nickel electrode surface showed that the main requirement for sensitive detection consists in the formation of a nickel(III) oxide–hydroxide layer in alkaline medium [9]. The same conditions may also be expected to apply to cobalt and copper electrodes. At low alkaline concentration, the oxidation process may not fully develop, and the oxide film is not sufficient to respond to the addition of amines. At high alkaline concentration, however, an unfavourable response occurs because of increasing participation of the equilibrium involving hydroxide ions. We found that the lowest detection limit was achieved at the optimum NaOH concentration of 0.075 M. Stulik et al. [13] also reported that copper electrodes respond to complexing agents only in a solution of pH > 6.0, and that the sensitivity increases with increasing pH and decreasing ionic strength.

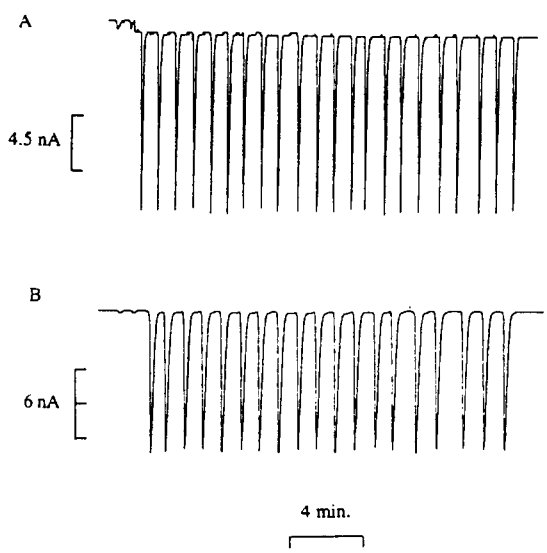

Fig. 4. FIA peaks showing the precision for 12 mmol methylamine detected at (A) cobalt and (B) copper electrodes. Carrier solution, 0.075 M NaOH, flow rate, 0.75 ml min^{-1}; potential, 0.4 V (cobalt) and 0.5 V (copper).

3.5. Flow rate

Decreasing the flow rate improves the resolution of the overlapping peaks, and the best compromise between resolution and retention time was achieved at a flow rate of 0.75 ml min^{-1}. At higher flow rates, propylamine moves in and masks the methylamine peak. These results support the previous report [22] that the optimum flow rate was achieved at 0.6 ml min^{-1}. Mass transfer in Aminex columns is slow, requiring a commensurately low flow rate to avoid band broadening.

3.6. Concentration of organic solvent

As the sensor is used in conjuction with the HPLC system, the effect of added organic solvent was studied. The addition of solutions of methanol between 0.1% and 2% to the carrier solution decreased the response of the cobalt wire electrodes to amines. The result is in agreement with those described in previous studies [13]. According to Stulik et al. [13], the presence of organic solvent suppresses the solubility of the passivating film and the interaction of the test substances with the passivating film. This in turn decreases the relative permittivity in the carrier, which generally causes a decrease in the rate constants for complex reactions. In contrast to the above, we found a positive response at a copper wire electrode when amine was injected into a carrier solution containing methanol. This result is also consistent with several reports on the amperometric detection of organic compounds by a copper wire electrode in an alkaline medium [9,11,13], in which direct oxidation yielding positive currents occurs.

Table 4
Comparison of stability of cobalt and copper electrodes

Injection number or time	Relative response (%)	
	Cobalt	Copper
10	100.0	100.0
20	99.5	99.0
50	102.4	74.4
After 3 h	99.2	55.0

After 9 h	99.4	–
RSD (%) ($n = 10$) [a]	1.3	1.9

Electrode potential (vs. Ag/AgCl), Co +0.94 V and Cu +0.5 V; sample, 12 nmol methylamine.
[a] (For the first 10 injections).

Although the FIA experiments at cobalt suggested that the addition of methanol significantly reduced the peak height, we invesitgated whether the addition of a low methanol concentration could improve the resolution of the amine peaks. An organic modifier penetrates and swells the organic backbone of the resin, so that decreased osmotic pressure decreases the intra-particle water volume. This to some extent may affect the resolution of the peaks.

The results in Table 3 show that the improvement in resolution of ovelapping peaks was not significant when methanol was added to the mobile phase. On the other hand, the peak heights were significantly reduced and the baseline was drifting. Therefore, the addition of organic modifier is not recommended with this method.

The effect of atmospheric oxygen in the solutions was studied, since the dissolution of copper in complex-forming media often depends on the presence of oxidants. However, no change occurred when oxygen was removed by passage of nitrogen for 30 min. Therefore, we conclude, in agreement with Stulik et al. [13], that the presence of atmospheric oxygen does not affect the detection.

Fig. 3 shows typical peaks obtained in the FIA system when responding to methylamine using both metallic cobalt and a copper wire electrode as detectors. Various structural types of amines were also investigated. Aliphatic primary, secondary and tertiary and aromatic amines can be

[b] LOD (limit of detection) = concentration that yields a current of three times the standard deviation of the background noise.

detected by this method. The sensitivity decreased with increasing chain length and with increasing number of substituents on the nitrogen atom.

3.7. Precision and stability

The precision of the electrode response was examined by injecting a sequence of 10 replicate samples of 12 nmol methylamine under the optimum conditions, using both cobalt and copper electrodes (Fig. 4). The mean values of the peak heights recorded were 23.0 and 14.3 nA with relative standard deviations (RSDs) of 1.3 and 1.9% for the cobalt and copper electrodes, respectively.

The stability of the electrode was tested by injection of 10, 25 and 50 replicate samples after 3,6 and 9 h without resurfacing the electrodes. The results in Table 4 indicate that good stability is obtained particularly with the cobalt electrode. The response eventually begins to decrease after 3–4 days of use but the former sensitivity was easily restored by cycling 10 times between −0.40 and +2.6 V. The long-term stability of the reference electrode must also be monitered. Redox processes at each of the electrodes may lead to poisoning and loss of performance.

The great stability offered by these systems may be due partly to the principle of detection, i.e. oxidation at a reversible layer consisting of high-valent metal oxide and metal hydroxide. The response thus results from the interaction of the analyte with higher valent metallic ions contained in the outer layer. This layer can be converted very rapidly to and from a layer of lower valence metal oxide, electrochemically or chemically thus renewing itself.

The detector cell design, which eliminates possible reactions with the Ag/AgCl reference electrode, may also contribute to the good stability of these sensors.

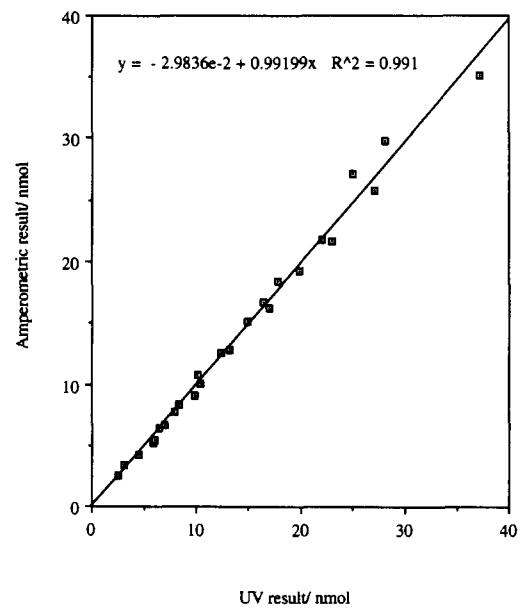

Fig. 6. Amperometric sensor with cobalt wire compared with UV spectrophotometric detection for amines. UV wavelength, 275 nm, carrier solution, 0.1 M NaOH; flow rate, 0.75 ml min^{-1}.

3.8. Analytical performance of the electrodes in the HPLC system

Typical chromatograms of six amines under the optimum chromatographic conditions, using an amperometric detector with cobalt and copper electrodes and a UV detector for comparison, are shown in Fig. 5. The amines separated in order of elution were methylamine, propylamine, butylamine, cysteamine hydrochloride, trimethylamine and benzylamine, with retention times of 10.1, 12.2, 19.8, 24.3, 39.0 and 67.9 min, respectively. All peaks were resolved sufficiently to allow the HPLC system to be of practical use for determining the six amines.

A good separation of the six amines was achieved in this system using only a 0.075 M NaOH carrier, without pre- or post-column derivatization. The retention times of isopropylamine and isobutylamine are identical with those of *n*-propylamine and *n*-butylamine, which suggests that the isomeric amines cannot be separated with this method.

The order of elution suggests that the less polar compounds (benzylamine) are retained more strongly than more polar compunds (methylamine), which shows that a reversed-phase partition is involved in this separation.

The detectors used, amperometric with cobalt and copper wire electrodes and a UV detector, gave similar chromatograms, with reasonable baseline separations of the amines tested. The RSDs of the retention times are $< 2.5\%$, which is good for an HPLC method.

3.9. Linearity, sensitivity and limit of detection

The calibration data for selected amines with amperometric detection at cobalt are shown in Table 5. The calibration graphs exhibit good linearity (correlation coefficients ranging from 0.984 for *n*-propylamine to 0.999 for benzylamine). The linear range of the voltammetric detector was between 30 (for benzylamine) and 300 (methylamine) times the limit of detection.

There was also a difference between the sensitivities of the various compounds shown by the amperometric sensors: the simpler the amines, the higher was the sensitivity. Their detection limits were consistent with their sensitivity which follows their degree of structural complexity. Methylamine could be detected at levels as low as 0.5 nmol whereas benzylamine could not be detected until about 6.3 nmol was present. The cobalt electrode exhibited higher sensitivities than the copper electrode for all amines tested. Compared with the electrode resonse in FIA, the amperometric response toward separated amines with a metallic electrode is lower. This discrepancy is probably due to the higher dispersion in the HPLC system and the difference in dynamic conditions between the two experiments.

Satisfactory precision (the RSD of the peak height was $< 2\%$) was obtained with five replicates, even at the lowest measured concentrations. Compared with a chemically modified electrode (CME) and mercury/gold amalgam electrodes, a cobalt electrode is more stable. A newly resurfaced gold amalgam electrode may operate efficiently for only a few minutes or hours. Using a CME, after some time the response is reduced. Some of the decrease in the electrode response is due to the gradual leaching of the modified chemicals from the CME surface. In fact, some decrease in response has been observed previously even for conventional carbon paste electrodes in electrochemical detection in liquid chromatography upon long-term exposure to a binary mobile phase containing a small fraction of organic components.

The design of the Ag/AgCl reference electrode may also contribute to the stability of this sensor. In this cell design, the silver wire which has been electrolysed with KCl solution was covered with solid agar gel containing 1.0 M KCl. The function of the solid agar gel containing 1.0 M KCl is similar to that of the Ag/AgCl reference electrode with a double junction.

The retention times are comparable to those achieved by Stamler and Loscalzo [27] using capillary zone electrophoresis for separation. As derivatization is not necessary, our method is simpler and cheaper. To our knowledge, this represents the first report on the use of cobalt and copper electrodes for constant-potential amperometric detection in conjunction with ion-moderated partition HPLC for the determination of amines.

3.10. Comparison with UV spectrophotometric detection

The performance in amine determination of a cobalt electrode was compared with that of a copper electrode and UV detection using the wavelength suggested by the instrument manufacturer [23]. Fig. 6 demonstrates the close agreement between amperometric detection with a cobalt electrode and UV detection.

Fig. 5 shows that compared with a UV detector, the cobalt electrode is more sensitive for the detection of methylamine and butylamine but less sensitive for propylamine, trimethylamine and benzylamine. Benzylamine absorbed UV radiation more strongly than other amines which are not aromatic. The UV detector placed prior to the amperometric detector also caused more dispersion. The constraints of working at UV wavelengths is that severe interference by organic compounds other than amines may occur.

Spectrophotometric determination of vitamin E (α-tocopherol) using copper(II)–neocuproine reagent

Esma Tütem*, Reşat Apak, Esma Günaydı, Kevser Sözgen

Department of Chemistry, Faculty of Engineering, Istanbul University, Avcılar 34850, Istanbul, Turkey

Received 23 November 1995; revised 22 May 1996; accepted 4 July 1996

Abstract

The possibility of the utilization of the copper(II)–neocuproine spectrophotometric method, which has previously been shown to permit the determination of various reducing agents, to the determination of vitamin E was investigated. The molar absorptivity for vitamin E was found to be $(2.1 \pm 0.1) \times 10^4$ l mol^{-1} cm^{-1} and Beer's law was obeyed between 2.4×10^{-6} and 9.0×10^{-5} M concentrations of α-tocopherol. The relative standard deviation of the slope of the absorbance vs. concentration plot was 2.1%. The results obtained by the copper(II)–neocuproine method were compared with those achieved by both the standard HPLC and the widely used iron(III)–bathophenanthroline method by means of a *t*-test which showed that the precision of the developed method was not essentially different from those of the others. The developed method was successfully applied to three commercial samples, two in dragée and one in ampoule form. The α-tocopheryl acetate contained in the samples, which did not respond directly to the Cu(II)–neocuproine reagent, was subjected to alkaline hydrolysis prior to the analysis of the hydrolysis product, i.e., α-tocopherol. The molar absorptivity due to Cu(I)–neocuproine at 450 nm against a reagent blank indicated a two-electron oxidation of vitamin E by Cu(II)–neocuproine, which may be slightly enhanced by solvent effects. Copper(II)–neocuproine is an oxidant of strength comparable to that of Fe(III)–bathophenanthroline. The developed method, although less sensitive, is easy to use in conventional laboratories, unlike the Fe(III)–bathophenanthroline method, which requires specially prepared reagents and solvents. The method is free from interferences from such common reductants as ascorbic acid and Fe(II) salts, found in pharmaceutical formulations, after washing the formulation with water and collecting vitamin E in the ether extract for subsequent analysis.

Keywords: Copper(II)–neocuproine reagent; Spectrophotometry; α-Tocopherol; Vitamin E

1. Introduction

Vitamin E, also known as α-tocopherol, is an important vitamin found largely in plant materials, e.g. wheat germ, corn, sunflower seed, rapeseed, soybean oils, alfalfa and lettuce. Its complex biological functions may include antisterility, an antioxidant role, i.e. prevention of peroxide attack on unsaturated fatty acids in membrane lipids, and a cofactor between cytochrome *b* and *c* in the respiratory chain. The beneficial role of vitamin E

* Corresponding author. FAX: 90-212-591 1997.

PII S0039-9140(96)02041-3

in preventing degenerative physiological processes and ageing is still being investigated.

Although vitamin E intake in normal diets usually meets the daily requirement of children and adults, there is a constant commercial demand for this vitamin especially by elderly customers. Thus, the development of simple and sensitive methods other than the more expensive HPLC [1–3] and voltammetric [4] techniques for the determination of this vitamin in pharmaceutical preparations has always been a matter of concern.

The existing spectrophotometric methods for vitamin E determination make use of the oxidizability of the 6-hydroxychroman ring of α-tocopherol to the corresponding quinone, i.e., α-tocopherylquinone, by oxidizing agents finally giving coloured products. The official method utilizes the Fe(III)–bipyridyl [5] or bathophenanthroline [6] complex reagent as the oxidizing agent. The Fe(III) in these reagents is reduced by vitamin E to the corresponding Fe(II) complex, the absorbance of which is measured at 520 and 534 nm. Derivative spectrophotometric methods [7], which are not as specific as direct methods, have also been introduced.

In recent years, copper(II)–neocuproine reagent has been developed for determining a number of reducing agents in ammonium acetate-buffered solution [8], and biologically important reductants such as hydrogen peroxide, ascorbic acid and cysteine [9] have been assayed by the use of this reagent. This work was undertaken in order to establish the copper(II)–neocuproine spectrophotometric procedure as a standard method for analysing vitamin E solutions and pharmaceutical preparations.

α-Tocopheryl acetate, which is practically unaffected by the oxidizing influence of air, daylight and UV radiation, is more stable than the parent vitamin, α-tocopherol [10]. Since the acetate derivative is preferentially used in the formulation of pharmaceutical preparations, the conditions for the hydrolysis of this compound to α-tocopherol also need to be investigated for establishing a thorough assay method for vitamin E.

2. Experimental

2.1. Chemicals and reagents

α-Tocopheryl acetate was supplied by Roche (Turkey). Absolute ethanol and light petroleum (b.p. 60–71°C) were prepared from 95% technical alcohol and technical light petroleum (b.p. 60–80°C), respectively [11]. Bathophenanthroline was obtained from Sigma, technical alcohol from Turkish Monopolies, light petroleum from Delta Chemicals (Turkey) and nitrogen gas (bomb) from Habaş (Turkey). All remaining chemicals were supplied by Merck and were of analytical reagent grade. Rovigon and Supradyn dragées and Ephynal ampoules (Roche), the active ingredient of which is α-tocopheryl acetate, were freely purchased in the Turkish market.

2.2. Instrumentation

The molecular absorption spectra and absorbances at selected wavelengths were recorded with a Hitachi 220 A UV–visible spectrophotometer equipped with quartz cells of 1 cm light path. The pH of solutions was measured with a Metrohm E-512 pH meter using a glass electrode. The chromatograph was from Cecil Instruments (Cambridge, UK), and consisted of a pump (CE 1100 HPLC pump), a 20 μl injection valve (Model 7125, Rheodyne, Cotati, CA, USA), an analytical stainless-steel column packed with Spherisorb S5ODS1 (25 cm × 4.6 mm i.d.) from Hichrom (Berkshire, UK) and a variable-wavelength UV detector (CE 1220). Detection was effected at 292 nm for α-tocopherol. Chromatograms were obtained using an integrator (HP 3395 from Hewlett-Packard). Injections were made with a 25 μl syringe from Hamilton (Reno, NV, USA).

2.3. Solutions

α-Tocopherol solution was prepared at 2.46×10^{-4} M concentration in diethyl ether and absolute ethanol and diluted as necessary.

Neocuproine (2,9-dimethyl-1,10-phenanthroline) and bathophenanthroline (4,7-diphenyl-1,10-

phenanthroline) were prepared separately in ethanol and absolute ethanol, respectively, at a concentration of 3.0×10^{-3} M.

The pH 7.0 buffer was a 1.0 M solution of ammonium acetate in water. Solutions of 1.0×10^{-2} M $CuCl_2 \cdot 2H_2O$ and concentrated KOH (160 g per 100 ml) were also prepared separately in water. The Iron(III) chloride solution of concentration 2.0×10^{-3} M was prepared from $FeCl_3 \cdot 6H_2O$ in absolute ethanol. Phosphoric acid solution contained 0.172 M H_3PO_4 in absolute ethanol.

A light petroleum–absolute ethanol mixture was prepared by diluting 600 ml of light petroleum (b.p. 60–71°C) to 1.0 l with absolute ethanol.

The mobile phase for HPLC analysis was acetonitrile–chloroform–2-propanol–water (73:15:3.5:8.5, v/v).

2.4. Procedures

2.4.1. Hydrolysis of α-tocopheryl acetate to α-tocopherol [6]

A 1.10 g amount of α-tocopheryl acetate was dissolved in 4.5 ml of absolute ethanol and 0.33 g of ascorbic acid was added. The mixture was brought to boiling under a nitrogen atmosphere in a round-bottomed flask (equipped with a reflux condenser) immersed in a water-bath. A 1.1 ml volume of concentrated KOH solution was added and the mixture was refluxed for 15 min.

The flask was rapidly cooled, 25 ml of water were added and the mixture was extracted with three successive portions of 30 ml of diethyl ether. The ether phase was successively washed with water until the aqueous phase was neutral to phenolphthalein, dried with anhydrous sodium sulfate, filtered, concentrated to 5 ml under a nitrogen atmosphere by gentle heating and finally diluted to 10 ml with diethyl ether.

The purity and hydrolysis efficiency of the product were determined by comparison of the UV spectra of the hydrolysate and standard mixtures of α-tocopherol and α-tocopheryl acetate prepared in various proportions until the A_{292} of the hydrolysate matched that of a standard mixture. The hydrolysate was further subjected to HPLC analysis by the method of Kaplan et al. [1].

The hydrolysis conditions described above were optimized by changing one of the hydrolytic parameters while keeping the remaining three parameters constant, i.e. initial amount of α-tocopheryl acetate, volumes of absolute ethanol and concentrated KOH solution and amount of ascorbic acid. Since any remaining ascorbic acid from the hydrolysis procedure would interfere with the analysis of the reaction product (α-tocopherol) using the copper(II)–neocuproine reagent [8], the hyrolysis was repeated with a reagent blank not containing α-tocopheryl acetate.

2.4.2. Determination of α-tocopherol by the Fe(III)–bathophenanthroline method [6]

An aliquot of x ml ($0.2 \leqslant x \leqslant 0.4$ ml) of α-tocopherol in diethyl ether or preferentially in absolute ethanol was placed in a test-tube and $4.0 - x$ ml of light petroleum–ethanol and 1.0 ml of bathophenanthroline solution were added. The mixture was agitated, 0.5 ml of $FeCl_3$ solution was added dropwise and the solution was reagitated. After 15 s, 0.5 ml of H_3PO_4 solution was added. The absorbance of the solution at 534 nm against a reagent blank was measured after 3 min, and the colour was stable for 90 min. The procedure was repeated for α-tocopherol hydrolysed from the acetate derivative, and applied to the analysis of Rovigon and Supradyn dragées and Ephynal ampoules.

2.4.3. Determination of α-tocopherol by the Cu(II)–neocuproine method

In a test-tube were placed 1.0 ml of $CuCl_2$ solution, 2.5 ml of neocuproine solution, $3.0 - x$ ml of ethanol, 1.0 ml of ammonium acetate buffer and x ml ($0.3 \leqslant x \leqslant 0.6$ ml) of α-tocopherol solution (in diethyl ether or preferentially in absolute ethanol), in that order. The mixture was agitated and its absorbance was measured after 30 min at 450 nm against a reagent blank containing Cu(II)–neocuproine, solvent and buffer (the colour was stable for at least 90 more min). It is recommended to run three standards along with the sample for each determination. The procedure was applied to the analysis of the hydrolysis product, Rovigon and Supradyn dragées and Ephynal ampoules.

2.4.4. Preparation of pharmaceutical preparations for analysis

Eleven Rovigon dragées were finely ground in an agate mortar and five samples each containing approximately 110 mg of α-tocopheryl acetate were taken. Each of the samples was extracted with four successive portions of absolute ethanol and hydrolysed using the standard procedure.

The contents of eight Ephynal ampoules were thoroughly mixed and five samples each containing approximately 110 mg of α-tocopheryl acetate were taken and subsequently hydrolysed.

Three Supradyn dragées, each having a declared content of 10 mg of vitamin E equivalent, were finely ground, washed with 60 ml of distilled water and dried in an oven at 50°C. The residue was extracted with 30 ml of diethyl ether, evaporated and the residue dissolved in 10 ml of absolute ethanol. The ethanol solution was analysed by HPLC and hydrolysed using the standard hydrolysis procedure except for the amounts of ascorbic acid and KOH solution, which were chosen as 0.033 g and 0.03 ml, respectively, owing to the low vitamin E content. The ether solution of the hydrolysis product was diluted to 10 ml and diluted 20-fold with absolute ethanol such that the final solution contained 5% (v/v) of ether.

The spectra of the hydrolysis products (except Supradyn) were compared with that of standard α-tocopherol. The hydrolysis products were analysed by both spectrophotometric procedures and HPLC for α-tocopherol, and the original α-tocopheryl acetate contents of the pharmaceutical preparations were calculated by taking the efficiency factor of hydrolysis into consideration.

3. Results and discussion

The colour (i.e. A_{450} against the reagent blank) of the Cu(I)–neocuproine complex formed as a result of vitamin E oxidation stabilized after 30 min and remained the same for at least a further 90 min following complex formation.

The UV spectra of α-tocopherol and α-tocopheryl acetate (both 2.46×10^{-4} M) in ethanol is shown in Fig. 1. Since Beer's law was obeyed for both compounds at 292 nm within the concentration range of interest, the hydrolysis efficiency of the corresponding α-tocopheryl acetate solutions was estimated by comparing the absorbances at 292 nm of the hydrolysate and binary standard mixtures at this wavelength. This efficiency was found to be 93%, confirmed by HPLC, and was exploited in the analysis of pharmaceutical preparations of α-tocopheryl acetate.

In the hydrolysis procedure, half to twice as much α-tocopheryl acetate was not affected by an excess of KOH; e.g. 1.1 ml of concentrated KOH solution was sufficient to hydrolyse efficiently 2.20 g of α-tocopheryl acetate. KOH at levels up to 10 times the usual amount did not have a negative effect on hydrolysis.

It was also confirmed that ascorbic acid, introduced for the protection of α-tocopherol from oxidation during the hydrolysis of tocopheryl acetate, could be completely removed from the reaction product by thoroughly washing the organic (ether) phase with successive portions of water. Analysis of the hydrolysed α-tocopherol using the Cu(II)–neocuproine reagent revealed that not even a detectable amount of the ascorbic acid, which would normally show a positive interference in the method [8], accompanied the analyte.

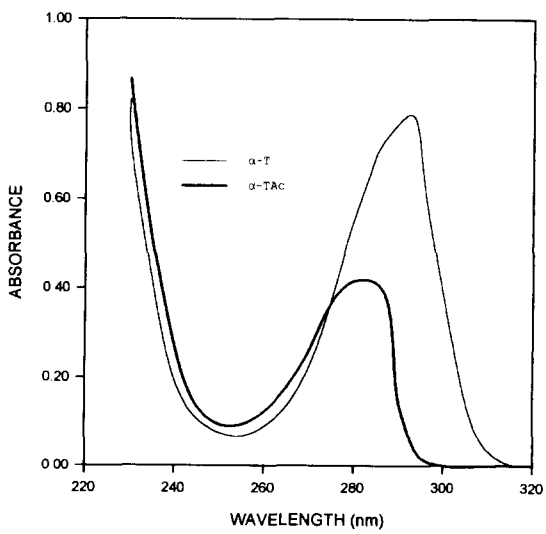

Fig. 1. UV spectrum of 2.46×10^{-4} M α-tocopherol and α-tocopheryl acetate in absolute ethanol.

The molar absorptivity, the concentration range for the validity of Beer's law and the precision of the developed method were found by the aid of absorbance measurements (at 450 nm) of standard α-tocopherol solutions. The spectrophotometric measurements were made on six-analyte sampling groups (whose absorbances (A_{450}) varied between 0.2 and 0.8) on three different occasions selected with 1 week time intervals. The within - and between-run precisions, also known as repeatability and reproducibility [12], respectively, were found by regression analysis of A_{450} vs. concentration curves, and expressed as the relative standard deviation (RSD, %) of the slope [13], i.e. of the molar absorptivity, of the absorbance vs. concentration regression lines.

The mean molar absorptivity was $\bar{\varepsilon} = 2.1 \times 10^4$ l mol^{-1} cm^{-1} with the RSD on each occasion being 2.3, 4.2 and 5.3% (repeatability). The overall linear equation relating the absorbance (A) and concentration (C in mol l^{-1}) of eighteen values at the 95% confidence level was

$$A = (2.1 \pm 0.1) \times 10^4 C + (0.68 \pm 1.7) \times 10^{-2}$$

with an RSD of the slope of 2.1% and a correlation coefficient of the linear plot $r = 0.996$ (reproducibility). Beer's law was obeyed between 2.4×10^{-6} and 9.0×10^{-5} M concentrations of α-tocopherol. The corresponding linear equation for calibration of the Fe(III)–bathophenanthroline method was found to be

$$A = (4.1 \pm 0.4) \times 10^4 C + (1.4 \pm 4.4) \times 10^{-2}$$

at the 95% confidence level with an RSD of 3.8% and $r = 0.996$. The latter method was slightly less reproducible and definitely more laborious (with respect to the preparation of reagents and solvents) than the developed method.

When the precisions of the developed Cu(II)–neocuproine and the standard HPLC method [1] using a slightly polarized mobile phase were compared (95% confidence level, 20 degrees of freedom), a pooled estimate of the standard deviation, s, may be calculated from the two individual standard deviations, s_1 and s_2, of the developed and reference methods (see Table 1):

$$s^2 = [(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2]/(n_1 + n_2 - 2) \quad (1)$$

Table 1
Comparison of the developed and reference methods for α-tocopherol determination

Sample number (n)	Amount of α-tocopherol found (μg)[a]	
	Cu(II)–neocuproine	HPLC
1	54.5	54.9
2	53.0	50.0
3	53.2	52.4
4	53.2	50.6
5	53.4	51.9
6	52.6	51.7
7	51.9	50.4
8	51.3	52.4
9	51.1	54.7
10	49.8	52.8
11	56.2	52.8
Standard deviation	$s_1 = 1.74$	$s_2 = 1.59$
Mean	$\bar{x}_1 = 52.7$	$\bar{x}_2 = 52.2$
Degrees of freedom	$n_1 + n_2 - 2 = 20$	
Critical t-value (95% confidence level)	2.09 [14]	

[a]Amount of α-tocopherol present = 53 μg.

$$t = (\bar{x}_1 + \bar{x}_2)/[s(1/n_1 + 1/n_2)^{1/2}] \quad (2)$$

where t has $n_1 + n_2 - 2 = 20$ degrees of freedom [14]. By applying Eqs. (1) and (2) to the data in Table 1, s was calculated as 1.67 and t was 0.70. Since this t value is smaller than the critical value, $t_{0.95}$, i.e. $0.70 < 2.09$, there is no significant difference between the developed and reference methods at the 95% confidence level, and the null hypothesis [14] is accepted.

Following the hydrolysis of α-tocopheryl acetate in commercial Rovigon and Supradyn dragées and Ephynal ampoules, inspection of the hydrolysates by UV and HPLC (only the latter applicable for Supradyn) confirmed that the hydrolysis product was essentially α-tocopherol. The analyses of these commercial preparations by HPLC and the two spectrophotometric methods are depicted in Table 2. Five samples of each preparation were analysed. The results confirm that the developed method is not inferior in precision to the literature spectrophotometric and HPLC methods, even in a complex multivitamin

Table 2
Comparison of analysis results of commercial formulations of vitamin E (after hydrolysis)

Sample[a]	Form	α-tocopheryl acetate declared (mg)	Amount of vitamin E found (mg)		
			HPLC	Cu(II)–neocuproine	Fe(III) –bathophenanthroline
Rovigon	Dragée	70	65 ± 2	66 ± 2	66 ± 3
Ephynal	Ampoule	100	102 ± 3	103 ± 3	103 ± 4
Supradyn	Dragée	30[b]	21 ± 1	23 ± 2	20 ± 2

[b] Amount of α-tocopheryl acetate before alkaline hydrolysis was found to be 22 ± 1 mg by HPLC.

and mineral combination such as Supradyn (containing 11 essential vitamins, five minerals comprising the reducing $FeSO_4$ and three oligo-elements of Cu(II), Zn(II) and Mo(VI)).

Since the observed molar absorptivity of the Fe(III)–bathophenanthroline method for vitamin E is approximately twice that of the literature value for this complex reagent [6,15], it may be deduced that vitamin E undergoes a two-electron oxidation with this reagent, possibly to α-tocopherylquinone [16]. In the original paper introducing the copper(II)–neocuproin reagent [8], the authors showed that a two-electron oxidation of a reducing analyte would normally be expected to exhibit a mean molar absorptivity of 1.6×10^4, although higher values were encountered such as those of glutathione ($\varepsilon = 8.5 \times 10^3$, le oxidation) and hydroxylamine ($\varepsilon = 1.8 \times 10^4$, 2e oxidation), depending on the nature of the analyte [8], and solvent effects may also cause some enhancement [17] owing to the affinity of the $[Cu\text{-neocuproine})_2]^+$ cation, i.e. the reduction product of Cu(II)–neocuproine, to add a solvent molecule as ligand in the charge-transfer excited state, thereby increasing the molar absorptivity to a certain extent. When the standard reduction potentials of the two complex reagents are considered, the $[Cu(neocuproine)_2]^{2+,1+}$ couple has been reported to exhibit a potential of $E_c^\circ = 0.603$ V [17–19], while the oxidizing power of Fe(III)–bathophenanthroline is considerably weaker than that of Fe(III)–phenanthroline ($E_c^\circ = 1.2$ V), which is reflected in the observation that Fe(III)–bathophenanthroline is not as easily reduced as the Fe(III)–phenanthroline analogue [20]. The Fe(III)–bathophenanthroline reagent should be an even less potent oxidant in the presence of phosphoric acid (as described in Section 2.4), because it is known that the 0.77 V standard potential of the uncomplexed $Fe^{3+,2+}$ redox couple is reduced to 0.44 V in 0.3 M H_3PO_4 medium [21]. Thus, both the Cu(II)–neocuproine and Fe(III)–bathophenanthroline reagents are oxidizing agents of comparable strength under the experimental conditions employed, and it is reasonable to assume that both reagents lead to 2e oxidation of α-tocopherol as accomplished with other oxidizing reagents such as tris(2,2′-bipyridyl)iron(III), $FeCl_3$ and $Fe(CN)_6^{3-}$ [16].

Although the molar absorptivity of the Fe(III)–bathophenanthroline method is greater than that of the developed method, allowing the achievement of greater sensitivity with the former, the Cu(II)–neocuproine method is less laborious and shows the potential to work better in complex formulations. Moreover, the introduced reagent performs its action in a neutral medium, i.e. ammonium acetate-buffered solution of pH 7.0, where some common potential interferents such as glucose (and reducing sugars with the —$(CHOH)_n$—CHO group) and oxalate would not be oxidized [8], unlike in acidic media where most oxidants should function, thereby adding some selectivity to the proposed method. As vitamin E is not soluble in water, pharmaceutically common interferents which are reducing agents, e.g. ascorbic acid and iron(II) sulfate, would also not interfer after a preliminary aqueous extraction stage. The method is capable of differentiating α-tocopherol from the pharmaceutically desired ana-

logue, α-tocopheryl acetate, where the latter may respond to the method only after hydrolysis.

Both the developed and alternative spectrophotometric methods have the advantage of working in the visible range, permitting the use of simple colorimeters where required instead of the more expensive spectrophotometers. The developed method has a slight superiority in that all solutions of this method except neocuproine are prepared in water while the Fe(III)–bathophenanthroline method requires the preparation of absolute EtOH and a certain boiling range fraction of light petroleum. Both methods have similar precision and, in addition, the Cu(II)–neocuproine reagent in a routine analytical laboratory, lacking more expensive HPLC and GC instruments, handling other reducing substances [8,9] would be more versatile.

Effects of cetylpyridinium bromide micelles on the spectrofluorimetric characteristics of polycyclic aromatic hydrocarbons

Juan H. Ayala, Ana M. Afonso, Venerando González*

Department of Analytical Chemistry, Nutrition and Food Science, University of La Laguna, E-38204 La Laguna, Spain

Received 15 January 1996; revised 8 July 1996; accepted 8 July 1996

Abstract

The presence of a micellar medium of cetylpyridinium bromide (CPB) causes, in relation to the aqueous medium, important bathochromic shifts in the excitation spectra of a considerable number of polycyclic aromatic hydrocarbons (PAHs). Furthermore, the CPB acts as a quencher, provoking inhibitions of the fluorescence intensity emitted by PAHs. The micellar inhibition factors show that, generally, the quenching affects alternant hydrocarbons to a greater extent. Some interesting relationships between the hydrocarbon structure and both the characteristic wavelengths of fluorescence spectra and the values of $\Delta\lambda$ are established.

Keywords: Cetylpyridinium bromide; Fluorescence quenching; Micelles; Polycyclic aromatic hydrocarbons

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) form a family of compounds widely found in the environment as common pollutants of the atmosphere, earth and water. The PAHs most studied, for their mutagenic or carcinogenic characteristics, are those which possess between three and six rings. Among those which contain a greater number of rings, only some show carcinogenic activity. Although it has not been demonstrated, such activity can be related to their low solubility. Consequently, it is frequently necessary to determine PAHs at low concentration in a wide variety of sample matrices. The techniques most used in the analysis of PAHs can be split into two large groups: chromatographic and spectroscopic. Usually, the hydrocarbons are analysed by gas chromatography [1–3], high-performance liquid chromatography [4–7] and supercritical fluid chromatography [8,9]. However, spectroscopic methods have shown strong development in this field owing to their sensitivity, selectivity, rapidity, low cost and possibility of automation. Among these, conventional and synchronous spectrofluorimetry stand out [10–19].

Mixtures of environmental importance rarely contain a single component. The majority of mix-

tures commonly encountered contain several isomeric pairs or structurally similar PAHs, which emit in approximately the same spectral regions. Use of selective fluorescence quenching agents simplifies observed emission spectra by eliminating signals from undesired chemical interferences having only slightly different molecular structures, so providing a greater selectivity to the analytical methods based on the measurement of fluorescence emission.

Micellar systems form microenvironments that can produce significant changes in the excitation and emission spectra of many molecules, as well as in the emitted fluorescence intensity. There are different factors that may explain these changes [20,21]. Among others, the following can be cited: the greater protection of the singlet state against collisional deactivation, the increase in the viscosity of the medium, the protection against quencher agents and the capacity of micelles to reorder reagents at molecular level and to enhance the interaction between analytes and reactives, quenchers and substrates.

Studies of quenching in micellar medium have been directed preferentially to show that solutes incorporated to a micellar phase are protected against the action of certain quenchers of fluorescence. Thus, it has been demonstrated in systems such as: anthracene–sodium dodecyl sulphate–iodide [22], naphthalene-sodium dodecyl sulphate–bromide [23] and anthracene–cetyltrimethylammonium bromide–pyridinium chloride [22]. On the other hand, Lissi et al. [24] have shown that the quenching of pyrene and 1-methylpyrene by iodide is enhanced by the incorporation of hydrocarbons in cetyltrimethylammonium chloride micelles.

Thus far, very few reports [25] have discussed analytical applications based on the fluorescence inhibition of PAHs in which the quencher is, furthermore, a substance capable of forming micellar aggregates in solution. With the use of a quencher/surfactant such as cetylpyridinium bromide (CPB), in the present work the conventional and synchronous spectrofluorimetric characteristics of an important number of PAHs in a micellar medium of CPB were established, the magnitude of the fluorescence inhibition was quantified and predictions of analytical interest were made. Likewise, and with the purpose of attempting to establish generalized behaviours, the conventional and synchronous signals are related to the structure of PAHs.

2. Experimental

2.1. Apparatus

Fluorescence measurements were made with a Perkin-Elmer LS-50 luminescence spectrometer equipped with a xenon discharge lamp and connected via an RS232C interface to an Epson PCAX2e computer. The control of the spectrometer was accomplished using Fluorescence Data Manager software. The fluorescenc measurements were made in standard 1×1 cm quartz cells, thermostated at 25 ± 0.1°C with a Selecta Frigitherm S 382 ultrathermostat.

2.2. Reagents

The PAHs used (naphthalene, anthracene, 9-methylanthracene, phenanthrene, 2-methylphenanthrene, pyrene, benz[*a*]anthracene, perylene, dibenz [*a*,*h*]anthracene, benzo[*a*]pyrene, fluorene, acenaphthene, acenaphthylene, fluoranthene and benzo[*b*]fluoranthene) were supplied by Aldrich Chemical. Stock solutions (5×10^{-4} M) of each PAH were prepared in ethanol (Merck). Stock solutions (5×10^{-2} M) of CPB (Sigma Chemical) were prepared in deionized water. All chemicals used were of analytical reagent grade.

2.3. Procedures

The conventional and synchronous fluorescence spectra of the PAHs in an aqueous medium were made with solutions incorporating 0.5% (v/v) ethanol. The representatives of the micellar medium corresponded to solutions containing CPB at a concentration of 2.6×10^{-3} M (0.1%, w/v), above its critical micellar concentration (cmc) (7.32×10^{-4} M). This value was determined conductimetrically under experimental conditions

Table 1
Spectrofluorimetric characteristic of PAHs in micellar medium of CPB

[a] The values in italics correspond to the excitation and emission maxima.

similar to those used in fluorescence measurements.

To calculate the micellar inhibition factor (MIF), straight-line calibration graphs for each of the PAHs were obtained by measuring the fluorescence intensity at the maximum excitation and emission wavelengths, in both aqueous and micellar media. The solutions used were prepared with the quantities of PAH and ethanol necessary to reach the desired concentration of PAH and 0.5% (v/v) of the organic solvent, to which was added the volume of CPB solution required so that the final solutions were 0 or 2.6×10^{-3} M in the surfactant, according to whether it was aqueous or micellar, respectively, and diluted with deionized water.

To study the influence of surfactant concentration on the fluorescence intensity of PAHs, measurements of fluorescence intensity were made at the maximum excitation and emission wavelengths corresponding to the aqueous medium, in solutions prepared in 25 ml calibrated flasks with volumes of 10^{-2} M CPB solution and containing a final concentration of 2×10^{-7} M PAH and 0.5% (v/v) of ethanol.

Three-dimensional spectra were obtained by the elaboration of a Basic program within the OBEY application of the Fluorescence Data Manager software. This program allows successive scanning of several emission or synchronous spectra with different excitation wavelengths or $\Delta\lambda$, respectively, and transforms them into a matrix of experimental data. The file containing this matrix is used as input in the commercial program SURFER to obtain three-dimensional projections and contour maps.

3. Results and discussion

3.1. Conventional fluorescence

Excitation and emission spectra of 15 PAHs in aqeuous and micellar medium of CPB were obtained. Table 1 summarizes some characteristics of the conventional fluorescence spectra of PAHs in the micellar medium and the shifts experienced by the wavelengths of the maxima of the excitation (D_{ex}) and emission (D_{em}) spectra on passing from an aqueous to a micellar medium. Upon

comparing the results, it is observed that in the micellar medium:

(1) The wavelengths of the emission maxima are similar to those which are obtained in aqueous medium, except for fluorene and benzo[*b*]fluoranthene.
(2) The excitation maxima of all PAHs present wavelength values higher than those of aqueous medium. These observed differences can be attributed to the disappearance, provoked by the micellar medium of CPB, of the signals corresponding to the lower wavelength zones in the excitation spectra, the region in which the maxima of aqueous medium tend to be found.

With regard to the relationship between the fluorescence spectral characteristics in the micellar medium and the structures of polycyclic aromatic hydrocarbons, some general trends were found, among which the following are notable:

(1) For a given number of aromatic rings, the linear systems fluoresce, generally, at longer wavelengths than non-linear systems. That is to say, a deviation at smaller wavelengths is produced when the aromatic system is branched.
(2) The methylation of an aromatic system tends to produce deviations to longer wavelengths.
(3) As the degree of conjugation increases, a shift to wavelengths longer than the emission maxima is observed. This phenomenon is sometimes associated with an increase in the emitted fluorescence intensity.
(4) For an aromatic system formed by a series of rings fused in a straight linear chain, the excitation and emission bands exhibit increasing wavelenths as the number of rings and conjugated double bonds increase.
(5) The excitation and emission spectra of the hydrocarbons formed by benzenic rings joined by a five-membered ring are similar to those shown by systems that only contain benzenic rings.

Irrespective of the process of quenching, these relationships between spectrofluorimetric and structural characteristics of the PAHs were similar to those reported by others for various PAHs in hexane [26].

From emission spectra, in aqueous and micellar media of CPB, the values of fluorescence intensity between the 0–0 band and the b_{1g} vibrational band (which is frequently known as the I_1/I_3 or I/III relation [27,28]) were established for all those hydrocarbons that present in the micellar medium a sufficient resolution in their emission spectra. The smallest values correspond to the micellar medium, which confirms the lower polarity of that medium compared with the aqueous medium. This fact and the hydrophobic nature of PAHs explain, generally, the increase in their water solubility in the presence of micelles.

3.1.1. Influence of surfactant concentration

The variation of the fluorescence intensity emitted by hydrocarbons as a function of CPB concentration is illustrated in Figs. 1 and 2. Generally, at concentrations below the cmc, the fluorescence of PAHs decreases suddenly on increasing the surfactant concentration, whereas at concentrations above the cmc, the fluorescence does not vary significantly. In these figures, the effect of a non-micelle-forming pyridinium derivative on the fluorescence inhibition is also compared with that with CPB. These experiments show the important effect of the micellar system and the formation of premicellar clusters on the fluorescence inhibition of PAHs in the presence of CPB. These exponential decreases in the fluores-

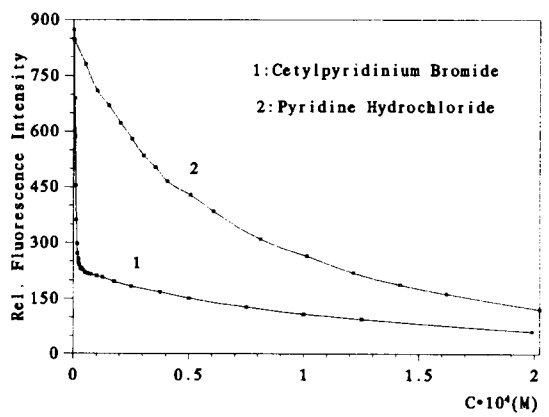

Fig. 1. Influence of the pyridinium salt concentration on the fluorescence intensity of 2×10^{-7} M 9-methylanthracene solutions and 0.5% (v/v) EtOH. Slits: 5 nm.

cence, whose intensity varies in a regular way with the quencher concentration, can be considered typical of quenching processes.

The intersection point of lines tangential to the initial and final zones of the curves of fluorescence intensity versus CPB concentration could be considered representative of the phenomenon of micellization and, consequently, it would have to represent the cmc of CPB. However, the values obtained, which oscillate between 2.0×10^{-6} and 3.77×10^{-4} M, are always below the cmc of CPB. It has been described [29] that the coexistence of hydrocarbon molecules and surfactants can induce the formation of micelles and, in this way, a decrease in the cmc of the surfactant is produced. However, the great differences lead us to think that fluorescence inhibitions of the PAHs studied in this work are produced, to a large extent, by the intervention of premicellar clusters.

3.1.2. *Quantification of fluorescence inhibition*

In order to quantify the fluorescence inhibition that PAHs experience in the micellar medium, we used the term micellar inhibition factor (MIF), which relates the behaviour of PAHs in both media. Instead of measurements of fluorescence intensity, we have preferred to employ analytical sensitivities to calculate this factor. Thus we defined this factor as

$$\mathrm{MIF} = B_a/B_m$$

where B_m and B_a represent the slopes of the calibration graphs obtained in the presence and absence, respectively, of 2.6×10^{-3} M CPB. The values of B_m and B_a were obtained using the wavelengths of the optimum excitation and emission maxima in each medium. The values of the MIF found for each one of the PAHs considered in this study are shown in Table 2.

It must be indicated that even though for some PAHs, such as benz[*a*]anthracene and 2-methylphenanthrene, the high values of MIF are associated with the smallest values of analytical sensitivity in the micellar medium, for other derivatives, such as 9-methylanthracene and benzo[*a*]pyrene, the high values of MIF are a consequence of the high sensitivity that these hydrocarbons present in an aqueous medium.

Considering PAHs as a whole, we can conclude that alternant hydrocarbons experience, generally, greater inhibitions that non-alternant hydrocarbons. Although the inhibition processes are complex, this fact could be related to the reduction potentials of PAHs [30], which for non-alternant derivatives are about 0.4 V more positive than for alternant hydrocarbons. Consequently, the latter are better electron donors [31].

The efficiency of a quenching process is a measure of the inhibition that the fluorescence intensity emitted by a fluorophore experiences in the presence of a given quencher concentration or, on the contrary, it can represent the concentration of quencher that produces a fixed decrease in the fluorescence of a fluorophore. Consequently, the efficiency of the quenching (E_Q), in relative terms, can be defined by the equation [32]

Table 2
Quantification of the inhibition of the fluorescence of PAHs in micellar medium of CPB

Compound	Calibration graphs			MIF	$(C_{CPB})_{90}$ ($M \times 10^4$)
	Linear range ($M \times 10^6$)	$b \times 10^{-6}$	r		
Alternant PAHs:					
Naphthalene	0–10	5.61	0.992	97.5	5.0
Anthracene	0–4	2.21	0.999	800.0	4.0
9-Methylanthracene	0–4	3.95	0.999	1234.6	1.3
Phenanthrene	0–10	1.41	0.945	406.5	4.9
2-Methylphenanthrene	0–40	0.35	0.997	1098.9	4.3
Pyrene	0–2	3.80	0.998	584.8	7.0
Benz[*a*]anthracene	0–10	0.59	0.976	1190.5	8.0
Dibenz[*a*,*h*]anthracene	0–2	3.63	0.987	2.5	9.8
Benzo[*a*]pyrene	0–10	0.96	0.987	1612.9	12.2
Non-alternant PAHs:					
Fluorene	0–4	18.90	0.999	66.7	5.0
Acenaphthene	0–2	14.80	0.999	148.6	8.6
Acenaphthylene	0–40	0.36	0.999	123.2	13.0
Fluoranthene	0–2	13.50	0.999	6.1	6.2
Benzo[*b*]fluoranthene	0–2	25.40	0.997	7.9	8.6

$$E_Q = 1 - F/F_0$$

where F and F_0 represent the fluorescence intensities of each of the hydrocarbons in the presence and absence of the quencher, respectively. We express this efficiency as the cetylpyridinium bromide concentration necessary to produce an inhibition of 90% ($E_Q = 0.90$) in the fluorescence emitted by PAHs.

Table 2 shows that the CPB concentrations necessary to reach inhibitions of 90% are, generally, lower or close to the cmc of the surfactant, except in the case of the hydrocarbons dibenz[*a*,*h*]anthracene, benzo[*a*]pyrene and acenaphthylene.

For the CPB concentration used (2.6×10^{-3} M), generally, virtually total inhibition of the fluorescence emitted by naphthalene, anthracene, 9-methylanthracene, phenanthrene, 2-methylphenanthrene and pyrene was obtained, whereas for the remaining PAHs the fluorescence decreased in relation to that observed in the absence of CPB, which exceeded 90% in all cases.

3.1.3. *Considerations of analytical interest*

From the study of the influence of the micellar medium of CPB on the spectrofluorimetric characteristics of PAHs, some predictions of analytical interest can be made. Thus, the important shifts observed in the excitation spectra of PAHs can favour the development of a selective method for their determination. In the same way, the great differences existing in the MIF values could show the potential usefulness of the micellar medium to eliminate interferences in the determination of those PAHs whose fluorescence is less affected by the presence of CPB. This would be the case for non-alternant PAHs that, except for acenaphthylene, possess higher analytical sensitivity and lower MIF than the alternant. The contour map in Fig. 3 shows the possibility of obtaining differentiated signals for complex mixtures of PAHs in the micellar medium of CPB.

Also, it is possible to predict the selective determination of some PAHs by conventional spectrofluorimetry. Thus:

(1) Benzo[*b*]fluoranthene and fluoranthene present characteristic emission spectra between 400 and 540 nm, formed by several bands. Their excitation at short wavelengths and the measurement of fluorescence intensities at emission wavelengths longer than 430 nm could allow one to obtain differentiated sig-

nals from those corresponding to the rest of the PAHs.

(2) The use of excitation wavelengths between 270 and 300 nm and emission wavelengths between 300 and 320 nm could lead to representative spectra of fluorene, which is slightly affected by the presence of other PAHs, with the exception of acenaphthene and naphthalene.

(3) The maximum emission wavelength of perylene is only comparable to those of fluoranthene and benzo[*b*]fluoranthene. On the other hand, the micellar medium causes a shift in the maximum excitation wavelength of perylene, being located more than 100 nm above that corresponding to the other two derivatives. The selective determination of perylene by conventional spectrofluorimetry can be thought of in this way.

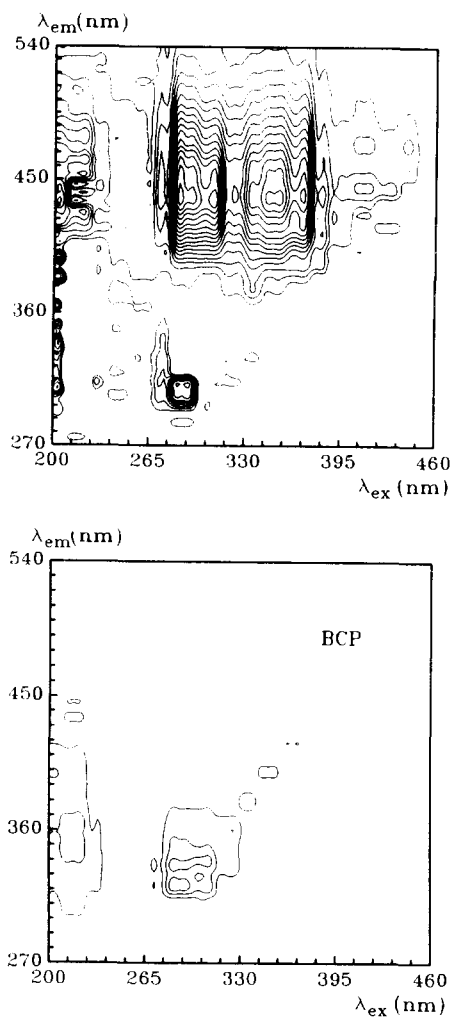

Fig. 3. Contour maps of a 2.6×10^{-3} M CPB solution and of an equimolar mixture of 15 PAHs in 2.6×10^{-3} M CPB corrected to subtract the blank.

3.2. *Synchronous fluorescence*

Synchronous spectra of the PAHs under study were obtained under the conditions indicated in the experimental section. Table 3 shows their main characteristics. Comparison of the micellar medium with the aqueous medium shows that the presence of CPB micelles does not produce important modifications in the Stokes shifts, except for naphthalene, anthracene, dibenz[*a*,*h*]anthracene and benzo[*b*]fluoranthene. The general trend observed could indicate that the micellar medium does not lead to important changes in the energetic distribution of the PAH molecules or that its effect is to stabilize the excited singlet states of the hydrocarbons.

Synchronous spectra must bear a certain relationship to conventional fluorescence spectra. For the purpose of comparison, the values of $\Delta\lambda$ representing the differences between the wavelengths of the emission and excitation maxima of conventional spectra, and also the corresponding values of the wavelength of excitation maxima and the Stokes shifts, can be obtained from Table 1. It can be observed that the values of $\Delta\lambda$ that produce the maximum intensity peaks of the synchronous spectra are near the $\Delta\lambda$ value obtained from conventional spectra. Furthermore, these $\Delta\lambda$ values almost coincide with the Stokes shift established for the hydrocarbons pyrene, perylene, benzo[*a*]pyrene, acenaphthene, acenaphthylene and fluorene. Likewise, it is observed that the wavelengths of the synchronous bands with the greatest intensity for each PAH are almost coincident with the wavelengths of the excitation maxima in conventional spectra for most of the PAHs. Only anthracene, with a difference of 19 nm, deviates from the general behaviour.

Table 3
Synchronous spectrofluorimetric characteristics of PAHs in a micellar medium of CPB

[a] Stokes shift in the absence of CPB.
[b] The values in italics correspond to the maximum fluorescence intensity.

The changes observed in the behaviour of the PAHs, together with the characteristics of the synchronous spectra, with regard to spectral simplification, small bandwidth and narrow spectral ranges, can provide satisfactory conditions for obtaining important selectivities in the individual determination of PAHs or in the resolution of their mixtures.

To select the optimum values of $\Delta\lambda$, synchronous contour maps were used instead of three-dimensional spectra. These maps were obtained by plotting fluorescence intensity as a function of the excitation wavelengths (horizontal axis) and of the difference ($\Delta\lambda$) between the emission and excitation wavelengths (vertical axis). Thus a set of contour lines that connect points of equal fluorescence intensity was obtained. Although the optimum values of $\Delta\lambda$ can also be selected through contour maps obtained from conventional spectra, the synchronous contour maps [19,33] can supply more selective information.

3.2.1. Consideration of analytical interest

From the synchronous contour maps (Fig. 4), we were able to make some predictions of analytical interest. The most interesting and numerous applications would be obtained at $\Delta\lambda < 50$ nm. Among these, the possible selective determination of perylene at $\Delta\lambda < 37$ nm, with $\lambda^0_{s,ex}$ around 430 nm, or fluorene at $\Delta\lambda \leqslant 10$ nm, with $\lambda^0_{s,ex} = 290$–300 nm, may be mentioned. With regard to the possible resolution of mixtures, Fig. 5 is a representative example of the potential that the combination of synchronous spectrofluorimetry and the micellar medium of CPB has for the analysis of complex mixtures of PAHs.

3.2.2. Relationship between synchronous signals and structure of PAHs in the micellar medium of CPB

As the synchronous signals of each PAH are confined to a limited number of bands within a definite spectral range, one can construct graphical representations which supply useful information about the relationship existing between characteristics of the synchronous spectrum of a PAH and its structure. Thus, Fig. 6 shows the wavelength value of the excitation (λ^0_{ex}) and emission (λ^0_{em}) peaks of PAHs, which present the

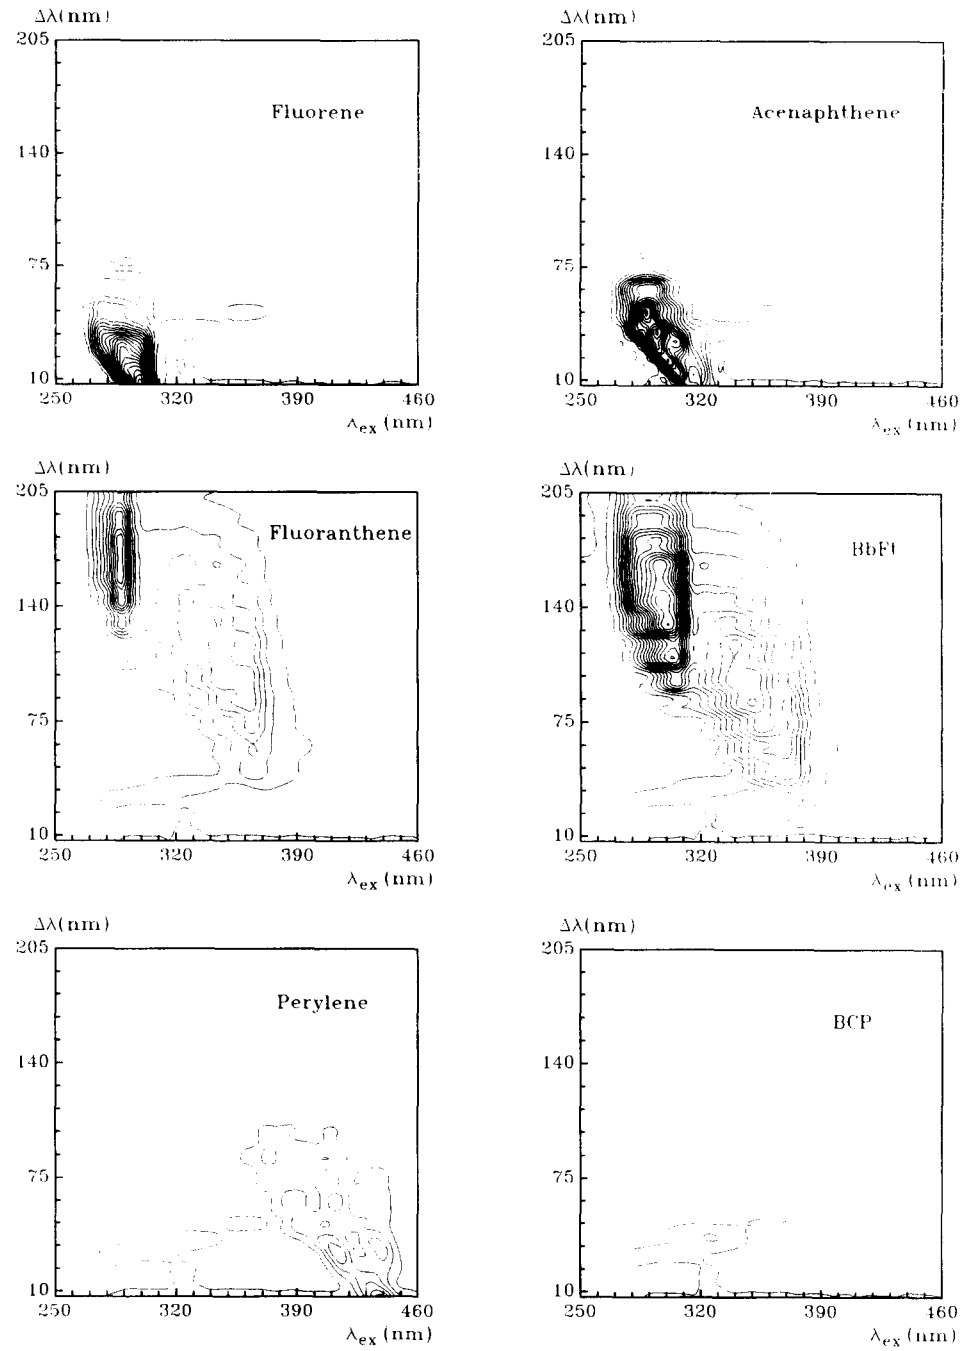

Fig. 4. Synchronous contour maps of a 2.6×10^{-3} M solution of CPB and of 2×10^{-6} M solutions of PAHs in a micellar medium of CPB. **BbFt**: benzo[*b*]fluoranthene.

highest and lowest values, respectively. As is known, both wavelengths limit the synchronous signal of each compound. From Fig. 6 we establish some interesting generalizations. Thus:

(1) Each PAH is identified by a point and significant differences are observed among most of them. The broken lines, representative of different values of $\Delta\lambda$, show that it is possible to obtain synchronous spectra of solutions containing complex mixtures of PAHs which would present characteristic bands for some hydrocarbons or groups of them.

(2) The signal of the 0–0 band of a hydrocarbon increases with increase in the number of rings of the PAH.

(3) Between the wavelengths λ^0_{ex} and λ^0_{em} for all the hydrocarbons considered, a good correlation ($r = 0.870$) exists, which improves considerably when the alternant PAHs are grouped (A) and when, the non-alternant PAHs are grouped (B). The correlation coefficients are 0.950 and 0.991, respectively. Also, the slopes of these lines can be considered as distinguishing parameters of both groups of PAHs.

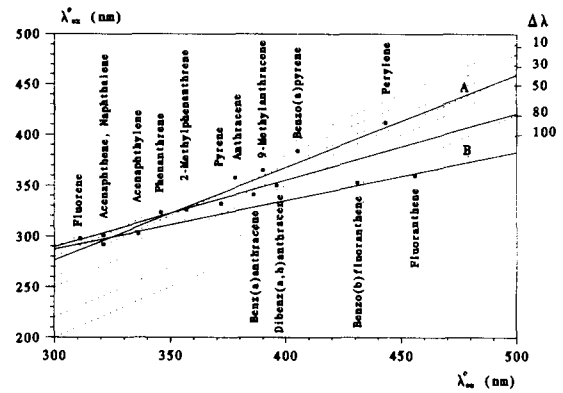

Fig. 6. Correlation between the structure of PAHs and synchronous signal. (A) Alternant PAHs; (B) non-alternant PAHs.

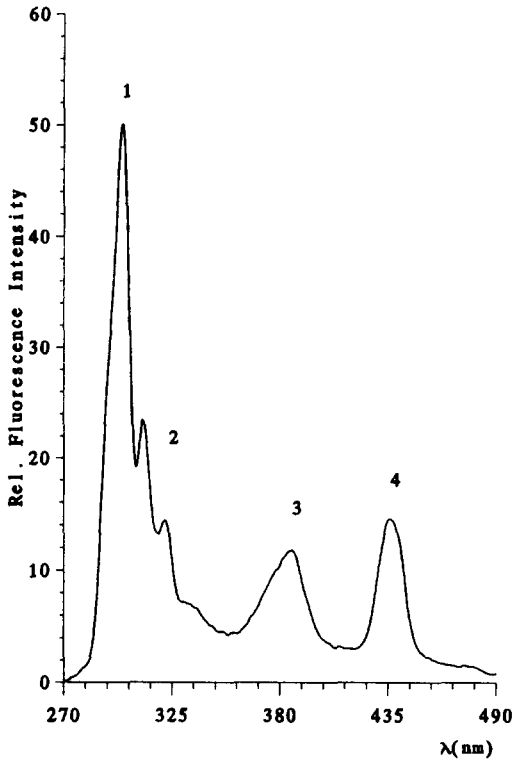

Fig. 5. Synchronous spectrum at $\Delta\lambda = 10$ nm of a mixture of 15 PAHs in a micellar medium of CPB. $C_{PAH} = 55.6$ ng ml^{-1}; $C_{CPB} = 2.6 \times 10^{-3}$ M. Slits: 5–6 nm. (1) Fluorene; (2) acenaphthene and naphthalene; (3) anthracene and 9-methylanthracene; (4) perylene.

It has already been mentioned [7] that there are certain relationships between the wavelengths in conventional fluorescence spectra and the structure of the respective PAHs. The data obtained from synchronous spectra show that also in this case, for a given $\Delta\lambda$ value, certain relationships are found which allow one to correlate values of $\lambda^0_{s,ex}$ with hydrocarbon aromaticity. For comparative purposes, Table 3 shows the wavelengths of the synchronous emission maxima ($\lambda^0_{s,ex}$) at different $\Delta\lambda$, corresponding to the different PAHs studied in a micellar medium of CPB.

From the experimental conditions used, some conclusions can be drawn, among which we would emphasize the following:

(1) Alternant PAHs:

Among these PAHs, which have only benzene rings, we can distinguish between:

(a) PAHs with a linear chain. Among the components of this subgroup, which have no substituents, an important bathochromic effect is observed when the number of aromatic rings

in the molecule increases. This was observed for naphthalene and anthracene.

The substitution of a methyl group in these PAHs leads to a slight bathochromic shift. This happens with 9-methylanthracene.

(b) PAHS with a non-linear chain. For an equal number of aromatic rings, the non-linear hydrocarbon shows a smaller wavelength of the synchronous maximum that the linear hydrocarbon. This is the case for anthracene and phenanthrene.

Also, among non-linear PAHs with an equal number of aromatic rings, a bathochromic shift is produced when the degree of condensation increases. This was observed for dibenz[*a*,*h*]anthracene, benzo[*a*]-pyrene and perylene.

With respect to the influence of the substituent, in the case studied, the introduction of a methyl group in phenanthrene does not lead to a considerable shift in the synchronous band of 2-methylphenanthrene.

(2) Non-alternant PAHs:

The substitution of an aromatic ring by another with a cyclic nature induces a hypsochromic shift. This was observed with anthracene and fluorene.

The introduction of a five-membered ring between two aromatic rings induces a low hypsochromic shift. This is the case for naphthalene and fluorene.

The introduction of a five-membered ring at the α, α'-position of naphthalene hardly induces any shift in the value of $\lambda^0_{s,ex}$.

The addition of one or two aromatic rings to a non-alternant PAH leads to bathochromic shifts. This occurs for acenaphthene, fluorene, fluoranthene and benzo[*b*] fluoranthene.

Flame atomic absorption spectrometric determination of copper, zinc, calcium, magnesium and iron in fresh eggs using microvolume injection

Sufen Shang* and Wang Hong

Department of Chemistry, He Bei University, 071002, Baoding, People's Republic of China

Received 12 April 1996; revised 2 July 1996; accepted 5 July 1996

Abstract

The flame atomic absorption spectrometric determination of copper, zinc, calcium, magnesium and iron in fresh eggs using a microvolume injection technique is described. The capillary tube and glass impact bead were removed from the nebulizer and a polypropylene tube was installed in the inlet of the capillary tube of the nebulizer as the interface for microvolume injection. The injection volume was 10 μl and calibration was carried out using aqueous standards. Beer's law was obeyed in the concentration ranges of 0.1–1.5, 0.1–3.0, 0.2–4.0, 0.5–4.0 and 1.0–6.0 mg l^{-1} for Cu, Zn, Ca, Mg and Fe, respectively, and the detection limits were 0.016, 0.016, 0.035, 0.010 and 0.10 mg l^{-1}, respectively. The reliability of the measurements was confirmed by analyzing a certified reference material, GBW 08551 Pork Liver. The precision was 2.6, 2.9, 3.0, 1.3 and 2.5% for Cu, Zn, Ca, Mg and Fe, respectively. The recovery with the standard additions method was good, ranging from 96.2 to 100.0%.

Keywords: Flame atomic absorption spectrometry; Fresh eggs; Metals; Microvolume injection

1. Introduction

Cu, Zn, Ca, Mg and Fe are essential elements in the human body and occur naturally in most fresh vegetables, meats, grains and eggs. The study of essential elements in foodstuffs is of great importance since they play a definitive role in the intrinsic mechanisms regulating vital biological processes [1–3]. Fresh eggs are among the most important and nutritious foods in the daily diet. Many methods have been developed for the determination of essential elements in eggs, such as spectrophotometry and atomic absorption spectrometry [4–6]. These methods usually include several tedious steps including preseparation and preconcentration. Additionally, the amount or volume of sample must be large owing to the low sensitivity of determination. Hence, they are time consuming, complicated and costly in application.

PII S0039-9140(96)02044-9

The purpose of the present investigation was to develop a simple and sensitive method for the determination of these essential elements in fresh eggs by flame atomic absorption spectometry (FAAS) with microvolume injection. The proposed method is based on the use of a polypropylene tube installed in the inlet of the capillary tube of the nebulizer as the interface for microvolume injection. The volume injected was 10 μl. The accuracy of this method was tested by the analysis of a certified reference material. The method is accurate, rapid and economical. The contents of these essential elements in fresh eggs from different districts of China are reported.

2. Experimental

2.1. Instrumentation

A Model WFX-1 F2 (Beijing, China) atomic absorption spectometer was used throughout. A metal-free Eppendorf adjustable-volume digital pipette was applied for microvolume injection. A polypropylene tube was coupled to the inlet of the capillary tube of the nebulizer (the capillary tube had already been removed) as the interface for microvolume injection.

The equipment used, polypropylene vessels, polytetrafluoroethylene (PTFE) calibrated flasks, pipettes and micropipette tips were throughly cleaned by soaking for 24 h in freshly prepared 15% HNO_3, rinsed with doubly distilled, deionized water and dried at 40°C in a dust-free environment.

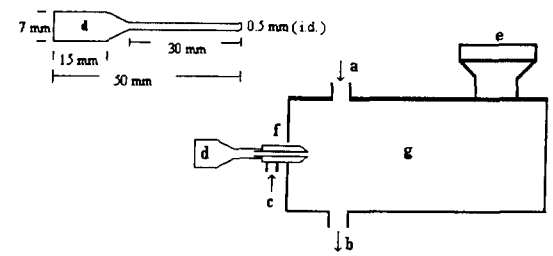

Fig. 1. Microvolume injection installation. a, Acetylene; b, drain; c, air; d, polypropylene tube; e, burner, f, nebulizer; g, spray chamber.

2.1. Reagents and materials

The certified reference material used was GBW 08551 (Pork Liver) from the National Bureau of Environment Protection (Beijing, China) with certified values of 17.2 ± 0.75, 172 ± 8.5, 197 ± 9.0, 747 ± 20 and 1050 ± 35 μg g^{-1} for Cu, Zn, Ca, Mg and Fe, respectively. All reagents were of analytical-reagent grade or better. Aqueous solutions were prepared with doubly distilled, deionized water. High-purity metal salts were used to prepare 1000 mg l^{-1} of stock standard solutions, which were stored in precleaned polypropylene bottles. Working standard solutions were freshly prepared by successive dilution of the stock standard solution to the desired concentration using 0.2% HNO_3.

2.3. Installation of microvolume injection

Some improvements to the instrument were made for the determination of elements with microvolume injection. The capillary tube and

glass impact bead were removed from the nebulizer. A polypropylene tube was installed in the inlet of the capillary tube of the nebulizer as the interface for microvolume injection (as shown in Fig. 1). The metal-free Eppendorf adjustable-volume digital pipette was used to draw the standard solution or sample solution and inject it into the polypropylene tube.

The nebulizer was rinsed with doubly distilled, deionized water and the pipette tips were replaced after each injection. The injection volume was 10 μl for standard solutions and sample solutions. The concentrations of Cu, Zn, Ca, Mg and Fe in the sample solutions were obtained from their respective calibration graphs. After the blank correction, the levels of Cu, Zn, Ca, Mg and Fe present in the sample were calculated.

2.4. Analytical conditions and calibration

The optimum analytical parameters used for the determination of the elements studied by FAAS with an air–acetylene flame are given in Table 1.

The light sources were single-element hollow-cathode lamps whose operating parameters were those recommended by the manufacturer.

Calibration against standard solutions was performed for all elements and the calibration graphs were linear in the ranges 0.1–1.5, 0.1–3.0, 0.2–4.0, 0.5–4.0 and 1.0–6.0 mg l^{-1} for Cu, Zn, Ca, Mg and Fe, respectively. The correlation coefficients were >0.999 for all calibration graphs. By considering the level of the elements in fresh egg samples and the convenience of determination, we chose narrower linear ranges for the determination of elements in fresh egg samples and the linear regression equations along with the sensitivity of the calibration graphs are listed in Table 2.

The limits of detection were calculated as twice the standard deviation of the mean blank value. Blank absorbance values were monitored throughout the period of the experiment and were subtracted from the readings before the results were calculated.

2.5. Digestion and measurement

The certified reference material was treated as follows: 1 g of sample was weighed accurately and placed in a PTFE bomb with 3 ml of HNO_3 and 1 ml of H_2O_2. The PTFE bomb was then placed in a microwave oven and irradiated for 10 min at 300 W. After cooling to ambient temperature, the

digest was diluted to 10 ml with doubly distilled, deionized water in a calibrated PTFE flask.

The egg samples were treated as follows: seven eggs were taken at random, broken and mixed in a homogenizer for a few seconds, then 1 g of sample was weighed accurately in a 50 ml glass beaker containing 3 ml of HNO_3 and 1 ml of H_2O_2. The beaker was placed on an electric heating plate and heated at 180–190°C. The dried digest was dissolved in doubly distilled, deionized water and transferred into a 5.00 ml PTFE calibrated flask and diluted to the mark for the determination of Cu, Fe, Ca and Mg. Another 0.25 g of sample was weighed accurately and placed in a PTFE bomb with 3 ml of HNO_3 and 1 ml of H_2O_2. The PTFE bomb was then placed in a microwave and irradiated for 7 min at 300 W. After cooling to ambient temperature, the digested was diluted to 2 ml with doubly distilled, deionized water in a calibrated PTFE flask for the determination of Zn.

The metal-free Eppendorf adjustable-volume digital pipette was used to draw the standard and sample solutions, which were then injected into the polypropylene tube (Fig. 1) and immediately aspirated from the polypropylene tube into the nebulizer by suction (venturi action) caused by the rapid flow of support gas (air) past the capillary tip. The nebulizer was rinsed with doubly distilled, deionized water and the pipette tip was replaced after each injection. The injection volume was 10 μl for standard and sample solutions. The concentrations of Cu, Zn, Ca, Mg and Fe in the sample solution were obtained from their respective calibration graphs. After the blank correction, the levels of Cu, Zn, Ca, Mg and Fe present in the sample were calculated.

2.6. Analytical quality validation

In order to validate the accuracy of the proposed method, the procedure was applied to a certified reference material (GBW 08551 Pork Liver). The results are shown in Table 3. The standard additions method was used for recovery studies of the elements determined and the results are listed in Table 4.

3. Results and discussion

3.1. Effect of integration time

It took 1.5 s for a 10 μl sample to reach a steady-state signal in the flame and it was also

[b] 95% of confidence level.

found that the largest signal was obtained when the integration time was chosen as 1.5 s. Considering the sensitivity of the determination, the integration time was set as 1.5 s.

3.2. Effect of injection volume

The influence of the injection volume was studied. The same results for the relationship between the integrated absorbance value and the injection volume were obtained for all five elements. For the five elements tested it was found that the integrated absorbance value increased with increases in the injection volume in the range 5–75 μl. If the injection volume was over 75 μl, the integrated absorbance value decreased because the amount of element exceeded the linear range of Beer's law. Moreover, the injection of large volumes produced serious contamination of the nebulizer and caused high background signals. Since an injection volume of 10 μl was sufficient for the determination of the elements studied, 10 μl was chosen as the injection volume for the analysis of standard and sample solutions.

3.3. Effect of temperature of spray chamber

The temperature of the spray chamber had no influence on the analytical results and it was found that if the temperature of the spray chamber was increased contamination of the spray chamber became very serious, especially for the determination of Mg and Fe. Hence the spray chamber was not heated.

3.4. Effect of glass impact bead

In the normal nebulization mode the sample uptake rate is usually 3–8 ml min^{-1} and a glass impact bead is used to improve the dispersion of liquid droplets to produce fine aerosol particles in conventional FAAS. Since the volume of sampling is just 10 μl, the fine aerosol particles were formed without using the glass impact bead. We also attempted to use the glass impact bead to obtain finer aerosol particles, but it was found that this decreased the sensitivity of the microvolume injection method and produced scattered analytical results. This is due to the contamination of elements determined on the surface of the glass impact bead, which became more serious for a 10 μl sampling volume corresponding to the general volume of sampling (i.e. ml level) in the normal nebulization mode. Therefore, the glass impact bead was removed to increase the sensitivity and repeatability of analysis.

The accuracy was verified by analyzing the certified standard reference material, as shown in Table 3. For all elements, the precision (R.S.D.) was better than 3.0%. The reliability of the analytical method was further assessed through recovery studies, by performing seven replicate spectrometric determinations of the elements under consideration in real samples with the standard additions

method. The average recoveries were better than 96% for all elements, as shown in Table 4.

3.5. Applications of the method

The proposed method was applied to the determination of Cu, Zn, Ca, Mg and Fe in fresh egg samples from four districts in China. The number of determinations for each element was seven and the analytical data treated statistically ($P = 0.05$). No significant skin-color difference was found and the Cu/Zn ratios also did not show significant differences for the eggs from the four districts, but the Ca/Mg ratios showed obvious differences due to the different sources of feed. The results are listed in Table 5.

The comparison of analytical results obtained in the normal nebulization mode with those obtained by the microvolume injection method are listed in Table 6. The fresh egg samples were from the city of Baoding. The results of comparison using statistical analysis ($P = 0.05$) showed that there were no significant differences for the standard deviations ($F_c < F_t$) and the mean values ($t_c < t_t$) of the two methods.

In conclusion, the FAAS microvolume injection technique described is a economical, simple and rapid means for the determination of trace elements in fresh eggs. The injection volume was just 10 μl for the determination of the elements studied. It is suitable for the routine determination of elements in foodstuffs. The method could be of interest in poultry and nutriology research and can be recommeded for routine analyses. The proposed method can also be applied to the determination of elements in other types of matrices.

Abstract

The complexation reaction between a macrocyclic polyether, 18-crown-6 (18C6), and potassium ion was studied in methanol (MeOH)–acetonitrile (AN), dimethylformamide (DMF)–AN and propylecarbonate (PC)–DMF binary solvent systems at different temperatures using a conductometric method. It was found that the stability of the 1:1 complex formed between K^+ ion and this ligand increases with decreasing temperature. Standard enthalpies and standard entropies of the complex formation were obtained from the temperature dependence of the stability constant. In all cases negative ΔH_c° and ΔS_c° values characterize the formation of 18C6–K^+ complex. The results obtained show that the stability of the complex is governed by the solvent medium and the thermodynamic parameters ΔH_c°, $\Delta S^\circ{}_c$ and $\Delta G^\circ{}_c$ are sensitive to the composition of the mixed solvents. In addition, it was found that the stability constant of the resulting 1:1 complex among various neat solvents used varies in the order PC > MeOH > AN > DMF.

1. Introduction

Crown ethers have been demonstrated to be highly selective complexing agents for many metal ions and can potentially be applied in thier separation [1–4] and determination. Thermodynamic studies of macrocyclic complexation reactions with metal ions not only result in important information on the thermodynamics of complexation reaction, but also lead to a better understanding of the high selectivity of these ligands towards different metal cations.

While macrocyclic complexes of alkali metal cations have been extensively investigated in aqueous solutions and in a wide variety of neat non-aqueous solvents [5–7], the complexation reactions of these complexes in mixed solvent systems have been investigated only to a very limited extent [7–10]. It is well known that the stability and selectivity of complexations strongly depend

PII S0039-9140(96)02045-0

on the solvating ability of the solvent. It was of interest to us, therefore, to investigate the dependence of the stability constant and thermodynamic parameters of the 18-crown-6 (18C6)-K^+ complex on the composition of several binary solvent mixtures in order to see how the thermodynamics of complexation are affected by the solvent composition.

A large number of physico-chemical techniques such as NMR spectrometry [11–18], calorimetry [19–22], polarography [23,24], spectrophotometry [25–27], conductometry [28–35] and potentiometry [36–39] have been used to study the complex formation between macrocyclic polyethers and alkali metal cations in solutions. Among these various methods, the conductometric technique is a sensitive and inexpensive method with a simple experimental arrangement for such investigations.

In the present study, the formation constant of the 18C6–K^+ complex in acetonitrile (AN)–methanol—(MeOH), AN–dimethylformamide (DMF) and propylene carbonate (PC)–DMF binary solvent systems was determined at different temperatures by the conductometric method.

2. Experimental

2.1. Reagents and solvents

All compounds were obtained from Merck. 18-crown-6 was recrystallized from acetonitrile and dried under vacuum for 72 h at room temperature [40]. Potassium perchlorate was recrystallized from deionized, distilled water three times, dried at 150°C and then kept in a vacuum desicinator over P_2O_5 for 48 h. The solvents were refluxed for 2 days over P_2O_5 dehydration agent, and then fractionally distilled. The middle 70% of the distillate was used. The conductivity of the final product was 2×10^{-7} Ω^{-1} cm^{-1} at 25°C.

The experimental procedure to obtain the formation constant of the 18C6–K^+ complex was as follows. A solution of potassium perchlorate (5×10^{-4} M, 200 cm^3) was placed in a titration cell, thermostated at a given temperature, and the conductance of the solution was measured. A step-by-step increase in the crown ether concentration was effected by a rapid transfer from crown ether solution prepared in the same solvent (2.5×10^{-3}–1.5×10^{-3} M) to the titration cell using a microburet, until the total concentration of the crown ether was approximately five times higher than that of potassium perchlorate. The conductance of the solution was measured after each transfer.

2.2. Apparatus

The conductance measurements were performed on a Metrohm (Herisau, Switzerland) Model 9100, conductometer in a water-bath ultrathermostat with a constant temperature maintained within ±0.05°C. The electrolytic conductance was measured using cells consisting of two platinum electrodes to which an alternating potential was applied. Two cells with cell constants of 0.64998 and 0.71699 cm^{-1} were used throughout.

3. Results

The variation of molar conductance versus the [18C6]/[K^+] mole ratio for the 18C6–K^+ crown ether complex in AN–DMF, MeOH–AN and PC–DMF binary mixtures were studied at different temperatures. As a typical example, the molar conductance–mole ratio plots for the 18C6–K^+ complex in MeOH–AN (75:25) is shown in Fig. 1. Similar behavior was observed with the other systems.

Since the 18C6 concentration was kept low ($\leq 2.5 \times 10^{-3}$ M) during these experiments, corrections for viscosity changes were neglected. It was also assumed that the association between the potassium ion and perchlorate ion in An, PC, DMF, MeOH and their binary mixtures is negligible under these highly dilute experimental conditions and that 18C6 forms a 1:1 complex with potassium ion in these non-aqueous solvents systems.

A conductometric method for the determination of the stability constants of complexes of crown ethers with metal ions has been used by several investigators [29–35]. The 1:1 binding of an alkali metal cation (M^+) with the crown ethers can be represented by the following equilibrium equation:

$$M^+ + L \rightleftharpoons ML^+ \quad (1)$$

$$\alpha[M]_t[L]_t - (1-\alpha)[M]_t(1-\alpha)[M]_t$$

where M^+, L, ML^+ and α are the alkali metal ion, the crown ether, the complex and the fraction of the free alkali metal ion, respectively. The complex formation constant in terms of the molar concentration can be expressed as

$$k_{ML^+} = \frac{[ML^+]}{[M^+][L]} = \frac{1-\alpha}{\alpha[L]} \quad (2)$$

The observed conductivity, k, at each point in the titration can be written as [35]

$$k = K_{MC10_4} + K_{MLC10_4} \quad (3)$$

where K_{MC10_4} and K_{MLC10_4} are the conductivities of the alkali metal perchlorate and alkali metal crown ether perchlorate, respecitvely. The molar conductivities are given by

$$\Omega_{MC10_4} = \frac{K_{MC10_4}}{[M^+]} = \frac{K_{MC10_4}}{\alpha[M]_t} \quad (4)$$

$$\Omega_{MLClO_4} = \frac{K_{MLClO_4}}{[ML^+]} = \frac{K_{MLClO_4}}{(1-\alpha)M_t} \quad (5)$$

where Ω_{MClO_4} and Ω_{MLClO_4} are the molar conductivities of the alkali metal perchlorate and alkali metal crown ether perchlorate, respectively. As a consequence of Eqs. (4) and (5), Eq. (3) can be transformed into

$$\Omega = \frac{K}{[M]_t} = \alpha\Omega_{MClO_4} + (1-\alpha)\Omega_{MLClO_4} \quad (6)$$

Substituting from Eq. (6) into Eq. (2) gives the following equation:

$$K_{ML^+} = \frac{\Omega_{MClO_4} - \Omega}{(\Omega - \Omega_{MClO_4})[L]} \quad (7)$$

where

$$[L] = [L]_t - \frac{[M]_t(\Omega_{MClO_4} - \Omega)}{\Omega_{MClO_4} - \Omega_{MLClO_4}}$$

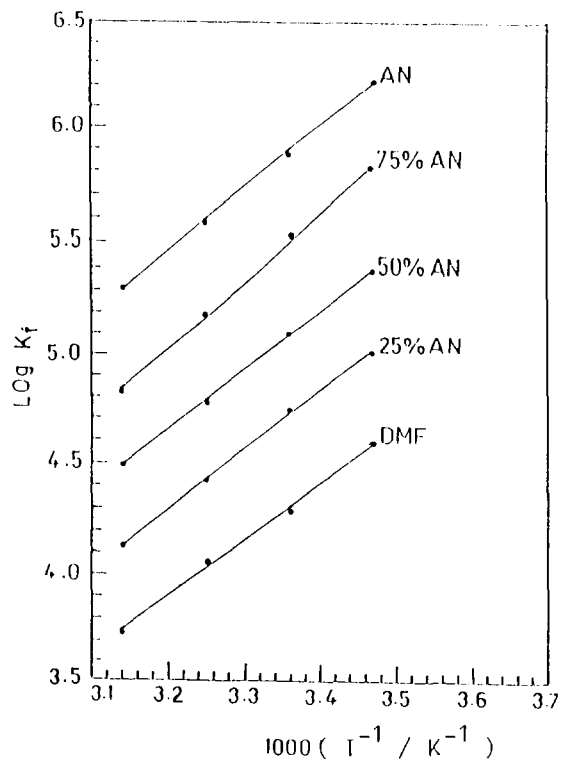

Fig. 2. Van't Hoff plots for 18C6–K^+ complex in AN and DMF and their binary mixtures.

The procedure for obtaining the K_{ML^+} value is as follows. The value of Ω_{MLClO_4} is estimated from the Ω values at points of large $[L]_t$ to $[M]_t$ ratios. The molar conductance data obtained from complexation studies were fitted non-linearly to the Eq. (7), using the Genplot package from Computer Graphic Service [41]. The K_{ML^+} and the estimated Ω_{MLClO_4} at large $[L]_t$ ratios were used as variables until best convergence was obtained.

All calculated normal stability constants K_f° for the 1:1 18C6–K^+ complex in various solvent systems are listed in Table 1. Assuming that the activity coefficients of potassium and 18C6 ions have the same value, K_f° is a thermodynamic equilibrium constant on the molar concentration scale, related to the Gibbs standard energy of the complexation reaction, ΔG°, on the same scale.

Van't Hoff plots of log K_f vs. 1/I for all the systems investigated were constructed. A typical example of these plots is shown in Fig. 2. The changes in the standard enthalpy (ΔH_c°) for the complexation reaction were obtained from the slopes of the van't Hoff plots and the changes in standard entropy ($\Delta_{S_c}^\circ$) were calculated from the relationship $\Delta G_{c,298}^\circ = \Delta H_c^\circ - 298.15\Delta S_c^\circ$. The results are summarized in Table 2.

4. Discussion

Macrocyclic ligands such as crown ethers have been used successfully for diverse processes such as ion transport across artificial and biological membranes, ionic separation and extraction, design of ion-selective electrodes and in the understanding of some natural processes through mimicry of metalloenzymes [42–45]. Their selectivity for specific ions suggests that they may be of utility in the treatment of metallurgical waste streams. Most applications of crown ethers are based on their selective binding with certain cations in solutions.

The stabilities and selectivities on complexation are mainly governed by the solvent medium and the relative sizes of the cation and crown ether cavity. During the complexation step, the ligand should be able to replace as completely as possible the solvent molecules in the first solvation shell of

the cation. As a result, variations in the nature of the solvent produce significant changes in the binding properties of the macrocyclic ligand, so that the stability and selectivity for a certain cation over others may be greatly altered according to the nature of the solvent.

Valuable chemical information could be obtained from thermodynamic studies of the interactions between macrocyclic crown ethers and ions in solutions. It was of interest to us to investigate the dependence of complex stabilities and thermodynamic parameters on the composition of several binary solvent mixtures in order to see how variations of the solvent composition affect the stability of complexation. For our initial studies we selected the K^+ ion as the probe cation and used conductometric measurements to determine the stability constant of the potassium complex with 18C6 at different temperatures.

It is obvious from Fig. 1 that addition of the ligand to K^+ ion in solution causes a continuous decrease in the molar conductance, which begins to level off at mole ratios >1. The slope of the corresponding mole ratio plots changes sharply at the point where the ligand to cation mole ratio is 1, indicating the formation of a relatively stable 1:1 complex.

However, in the case of pure DMF (Fig. 3), a gradual decrease in the molar conductance of K^+ ion on addition of the ligand is observed which does not exhibit any considerable change in curvature at a mole ratio of ca. 1, indicating that a weaker 1:1 complex is formed.

The solvation of the ligand and metal cation is influenced by the donor ability and dielectric constant of the solvent and by the shape and size of the solvent molecules. Generally, we expect that in solvents with a high donor ability and dielectric constant, the stability constant of the complex should decrease owing to the competition between the ligand and the solvent molecules for the metal ion. However, it has been shown that the donor ability of the solvent plays the most important role in the behaviour of alkali metal–crown ether complexes in non-aqueous solvents [46]. The results obtained in this work fit this generality with the exception indicated above.

As an example, the variation of the stability constant with the composition of the MeOH–AN binary system is shown in Fig. 4. Similar behavior was observed in the other sytems, i.e. as the mole fraction of MeOH, AN and PC increases in AN–MeOH, AN–DMF and PC–DMF binary mixtures, the stability constant of the 18C6–K^+ complex increases linearly at all temperatures.

As is obvious from Table 1, the stability constant of the 18C6–K^+ complex among various neat solvents decreases in the order PC > MeOH > AN > DMF. This behavior reflects the much stronger cation solvation by DMF, compared with the other solvents, with which the polyether has to complete. DMF (Donor Number = 26.6 K·cal mol^{-1}) with a high donor ability can solvate the K^+ ion strongly and, therefore, compete with the ligand for the potassium ion. Therefore, in this solvent the formation of the 18C6–K^+ complex is weakened.

In strong solvating sovents, such as DMF, the complex formation is poor, whereas in solvents with medium donicites, such as PC and AN, a more stable complex is formed. It is interesting that although DMF and AN have comparable dielectric constants, the formation constant of the complex in AN, a poor donor solvent, is much higher than that in DMF, which has a larger donor number. This indicates that the dielectric constant of the solvent is not a dominant factor in this complexation reaction.

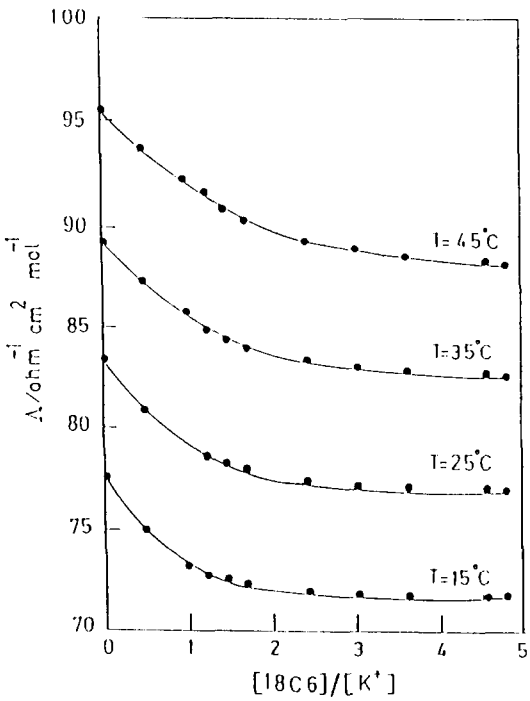

Fig. 3. Molar conductance–mole ratio plots for 18C6–K^+ complex in DMF at different temperatures. Concentration of $KClO_4 = 5 \times 10^{-4}$ M.

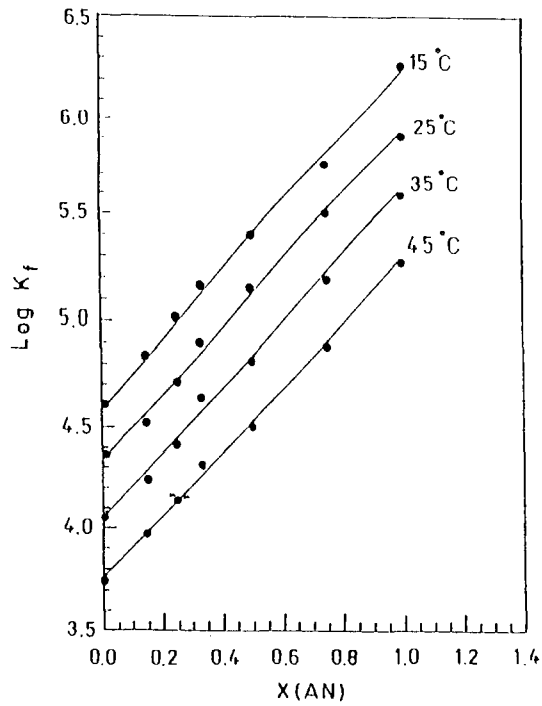

Fig. 4. Variations of stability constant of 18C6–K^+ complex with the composition of the AN–DMF binary system at different temperatures.

Although the donor ability of MeOH is greater than that of AN, the stability constant of the crown ether–K^+ complex in AN is lower than that in MEOH. This behaviour may be due to the fact that the AN molecules form a molecular complex with 18C6 [24].

The normal stability constant (K_f°) of the complex is related to the net changes of standard free energy, ΔG_c°, standard enthalpy, ΔH_c°, and standard entropy, ΔS_c°, of complexation. From these functions, important conclusions may be drawn about the various factors governing complex formation, such as solvation effects, the character of the coordinating bond and the changes in the structure that often take place during complex formation.

The thermodynamic parameters for complex formation are given in Table 2. As expected, the values of ΔH_c° and ΔS_c° depend strongly on the

nature of the medium used. The value and the sign of the standard entropy changes are expected to vary with different parameter, such as changes in flexibility of the macrocyclic ligands during the complexation processes and the extent of cation–solvent, crown ether–solvent and complex–solvent interactions.

Experimental values of ΔH_c° and ΔS_c° for the 18C6–K^+ system in AN–DMF, AN–MeOH and PC–DMF show that in all cases the complexes are enthalpy stabilized but entropy destabilized. On the other hand, the thermodynamic parameters (ΔG_c°, ΔH_c° and ΔS_c°) are sensitive to the composition of the mixed solvents.

It seems reasonable to assume that the decrease in entropy on complexation is related to a change in the conformational entropy of the ligand. It is known that macrocyclic ligands are fairly flexible in free state, and therefore the negative entropy changes may be attributed to the increased ligand rigidity on coordination. It should be stressed, however, that the conformational change of the ligand is not the only factor governing the change in entropy of complexation. The complexation reaction involves not only a change in the solvation of the cation, but also that of the ligand. The relative enthalpy and entropy changes can be understood if ligand solvation is taken into consideration. Information on the interaction of macrocyclic ligand with the solvent molecules is sparse, and addtional studies on the ligand–solvent interaction are necessary before the thermodynamic behavior of macrocyclic complexes in non-aqueous solvents can be better understood.

The data in Table 2 show that in DMF–AN and DMF–PC binary mixtures, lowering the concentration of DMF results in a decrease in ΔG_c° and ΔH_c° but an increase in ΔS_c°. In a strong solvating solvent such as DMF the solvation of the metal ion (and probably that of the ligand) will be stronger than in solvents of lower solvating ability such as AN and PC. Therefore, less energy is necessary for desolvation step of the cation (and probably of the ligand) in the case of AN and PC than DMF solutions.

Received 22 January 1996; revised 8 July 1996; accepted 12 July 1996

Abstract

This paper deals with the development and standardization of procedures for the determination of uranium on a routine basis in various process streams of a uranium extraction plant, covering a wide range of concentrations from 350 g l^{-1} down to 5 mg l^{-1} using only a spectrophotometric technique. The self-absorption of uranyl ion in dilute phosphoric acid and the violet–blue colour of the UO_2^{2+}–Arsenazo III complex in 4 M HCl were exploited for high and low concentrations of uranium, respectively. The methods described were applied to samples of varying nature such as aqueous, organics and solids, involve minimal sample preparation and do not require prior separation of uranium from impurities. The interfering impurities in different process streams were also studied. Large quantities of silica as undissolved material poses a serious interference in the case of UNS and UNF. Considerable quantities of iron in UNS, UNF, UNR and UNRC cause interference. Possible remedies in these cases are suggested. Problems with the direct spectrophotometric measurement of organic samples is discussed. The effect of the presence of large quantities of ammonium nitrate and sodium nitrate in WD samples on the determination of uranium is also discussed. The results are compared with those obtained by volumetry and X-ray fluorescence spectrometry for higher concentrations of uranium and by extraction–spectrophotometry (ethyl acetate–thiocyanate method) for lower concentrations. Relative standard deviation of 1% and 5% for high and low concentrations, respectively, were obtained, which are adequate as far as process stream samples are concerned. The compared results are in fair agreement. The problems associated with the determination of uranium in these process streams are discussed. Experimental results for 10 different process streams normally encountered in a uranium extraction plant are tabulated.

Keywords: Process streams; Spectrophotometry; Uranium

1. Introduction

Uranium dioxide powder is a starting material for the manufacture of fuel pellets which are widely used in nuclear power reactors. Its produc-

tion involves various steps: leaching of uranium from the ore with sulphuric acid [1], purification using anion exchange [2], precipitation of uranium as magnesium diuranate (MDU), purification through solvent extraction [3], precipitation of uranium as ammonium diuranate (ADU) [4], drying, calcination and reduction to uranium dioxide. In our uranium extraction plant, MDU is dissolved in nitric acid and uranium is extracted with tri-*n*-butyl phosphate (TBP) in kerosene and after stripping is precipitated as ADU. In this process, one encounters various process streams such as uranyl nitrate slurry (UNS), uranyl nitrate feed (UNF), uranyl nitrate pure solution (UNPS), uranyl nitrate pure solution evaporated (UNPE), uranyl nitrate extract (UNE), uranyl nitrate lean solvent (UNLS), uranyl nitrate raffinate (UNR), uranyl nitrate raffinate cake (UNRC) and waste disposals (WD1 and WD2). The monitoring of the concentration of uranium in these process streams is essential, each for a different purpose. For example, the knowledge of concentration of uranium in UNR is important for evaluating the efficiency of extraction, in UNE for effective utilization of the extractant and in UNLS for the efficiency of stripping. Some of these process streams, such as UNS, UNF, UNR and UNRC, contain a host of impurities which originate from the eluate in the anion-exchange purification stage as it contains some of the impurities present in the ore and those picked up due to the addition of calcined dolamite to precipitate uranium as MDU. Thus, the determination of uranium in these process streams on a routine basis, covering a wide range of concentrations and without its separation from the impurities, by a single technique having the advantages of simplicity, rapidity, sensitivity, adequate accuracy and precision and cost effectiveness is highly desirable.

There are various techniques, such as gravimetry [5], volumetry [6a], fluorimetry [7], potentiometry [8] polarography [9], coulometry [10], X-ray fluorescence spectrometry (XRF) [11] and spectrophotometry [12,13], for the determination of uranium, spanning very high to very low concentrations. Gravimetric methods require, in general, the absence of or prior separation of interfering elements. Also, they are used for high concentrations of uranium and are time consuming. Volumetric methods involve a number of steps and the use of many chemicals. Fluorimetry, being a sensitive technique, is applicable to low levels of uranium. Electroanalytical techniques, in general, are not preferred on a routine basis. XRF, especially the wavelength-dispersive method, is not sensitive for estimations at low levels and is not cost effective.

Spectrophotometry is increasingly employed in process control owing to its simplicity and adaptability for automation [14,15]. Hence it was decided to exploit this technique for the present purpose. A study of the available information revealed that most of the spectrophotometric methods for low levels of uranium involve prior separation of uranium from impurities by solvent extraction and reduction of Fe(III) to Fe(II) to avoid its interference, followed by the addition of chromophoric reagents such as thiocyanate [16], hydrogen peroxide [17] or hexacyanoferrate(II) [18] to the organic phase. The methods for the determination of macro amounts of uranium in various mineral acids such as HCl [19] and HNO_3 [20] and the determination of uranium directly in TBP are applied mainly to pure solutions and to the extracts obtained with analytical reagent grade TBP [21a], respectively. Also, the information is scattered in various publications and does not emphasize the applicability of the methods to industrial solutions such as the process streams mentioned above. Hence a systematic study was undertaken to develop and standardize procedures for the determination of uranium, on a routine basis, in industrial solutions, where the concentration spans the range from 350 g l^{-1} to as low as 5 mg l^{-1}, using only a spectrophotometric technique.

For this purpose, the low molar absorptivity of the self-absorption of uranyl ion and the selectivity of Arsenazo III (3,6-bis[(arsenophenyl)azo]-4,5-dihydroxy-2,7-naphthalenedisulphonic acid) towards uranyl ion in 2–4 M HCl and the high molar extinction coefficient of the UO_2^{2+}–Arsenazo III complex were exploited for high and low concentrations of uranium, respectively.

2. Experimental

2.1. Reagents

All the reagents used were of analytical grade. Demineralized (DM) water was used for dilution wherever it is not specified. Phosphoric acid (1:1) was taken as a dilute acid.

To prepare 0.1% Arsenazo III solution, 0.1 g of Arsenazo III and 0.5 g of sodium acetate were dissolved in 100 ml of water. The solution was stored in an amber-glass bottle.

A standard solution of uranium was prepared as follows. Nuclear grade uranium metal turnings were degreased with carbon tetrachloride, pickled with 1:1 nitric acid and washed with 1:3 hydrochloric acid followed by DM water and finally with acetone. A weighed quantity (ca. 500 mg) of the cleaned uranium metal turnings were dissolved in nitric acid and evaporated to dryness. The residue was dissolved in water and diluted to 100 ml. This solution was used as a stock standard solution and the requisite working standard solutions were obtained by appropriate dilution.

2.2. Instrumentation

Absorption measurements were carried out on a Shimadzu UV-240 Graphicord UV–visible recording spectrophotometer. Matched glass cells of 1 cm path length were used. The baseline and digital absorbance readings were adjusted to 0.000 for a reagent blank before each set of measurements.

2.3. Procedures

The procedures for the various process stream samples is described under the respective headings. In all cases, the concentration of uranium in the sample was calculated by the method of standard additions against a reagent blank.

In the following samples, the absorbance of the final solution was measured at 420 nm for samples 1, 2 and 3(a) and at both 422 and 500 nm for samples 3(b) and 4.

(1) UNS/UNF. A 10 ml volume of the sample was pipetted into a 250 ml volumetric flask and diluted to volume. A portion of solution was centrifuged and to 20 ml of this solution 5 ml of dilute phosphoric acid were added and made up to 50 ml.

(2) UNPS/UNPE. To 5 ml of sample, 5 ml of dilute phosphoric acid were added and made up to 50 ml.

(3) UNE. Two different methods were followed in this case.

(a) Method 1. To 1 ml of sample, 5 ml of concentrated nitric acid and 2 ml of perchloric acid were added. The organic matter was destroyed completely by heating the mixture on a hot-plate, capable of achieving temperatures of about 200–250°C and provided with heat control, for about 30 min. The clear yellow solution, after cooling to room temperature, was transferred quantitatively into a 50 ml volumetric flask. To this solution, 5 ml of dilute phosphoric acid were added and made up to volume.

(b) Method 2. A 5 ml volume of sample was stripped with 50 ml of 1 M phosphoric acid and the aqueous phase was centrifuged for about 10 min on a REMI centrifuge (220/230 V a.c., 50 Hz) at 3500 rpm. The centrifuged solution was used for absorbance measurements.

(4) UNLS. A 10 ml volume of the sample was stripped with 20 ml of 1 M phosphoric acid and the aqueous phase was centrifuged for ca. 10 min and used for absorbance measurements.

In the following samples, the absorbance of the final solution was measured at 655 nm against a reagent blank. In the case of WD samples the reagent blank was prepared by taking 10 ml of the respective nitrate solution (100 g l^{-1} ammonium nitrate in the case of WD1, 250 g l^{-1} sodium nitrate in the case of WD2 samples) and 1 ml of sulphamic acid was added. After a few minutes about 5 ml of 4 M HCl followed by 2 ml of 0.1% Arsenazo III solution were added and diluted to 25 ml with 4 M HCl.

(5) UNR. To a 1 ml aliquot of the filtered sample in a 25 ml volumetric flask, 1 ml of sulphamic acid was added and after a few minutes about 5 ml of 4 M HCl followed by 2 ml of 0.1% Arsenazo 1II reagent were added and made up to volume with 4 M HCl.

(6) UNRC. The sample (as received) was accurately weighed and digested with 20 ml of concentrated nitric acid on a hot-plate (ca. 15 min). The digested slurry was transferred quantitatively into a 100 ml volumetric flask and diluted to volume and filtered. Taking 2 ml of filtrate, the procedure described for UNR was followed.

(7) Waste disposal (WD1 and WD2). The procedure followed was the same as that for UNR, but with a sample aliquot of 10 ml from a filtered solution of the sample.

An outline of the experimental procedure(s) for the outer methods follows for comparison of results.

2.3.1. Volumetric method [6b]

U(VI) in the sample was reduced to U(IV) in phosphoric acid medium using Fe(II). The excess of Fe(II) present in the solution was destroyed with a mixture of sulphamic acid and nitric acid in the presence of a Mo(VI) as catalyst. U(IV) was oxidized back to U(VI) in sulphuric acid medium. Uranium was determined by titrating the Fe(II) generated (which is quantitatively equivalent to uranium) with standard potassium dichromate solution using barium diphenylamine sulphonate as indicator.

2.3.2. X-ray fluorescence method [21b]

A PW 1404 wavelength-dispersive X-ray spectrometer (Philips, Eindhoven, The Netherlands) with X44 software was used for the determination of uranium concentration. In this method, the primary X-rays were generated from a rhodium target and an LiF_{220} crystal was used for the diffraction at a 2θ angle of 37.235°. Measurements were carried out by exposing standards and samples in a liquid sample cell with a Mylar film. The concentration of uranium in the sample was calculated using a calibration graph of concentration of uranium versus count rate. The necessary normalization was performed to avoid matrix interferences and the required dilutions were made to keep the uranium concentration within the linear dynamic range of the present system (uranium concentrations up to 30 g l^{-1}).

2.3.3. Extractive spectrophotometric method

In this method, the uranium present in the sample aliquot was extracted with ethyl acetate in the presence of aluminium nitrate as a salting-out agent followed by colour development with ammonium thiocyanate in ethanol–ethyl acetate medium. The interference from iron was avoided by reducing it to Fe(II) using tin(II) chloride.

3. Results and discussion

A typical chemical analysis of MDU is given in Table 1. It is clear that MDU contains a host of impurities. These impurities are present in some of the process streams such as UNS, UNF, UNR and UNRC, and silica and iron become problematic or cause serious interference during the determination of uranium in these samples. Silica present as suspended particles in solution and iron present as coloured complexes lead to positive errors.

The flow sheet for the extraction process of uranium with the sampling points for the various process streams is shown in Fig. 1. The typical ranges of concentration of uranium and free nitric acid in these streams are given in Table 2. The high concentrations of uranium in UNS, UNF, UNPS, UNPE, UNE require dilution. Although it appears to involve a dilution error, especially in the case of UNS/UNF samples, calculations revealed that the error is within the precision. It may be of relevance to note that the same degree

Table 1

of dilution is involved in the other alternative techniques such as XRF and volumetry.

The self-absorption of uranium is used for its determination after removing the interferences due to nitrate ions and other impurities such as iron and silica if they are present in the sample (Table 3). Nitrate ions do not interfere at 420 nm, as they absorb below 350 nm. While uranyl ions are known to form a series of nitrate complexes depending on the nitric acid concentration, each having a different characteristic absorption spectrum [22], it appears that the variations in the free nitric acid concentration in a sample affect the absorbance of uranium. However, the nitric acid concentration decreases to less than 0.1 M on dilution of the sample and the absorbance remains unaffected. This is confirmed by the invariance of absorbance of uranium at this wavelength in its standard solutions in different concentrations of nitric acid up to 0.5 M.

Table 2
Typical range of concentrations of uranium and free acidities in various process streams

Process	Concentration stream ($g\ l^{-1}$)	Free nitric of uraniumacid (M)
UNS	350–375	0.5–3.0
UNF	240–300	2.0–2.5
UNPS	90–110	0.2–0.3
UNPE	115–145	0.3–0.5
UNE	110–120	–
UNLS	6–12	–
UNR	0.1–1.5	2–3
UNRC	0.1–1.5	–
WD1	0.01–0.04	–
WD2	0.005–0.01	–

The concentrations of iron in UNS and UNF samples are 2.5–3 and 1.6–2 $g\ l^{-1}$, respectively. Even after dilution, its interference is significant and causes a positive bias of as high as 10% in terms of the concentration of uranium. However, in the presence of phosphoric acid, Fe(III) is effectively masked by phosphate, thus eliminating its interference. Although UNPS and UNPE do not contain iron, phosphoric acid is added even to

Table 3
Typical concentrations of various interfering impurities in different process streams

Process stream	Concentration of impurity (g l^{-1})				
	Fe	SiO_2	Ca	Mg	Th
UNS	3	25	37	4	0.03
UNF	2	19	28	3	0.02
UNPS	0.01	0.003	0.025	0.01	0.003
UNPE	0.01	0.003	0.025	0.025	0.003
UNR	3	Traces	9	22	0.001
UNRC soln.	0.5	Traces	2	5	0.0002
WD1	Ammonium nitrate:			100–120	
WD2	Sodium nitrate:			250–300	

Calcium and magnesium do not interfere in a spectrophotometric determination as they do not possess any colour and do not form coloured complexes with the reagents used. However, it puts a restriction on the method that the colour development should not be in the (sensitive) pH region. In the case of UNE and UNLS samples, the colour imparted due to the repetitive use of 35% TBP (in kerosine) in a counter-current extraction system causes interference in the determination of uranium.

these samples in order to maintain a uniform procedure for the determination of uranium on a routine basis.

The presence of undissolved silica in UNS and UNF samples is removed by filtration through Whatman filter-paper (No. 540, pore diameter 1.6 μm). This can even be achieved by centrifugation. The form of silica in these samples is such that its presence in the solution as undissolved material can easily be identified by simple visual inspection of the solution after filtration/centrifugation. Therefore, no chemical estimation is necessary for its identification. The concentration of dissolved silica in these samples was observed to be about 0.5 g l^{-1}. This was estimated by a gravimetric method involving dehydration of silica followed by hydrofluorination. However, for the determination of uranium by the present spectrophotometric method, the presence of dissolved silica does not cause any interference and need not be determined. Comparison of the results obtained by the present method with those obtained by volumetry and XRF for UNS, UNF, UNPS and UNPE show excellent agreement (Tables 4–7).

Table 4
Comparison of results obtained for UNS samples (values in g l^{-1})

Sample code	Present method	Volumetry	XRF

Measurement of the absorbance of uranium directly in organic streams such as UNE/UNLS is not possible because of the serious interference from the coloration in these samples due to the prolonged use of TBP–kerosene in nitric acid. Therefore, pre-separation of uranium by stripping or destruction of organic matter becomes necessary. Normally, the estimation is done by redox titrimetry after multi-stage stripping of uranium with a solution of sodium carbonate [23]. This method is tedious and undesirable on routine basis. Alternatively, in one case, the organic matter is completely destroyed by non-hazardous wet chemical oxidation of organic matter using perchloric acid in combination with nitric acid [24]. At about 86°C, nitric acid boils, forming a black solution. On further heating (at about

204°C), the boiling perchloric acid oxidizes carbon and the solution becomes clear yellow. The clear solution is taken for absorption measurements. The results obtained for the UNE samples by the present method are in good agreement with those obtained by volumetry (Table 8). However, in UNLS samples, the low concentration of uranium (6–12 g l^{-1}) demands a large sample aliquot (ca. 10 ml) and this procedure therefore becomes cumbersome. In the second case, the sample is stripped with 1 M phosphoric acid and the absorbance of the centrifuged aqueous phase is measured at the wavelength of interest.

Single stripping of the organic phase with 1 M phosphoric acid has been observed to yield about 99% of uranium in the aqueous phase. It has been observed that the efficiency of stripping is independent of the concentration of uranium in the range of concentrations of interest. This was verified by taking different synthetic standards in 35% TBP (in kerosene) having uranium concentrations between 100–130 g l^{-1} and 5–15 g l^{-1} and stripping with a suitable volume of 1 M phosphoric acid, keeping the organic to aqueous ratios at 1:10 and 1:2, respectively, as is the case with UNE and UNLS. In both these cases excellent linearity was obtained. Therefore, once the calibration is established, the amount of uranium that has been actually stripped into the aqueous phase becomes irrelevant as far as the determination of uranium is concerned.

The baseline in the absorption spectrum of the aqueous phase obtained by stripping a UNLS sample with 1 M phosphoric acid has been shifted considerably. This shift was thought to be due to the uniform dispersion of traces of organic matter in the aqueous phase. Interestingly, however, such a baseline shift was not observed in the absorption spectrum of an aqueous phase obtained by stripping a synthetic UNLS sample (prepared using fresh 35% TBP (in kerosene)) with 1 M phosphoric acid. It is observed that the prolonged use of 35% TBP in a counter-current extraction system of a uranium extraction plant imparts a characteristic colour due to nitration, and when the sample is stripped with phosphoric acid this colour is slightly carried away into the aqueous phase, which is responsible for the considerable absorbance over a wide range of wavelength re-

gion and hence for the baseline shift. Also, careful visual observation of the aqueous phase reveals slight haziness in the solution which also must be contributing towards the baseline shift. It was thought that centrifugation of the aqueous phase might help in the removal of the haziness and eliminate the baseline shift. Centrifugation of the aqueous phase did make the solution clear and the magnitude of the baseline shift also decreased significantly (ca. 70%). However, the baseline shift did not disappear completely even after prolonged centrifugation; rather, it remained constant at a particular value irrespective of the centrifugation time. This led us to conclude that the shift is due more to physical reasons.

Visual inspection of the spectrum of the uncentrifuged aqueous phase revealed that in the wavelength region 325–500 nm, the whole spectrum is shifted above the baseline and within this wavelength region at no wavelength is the absorbance less than than at 500 nm. Under these circumstances, it was thought that it is justified to subtract the absorbance at 500 nm from that at 422 nm in order to correct it for the additional absorbance due to the baseline shift and to obtain the actual absorbance of uranium.

The absorption spectra of the uncentrifuged and centrifuged aqueous phase obtained by stripping a UNLS sample with 1 M phosphoric acid are shown in Fig. 2. The molar absorptivity ($\varepsilon_{422\ nm}$) of uranyl ion in 1 M phosphoric acid under the experimental conditions is 16.4 l mol^{-1} cm^{-1}. The concentrations of uranium calculated based on the corrected absorbances agree well with those obtained by volumetry (Tables 9 and 10).

The concentration of uranium in UNR, UNRC and WD samples is very low (Table 2) and hence its self-absorption cannot serve the purpose for its determination. Also, the presence of the main interfering impurity iron, both in UNR and in the solution obtained from UNRC, in high concentrations (2–3 g l^{-1}) and large amounts of ammonium nitrate (100–120 g l^{-1}) in WD1 and sodium nitrate (250–300 g l^{-1}) in WD2 samples lead to further complications. Therefore, the use of a suitable chromophoric agent becomes mandatory.

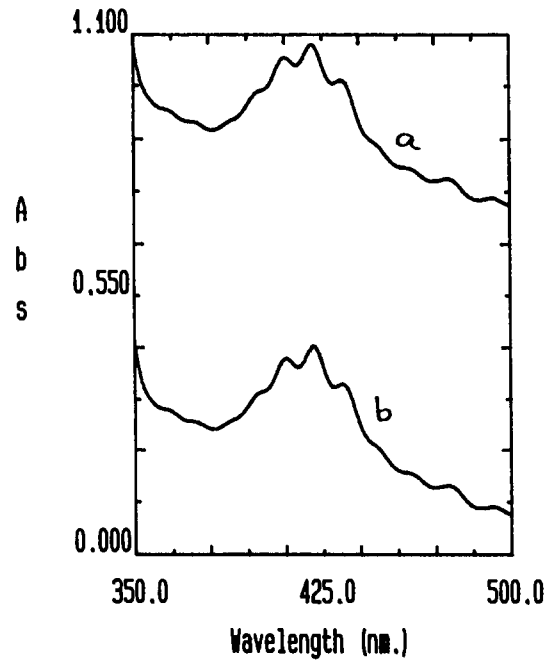

Fig. 2. Absorption spectrum of (a) uncentrifuged and (b) centrifuged aqueous phase. Extraction carried out with 1 M phosphoric acid; [UO_2^{2+}] = 10 g l^{-1}.

The yellow H_2O_2–UO_2^{2+} complex has been used [25] for the determination of uranium without a prior separation, where the interference from iron is avoided by formation of a violet Fe^{3+}–H_2O_2–EDTA complex in an alkaline medium [26]. However, when this procedure was attempted for UNR and UNRC samples, the authors encountered violent decomposition of hydrogen peroxide, presumably due to impurities.

It has been reported that Arsenazo III is the most sensitive reagent [27] for the determination of uranyl ions and quantitative work is best carried out at pH 7–8, but serious interferences are caused by Th^{4+}, Zr^{4+}, Fe^{3+}, rare earths, etc. [28–30]. Hence the determination of uranium under these conditions is not possible for samples of UNR and UNRC. Photometric determinations in strong acid media are preferable for these samples because (i) difficulties caused by partial hydrolysis of ions are eliminated, (ii) careful maintenance of pH is not required and (iii) the selectivity can be increased. It is also known that in HCl medium Arsenazo III reacts selectively with uranyl ions even in the presence of iron and rare earths [31]. Moreover, the interference from Th^{4+}, Zr^{4+}, etc., is insignificant in these samples owing to their very low concentrations compared with uranium. The concentrations of thorium in UNR and UNRC samples are observed to be in the range 1–2 mg l^{-1} and 0.001–0.005% (w/w), respectively, and zirconium was found only in traces. Since the reaction of uranyl ions with Arsenazo III in acid solutions gives rise to the formation of two complexes of the type ML, their proportions being dependent upon acidity [32], the determination is carried out in 4 M HCl using Arsenazo III without any prior separation of uranium.

The absorption spectra of free Arsenazo III and UO_2^{2+}–Arsenazo III in 4 M HCl are given in Fig. 3. The overcompensation due to the absorption of free Arsenazo III at the wavelength of interest (655 nm) is negligibly small.

The violet–blue colour of the UO_2^{2+}–Arsenazo III complex fades rapidly when developed with a WD sample directly. This cannot be attributed to the presence of large quantities of nitrate in these samples because the same complex in 5–6 M HNO_3 has been used for the determination of uranium [33]. As the presence of nitrite in these samples was detected in our studies on the determination of uranium in WD samples by polarography, the fading of the colour of the complex is attributed to nitrite. These WD samples, along with UNR and UNRC, contain nitrite picked up from the commercial nitric acid used in the process. Therefore, removal of nitrite becomes an essential step in the analysis of these samples.

It is known [34] that nitrite can be quantitatively reduced to nitrogen with sulphamic acid and the reduction is completed in 2–3 min at room temperature. The reaction can be written as

$$NO_2^- + HSO_3NH_2 \rightarrow N_2 + HSO_4^- + H_2O$$

Under these conditions, nitrates do not react. Nitrite is destroyed by the addition of a small

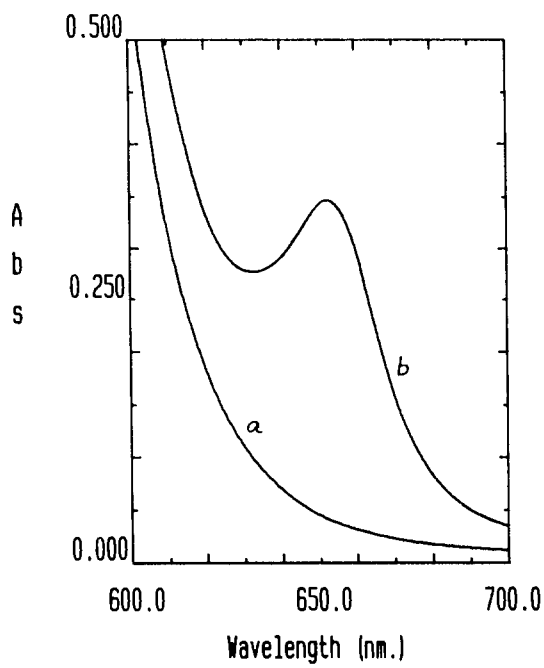

Fig. 3. Absorption spectra in 4 M HCl: (a) free Arsenazo III (against 4 M HCl); (b) U(VI) with Arsenazo III (against reagent blank). $[UO_2^{2+}] = 1.681 \times 10^{-5}$ mol l^{-1}.

quantity of sulphamic acid prior to the addition of Arsenazo III. As it was observed that the action of sulphamic acid is better at lower acidity, it is preferable to add it directly to the sample before addition of 4 M HCl. Considerable variations in the concentration of sulphamic acid did not affect the absorbance of the complex significantly at the wavelength of interest.

It was observed that the presence of large quantities of nitrate enhance the absorbance of the complex (Fig. 4). This could be attributed to the replacement of H_2O in the primary coordination sphere of UO_2^{2+} by nitrate, leading to a slight change in the chemical environment in the resulting complexes, which have considerable differences in their molar absorptivities. The enhancement was quantified by measuring the absorbance of the UO_2^{2+}–Arsenazo III complex in the presence of various amounts of nitrate. Interestingly, the absorbance of the complex increases linearly with increase in the content of nitrate for a particular concentration of uranium. Also, the percentage of enhancement for the same concentration of nitrate ion is greater with sodium nitrate than with ammonium nitrate. The variation of the absorbance of the complex with variation in the amounts of nitrate (NH_4NO_3 and $NaNO_3$) is shown in Fig. 5. The considerable difference in the extent of enhancement can be well understood in terms of the availability of more free nitrate ion for complexation in the former, which is a salt of a strong acid (HNO_3) and a strong base (NaOH), than in the case of the latter, which is a salt of a strong acid (HNO_3) and a weak base (NH_4OH). As more nitrate ion is available, the amount of a particular complex containing nitrate ion in the primary coordination sphere may be increasing and may be responsible for the linear rise in the observed absorbance value with increasing nitrate concentration. This situation may be better explained by the following simple equation:

$$[UO_2(H_2O)_6]^{2+} + R + nNO_3^- \rightarrow [UO_2(H_2O)_{6-n}(NO_3)_n]R + nH_2O$$

where R is Arsenazo III. The observed absorbance depends on the amount of the complex $[UO_2(H_2O)_{6-n}(NO_3)_n]R$ formed in the solution, which in turn depends on the quantity of nitrate available in the solution. The fact that the pres-

ence of nitrate enhances the absorbance of the UO_2^{2+}–Arsenazo III complex can be exploited for the estimation of the content of nitrate (ammonium or sodium salt) in waste disposal samples, which is also a required parameter to be analysed on a routine basis [34].

The results obtained for UNR/UNRC samples by the present method and those obtained by extraction–spectrophotometry are in fair agreement (Tables 11 and 12). Also, the estimated and added quantities of uranium in the case of the two types of waste disposal samples compare well (Tables 13 and 14). The overall analytical scheme for the determination of uranium in the entire range of process stream samples is shown in Fig. 6.

Table 12

Tables 13 and 14 show the concentration of uranium determined in the waste disposal samples. These were generated to observe the applicability of the present method to different ranges of concentration of uranium containing the sample matrix (especially either large amounts of ammonium nitrate or sodium nitrate). These samples were prepared by taking known amounts of uranium in a beaker followed by evaporation to near dryness and finally making the volume up to 500 ml with a waste disposal sample solution.

The Arsenazo III method for low levels of uranium has the advantage of direct determination of uranium in the presence of impurities, especially iron. It does not involve steps such as solvent extraction and reduction, unlike the well established ethyl acetate–thiocyanate method, which is usually employed for low levels of uranium. Also, the present method is relatively much more sensitive.

Short communication

A selective catalytic voltammetric determination of vitamin C in pharmaceutical preparations and complex matrices of fresh fruit juices

M.H. Pournaghi-Azar*, R. Ojani

Electroanalytical Chemistry Laboratory, Faculty of Chemistry, University of Tabriz, Tabriz, Iran

Received 8 November 1995; revised 4 April 1996; re-revised 20 May 1996; accepted 20 May 1996

Abstract

A simple, selective and precise voltammetric method for the determination of ascorbic acid in pharmaceutical preparations and fresh fruit juices—complex matrices containing various reducing compounds—is described. The method is based on the electrocatalytic oxidation of ascorbic acid in homogeneous solution using electrogenerated ferriciniumcarboxylic acid as mediator. The pH and mediator concentration affecting the performance of the electrocatalytic oxidation of the analyte were optimized. The method was applied to determine vitamin C in deeply coloured, viscous and turbid fruit juice samples with ascorbic acid contents ranging from 15–45 mg per 100 ml, without further dilution, concentration or other pre-treatment of the samples. The amount of mediator used varied depending on the ascorbic acid concentration in the samples. The method was also used for pharmaceutical analysis using a calibration graph. For fruit juice samples the standard addition technique was adopted to prevent the matrix affecting the accuracy of the determination. The relative standard deviation for the analysis of vitamin C in fruit juices ranged from 1.5–5%. The reliability of the method was established by parallel determination against the official methods.

Keywords: Ascorbic acid; Catalytic voltammetry; Fruit juices; Pharmaceutical analysis; Vitamin C

1. Introduction

Ascorbic acid occurs naturally in fruits and vegetables. All current methods for the determination of ascorbic acid take advantage of its redox properties: it can be easily oxidized to dehydroascorbic acid. Some oxidimetric titration methods for the determination of ascorbic acid involve titration with an oxidizing agent such as iodine [1], 2,6-dichlorophenolindophenol [2] or *N*-bromosuccinimide [3]. However, the ascorbic acid concentration can be overestimated if a background determination is not carried out to ac-

* Corresponding author.

PII S0039-9140(96)02003-6

count for interfering compounds. Coloured fruit juices are hard to work with. Some voltammetric methods using conventional electrodes [4–6], a microdisc electrode [7] and a microband electrode [8] have been reported. These methods suffer from interference, loss of response with repeated use because of electrode fouling by oxidation products or a lack of generality. Ascorbic acid often has to be quantified in complicated matrices where the exploitation of heterogeneous as well as homogeneous electrocatalytic oxidation might be advantageous. This provides selectivity and prevents the fouling of the electrode surface. Some research works have been reported in this context [9–16]. A method using a flow-injection system with square-wave voltammetric detection was also reported [17].

Recently we [18] have demonstrated that a polypyrrole/hexacyanoferrate(II)-modified glassy carbon electrode can be used for the catalytic determination of ascorbic acid in buffered solution at pH 4. The method was used for pharmaceutical analysis but was not suitable for the determination of vitamin C in fruit juices. In addition we [19] have reported that ascorbic acid can be oxidized catalytically in homogeneous solution by some electrogenerated ferricinium derivatives in buffered solution at pH 4. The method was used successfully for the simultaneous determination of ascorbic acid and dopamine in the same sample.

The purpose of this communication is to report the results of the voltammetric determination of vitamin C in pharmaceutical preparations and fruit juices exploiting the catalytic oxidation of ascorbic acid in homogeneous solution by electrogenerated ferriciniumcarboxylic acid.

2. Experimental

2.1. Reagents and chemicals

The solvent used for electrochemical studies was doubly-distilled water. Lithium or sodium perchlorate from Fluka was used as supporting electrolyte. The ferrocenecarboxylic acid was from Janssen and was used without further purification. The following solutions were used: ascorbic acid (Sigma): a stock solution was prepared in 0.5% citric acid to give a final concentration of 0.01 M and stored in a refrigerator; 3% m/v methaphosphoric acid–8% v/v acetic acid solution (HPO_3–HOAc); 2,6-dichlorophenolindophenol solution: 0.25 g l^{-1} 2,6-dichlorphenolindophenol (sodium salt) and 0.25 g l^{-1} sodium hydrogen carbonate; iodine solution, 0.05 M; starch solution, 1% m/m; thiosulphate solution, 0.01 M. All other reagents were of analytical grade. The solutions were bubbled with N_2 gas (99.999%) and kept under a nitrogen atmosphere during the electrochemical experiments.

2.2. Pharmaceutical preparations

The following commercial ascorbic acid formulations available from local sources were subjected to the described analytical procedure:

(1) tablets containing ascorbic acid as a single component (chewable tablets);

(2) tablets containing sodium carbonate combined with ascorbic acid (effervescent tablets);

(3) powdered vitamin C;

(4) ampoules containing ascorbic acid as the single component;

(5) multivitamin capsules containing vitamins A, B complex, D_2 and E, nicotinamide, calcium pantothenate, and folic acid together with minerals (Fe^{2+}, Ca^{2+}, Mg^{2+}, Mn^{2+}, Cu^{2+}, Zn^{2+} and Mo^{2+});

(6) multivitamin tablets containing vitamins A, B complex, D_2 and E, nicotinamide, calcium panthothenate, folic acid.

2.3. Instrumentation

The electrochemical experiments were carried out using an EG&G potentiostat/galvanostat model 273 coupled with an IBM personal computer connected to an Epson model FX-850 printer. A conventional three-electrode cell thermostatted at 25 ± 0.1°C with calomel electrode as reference electrode, a platinum wire as auxiliary electrode and a glassy carbon disk as working electrode ($A = 0.126$ cm^2 from EG&G) was used. A pH-meter model 654 (Metrohm) was used. The

working electrode was polished with alumina powder (0.05 μm) and then washed with water and acetone in turn before each voltammetric measurement.

2.4. Procedures

2.4.1. For pharmaceutical preparations

2.4.1.1. Vitamin C tablets, capsules or powders.

An accurately weighed portion of finely powdered sample equivalent to about 100 mg of ascorbic acid was transferred to a 10 ml assay tube and ascorbic acid was extracted with two 5 ml portions of 0.5% citric acid in bidistilled water. The extracts were combined in a 50 ml flask and diluted to volume. A 1 ml portion of extract was diluted with 10 ml of glycine buffer pH 4, containing 0.1 M $LiClO_4$ and 0.1 mM ferrocenecarboxylic acid, in a voltammetric cell and a cyclic voltammogram was recorded using a well polished glassy carbon (GC) electrode. The amount of ascorbic acid was determined by means of a calibration graph.

2.4.1.2. Injection.

An accurate ampoule volume equivalent to about 100 mg of ascorbic acid was transferred to a 50 ml flask and diluted to volume with 0.5% citric acid solution. A 1 ml portion of the solution was diluted in a voltammetric cell to 10 ml as described for tablets and the cyclic voltammogram was recorded using the GC electrode.

2.4.2. For fruit juices

Fresh juice—orange, sweet lemon, lime and grapefruit—was obtained by squeezing the fruit between two glass beakers to avoid contamination from metal ions which could interfere in the determinations. Tomato, strawberry and kiwi juices were obtained using a hand squeezer (polymer material). The juices obtained were filtered into a beaker, a 10 ml portion of the filtrate was transferred into an electrochemical cell, the required amount of $LiClO_4$ (0.1 M) was added as supporting electrolyte, the solution was buffered by direct dissolution of glycine (0.5 M) and the pH was adjusted with a concentrated solution of sodium hydroxide. The concentration of ferrocenecarboxylic acid was optimized for each sample solution in order to record a full catalytic voltammogram (see Section 3). For the determination of ascorbic acid in the sample the standard addition technique was used.

2.4.3. Iodine titration method

A 0.05 M iodine solution was standardized in the usual way with a primary standard of As_2O_3 or titrisol thiosulphate solution. For pharmaceutical analysis an iodimetric procedure described in the US Pharmacopeia (USP) was used [20].

2.4.4. 2,6-Dichlorophenolindophenol (DCPIP) titration method [2]

The indophenol solution was standardized by titration with 2.0 ml of standard ascorbic acid solution and 5 ml of HPO_3–HOAc solution to the end-point (a persistent rosy-pink colour). The consumption of the blank was determined by titrating indophenol solution with 7 ml of HPO_3–HOAc solution plus a given amount of water equivalent to the volume of indophenol solution used in the previous standardization titration.

For sample titration, 100 ml of juice was mixed with an equal volume of HPO_3–HOAc solution before filtering. A volume of the filtrate equivalent to about 250 mg of ascorbic acid was then titrated with indophenol solution using the same procedure as described above, including the titration of the blank.

3. Results and discussion

3.1. Primary investigations

We [19] have reported previously that some electrogenerated ferricinium derivatives are able to catalyse the electrochemical oxidation of ascorbic acid in buffered aqueous solutions at pH 4–5 via a homogeneous process when the ferrocene derivatives are present in dissolved forms (see Scheme 1).

$$\mathrm{FC\ (ferrocene)} \rightleftharpoons \mathrm{FC^{+}\ (ferricinium)} + \mathrm{e}$$

$$\mathrm{2FC^{+} + H_2A\ (ascorbic\ acid)} \rightarrow \mathrm{2FC + A\ (dehydro\text{-}ascorbic\ acid) + 2H^{+}}$$

Scheme 1.

The catalytic peak current is linearly dependent on the ascorbic acid concentration and the range of linearity depends on the amount of mediator in the solution. The analysis of chemically-coupled reactions between the electrogenerated ferricinium derivatives and ascorbic acid reveals that the largest second-order rate constant (k^0) belongs to ferriciniumcarboxylic acid. Therefore in this work we have used ferrocenecarboxylic acid as the most suitable mediator for the mediated oxidation of ascorbic acid (Fig. 1).

3.2. Calibration graph and precision

In the presence of 0.1 mM ferrocenecarboxylic acid in buffered solution with glycine at pH 4 the anodic peak current for cyclic voltammograms with a scan rate of 10 mV s^{-1} was proportional to the ascorbic acid concentration within the range 5×10^{-5}–1×10^{-3} M with only a small intercept. The regression equation was: $i(\mathrm{mA}) = -1.28 + 9757C(\mathrm{M})$; $r = 0.999$, $n = 6$. The mean of three replicate analyses of a solution of ascorbic acid at

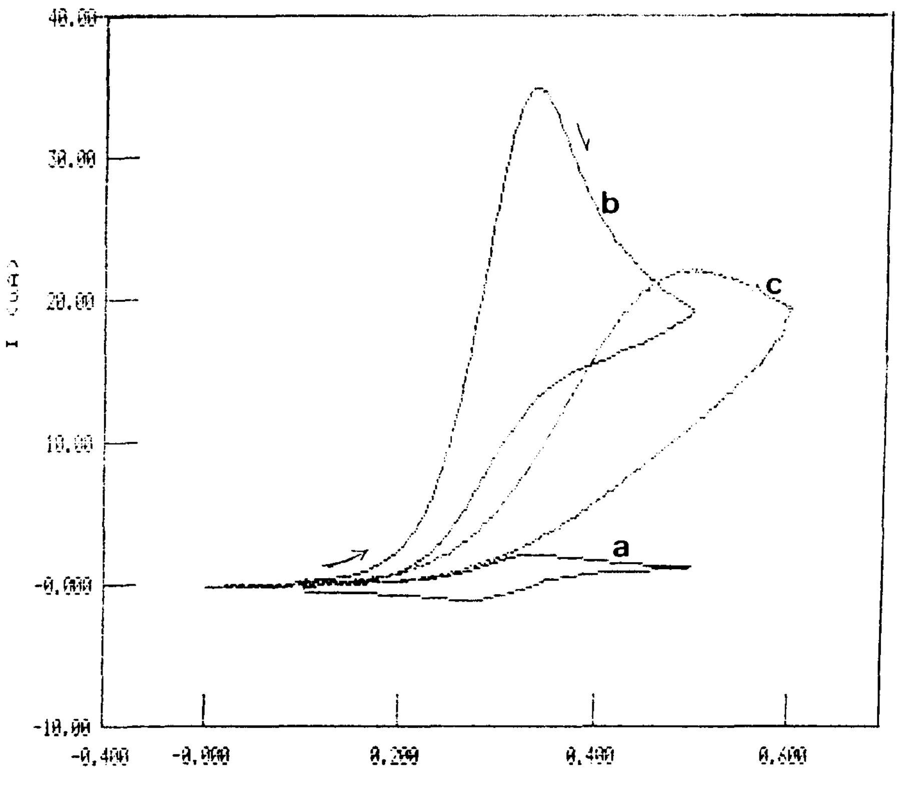

Fig. 1. Cyclic voltammograms of (a) 2 mM ferrocenecarboxylic acid in 0.5 M glycine buffer +0.1 M $LiClO_4$ at pH 4, (b) as for (a) but with addition of 5 mM ascorbic acid, (c) 5 mM ascorbic acid in buffer solution pH 4. Scan rate: 5 mV s^{-1}.

[a] Results based on three replicate determinations per sample.

a concentration of 5×10^{-4} M assayed at its prepared value gave a relative standard deviation of 2.5%. This level of precision is adequate for the quality control analysis of pharmaceutical preparations and natural products.

3.3. Analysis of pharmaceutical preparations

The proposed method was applied to the analysis of several pharmaceutical dosage forms containing ascorbic acid—tablets, powder, ampoules or capsules—purchased from local sources without interference from excipients and other drugs encountered. The evaluation of the ascorbic acid concentration was found to be more suitable with the aid of a calibration graph. The results for the analysis of these preparations with the voltammetric method compared favourably with those obtained by the USP standard method (Table 1).

3.4. Analysis of fresh fruit juices

3.4.1. Optimization of the mediator concentration

The normal concentration range of ascorbic acid was reported [21] for various fruit juices to range from 10–40 mg per 100 ml. Preliminary experiments showed that in order to obtain a full catalytic cyclic voltammogram "increasing the anodic current of the mediator redox couple and substantial elimination of the corresponding cathodic peak on the reverse voltage scan, in the presence of ascorbic acid" for each fruit juice sample (see Fig. 1, curve b), an optimum concentration of the mediator which depends on the vitamin C content of the samples is desirable. Therefore the optimal amount of ferrocenecarboxylic acid that should be added to the test solution was obtained by adding the mediator in increasing amounts until the original oxidation peak of ascorbic acid found at more positive potential disappeared and a full catalytic cyclic voltammogram was obtained. This procedure may be performed quickly and easily by pre-estimation of the ascorbic acid content of the sample with the aid of the non-catalytic signal of ascorbic acid and then adding the mediator into the voltammetric cell at two different times.

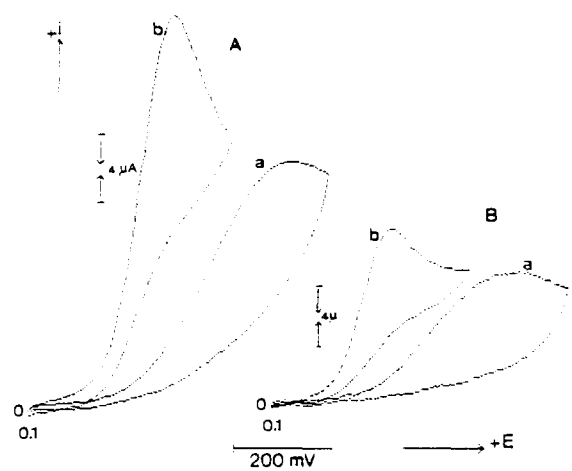

Fig. 2. Cyclic voltammograms recorded in fresh juices: (A) orange; (B) strawberry. A (a) and B (a): pH 4 (glycine buffer), 0.1 M $LiClO_4$. A (b): A (a) + 0.5 mM ferrocenecarboxylic acid. B (b): B (a) + 0.25 mM ferrocenecarboxylic acid. Scan rate: 10 mv s^{-1}.

Tomato	7.8 (2.6)	8.1 (3.3)	1.8	1.53

[a] Results based on three replicate determinations per sample.

Fig. 2 shows typical cyclic voltammograms recorded for the mediated oxidation of ascorbic acid in 10 ml of fresh orange juice with very low viscosity and strawberry juice with very high viscosity in the presence of a optimal amount of ferrocenecarboxylic acid in buffered solution at pH 4 as described above. As seen in Fig. 2 the anodic peak currents could be easily evaluated and were found at potentials corresponding to ferrocenecarboxylic acid oxidation without any discernible cathodic peak on the reverse scan (full catalytic voltammograms). The voltammograms were reproducible and variation of the anodic peak current for cyclic voltammograms vs. ascorbic acid concentration added directly to the sample solution was linear with a correlation coefficient better than 0.999. The slopes of the regression equation for graphs obtained from the standard addition technique were quite different from that obtained from the calibration graph in pure buffered solution. Therefore the standard addition technique was adopted for the determination of ascorbic acid in fruit juice samples. Table 2 gives the vitamin C content of some fresh fruit juices determined by the proposed voltammetric method and with a DCPIP titration method (recognized official method of determination of vitamin C [2]). The results of statistical calculation shown in Table 2 indicate a good precision and good agreement between the repeatability of the proposed and DCPIP methods (F-test), and the mean values obtained (t-test).

3.4.2. Interference study

The signals obtained for vitamin C added to the fruit juices were calculated to be 75–85% of the signal in buffered solution depending on the fruit juice sample. This suggests that interference from concomitant reducing agents in the sample is unlikely. This reduced response may be attributed to the high vicosity of the juice matrices, which affects the diffusion coefficient of ascorbic acid, or the matrix effect for electrode fouling.

Fresh fruit juices contain a number of organic acids and sugars such as citric acid, tartaric acid, malic acid, lactic acid, and glucose, fructose and sucrose. These components were added in increasing amounts to 1 mM ascorbic acid in buffered solution and no serious effect was observed even in great excess (up to 50 mM). Some reducing ions, such as Fe(II), Cu(I), Sn(II) and sulphite, may be present in fresh fruit juices. The experimental investigation showed that these ions did not interfere in buffered solution up to 50, 20, 100 and 100 mM respectively. However, in the presence of some organic acids which are naturally occurring in fruit juices, mentioned above, Fe(II) began to interfere as the reducing agent, when its concentration in the solution exceeded 3 mM, due to the modification of the Fe(III)/Fe(II) standard potential in the presence of the complexing acids. Furthermore, the results of the analysis of some pharmaceutical preparations using the proposed method compared favourably with those obtained by the USP method (see Table 1), confirming that

no interference was observed from concomitant mineral ions, other vitamins, glucose, sucrose, nicotinamide and tablet excipients.

4. Conclusion

The proposed voltammetric method is rapid (time spent on manipulations and measurement is less than 15 min), simple, precise, suitable for routine control and can be carried out directly without any pre-treatment for a large number of fruit juice samples. The present method has a high degree of specification for determination of ascorbic acid in fruit juices due to the selective electrocatalytic oxidation of ascorbic acid with ferrocenecarboxylic acid and could be used as a quality control and stability indicating assay for vitamin C. The method has a clear advantage over the spectrophotometric methods for the analysis of samples containing fine particles or of deep colour and high viscosity.

Received 9 August 1995; revised 27 March 1996; accepted 5 April 1996

Abstract

Cathodic stripping voltammetry was used to determine 5-fluorouracil (5-FU) in the presence of traces of Cu(II). It was found that the addition of 5×10^{-9} mol dm^{-3} Cu(II) to the measurement cell greatly enhanced the peak current of the adsorbed molecule. Different parameters were tested to optimize the conditions for the determination of 5-FU. The adsorbed form is reduced irreversibly. It was observed that by controlling the deposition potential, the technique could be directed to the determination of Cu(II) or the drug. The linear range was from 5×10^{-9} to 6×10^{-8} mol dm^{-3} for 5-FU and from 6×10^{-9} to 5×10^{-8} mol dm^{-3} for Cu(II). Detection limits of 4.6×10^{-10} and 5×10^{-10} mol dm^{-3} were obtained for 5-FU and Cu(II), respectively. The method was applied to urine and molecules or ions which may interfere were studied. © 1997 Elsevier Science B.V.

Keywords: 5-Fluorouracil; Interferences; Stripping voltammetry

1. Introduction

5-Fluorouracil (5-FU) is an antineoplastic agent used for the treatment of solid tumors of the breast and rectum [1]. The polarographic behavior of 5-FU has been examined and it was shown that it undergoes reduction at pH 1.8–11 with the best defined wave at pH 6–8 [2]. Guerrieri et al. [3] studied the formation of an insoluble mercury compound in the presence of 5-FU using different electrochemical techniques.

Different methods have been reported for the determination of 5-FU, including cathodic stripping voltammetry [4–6]. This technique is based on the interfacial accumulation of the analyte on the working electrode prior to voltammetric measurements of the surface-bound compound. Liquid chromatography with anodic amperometric detection has also been used for the determination of 5-FU and a detection limit of 15 ng/ml can be achieved [7].

The present work is a continuation of our studies in the field of drug analysis using mercury and modified carbon paste electrodes [8–10]. The

PII S0039-9140(96)01957-1

aim was to investigate the adsorptive voltammetric behavior of 5-FU in the presence of traces of Cu(II). Also, 5-FU was used as a ligand to determine Cu(II) at low levels by stripping voltammetry following chelation.

2. Experimental

2.1. Instrumentation

For the voltammetric measurements, an EG&G PAR Model 263 polarographic analyzer with 250/270 research electorchemistry software version 4.0 was used with a PAR 303 static mercury drop electrode (SMDE). Silver/silver chloride (saturated KCl) was used as a reference electrode and a platinum wire as an auxiliary electrode.

All the pH meaurements were made with an Orion Model 601 A digital ionalyzer.

2.2. Chemicals

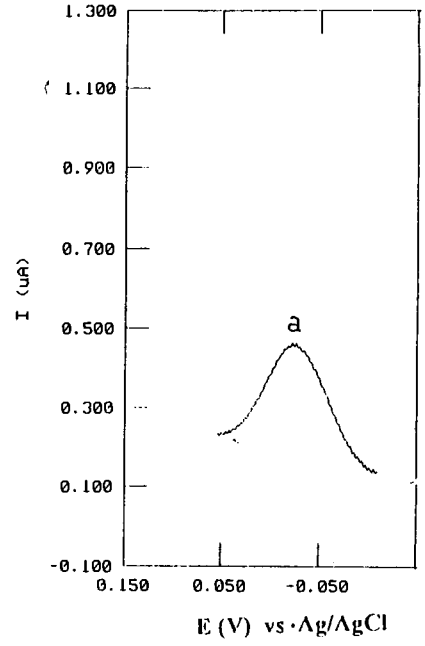
A stock solution of 1×10^{-3} mol dm^{-3} 5-FU was prepared daily by dissolution of the appropriate amount in doubly distilled water. Borax solution was prepared and adjusted to pH 10 with sodium hydroxide. All other reagent were of analytical grade.

2.3. Procedure

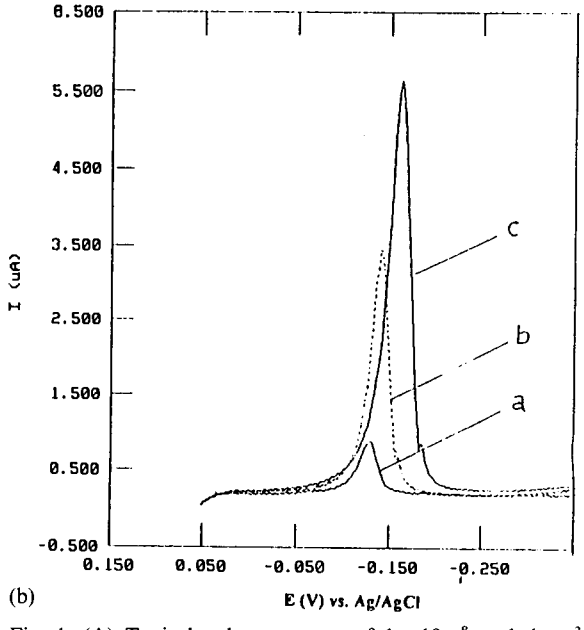
After deaeration with nitrogen for 8 min, a hanging mercury drop electrode (medium size) was formed and the selected deposition potential was applied with stirring for a given time interval while accumulation of the analyte at the electrode proceeded. After a selected deposition time and a rest period of 15 s, the potential was scanned from positive to negative.

3. Results and discussion

Fig. 1(A) shows the reduction peak of the mercury(II) salt of 5-FU [3] and Fig. 1(B) illustrates the same peak in the presence of Cu(II). It can be seen that the addition of Cu(II) enhances the peak



(a)



(b)

Fig. 1. (A) Typical voltammogram of 1×10^{-8} mol dm^{-3} 5-FU in the absence of Cu(II) ions. Borax, pH 10, scan rate, 150 mV s^{-1}; deposition potential, +0.05 V; preconcentration time, 180 s. (B) Typical voltammograms of (a) 1×10^{-8}, (b) 6×10^{-8} and (c) 1×10^{-7} mol dm^{-3} 5-FU in the presence of 5×10^{-9} mol dm^{-3} Cu(II) ions. Borax, pH 10; $t_{acc} = 30$ s; scan rate, 150 mV s^{-1}.

current greatly. Also, Fig. 1(B) indicates that the peak potential shifts to the more negative side with increase in 5-FU concentration.

The mechanism of the effect of Cu^{2+} on the peak current has not yet been established. The reduction process of the adsorbed form, investigated by cyclic voltammetry, shows that the phenomenon is totally irreversible. The resulting peak current was characterized with respect to the media, pH and other variables.

3.1. Cyclic voltammetric measurements

Repetitive cyclic voltammograms suggest rapid desorption of the adsorbed form; the peak current decreases in the second and third cycles. Hence linear sweep voltammetry with a fast scan rate (150 mV s^{-1}) is preferable in such cases.

3.2. Effect of supporting electrolyte and pH

A series of supporting electrolytes were tested (sodium acetate, disodium hydrogenphosphate, potassium nitrate, borax). Both the peak height and the peak shape were taken into consideration when choosing the supporting electolyte. The results showed that borax gave the best response. The solution conditions such as the pH and the concentration of 5-FU, affect the peak potential and peak current significantly. The supporting electrolyte concentration has no observable effect on the peak current. The effect of pH was investigated. A small current was observed at pH < 5, which increases gradually up to pH 9 and then increased sharply with a maximum at pH 10. At higher pH, the mercury dissolution current obscured the required peak.

3.3. Effect of accumulation potential and scan rate

The effect of the accumulation potential on the stripping peak current was examined over the range +0.15 to −0.05 V. Fig. 2(a) illustrates the peak current obtained as a function of deposition potential. The graph indicates that on going in the positive direction from −0.05 to 0.15 V, the peak height increases with a maximum at +0.05 V.

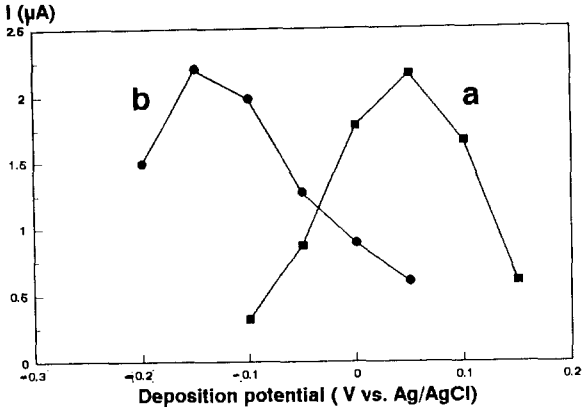


Fig. 2. Effect of accumulation potential on the peak current of (a) 5×10^{-9} mol dm^{-3} 5-FU in the presence of 5×10^{-9} mol dm^{-3} Cu(II) and (b) 1×10^{-8} mol dm^{-3} Cu(II) ions in the presence of 1×10^{-6} mol dm^{-3} 5-FU. t_{acc} = 240 s; borax, pH 10.

The effect of scan rate was studied by varying it from 20 to 500 mV s^{-1}. It was found that the peak current increases and the peak potential shifts to more negative values with increasing scan rate. The peak becomes broader at scan rates higher than 200 mV s^{-1}. For subsequent work, 150 mV s^{-1} was selected. The plot of I vs. V gave a straight line with a slope of 1.08. A slope of 1.0 is expected for ideal reaction of surface species [5]. The shape of curve b in Fig. 2 corresponds to copper behavior and will be explained further below.

3.4. Effect of preconcentration time, interferences and reproducibility

Fig. 3 shows the effect of preconcentration time in the presence of different concentrations of 5-FU. The peak current increased linearly with preconcentration time up to 180 s for 1×10^{-8} mol dm^{-3} 5-FU. A deviation from the linearity was observed at accumulation times longer than 60 and 45 s for 6×10^{-8} and 1×10^{-7} mol dm^{-3} 5-FU, respectively. Table 1 illustrates the data collected. On plotting the peak current against the square root of time, a straight line was obtained with a correlation coefficient of 0.998 and a slope of 0.96. This behavior is expected for mass transport controlled by adsorption [11].

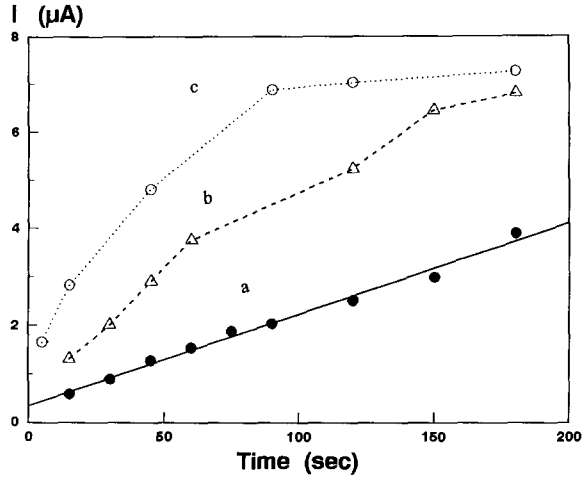

Fig. 3. Effect of accumulation time on the linear sweep voltammetric response of (a) 1×10^{-8}, (b) 6×10^{-8} and (c) 1×10^{-7} mol dm^{-3} 5-FU. Other conditions as in Fig. 1.

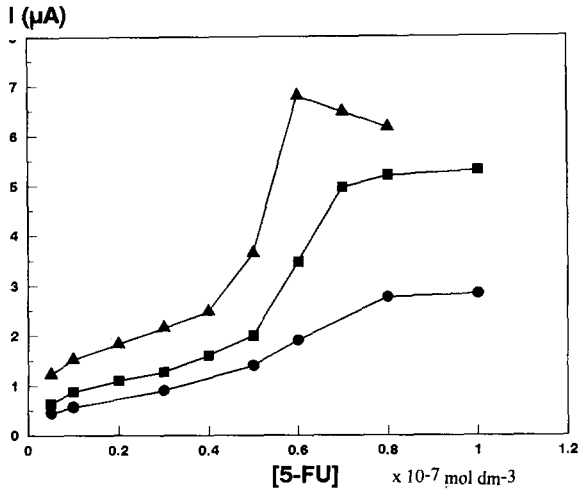

Fig. 4. Current–concentration graphs after preconcentration times of (a) 15, (b) 30 and (c) 90 s for 5-FU in the presence of 5×10^{-9} mol dm^{-3} Cu(II) ions.

The effect of Cu(II) concentration over the range 1×10^{-9}–5×10^{-9} mol dm^{-3} on the stripping peak current of 1×10^{-8} mol dm^{-3} 5-FU was examined. No significant effect on the peak current height was observed and 5×10^{-9} mol dm^{-3} Cu(II) was adopted in subsequent work.

The reproducibility of the results can be attributed to the reproducible area and self-cleaning control provided by the instrument used. The relative standard deviation was calculated for eight successive measurements of 1×10^{-8} mol dm^{-3} 5-FU and was found to be 2.6%.

3.5. Calibration plot

A well defined stripping peak was observed over the concentration range. 1×10^{-8}–1×10^{-7} mol dm^{-3} after 15, 30 and 60 s with stirring at +0.05 V. The resulting calibration plots for these concentrations are shown in Fig. 4. The graphs show positive deviations from linearity at concentrations higher than 6×10^{-8}, 5×10^{-8} and 4×10^{-8} mol dm^{-3} 5-FU, respectively. This phenomenon and the change in the slope of the response might be attributable to surface effects of the investigated molecule [3]. The data obtained from the least-squares analysis are given in Table 2.

Table 1
Characteristics of current–time curves established using different 5-FU concentrations with borax (pH 10)

[5-FU] (mol dm^{-3})	Linearity range (s)	Correlation coefficient	Slope (μA s^{-1})	Intercept (μA)
1×10^{-8}	0–180	0.9896	0.0187	0.348
6×10^{-8}	0–60	0.9974	0.0530	0.425
1×10^{-7}	0–45	0.9813	0.0757	1.43

Table 2
Characteristics of the calibration curves established using different deposition times

Deposition time (s)	Linearity range (mol dm^{-3})	Correlation coefficient	Slope (μA per 10^{-8} mol dm^{-3})	Intercept (μA)
15	5×10^{-9} 6×10^{-8}	0.9784	0.2817	0.1774
30	5×10^{-9} 5×10^{-8}	0.9717	0.2746	0.548
60	5×10^{-9} 4×10^{-8}	0.9997	0.3211	1.196

3.6. Detection limit

The detection limit was calculated from three times the noise using the measurements of 1×10^{-8} mol dm^{-3} and was found to be 4.6×10^{-10} mol dm^{-3} based on a signal-to-noise ratio of 3. This is a significant improvement over the literature data [5,7].

3.7. Interferences and application to biological samples

The influence of ascorbic acid, which is potent interfering compound present in biological samples, was investigated. It was found that an equimolar concentration of ascorbic acid had no effect on the peak response of 5-FU. However, at a higher molar excess (100:1) of ascorbic acid, a depression of the peak response by about 25% was observed.

The method was applied to the determination of 5-FU in spiked urine. The sample was treated with concentrated sulfuric acid to destroy the organic matter, then the pH was raised to 10 by addition of borax and sodium hydroxide. The voltammograms were recorded in the presence of 5×10^{-9} mol dm^{-3} Cu(II). A linear dependence on the 5-FU concentration was observed between 1×10^{-7} and 1×10^{-6} mol dm^{-3} ($r = 0.9985$).

The reproducibility of the results was tested and the relative standard deviation was found to be 3.4% ($n = 8$).

3.8. Determination of Cu(II) in the presence of 5-FU

Cathodic linear sweep voltammetry was used to determine Cu(II) using 5-FU as a complexing agent. The literature showed that Cu(II) forms a complex with this ligand [12]. In the present work we tried to take advantage of the accumulation of the complex by adsorption to determine Cu(II) electroanalytically. It was found that the peak current of 1×10^{-8} mol dm^{-3} Cu(II) increased by a factor of 16 on adding 1×10^{-6} mol dm^{-3} 5-FU. The peak current response was

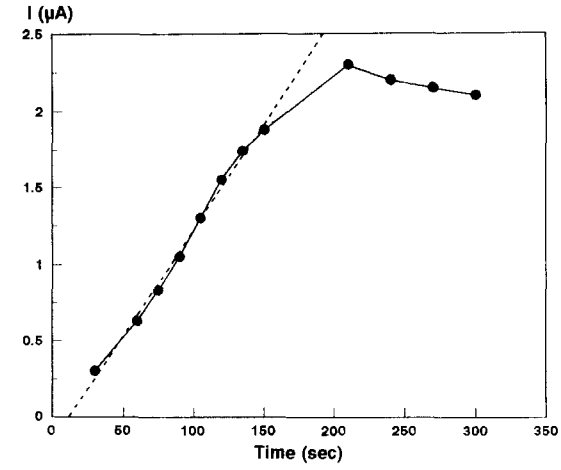

Fig. 5. Peak current of Cu(II)–5-FU complex as a function of deposition time in a borax electrolyte (pH 10) with a deposition potential of -0.15 V.

characterized with respect to the supporting electrolyte, pH, deposition potential and other parameters.

The deposition potential, as can be seen in Fig. 2(b), greatly affects the peak current of Cu(II) and this factor is taken into account to direct the technique toward the determination of 5-FU or Cu(II). After selecting a suitable supporting electrolyte (borate buffer, 0.1 mol dm^{-3}), a concentration of 1×10^{-8} mol dm^{-3} Cu(II) was studied in the presence of 1×10^{-6} mol dm^{-3} 5-FU using linear scan voltammetry at different deposition potentials. It was found that accumulation at an applied potential of -0.15 V gave the best response. The concentration of the drug was investigated as an effective parameter in complexation, i.e. the quantity adsorbed. The ligand concentration was increased from 1×10^{-7} to 1×10^{-5} mol dm^{-3} in the presence of a constant concentration of Cu(II). It was observed that the peak response increases on increasing the ligand concentration up to 1×10^{-6} mol dm^{-3}, then a depression of the peak response occurs, probably owing to surface saturation.

The results obtained on the effect of deposition time on the peak response indicated that on increasing the preconcentration period, the peak current shows a linear relationship with Cu(II)

concentration, y (μA) = 0.0138x (s) − 0.165, until a leveling off is observed corresponding to a maximum degree of surface coverage at $t_{acc} > 180$ s (Fig. 5). An adsorption isotherm is produced which can be described by the Langmuir equation. At the current maximum the electrode is covered by a monolayer of complex ion [13].

A detection limit of 5×10^{-10} mol dm^{-3} Cu(II) was calculated from 5×10^{-9} mol dm^{-3} Cu(II) based on a signal-to-noise ratio of 3. The relative standard deviation was calculated for seven experiments and was found to be 2.9%.

4. Conclusion

The addition of traces of Cu(II) to the preconcentration cell of 5-FU improved significantly the sensitivity of the cathodic stripping voltammetric determination of 5-FU. A detection limit of 4.6×10^{-10} mol dm^{-3} (0.52 ng per 10 ml) was obtained, compared with reported values of 3×10^{-9} mol dm^{-3} [5] and 15 ng per 10 ml [7]. The method was applied to biological samples (urine). A linear dependence of the peak current on 5-FU concentration was observed over the range 1×10^{-7}–1×10^{-6} mol dm^{-3} with a correlation coefficient of 0.9985.

Abstract

A rapid, simple, selective and sensitive spectrophotometric method for the determination of cerium(III) using the title azo dyes [1,3-phenylenediamine bisazoacetylacetone ($\mathbf{I}_a$);1,3-phenylenediamine bisazobenzoylacetone ($\mathbf{I}_b$);1,4-phenylenediamine bisazoacetylacetone ($\mathbf{I}_c$); and 1,4-phenylenediamine bisazobenzoylacetone ($\mathbf{I}_d$)] has been developed in neutral and slightly alkaline (pH 7.00, 7.50, 8.00 and 7.00) media. The 1:1 and 2:1 (M:L) complexes formed exhibit their highest absorbances in 30% (v/v) dioxane solutions, having formation constants (log K) of 4.44, 4.95. 5.63 and 5.22 and 8.51, 8.76, 9.73 and 9.37 respectively. Beer's law is obeyed over the concentration ranges 0.10–2.50, 0.05–3.00, 0.05–3.75 and 0.10–3.50 μg ml^{-1} of cerium(III). More accurately, Ringbom optimum concentration ranges are 0.2–2.25, 0.2–2.6, 0.2–3.5 and 0.2–3.3 μg ml^{-1} for the complexes of reagents $\mathbf{I}_a$,$\mathbf{I}_b$,$\mathbf{I}_c$ and $\mathbf{I}_d$ respectively. The molar absorptivities, Sandell sensitivities and relative standard deviations were also calculated. The interferences of 50 foreign ions on the determination of cerium(III) were studied. The method allows the determination of cerium(IV) after prior reduction to the trivalent state. The proposed method was used for cerium determination in two different monazite samples and the results were compared with certified values obtained using atomic absorption spectrometry, indicating that the procedure provided accurate and precise results. © 1997 Published by Elsevier Science B.V.

Keywords: Bisazo dyes, Cerium determination; Monazite analysis; Spectrophotometry.

1. Introduction

The spectrophotometric analysis of cerium(III) is usually carried out with dyestuffs. Of those commonly used, only carboxyarsenazo [1] give both sensitive and selective determination. The reactions of cerium(III) with orthanilic K [2] and 4-(2-pyridylazo) resorcinol [3] lack both sensitivity and selectivity, whereas those with Methylthymol Blue [4], sulpharsazen [5] and Alizarin Red S [6] have low sensitivities. The

PII S0039-9140(96)02011-5

complex formed with Bromopyrogallol Red [7] is formed only on heating the reactant for 10 min at 80–90°C, whereas that formed with Chrome Azurol S [8] is stable for less than 50 min. Although carboxynitrazo [9] and thiazolylazo dyes [10,11] are the most sensitive reagents reported so far for the determination of Ce(III), the maximum development of the coloured complex requires at least 30 min.

In the present study, a method is developed for the rapid, accurate and sensitive determination of Ce(III) using some bisazophenyl-β-diketones as chromogenic reagents due to their selectivity in the reaction with Ce(III). The most favourable conditions are established, and the composition, conditional and real stability constants of the complexes, the molar absorptivity (ε_{MAX}) and the Sandell sensitivity are determined.

2. Experimental

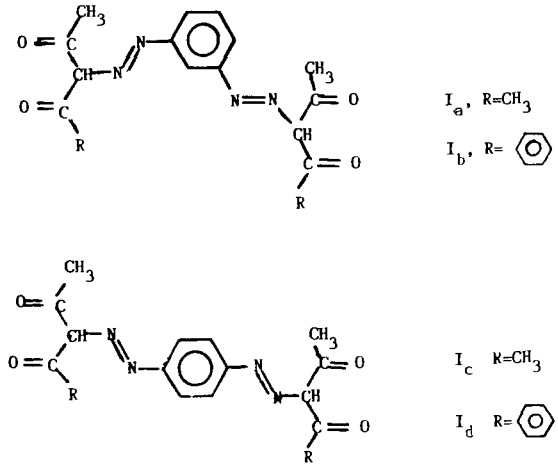
2.1. Apparatus

An Orion Research Model 601 A/Digital Ionalyzer pH-meter with a combined saturated calomel–glass electrode was used for pH measurements. A Perkin-Elmer λ3B recording spectrophotometer equipped with 10 mm matched silica cells was used. The atomic absorption measurements for the determination of cerium ion were carried out using an Hitachi atomic absorption Z-6100 polarized Zeeman spectrometer. All experiments and measurements were carried out at ambient temperature.

2.2. Reagents

All chemicals were of analytical-reagent grade, unless otherwise stated.

The bisazo dyes used in the present investigation were prepared according to the procedure described previously [12]. The four reagents used have the following structures.



A stock solution of Cerium(III) was prepared by dissolving 0.5556 g of Cerium(III) sulphate octahydrate (Fluka) in 250 ml of bidistilled water containing 1.0% sulphuric acid. The solution was standardised complexometrically [13] and was found to contain 1 mg ml^{-1} cerium. Working solutions were prepared by appropriate dilution of the stock solution.

1×10^{-3}M solutions of reagents $\mathbf{I}_a$–$\mathbf{I}_d$ were prepared by dissolving an accurately weighted amount of the purified solid reagent in 100 ml of dioxane.

Sodium tetraborate, $Na_2B_4O_7$, buffer solutions (0.05 M) of the required pH were prepared [14].

2.3. General procedure

For each of the systems investigated, an aliquot of slightly acidic solution containing < 100 μg of Cerium(III) was mixed with 12.5 ml of borate buffer of pH 7.0, 7.5, 8.5 or 7.0, and then mixed with 2.5 ml of 1×10^{-3}M $\mathbf{I}_a$,$\mathbf{I}_b$,$\mathbf{I}_c$ or $\mathbf{I}_d$ respectively, to form the complexes. A further 5 ml of dioxane was added to dissolve any complex precipitated. The contents were then diluted to 25 ml with bidstilled water in a volumetric flask. The absorbance was measured at 573, 533, 511 and 638 nm for Cerium(III) complexes of ligands $\mathbf{I}_a$, $\mathbf{I}_b$, $\mathbf{I}_c$ and $\mathbf{I}_d$ respectively, against appropriate reagent blanks prepared under identical conditions.

2.4. Procedure for the determination of cerium in monazite samples

To 1.0 g of the sample, 20 ml of 8.0 M sulphuric acid was added and heat was applied to decompose the sample. After cooling to room temperature the residue was dissolved in water. The solution was transferred to a 50 ml separating funnel containing 20 ml of tri-*n*-butylphosphate to extract Ce(IV) and Th(IV). By adding 5 ml of 1.0 M sodium nitrite, the Ce(IV) was reduced to Cerium(III) which returned to the aqueous phase and was then separated. The resulting aqueous solution was placed in a 25 ml calibrated flask and made up to the mark with water. An appropriate volume was taken and the above procedure for cerium determination was followed.

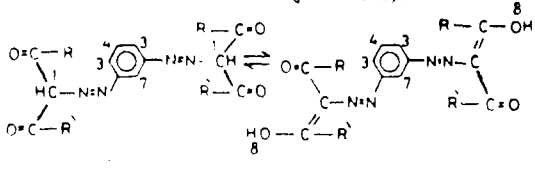
3. Results and discussion

Cerium(III) was found to react instantaneously with ligands I_a–I_d in neutral and slightly basic media to form slightly soluble orange–red complexes. Investigations were carried out to establish the most favourable conditions to achieve maximum colour development in the quantitative determination of Cerium(III). The influence of each of the following variables on the reaction was tested.

3.1. Effect of pH

The protonation constants of the reagents under consideration were calculated [15] and found to be 10.97, 7.57, 11.43 and 8.11 for reagents I_a, I_b, I_c and I_d respectively. The protonation reaction [15] can be represented as

m-Bis-azobenzene-di(β-diketone) :



p-Bis-azobenzene-di(βdiketone) :

I,3-Phenylenediamine bisazobenzoylacetone	533	2.43	Rapid, selective, without heating or extraction	This work
1,4-Phenylenediamine bisazoacetylacetone	511	2.39	Rapid, selective, without heating or extraction	This work
1,4-Phenylenediamine bisazobenzolyacetone	638	2.28	Rapid, selective, without heating or extraction	This work

On varying the pH of the reaction mixture from 5.0 to 10.5, complexes with the four ligands gave maximum absorbance values in the pH ranges 6.5–7.5, 7.0–8.0, 7.5–9.5 and 6.0–8.0 for $\mathbf{I}_a$, $\mathbf{I}_b$, $\mathbf{I}_c$ and $\mathbf{I}_d$ complexes resprctively (Fig. 1). The absorbance–pH curves are parabolic relations, indicating the increased formation of the complexes with increasing pH due to the decreased acidity of the medium and enhanced ionisation of the active protons on the ligands. The decrease in absorbance on the alkaline pH side is due to either the hydrolysis of the complexes or the formation of other types of hydroxoazo complexes having lower absorbance. This behaviour is quite common for complexes formed by proton displacement from the ligand through the metal ion [16]. Hence, the pH values of 7.0, 7.5, 8.5 and 7.0 were chosen for all further studies with $\mathbf{I}_a$, $\mathbf{I}_b$, $\mathbf{I}_c$ and $\mathbf{I}_d$ respectively. It was also observed that the absorbance remained constant with the addition of >10 ml of borate buffer in each case. Accordingly, 12.5 ml of buffer solution of appropriate pH value was used for all further studies.

3.2. Effect of reagent concentration

When the volume of the reagent added to an aliquot of solution containing 50 μg of Cerium(III), was varied from 0.5 to 5.0 ml, the maximum absorbance was observed with the addition of 1.5 ml for Cerium(III)–$\mathbf{I}_a$ and Cerium(III)–$\mathbf{I}_c$ complexes whereas 2 ml was required for Cerium(III)–$\mathbf{I}_b$ and Cerium(III)–$\mathbf{I}_d$ complexes. Hence, 2.5 ml of 10^{-3} M reagent solution was employed for all further studies.

3.3. Effect of solvent ratio

Dioxane was found to be the best solvent to dissolve the slightly soluble Cerium(III) $\mathbf{I}_a$–$\mathbf{I}_d$ complexes and the maximum absorbance was observed in the presence of 25–35% (v/v) dioxane. At least 6.3 ml of dioxane was required for the dissolution of the complex and the absorbance decreased with the addition of >10 ml. All measuremetns were therefore made in the presence of 7.5 ml (30% v/v) of dioxane.

Table 3
Results for the determination of Cerium(III) in two different monazite samples

Sample No.[a]	Reagent	Reference value (%)[b]	Found (%)[c]	Recovery (%) (±SD)	% RSD	t-test[d]	F value[e]
Monazite I		54.85					
	$\mathbf{I}_a$		54.40	99.18 (0.61)	1.95	1.14	2.19
	$\mathbf{I}_b$		54.25	98.91 (0.83)	1.60	1.33	2.47
	$\mathbf{I}_c$		55.10	100.46 (0.52)	2.17	0.99	1.81
	$\mathbf{I}_d$		54.55	99.45 (0.47)	1.44	1.78	2.69
Monazite II		66.20					
	$\mathbf{I}_a$		66.75	100.68 (0.58)	1.82	1.05	2.11
	$\mathbf{I}_b$		67.00	101.21 (0.64)	2.26	1.57	2.36
	$\mathbf{I}_c$		65.75	99.32 (0.49)	1.53	1.24	2.28
	$\mathbf{I}_d$		66.80	100.91 (0.76)	1.72	1.82	2.66

[a]The samples were provided by the Geology Department, Faculty of Science, Benha University, Egypt.
[b]Obtained by atomic absorption spectrometry.
[c]Average of six determinations.
[d]Theoretical value for t-test is 2.57.
[e]Theoretical value for F value is 5.05.

3.4. Spectral characteristics

Absorption spectra of the Cerium(III) complexes with ligands $\mathbf{I}_a$–$\mathbf{I}_d$ were recorded (Fig. 2) at the recommended pH values. As the complexes exhibited maximum absorbances at 573, 533, 511 and 638 nm and their exhibited maximum absorbances at 407, 363, 404 and 410 nm respectively, all measurements were made at corresponding λ_{MAX} values for each complex.

3.5. Composition of the complex

Under the optimum conditions of pH, reagent concentration and solvent ratio described above, the metal: ligand ratios were found to be 1:1 and 2:1, using Job's continuous variation and molar ratio methods. The conditional formation constants (log K), calculated using the Harvey–Manning equation [17], were found to be 4.44, 4.95, 5.63 and 5.22 for the (1:1) complexes, whereas the real constants were 4.75, 5.20, 6.00, and 5.50 respectively. For (2:1) complexes, the conditional formation constants (log K) amount to 8.51, 8.96, 9.73 and 9.37 for $\mathbf{I}_a$, $\mathbf{I}_b$, $\mathbf{I}_c$ and $\mathbf{I}_d$ respectively, while the true constants were 8.88, 9.20, 10.05 and 9.50 respectively. The values indicate that the stability of the complexes increases in the order $\mathbf{I}_a < \mathbf{I}_b < \mathbf{I}_d < \mathbf{I}_c$.

3.6. Beer's law, sensitivity and stability

The absorbance values of the Cerium(III)–$\mathbf{I}_a$–$\mathbf{I}_d$ complexes followed Beer's law over the concentra-

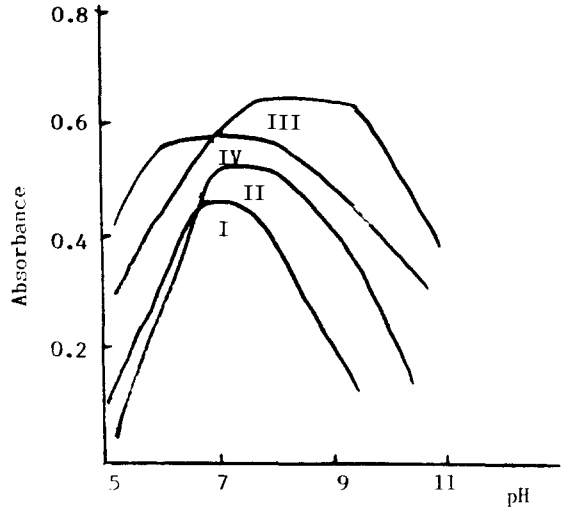

Fig. 1. Effect of pH on the absorbance of I-Ce(III)-I_a complex, II-Ce(III)-I_b complex, III-Ce(III)-complex and IV-Ce(III)-I_d complex.

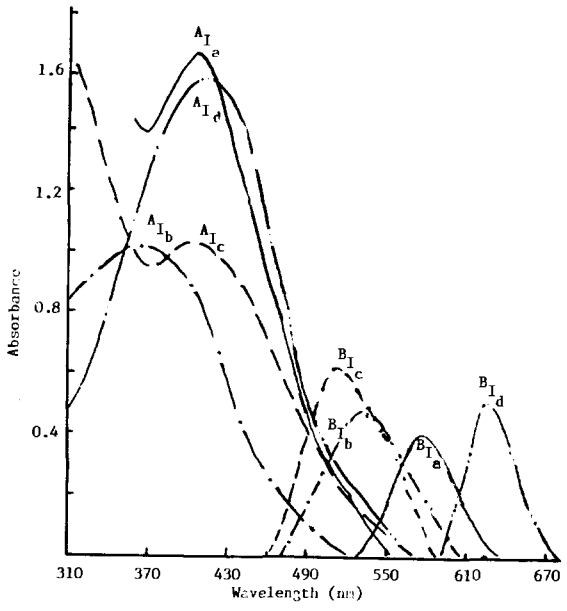

Fig. 2. Absorption spectra of: (A) 1×10^{-4} M ligands I_{a-d} at pH 7.0, 7.5, 8.5 and 7.0 against buffer of the same pH value. (B) 1×10^{-4} M ligands $I_{a-d} + 1 \times 10^{-4}$M Ce(III) at pH 7.0, 7.5, 8.5 and 7.0 against 1×10^{-4} M ligands (I_{a-d}) at the same pH value.

tion ranges 0.10–2.50, 0.05–3.00, 0.05–3.75 and 0.10–3.50 μg ml^{-1} respectively in the measured solutions. They have molar absorptivities of 2.58, 2.43, 2.39 and 2.28 $\times 10^4$ l mol^{-1} cm^{-1} and Sandell sensitivities of 5.4, 5.8, 5.9 and 6.1 ng cm^{-2} respectively. For more accurate results Ringbom optimum concentration ranges were established and were found to be 0.2–2.25, 0.2–2.60, 0.2–3.50 and 0.2–3.30 μg ml^{-1} using $\mathbf{I_a}$, $\mathbf{I_b}$, $\mathbf{I_c}$ and $\mathbf{I_d}$ respectively.

Although the proposed method offers a sensitivity equal to that of Gaokar and Eshawar [11], the proposed method showed longer stabilities of the complexes formed: 3.0, 4.5, 6.0 and 5.0 h using $\mathbf{I_a}$, $\mathbf{I_b}$, $\mathbf{I_c}$ and $\mathbf{I_d}$ respectively compared to stabilities of 1.5 and 2.0 h using 4-(2-thiazolylazo) resorcinol and 1-(2-thiazolylazo)-2-naphthal respectively [11].

3.7. Effect of foreign ions

The interference of various ions in the determination of cerium(III) was studied. The tolerance limit was set as that which causes an error of $\pm 2.0\%$ in the determination of 2.0 μg of Cerium(III) per millimeter. EDTA caused a negative interference due to its complexing action on Ce(III), hence decreasing the effective concentration of the Ce(III)–bisazo-β-diketone complexes. Mn(II), Ni(II), Cu(II), Co(II), Hg(II), Fe(III), Sc(III), Y(III) and La(III) caused positive interferences based on their ability to form complexes with the bisazo-β-diketone which absorbed in the same spectral region as the Ce(III) complexes. The tolerance limits of the various ions are given in Table 1.

Comparison of the proposed method with others (Table 2) shows that the proposed method is simple, rapid, sensitive and selective. It does not require heating, standing time or extraction with organic solvents.

3.8. Precision and accuracy

The relative standard deviation and relative mean error, calculated from 10 replicate determinations with 2.0 μg of Ce(III) per millilitre were found to be $\pm 0.88\%$ and $\pm 0.65\%$ for the Ce(III)–$\mathbf{I_a}$ system, $\pm 0.51\%$ and $\pm 0.33\%$ for the Ce(III)–$\mathbf{I_b}$ system, $\pm 0.67\%$ and $\pm 0.42\%$ for the Ce(III)–$\mathbf{I_c}$ system and $\pm 0.75\%$ and $\pm 0.65\%$ for the Ce(III)–$\mathbf{I_d}$ system.

3.9. Analytical applications

3.9.1. Determination of cerium (IV)

It was found to be possible to use the described method for the determination of Cerium(IV) after prior reduction to Cerium(III) with a reducing agent. Hence 2 ml of solution containing 50 μg of Cerium(IV) in a 25 ml measuring flask was reduced with 300 μg of hydroxylammonium chloride and the resulting cerium(III) solution was analysed with reagent $\mathbf{I_a}$, $\mathbf{I_b}$, $\mathbf{I_c}$ or $\mathbf{I_d}$, as described in Section 2.3 indicating the same sensitivity and limits of determination as in the case of Ce(III).

3.9.2. Determination of cerium in monazite samples

In order to confirm the usefulness of the proposed method, it has been applied to the determina-

tion of Cerium(III) as Ce_2O_3 in two monazite samples. The results observed are compared with those obtained using the atomic absorption technique (Table 3) and indicate that the method is reliable and accurate.

The results obtained by the proposed method were compared with those of the AAS method using the t-test for accuracy and the F-value for the assessment of precision [18] for five degrees of freedom and a 95% confidence level. The calculated values did not exceed the corresponding theoretical values, indicating insignificant differences between the results (Table 3).

4. Conclusion

The data obtained above indicate that the proposed method described for the spectrophotometric determination of Ce(III) ions is quite rapid, precise and sensitive. Thus the chromogenic reagents utilised in the described method above can safely be used under the proper conditions for the satisfactory analysis of Ce(III) ion in solution. The proposed method was successfully applied to the determination of cerium in two different monazite samples. The method also allows the determination of Ce(IV) after prior reduction to Ce(III).

Determination of nanogram levels of zirconium by chelating ion exchange and on-line preconcentration in flow injection UV–visible spectrophotometry

Rajesh Purohit[1], Surekha Devi*

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda-390 002, India

Received 21 February 1996; revised 11 June 1996; accepted 25 June 1996

Abstract

Trace quantities of zirconium were preconcentrated on a series of chelating resins. The experimental conditions for preconcentration such as pH, time and metal ion concentration were optimized for the batch processes. Continuous flow manifolds were developed for the on-line preconcentration of zirconium using microcolumns containing chelating resins. Calibration plots were obtained with correlation coefficients of 0.9990 ± 0.0008. The determination of zirconium was performed using Xylenol Orange at 535 nm. Binary and ternary mixtures of zirconium, thorium and titanium did not show any cross-contamination during column chromatographic separation. © 1997 Published by Elsevier Science B.V.

Keywords: Chromatographic separation; Flow injection; Preconcentration; Zirconium

1. Introduction

The determination of trace amounts of metal ions by on-line preconcentration through liquid–liquid extraction or ion exchange and flow injection analysis has been reported for most metal ions. However, there are few reports on the determination of zirconium using flow injection analysis. Zirconium, being transparent to thermal neutrons, is widely used in nuclear reactors. It is highly active metal but, like aluminium, has a tendency to form a stable cohesive protective oxide film. Hence nanogram level determinations of zirconium are critically important. Various types of supports such as alumina [1], Chelex-100 [2], resin 122 [3] and 8-hydroxyquinoline (oxine)-based resins [4] have been reported for the preconcentration of metal ions before determination. The reported chelating resins containing oxine groups [5–7] exhibited low metal exchange capacities and slow exchange rates. Attempts were made to improve these properties but these resins required moist storage and were unstable at $\geqslant 2$

[a] Abbreviations represent resins synthesized using 8HOQ = 8-hydroxyquinoline, F = formaldehyde, Fu = furfuraldehyde, B = benzaldehyde, R = resorcinol and HQ = hydroquinone.

M acid conditions. Oxine-based chelating resins synthesized by a modified route have been reported [8] which are stable above 2 M acid conditions and do not require moist storage. They have been used successfully for the preconcentration and separation of copper [8], nickel [9], zinc [10] lead [11] and cadmium [10].

Preconcentration of zirconium was carried out by Blasius and Kynst [12] using catechol *O,O*-diacetic acid derivatives. Dowex 50W X4 was used by Fritz and Palmer [13] whereas Vernon [14] and Phillips [15] reported poly(hydroxamic acid) resins for the preconcentration of zirconium. We report here the use of oxine-based resins for the preconcentration of zirconium at the batch level and an on-line continuous flow method.

2. Experimental

2.1. Reagents

AR-grade zirconium oxychloride and high-purity deionized water were used to prepare a standard solution of zirconium. The zirconium solution was standardized using a colorimetric method [16].

Acetate buffers of different pH were prepared from 0.2 M sodium acetate and acetic acid. Xylenol Orange concentration of 0.5% (w/v) was prepared freshly.

2.2. Synthesis of resins

Resins based on 8 hydroxyquinoline (8HOQ), resorcinol (R) or hydroquinone (HQ) and formaldehyde (F), furfuraldehyde (Fu) or benzaldehyde (B) cross-linking agents were synthesized as described earlier [8]. the relevant physico-chemical properties of the resins are given in Table 1. The series of resins were used for batch and column chromatographic studies of zirconium exchange. The optimum pH for the exchange of zirconium and $t_{1/2}$(time required for 50% exchange of metal ions) in batch processes were determined according to literature methods [17]. Zirconium was determined colorimetrically [16] in the supernatant solution and also on elution from the resin.

The kinetics of the zirconium exchange and the mode of diffusion of zirconium towards the resin were determined through an interruption test [17, 18] and were also confirmed by the method reported by Nativ et al. [19]. During the interruption test, resin beads were interrupted by removing them from the solution for 10 min and then reimmersing them in the solution, and metal exchange was further studied. From the nature of the plot of percentage exchange against time, the mode of diffusion of the metal was determined [15]. The efficiency of elution of zirconium from the resin was tested by using various eluents of different strength.

[a] Metal concentration 1 mg cm^{-3}; flow rate 1 cm^3 min^{-1}.
[b] Breakthrough capacity/total capacity.

2.3. Chromatographic separations

Chromatographic columns of 10–18 cm length and 7 mm i.d. were prepared using synthesized resins: 8HOQFR, 8HOQFHQ, 8HOQFuR, 8HOQFuHQ and 8HOQBR. Breakthrough and column capacities and interstitial volumes were determined according to the reported methods [20] and results are given in Table 2. Binary and ternary mixtures of zirconium, titanium and thorium containing 400 μg cm^{-3} metal in ratios of 1:1 and 1:1:1 were passed through the column at the pre-established pH and a flow rate of 1 cm^3 min^{-1}. The columns were thoroughly washed with deionized water. Separation of metals was achieved by following the selective desorption technique. Cross-contamination in the separation was studied by estimating each component individually in all fractions of the column effluent.

2.4. On-line preconcentration of zirconium

A continuous flow manifold for the preconcentration of zirconium at the nanogram was constructed as shown in Fig. 1. A Gilson Minipuls peristaltic pump was used along with a Rheodyne RH 5020 rotary injection valve. Microcolumns of 40 mm length and 2 mm i.d. containing the resins under study were connected to the manifold using 0.5 mm i.d. Teflon tubing. A UV–visible spectrophotometer with a 20 μl flow cell was used as a detector. The absorbance vs. time response was recorded on an x–t chart recorder at 535 nm. Experimental conditions influencing the extent of preconcentration, such as pH, microcolumn length, flow rate and metal concentration, were optimized. The chelated zirconium(IV) was eluted from the microcolumns by injecting 20 μl of 2 M hydrochloric acid followed by the appropriate acetate buffer to avoid carryover of the samples. A three-way valve was used to control the flow of zirconium solution and buffer.

3. Results and discussion

The relevant physico-chemical properties of the resins are given in Table 1. These resins were further used to study the exchange of zirconium(IV) ions. The nature of the cross-linking agent and the type of monomer play important roles in the sodium exchange process and resins containing hydroquinone always showed a higher exchange capacity than the corresponding resorcinol-containing resins. Variations in the cross-linking agent affected the exchange capacity considerably. However, for the exchange of zirconium such variations in the nature of resins had little effect on the chelating properties or on the $t_{1/2}$ values.

The effect of pH on zirconium exchange is illustrated in Fig. 2. The maximum exchange was observed at pH 4, suggesting potential use of resins in acidic effluent treatment. The zirconium selectivity order of the resins based on the distribution coefficient K_d and the exchange capacity was observed to be 8HOQFHQ = 8HOQFuHQ = 8HOQBR > 8HOQFR = 8HOQFuR. The study of the effect of the zirconium ion concentration on the exchange capacity indicated the exchange process is concentration dependent and all the resins, irrespective of their structure, show saturation at a 0.1 M zirconium concentration.

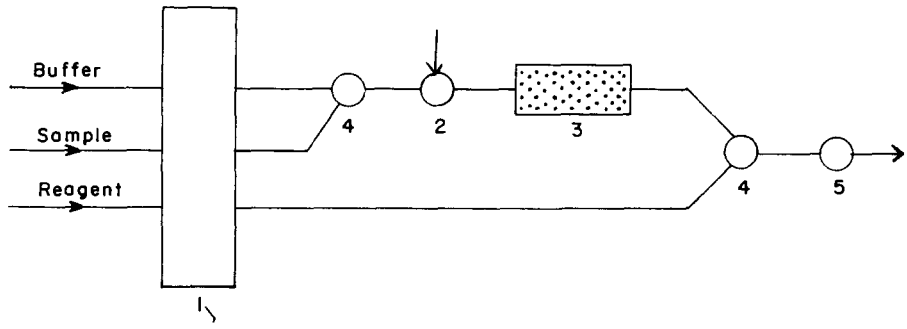

Fig. 1. Flow injection manifold for on-line preconcentration and determination of Zr(IV) using Xylenol Orange as reagent. 1, Peristaltic pump; 2, injection valve; 3, resin column; 4, three-way valve; 5, detector.

From the kinetics of the zirconium exchange, it was observed that complete exchange takes place in less than 4 h and the $t_{1/2}$ values for 8HOQFR, 8HOQFHQ, 8HOQFuR, 8HOQFuHQ and 8HOQBR are 17, 23, 30, 24 and 14 min, respectiviely. The exchange process was observed to be diffusion controlled through the interruption test. As discussed earlier in the interruption test, the interruption pause gives time for the concentration gradient in the beads to level off, hence resulting in an increased exchange rate after reimmersion of the resin particles in the particle diffusion controlled process. In film diffusion, no such concentration gradient exists in the beads and the exchange rate depends on the concentration differences across the film. In this case, interruption does not affect the concentration across the film and hence has no effect on the exchange rate. From the nature of the plots, it is observed that zirconium exchange is a particle diffusion and not a film diffusion process. Particle diffusion was also confirmed with the mathematical model proposed by Nativ et al. [19]. A plot of time vs. $[1-3(1-x)^{2/3}+2(1-x)]$ was constructed, where x is the fractional conversion of the resin, which is the ratio between the measured and maximum exchange capacities. According to this model, film diffusion gives a straight line passing through the origin. The plots with straight line giving an intercept on the abscissa indicate that the diffusion is not a film diffusion but is a particle diffusion process (Fig. 3) in zirconium exhange.

The simple Langmuir isotherm equation [21] for the adsorption of a single adsorbate on a single site surface is still frequently applied in ion-exchange reactions with specific assumptions. The first assumption is that the selectivity coefficient or separation factor remains unchanged or hardly changed during the exchange involved, and the second is that for homovalent and heterovalent exchange, the concentration of one of the ions or of the adsorbed solution is constant. Based on these assumptions, Misak [22] derived certain equations for the study of ion exchange through the Langmuir isotherm for single site heterovalent exchange.

$$\frac{C_A}{q_A}=\frac{C_A}{Q}\left(1-\frac{m}{\alpha n}\right)+\frac{C_0}{\alpha n Q}$$

where C_A = equilibrium concentration of exchanging ion A in solution (mol cm^{-3}), q_A = amount of metal A sorbed (mequiv. g^{-1}), Q = maximum sorption capacity (mequiv g^{-1}), α = separation factor and C_0 = initial concentration of ion A in the solution.

This equation was applied to the data obtained from the kinetic study of zirconium exchange at 0.1 M concentration. From the plot of C_A/q_A against C_A the exchange capacity Q was calculated from the slope, taking $m=4$ and $n=1$ for zirconium ion and resin. The value of Q calculated graphically using the equation based on the Langmuir isotherm for ion exchange agrees well with the experimental value. Hence the proposed

mathematical equation for ion exchange is assumed to be valid with the above-mentioned assumption. From the results for Q and α selectivity coefficient K was calculated by using the equation

$$K = \alpha^{n} \left(\frac{q_A/Q}{C_A} \right)^{n-m}$$

and was found to be 0.04986. It was observed that the selectivity coefficient for the resins under study remains almost unchanged, indicating the similar behaviour of the resins towards zirconium exhange.

3.1. Elution of zirconium from resins

Various eluents of different strengths were used for the elution of zirconium from the resins. It was observed that zirconium can be quantitatively eluted with 0.2–1.0 M hydrochloric acid, sulphuric acid, nitric acid, sodium citrate, sodium tartrate and potassium thiocyanate, whereas phosphoric acid, perchloric acid, sodium chloride and thiourea were not able to elute zirconium from the resins.

3.2. Binary and ternary separations

Volumes of 25 cm^3 of mixtures of zirconium and titanium or zirconium and thorium solutions each containing the metal ions in a 1:1 ratio were passed through the columns with characteristic properties as given in Table 2 at pH 5 and a flow rate of 1 cm^3 min^{-1}. The column effluent did not show any metal, confirming quantitative uptake of the metal ions. The element systems were selected in such a way that no cross-contamination was observed. Each aliquot was analysed for the metals in the mixture. Zirconium and titanium

Table 3
Efficiency of recovery of zirconium, titanium and thorium from binary and ternary mixtures.

Mixture	Resin	Zirconium			Titanium			Thorium		
		Taken (mg)	Recovered (mg)	Recovery (%)	Taken (mg)	Recovered (mg)	Recovery (%)	Taken (mg)	Recovered (mg)	Recovery (%)

	HOQFuHQ	10	10.08	100.8	10	10.29	102.9	10	9.86	98.6
	8HOQF	10	9.98	99.80	10	10.16	101.6	10	10.37	103.7

Values given are the means of five measurements (standard deviations 0.158–0.246).

[16] were determined colorimetrically using Xylenol Orange and chromotropic acid, respectively, and thorium titrimetrically using EDTA. Zirconium was masked with potassium oxalate wherever necessary. The results are given in Table 3 and in Fig. 4. The results of triplicate determinations showed 99.2–102.8% recoveries. The separation of ternary mixtures of zirconium, titanium and thorium at pH 5 was achieved without any cross-contamination using specific eluents as shown in Fig. 4. The observed recoveries for triplicate sets were 98.8–102.8%, as shown in Table 3.

3.3. Flow injection system

The determination of zirconium at nanogram levels was carried out after on-line preconcentra-

tion on microcolumns containing 8HOQFR, 8HOQFHQ, 8HOQFuR, 8HOQFuHQ and 8HOQBR resins in a continuous flow system as shown in Fig. 1. Solutions containing 50 ng cm^{-3} (1×10^{-7} M) zirconium were passed through the systems at a flow rate of 3 cm^3 min^{-1}. Continuous monitoring of the column effluents showed a quantitative uptake of the zirconium by all the resin columns. From the study of the effect of pH on the on-line preconcentration in the flow system than in a batch system (Fig. 2). However, 20 μl of 2 M hydrochloric acid could elute zirconium quantitatively from all the resin columns. The dispersion of the system under study was calculated by using 5 μg cm^{-3} of zirconium solution in the sample channel (Fig. 1) and also injecting 20 μl of 5 μg cm^{-3} of zirconium solution through the manifold with an empty microcolumn and also without a microcolumn. Introduction of the microcolumn did not influence the dispersion coefficient to a significant extent. The dispersion coefficient was calculated to be 2.2. The sharp elution peaks obtained showed faster kinetics during exchange processes.

From the study involving different column lengths for the preconcentration, it was observed that 4 cm long columns of 2 mm i.d. are sufficient for the preconcentration and longer (>6 cm) columns increase the dispersion. Similarly, a 2 cm^3 min^{-1} flow rate was observed to be optimum whereas at lower and higher flow rates either the peaks were not sharp or greater dispersion was observed.

A calibration plot for the preconcentration of 5 cm^3 of zirconium solution in the conentration range 0.5–2.5 μg cm^{-3} was obtained for each resin after elution of zirconium with 20 μl of 2 M hydrochloric acid. The results were recorded in triplicate as shown in Fig. 5. The regression coefficients were 0.9982, 0.9996, 0.9986, 0.9992 and 0.9976 for the resins 8HOQFR, 8HOQFHQ, 8HOQFuR, 8HOQFuHQ and 8HQOBR, respectively. The lowest detection limit was found to be 10 ng cm^{-3}, which was based on twice the standard deviation of the blank signals. The RSD values were in the range 0.8–2.65%.

From this study, it is concluded that the synthesized resins are effective for the preconcentration of zirconium at the nanogram level using a flow injection manifold. The colorimetric method established using Xylenol Orange reagent was successful for the determination of zirconium in the presence of Cu(II), Ni(II), Pb(II), Zn(II), Cd(II), Fe(II), Mn(II), Al(III), Cr(VI), Mo(VI), Th(IV), V(V), Ce(IV), UO_2^{2+} and Ti(IV) under optimized conditions. The efficient separation of zirconium from titanium and thorium was achieved by column chromatography. Continuous recording gave no signal during preconcentration, indicating the high efficiency of the resins for the removal of zirconium from the solution.

Extraction equilibria of some transition metal ions by bis(2-ethylhexyl)phosphinic acid

Yukio Nagaosa *, Yao Binghua

Faculty of Engineering, Fukui University, Bunkyo, Fukui 910, Japan

Received 18 December 1995; received in revised form 9 July 1996; accepted 12 July 1996

Abstract

Measurements of dimerization constants ($K_{d,HR}$) and distribution constants ($K_{D,HR}$) of bis(2-ethylhexyl)phosphinic acid (PIA-8) in three kinds of organic diluents were carried out by a potentiometric two-phase titration technique at 298 ± 0.1 K. Extraction of iron(III), zinc(II), copper(II), manganese(II), cadmium(II), cobalt(II) and nickel(II) by PIA-8 from 1.0 mol dm^{-3} ammonium sulfate solution into heptane was investigated as a function of pH and extractant concentration. The data have been analyzed both graphically and numerically to determine the stoichiometry of extracted species and their extraction constants. The extracted metal species were found to be $FeR_3 \cdot 2HR$ for iron(III), ZnR_2 and $ZnR_2 \cdot 3HR$ for zinc(II), $CuR_2 \cdot HR$ and $CuR_2 \cdot 5HR$ for copper(II), $MnR_2 \cdot 2HR$ and $MnR_2 \cdot 3HR$ for manganese(II), $CdR_2 \cdot 3HR$ for cadmium(II), $CoR_2 \cdot HR$ and $CoR_2 \cdot 4HR$ for cobalt(II) and $NiR_2 \cdot 3HR$ and $NiR_2 \cdot 6HR$ for nickel(II), respectively. © 1997 Elsevier Science B.V.

1. Introduction

Organophosphorus acid extractants have been widely studied for the separation and recovery of several metals in acidic media [1–5]. Particularly, enhanced selectivity has been reported with dialkylphosphinic acids like bis(2,4,4-trimethylpentyl) phosphinic acid (Cyanex 272), e.g. in the separation of cobalt(II) and nickel(II) [6]. Cyanex 272 as an extractant, however, possesses a high selectivity for the separation of cobalt(II)–nickel(II) and an ability to reject calcium(II); two problems concerning the viscosity of the organic phase and the extraction rate have been reported. The polymers are formed in the organic phase as the loaded cobalt increases, and as a result the viscosity of the organic phase increases as reported by Komasawa et al. [7]. Consequently, the loading ability of the organic phase has to be limited to prevent any large increase in viscosity, and a subsequent decrease in mass transfer rates occurs. Dreisinger and Cooper [8] also reported that the extraction rate of metal ions by Cyanex 272 extractant was considerably lower than that with bis(2-ethylhexyl)phosphoric acid (D2EHPA).

Little is known about bis(2-ethylhexyl)phosphinic acid (PIA-8) as an organophos-

PII S0039-9140(96)02047-4

phorus acid extractant for the separation by solvent extraction of transition metal ions to date. Therefore, we first have estimated the dimerization constants and the distribution constants of PIA-8 in some organic diluents by a potentiometric two-phase titration technique. The extraction equilibria of iron(III), zinc(II), copper(II), manganese(II), cadmium(II), cobalt(II) and nickel(II) by PIA-8 from 1.0 mol dm^{-3} ammonium sulfate solution into heptane have then been investigated. The stoichiometry of the extracted metal species and their conditional extraction constants have also been determined by means of numerical and graphical analyses. In this paper, the results of the studies will be discussed.

2. Experimental

2.1. Reagents and apparatus

PIA-8 was delivered from Daihachi Chemical Industry (Osaka, Japan). No further purification was made before use (the purity was 96.6%). Heptane of analytical reagent grade (Wako Pure Chemicals, Osaka, Japan), kerosene (a mixture of aliphatic hydrocarbons C_{11}–C_{13}, which had a density of 790 kg m^{-3} at 295 K, Nacalai Tesque, Kyoto, Japan) and Naphtezol M (a mixture of aromatic hydrocarbons containing 55% naphtens, 35% iso-paraffins and 10% *n*-paraffins, which had a density of 816 kg m^{-3} at 288 K, Nippon Petrochemistry, Tokyo, Japan) were used as organic diluents without purification. The standard stock solutions of iron(III), zinc(II), copper(II), cadmium(II), manganese(II), cobalt(II) and nickel(II) were prepared by dissolving their sulfates in 0.1 mol dm^{-3} sulfuric acid. All inorganic reagents were of analytical reagent grade and used without further purification.

An Iwaki Model 2366 KM Shaker was used to equilibrate the two phases. A Toa Model HM-30S pH meter (TOA Electronic, Tokyo, Japan) was used for pH measurements. Metal ion concentrations were determined by the titration method using ethylenediaminetetraacetic acid (EDTA) or a Seiko Model SPS-7000 Plasma Spectrometer (Seiko Electronic, Tokyo, Japan).

2.2. Procedures

2.2.1. Two-phase potentiometric titration

Equal volumes (35.0 cm^3 each) of distilled water and organic diluent were placed into a 100 cm^3 stoppered conical Erlenmeyer flask in a thermostatted water bath at 298 ± 0.1 K. A potentiometric two-phase titration was carried out while maintaining both the neutralized fraction constant and the phase ratio equal to unity. This was achieved by successively adding 1.0 ml of each of 0.100 mol dm^{-3} PIA-8 in organic diluent and 1.0 cm^3 of 5.00×10^{-2} mol dm^{-3} sodium hydroxide solution. The two phases were stirred for 1800 s and allowed to stand for 900 s. The pH value of the aqueous phase was then measured. Nitrogen was used to prevent the dissolution of carbon dioxide.

2.2.2. Measurement of extraction equilibrium

Equal volumes (15.0 cm^3 each) of organic and aqueous phases were placed in a 50 cm^3 separation funnel, and the two phases were then shaken for 600 s on the mechanical shaker at 298 ± 0.1 K.

Preliminary experiments showed that the extraction equilibria were accomplished for a shaking time of 600 s. The aqueous phase was prepared by diluting the standard stock solution, to which 2.0 mol dm^{-3} ammonium sulfate solution was added in order to maintain the ion strength constant. The initial concentration of metal ions was 2.00×10^{-2} mol dm^{-3}, and the initial concentration of PIA-8 in the organic phase ranged from 0.1–0.48 mol dm^{-3} as the dimeric acid [$(HR)_2$]. After phase separation, the pH value of the aqueous phase was measured by using the pH meter. The concentration of metal ions in the aqueous phase was determined by using the Plasma Spectrometer or by titration with 2.00×10^{-2} mol dm^{-3} EDTA using Cu-PAN (PAN was used for copper(II) and Tiron for iron(II)) as the indicator. The concentration of metal ion in the organic phase was calculated from the concentration of metal ion in the aqueous phase according to the mass balance law. The distribution ratio (D) was calculated in the usual manner.

3. Results and discussion

3.1. Aggregation and distribution of extractant

Organophosphorus acid extractants are known to be present as dimers in such organic diluents as heptane, toluene and carbon tetrachloride [9] and to be as monomers in methyl alcohol and *n*-decyl alcohol [10]. In general, it is important to know the aggregation degree of the extractant in organic solvents and the distribution of the extractant between the aqueous and organic phases in order to clarify the extraction mechanism of the metal ions.

Several equilibrium constants concerning PIA-8 as the extractant can be expressed as the following equations:

$$2(HR)_{org} = (HR)_{2,org}$$

$$K_{d,HR} = [(HR)_2]_{org}/[HR]^2_{org} \quad (1)$$

$$(HR)_{aq} = (HR)_{org}$$

$$K_{D,HR} = [HR]_{org}/[HR]_{aq} \quad (2)$$

$$(HR)_{aq} = H^+_{aq} + R^-_{aq}$$

$$K_a = [H^+]_{aq}[R^-]_{aq}/[HR]_{aq} \quad (3)$$

where $K_{d,HR}$, $K_{D,HR}$ and K_a are the dimerization constant, the distribution constant and the acid dissociation constant, respectively. In the case of the potentiometric two-phase titration, the two-phase dissociation constants of K_{aE} and K_{2aE} can be expressed by using K_a, $K_{D,HR}$ and $K_{d,HR}$ [11]:

$$K_{aE} = [H^+]_{aq}[R^-]_{aq}/([HR]_{aq} + [HR]_{org})$$
$$= K_a/(1 + K_{D,HR}) \quad (4)$$

$$K_{2aE} = [H^+]^2_{aq}[R^-]^2_{aq}/[(HR)_2]_{org} = K^2_{aE}/K_{d,HR} \quad (5)$$

then,

$$\log K_{d,HR} = pK_{2aE} - 2pK_{aE} \quad (6)$$

$$\log K_{D,HR} = pK_{aE} - pK_a \quad (7)$$

According to the mass balance law, the total concentration of extractant can then be written as

$$C_{HR} = [HR]_{org} + [HR]_{aq} + [R^-]_{aq} + 2[(HR)_2]_{org} \quad (8)$$

When Eqs. (4) and (5) are substituted into Eq. (8), the following equation is obtained.

$$\frac{C_{HR} - [R^-]_{aq}}{[H^+]_{aq}[R^-]_{aq}} = \frac{1}{K_{aE}} + \frac{2}{K_{2aE}}[H^+]_{aq}[R^-]_{aq} \quad (9)$$

Here the value of the $[R^-]_{aq}$ can be calculated from the mass balance [12]: $[R^-]_{aq} = ghC_{HR} + 10^{-pH} - 10^{pH-14}$, where g is the neutralization percentage, and h is the correction factor of the aqueous volume. Thus, a plot of $(C_{HR} - [R^-]_{aq})/([H^+]_{aq}[R^-]_{aq})$ against $[H^+]_{aq}[R^-]_{aq}$ should obtain a straight line with a slope of $2/K_{2aE}$ and an intercept of $1/K_{aE}$. As shown in Fig. 1, good linear relationships were obtained for PIA-8 in the diluents. From their intercepts and slopes obtained, further, the $K_{d,HR}$ and $K_{D,HR}$ values were calculated by using Eqs. (6) and (7), as summarized in Table 1 (where $pK_a = 4.48$ was determined in our previous paper [12]). The results indicate that

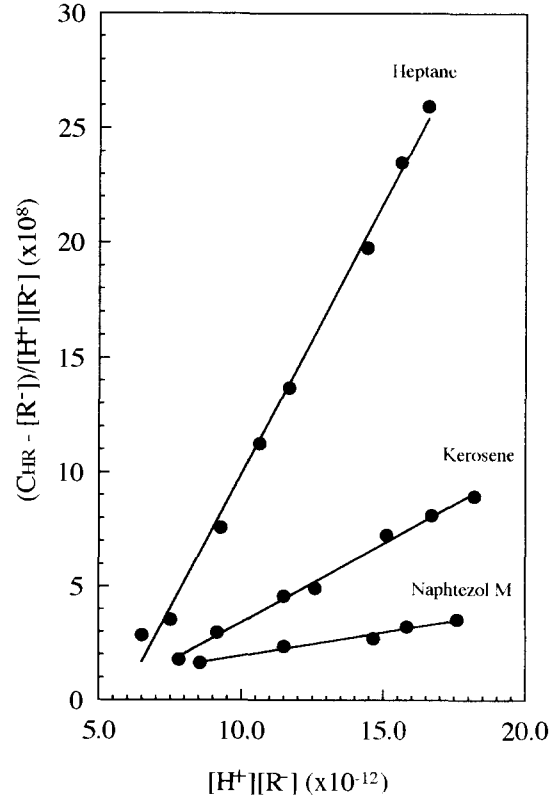

Fig. 1. Regression curves of titration data with PIA-8 solutions in various diluents.

Table 1
Dimerization constants and distribution constants of PIA-8 in various diluents at 298 K

Organic diluent	pK_{aE}	pK_{2aE}	$\log K_{d,HR}$	$\log K_{D,HR}$
Heptane	9.17	20.1	1.75	4.69
Kerosene	8.55	19.5	2.44	4.07
Naphtezol M	7.11	19.0	4.80	2.63

PIA-8 exhibited the largest $\log K_{D,HR}$ value and the smallest $\log K_{d,HR}$ value in the heptane/water system. In order to ascertain the validity of the potentiometric titration method used, the $K_{d,HR}$ and $K_{D,HR}$ values of Cyanex 272 in kerosene/water were also estimated to be $\log K_{d,HR} = 4.56$ and $\log K_{D,HR} = 3.20$, respectively. Both values are close to those already reported ($\log K_{d,HR} = 4.20$, $\log K_{D,HR} = 2.97$ for Cyanex 272 in the kerosene/water system) [13]. Accordingly, it is concluded that the potentiometric two-phase titration technique is acceptable to estimate the dimerization and distribution constants of PIA-8.

3.2. Extraction equilibria of metal ions

It is well known that transition metal ions easily form the corresponding ammine complexes with ammonia in aqueous media.

$$M_{aq}^{n+} + pNH_3 = [M(NH_3)_p]_{aq}^{n+} \tag{10}$$

$$\beta_p = \frac{[M(NH_3)_p^{n+}]_{aq}}{[M^{n+}]_{aq}[NH_3]_{aq}^{p}} \tag{11}$$

where β_p is the stability constant of the complex $[M(NH_3)_p^{n+}]_{aq}$ ($p = 1, 2, \ldots, 6$). For the system investigated, the constants $\beta_1 - \beta_6$ for cobalt(II) and nickel(II), and $\beta_1 - \beta_4$ for zinc(II), copper(II) and cadmium(II) are available except for iron(III) and manganese(II), respectively. Furthermore, the total concentration of the metal ion in ammonium sulfate solution can be expressed as follows:

$$C_{M,aq} = [M^{n+}]_{aq} + \sum [M(NH_3)_p]$$

$$= [M^{n+}]_{aq}(1 + \sum \beta_p [NH_3]^p) \tag{12}$$

The concentration of the free metal ion can therefore be calculated by using the following relationship:

$$[M^{n+}]_{aq} = \frac{C_{M,aq}}{1 + \sum \beta_p [NH_3]^p} \tag{13}$$

Assuming that the metal ion (M^{n+}) is extracted as a form of oligomerized species $(MR_n \cdot mHR)_x$ by the dimer PIA-8 ($(HR)_2$) into an organic diluent from aqueous media. The general extraction reaction can be expressed as follows:

$$xM_{aq}^{n+} + \frac{x(m+n)}{2}(HR)_{2,org}$$

$$= (MR_n \cdot mHR)_{x,org} + xnH_{aq}^{+} \tag{14}$$

The extraction equilibrium constant (K_{ex}) for this reaction is

$$K_{ex} = \frac{[(MR_n \cdot mHR)_x]_{org}[H^+]_{aq}^{xn}}{[M^{n+}]_{aq}^{x}[(HR)_2]_{org}^{x(m+n)/2}} \tag{15}$$

where n, m and x represent the valence of the metal ion, the coordination number of the extractant in the extracted species, and the oligomerization number of the extracted species, respectively. According to the mass balance law, the total concentration of metal ions in the organic phase, $C_{M,org}$, can be written as

$$C_{M,org} = \sum_{x=1} \sum_{m=1} x[(MR_n \cdot mHR)_x]_{org}$$

$$= \sum_{x=1} \sum_{m=1} xK_{ex}[M^{n+}]_{aq}^{x}$$

$$\times [(HR)_2]_{org}^{x(m+n)/2}[H^+]_{aq}^{-xn} \tag{16}$$

If the extracted metal species exists only as $(MR_n \cdot mHR)_x$ (x = a constant) in the organic phase, the following expression can be obtained:

$$C_{M,org} = [M^{n+}]_{aq}^{x}[H^+]_{aq}^{-nx} \sum_{m=1} xK_{ex}$$

$$\times [(HR)_2]_{org}^{x(m+n)/2} \tag{17}$$

or

$$\log C_{M,org} = x(\log[M^{n+}]_{aq} - n \log[H^+]_{aq}) + \log \sum_{m=1} xK_{ex}[(HR)_2]_{org}^{x(m+n)/2} \quad (18)$$

The value of the oligomerization number (x) of the extracted species can thus be obtained from the slope for the plots of $\log C_{M,org}$ against ($\log [M^{n+}]_{aq} - n \log [H^+]_{aq}$) at a constant extractant concentration. Table 2 summarizes the results of the slope analysis for several metal ions at 0.32 mol dm^{-3} extractant concentration [$(HR)_2$]. It can be seen that the regression straight lines with slopes close to unity were obtained at the low concentration of the metal ions investigated. this indicates that the metal ions were extracted as monomers ($MR_n \cdot mHR$), that is, $x = 1$.In the case of $x = 1$, the following expressions can be derived from Eqs. (13) and (17).

$$C_{M,org} = K_{ex}[(HR)_2]_{org}^{(m+n)/2}[M^{n+}]_{aq}[H^+]_{aq}^{-n} \quad (19)$$

$$C_{M,aq} = [M^{n+}]_{aq}(1 + \sum_{p=1} \beta_p[NH_3]_{aq}^p) \quad (20)$$

The distribution ratio D for the metal ion between the aqueous and organic phases becomes

$$\log D = \log K'_{ex} + (m+n)/2 \log [(HR)_2]_{org} + n\text{pH} \quad (21)$$

where $K'_{ex} = K_{ex}/(1 + \Sigma \beta_p[NH_3]^p)$ represents the conditional extraction constant of the metal ions.

Table 2
Results of slope analysis for the determination of x values in the extraction of metal ions by 0.32 mol dm^{-3} PIA-8 in heptane at 298 K[a]

Metal ion	$\log C_{M,org}$ against ($\log [M^{n+}]_{aq} - n \log[H^+]_{aq}$)			
	Intercept	Slope	Point	Coefficient
Fe(III)	−5.15	0.98	8	0.999

[a] Aqueous phase: 0.02 mol dm^{-3} metal ion and 1.0 mol dm^{-3} ammonium sulfate solution; organic phase: 0.32 mol dm^{-3} PIA-8 in heptane; phase ratio: O/A = 1:1; shaking time: 600 s.

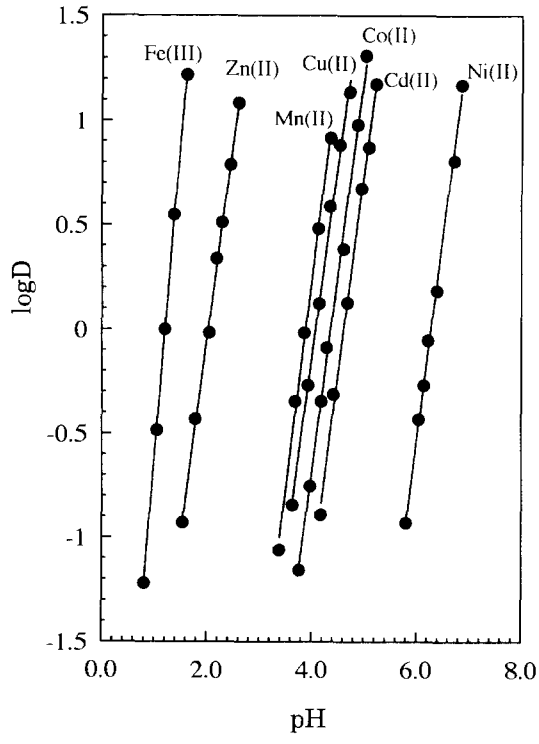

Fig. 2. Plots of log D against pH for the extraction of metal ions by PIA-8 in heptane. Organic phase: 0.32 mol dm^{-3} PIA-8 solutions in heptane; aqueous phase: 0.02 mol dm^{-3} metal ion in 1.0 mol dm^{-3} ammonium sulfate solution; shaking time: 600 s at a phase-volume ratio of 1:1.

Plots of log D against pH at a constant extractant concentration should therefore give a straight line of slope n. As is evident from Fig. 2, good linear relationships were obtained for all metal ions. The slopes were close to two for all divalent metal ions and three for iron(III). The results of $n = 2$ and 3 indicate that the extracted metal species included two and three ligand anions, respectively.

In order to investigate the stoichiometry of the extracted metal species, the plots of ($\log D - xn\text{pH}$) against $\log [(HR)_2]_{org}$ were carried out using the experimental data at a constant pH for each metal ion. Table 3 summarizes the results of the slope analysis. It can be seen that the m values were close to three and two for the extraction of iron(III) and cadmium(II), respectively. This indicates that iron(III) and cadmium(II) are predominantly ex-

Table 3

[a] Aqueous phase: 0.02 mol dm^{-3} metal ion and 1.0 mol dm^{-3} ammonium sulfate solution; organic phase: 0.1–0.48 mol dm^{-3} PIA-8 in heptane; phase ratio: O/A = 1:1; shaking time: 600 s.

tracted as the forms $FeR_3 \cdot 2HR$ and $CdR_2 \cdot 3HR$ into the organic phase, respectively. The extracted species FeR_3 has already been reported for the extraction of iron(III) by mono(n-octyl)phosphinic and di(n-octyl)phosphinic acids [14]. This may be due to the relatively higher HR concentration used in this work. In the extraction of cadmium(II), on the other hand, the species $CdR_2 \cdot 3HR$ described above was found with bis(2-ethylhexyl)phosphoric acid in dodecane [14,15]. The different species $CdR_2 \cdot 2HR$ and $CdR_2 \cdot 3HR$ or $CdR_2 \cdot 4HR$ were also reported for the extraction of cadmium(II) by Cyanex 272 [16,17]. Table 4 gives their conditional extraction constants graphically determined by the slope analysis, together with those numerically calculated by the usual computer program [18]. Both constants were so coincident that the numerical calculation was valuable for the determination of the exact extraction constant for the one species extracted. In Table 3, on the other hand, the fractional values of m were obtained for the extraction of zinc(II), copper(II), manganese(II), cobalt(II) and nickel(II). This indicates that two or more kinds of metal species coexist in the organic phase. In this case, the stoichiometry of the extracted species should be determined by means of numerical analysis, instead of the slope analysis.

Table 4
Extracted species and conditional extraction constants for Fe(III) and Cd(II) with PIA-8 in heptane at 298 K

Metal ion	Extracted species	$-\log K'_{ex}$	
		Numerical[a]	Graphical[b]
Fe(III)	$FeR_3 \cdot 2HR$	3.44 ± 0.06	3.4
Cd(II)	$CdR_2 \cdot 3HR$	7.78 ± 0.07	7.7

[a] The results were obtained from the numerical calculation, and the error given corresponds to $3\sigma(\log K'_{ex})$, in which $\sigma(\log K'_{ex})$ was defined to be $(\Sigma((\log K'_{ex})_i - (\log K'_{ex})_{average})^2/(N_p - 1))^{1/2}$.
[b] The $\log K'_{ex}$ value was averaged from values obtained by plotting $(\log D - n\mathrm{pH})$ against $\log[(HR)_2]_{org}$ and $(\log D - (m+n)/2 \log[(HR)_2]_{org})$ against pH.

Assuming that two kinds of metal species are coextracted into the organic phase, Eq. (19) can be written as

$$C_{M,HR} = [MR_n \cdot iHR]_{org} + [MR_n \cdot jHR]_{org} \quad (22)$$

The distribution ratio D for the metal ion is then expressed as

$$D = \frac{[MR_n \cdot iHR]_{org} + [MR_n \cdot jHR]_{org}}{C_{M,aq}} \quad (23)$$

Substituting Eq. (15) into Eq. (23), the following equation can be obtained

$$\frac{D \cdot [H^+]^n_{aq}}{K'_{ex}(i) \cdot [(HR)_2]^{(i+n)/2}_{org}} = 1 + \frac{K'_{ex}(j)}{K'_{ex}(i)} [(HR)_2]^{(j-i)/2}_{org} \quad (24)$$

where $K'_{ex}(i)$ and $K'_{ex}(j)$ represent the conditional extraction constants of the metal ions extracted as the type $MR_n \cdot iHR$ and $MR_n \cdot jHR$, respectively.

Table 5
Extracted species and conditional extraction constants for Zn(II), Cu(II), Mn(II), Co(II) and Ni(II) with PIA-8 in heptane at 298 K

Metal ion	(i,j)	Extracted species	Q_{min} ($\times 10^2$)	$\sigma(\log D)$ ($\times 10^2$)	$-\log K'_{ex}(i)$	$-\log K'_{ex}(j)$
Zn(II)	(0,3)	ZnR_2, $ZnR_2 \cdot 3HR$	0.042	0.91	3.78 ± 0.03	2.96 ± 0.03
Cu(II)	(1,5)	$CuR_2 \cdot HR$, $CuR_2 \cdot 5HR$	0.278	2.36	6.89 ± 0.07	6.12 ± 0.07
Mn(II)	(2,3)	$MnR_2 \cdot 2HR$, $MnR_2 \cdot 3HR$	0.569	3.38	7.43 ± 0.08	6.79 ± 0.08
Co(II)	(1,4)	$CoR_2 \cdot HR$, $CoR_2 \cdot 4HR$	0.135	1.64	8.07 ± 0.05	7.43 ± 0.05
Ni(II)	(3,6)	$NiR_2 \cdot 3HR$, $NiR_2 \cdot 6HR$	0.019	0.62	10.56 ± 0.0	10.60 ± 0.02

Although the values of i, j and $K'_{ex}(i)$, $K'_{ex}(j)$ can be obtained by some graphical method [19–21], it is more convenient to determine them by means of numerical analysis [18]. Defining two variables, Y and X, and a parameter z as

$$\log Y = \log D - 2\mathrm{pH} - (i+n)/2 \log [(\mathrm{HR})_2]_{org} - \log K'_{ex}(i) \quad (25)$$

$$\log X = \frac{1}{z}(\log K'_{ex}(j) - \log K'_{ex}(i)) + \log[(\mathrm{HR})_2]_{org} \quad (26)$$

$$z = (j-i)/2 \quad (27)$$

and substituting Eqs. (25)–(27) into Eq. (24), the resultant equation is

$$\log Y = \log(1 + X^z) \quad (28)$$

Using Eq. (28), a set of theoretical curves of $\log Y$ against $\log X$ for different z values was constructed by the computer program, which was written for the system of two kinds of extracted species, and then compared with the experimental curves of $(\log D - 2\mathrm{pH} - (i+n)/2 \log [(\mathrm{HR})_2]_{org})$ against $\log [(\mathrm{HR})_2]_{org}$ for different i values. This program orders the computer to search for the best set of conditional extraction constants $K'_{ex}(i)$ and $K'_{ex}(j)$ by minimizing the error squares sum defined by

$$Q = \sum(\log D_{exp} - \log D_{calc})^2 \quad (29)$$

where D_{exp} is the distribution ratio of metal ions determined experimentally and D_{calc} is the value calculated by the computer program. This program also calculated the standard deviation $\sigma(\log D)$, defined by $\sigma(\log D) = (Q/(N_p - 1))^{1/2}$, where N_p is the total number of experimental points. The free reagent concentration $[(\mathrm{HR})_2]_{org}$ used in the plots given by Eq. (30) on a dimeric basis

$$[(\mathrm{HR})_2]_{org} = C_t - (i+j+n)/2C_{M,org} \quad (30)$$

where C_t and $C_{M,org}$ are the total concentration of extractant and the concentration of metal ion in the organic phase, respectively.

By superimposing the experimental curves on the theoretical model function, a position was found where the experimental curves coincide with one of the theoretical curves. In other words, the error squares sum Q is the smallest (expressed as Q_{min}) in this position. As seen from Fig. 3, the best fit was found to be $i = 0$, $z = 1.5$ for zinc(II), $i = 1$, $z = 2$ for copper(II), $i = 2$, $z = 0.5$ for manganese(II), $i = 1$, $z = 1.5$ for cobalt(II) and $i = 3$, $z = 1.5$ for nickel(II), respectively. This indicates that the metal species extracted into the organic phase may be considered to be ZnR_2 and $ZnR_2 \cdot 3HR$ for zinc(II), $CuR_2 \cdot HR$ and $CuR_2 \cdot 5HR$ for copper(II), $MnR_2 \cdot 2HR$ and $MnR_2 \cdot 3HR$ for manganese(II), $CoR_2 \cdot HR$ and $CoR_2 \cdot 4HR$ for cobalt(II), and $NiR_2 \cdot 3HR$ and $NiR_2 \cdot 6HR$ for nickel(II), respectively. The corresponding values of Q_{min} and $\sigma(\log D)$ are summarized in Table 5.

The extracted species described above were compared with the reported for the extraction of divalent metal ions with other organophosphorus acids. For the extraction of copper(II) and zinc(II), the m values of the extracted species are different from those obtained with Cyanex 272 in Isopar-H from 0.1 mol dm^{-3} sodium nitrate solution; the extracted species were determined to be $CuR_2 \cdot 2HR$ for copper(II), and $ZnR_2 \cdot HR$ and

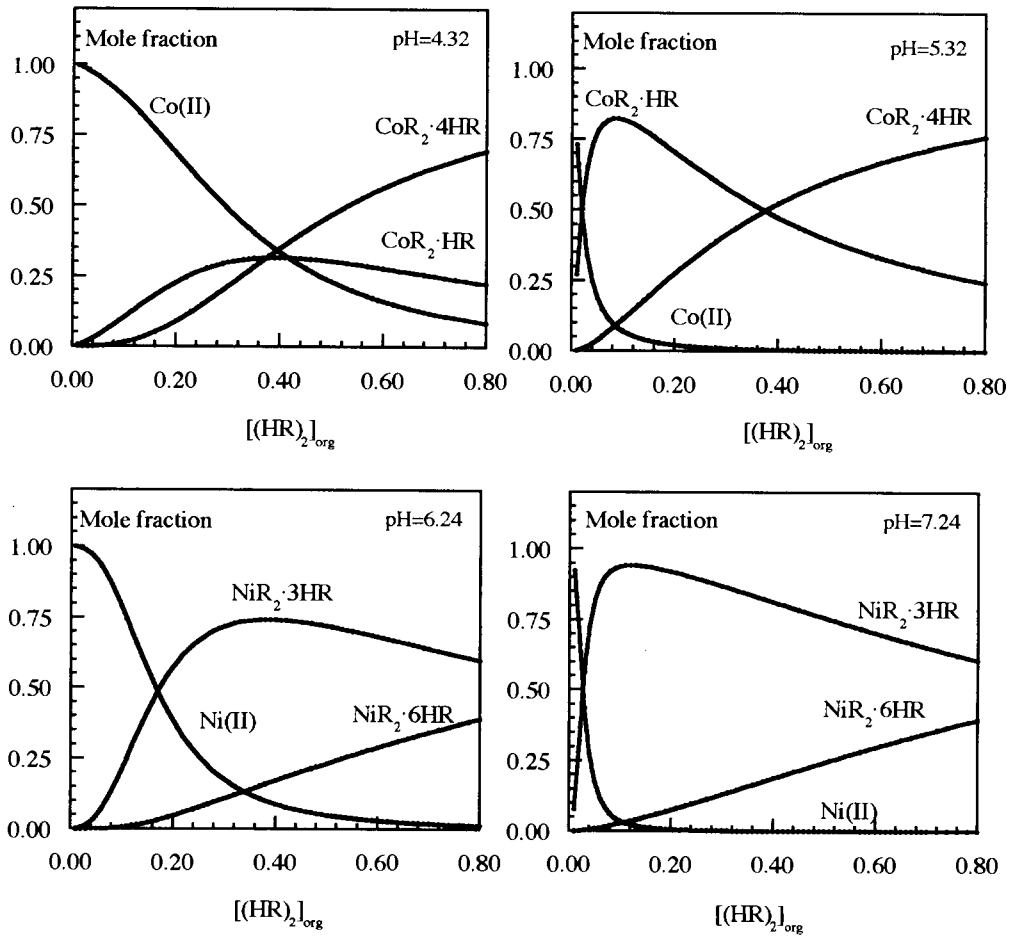

Fig. 4. Distribution diagrams of metal ions as a function of the total HR concentration at two selected pH values.

$ZnR_2 \cdot 2HR$ for zinc(II), respectively [16]. The extracted species $CoR_2 \cdot 2HR$ and $NiR_2 \cdot 4HR$ were reported for the extraction of cobalt(II) and nickel(II) by di(*n*-octyl)phosphinic acid in toluene and bis(2-ethylhexyl)phosphoric acid in dodecane from 1.0 mol dm^{-3} sodium nitrate solution, respectively [14,15]. The differences in the m values may be mainly due to the different concentration ratio of extractant HR to the metal ion investigated. The diluents may also affect the stoichiometry of the extracted species. The general stoichiometry can be written as $MR_n \cdot mHR$, ($n = 2$ or 3, $m = 1, 2, \ldots, 6$) for the present extraction system.

Using the Eqs. (25) and (26), the conditional extraction constants [$K'_{ex}(i)$ and $K'_{ex}(j)$] and the corresponding standard derivations for zinc(II), copper(II), manganese(II), cobalt(II) and nickel(II) were calculated. The results are summarized in Table 5.

In order to investigate the contributions of free metal ion and the extracted metal species in the extraction system, the mole fractions of them as a function of total HR concentration were calculated at two selected pH values. As shown in Fig. 4, the dominant extracted species were found to be ZnR_2 for zinc(II), $CuR_2 \cdot HR$ for copper(II), $CoR_2 \cdot HR$ for cobalt(II) and $NiR_2 \cdot 3HR$ for nickel(II) at relatively higher pH values and lower HR concentrations ($[(HR)_2]_{org} < 0.2$ mol cm^{-3}). How-

ever, the mole fractions of ZnR_2, $CuR_2 \cdot HR$ and $CoR_2 \cdot HR$ decreases sharply and are gradually substituted by $ZnR_2 \cdot 3HR$, $CuR_2 \cdot 5HR$ and $CoR_2 \cdot 4HR$ as the HR concentration increases, respectively. For the extraction of manganese(II), the metal species $MnR_2 \cdot 3HR$ dominates in the whole range of HR concentration, and its mole fraction is always larger than 0.75 ($[(HR)_2]_{org} > 0.3$ mol dm^{-3}). The mole fraction of $MnR_2 \cdot 2HR$, on the other hand, is relatively small and decreases gradually with increasing HR concentrations. For the extraction of nickel(II), it can be seen that the extracted species $NiR_2 \cdot 3HR$ is predominant in the whole range of experimental conditions used, and its mole fraction first sharply increases and then gradually decreases with increasing HR concentrations. At relatively lower HR concentrations ($[(HR)_2]_{org} <$ 0.2 mol dm^{-3}), the mole fraction of the species $NiR_2 \cdot 6HR$ is very small, whereas it increases linearly with increasing HR concentrations ($[HR)_2]_{org} > 0.2$ mol dm^{-3}).

4. Conclusions

The extraction equilibria of some transition metal ions by PIA-8 from 1.0 mol dm^{-3} ammonium sulfate solution into heptane were studied at 298 ± 0.1 K, and the following conclusions were obtained.

(1) The dimerization constant ($K_{d,HR}$) and the distribution constant ($K_{D,HR}$) of PIA-8 in heptane, kerosene and Naphtezol M diluents were determined by the potentiometric two-phase titration technique. The two equilibrium constants are closely related to the characteristic of the organic diluent.

(2) The oligomerization number x of the metal species extracted into heptane was determined to be close to unity for all metal ions investigated at lower metal ion concentrations. Accordingly, the metal ions were extracted as monomers ($MR_n \cdot mHR$) into the organic phase.

(3) The extraction equilibria of some transition metal ions were studied by both the slope analysis and the numerical analysis. The metal species extracted into the organic phase are considered to be $FeR_3 \cdot 2HR$ for iron(III), ZnR_2 and $ZnR_2 \cdot 3HR$ for zinc(II), $CuR_2 \cdot HR$ and $CuR_2 \cdot 5HR$ for copper(II), $MnR_2 \cdot 2HR$ and $MnR_2 \cdot 3HR$ for manganese(II), $CdR_2 \cdot 3HR$ for cadmium(II), $CoR_2 \cdot HR$ and $CoR_2 \cdot 4HR$ for cobalt(II) and $NiR_2 \cdot 3HR$ and $NiR_2 \cdot 6HR$ for nickel(II), respectively. The conditional extraction constants for the metal species are summarized in Tables 4 and 5. In the relatively high pH region, the extracted species ZnR_2 for zinc(II), $CuR_2 \cdot HR$ for copper(II), $CoR_2 \cdot HR$ for cobalt(II) and $NiR_2 \cdot 3HR$ for nickel(II) dominated at lower extractant concentrations ($[(HR)_2]_{org} < 0.2$ mol dm^{-3}), and their mole fractions decreased sharply with increasing extractant concentrations except for $NiR_2 \cdot 3HR$. With respect to the extraction of manganese(II), the species $MnR_2 \cdot 3HR$ dominated in the whole extractant concentration range investigated.

Abstract

Alcohol dehydrogenase (ADH) has been immobilized on a nickel hexacyanoferrate modified microband gold electrode surface by a glutaraldehyde/bovine serum albumin (BSA) cross-linking procedure to provide a new amperometric sensor for the assay of ethanol. The resulting enzyme electrode exhibits excellent electrocatalysis for the oxidation of reduced nicotinamide-adenine dinucleotide (NADH). The amperometric determination is based on the electrochemical detection of NADH which is generated in the enzymatic reaction of ethanol with NAD^+ under catalysis of ADH. The influence of various experimental conditions was examined for the determination of the optimum analytical performance. The sensor responds rapidly to ethanol with a detection limit of $(5.0 \pm 0.3) \times 10^{-7}$ mol l^{-1}. The response current increases linearly with ethanol concentration up to 5 mmol l^{-1}. The sensor remains relatively stable for about 1 week. © 1997 Published by Elsevier Science B.V.

1. Introduction

Ethanol is an important compound in medicine, biotechnology and the food industry, etc., and it is often monitored for toxicological and psychological effects. In certain industrial fields, such as fermentation and distillation, the ethanol concentration can reach toxic levels, causing inflammation of the nasal mucous membrane and conjunctiva, irritation of the skin and, at high levels, even alcohol poisoning. Hence, several analytical methods have been developed for the determination of ethanol and some other aliphatic alcohols [1–3]. Much work has been performed to enhance the detection of aliphatic alcohol at platinum and gold electrodes using preprogrammed multistep potential waveforms; this was developed by Johnson and co-workers [4,5]. However, the oxidation of aliphatic alcohol exhibits a large overpotential at common electrode surfaces. A mixed-valent ruthenium oxide–ruthenium cyanide (mRuO/RuCN) modified glassy carbon electrode was used to catalyze the oxidation of ethanol by Kulesza and Bandoch [6,7], and Cataldi and co-

workers [8,9], respectively. In this paper, we report the results of the determination of ethanol based on the electrocatalytic oxidation of reduced nicotinamide-adenine dinucleotide (NADH) at a modified microelectrode.

Although the direct oxidation of coenzyme NADH at the electrode surface, after an enzyme turnover (e.g. a dehydrogenase), is a reasonable approach for substrate determination, it is not very useful analytically. There are several reason for this. The direct oxidation of NADH at a bare electrode surface is irreversible and requires a high overpotential, which is increased further by the presence of the enzyme [10]. It has been reported that the oxidation of NADH at a solid electrode proceeds via two successive one-electron transfer steps involving radical intermediates, which often cause side reactions and lead to electrode fouling [11]. In addition, the process of electrochemical oxidation of NADH is not very reproducible since it has been shown to depend on the history and pretreatment of the electrode surface. The high overpotential and poor reproducibility usually limit its use for the direct electrochemical detection of NADH in enzymatic reaction.

However, these problem can be circumvented when the electrode is modified with mediators. Many compounds were found to enhance the electron transfer rate and reduce the overpotential for the oxidation of NADH. Alkylphenazinium ions [12], *o*– and *p*-quinones [13–17] and methylene blue [18], etc. have been immobilized on the surface of the carbon electrode through covalent binding, direct absorption or through adsorption of a polymer containing the mediating functional group which was used to catalyze the oxidation of NADH. For example, Hajizadeh and co-workers [19] have shown that thionine can modify the surface of a spectroscopic graphite electrode by cross-linking. When such a chemically modified electrode was used in flow injection determination of NADH, a linear range of $7.0 \times 10^{-7} \sim 1.8 \times 10^{-3}$ mol l^{-1} was obtained. Gorton, Johansson and co-workers [20–29] have extensively investigated the electrocatalytic oxidation of NADH by adsorbed aromatic compounds containing catechol functionalities and adsorbed phenoxazines. Albery and Bartlett [30] have reported the oxidation of NADH on electrodes made of a conducting organic salt. Bernadette and Christopher [31] reported the oxidation of NADH at a hexacyanoferrate modified nickel electrode.

Electrocatalytic oxidation of NADH at the conducting polymer (such as poly(3-methylthiophene [32]), poly(metallophthlocyanine) [33], poly(thionine) [34], poly(idole-5-carboxylic acid) [35], poly(-methylene blue) [36], poly(3,4-dihydroxybenzaldehyde) [37] etc.) modified electrode was reported recently. Using cyclic voltammetry and scanning electrochemical microscopy (SECM), Grundig and co-workers [38] studied the NADH oxidation at *N*-methyl phenazine (NMP^+) methosulfate, 1-methoxy-5-methyl phenazine ($M\text{-}NMP^+$) methosulfate and Meldola blue etc., containing composite electrodes.

Other compounds, such as oxometalates [39], ruthenium complexes [40], pyrroloquinoline quinone [41] etc. were also reported to act as a catalyst for the oxidation of NADH.

Recently, Norwell and Kuhr's [42] experimental results indicated that NADH could be directly oxidized at a carbon fibre electrode with a low overpotential after the carbon fibre electrode had been treated electrochemically.

The alcohol dehydrogenase (ADH) has been widely studied and immobilized onto the electrode surface by several methods. For example, Karyakin et al. [43] immobilized ADH onto the surface of poly(neutral red) modified glassy carbon electrode through the Nafion membrane, and investigated the response of the resulting enzyme electrode to reduction of acetaldehyde. Somasundrum and Bannister [35], Bernadette and Christopher [31] immobilized ADH onto a poly(indole-5-carboxylic acid) modified glassy carbon electrode and a hexacyanoferrate modified porous nickel electrode respectively, by a glutaraldehyde/albumin cross-linking procedure and measured the response of the enzyme electrode to ethanol. They also determined the apparent Michaelis–Menten constant for the enzyme. For coimmobilization of the ADH and the cofactor, Mizutan and Yabuki [44] entrapped ADH,

NAD^+ and Medola blue in polypyrrole film. But they found that the sensor lacked stability and sensitivity. Grundig et al. [38] used the following method to immobilize ADH and the cofactor. They deposited ADH and the polyethylene glycol modified NADH containing solution of prepolymer of the polyurethanehydrogel onto a dialysis membrane. Then the dialysis membrane layered with immobilization gel was fixed onto the surface of a mediator modified electrode.

On the other hand, microelectrodes have received considerable attention in some applications due to their many advantages in comparison with conventionally sized electrode. Although, there are many studies on the electrochemical oxidation of NADH and the ADH based enzyme electrode using various types of mediators at conventionally sized electrodes, few have studied the elctrocatalytic oxidation of NADH and the NAD^+/NADH dependent enzymatic reaction at microelectrodes for the development of a microsensor which depends on NADH for in vivo analysis and biotechnology. Recently, we [45] demonstrated that the nickel hexacyanoferrate modified microband gold electrode (NiHCH/Au) exhibited excellent electrocatalytic activity for the oxidation of NADH in phosphate buffer solution. A noticeable reduction of the overpotential for the oxidation of NADH and a remarkably stable voltammetric response at the NiHCF/Au microelectrode were observed. The aim of this study is to immobilize enzyme (ADH) on the NiHCF/Au surface and investigate the resulting enzyme electrode in the determination of ethanol.

2. Experimental

2.1. Chemicals

β-Nicotinamide adenine dinucleotide (NAD^+) and alcohol dehydrogenase (ADH, alcohol: NAD^+ oxidoreductase; EC 1.1.1.1, from baker's yeast, had an activity of 300 U mg^{-1}) were obtained from Sigma Chemical Company and used as received. Glutaraldehyde (25% w/v), obtained from Aldrich Chemical Company, was diluted to 2.5% w/v with distilled water. Bovine serum albumin (BSA) was obtained from Shanghai Industry of Biochemistry, Chinese Academy of Sciences. Absolute ethanol (99.7%) was purchased from the Second Reagent Factory of Shanghai and used as received. Other reagents used were of analytical grade. The phosphate buffer solution was made up with 0.1 mol l^{-1} Na_2HPO_4 and 0.1 mol l^{-1} NaH_2PO_4. All solutions were prepared with doubly distilled, deionized water. The ethanol aqueous solution was prepared with phosphate buffer solution (pH 7.5). The ADH stock solution was prepared with phosphate buffer solution (pH 7.5) and stored at 4°C.

2.2. Instrumentation

Electrochemical experiments were performed with a PAR M270 electrochemical system (EC&G, USA). A type 501 thermostat (Shanghai, China) was used to control the experimental temperature. A three-electrode water-jacketed electrochemical cell, with a platinum wire as the counter electrode, a saturated calomel electrode (SCE) as the reference electrode and a modified microband gold electrode (ca. 0.1 μm × 1.0 cm) as the working electrode, was employed. The electrolytic cell volume is about 5 ml. The fabrication of the microband gold electrode was the same as previously reported [46]. The working electrode was polished with sandpaper and 0.05 μm alumina slurry, and then cleaned ultrasonically in double distilled water. Prior to use, the electrode was pretreated by continuous cyclic scans from 0 to -2.0 V at 50 mV s^{-1} in phosphate buffer solution (pH 7.5) until a constant background was observed.

2.3. Preparation of the NiHCF/Au electrode

The NiHCF film was electrochemically grown on the microband gold electrode in 2×10^{-4} mol l^{-1} $Ni(NO_3)_2$ and 2×10^{-4} mol l^{-1} $K_3Fe(CN)_6$ aqueous solution containing 0.1 mol l^{-1} $NaNO_3$ as the supporting electrolyte by a continuous scan between -0.1 and $+1.0$ V at a scan rate of 50 mV s^{-1}. The film thickness can be controlled by the cyclic scan times. In our experiment, five continuous scan were used, which corresponds to

a surface coverage of NiHCF of about 3.1×10^{-9} mol cm^{-2}. The cyclic voltammetric experiments of the modified electrode were performed in the potential range of $0 \sim +0.8$ V. A couple of well-defined redox peaks occurred with the formed potential of $+0.42$ V, which corresponded to the hexacyanoferrate(II/III) redox couple [45].

2.4. Biosensor preparation

ADH was immobilized on the NiHCF/Au electrode by a glutaraldehyde/BSA cross-linking procedure. The ADH (3 mg) was dissolved in 100 μl of 0.1 mol l^{-1} phosphate buffer solution (pH 7.5) containing 4 mg BSA. Then the glutaraldehyde (2.5% w/v), which is a bifunctional cross-linking agent, was added to the ADH solution up to a final concentration of a 0.9% w/v. In the process, the mixture was stirred thoroughly. The NiHCF/Au microelectrode was dipped into this solution for 2–3 s and then removed. The enzyme electrode was placed in a desiccator for some time to allow the gel formation. This procedure was repeated three or four times. The resulting enzyme electrode (defined as NiHCF/ADH/Au) was incubated in phosphate buffer solution (pH 7.5) at 4°C for at least 5 h before use.

2.5. Amperometric measurements

The amperometric measurements were carried out with the NiHCF/ADH/Au enzyme electrode under constant stirring at a fixed potential of $+0.55$ V in phosphate buffer solution (pH 7.5) containing NAD^+. The background current was first allowed to decay to a constant value, then the ethanol was added. After the solution was stirred for a short while, the steady-state current was measured. All test solutions were deaerated by passing highly pure nitrogen for 30 min before the electrochemical experiments, and a continuous flow of nitrogen was maintained over the sample solution during experiments. The electrochemical experiments were performed inside a Faraday cage at 25 ± 0.1°C.

3. Results and discussion

3.1. Detection of NADH generated by enzymatic reaction

We [45] have shown that the NiHCF modified microband gold electrode can catalyze the oxidation of NADH in solution, with a reduction of overpotential of about 340 mV. The steady-state current increases linearly with NADH concentration in the range 0.5–8.0 mmol l^{-1}. The present experimental results show that the NiHCF/Au microelectrode can also catalyze the oxidation of NADH, which is generated from the reaction of NAD^+ and ethanol catalyzed by ADH.

The electrochemical experiments were performed by the following procedures. Firstly, the cyclic voltammogram of NiHCF/Au in a phosphate buffer solution was recorded, then NAD^+ and ethanol were added to the buffer solution to assess their effects on the electrochemical behavior of the NiHCF/Au electrode and finally the cyclic voltammogram of the NiHCF/ADH/Au electrode in the NAD^+ and ethanol containing solution was recorded to determine whether the anodic current increases. Curve a in Fig. 1 shows

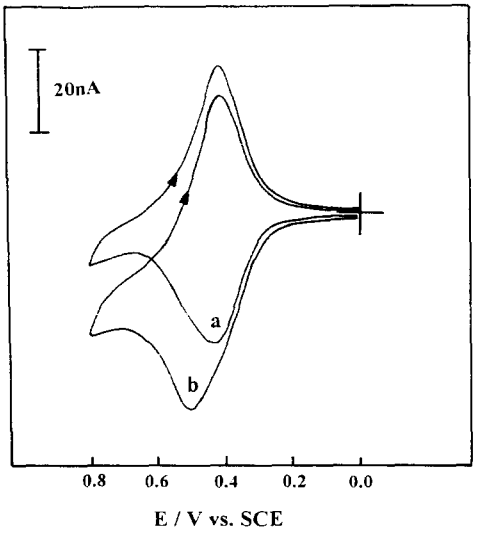

Fig. 1. Cyclic voltammograms of the NiHCF/Au (a) and NiHCF/ADH/Au (b) electrode in 0.1 mol l^{-1} phosphate buffer solution (pH 7.5) containing 1.0 mmol l^{-1} NAD^+ and 1.0 mmol l^{-1} ethanol at a scan rate of 5 mV s^{-1}.

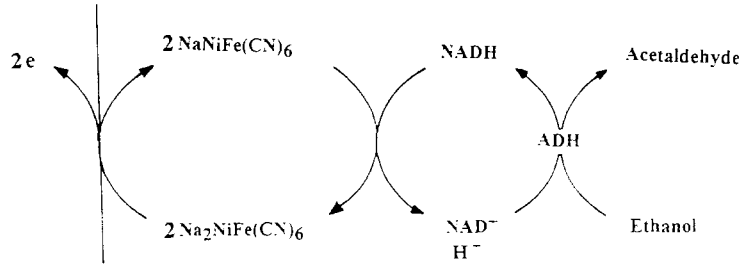

Fig. 2. Scheme of the respective reaction sequences of the electrochemical coupled enzymatic oxidation of ethanol.

the cyclic voltammogram of the NiHCF/Au electrode in a phosphate buffer solution containing NAD^+ and ethanol. This voltammogram is almost the same as that of NiHCF/Au in phosphate buffer without NAD^+ and ethanol (not shown here, Fig. 4a in Ref. [45]). This result indicates that NAD^+ and ethanol had only a minor influence on the electrochemical behaviour of the NiHCF/Au electrode. In Fig. 1, curve b is the cyclic voltammogram of NiHCF/ADH/Au in phosphate buffer in the present NAD^+ and ethanol. It can be seen that there is a great increase in the anodic current, corresponding to the oxidation of hexacyanoferrate(II) to hexacyanoferrate(III), compared to the voltammogram of NiHCF/Au in the same solution (Fig. 1a). ADH catalyzes the oxidation of ethanol with a simultaneous reduction of an equivalent amount of NAD^+ to NADH. The NADH reduces the hexacyanoferrate(III) to hexacyanferrate(II). Thus hexacyanoferrate(II) is regenerated by NADH during the scan, and the anodic peak current increases greatly. The overall reaction process is shown in Fig. 2. The catalytic current is not observed if any component shown in the scheme is absent.

By fixing the concentration of NAD^+ in solution, the increase of the peak current should depend on the concentration of ethanol at the same NiHCF/ADH/Au electrode. This is the basis for the determination of ethanol by detecting NADH amperometrically with the NiHCF/ADH/Au enzyme electrode.

3.2. *Effect of potential*

To find an optimum operating potential for amperometric measurements, the potential dependence of the ethanol response at the NiHCF/ADH/Au electrode is examined. Fig. 3 displays a hydrodynamic voltammogram in the 0.1 to 0.8 V potential range. The amperometric response of ethanol starts at +0.2V. With increasing oxidation potential, the response rises sharply and reaches a limiting value at potentials higher than +0.55 V. Such a potential dependence profile is in agreement with the cyclic voltammogram results (Fig. 1). A quite similar hydrodynamic

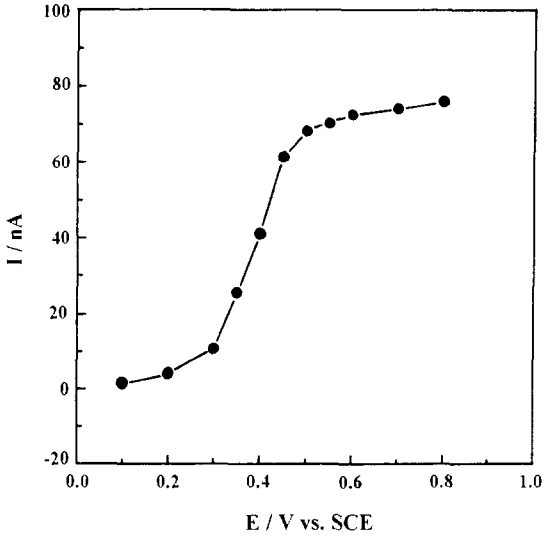

Fig. 3. Hydrodynamic voltammogram obtained at the NiHCF/ADH/Au electrode for 4.0 mmol l^{-1} ethanol in 0.1 mmol l^{-1} phosphate buffer solution (pH 7.5) containing 1.0 mmol l^{-1} NAD^+. Stirring rate: 300 rev min^{-1}.

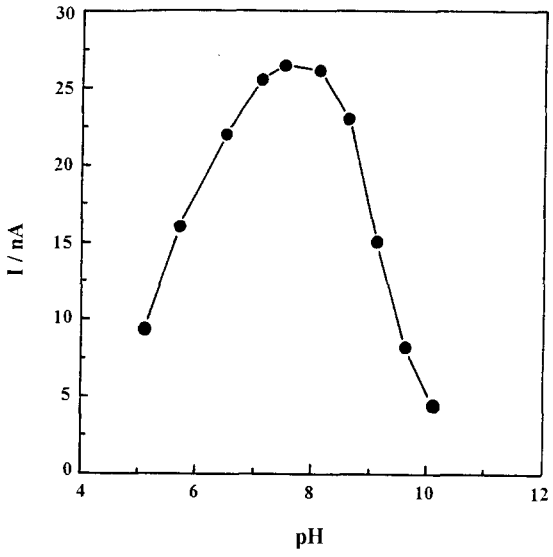

Fig. 4. Effect of solution pH on the response to 1.5 mmol l^{-1} ethanol. The operating potential is +0.55 V vs. SCE. Other conditions are the same as Fig. 3.

voltammogram can be obtained when the NiHCF/Au electrode performed in phosphate buffer solution containing NADH. This result indicates that the response to ethanol is attributed to NADH formation in the process of catalytic oxidation on the NiHCF/ADH/Au electrode.

3.3. Effect of solution pH

The effect of solution pH on the ethanol response at the NiHCF/ADH/Au electrode is shown in Fig. 4. Different volumes of 0.1 mol l^{-1} Na_2HPO_4/NaH_2PO_4 and 0.1 mol l^{-1} $Na_2B_4O_7/Na_2CO_3$ buffers were used to adjust the pH. The amperometric response is enhanced by increasing the solution pH in the range of pH 6.0 to 7.0, and reaches a maximum value between pH 7.0 and 8.0. It decreases markedly with an increase in pH above 8.5. Our previous report has shown that the NiHCF/Au electrode is stable in the pH range of 5.0 to 8.0. Therefore, pH 7.5 is selected by considering both the sensitivity and the stability of the electrode; consequently further studies were carried out at this pH.

3.4. Effect of NAD^+ concentration

NAD^+ is necessary in the reaction catalyzed by ADH. The effect of NAD^+ concentration on the response of the enzyme electrode to ethanol was studied at an ethanol concentration of 4 mmol l^{-1}. A plot of the steady-state current as a function of NAD^+ concentration is presented in Fig. 5. It is evident that the steady-state current increases with increasing concentration of NAD^+ for concentration below 0.6 mmol l^{-1}, whereas the response levels off for NAD^+ concentrations above 0.7 mmol l^{-1}. Based on these results and in order to ensure that the response of the sensor was independent of NAD^+ concentration, a value of 1.0 mmol l^{-1} NAD^+ was employed in the following measurements.

Consequently, the amperometric experiments in the present study are performed in 0.1 mol l^{-1} Na_2HPO_4/NaH_2PO_4 buffer solution (pH 7.5) containing 1.0 mmol l^{-1} NAD^+ at the potential of +0.55 V.

3.5. Response of ethanol at the NiHCF/ADH/Au electrode

Fig. 6 shows the amperometric response of the NiHCF/ADH/Au enzyme electrode to successive

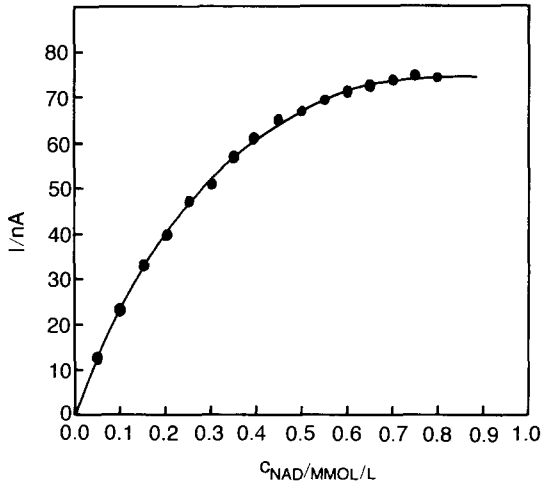

Fig. 5. Plot of response current as a function of NAD^+ concentration at an ethanol concentration of 4.0 mmol l^{-1}. Other conditions are the same as Fig. 4.

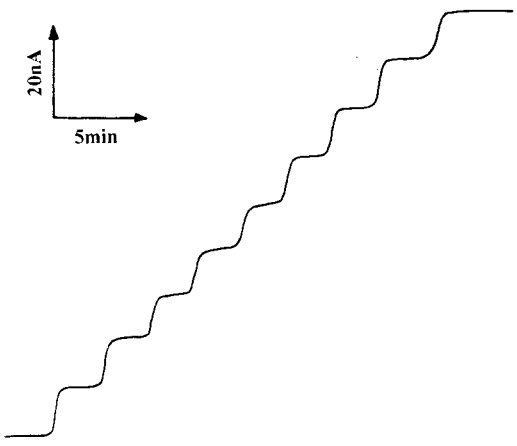

Fig. 6. Amperometric response to successive increments of 0.5 mmol l^{-1} ethanol. Other conditions are the same as Fig. 4.

injections of ethanol. The enzyme electrode rapidly responses to the ethanol concentration changes and reaches a steady state with 50 s. The calibration plot of response current against the concentration of ethanol is presented in Fig. 7. The linear response is observed up to 5 mmol l^{-1}. The lack of linearity in the high range of ethanol concentration might be due to the ADH saturation by ethanol. The detection limit of ethanol, at a signal-to-noise ratio of three, is found to be $(5.0 \pm 0.3) \times 10^{-7}$ mol l^{-1}. The results indicate that the NiHCF/ADH/Au electrode is an excellent detector for ethanol, because a wide linear range and low detection limits can be achieved.

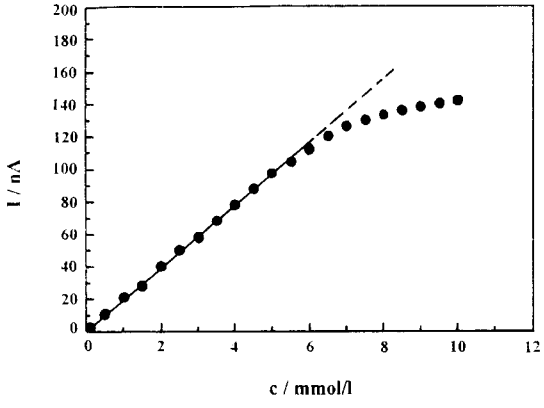

Fig. 7. Calibration curve for ethanol at a NiHCF/ADH/Au electrode.

The average current response of 38.2 nA, with the relative standard deviation of 2.5%, is obtained for ten successive determinations at the ethanol concentration of 2.0 mmol l^{-1}, which shows that the modified electrode can be used to determine ethanol precisely. The stability of the NiHCF/ADH/Au electrode was evaluated by measuring periodically the response to ethanol. The response remained at 90% of the initial value for two days and decayed to half of the initial value after one week, indicating the NiHCF/ADH/Au enzyme electrode display a highly stable response for ethanol. The decrease in the response to ethanol might be mainly due to the loss of ADH enzyme activity, because the NiHCF/Au electrode exhibited excellent stability for NADH oxidation and the NiHCF did not dissolve into solution from the electrode surface for at least one week.

For immobilized enzymes used in amperometric biosensors, the observed electrochemical response may be either mass transport limited or kinetically controlled [47]. Mell and Malloy [47] suggested that for an immobilized enzyme reaction that is kinetically controlled, the steady-state current, i_{SS}, is proportional to the initial rate of the enzymatic process. In this case, a plot of i_{SS} vs. the substrate concentration, c, gives a typical Michaelis–Menten type response. To perform kinetic analysis on the enzyme electrode, we analyze it simply using the Eadie–Hofstee form of the Michaelis–Menten equation. The Eadie–Hofstee plot of ethanol is shown in Fig. 8. The plot of i_{SS} vs. i_{SS}/c for the ethanol is linear with a slope of -42.5 mmol l^{-1}. This implies that the rate-controlling process is the enzymatic reaction. An average value of the apparent Michaelis–Menten constant (K_M^{app}) of 41.7 ± 2.3 mmol l^{-1} for ethanol is obtained.

A survey of the literature shows that K_M^{app} for ethanol in the presence of ADH has been extensively studied by various methods. Ciolkosy and Jordan [48], working at pH 8.8, obtained $K_M^{app} =$ 3.2 mmol l^{-1} using the electrochemical method; Somasundrum and Bannister [35] determined K_M^{app} to be 9.2 mmol l^{-1} using the same method and the same pH as Ref. [48]; Dickinson and Monger [49] obtained $K_M^{app} = 21.7$ mmol l^{-1} at pH 7.05 using a spectrophotometrical method. These val-

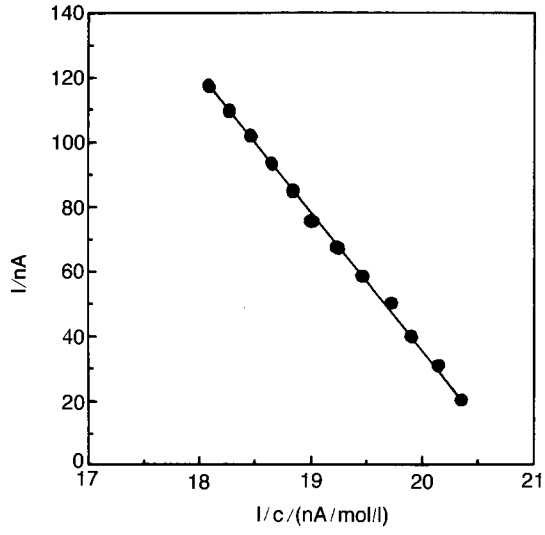

Fig. 8. Electrochemical Eadie–Hofstee plot of ethanol for the enzyme electrode using the data of Fig. 7.

ues and the present experimental result are quite different. The reason for this is that K_M^{app} is not an intrinsic property of the enzyme, but of the system. The microenvironment around the immobilized enzyme might greatly affect the value of K_M^{app}. In addition, the present result was obtained at a microelectrode while the literature's results were obtained using conventionally sized electrodes. The difference between planar and radial diffusion at a conventionally sized and microelectrode might also affect the K_M^{app} value. So the results characterizes the enzyme electrode and not the enzyme.

4. Conclusions

We have prepared and characterized the performance of an ethanol biosensor based on immobilization of ADH on the NiHCF modified microband gold electrode surface by the glutaraldehyde/BSA cross-linking procedure. The analytical signal is based on the electroacatalytic oxidation of enzymatically generated NADH at a NiHCF/Au electrode. We have characterized the response of the biosensor in terms of the effects of operating potential, pH of the solution and the concentration of NAD^+. The sensor exhibits high sensitivity and a limit of detection as well as a rapid response.

Received 14 May 1996; received in revised form 17 July 1996; accepted 22 July 1996

Abstract

A photo-cured membrane selective to calcium, based on the calcium bis [4-(1′,1′,3′,3′-tetramethylbutyl)phenyl]phosphate ionophore and incorporating the lipophilic additive, potassium tetraki(4-chlorophenyl)borate, that can tolerate up to 200 nM perchlorate ionic background in the flow injection potentiometry mode has been previously reported (T. Dimitrakopoulos, J.R. Farrell and P.J. Ives, Electroanalysis, 8 (1996) 391). Improvements in the electrode slope and sensitivity of the previously described photo-cured calcium membrane-based electrode were achieved when anhydrous calcium chloride salt was dissolved into the pre-cured membrane composition and then photo-cured. Similar to the previously reported photo-cured calcium ion-selective electrode (ISE), the improved photo-cured calcium ISE can measure calcium in a high perchlorate background in the flow injection potentiometric mode. © 1997 Elsevier Science B.V.

Keywords: Calcium selective electrodes; Flow injection potentiometry; Perchlorate tolerance; Photo-cured membranes

1. Introduction

Poly (vinyl chloride) (PVC) has been universally accepted as the preferred polymer base for liquid membranes, and is employed in numerous commercially available ion-selective electrodes (ISEs). However, the manufacture of PVC membranes poses a disadvantage that arises from the solvent-cast procedure that can take up to 2 days, producing a liquid membrane that is durable and flexible, but exhibits poor adhesion to solid-contact electrodes [1].

An alternative method for the rapid manufacture of liquid polymer membranes that are more robust than the PVC-based membranes has been reported [1–11] and involves a photopolymerisation process. The photopolymerisation process involves the photo-curing of acrylate-based membranes that are cross-linked with an ester and initiated by a benzophenone photoinitiator for up to 40 min using an ultra-violet mercury vapour lamp. Membranes formed with the photo-curing

PII S0039-9140(96)02057-7

technique are mechanically stronger and more hydrophobic than PVC membranes, due to the lower amount of plasticiser required in these photo-cured membranes. Other advantages of photo-cured membranes were good sensitivity, fast response and excellent adhesion to solid-contact electrodes. Photo-cured membranes have been developed to date for ammonium [3], calcium [1,2,4,5], lithium [6], nitrate [7], pH [8], potassium [9,10] and sodium [11] ISEs, most of which were applied to flow injection potentiometric (FIP) measurements.

A recent report on a photo-cured calcium ISE which was base on the calcium bis[4-1′,1′,3′,3′-tetramethylbutyl)phenyl]phosphate ionophore and the potassium tetrakis(4-chlorophenyl)borate lipophilic additive exhibited an excellent tolerance to high levels of perchlorate in the FIP mode [2], compared with other reported calcium ISEs [12,13]. The photo-cured calcium ISE was successfully used to determine total calcium levels in nitric/perchloric acid-digested milk samples in the FIP mode. However, this photo-cured membrane-based ISE experienced severe interferences from barium and zinc ions. The observed zinc ion interference for the photo-cured calcium ISE has been observed with other calcium ISEs based on similar phosphate ester-based ionophores [14]. However, the barium ion interference reported was unique and was believed to be due to the introduction of the lipophilic addictive, potassium tetrakis(4-chloropheny)borate, whereby this lipophilic anion exhibited some ion-exchange process between the potassium and the barium ion at the membrane/aqueous interface.

In this study, the introduction of anhydrous calcium chloride salt into the pre-cured membrane and then photo-curing results in a modified photo-cured calcium ISE that exhibits a hyper-Nernstian response, an improved selectivity over divalent ions, including barium and zinc, and a wider pH independent range, compared with a photo-cured membrane of similar membrane composition but without calcium chloride [2]. The modified photo-cured calcium ISE exhibits an excellent tolerance to lipophilic sample anions, such as perchlorate, and was used to determine the total calcium level in nitric/perchloric acid-digestion, cows' milk in the FIP mode.

2. Experimental

2.1. Materials

Metal chloride salts were used in this study and were all of analytical reagent grade. In addition, anhydrous calcium chloride (Mallinckrodt, Aanalytical reagent), nitric acid (Mallinckrodt, Analytical reagent), perchloric acid (BDH, AnalaR), sodium hydroxide (May and Baker Australia Pty Ltd., Analytical reagent), sodium perchlorate anhydrous (Mallinckrodt, Analytical reagent), and distilled water were used throughout this study.

The polymer matrix of the photo-cured membrane prepared in this study consists of Ebcryl 600 (bisphenol A epoxyacrylate) and Uvecryl P36 (copolymerisable benzophenone photoinitiator), both of which were obtained from UCB Chemical Sector (Belgium), and 1,6-hexanediol diacrylate was obtained from Anchor Chemicals Australia Pty. Ltd. The lipophilic additive used was potassium tetrakis(4-chlorophenyl)borate and the ionophore used was calcium bis[4-(1′,1′,3′,3′-tetramethylbutyl)phenyl]phosphate, both obtained from Fluka (AG purum). The plasticiser used was dioctyl phenylphosphonate (DOPP), obtained from Sigma Chemical Co.

2.2. Electrode preparation

The composition of pre-cured membrane mixtures investigated in this study are presented in Table 1. The pre-cured membrane mixtures were each mixed in a centrifuge for 30 min and blended with a thin glass rod until a homogeneous mixture was achieved. Each pre-cured membrane was applied directly onto a 6 mm copper disk embedded in a 12 mm diameter poly(methyl methacrylate) body, and exposed to a high intensity medium pressure (150 W) mercury vapour lamp for 5 min under a nitrogen atmosphere, producing photo-cured membranes approximately 0.2 mm thick. A minimum of three photo-cured membranes was prepared and evaluated form each membrane composition presented in Table 1. The resultant photo-cured calcium ISEs were conditioned in 100 mM calcium chloride for a minimum of 10 min prior to any measurements.

2.3. Flow injection potentiometric measurements

The electrode flow-through cell used in FIP measurements and FIP instrumentation employed in this study have been described elsewhere [2,15]. The carrier and the reference streams used in the flow cell were 100 mM NaCl. Manual injections were carried out using a Rhenodyne 5020 teflon injection valve fitted with a 100 μl sample loop. The background solutions were pumped through the electrode flow cell at a flow rate of 1.5 ml min^{-1} using a four-channel peristaltic pump (Ismatec Sa).

2.4. Steady-state measurements

Steady-state measurements with the calcium ISE were performed with an Orion double junction reference electrode (Ag/AgCl/saturated KCl// 10% KNO_3). The electrode potential was monitored by an Orion 701A meter and a Hitachi (QD 25) pen chart recorder was used to record the response profile of the ISE. The stability criterion used in this arrangement was ± 0.2 mV for 2 min.

The calcium ion activities were calculated using Debye–Hückel equation [16]. Calculation of the electrode slope and standard deviation were determined using a Macintosh application called Macurvefit Ver. 0.7 e written in THINK C by Kevin Raner (CSIRO, Division of Chemical and Polymers, Melbourne, Australia).

Table 1
Pre-cured membrane compositions prepared and investigated in this study

Membrane components	Ca1 membrane (wt.%) [2]	Ca2 membrane (wt.%)
Ebcryl 600	44.8%	44.7%
1,6-hexanediol diacrylate	22.4%	22.3%
Uvecryl P36	5.4%	5.3%
Duictyl phenylphosphonate	20.8%	20.8%
Ca-MBPP ionophore	606%	5.9%
KCITPB	0.5%	0.5%
$CaCl_2$ anhydrous	—	0.5%

Ca-MBPP, calcium bis[4-(1′,1′,3′,3′-methylbutyl)phenyl]phosphate; KCITPB, potasssium tetrakis(4-chlorphenyl)borate.

3. Results and discussion

The pre-cured membrane compositions that were investigated for this study are presented in Table 1. The photo-cured Ca1 membrane-based ISE has been studied and evaluated previously [2]. The pre-cured mixture of the Ca2 membrane was developed by taking a portion of the pre-cured Ca1 membrane mixture and dissolving anhydrous calcium chloride into it. Similar to the Ca1 membrane, the photo-cured Ca2 membrane was hard and transparent.

The anhydrous calcium chloride was dissolved in the Ca2 pre-cured membrane mixture without the aide of any volatile solvents, such as tetrahydrofuran. The solubility of the introduced calcium salt was enhanced by the DOPP plasticiser. It is well known that DOPP is a coordinating plasticiser and can interact with the calcium ion [13,17,18], and this enhanced the solubility of the introduced calcium chloride into the Ca2 membrane mixture.

3.1. Calcium response of the photo-cured Ca2 ISE

The photo-cured Ca2 ISE exhibited a hyper-Nernstian slope of 35.4 ± 0.4 mV change per activity decade, a log–linear rante between 0.01 and 100 mM and a detection limit of 0.001 mM in pure calcium chloride solution in the steady-state mode. Hyper-Nernstian responses are not uncommon in liquid polymer membrane type solid-contact electrodes [2,5]. It is not clearly understood how a given substrate can facilitate an electron exchange process at the membrane/metal interface. However, applying liquid polymer membranes onto metal substrate will result in analytically useful potentiometric devices, and the performance of these solid-contact-based membrane ISEs are determined solely by the liquid polymer membrane [14].

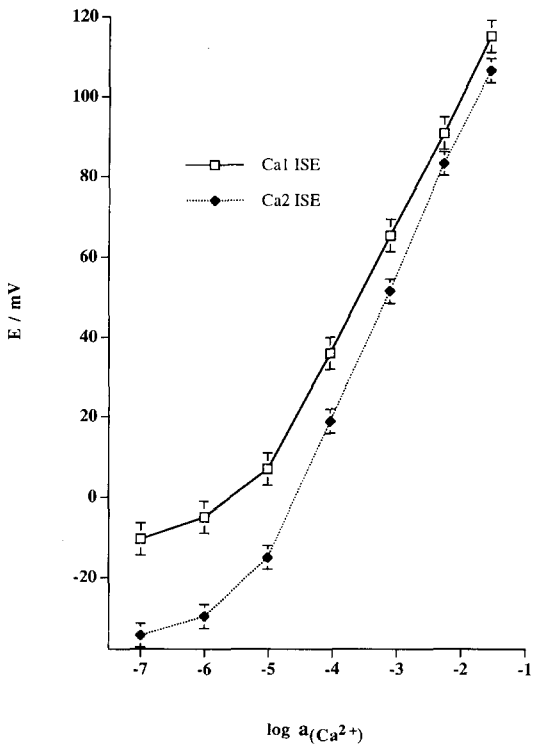

Fig. 1. Comparison of the calibration plots for the photo-curved Ca1 [2] and Ca2 ISEs in pure calcium chloride solution in the steady-state mode.

Comparison of the electrode performance between the photo-cured Ca1 and Ca2 ISEs shows a similar log–linear range and detection limit, however the electrode slope of the Ca2 ISE was higher than that of the Ca1 ISE. Comparative calibration curves for the photo-cured Ca1 and Ca2 ISEs in the study-state mode are given in Fig. 1. The increased hyper-Nernstian response exhibited by the photo-cured Ca2 ISE compared with the Ca1 ISE [2], was unlikely due to the presence of the lipophilic calcium–phosphonyl oxygen complex in the membrane phase.

The membrane resistances determined for the Ca1 and Ca2 ISEs were 6.2×10^9 Ω cm (3.5% relative standard deviation (RSD), $n = 3$) and 9.6×10^8 Ω cm (4.8% RSD, $n = 3$), respectively. A significant reduction in the resistane of the photo-cured Ca2 membrane would facilitate the increase in the electrode slope of this ISE. The photo-cured Ca2 ISE was stored in a 100 mM calcium chloride solution when not in use and was still operational after 3 months with no adverse effect on the observed hyper-Nernstian response and the log–linear range.

Previous studies have looked at the role of the DOPP plasticiser in liquid polymer membranes containing phosphate ester type ionophore [13,17]. Two blank photo-cured membranes (B1 and B2) were prepared without either calcium bis[4-1′,1′,3′,3′-tetramethylbutyl)phenyl]phosphate ionophore or the lipophilic additive potassium tetrakis(4-chlorophenyl)borate; membrane B1 contained the DOPP plasticier only and membrane B2 contained the DOPP plasticiser and the anhydrous calcium chloride. The calcium ion responses observed for the B1 and B2 ISEs are presented in Fig. 2. As demonstrated in previous studies for PVC-based ISEs [17], the photo-cured B1 and B2 membrane-based ISEs both exhibited

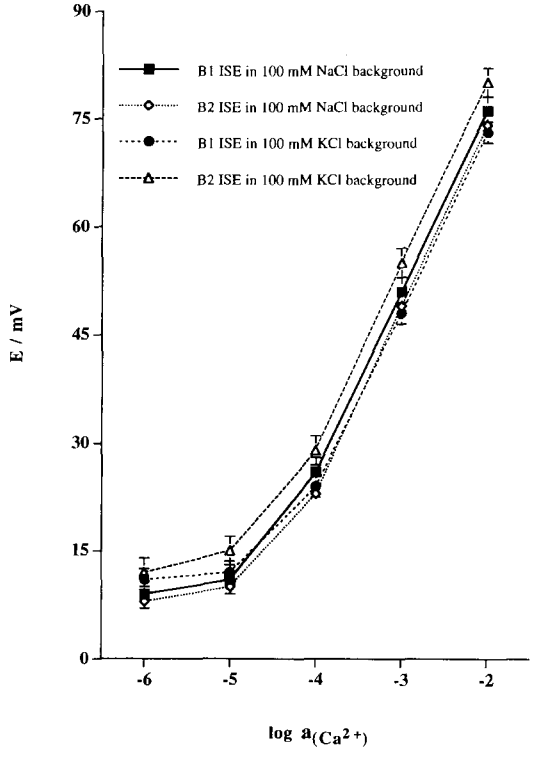

Fig. 2. Comparison of the calibration plots for the photo-cured B1 and B2 ISEs in the steady-state mode with calcium chloride solutions in a 100 mM NaCl and a 100 mM KCl background.

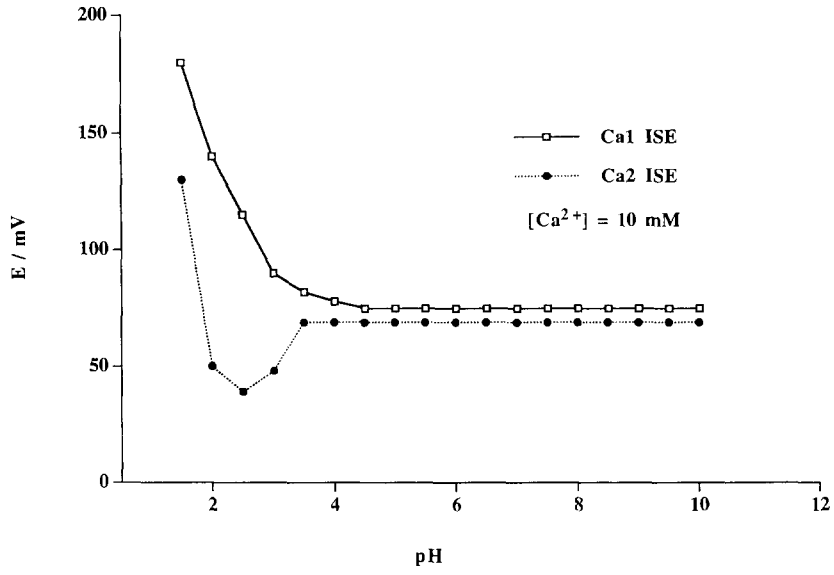

Fig. 3. Comparison of the pH profiles for the photo-cured Ca1 [2] and the Ca2 ISEs.

sub-Nernstian responses of 24.5 ± 0.2 and 26.3 ± 0.6 mV change per activity decade, respectively, and a log–linear range between 0.1 and 10 mM with calcium standards in a 100 mM sodium chloride background. Similar electrode slopes were observed for the B1 and B2 ISEs with calcium standards in 100 mM potassium chloride background as shown in Fig. 2. The B1 and B2 ISEs clearly demonstrated a favourable response to calcium ion, even in the presence of interfering ions, sodium and potassium, and reinforces the known chelating properties of the DOPP plasticiser towards the calcium ion [13,17,18].

These observations strongly suggest that the calcium chloride introduced into the Ca2 pre-cured membrane was complexed with the DOPP plasticiser forming a lipophilic calcium–phosphonyl oxygen in the Ca2 membrane phase [2,13]. The positivity charge calcium phosphonyl oxygen complex would then be counterbalanced by the lipophilic tetrakis(4-chlorophenyl)borate anion in the membrane phase [2], so that it would not compete against the phosphate ester type ionophore for the determinant. It is still not clear what role the calcium–phosphonyl oxygen complex has in the Ca2 membrane phase of the photo-cured electrode, however, some improvements in the electrochemical behaviour were observed when compared with the photo-cured Ca1 ISE.

3.2. Comparing the pH profiles for the photo-cured Ca1 and Ca2 ISEs

Fig. 3 compares the pH profiles for the Ca1 and Ca2 ISEs. The Ca2 ISE showed a wider negligible response to hydrogen ions between $3.5 < pH < 10.0$, compared with the Ca1 ISEs, $4.5 < pH < 10.0$. However, the most striking difference in the pH profiles was the observed 'pH dip' for the Ca2 ISEs, that was not observed for the Ca1 ISE.

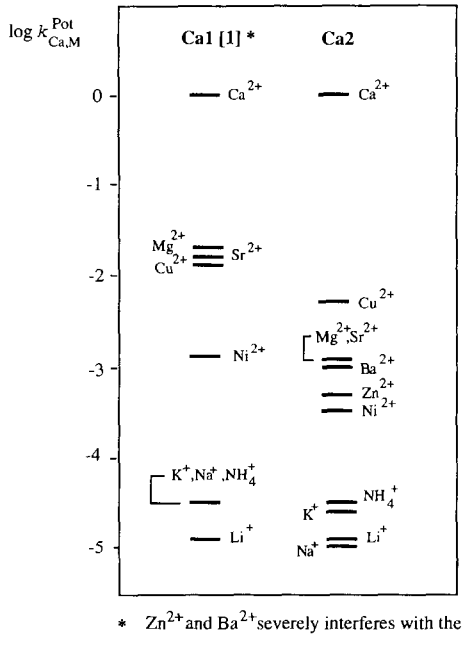
The 'pH dip' observed for the photo-cured Ca2 ISE is typical of other reported calcium ISEs that employed similar phosphate ester type ionophores [17,19]. As discussed in previous studies [17], the 'pH dip' is the result of the extraction behaviour of the organophosphates present in liquid polymer membranes and these complexes of different stoichiometries can be extracted depending on the pH. Clearly, the discrepancy in the observed pH profiles of the photo-cured Ca1 and Ca2 ISEs suggests that the presence of the calcium–phosphonyl oxygen complex in the photo-cured Ca2 membrane has influenced the extraction process

of the organophosphates in acidic conditions. The pH dependence of the photo-cured Ca2 ISE has shifted to pH $\leq$ 3.5 compared with the Ca1 ISE at pH $\leq$ 4.5 [2]. However, further research is still required to thoroughly understand the mechanism and explain these observations.

3.3. Selectivities

The selectivity coefficients for the photo-cured Ca1 and Ca2 ISEs were determined by the fixed interference methods and are given in Fig. 4. The selectivities for calcium over interfering monovalent ions were comparable between the photo-cured Ca1 and Ca2 ISEs. However, differences between the photo-cured Ca1 and Ca2 ISEs were observed with selectivity coefficients for calcium over interfering divalent ions as shown in Fig. 4. The photo-cured Ca1 ISE experienced severe interference with measurements conducted in barium and zinc ionic backgrounds, and this has been discussed in detail in a previous study [2].

The selectivity observed for the photo-cured Ca2 ISE over interfering divalent ions was superior and included the observed selectivity over barium and zinc ions compared with the photo-cured Ca1 ISE. The enhanced selectivity observed for the Ca2 ISE over interfering divalent ions compared with the Ca1 ISE can be attributed to the presence of the calcium–phosphonyl oxygen complex in the Ca2 membrane phase and this well be further investigated. Varying the amount of anhydrous calcium chloride in photo-cured membranes similar in composition to the Ca2 membrane, showed no significant difference in selectivity compared with that observed for the Ca2 membrane-based ISE.



* Zn^{2+} and Ba^{2+} severely interferes with the Ca1 ISE.

Fig. 4. The determined selectivity coefficients for the photo-curved Ca2 ISE compared with the Ca1 ISE [2].

3.4. The photo-cured Ca2 ISEs in FIP mode

The time taken for the photo-cured Ca2 ISE to achieve 90% of complete steady-state was 3 s, making the Ca2 ISE ideally suited for FIP measurements. The photo-cured Ca2 ISE exhibited an electrode slope of 30.3 $\pm$ 0.3 mV change per activity decade and a log–linear range between 0.01 and 10 mM of calcium in a 100 mM sodium chloride background in the FIP mode. Typical flow injection peak heights are presented in Fig. 5. The peak heights in the FIP mode represent 95% of complete steady-state. A sample throughput rate of 150 injections h^{-1} with a high precision was achieved and baseline drifting of 5 mV day^{-1} was observed for the photo-cured Ca2 ISE in the FIP mode. Baseline drifting of the Ca2 ISE was observed at the higher concentration in the FIP mode; however, electrode drifting in flow injection has little effect on calibrations since data processing can account for any drift when calculating peak heights.

Similar to the Ca1 ISE, the Ca2 ISE could tolerate high levels of perchlorate background in the FIP mode, without any pernicious effect on the calcium ion response. The photo-cured Ca2 ISE exhibited a near-Nernstian slope of 28.2 $\pm$ 0.4 and 24.7 $\pm$ 0.3 mV change per activity with calcium standards containing a 10 mM sodium perchlorate and a 100 mM sodium perchlorate background, respectively in the FIP mode. The log–linear range for the Ca2 ISE was between 0.01 and 10 mM in the FIP mode. The calibration plots for the Ca2 ISE in various perchlorate back-

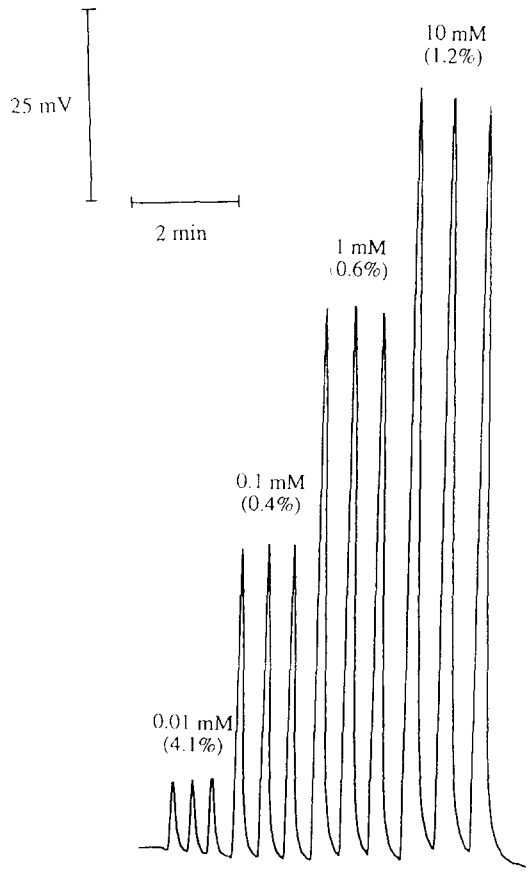


Fig. 5. Typical peak heights observed for the photo-cured Ca2 ISE in the FIP mode; the carrier and the referencev streams were 100 mM NaCl, the total flow rate was 1.5 ml min^{-1} and the sample volume was 100 μl. Relative standard deviations are given in parentheses.

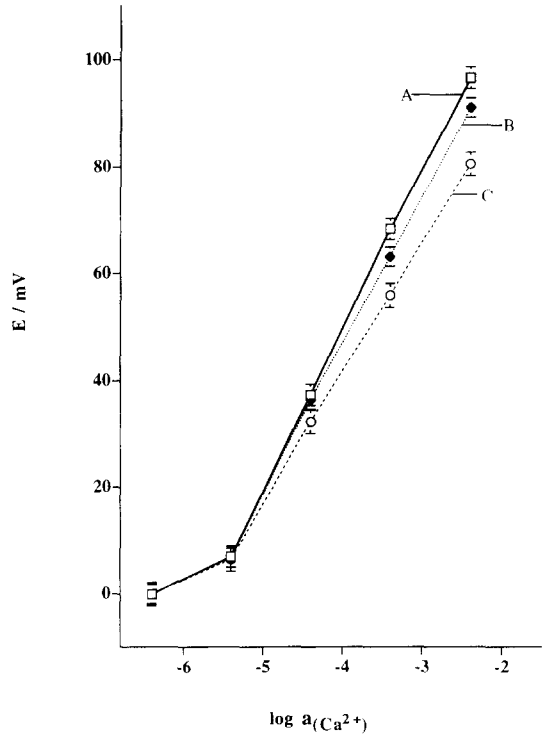

Fig. 6. FIP calibration plots for the photo-cured Ca2 ISE with calcium standards in (A) 100 mM NaCl; (B) 90 mM NaCl/10 mM NaClO 4 (C) 100 mM NaClO 4 backgrounds. Total flow rate was 1.5 ml min^{-1} and the sample volume was 100 μl.

grounds in the FIP mode are presented in Fig. 6. Comparison of the electrode performance between the photo-cured Cal and Ca2 ISEs in the FIP mode are summarised in Table 2. Clearly, the photo-cured, Ca2 ISE exhibits a higher electrode slope than the Cal ISE in the FIP mode.

To determine the reliability of the photo-cured Ca2 ISE, the total calcium level in a full cream milk sample that was digested with a nitric/perchloric acid mixture was measured. The acid digestion of the milk sample was necessary in order to release all the complexed calcium. The nitric/perchloric acid digestion of the milk samples was performed in triplicate and the procedure has been reported elsewhere [2]. The acid-digested samples were diluted 250-fold and the final background was 200 mM sodium perchlorate and 100 mM NaCl. The background of the calcium standards used in this experiment matched the acid-digested milk samples. The calcium levels determined in the acid-digested milk samples by

the photo-cured Ca2 ISE in FIP mode, compared favourably with atomic absorption spectroscopy (AAS) measurements and the results are presented in Table 3.

4. Conclusion

The introduction of anhydrous calcium chloride into the photo-cured membrane of the Ca2 ISE resulted in an improvement in the selectivity over interfering divalent ions, as wider pH independent range, and a greater electrode slope compared with the photo-cured Ca1 ISE [2]. The calcium chloride added to the Ca2 membrane dissolved easily with the aid of the DOPP plasticiser which is known to coordinate with calcium, and a lipophilic calcium–phosphonyl oxygen complex is believed to have formed. The formation of the calcium–phosphonyl oxygen complex in the Ca2 membrane had lowered the membrane resistance compared with the photo-cured membrane of the Ca1 ISE, and this could have prompted the hyper-Nernstian slope and improved selectivity over divalent interfering ions that was observed for the Ca2 ISE. Further research is in progress to explain the improved selectivity observed for the photo-cured Ca2 ISE compared with the Ca1 ISE, including pH, and the role of the calcium–phosphonyl oxygen in these photo-cured membranes. Similar to the photo-cured Ca1 ISE, the reliability and sensitivity of the photo-cured Ca2 ISE in FIP mode was demonstrated, since both ISEs were used to potentiometrically measure 0.1 mM calcium a 200 mM perchlorate background for the digested milk samples.

Biotin ligands labeled with daunomycin as an electrochemical probe for avidin and biotin interaction

Shunitz Tanaka *, Fumie Yamamoto, Kazuharu Sugarwara[1], Hiroshi Nakumura

Division of Material Science, Graduate School of Environmental Earth Science, Hokkaido University, Sapporo, 060, Japan

Received 2 April 1996; received in revised form 6 August 1996; accepted 9 August 1996

Abstract

Electroactive biotin ligands were prepared by the reaction of daunomycin with biotinylating reagents with a different spacer. These biotin ligands exhibited similar electrochemical properties to those of daunomycin, but the adsorptivity of the ligands on the electrode increased with increasing length of the spacer. The electrode response of these ligands decreased when specifically bound with avidin. This made it possible to detect electroinactive avidin indirectly. Biotin was detected by observing the competitive reaction between biotin and the ligands for the limited binding sites of avidin. The binding strength of the labeled biotins with avidin was compared with that of unlabeled biotin by using an enzyme assay. © 1997 Elsevier Science B.V.

Keywords: Avidin–biotin interaction; Daunomycin-labeled biotin ligands; Electrochemical detection

1. Introduction

Avidin–biotin binding is one of the strongest bindings between proteins and ligands. Therefore, the strong interaction has been applied in various fields and is referred to as avidin–biotin technology [1–5]. An avidin–biotin binding assay is one of the typical avidin–biotin technologies using this strong interaction. In these assays, it is necessary to detect the information about the binding by using various methods. Generally, the avidin–biotin interaction has been investigated by a photometric procedure which uses fluorescent ligands and enzyme conjugates [6,7]. However, these methods usually require the use of a separation procedure such as filtration or centrifugation before measuring in order to separate a free labeled biotin from a bound biotin. Radioisotopic ligands are very useful but the handling and disposal of the ligands is problematic. An avidin–biotin assay using an electrochemical procedure is difficult because both avidin and biotin are electroinactive. If it were possible to evaluate the avidin–biotin interaction electrochemically, a new electrochemical assay without a separation procedure could be developed. Therefore, we attempted to detect avidin–biotin interaction electrochemically by preparing biotins labeled with an electroactive compounds (LBs). When the LB and avidin are

[1] Present address: Faculty of Engineering, Kigami Institute of Technology, Kitami 090, Japan.

PII S0039-9140(96)02062-0

mixed, the LB becomes electroinactive through binding with avidin. Therefore, the electroinactive avidin can be detected indirectly from the change of the electrode response of the LB. The biotin can also be detected by observing the competitive reaction biotin and the LB for the limited binding sites of avidin. Previously, we prepared a labeled biotin ligand with daunomcyin as an electroactive compound. We then evaluated the interaction between avidin and biotin using the biotin ligand electrochemically [8].

It has also been reported that the affinity for labeled ligand–protein binding depends on the length of the spacer. The role of a spacer is to remove steric hindrance between two functional moieties and to facilitate the specific binding. If the length of the spacer is too short, the binding will be affected by steric hindrance. In this study, we prepared three LBs having spacers of different lengths as electrochemical probes for avidin–biotin binding assay. Subsequently, we observed the electrochemical behaviors of these LBs in the absence and presence of avidin. We also attempted to detect biotin using the competitive reaction of biotin and the LBs. Finally, the binding strength of these LBs with avidin was compared with that of biotin by an enzyme assay using a microtiter plate.

2. Experimental

2.1. Materials

Sulfosuccimidyl D-Biotin (Biotin-Sulfo-Osu), sulfosuccinimidyl *N*-(D-biotinyl)-6-aminohexanoate (Biotin-AC_5-Sulfo-Osu) and sulfosuccinimidyl *N*-[*N'*-D-biotinyl-6-aminohexanoyl]-6'-aminohexamoate (Biotin-$(AC_5)_2$-Sulfo-Osu) were purchased from Pierce Rockford (IL, USA). Daunomycin was supplied by Sigma, St. Louis, (MO, USA) and avidin and biotin by Wako Pure Chemicals (Osaka, Japan). Biotinamidocaproyl bovine serum albumin (Biotin-BSA; ca. 9.6 mol of biotin per mole of BSA), bovine serum albumin fraction V(BSA) and 3',3,5,5'-tetramethylbenzidine (TMB) were supplied by Sigma. Horseradish peroxidase avidin D conjugate (Av-P, 1.5 M peroxidase–1 M avidin) was purchased from Vector Labs Burlingame (CA, USA). Phosphate buffer was prepared with 0.1 MKH_2PO_4 and the pH was adjustable to pH 7 with the addition of 0.1 M NaOH. High quality nitrogen gas was used for deaeration of solutions for electrochemical measurements. All other reagents were of analytical-reagent grade.

2.2. Apparatus

All electrochemical measurements were carried out using a Yanaco P-1100 polarographic analyzer (Yanagimoto Scientific, Kyoto, Japan) with a Rikadenki Electronic Model RY-101AT recorder (Rikadenki Kogyo, Tokyo, Japan). Visible spectra of daunomycin and several biotins modified with daunomycin were measured with a Shimazu UV-2200 UV–VIS recording spectrophotometer (Shimazu Tokyo, Japan).

2.3. Electrode

A glassy carbon electrode (Model No. 11-2012, 3.0 mm diameter; Bioanalytical Systems (BAS, West Lafayette IN, USA)) was used as the working electrode. Before a measurement was carried out, the electrode was polished with 1.0, 0.3 and 0.05 μm alumina (Baikoski International, Charlotte, NC, USA) followed by 10 min of ultrasonication. An Ag/AgCl electrode (Model No. 11-2020; BAS) was used as the reference electrode and a platinum wire as the counter electrode. All potentials were measured against the Ag/AgCl electrode. Strong adsorption of the LBs on the electrode required us to reproduce a new electrode surface for all subsequent attempts of the procedure described above.

2.4. Preparation of LB

LBs were prepared as follows: 2 mM biotinylation reagent in DMF (500 μl) and 1 mM daunomycin in 50 mM phosphate buffer (pH 7.0) (250 μl) were mixed and incubated for 24 h at 4°C. The reaction product was separated from the biotiny-

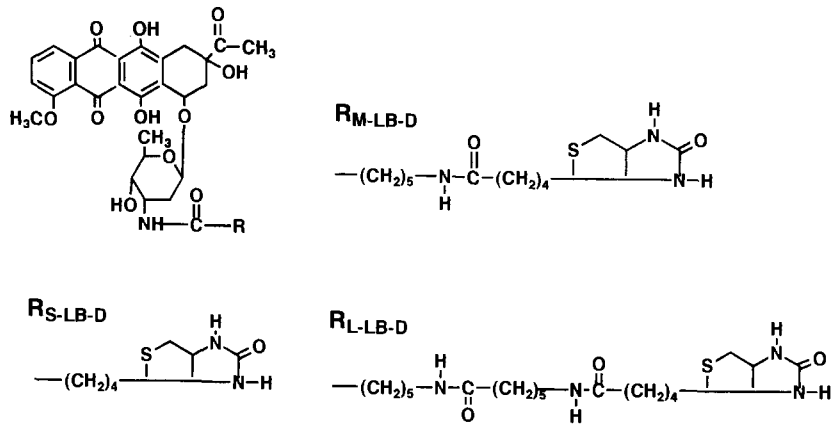

Fig. 1. Structure of labeled biotins prepared in this study.

lation reagent by TLC (Developing solvent chloroform–methanol–formic acid (80:20:2)). The concentration of LBs was determined from the absorbance at 475 nm because the spectra of the LBs were identical with that of daunomycin in visible region. The proposed structures of the LBs as shown in Fig. 1, and were supported by NMR data. The LBs labeled with Biotin-Sulfo-Osu, Biotin-AC_5-Sulfo-Osu and Biotin-$(AC_5)_2$-Sulfo-Osu are abbreviated to S-LB-D, M-LB-D and L-LB-D, respectively.

To examine the stability of the reagent, the spectra of LBs were measured. After 2 months, the spectra were the same as those at the time of preparation. Only one spot was observed on TLC even it was developed 2 months later. Therefore, it was concluded that the LBs were stable for at least 2 months.

2.5. Procedure for electrochemical avidin–biotin assay

Avidin and the LBs were mixed in 10 ml of 0.1 M phosphate buffer solution (pH 7.0) and the solution was incubated for 1 h at room temperature while being stirred. To investigate the competitive reaction between the LBs and biotin, biotin was added to a solution containing LB and the avidin. The solution was incubated under same conditions as described above. After the incubation, the solution (10 ml) was subjected to a voltammetric measurement. Deaeration of the solution was carried out for 15 min under nitrogen, then a polished electrode was immersed in the solution and a potential of -1.00 V was applied to the electrode for 5 min to reduce and accumulate the LB with stirring. After a rest time of 15 s, voltammograms of the LB were recorded by scanning the potential from -1.00 to -0.30 V using differential-pulse polarography (scan rate 5 mV s^{-1}).

2.6. Procedure for enzyme assay

After microtiter plates (Wako Pure Chemicals) had been washed with a detergent solution and water, 0.002% biotin BSA (200 μl) in phosphate buffer solution was added to the wells of the plate, which was left to stand at 4°C for 16 h. The plate was then washed three times with 10 mM phosphate buffer containing 0.1 M sodium chloride (pH 7.4) and 0.1% BSA (PBS-B) solution. Furthermore, 1% BAS solution (200 μl) was added to each well and kept for 1 h at 4°C to eliminate all remaining hydrophobic binding sites. The solution was discarded and the plate rinsed three times with PBS-B and subsequently once with PBS-B before being used.

Sample (100 μl), PBS-B (50 μl) and Av (0.12 nM, 50 μl) were mixed in the wells. The mixture was incubated overnight at 4°C with continuous shaking at 80 oscillations min^{-1} on a Thermo Shaker NTS-1300 (Eyela, Tokyo, Japan). After incubation, the wells of the plate were washed five

times with a 10 mM phosphate buffer containing 0.1 M sodium chloride (pH 7.4) (PBS), then TMB solution (100 μl) was added to each well. The enzyme reaction began with the addition of 0.01% hydrogen peroxide (50 μl). This mixture was shaken for 30 min. The reaction was stopped by adding 0.1 M sulfuric acid (50 μl). The absorbance of this solution was measured at 450 nm. The absorbance of a blank solution was taken as the unit (1.0) and the absorbance with 1×10^{-5} M biotin was taken as zero, and the ratios of the absorbances at various concentrations of biotin and LBs were plotted against concentration.

3. Results and discussion

3.1. Adsorptive behavior of LB on an electrode

Daunomycin has two pairs of redox peaks. The oxidation peak at −0.65 V and the reduction peak at −0.70 V were based on the redox reaction of the quinone part of the reagent molecule. The oxidation peak at +0.5 V and the reduction peak at +0.30 V were due to the redox reaction of the hydroquinone part [9]. The biotins labeled with daunomycin (LBs) also have the same pairs of redox peaks at the same potentials as for daunomycin itself. This suggests that labeling with biotin did not affect the electrochemical behavior of the daunomycin moiety. We investigated the binding behavior by using the oxidation peak at −0.65 V vs. (Ag/AgCl) by differential-pulse voltammetry because this peak was the sharpest among the four peaks.

Fig. 2 shows the relationship between the peak current and the accumulation time for 4×10^{-7} M daunomycin and LBs on the electrode. Daunomycin was adsorbed on the glassy carbon electrode and the peak current increased linearly until 15 min. The peak currents of M-LB-D and S-LB-D increased with increasing accumulation time up to 10 min and L-LB-D up to 5 min. When sufficient accumulation time had elapsed, the peak currents remained constant. These values are probably due to the adsorptive equilibrium of the LBs on the electrode surface. The peak current of M-LB-D is similar to that of L-LB-D, but is larger than those of S-LB-D and daunomycin. It was found that the adsorption of M-LB-D and L-LB-D on the electrode is stronger than that of S-LB-D and daunomycin. This enhancement of the adsorbing properties of the ligands may be attributed to the increase in hydrophobicity with increasing length of the spacer and by converting the ionic amino group of daunomycin into a more hydrophobic biotin moiety.

3.2. Change of the LB electrode response based on the interaction with avidin

The different pulse voltammograms of M-LB-D and daunomycin with and without avidin are shown in Fig. 3. The peak shape of the LB in the solution containing avidin was similar to that without avidin, but the peak current of the LB decreased considerably. When avidin was added to the solution containing daunomycin, the peak current of daunomycin did not decrease even after 2 h. Accordingly, it was concluded that the decrease in the peak current of LB was not due either to hindrance of the electrode reaction by the adsorption of protein on the electrode or to non-specific binding of ligand with protein. Therefore, the change in the peak current of the LB was considered to be due to the specific binding between avidin and biotin.

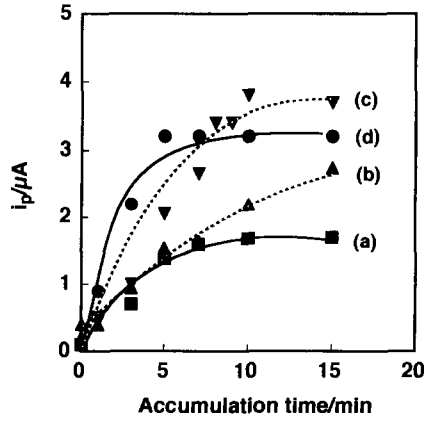

Fig. 2. Dependence of peak current on accumulation time 4×10^{-7} M S-LB-D (a), daunomycin (b), M-LB-D (c) L-LB-D (d). Results obtained by differential-pulse voltammetry (0.01 M phosphate buffer, $E_a = -1.0$ V, $t_a = 5$ min, scan rate = 5 mV s^{-1}).

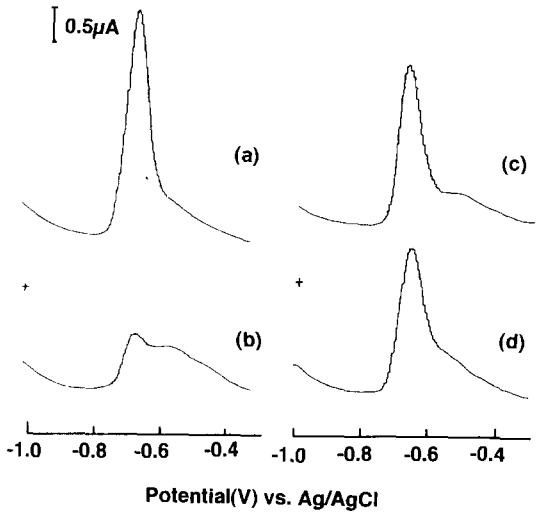

Fig. 3. Voltammograms of daunomycin and M-LB-D with and without avidin. (a) 4×10^{-7} M M-LB-D; as (a) $+ 6 \times 10^{-8}$ M avidin; (c) 4×10^{-7} M daunomycin; (d) as (c) $+ 1.2 \times 10^{-7}$ M avidin.

The dependence of the peak current of the LBs on the concentration of avidin is shown in Fig. 4. The peak current of the LBs decreased with increasing concentration of avidin, which made the detection of the electroinactive avidin possible. The detection limits for avidin calculated from the relative standard deviation (10%) of the peak current without avidin were 5×10^{-9} M using S-LB D, and 2×10^{-9} M using M-LB-D and L-LB-D. When a sufficient amount of avidin was added to bind all of the LBs, the peak current became close to zero. It can be suggested that the LB lost its electroactivity because the electroactive part of the daunomycin was covered with a large volume of avidin. If so, the length of the spacer should affect the electrode response of the LB-avidin conjugates. More detailed observations showed that when a high concentration of avidin was added, the peak current of S-LB-D was almost zero but M-LB-D and L-LB-D showed a small peak current even when a high concentration of avidin was added. This suggests that when avidin binds with M-LB-D and L-LB-D, the electroactive part is not completely covered with avidin because the electroactive part is located far from the binding site of avidin owing to the presence of a longer spacer. Therefore, the electroactivity of the ligands can be maintained but the diffusion constant decreases considerably. In contrast, the electroactive part of S-LB-D is covered completely with avidin because of the short spacer length.

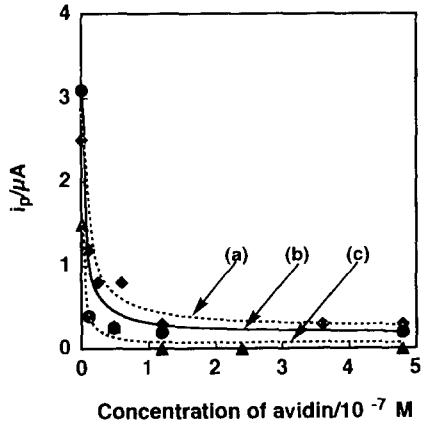

Fig. 4. Effect of avidin on peak current. 4×10^{-7} M L-LB-D (a) M-LB-D (b) and S-LB-D (c).

3.3. Competitive assay for biotin

The competitive reaction of the LB ad biotin for the limited binding sites of avidin makes the assay of biotin possible. When biotin, at various concentrations, was incubated in a solution containing a constant concentration of avidin and the LB, the peak current of the LB increased with increasing the concentration of avidin and the LB, the peak current of the LB increased with increasing the concentration of biotin, as shown in Fig. 5. This is because biotin occupies the binding sites of avidin and, as a result, the amount of free LB increases with increase in biotin content. The response curves of three types of LBs were not as varied. The best response curve was obtained by using L- and M-LB-D, as shown in Fig. 5. The relative standard deviation of the peak current at 1×10^{-7} M was 12% using M-LB-D.

3.4. Enzyme assay using microtiter plate

To investigate the strength of the binding of these ligands with avidin, an enzyme assay [10] was carried out and the results are shown in Fig.

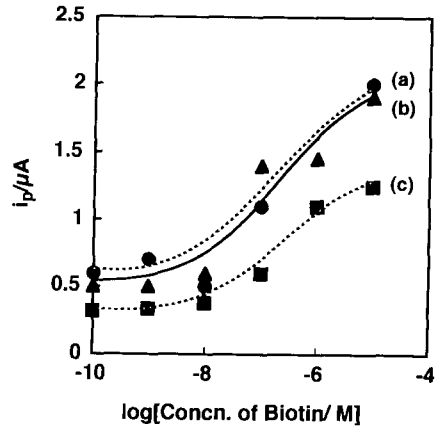

Fig. 5. Competitive binding assay for biotin using LBs by the electrochemical procedure. 4×10^{-7} M L-LB-D (a), M-LB-D (b), S-LB-D (c). Concentration of avidin 1.2×10^{-7} M.

6. The order of the binding strength was M-LB-D > L-LB-D > biotin > S-LB-D. This is due to the difference in the length of spacer between biotin and the daunomycin part. The binding constant of M-LB-D is the largest of the LBs and that of S-LB-D is the smallest. Since the distance between the biotin part and the electroactive compound is short in S-LB-D, it is thought that steric hindrance weakens the binding between the LB and avidin. The distance of the spacer does not affect the binding. The binding strength of M-LB-D and L-LB-D seemed to be slightly larger than that of biotin. If the distance of the spacer is too long, the compounds have high hydrophobicity.

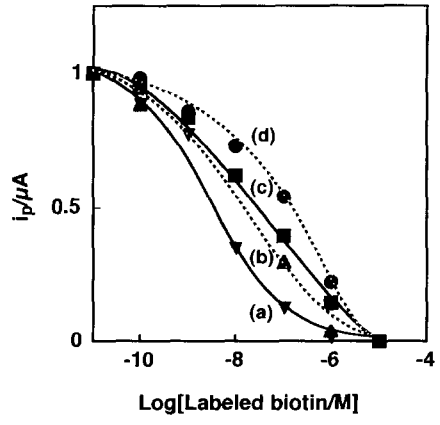

Fig. 6. Enzyme assay using microtiter plate for LBs and biotin (a) M-LB-D; (b) L-LB-D; (c) biotin; (d) S-LB-D.

The increase in the hydrophobicity of the ligand due to labeling caused it to bind non-specifically with avidin, having hydrophobic properties.

4. Conclusion

Three electroactive ligands for avidin-biotin assay were prepared. The binding behaviors of these LBs with avidin were investigated by using electrochemical and enzyme assay methods. These ligands, adsorbed strongly on the electrode, were detected sensitively by accumulation voltammetry. It was found that the adsorption of the ligands becomes stronger as the length of the spacer increases because of an increase in hydrophobicity. The electrode response of these LBs decreased drastically by binding with avidin. Therefore, the detection of 10^{-9} M avidin became possible. Biotin was also detected electrochemically using the competition reaction with these LBs. It is concluded that these LBs represent a new electrochemical probe for the measurement of the avidin–biotin interaction.

Extractive separation of trivalent lanthanide metals with a combination of Di(2-ethylhexyl)phosphoric acid and 1,10-phenanthroline

Md. Hasan Zahir, Yoshitaka Masuda *

Division of Science of Materials, Graduate School of Science and Technology, Kobe University, Rokkodai Nada-ku, Kobe 657, Japan

Received 12 January 1996; received in revised form 14 August 1996; accepted 16 August 1996

Abstract

The equilibrium extraction behavior of a series of trivalent lanthanide ions (Ln^{3+}) using a chloroform–Kerosine solution containing Di(2-ethylhexyl)phosphoric acid, combined with an adductant, 1,10-phenanthroline monohydrate (phen), was studied. The enhancement of the extraction by addition of such a neutral adductant is explained in terms of the extraction of the quaternary complex, $M(HX_2)_3(phen)_2$, in addition to the neutral complex, $M(HX_2)_3$, into the organic phase. The stoichiometry, extraction constants and separation factors of these systems were determined. The extraction constants of these systems partially follow the order of the atomic numbers. The synergistic extraction constants increased in the other Gd > Er > Ho > Eu > Ce > La > Pr and the highest separation factor was observed for Er–Ho (2.09). $pH_{1/2}$ values were also obtained. In this synergistic extraction system, both the extraction equilibrium constants and the separation factors were found to be greater than those of commercial extractants. © 1997 Elsevier Science B.V.

1. Introduction

The separation of trivalent lanthanides by solvent extraction is still an interesting and formidable problem. As a part of a systematic evaluation of the use of chelating extractants in extracting and separating trivalent lanthanides, the equilibrium extraction behavior of a series of representative lanthanide ions with chloroform containing one of several kinds of ligands alone or combined with adduct-forming agents has been studied in detail [1–6]. Many acidic organophosphorus compounds have been studied for the extraction of lanthanide metals [7–10]. One of the most important acidic organophosphorus compounds is Di(2-ethylhexyl)phosphoric acid (HDEHP), whose extraction behavior has been described by Marcus et al. [10]. HDEHP and its analogs, in organic solvents of low polarity, are present as dimers [10,11].

PII S0039-9140(96)02067-X

In synergistic systems, the extracting power of the mixture exceeds the sum of the extracting powers of its components. This phenomenon greatly enhances extraction or synergism with a mixture of extractants and has attracted considerable attention in recent years. Handley and Dean [12,13] examined Di(2-ethylhexyl)phosphorodithioic acid (HDEHPDT) as a metal extractant. According to their results, americium and europium could be extracted into dodecane fairly well with HDEHPDT. That a 'hard' metal ion such as Eu^{3+} can be extracted with a 'soft' ligand such as DEHPDT was reminiscent of our findings that a nitrogen ligand such as 1,10-phenanthroline (phen) seemed to bond with lanthanide chelates at least as readily as with the hydrated lanthanide ions [3].

Komatsu and Freiser [14] have reported extensive investigations on the solvent extraction of trivalent lanthanide metal ions (Ln^{3+}) with mixed ligands. They described the adduct formation of La(III), Pr(III), Eu(III), Ho(III) and Yb(III) with bis(2,4,4-trimethylpentyl)phosphinic acid (HBTMPP), tri-*N*-octylphosphine oxide (TOPO), octyl(phenyl)

-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) and methylenebis(diphenylphosphine) oxide (MBDPO) in chloroform. The equilibrium extraction behavior of series of representative trivalent lanthanide ions (La, Pr, Eu and Yb) was studied with either chloroform solutions of selected 1-phenyl-3-methyl-4-acyl-5-pyrazolones (acyl = decanoyl, phenacetyl, 3-phenylpropionyl and *p*-*tert*-butylbenzoyl) (HP) alone or these solutions in combination with phen, TOPO or methyltrioctylammonium chloride (R_3R' NCl) [15]. Extraction of La(III) and Y(III) [16] and Eu(III) [17] with HDEHP was carried out by Peppard and co-workers, and the extraction behavior of the metals was clarified.

Nitrogen bases such as 1,10-phenanthroline, which have high proton affinity, are appropriate auxiliary ligands. This paper reports a study of adduct formation reactions between the lanthanides and auxiliary ligands aimed at obtaining a better understanding of the extractive separation of lanthanides. The role of the diluent was also examined for the evaluation of the association constant.

2. Experimental

2.1. Apparatus

Extraction was carried out in a Taiyo M incubator at 25 ± 0.1°C. Ultraviolet and visible absorption spectra were measured with a Shimadzu self-recording spectrophotometer (Model 240-UV–Vis) with 10 mm optical path glass cells. The pH of the aqueous phase was measured with a Hitachi Horiba M-7II pH-meter. A Kokusan H-200 centrifuge was also used for rapid and complete separation of the phases.

2.2. Materials

A 1×10^{-2} standard solution of lanthanide nitrates was prepared by dissolution of a suitable amount of the pure oxide (99.99%) (gadolinium was purchased from Santoku Chemicals, Osaka, Japan, hydrated $Ce(NO_3)_3$ from Wako Pure Chemical Industries, Osaka, Japan, and other rare earths from Nacalai Tesque, Kyoto, Japan) in a small volume of concentrated nitric acid, followed by dilution with distilled water. The solution was then heated in order to remove any excess acid. The solution was diluted to 100 ml with distilled water and the concentration was determined as 1×10^{-3} M. The solution was standardized complexometrically at pH 5.1–5.6 with xylenol orange as metal indicator [18]. The prepared solution was then stored in a polyethylene bottle.

2.3. Preparation of Di(2-ethylhexyl)phosphoric acid stock solution

For the preparation of a stock solution of HDEHP, 348 cm^3 of chemically pure HDEHP (DP-8R, Daihachi Chemicals) were placed in a clean, 1 dm^3 volumetric flask and diluted to volume with chloroform–kerosine so that the solution was 1 mol dm^{-3}. This solution was washed three times with 500 cm^3 of 6 mol dm^{-3} HCl and three times with 500 cm^3 of distilled water, after

[a] [Metal nitrate ion] = 1×10^{-4} M; [ligand] = 2×10^{-3} M; [phen] = 2×10^{-3} M; [succinic acid] = 2×10^{-3} M; 25°C.

which the solution was left overnight. Since water is slightly soluble in HDEHP, the final HDEHP contains a small amount (1–2%) of water, which can be removed by using a rotating evaporator at 50°C and 15 mmHg pressure [8]. A 0.01 M phen solution was prepared by dissolving 1.9823 g of 1,10-phenanthroline monohydrate (Nacalai Tesque) in chloroform and diluting it to 100 cm^3 with the same solvent. A 0.001 M Arsenazo III solution was prepared by dissolving 0.0776 g of the reagent (Dojin Chemicals) in 100 cm^3 of distilled water. This solution was freshly prepared each week. Chloroform was used after distillation. All other chemicals were of analytical grade.

2.4. Solvent extraction procedure

The distribution experiments were performed at room temperature. An aliquot (10 cm^3) of the aqueous solution containing the metal ion (1×10^{-4} M) was placed in a stoppered 50 cm^3 glass tube. After the addition of 10 cm^3 of synergistic mixture containing the extractant solution (2×10^{-3} M) and neutral adductant solution (2×10^{-3} M), the mixture was shaken for 10 min at 200 strokes min^{-1} at 25 ± 0°C, which was sufficient for equilibration. The mixture was then centrifuged at 2000 rpm for 5 min and the pH of the aqueous phase was measured. The metal content in the aqueous phase was determined spectrophotometrically by the Arsenazo III method [19], as was the lanthanide concentration in the organic phase following back-extraction into hydrochloric acid. The concentration of metal ion in the organic phase was determined after back-extraction into 6 M hydrochloric acid for 30 min; 5 cm^3 of strip liquor thus obtained were transferred in to a separating funnel and washed once with 5 cm^3 of pure chloroform to remove the free ligand completely, then the strip liquor was allowed to evaporate. The residue was decomposed and diluted, then the pH was adjusted to 2.5. The solution was transferred into a 10 cm^3 volumetric flask, 0.5 cm^3 of the Arsenazo III was added and the mixture was diluted to volume with distilled water. The absorbance was measured at 650 nm. Neither the extractant nor its complexes in chloroform showed appreciable absorption in the visible region, hence Arsenazo III was used in the dual role of a calorimetric reagent and a scavenger for the lanthanides.

3. Results and discussion

3.1. Effect of pH on lanthanide(III) extraction systems containing HDEHP and adductant into chloroform–kerosine

First, we determined the percentage extraction of metal nitrates at pH 3–3.5 into chloroform (shown in Table 1). The effective extraction of lanthanides with HDEHP in the presence of phen occurs at aqueous phase pH values ranging from 3.00 to 3.35 for La^{3+}, 3.10 to 3.45 for Ce^{3+}, 3.15 to 3.40 for Pr^{3+}, 2.89 to 3.20 for Sm^{3+}, 2.99 to 3.25 for Eu^{3+}, 2.77 to 3.00 for Gd^{3+}, 2.85 to 3.20 for Tb^{3-}, 2.76 to 3.25 for Dy^{3+}, 2.88 to 3.10 for Ho^{3+}, 2.90 to 3.10 for Er^{3+}, 2.99 to 3.30 for Yb^{3+}, 2.80 to 3.20 for Lu^{3+} and 2.77 to 3.15 for Y^{3+}. The logarithmic distribution coefficients diminish monotonically with increasing aqueous acidities (at pH > 6.0), implying that the extractions are dominated by an ion-exchange reaction in which hydrogen is liberated. Gaikwad and Damodaran [20] studied the extraction behavior of Ho(III) with (2-ethylhexylphosphoric acid mono-2-ethylhexyl ester) (EHPNA) and they con-

cluded that there is no clear separation of phases at higher pH values. The percentage extraction of Ln^{3+} reaches the maximum in the case of phen adduct formation at pH 2.9–3.50.

3.2. Percentage extraction

The order of extraction with 2-thenoyltrifluoroacetone (1-(2-thienyl)-4,4,4-trifluorobutane-1,3-dione) (HTTA) in the presence of a bidentate heterocyclic amine, phen or 2,9-dimethyl-1,10-phenanthroline (dmp), was scandium(III) > lutetium(III) > europium(III) > neodymium(III) > praseodymium(III) > lanthanum(III), but enhancement of the extraction by tba^+ (tetrabutylammonium cation) was nearly the same with lanthanum(III) to europium(III); enhancement was negligible in the case of scandium(III) delated [21]. The results (shown in Table 1) were compared with the previous data concerning the synergistic enhancement of these metal complexes; the similarity of ternary complex extraction and synergistic extraction was also considered. In the case of Ce^{3+}, Eu^{3+}, Er^{3+} and Gd^{3+} the extraction of $M(HX_2)_3B_2$ is much greater than that of $M(HX_2)_3$, to the point where extraction of $M(ClO_4)(HX_2)_3$ is also negligible. It is concluded that synergistic extraction systems in which adduct formation occurs enhance the separation capability. In a mixed complex system containing 7-dodecenyl-quinolin-8-ol (DDQ), the donating ability of quinolin-8-ol (HQ) is not sufficient to form an adduct [4]. The effect of phenanthroline on the extraction of Eu(III) with DDQ-8 (quinolinol mixtures) was examined and it appeared that the formation with mixed complexes with a mixture of two chelating extractants and adduct formation with mixed complexes further enhance the separation capability in the lanthanide series. On the other hand, in the case of both La^{3+} and Pr^{3+}, the extraction of $Ln(HX_2)_3B_2$ take place in a similar pH region, resulting in the extraction behavior shown in Fig. 1. In Table 1, the enhancement of the extraction of La^{3+} and Pr^{3+} is not very marked, and the slopes for the straight portion are 2.7 for La^{3+} and Pr^{3+}. Obviously, lanthanides are extracted by a different mechanism under these conditions.

3.3. Slope analysis

A traditional and effective means of obtaining both stoichiometric and equilibrium constant information about extraction processes, slope analysis, is based on an examination of the logarithmic variation of the distribution ratio, D, with relevant experimental variables. The log–log plots of the extraction in the form of D vs. a concentration variable indicate the stoichiometry of the formation of the extractable complex and thus leads to the derivation of a suitable equilibrium expression and then to the calculation of equilibrium constants.

Plots of log D vs. variables such as the pH of the aqueous phase and the logarithm of the concentration of $[(HX)_2]$ were constructed [22]. Straight lines with a slope of +3 for lanthanides were obtained with a low extent of metal extracted. Thus the extraction reaction can be written as

$$Ln^{3+} + 3(HX)_{2(o)} \rightarrow Ln(HX_2)_{3(o)} + 3H^+ \quad (1)$$

Examination of Eq. (1) leads to the conclusion that the slope of a log D vs. pH plot should be +3, indicating that three hydrogen ions are released in the extraction of the metal ion (the subscript (o) designates concentration in the organic phase). The extraction constant, K_{ex}, for this reaction

$$K_{ex} = [Ln^{3+}(HX_2)_3]_o[H^+]^3/[Ln^{3+}][(HX)_2]^3 \quad (2)$$

or

$$\log K_{ex} = \log D_o - 3pH - 3\log[(HX)_2] \quad (3)$$

As mentioned above, the adduct formation of tris-DEHPA complexes of Ln^{3+} with the nitrogen-containing chelating agent phen with a representative =N–C–C–N= donor group was studied. It was found that HDEHP complexes showed an exceptionally large tendency to form adducts with the nitrogen-containing the chelating agent phen. The data support the conclusion that the plot of log D vs. $\log[(HX)_2]_o$ exhibits a slope of +3 (Fig. 2), that the plot of $\log D/D_o$ vs. $\log[phen]_o$ is linear with a slope of 2, indicating that two molecules of phen are included in the extracted species [22], where D represents the distribution ratio with time of adduct formation (Fig. 3) and that the plot of log D vs. pH also has a slope of +3 (Fig. 1). Thus,

$$Ln^{3+} + 3(HX)_{2(o)} + 2B_{(o)} \rightarrow Ln(HX_2)_3B_{2(o)} + 3H^+ \quad (4)$$

$$\log D/D_o = \log K_{ex(B)}/K_{ex} + n \log[B]_o \quad (5)$$

where $K_{ex(B)}$ represents the extraction constant with the adduct formation and K_{ex} the extraction constant with HDEHP.

The results of the extraction of lanthanides using a mixture of HDEHP and phen are shown in Table 1, where it is seen from the lower $pH_{1/2}$ (pH of 50% extraction) values that highly enhanced extractions are achieved in the presence of as little as 10^{-3} M auxiliary reagent. According to Eq. (4), the values for log $K_{ex(B)}$ were evaluated as 6.22, 5.81, 5.33, 5.15, 4.90, 3.95 and 3.95 for Gd^{3+}, Er^{3+}, Ho^{3+}, Eu^{3+} Ce^{3+}, La^{3+} and Pr^{3+}, respectively. As seen from the above data, remarkable extraction efficiencies and selectivities were observed. This strongly indicates a new possibility that the separation efficiency can be improved, even in the synergistic solvent extraction system. However, HDEHP in a synergistic extraction system has proved to be an efficient extractant because of its higher separation factors for consecutive elements. Although heavy rare earths were selectively extracted with these extractants, the extraction sequence of yttrium with respect to rare earths was Dy > Y > Lu. (Table 1).

Generally, in the chelate extraction of lanthanides; the extraction constant increases with increasing atomic number [23]. This general tendency was also observed in the present system. The extraction constant increases as the atomic

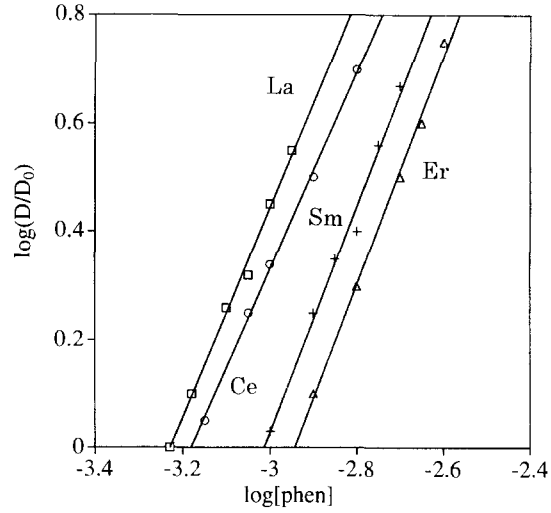

Fig. 3. Plots of $\log D/D_o$ vs. log[phen] at constant HDEHP and pH (3.10). Aqueous phase: $[Ln^{3+}] = 1 \times 10^{-4}$ M; succinic acid = 2×10^{-3} M. Organic phase: HDEHP = 2×10^{-3} M; [phen] = 2×10^{-3} M.

Table 2
Summary of results for extraction of lanthanides with HDEHP and phen as neutral ligand[a]

Element	Slope[b]	$pH^{c}_{1/2}$

Ce	3.00 ± 0.09	2.9
Pr	2.80 ± 0.03	3.15
Eu	3.15 ± 0.07	2.76
Gd	3.00 ± 0.31	2.1
Ho	3.05 ± 0.02	2.7
Er	3.22 ± 0.07	2.55

[a] $[HDEHP]_{(o)} = 2 \times 10^{-3}$ M; $[phen]_{(o)} = 2 \times 10^{-3}$ M in chloroform.
[b] Mean ± S.D. ($n = 2$).
[c] $pH_{1/2}$ is the pH value at which $\log D = 0$.

number increases until Gd^{3+}, and then it starts to decrease. It is interesting that the extraction constants $K_{ex(B)}$ of La^{3+} and Pr^{3+} are much smaller than those of the other six trivalent metal complexes with the same ligand and the $K_{ex(B)}$ values of the quaternary compounds from the neutral complex of europium(III), holmium(III) and erbium(III) are similar to each other, although the values for the cerium(III) complexes are slightly smaller than those for the other complexes. It is very interesting that the values of $\log K_{ex(B)}$ with HDEHP are very large compared with those with HDEHP alone in chloroform. This is because the steric hindrance of the synergistic mixture is low. In Table 2, the values of $pH_{1/2}$ show that lanthanide(III) can be extracted at slightly lower pH in the system with HDEHP alone than in the mixed system under the same extraction conditions and may be influenced by the distribution constant of the $Ln(HX_2)_3$ complex. In the present study, chloroform was employed as the solvent. It was observed that the extraction constant $K_{ex(B)}$, given by Eq. (5), is more than one order of magnitude larger in chloroform than in kerosine.

Fig. 4 shows the $\log K_{ex(B)}$ values for the systems studied here as a function of atomic number of the lanthanide metal ions. It is interesting that the relationship is linear up to Gd^{3+} and suggests that the slope might provide a good way of describing the selectivity of extractants used for the Ln^{3+} group.

3.4. Separation factor

The separation factor (SF) is the ratio of the distribution coefficients of two solutes measured under the same conditions. By convention, SF is greater than unity and a synonym for it is the separation coefficient. Mathematically it can be written as $SF = \log D_I / \log D_{II}$, where the subscripts I and II refer to two distinct metal ions.

In the study of metal ion separations, the dependence of the separation factors on metal ion concentrations, aqueous acidities, organic phase extractant concentrations, temperature of extractions and adduct concentration was investigated in order to determine the optimum experimental conditions in order to achieve the greatest separation factors. For evaluation of the selectivity of HDEHP, we compared the separation factors for different pairs of lanthanide(III). The values of $\log (D_I/D_{II})$ show that the separation of lanthanides becomes better only for Er–Ho, Gd–La and not for Gd–Ce. However, there is a very small gain or no gain in the separation of Ce–Ho and Eu–La, as shown by the values of $\log (D_I/D_{II})$ in Table 3.

All experiments were performed in the absence of perchlorate ion. In the absence of the perchlorate ion, the slope of the $\log D$ vs. pH lines was found to be 2.97, but when the perchlorate ion was present the slope was 1.98 [24]. Thus in the

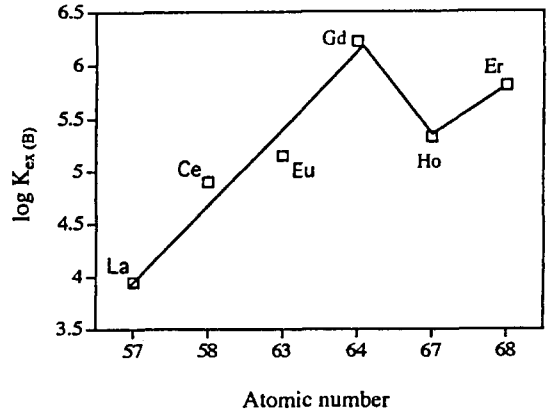

Fig. 4. Relationship between $\log K_{ex(B)}$ and the atomic number of lanthanide ions. Organic phase containing HDEHP with phen, in the absence of sodium perchlorate.

Table 3
Logarithmic separation factors in the extraction of lanthanide(III) with HDEHP and 1,10-phenanthroline

Separation	Log (separation factor)
Er–Ho	2.09
Gd–La	1.84
Ho–La	1.79
Ce–Ho	1.75
Eu–La	1.45
Gd–Ce	1.26

case of lanthanide(III) ion extraction, the following equation can be written:

$$Ln^{3+} + 3(HX)_{2(o)} + 2phen \rightarrow Ln(HX_2)_{3(o)}(phen)_2 + 3H^+ \quad (6)$$

Although all the systems examined exhibit excellent extractability, the selectivities are inferior in case of La(III) and Pr(III). It is notable that addition of phen improves the separation of the heavier lanthanides by virtue of a surprising increase in the extractability of the lighter metal (Ce^{3+}) to a greater extent than those of the heavier metals. Hence such a system would be of practical value in extracting the lanthanides as a group.

Comparison of different methods for the determination of volatile organic compounds in water samples

Raimo A. Ketola *, Vesa T. Virkki, Marja Ojala, Veikko Komppa, Tapio Kotiaho

VTT Chemical Technology, P.O. Box 1401, FIN-02044 VTT, Finland

Received 1 April 1996; received in revised form 16 August 1996; accepted 20 August 1996

Abstract

The aim of this work was to compare the characteristics of three methods, membrane inlet mass spectrometry (MIMS), purge-and-trap gas chromatography–mass spectrometry (P&T) and static headspace gas chromatography (HSGC), for the determination of volatile organic compounds in water samples as used in routine analysis. The characteristics examined included linear dynamic ranges, detection limits of selected environmentally hazardous volatile organic compounds (e.g. toluene, benzene and trichloroethene) in water, required analysis time and reproducibility of the analytical methods. The MIMS and P&T methods had the lowest detection limits for all the tested compounds, ranging from 0.1 to 5 $\mu g\ l^{-1}$. Linear dynamic ranges using the MIMS method were about four orders of magnitude and using the P&T method about two orders of magnitude. Detection limits of the HSGC method were 10–100 times higher than those of the other two methods, but the linear dynamic ranges were larger, even up to six orders of magnitude. The analysis time per sample was shortest for the MIMS method, from 5 to 10 min, and ranged around from 35 to 45 min for the HSGC and P&T methods. The reproducibilities of the methods were of the same order of magnitude, in the range of 1–13%. Agreement between the analytical results obtained for spiked samples and for environmental water samples by the three different methods was very good. © 1997 Elsevier Science B.V.

1. Introduction

In order to demonstrate the excellent capabilities of membrane inlet mass spectrometry (MIMS) in environmental analysis and to enhance the acceptance of MIMS among analytical chemists, we have compared the MIMS method developed at VTT Chemical Technology with the routine water analysis methods used at VTT Chemical Technology, viz. purge-and-trap gas chromatography–mass spectrometry (P&T) and static headspace gas chromatography (HSGC), in the determination of environmentally significant compounds in water.

MIMS is an analytical technique based on the separation of organic compounds from water or air by a thin membrane, which is installed between the sample and the ion source of a mass spectrometer [1]. Organic compounds, as well other compounds, dissolve in the membrane, diffuse through it and finally evaporate directly into the ion source of the mass spectrometer. As the flow of water or the major constituents of air (nitrogen and oxygen) through the membrane is smaller than the flow of organic compounds, 10–100-fold enrichment of the organic compounds compared with water or air may be obtained [2]. The main reason for this is the greater solubility of organic compounds in the typically used dimethylsilicone membrane compared with the solubility of water or gases. The first application of a membrane as an interface between a sample and a mass spectrometer was reported by Hoch and Kok in 1963 [3]. They studied the kinetics of photosynthesis by determining in situ the amounts of oxygen and carbon dioxide. Since then, MIMS has frequently been used for monitoring of fermentation and biochemical reactions [1,4–7].

A very rapidly expanding application field of MIMS is environmental monitoring, as evidenced by some recent reviews [1,8–10]. For example, MIMS has been used to monitor hazardous organic compounds, such as halogenated aliphatic compounds, volatile aromatic compounds, chloramines, low molecular weight aldehydes, acrolein and acrylonitrile in water samples. MIMS has recently also been shown to have very good capabilities for the high-precision measurement of dissolved gases in environmental water samples [7] and for the measurement of dissolved gases in sediment samples [11]. An interesting series of MIMS studies was also recently published, demonstrating the on-site analysis capabilities of membrane inlet mass spectrometry during the characterization of a waste dump [8], detection of organic compounds at parts per 10^{15} levels in aqueous solutions [12], direct determination of organic compounds at parts per 10^{9} levels in air [13] and measurement of microbial degradation of halogenated compounds at parts per 10^{12} levels [14]. Various trapping methods combined with conventional membrane inlet mass spectrometric methods have also been designed recently in order to gain more selectivity or to enhance the detection limits of compounds which are difficult to measure using conventional MIMS method [15–17]. One of these studies showed how an affinity membrane can be used to gain more selectivity in the analysis of aldehydes from water samples [16]. Perhaps the most promising method is the trap-MIMS method introduced by Leth and Lauritsen [17] for the determination of semi-volatile organic compounds. A detection limit of 10 ppb was obtained for pentachlorophenol, an improvement of more than 30 times over the conventional MIMS method.

Static or dynamic headspace methods are the primary methods currently used to extract volatile organic compounds from water samples. These headspace methods rely on the establishment of equilibrium partitioning of an analyte between dissolved and gas phases. In the static headspace method (HSGC), a water sample is placed in a headspace vial and an aliquot of the closed airspace above the water phase is sampled directly to a gas chromatographic column with split injection. Owing to the high detection limits of the static headspace method, sample pretreatment is often used, e.g. salting-out with sodium sulfate or chloride and adjustment of pH. In dynamic headspace methods, of which the purge-and-trap method (P&T) is the commonest, the analytes are removed from the water phase by bubbling them with an inert gas such as helium or nitrogen, collecting them in an adsorbent trap, such as Tenax or activated charcoal, and desorbing them from the trap into a gas chromatographic column via a cold trap. The theory and construction of headspace methods have been reviewed by Koester and Clement [18], Crompton [19], Soniassy et al. [20] and Poole and Schuette [21]. These techniques provide a clean sample, free from its matrix, and are best suited for the determination of low molecular weight, slightly water-soluble volatile organic compounds. Theoretical considerations of the P&T method have been studied in detail by Pankow and co-workers [22–24]. Both headspace methods can be automated by commercially available headspace autosamplers. The P&T method has been used in the

determination of vinyl chloride and dichloroethenes in water samples [25] and of volatile halogenated hydrocarbons in rainwater and ambient air [26]. Automation of the P&T method has been studied for the rapid determination of volatile compounds [27] and optimization of the parameters of the P&T [28] and HSGC methods has also been studied [29].

Harland and Nicholson [30] compared the MIMS method with two purge-and-trap methods (GC-FID and GC–MS) in one intercomparison study in which six volatile halogenated hydrocarbons were determined in five environmental samples. The MIMS method was used in the selected-ion monitoring (SIM) mode. The concentration levels of the hydrocarbons in the samples were from < 0.1 to 90 $\mu g\ l^{-1}$, and the analytical results were in good agreement. However, the comparison included only this intercomparison exercise and not a detailed study of the characteristics of the methods.

In the following, the results of a comparison of the MIMS method with the conventional water analysis methods, purge-and-trap gas chromatography–mass spectrometry (P&T) and static headspace gas chromatography (HSGC), are presented. The analytical characteristics compared include detection limits and linear dynamic ranges of a set of environmentally significant organic compounds (e.g. benzene, toluene and trichloroethene), reproducibility of the methods, agreement of the results obtained by the different methods and the required analysis time.

2. Experimental

2.1. Membrane inlet mass spectrometry

Samples were analyzed using a quadrupole mass spectrometer with a mass range of 1–500 u and equipped with an open cross-beam electron impact (70 eV) ion source (QMG 421C, Balzers, Liechtenstein). Either a capillary or a sheet membrane inlet was used for sample introduction. The design of the capillary inlet has been described in detail [8]. The capillary membrane used was a hollow-fibre dimethylsilicone membrane (Silastic, Dow Corning, Midland, MI, USA), length 40 mm, o.d. 0.635 mm and i.d. 0.305 mm. The interface between the ion source of the mass spectrometer and the capillary membrane inlet was constructed on a standard 70 mm Conflat flange. Samples from the capillary inlet were directed to the ion source of the mass spectrometer using 50 cm × 0.22 mm i.d. deactivated silica capillary tubing and a 1 ml min^{-1} flow of helium through the membrane inlet and the interface silica capillary. The sheet membrane inlet was built on the basis of the design of Lauritsen [31]. The material of the sheet membrane was also dimethylsilicone (Specialty Silicone Products, Ballston Spa, NY USA) and had thickness 100 μm and contact area 28 mm^2. The interface and the membrane inlets were electrically heated to 70°C.

During operation of the system, a water stream is continuously supplied to the membrane inlet via a peristaltic pump (IPS4, Ismatec, Switzerland), typically at a flow-rate of 10 ml min^{-1}, and aliquots of sample solution are sampled into this stream as needed. A typical sampling lasts 3 min. The temperature of the flowing water was equilibrated at 70°C with a circulating water-bath (Lauda M3, MGW, Germany). Detection limits (signal-to-noise ratio 3:1) and linear dynamic ranges of the test compounds were measured by SIM. Identification and quantification of the compounds in samples were accomplished by scanning the mass range (45–200 u) of the sample and processing the spectrum obtained with a calculation program designed at VTT Chemical Technology [32]. This calculation program uses a modified algorithm of the general deconvolution method, which assumes that the intensity of any mass-to-charge ratio (m/z) is a linear function of the concentration of the chemical compounds which contribute to that particular m/z. The testing of the calculation program is still in progress, and the results will be published elsewhere.

2.2. Static headspace gas chromatography

Samples were analyzed using a Model 5890 Series II gas chromatograph (Hewlett-Packard, Palo Alto CA, USA) equipped with a Hewlett-

Packard Model 7694 headspace sampler, two flame ionization detectors (FID) and two capillary columns, 30 m × 0.32 mm i.d. SPB-1, film thickness 1.0 μm (Supelco, Bellefonte, PA, USA), and 30 m × 0.32 mm i.d. × OV-1701, film thickness 1.0 μm (J&W Scientific, Folsom, CA, USA). The carrier gas was hydrogen. The temperatures of the sampler oven, the sample loop and the transfer line of the headspace sampler were 80, 120 and 120°C, respectively. The GC cycle time was 43 min, the sample vial equilibrium time 30 min and the injection time 1.0 min. Analyses were carried out using the following temperature program: 45°C, held for 5 min, then increased at 10°C min^{-1} to 210°C, held for 2 min. The temperature of the injector was 220°C and that of the detectors 250°C. Sample volumes were 10 ml in 20 ml headspace bottles. Detection limits of the compounds were calculated from those peaks for which the signal-to-noise ratio was at least 3:1.

2.3. Purge-and-trap gas chromatography–mass spectrometry

Samples were analyzed using a system consisting of an LSC 2000 purge-and-trap sampler (Tekmar, Cincinnati, OH, USA), a Model 5890 Series II gas chromatograph (Hewlett-Packard) equipped with a DB-1 capillary column, 30 m × 0.32 mm i.d., film thickness 1.0 μm (J&W Scientific) and a JMS-AX505WA mass spectrometer with electron impact ionization at 70 eV (Jeol, Tokyo, Japan). The conditions of the purge-and trap sampler were as follows: standby time 30 min, prepurge time 0 min, preheat time 0 min, sample time 20 min, purge time 6 min, dry purge time 2 min, cool down temperature −120°C, desorb preheat temperature 200°C, desorb time 4 min at 225°C, inject time 2 min at 250°C and bake time 8 min at 250°C. The GC temperature program was as follows: 30°C, held for 5 min, then increased at 20°C min^{-1} to 110°C and at 10°C min^{-1} to 300°C, held for 5 min. The carrier gas and purging gas was helium and the sample volume was 5 ml. Identification of compounds in the samples was accomplished by analysing mass spectra obtained over the mass range 29–400 u. Quantification was performed on the basis of the peak areas obtained from the single ion chromatograms extracted from the data measured in the scanning mode. Detection limits of the compounds were calculated from those peaks for which the signal-to-noise ratio was at least 3:1. Better detection limits can be obtained in the SIM mode, but to save analysis time the samples were analysed only in the scanning mode.

Aqueous standard solutions were prepared by volumetrically diluting stock standard solutions (typically 10 g l^{-1} in methanol) of commercial reagents using deionized water. The final concentrations of the standard solutions were in the range 0.1–500 μg l^{-1}. The commercial reagents used were trichloroethene [79-01 – 6] (99.5%), benzene [71-43-2] (99.5%), tetrachloroethene [127-18-4] (99%), carbon tetrachloride [56-23-5] (99.7%), xylenes (mixture of isomers) [95-47-6], [108-38-3], [106-42-3] (99.8%), toluene [108-88-3] (99.5%), chloroform [67-66-3] (99%), benzaldehyde [100-52-7] (99%), butan-2-one [78-93-3] (99.5%) from Merck (Darmstadt, Germany), acetone [67-64-1] (99.5%) from Mallinckrodt, St. Louis, MO, USA) and methyl *tert*-butyl ether [1634-04-4] from Neste Oy (Finland).

Spiked samples were prepared by diluting the stock standard solutions (10 g l^{-1}) with methanol to a concentration of 100 mg l^{-1} and diluting these solutions to the final concentration with deionized water. The content of methanol in the spiked sample was about 1%. All unknown and spiked samples were stored in 100 ml headspace vials and similar headspace vials were also used as sample vials in the MIMS method. The 12 environmental water samples analyzed were obtained from various customers of VTT Chemical Technology. Appropriate dilutions of the samples were made with deionized water when needed for both the MIMS method and the P&T method.

3. Results and discussion

The analytical characteristics of the MIMS, P&T and HSGC methods were studied with nine different volatile test compounds presented in Table 1, including six halogenated organic compounds and three aromatic compounds. Note that

Table 1
Detection limits and linear dynamic ranges (LDR) of selected compounds (in μg l^{-1}) measured by MIMS, P&T and HSGC

Compound	MIMS		P&T		HSGC[a]	
	Detection limit	LDR	Detection limit	LDR	Detection limit	LDR
Toluene	0.1	0.3–1000	0.2	0.2–15	3	3–380 000
Benzene	0.1	0.1–1000	0.2	0.2–20	4	4–100 000

[a] The upper limit of LDR by the HSGC method is partly determined by the solubilities of the tested compounds in water.

the P&T and the HSGC methods are the analytical methods used in routine water analysis at VTT Chemical Technology. All methods were optimized for routine analysis and for this reason the operating conditions used were a compromise between several different factors (e.g. detection limits required by government regulations, speed of analysis and capability to identify unknowns) and therefore the best performance characteristics of these techniques were not necessarily obtained. For example, lower detection limits with all three different methods can be obtained. Typical detection limits using the P&T method range from 0.01 to 0.1 μg l^{-1} [33], but detection limits below 1 ng l^{-1} have been reported [34]. With the MIMS method the typical detection limit range is 0.1–10 μg l^{-1}. However, it has already been demonstrated that under optimum conditions detection limits at parts per 10^{15} (ppq) levels can be achieved, for example a detection limit of 500 ppq was measured for toluene in water [12]. With the HSGC method, detection limits of 0.1–1 μg l^{-1} are often obtained [35,36]. Organic chloro compounds, e.g. trichloroethene and chloroform, can be measured by the HSGC method even at lower levels under optimum conditions, i.e. at 0.05–0.2 μg l^{-1} using an electron-capture detector (ECD) [37].

In this study, the main interest was to measure the detection limits and the linearity of the signals of these compounds with the three different routine analysis techniques. The detection limits (signal-to-noise ratio 3:1) for most of the compounds are comparable for the MIMS method and for the P&T method, being in the range 0.1–1.0 μg l^{-1}. In the case of the HSGC method the detection limits are about 10–100 times higher than those for the other two methods. The reason for this is that in the MIMS and P&T methods, compounds can be concentrated very effectively by the membrane or by the adsorbent trap, respectively. In the HSGC method this kind of concentration step is lacking and the concentrations of the compounds detected are determined by their Henry's laws coefficients at the temperature of measurement. For this reason the total amount of a compound detected is not as large in the HSGC method as in the MIMS and P&T methods.

The linear dynamic ranges of test compounds by the MIMS method are three to four orders of magnitude, which is more than sufficient for the analysis of unknown samples with varying concentrations. For the P&T method the linear dynamic ranges are much narrower, about two orders of magnitude, owing to the limited capacity of the adsorbent trap and the cryofocusing trap. These narrow linear dynamic ranges can cause problems in the analysis of samples containing analytes in a wide concentration range. However, with a different P&T configuration a linear dynamic range up to 5000 μg l^{-1} has been achieved [38]. The best performance in this respect was obtained with the HSGC method, for which linear dynamic ranges up to six orders of magni-

Table 2
Analytical results for a spiked sample measured by the three methods and RSD between calculated and measured concentrations

Compound	Concentration (μg l^{-1})				RSD (%)		
	Spiked	MIMS	HSGC	P&T	MIMS	HSGC	P&T

Mean[b]					13	6	16

[a] Sum is the total amount of analytes.
[b] Mean is measured as an average of the RSDs between observed and spiked concentrations.
[c] Not found.
[d] Not measured.

tude were measured, owing to the very wide dynamic range of the flame ionization detector. The linear dynamic ranges of some compounds might be even wider, but for practical reasons the upper limit in the measurements was limited to 100 mg l^{-1} except in the case of toluene. For the HSGC method our results are in good agreement with the literature, e.g. using the HSGC method with a photoionization detector (PID) followed by FID the useful working range was reported to be 1–15 000 μg l^{-1} [35].

The identification and quantitation capabilities of the three methods were compared by analyzing spiked samples. A good example of these results is presented in Table 2. The concentrations of the analytes were calculated for each method using external standards. For the MIMS method the results were calculated using the calculation program developed at VTT [32] and external standards of three different concentration levels (5.0, 20 and 50 μg l^{-1}). Three different external standards (1.0, 5.0 and 10 μg l^{-1}) were also used for the P&T method. For the HSGC method, however, external standards of five different concentration levels were used (10, 50, 100, 500 and 1000 μg l^{-1}). Note that the notation C2-benzenes and C3-benzenes in Table 2 indicates the sum of benzene derivatives substituted by two (dimethylbenzenes and ethylbenzene) or three carbons (trimethylbenzenes, ethylmethylbenzenes, propylbenzene and isopropylbenzene), respectively. These compounds can be quantitated separately using the HSGC and P&T methods due to the chromatographic separation. The sum of these compounds can also be calculated with the MIMS method, but the identification of individual compounds is difficult.

The results presented in Table 2 show that compounds with low concentrations can be quantified reliably by all the three methods, even if the concentration difference between some compounds is as much as two orders of magnitude. The small variations between the observed and spiked concentrations are believed to be due to evaporation of the compounds during the preparation of the spiked sample and standards. The loss of volatile compounds in the sample handling has been experienced before, e.g. by Wise et al. [39]. Note that the high content of methanol in the sample did not seem to affect the analysis, although it can interfere with the chromatographic behavior of low molecular weight com-

pounds. The smallest mean difference between observed and spiked concentrations was obtained with the HSGC method (6%) and the largest with the P&T method (16%). The largest differences between observed and spiked concentrations with the MIMS and the P&T methods were observed in the case of tetrachloroethene, probably owing to its low concentration. In the case of the P&T method, relatively large errors were also observed in the determination of 1,2-dichloroethane and benzene. The former error was probably due to inadequate chromatographic separation of 1,2-dichloroethane from 1,1,1-trichloroethane when a dimethylpolysiloxane column was used. The latter error was due to the leakage of benzene from the Tenax adsorbent trap, which was observed in the analysis of blank samples. The leakage of benzene and alkylbenzenes from the adsorbent is due to decomposition of the Tenax trap material [40]. From Table 2, it can also be seen that the MIMS method gives the closest result for the total amount of volatile organic compounds in the sample.

A number of unknown environmental water samples were also analyzed during this study in order to compare the capabilities of these three methods in the analysis of typical water samples delivered to VTT by customers of the laboratory. The analytical results for two of these samples are presented in Table 3. The samples were waste water samples containing hazardous organic compounds in various concentrations. The results show that all three methods produced same results, i.e. the same compounds are identified and the concentrations of the compounds are about the same. They also show that in some cases the MIMS method overestimate the concentrations of some of the analytes. This is due to the fact that in the MIMS method all the compounds are analyzed at the same time on the basis of a multicomponent mass spectrum and therefore unidentified minor compounds can cause overestimation of the concentration of the identified compounds if the minor compounds produce the same fragment ions as the identified major compounds. However, it should be noted that in all cases presented the errors are small and that the same

Table 4
Agreement of analytical results obtained by three methods (MIMS, HSGC and P&T) by calculating the RSD for the analytical results of unknown or spiked samples (the total number of samples was ten)

Compound	No. of analytes	Concentration range (μg l^{-1})	RSD range (%)	Mean RSD (%)
Halogenated compounds	31	0.2–4700	2–71	26
Aromatics	26	0.2–27000	4–52	25

compounds were identified with the MIMS method as with the other two methods.

On the basis of the results presented above, the analysis time per sample for the three different methods can also be discussed. The analysis time is shortest for the MIMS method, the cycle time from sampling of one sample to sampling of the next being 5–10 min. The cycle time can easily be changed by varying the sampling time; especially for high-concentration samples, very short sampling times (1 min or less) can be used. At low compound concentrations very short cycle times, less than 5 min, can be obtained, since the signals of the monitored ions return from their maximum to the ground level very rapidly. In the HSGC and P&T methods the analysis time depends on the GC run time and the headspace parameters. In our experiments the analysis time was 43 min for the HSGC method and 40 min for the P&T method. In both cases the analysis time can be shortened by a few minutes, at the expense of accuracy and reproducibility. This comparison clearly shows that a much larger sample throughput can be obtained with the MIMS method than with the other two methods.

Table 5
Characteristics of the three analytical methods

Characteristic	MIMS	P&T	HSGC
Detection limit (μg l^{-1})	<1	<1	1–10
Linear dynamic range	10^4	10^2	10^6
Repeatability (%)	1–11	2–13	1–8
Analysis time (min)	5–10	35–45	35–45
On-line monitoring capability[a]	+++	+	+
Identification capability[a]	++	+++	++[b]
Simplicity of instrumentation[a]	++	+	+++

[a] +++, Very good; ++, good; +, fair.
[b] Flame ionization detector used.

The repeatability of the analysis method was measured from three successive injections of the same sample and calculating the relative standard deviation (RSD) of the repeated injections from the measured concentrations of compounds in the sample. The repeatability obtained from ten individual measurements with each method ranged between 1 and 11% (mean 8%) for the MIMS method, 1 and 8% (mean 6%) for the HSGC method and 2 and 13% (mean 8%) for the P&T method. The results obtained are very close to those reported earlier by Ho [33] (1–10% with the P&T method) and Roe et al. [36] (2–8% with the HSGC method). As can be seen from these results, the repeatabilities of all three methods were good, demonstrating that minor changes in the measurement conditions do not affect the analytical results.

The agreement of the analytical results obtained by the three different methods was estimated by calculation of the RSD of the analytical results measured for unknown or spiked samples (Table 4). The total number of compounds measured was 57 (31 halogenated compounds and 26 aromatic compounds) from ten unknown samples. The RSDs were usually good, ranging from 2 to 40%, demonstrating that all three methods gave comparable results in the determination of volatile organic compounds in water. Larger RSD values (40–71%) were normally obtained for samples containing low concentrations of analytes, i.e. at concentration levels close to detection limits, whereas very good agreement (RSD < 10%) was obtained in the concentration range from 10 to 1000 μg l^{-1}. The mean RSDs of both compound classes (halogenated and aromatic compounds) were almost the same, indicating that equally

good data can be obtained for these classes of compounds.

4. Conclusions

The analytical characteristics of the three methods are summarized in Table 5. As can be seen, in the determination of volatile organic compounds MIMS is very comparable to the conventional P&T and HSGC methods. The main advantages of the MIMS method are low detection limits and short analysis times. The MIMS method is also the only method of these three which can be used for continuous on-line monitoring [41–44]. The major difficulty with the MIMS method is the lack of chromatographic resolution of components, especially with heavily contaminated samples, but the recently developed deconvolution program for multicomponent mass spectra resolves this problem in many cases. The major advantages of the P&T method are low detection limits and the capability to analyze very complex mixtures owing to the gas chromatographic separation. In addition, identification of unknowns is relatively easy since commercial reference libraries of electron impact mass spectra can be used to assist the identification. The best qualities of the HSGC method are the wide dynamic range, separation of compounds by GC and simpler instrumentation than for the other two methods. The major disadvantages of the HSGC method are poor detection limits compared with the other two methods and poor identification capability when a flame ionization detector is used. The measured results also showed that the reproducibilities of the methods are of the same order of magnitude and that agreement between the analytical results obtained by the three different methods is very good.

The main conclusion of this study is that in many cases MIMS can produce much faster analytical results of the same quality as the conventional P&T and HSGC methods for water analysis, and therefore it should be the preferred method especially when high throughput is required.

Received 6 June 1996; received in revised form 26 August 1996; accepted 26 August 1996

Abstract

The design of a simple, highly miniaturized instrument for manual microsequence analysis of proteins and peptides is described. The reaction chamber is made of fused silica capillary tubing with all reagents and solvents necessary for coupling and cleavage delivered via two valves and a syringe-based dispenser. Only two pressure regulators are required. A section of the flow-through reaction chamber is heated by thermoelectric modules to control the sequencing reaction temperature. Conversion of the extracted amino acid product to the more stable phenylthiohydantoin (PTH) form is performed off-line so that it may be dissolved in 1 μl buffer for identification. Approximately 0.1% of this PTH product is analyzed by micellar electrokinetic capillary chromatography (MECC) with thermo-optical absorbance detection (TOAD), providing femtomole detection of the phenylthiohydantoin amino acids. Preliminary results at the 50 pmol level for both adsorptive and covalent sequencing methods are presented. © 1997 Elsevier Science B.V.

1. Introduction

The determination of the primary amino acid sequence of minute amounts of proteins remains important in biology. Current technology relies on the repetitive application of the Edman degradation reaction [1]. In this reaction, the N-terminal amino group of the polypeptide reacts with

phenylisothiocyanate (PITC) under basic conditions (the coupling reaction) to form the phenylthiocarbamyl (PTC) derivative. After excess reagent is extracted, the PTC peptide is treated with anhydrous acid (the cleavage reaction) to release the cyclic anilinothiazolinone (ATZ) amino acid. In the process, the peptide is truncated by one amino acid residue. Last, the ATZ product is extracted from the truncated peptide and treated with aqueous acid (the conversion reaction) to produce the more stable phenylthiohydantoin (PTH) amino acid. There are also two common side products produced in the sequencing reaction, diphenylthiourea (DPTU) and dimethylphenylthiourea (DMPTU). Cysteine does not survive the Edman degradation reaction. As a result, there are 19 possible PTH amino acid products for unmodified amino acids, plus the two main interfering products. Chromatographic analysis of the PTH product obtained from each degradation cycle is compared with a standard chromatogram of the 21 possible products for positive amino acid identification.

Introduction of the gas–liquid–solid phase (adsorptive sequencing) instrument in 1981 revolutionized microsequencing by providing sequence information on as little as 5 pmol of protein [2]. In the last 15 years most reports on improving the sensitivity of Edman degradation have not progressed significantly beyond the picomole barrier [3–9]. Kent et al. [10] have pointed out that rare proteins are only present at the 30–300 fmol level on 2D-polyacrylamide gels and that sequencing improvements ranging from better immobilization of the sample to better data analysis of the products was necessary to achieve a significant increase in sequencing sensitivity over methods that were currently being used. This task remains important as protein analysis progresses [11].

In response to this challenge, improvements in sequencing sensitivity have come from many sides. Miniaturization and modification of sequencer components, from separation column to reaction cartridge, are typical. Reduction of HPLC column inner diameter from 4 to 2 mm resulted in a four-fold improvement in sensitivity. The continuous flow reactor described by Shively's group consisted of concentric Teflon tubes in which Polybrene-coated silica beads [3] or polyvinylidene difluoride (PVDF) membrane [7] were used for adsorptive immobilization of polypeptide sample. While high sensitivity sequence analysis on PVDF-bound protein at the 5 pmol level was reported, the authors suggested that at least 10 pmol protein sample be loaded for accurate sequencing results. Similarly, the Hewlett–Packard biphasic reaction column sequencer relies on adsorption for sample immobilization. The hydrophobic packing doubles as a clean-up column for removal of salts, urea and sodium dodecyl sulfate that may be present after protein purification. The biphasic column system can sequence less than 5 pmol protein [12], but routine use at this level is difficult. Regardless of configuration, miniaturizing the reaction cartridge volume permits the use of less reagent and thereby reduces the level of non-specific reactions that give rise to background noise in the chromatographic identification of sequencing products.

From another perspective, advances in the Edman degradation chemistry for amino-terminal sequencing have focused on PITC analogs to provide enhanced sensitivity of the amino acid derivatives through a variety of detection methods. For example, detection limits were 300 amol for ethylenetrimethylamino phenylthiohydantoins (P(ETAP)THs) [13] by HPLC-electrospray mass spectrometry (ESI-MS), 100 amol for dimethylaminoazobenzene thiohydantoins (DABTHs) [14] by micellar electrokinetic capillary chromatography-thermo-optical absorbance detection (MECC-TOAD), and 2 zmol for fluorescein thiohydantoins (FTHs) [15] by capillary electrophoresis (CE) with laser induced fluorescence detection. Unfortunately, these reagents have not found use in routine sequencing because of their poor coupling chemistry. Only recently, the PITC analog 4-(3-pyridinylmethylaminocarboxypropyl) phenylisothiocyanate [16] was used successfully to sequence 500 fmol of synthetic peptide in a commercial sequencer with modified adsorptive sequencing chemistry and HPLC-ESI-MS analysis of thiohydantoins [17]. Alternatively, postcleavage reaction of the ATZ derivatives with 4-aminofluorescein demonstrated sequence analysis on 500 fmol protein using HPLC with fluores-

cence detection [18]. For non-chemical degradation, tandem mass spectrometry has demonstrated rapid and sensitive primary sequence determination [19], but is typically limited to peptides smaller than 10 residues; large peptides generate very complex spectra that are difficult to interpret. However, ESI-MS coupled to capillary electrophoresis has been successfully used for protein identification by peptide mass mapping of 38 fmol of a tryptic digest from bovine serum albumin [20].

Given the reliance of routine microsequencing on PITC degradation chemistry, further improvements in sequencing sensitivity have focused on the UV-absorbing PTH amino acid derivatives. Increasing yields and reducing non-specific reactions with PITC to improve signal/noise have typically been achieved by modification of sequencing protocols and sample loading techniques [8]. Efforts to improve chromatographic identification include injecting a larger proportion of the conversion product [21], improving the resolution of PTH peaks from degradation by-products peaks [22], and reducing sequencing times to improve throughput. However, further miniaturization of sequencer components has not progressed much because of the large amounts of PTH product required for detection in HPLC. It remains that detection of PTHs at very low levels, amongst a high background of UV-absorbing by-products, is the limiting factor to improving polypeptide sequencing sensitivity. As Calaycay et al. [7] pointed out, "The sequencing levels depend heavily on the performance of the narrow-bore HPLC system. It is clear that further improvements in the detection of all the PTH amino acids are in order before femtomole level sequencing can be achieved". It is our feeling that advances in detection techniques have not been fully investigated as a means of improving sequencing sensitivity.

We reported subfemtomole detection of PTH amino acids in 1992 [23] using a MECC-TOAD technique. While it is trivial to apply MECC-TOAD determination of the PTHs to manual sequencing studies [24], it has been difficult to efficiently transfer this analysis method to automated sequencers. The bottleneck comes from interfacing the large volumes of product formed in commercial sequencers ($> 100\ \mu l$) to the small volumes injected into the CE (< 10 nl). In order to address this 10 000 fold volume differential, we have investigated additional miniaturization of the sequencer first described by Hewick et al. in 1981. This work describes two configurations of a protein microsequencer and presents some preliminary sequencing results.

2. Experimental

2.1. Materials

Sequencing grade ethyl acetate, *n*-heptane, 12.5% trimethylamine (TMA) in water, polytetrafluoroethylene (PTFE) membrane (Zitex™) and PTH amino acid standard were purchased from Applied Biosystems (Foster City, CA). Sequencing grade PITC, anhydrous trifluoroacetic acid (TFA), Polybrene, oxidized insulin chain B, oxidized insulin chain A, β-lactoglobulin-A and Tyr-bradykinin were from Sigma Chemical (St. Louis, MO). Glass fibre filter disks (GFF) pre-cycled with Polybrene were received as a gift from R. Aebersold. Porton sequencing disks were received as samples from Beckman Instruments. Sodium dodecyl sulfate (SDS), sodium dihydrogen orthophosphate and HPLC-grade acetonitrile were obtained from BDH, (Toronto, ON). Sodium tetraborate and 1-chlorobutane were supplied by Fisher Scientific (Fair Lawn, NJ). Covalent sequencing reagents (NMM: 5% *N*-methylmorpholine in 70% methanol, 50/50 heptane/ethyl acetate, methanol), Immobilon-CD membrane, PVDF, Sequelon-AA (aryl amine) reagent kit and Sequelon-DITC (diisothiocyanate) myoglobin standard were purchased from Millipore Canada (Nepean, ON). Porasil T silica beads were donated by F. Cantwell. Pre-purified argon (Union Carbide Canada, Edmonton, AB) was passed through an OT-3-2 oxygen trap from Chromatographic Specialties (Brockville, ON). Distilled water was purified with a NANOpure ultrapure water system (Barnstead Corp., Dubuque, IA) for buffer preparation. Teflon tubing, large-bore fused silica tubing, and Hamilton

glass syringes were obtained from Chromatographic Specialties (Brockville, ON). Narrow-bore fused silica tubing and Innerlok™ connectors were purchased from Polymicro Technologies (Phoenix, AZ).

2.2. Identification of PTH amino acids

Separation and detection of PTH amino acids was performed using the MECC-TOAD instrument described in detail elsewhere [23,24]. A 40 cm long fused silica capillary (50 μm i.d., 190 μm OD) was used for the separations. The column length from injection (anode) to detection was 35 cm. Separation buffer of 10.7 mM sodium phosphate, 1.8 mM sodium tetraborate and 25 mM SDS, pH 6.7, was filtered through a Millex-GS 0.22 μm syringe filter unit (Millipore, MA) before use. Sequencing produce was dissolved in 1 μl 10% acetonitrile/90% running buffer spiked with internal standard (5×10^{-5} M PTH-tyrosine or PTH-alanine). The dry PTH amino acid standard was dissolved in acetonitrile (5×10^{-5} M) and stored at −20°C. A 5 μl aliquot of standard was dried and re-dissolved in the same volume of 10% acetonitrile/separation buffer for injection into the CE system. Samples and standard were injected hydrodynamically (injection volume 1 nl) and separated at 10 kV. The current was 8 μA.

2.3. Instrument design

A schematic of the instrument is shown in Fig. 1A. Purified argon was directed to two stainless steel manifolds (M1, M2) each equipped with a pressure regulator (M1 at 3.5 psig, M2 at 8.0 psig), pressure relief valve, and twelve 1/16 in. fittings (Swagelok). Reagents and solvents were delivered to the Valco 16-position multiport valve V1 (machined from Hastalloy C, Chromatographic Specialties) through capillary tubing feed lines from delivery vessels pressurized via 1/16 in. Teflon tubing from manifold M1. The delivery vessels were adapted from amber 5 ml Reactivials (Chromatographic Specialties) and Teflon 1/16 in. male-run tees (Cole-Parmer) that were screwed into inserts (threaded inside with 1/8 in. NPT, machined in-house from Teflon) that fit through the holes in the Reactivial caps. The top arm of each tee was connected to 360 μm OD fused silica capillary tubing adapted with a 2 cm long Teflon sleeve to provide a gas-tight fitting against the ferrule. The tubing from manifold M1 to the TMA and TFA vials was adapted with 0.3 psi check-valves (Swagelok) to prevent back flow of solvent vapours into M1.

The capillary tubing feed lines, connected to valve V1 using fused silica tubing adapters (Valco), had inner diameters of either 75, 100 or 250 μm and lengths from 30 to 60 cm depending on desired flow rate. The V1 outlet was connected to the reaction chamber RC via 250 μm i.d. capillary tubing (12 cm) and an Innerlok compression fitting, IL. The tapered inner diameter of the IL provided an excellent compression seal with the polyimide-coated capillary and allowed rapid connection to the reaction chamber. The outlet of the reaction chamber was left open for manual collection of waste or anilinothiazolinone (ATZ) amino acid derivative. Electronic switching of valve V1 provided sequential access to the sixteen ports for timed deliveries of solvents, reagents and argon. Manipulation of argon pressure, capillary length, and capillary i.d. were used to control flow rates of reagents and solvents to the reaction chamber. Wetted pH paper held at the reaction chamber outlet was used to monitor the pH during coupling and cleavage. Sequencing reagents were delivered according to the protocol in Table 1.

The coupling reaction was carried out at 55°C and the cleavage at 48°C. The extracted ATZ product was collected directly into a 600 μl microcentrifuge vial containing 10 μl 25% TFA for off-line conversion. The mixture was vortexed and rapidly dried by vacuum centrifuge. The dried ATZ amino acid was converted to the PTH form by adding 20 μl 25% TFA, flushing with argon, and heating 10 min at 60°C in a dry block. The converted PTH amino acid derivative was dried and stored at −20°C or reconstituted in 1 μl acetonitrile/running buffer from which 1 nl (0.1%) was injected for identification by MECC-TOAD.

The single-valve instrument was later modified by adding a Hamilton Microlab-500 dual-syringe dispenser, ML, (Chromatographic Specialties) for

accurate PITC delivery, and a 5-way PTFE micro-tubing distribution valve, V2, (Cole-Parmer) as shown in Fig. 1B. Valve V1 was coupled to position 1 of valve V2 through 5 cm of 250 μm i.d., 1/16 in. OD Teflon tubing. The ML syringe dispenser was equipped with one 25 μl syringe (SY1) and one 250 μl syringe (SY2) whereby each could be programmed to deliver a specific volume at a given speed. SY1 was used to deliver R1 (PITC in solvent). SY2 was connected to argon manifold M1. A low-volume tee (machined in-house from Teflon) was used to connect the

[b] R1, 5% PITC in heptane; R2, 12.5% TMA in water (vapour); R3, anhydrous TFA (vapour); S1, ethyl acetate; S2, benzene; S3, 1-chlorobutane.

Teflon tubing outlets of the ML dispenser to position two of valve V2 through 5 cm of 250 μm i.d. Teflon tubing. A combination of electronic switching of valve V1, activation of the ML dispenser and manual switching of valve V2 were used to time the delivery of solvents and reagents to the reaction chamber for coupling and cleavage, following the protocol in Table 2. Coupling temperature, cleavage temperature, and conversion conditions were the same as for the initial instrument design.

The modified instrument was adapted for covalent sequencing by replacing reagents and solvents with those suitable for covalently bound polypeptide (Table 3). A glass syringe containing anhydrous TFA for both cleavage and ATZ product extraction was connected to position three of valve V2, as shown in Fig. 1C. Concurrent delivery of PITC (via syringe SY1) and *N*-methylmorpholine (NMM) coupling buffer (via syringe SY2) was necessary as the Microlab-500 (ML) could only activate the syringes simultaneously. Position four and nine of valve V1 were unused (plugged). The argon manifolds M1 and M2 were maintained at 3 and 30 psig, respectively. Delivery of reagents and solvents for covalent coupling and cleavage reactions followed the protocol in Table 3. The reaction chamber was held at 56°C for all eighteen steps. The extracted ATZ product was collected into a 200 μl polypropylene microvial containing 10 μl 25% TFA, and was dried with a stream of argon for 2 min. The ATZ amino acid was converted to the PTH form as described above, except heating was at 67°C.

2.4. Reaction chamber

The flow-through reaction chamber, analogous to the reaction cartridge described by Hewick in 1981 [2], was constructed from two lengths of polyimide-coated fused silica capillary tubing and a mat of porous PTFE membrane as shown in Fig. 2. The upper 4 cm length of 400 μm i.d., 525 μm OD capillary was easily cut to very flat ends using a fused silica cutting stone (Chromatographic Specialties). By gently pushing and turning the capillary tube end against a piece of PTFE, a tiny mat exactly the size of the tube's inner diameter could be cut. The mat was pushed into place using the lower 8 cm length of 100 μm i.d., 360 μm OD capillary. The reaction chamber was secured by gluing the two capillaries together with 5 min epoxy.

[a] Conversion reaction was carried out off-line.
[b] Positions 3 and 4 of V2 were unused (plugged).
[c] See Table 1.

The elevated temperature required for coupling and cleavage was generated with thermoelectric modules, made in-house from copper blocks and solid-state thermoelectric devices (Melcor, Trenton, NJ), as shown in Fig. 3. Temperature control was achieved by adjusting the voltage applied to the thermoelectrics with a 10 volt/10 ampere power supply (Kepco, Flushing, NY). The copper heat sinks (10 × 20 × 2 mm) and grooved copper plates (6 × 15 × 1 mm) were attached to the thermoelectrics with heat conducting glue made from silver paint and epoxy. These thermoelectric modules, TM, were mounted on a Hoffman open-side tubing clamp (Fisher Scientific) which could be easily opened to insert the reaction chamber along the groove in a few seconds. To calibrate the applied voltage versus temperature, the reaction chamber was filled with water and a thermocouple (Digi-Sens, Cole-Parmer) was inserted to the level of the PTFE mat. The voltage versus temperature curve was linear from 25 to 70°C, with the desired temperature being reached in 50 s. During degradation, the thermocouple was coated with a thermal compound (Dow Corning) and inserted into a small hole (0.5 mm i.d.) drilled in one copper plate to monitor the temperature, which stayed within ± 2°C of the set point.

A variety of sample immobilization techniques were tried for adsorptive sequencing in the reaction chamber. A mat from either a glass fibre disk (GFF precycled with Polybrene) or a Porton disk was cut and inserted into the reaction chamber in the same manner as the PTFE mat. For some experiments, porous silica beads (Porasil T) precoated with Polybrene solution (100 mg ml^{-1} in 50% methanol) and dried in a vacuum desiccator were poured into the reaction chamber using a pipette tip as a funnel. A loosely packed bed of beads was obtained by gently tapping the tube as the particles were poured.

2.5. Sample loading

Samples consisted of aqueous solutions of polypeptide, approximately 0.1 mM in 0.3% TFA. A sample volume of 0.2 μl or less was drawn

[d] R1, 10% PITC in acetonitrile; R2, 5% NMM in 70/30 methanol:water (liquid); R3, anhydrous TFA (liquid); S1, methanol; S2, 50/50 heptane/ethyl acetate.

through either the upper or lower half of the reaction chamber, to the adsorptive support, via an Innerlok attached to a 1 μl glass syringe. The difference in weight of the reaction chamber before and after protein loading (at a known concentration) was used to estimate the amount of loaded sample. The loaded sample was dried with a stream of argon.

For non-Polybrene immobilization, small pieces (1 × 5 mm) of PVDF or Immobilon-CD membrane were pre-wet with methanol and 1 μl of polypeptide sample applied. The pieces were further cut into 0.3 mm strips using a razor blade and inserted into the reaction chamber using tweezers. Similarly, Sequelon disks with covalently bound polypeptide were cut and inserted into the reaction chamber for covalent sequencing. A larger diameter reaction chamber was used (4 mm of 530 μm i.d., 700 μm OD) to simplify insertion of the membrane strips. Insulin chain B was bound to Sequelon-AA following the manufacturer's directions, and stored at −20°C. The weight of membrane inserted into the reaction chamber versus total weight of disk (with known amount of bound polypeptide) was used to calculate the amount of sample loaded into the reaction chamber.

3. Results

3.1. Identification of PTH amino acids

Optimization of the MECC separation of 19 PTH amino acids and two degradation by-products has been described elsewhere [24]. For this work, PTH product from each cycle was dissolved in 10% acetonitrile: 90% separation buffer compared with 100% separation buffer described previously. The addition of 10% acetonitrile improved PTH product solubility without significantly altering the MECC elution profile. An internal standard of either PTH-tyrosine (PTH-Y) or PTH-alanine (PTH-A) was also added to permit quantification of the PTH product.

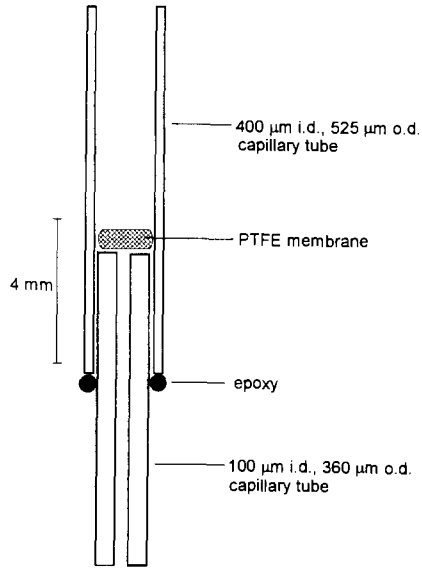

Fig. 2. Schematic of fused silica capillary-based reaction chamber.

3.2. Instrument design

The primary objective in the design of the sequencer was to miniaturize the reaction volume to improve compatibility with the nl injection volumes required for capillary electrophoresis. A second objective was to simplify the plumbing in comparison to commercial sequencers, which typically have four or more pressure regulators and six or more valves. A third objective was to design a system made mostly from commercially available parts so that it could be constructed and used in any laboratory. The initial instrument design shown in Fig. 1A required only two pressure regulators and one valve for the coupling, cleavage and extraction steps.

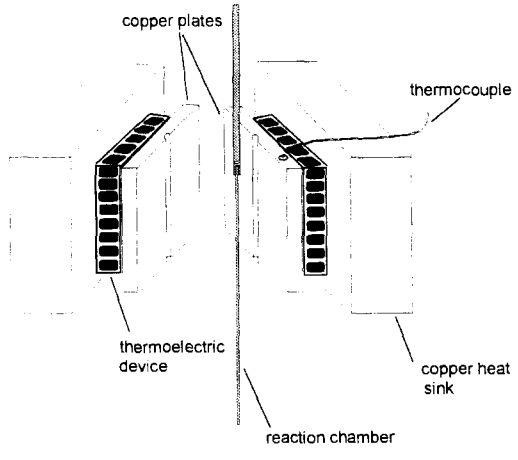

Fig. 3. Schematic of thermoelectric modules for temperature control during coupling and cleavage reactions.

Polyimide-coated fused silica capillary tubing was used for delivery of solvents and reagents to the Valco multiposition valve (V1) because it was impermeable to oxygen, flexible, inert, simple to connect and costs about the same as Teflon tubing when bought in bulk. Several different inner diameters of capillary tubing were investigated for delivery. Either 75 or 100 μm i.d. tubing proved best for delivery of argon and gas phase reagents (TMA vapours and TFA vapours) whereas 250 μm i.d. tubing was required for delivery of solvents to keep working pressures below 30 psig.

The use of valve V1, originally designed for capillary GC and LC, simplified the sequencer plumbing compared with commercial designs. However, the sequential nature of activation of valve V1 limited the sequencer to 16 steps for reagent and solvent delivery and drying (Table 1). This constraint required that extracted ATZ amino acid product be converted to the PTH form off-line. Additional drawbacks of valve V1 were its relatively large internal volume (~ 8 μl) and internal flow path (circular), neither of which were well matched to the reaction chamber volume (0.3 μl). A small volume (1–2 μl) of reagent R1 (PITC in heptane) delivered from the pressurized vessel was trapped inside valve V1 when argon was applied in the ensuing step. Essentially, a widening of the flow path from 250 μm i.d. (delivery line to V1) to 760 μm i.d. (the port diameter of V1) caused the reagent plug to become meniscus-like and rupture upon application of argon pressure. The result was that reagent R1 adhered to the valve's inner surface, never reaching the reaction chamber, until it was washed through with solvent. Consequently, R1 delivery was inconsistent, ranging from 3.5 to 8 μl.

Delivering an excess volume of R1 (PITC in heptane) in order to overcome the V1 valve design was also problematic. The sample support was

unable to absorb the excess liquid. Drying with argon left an insufficient amount of PITC for coupling. When some R1 was purposely allowed to remain in the reaction chamber, residual heptane impeded coupling. The best yields achieved for sequencing either insulin chain B or β-lactoglobulin-A were 15% in cycle one, and 0% in cycle two. Increasing the PITC concentration to 10% in heptane did not significantly improve yields because this mixture did not leave sufficient PITC on the sequencing support. The higher concentration of PITC led to DPTU contamination of valve V1. Extraction of the ATZ amino acid was initially done with 1-chlorobutane and later benzene, which reduced the background peaks in the MECC analysis.

The Microlab-500 syringe dispenser, ML, was added to the sequencer both for accurate delivery of R1 to the reaction chamber and to compensate for lack of random access (via valve V1) to reagents, solvents and argon for gas-phase coupling. Unfortunately, the PTFE valve V2 that was used to interface the ML dispenser and valve V1 to the reaction chamber had a fairly large internal volume and delivery of less than 2 μl was problematic. Nevertheless, reproducible delivery of PITC in heptane, R1, was made possible by programming syringe SY1 for 3 μl of R1 at maximum syringe speed and syringe SY2 for 18 μl of argon at slower syringe speed as a means to transfer R1 to the reaction chamber. Three deliveries of R1/argon were made during coupling to increase the amount of PITC available for reaction. Long argon drying steps after each R1 delivery made no difference in sequencing yields and were eliminated as indicated in Table 2. This sequencer protocol was used for all subsequent adsorptive sequencing studies.

The miniaturized instrument was adapted for covalent sequencing by changing the reagents and solvents and adding a source of liquid TFA for cleavage and product extraction (Fig. 1C). Simultaneous delivery of R1 (PITC in acetonitrile) and liquid phase R2 (coupling buffer), which are fully miscible, circumvented the need for R1 solvent removal. A large amount of R2 (42 μl, equal to the dead volume from valve V2 to reaction chamber RC) was used for coupling (Table 3) to ensure that the sample support stayed wet with reagent after each delivery from the ML dispenser. Ideally, another syringe to accurately deliver and hold a smaller R1/R2 liquid plug would have been preferable; a syringe-based sequencer that addresses this is described in Li et al. [25], the following paper in this series. The third port of valve V2 was used for TFA (liq), which could not be delivered through V1 as it adsorbed strongly to the inner surfaces of valve V1, requiring several rinses with ethyl acetate. A 45 μl aliquot of TFA was delivered such that the leading edge of the plug just wet the sample support. Ideally, a 5 μl plug of TFA would be sufficient if a deliver-hold-transfer mechanism were used. When the cleavage reaction was complete, the remainder of the TFA plug was passed slowly through the reaction chamber by argon pressure to extract ATZ product for off-line conversion to PTH amino acid.

3.3. Reaction chamber and sample loading

The reaction chamber (Fig. 3) was analogous to the Hewick et al. adsorptive sequencing reaction cartridge [2], except with 1000 times smaller volume to better match that needed for capillary electrophoresis analysis. The aim was also to develop a simple method for making the reaction chamber. Construction of the reaction chamber from fused silica tubing was based on several considerations. First, tubing with a variety of inner diameters is commercially available. Second, fused silica has good thermal conductivity for temperature control during coupling and cleavage. Third, the polyimide coating keeps the tubing flexible yet is transparent so reagent flow can be visually monitored. Last, it is compatible with performing electrophoretic separations for future on-line CE injection of sequencing products.

Approximately 15 min were required to build five reaction chambers at a cost of about $2 each. Over 100 mats could be made from each piece of PTFE, which was used primarily because the glass fibre mat had very little structural integrity when wet and tended to collapse into the lumen of the lower capillary. Several methods of loading sample for adsorptive degradation were tried. The

Table 4
Initial yields for adsorptive sequencing

β-Lactoglobulin A		Insulin chain B		Insulin chain A		Y-Bradykinin	
Sample (pmol)	% Yield (PTH-leu)	Sample (pmol)	% Yield (PTH-phe)	Sample (pmol)	% Yield (PTH-gly)	Sample (pmol)	% Yield (PTH-tyr)
52	17	40	75	95	61	66	26
60	8	150	71				
200	20	180	36				
220	14	190	11				
1000	6	250	13				
		260	36				
		890	10				

simplest and quickest method was to draw protein solution up through the lower half of the reaction chamber using a 1 μl syringe and Innerlok. For example, a 10 mm long plug of solution in 100 μm i.d. tubing equals 0.08 μl, which could easily be seen in the tube. Ideally, one wants to just wet the support and evaporate the solvent leaving a residue of polypeptide, similar to the requirement for R1 delivery. Unfortunately, as little as 0.05 μl of solution would more than soak a glass fibre mat since its surface area was only 0.12 mm^2. Very long drying times at 8 psig argon were required to remove solvent and frequently some of the sample solution was lost from the end of the reaction chamber.

In general, poor sequencing results were obtained using mats made from either the glass fibre or Porton disks. A sample of 240 pmol insulin chain B loaded into a reaction chamber containing one PTFE and two glass fibre mats gave less than 10% yield of PTH-phenylalanine (PTH-F) in cycle 1 and no PTH-valine (PTH-V) in cycle 2. A sample of 120 pmol insulin chain B loaded into a reaction chamber containing one Porton mat with PTFE yielded about 28% PTH-F in cycle 1 but no PTH-V in cycle 2. Unfortunately, both cycles performed using the Porton support showed a large amount of peptide in the extract, indicating that sample washout had occurred. Haniu and Shively [26] attributed similar results to the low mass of the supporting material. Sample loading onto PVDF or Immobilon-CD membrane suffered from the same problems as glass fibre mats. Very poor adsorptive sequencing results were obtained with both these membrane supports: less than 5% yields in cycle 1 and 0% yield in cycle 2, for both insulin chain B and β-lactoglobulin-A samples.

In order to increase absorption of solution into the sample support and facilitate protein adsorption, a bed of porous silica beads analogous to Shively's continuous flow reactor [3] was used. Porasil T (25–37 μm, pore size = 15 nm, surface area = 300 $m^2\ g^{-1}$) was coated with Polybrene and packed into the reaction chamber as described in the methods section. The bed depth was kept less than 5 mm Porasil T to minimize backpressure during sequencing. Coatings from 5 to 50% (w/w) Polybrene to Porasil T were investigated for sample loadings ranging from 25 to 250 pmol insulin chain B. Poor yields (< 5%) in the first cycle were seen when less than 10% Polybrene was used and no correlation between yield and percent Polybrene was found for 20–50% coating. Precycling of Polybrene-coated Porasil T had little effect on sequencing yields but did decrease the number of background peaks in the electropherograms of cycles 1 and 2. Unfortunately, any traces of Polybrene in the extracted ATZ product adversely affected the CE analyses by altering the electroosmotic flow. Therefore, a loading of 20% Polybrene to Porasil T was used for further work. Table 4 presents a summary of initial yields for various polypeptide sample sizes sequenced following the protocol of Table 2 after immobilization on 20% Polybrene to Porasil T. It is

Table 5
Demonstration of lag observed with adsorptive sequencing. All samples were immobilized on 20% Polybrene:Porasil T.

[b] Not quantified due to noise in electropherogram.

important to note also that the proportion of protein to total Polybrene (w/w) in the reaction chamber was typically 10 times less than in commercial systems yet no sample wash-out was observed in the electropherograms.

Occasionally, incomplete coupling or cleavage in a given degradation cycle can lead to lag, the phenomenon in which amino acid product from cycle $n-1$ is detected in cycle n. Lag was often observed in both the second and third degradation cycles and was particularly severe for large samples such as 1 nmol of β-lactoglobulin-A. Table 5 demonstrates lag from samples sequenced by adsorption on Porasil T coated with 20% Polybrene following the protocol in Table 2. Although the volume of R1 delivered contained a large molar excess of PITC, it is conceivable that much less remained on the sample support because of overwetting. Coupling times of 40 min, additional R1 deliveries to the reaction chamber and cleavage times of 15 min made little difference in either the sequencing yields or the appearance of lag. These results suggest that insufficient PITC was present rather than an incomplete coupling reaction. Shively et al. [3] indicated that overloading (overwetting) a glass fibre disk may result in loss of the sample, or in our case loss of reagent.

Improved yields were observed with covalent sequencing. Using the protocol in Table 3, seven cycles of 55 pmol myoglobin covalently bound to

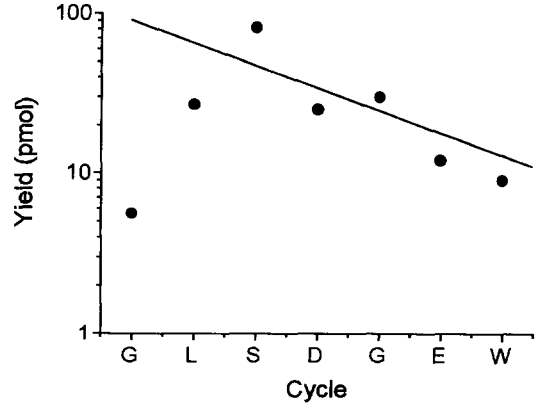

Fig. 4. Cycle yields for the covalent sequencing of 55 pmol horse heart myoglobin covalently attached to Sequelon-DITC membrane.

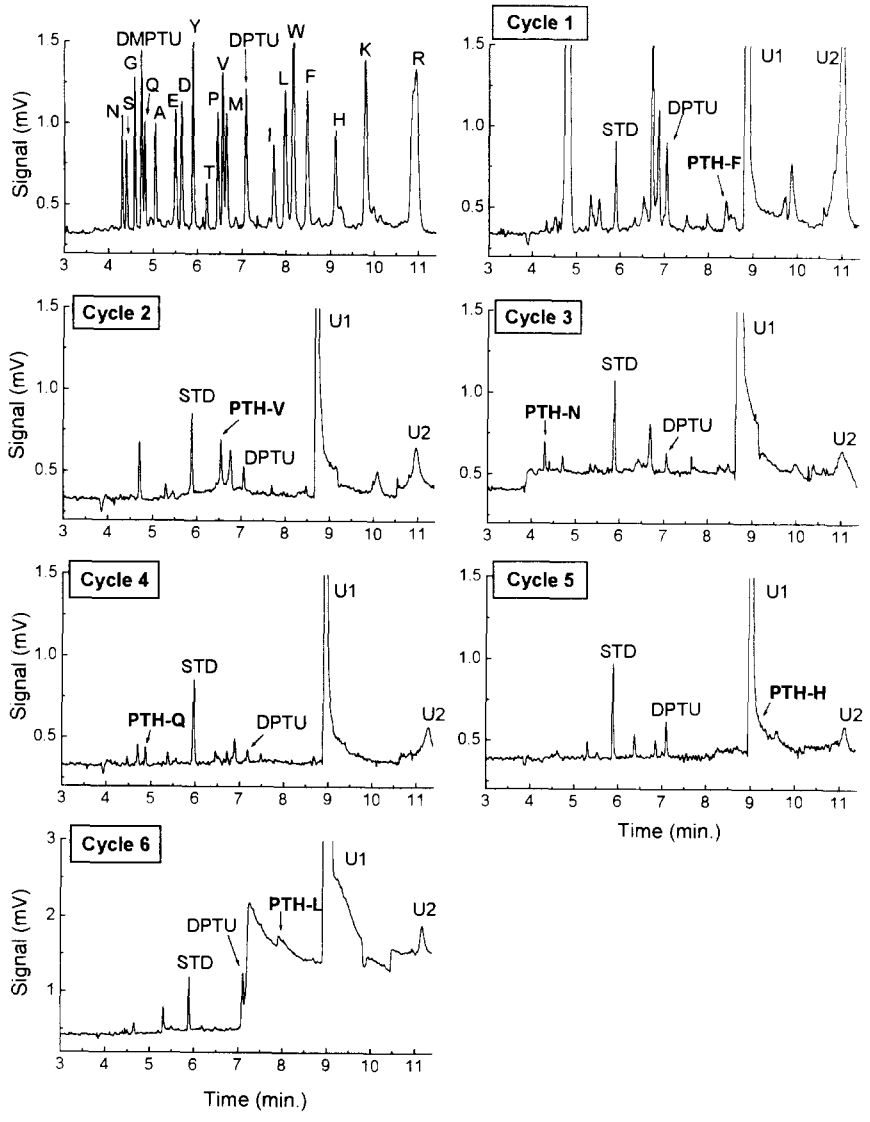

Fig. 5. Electropherograms showing covalent sequencing results for 53 pmol insulin chain B covalently attached to Sequelon-AA membrane. Top left panel: injection of 50 fmol standard PTH mixture, labelled with the one-letter amino acid abbreviations. Remaining panels: cycles 1–6 results, in which 0.1% of PTH amino acid product from sequencing was injected. U1, U2: unconfirmed by-product peaks.

Sequelon-DITC were sequenced with a repetitive yield of 73%. The repetitive yield was calculated from the slope of a plot of log [yield] versus cycle number 2–7 as shown in Fig. 4. The cycle 1 result was not included in the calculation because it is the N-terminal amino acid covalently bound to the membrane. The first seven amino acid residues in myoglobin are: G_1 (glycine), L_2 (leucine), S_3 (serine), D_4 (aspartic acid), G_5, E_6 (glutamic acid), W_7 (tryptophan). The covalent sequencing protocol (Table 3) was later modified to increase the ratio of R1 to R2 (from 4:42 μl to 3:9 μl) and to reduce the total volume of reagents delivered to the reaction chamber. Valve V1 was kept at posi-

tion 3 (argon) for steps 4–6 and valve V2 was opened briefly after each delivery of R1:R2 to facilitate reagent transfer to the reaction chamber.

Sequencing results for 53 pmol insulin chain B covalently bound to Sequelon-AA using the modified coupling reaction volumes are presented in Fig. 5. The first six amino acid residues in insulin chain B are: F_1 (phenylalanine), V_2 (valine), N_3 (asparagine), Q_4 (glutamine), H_5 (histidine), L_6 (leucine). For each cycle, an internal standard (STD) of 5×10^{-5} M PTH-tyrosine was added. A standard mixture of 19 PTH amino acids and two by-products is shown in the first panel. The first degradation cycle showed several large background peaks resulting from contamination acquired during sample storage. The polypeptide sample had been covalently coupled to the membrane and stored at -20°C for approximately 1 month before being sequenced. The unidentified peaks labelled U1 and U2 were seen in all degradation cycles. U1 was presumed to be diphenylurea (DPU) which typically migrates between PTH-F and PTH-H in standard solutions (data not shown). The unlabelled by-product peaks seen in cycle 1 gradually diminished over the course of the six degradation cycles, emphasizing the importance of the wash steps in the sequencing protocol. In cycle 5, PTH-histidine (PTH-H) was obscured by the unidentified by-product peak U1 and could not be detected, as discussed further in the next section. The baseline in cycle 6 rose sharply after DPTU eluted, caused by a contamination in the separation capillary, however PTH-leucine (PTH-L) was quantified by its peak height minus the increased baseline relative to the internal standard peak height (STD = 5×10^{-5} M PTH-Y). The repetitive yield for cycles 1–6 was 89%. The negative peak (acetonitrile) seen at 3.93 min in cycles 1–6 indicates the electroosmotic flow.

4. Discussion

Capillary electrophoresis has steadily grown as a separation method for biomolecules since its resurgence in 1981 [27]. CE has demonstrated improved efficiency, resolution, and speed compared with HPLC for the separation of the PTH amino acids. In addition, the low cost of capillary tubing and the minute solvent consumption in CE reduce the overall operating cost compared to HPLC. On the other hand, difficulties associated with manipulating the small volumes of CE are many. These difficulties dominate the design of our miniaturized sequencer.

The difficulties we found with absorbing liquid samples onto the tiny glass fibre supports were multiplied when delivering liquid reagents during sequencing, particularly reagent R1, the PITC in solvent. The conditions necessary for efficient coupling are that PITC be in large molar excess of polypeptide and that the reaction take place under aqueous, alkaline conditions. For adsorptive sequencing, it is essential that R1 solvent (e.g., heptane) be evaporated if it is not miscible with the coupling buffer. Ideally, a film of PITC is deposited on the support and comes in contact with the sample for coupling. Whereas the 12 mm disks used in many sequencing instruments may have regions that are not totally wet by reagents, our problem was overwetting. For example, a single glass fibre mat was fully wet with only 0.05 μl liquid, a strip of PVDF with 0.2 μl and a bed of Porasil T with 1 μl, all of which were volumes too small to deliver through V1. The smallest volume of reagent R1 that could be delivered (3.5 μl) contained 850 nmol PITC, which remained dissolved in heptane leaving an insufficient amount deposited on the support for quantitative coupling. This phenomenon was blamed for the low sequencing yields ($< 10\%$) using the protocol in Table 1.

Purposely allowing R1 to remain in the reaction chamber, after delivering coupling buffer which deprotonates the N-terminus, also gave poor results. The presence of heptane created an organic–aqueous interface, which retarded phase transfer across the interface. Aqueous conditions are necessary for the polypeptide-PITC reaction, not only to establish an alkaline environment but also because water may act as a catalyst in the coupling reaction [28]. Whether the coupling base acts as a buffer [29], a catalyst [30,31], or simply a means to guarantee deprotonation of the N-terminus is not clear.

To ensure that sufficient PITC was available for coupling, three deliveries of R1 followed by 300 s coupling buffer (R2) were used. Although the cycle yields presented in Table 4 are less than half of those reported for the continuous flow reactor (CFR) sequencer packed with Porasil B [3], or for the CFR with PVDF membrane [7], they are promising. Our reaction chamber had about 15 times smaller volume than the CFR, e.g., a 15-fold lower capacity to absorb liquid. Precise deliveries of reagent R1 and solvent S2 are crucial to sequencer performance, hence the limiting factor for our adsorptive sequencing system.

The importance of reaction volume on sequencing efficiency is evident from the advancements in polypeptide degradation since 1951. The Edman reaction [1] was initially carried out in 2 ml solution, the first automated sequencer [32] required 0.4 ml each of sample and PITC to create a thin film in a spinning cup and the current commercial sequencing instruments are based on ca. 100 μl sized reaction cartridges [12]. Microscale chemical reactors such as the automated micro batch analyzer developed by Sweileh and Dasgupta [33] typically have 100–1000 μl volumes, requiring ng amounts of sample and μl volumes of reagent. Although such reactor designs are ideal for complex, multi-step chemical reactions and direct measurement, miniaturization to accommodate pg samples and nl volumes is challenging. On the other hand, successful peptide mapping analysis of 3 nl β-lactoglobulin by enzymatic digestion in a capillary tube was accomplished by injecting 37 nl of enzyme followed by the protein sample [34]. Unfortunately, the step-wise nature of the Edman degradation and its complicated chemistry prevent the use of such a simple analysis technique. To overcome the dilemma of sub-μl liquid deliveries to our reaction chamber—the amounts needed to achieve effective PITC solvent evaporation—covalent sequencing was pursued.

Covalent sequencing, whereby polypeptide is covalently bound to a solid support, is typically used when there is a danger of sample wash-out from solvents and reagents. Our goal was to take advantage of the miscibility of acetonitrile (R1 solvent) and *N*-methylmorpholine (R2) (Table 3) to make PITC and polypeptide soluble in the same phase for chemical reaction. Repetitive yields for covalent sequencing were increased over those for adsorptive sequencing, presumably because coupling efficiency and product extraction were improved. The low initial yield (6 pmol, Fig. 4) for degradation of 55 pmol myoglobin (on Sequelon-DITC) was expected because of the covalently bound N-terminal amino acid. The high yield for PTH-serine (PTH-S) in cycle 3 (80 pmol) was attributed to the quantification method and age of the PTH standard (14–21 days). Peak height comparison is ideally made with a freshly prepared standard, otherwise PTH-S is partially converted to PTH-dehydroalanine and an erroneous signal response is obtained.

Repetitive yield was improved for the degradation of 53 pmol insulin chain B on Sequelon-AA (Fig. 5) by reducing the total volume of coupling reagent and increasing the proportion of PITC. Unfortunately, the by-product U1 (possibly diphenylurea, DPU) was frequently seen accompanied by relatively low amounts of DPTU. The presence of DPU suggests desulfurization of DPTU or PITC by atmospheric oxygen. When U1 was present in nmol amounts it did not interfere with sequence assignment. However, at the μmol level seen in cycle 5 of Fig. 5, U1 co-migrated with PTH-histidine. On-line conversion (currently under design) will provide an oxygen-free atmosphere during conversion and should eliminate peak overlap by U1. The unidentified peak U2 eluting at the same time as PTH-arginine (PTH-R) was seen in both adsorptive and covalent sequencing results. This peak was persistent regardless of extraction solvent (chlorobutane, benzene or TFA) and its migration time implied either a cationic species (like PTH-R) or, more likely, a hydrophobic species well retained in the micellar separation phase. We are working to identify and reduce this by-product. Despite the numerous unidentified peaks, relatively few overlapped exactly with analyte peaks in cycles 2–6. Nevertheless, reducing the background of by-product and contamination peaks is imperative to the identification of PTH amino acids in an unknown sample.

5. Conclusions

A major difficulty with miniaturization of the protein microsequencer was that of accurately delivering very small reagent volumes. These constraints made adsorptive sequencing in the capillary-based reaction chamber difficult. For the same reason, methods of sample loading were limited. The reaction chamber would not be useful, for example, with peptides purified by HPLC or by other large volume techniques. However, emerging methods of preparative micro-LC and CE would be compatible with the nanosequencer, given the development of a device for automated transfer. It should be possible to achieve compatibility with electroblotted samples if the delivery of sub-ml volumes can be achieved. Adsorptive sequencing with liquid TFA cleavage and extraction, which is used in newer commercial instruments, would also be possible with nl volume manipulation. Liquid TFA would permit a smaller extraction volume to be used and conversion to the PTH without drying may be possible, a necessary step for a capillary-based conversion chamber.

The ability to identify femtomole quantities of PTH amino acids drives our effort to sequence femtomole quantities of polypeptides. To realize this goal, a larger proportion of converted extract must be injected onto the CE column. Unfortunately, injection of more than 5 nl in CE separations leads to severe peak broadening and loss of resolution. Therefore, development of automated on-line injection will be necessary whereby the PTH amino acid derivative is formed in a minute volume and electrophoretically directed into the separation capillary.

The results reported represent preliminary results in the development of a fully automated nanosequencer using capillary electrophoretic analysis of the degradation products. The next paper in this series demonstrates that many of the difficulties encountered with this instrument can be eliminated through the use of syringe-driven reagent delivery and the elimination of the reagent valves [25].

Abstract

A miniaturized protein and peptide microsequencer consisting of a fused silica capillary reaction chamber is described. Extremely small volumes of reagents, 2 μl or less, were delivered directly to the reaction chamber through individual fused silica capillary lines using low pressure syringe pumps. Other than an argon gas controller, no valves were used in the delivery system. The short flow path and very low dead volume were achieved by directly connecting the narrow-bore capillaries to the reaction chamber. This configuration minimized side reactions. The elimination of valves, as well as the use of capillaries for the reaction chamber and delivery lines, greatly simplified the construction of the sequencer. The performance of the sequencer was evaluated by sequencing 8–33 picomoles of myoglobin and insulin chain B that were covalently attached to Sequelon-DITC and Sequelon-AA membranes. © 1997 Elsevier Science B.V.

1. Introduction

Since Edman first automated the isothiocyanate degradation chemistry for peptide sequencing in 1967 [1], this technology has been improved drastically [2] through the immobilization of proteins and peptides [3–5], improvements in degradation chemistry [6–9], miniaturization and automation of the sequencers [10–15], and the incorporation of HPLC separation and UV detection of phenylthiohydantoin (PTH) amino acids [16,17]. Edman degradation chemistry is still the most useful method for determining the primary structures of proteins and peptides [18]. However, the performance of the Edman chemistry depends heavily on the design of the sequencer [5,13,19].

Commercial sequencers can routinely determine sequence of 20 residues from 10–100 picomoles of peptides [5,19,20]. Still, there is a continuous demand for higher sensitivity in the overall sequencing process [19].

The sensitivity of commercially available sequencers is limited by the UV detection of phenylthiohydantoin (PTH)—amino acids [18]. Our group has developed a sensitive CE-based system for PTH-amino acid determination: micellar electrokinetic capillary chromatography with thermooptical absorbance detection (MECC-TOAD) [21]. The mass detection limits of this system for determination of PTH-amino acids are less than 1 femtomole [22]. However, the CE system can not be coupled directly to commercially available protein sequencers because of incompatibility of volume. Less than 10 nl of the sample solution is typically injected into the CE to preserve the high efficiency of separation, whereas more than 100 μl of solution is collected from existing commercial sequencers. Thus, miniaturization of the sequencer is essential in order to overcome this volume mismatch and to take advantage of the sensitive, fast and efficient determination of PTHs by MECC-TOAD.

We described the design of a miniaturized sequencer consisting of a capillary-sized reaction chamber and a multiport valve delivery system to address the problem of volume compatibility with CE [23]. However, that sequencer could not reproducibly deliver sub-μl volumes of reagent because of μl dead volumes in the multiport valves. The gas-liquid phase Edman degradation of picomole levels of proteins adsorbed on Polybrene-coated silica beads or polyvinylidene difluoride (PVDF) membranes was not successful. Adequate sequencing results were only obtained when proteins were covalently bound to solid supports, but the background peaks were large. By reducing the amounts of reagent used for Edman degradation, we observed a trend of reduced background peaks, as others have already pointed out [13,15]. Unfortunately, the multiport valve and argon pressurized delivery system described by Waldron et al. [23] precluded the use of less than 4 μl of reagent or solvent. Therefore, in order to further reduce the reagent volumes, we redesigned the miniaturized microsequencer to eliminate the valves and the argon pressurized delivery system. In this paper, we describe the design of a miniaturized sequencer where syringe pumps are directly coupled via capillary tubing to the reaction chamber to deliver reagents and solvents for covalent polypeptide sequencing. This system is able to deliver less than 2 μl of each reagent. As a result, the background peaks are significantly reduced. Preliminary results for this microsequencer are presented.

2. Experimental

2.1. Materials

All the reagents and solvents used for Edman degradation were sequencing grade. Coupling buffer (NMM, 5% *N*-methylmorpholine in 70/30 methanol:water with 0.1% cyclohexylamine), wash solvent 1 (WSH1, 0.1% cyclohexylamine in methanol), wash solvent 2 (WSH2, 1:1 heptane/ethylacetate with 0.1% cyclohexylamine), Sequelon-DITC (diisothiocyanate) Performance Evaluation Standard (Sequelon-DITC-myoglobin, horse heart), and the solid phase covalent attachment kits including Sequelon-DITC and Sequelon-AA (aryl amine) were purchased from Millipore Canada (Mississauga, ON). A mixture of 19 PTH-amino acids, diphenylthiourea (DPTU) and dimethylphenylthiourea (DMPTU) standard, and 5% phenylisothiocyanate (PITC) in heptane were bought from Applied Biosystems (Foster City, CA). Anhydrous trifluoroacetic acid (TFA) was obtained from Sigma Chemical (St. Louis, MO). Fused silica capillary was purchased from Polymicro Technologies (Phoenix, AZ).

2.2. Design of the miniaturized microsequencer

A schematic of the microsequencer is shown in Fig. 1. The plumbing system for delivery of reagents and solvents consisted of five syringe pumps (Model sp210iw, World Precision Inst., Sarasota, FL) equipped with Hamilton gas-tight syringes (250 or 500 μl, Chromatographic Specialties, Brockville, ON) and six 10 cm long fused

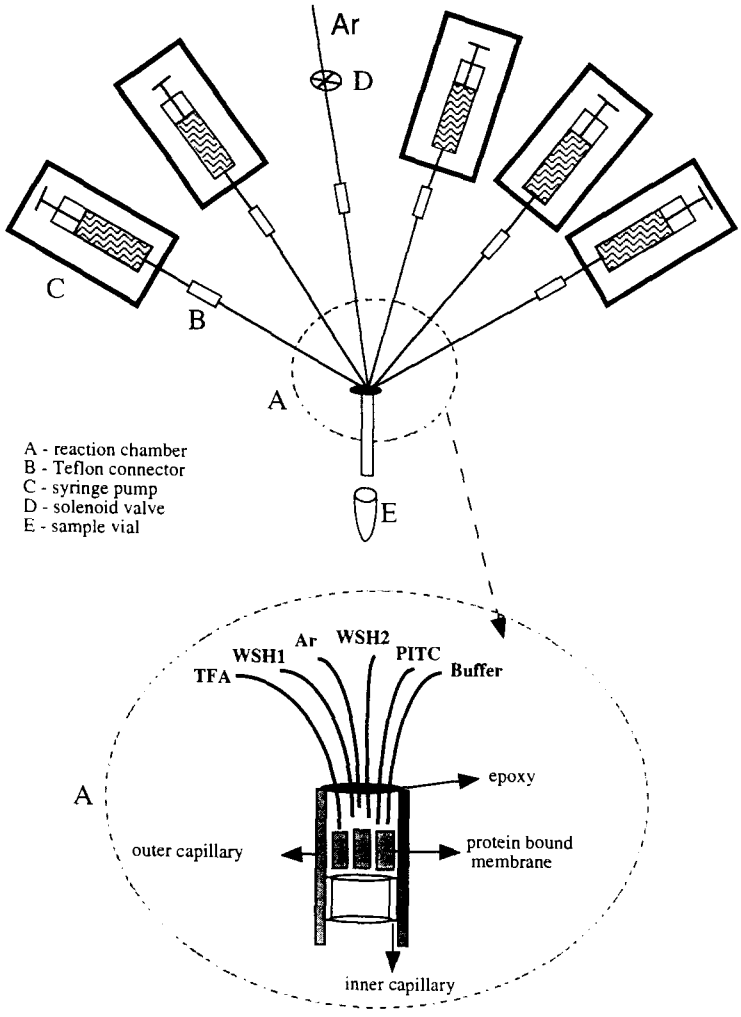

Fig. 1. Schematic of the syringe-pump-based microsequencer. Insert A describes the details of the reaction chamber assembly, showing the positions of the reagent/solvent inlet capillaries relative to the protein-bound membrane. A, reaction chamber; B, Teflon connector; C, syringe pump; D, solenoid valve; and E, sample vial.

silica capillary tubes (100 μm i.d., 200 μm o.d.). The reagents and solvents required to perform Edman degradation cycles were delivered individually by the syringe pumps each connected via the capillaries to the reaction chamber. Connection between each capillary and syringe was simply made with a 1 cm long piece of Teflon tubing (0.2 mm i.d.) from LC Packings International (San Francisco, CA). Argon gas (5 psig) was used for all drying steps and to facilitate collection of the extract from each Edman degradation cycle. The flow of argon was controlled electronically using an on/off solenoid valve (Lee Company, Westbrook, CT).

A miniature reaction chamber was constructed from a 4 cm long piece of wide-bore fused silica capillary (750 μm i.d., 850 μm o.d.) to which the six inlet capillaries for the delivery of reagents (NMM, PITC, TFA), solvents (WSH1, WSH2) and argon were connected using epoxy (Fig. 1A). The distances between the ends of the inlet capillaries and the membrane were varied: 1 mm for

the capillaries delivering PITC, NMM and TFA, 2 mm for WSH1 and WSH2, and 4 mm for argon. This configuration was used to reduce cross contamination between the reagents and solvents. The specific positions were obtained by aligning the inlet capillaries (cut from stock) on a piece of masking tape before they were inserted into the reaction chamber. The desired arrangement is shown in Fig. 1A. The six inlet capillaries were then inserted into the 4 cm long wide-bore capillary reaction chamber and fixed in place with epoxy (1:2, glue/hardener). The epoxy was allowed to dry completely for at least 30 min. The dry epoxy plug is resistant to the organic solvents used in the experiments. The reaction chamber-inlet capillary assembly was cleaned with methanol by connecting the free end of the wide-bore capillary to a syringe and withdrawing the solvent through the inlet capillaries from a reservoir. The assembly was then dried by argon and weighed on an analytical balance.

2.3. Sample loading

Membrane strips (0.5–0.8 mm wide) containing immobilized polypeptide were cut from an 8 mm disk and loaded into the wide bore capillary reaction chamber using a pair of tweezers. The membrane was gently pushed into place with a free piece of capillary and the reaction chamber assembly was re-weighed. The amount of protein loaded was calculated based on the weight of the membrane used to that of the 8 mm disk containing 120 pmol of myoglobin or insulin chain B. Finally, the loaded reaction chamber assembly was connected to the syringes, which had been preloaded with the degradation reagents and solvents and positioned on the syringe pumps. The sequencer was ready to perform Edman degradation cycles.

2.4. Edman degradation cycles

The reaction chamber was held and preheated by the thermoelectric modules described previously [23]. A temperature of 51°C was used for both coupling and cleavage. A typical sequencing program describing the amounts of reagents and solvents, order of delivery, and timing of the coupling and cleavage reactions is given in Table 1. The flow rate (8 μl min^{-1}) and the desired amount of each reagent or solvent was manually programmed with the syringe pump microprocessors. During the method development, a microscope (model STEMI 1000, Carl Zeiss Canada, Don Mills, ON) was used to determine whether sufficient reagent was delivered to wet the membrane completely. This procedure helped to minimize the consumption of reagents and solvents.

Conversion of the ATZ-amino acids (extracted with TFA) to the PTH form was carried out off-line. The extract from each Edman degradation cycle after cleavage was collected into a 200 μl vial, to which 25 μl of 25% aqueous TFA solution was added and mixed. The solution was heated at 67°C for 10 min and then dried on a vacuum centrifuge. The residue in the vial was dissolved in 1 μl of internal standard (5.8×10^{-5} M PTH-tyrosine (PTH-Y) in 10% acetonitrile/90% water) and then analyzed by MECC-TOAD for identification of the PTH-amino acid.

Table 1
General sequencing protocol

Step No.	Reagent/solvent delivered[a]	Time, s
1	NMM, 2 μl	
2	PITC, 2 μl	
3	Coupling reaction	300
4	Ar, 5 psi	10
5	PITC, 2 μl	
6	NMM, 2 μl	
7	Coupling reaction	300
8	Ar	30
9	WSH1, 8 μl × 3	
10	Ar	30
11	WSH2, 8 μl × 4	
12	Ar	180
13	TFA, 3 μl[b]	
14	Cleavage reaction	300
15	TFA, 4 μl × 3[b]	Collect extract
16	Repeat solvent wash steps 9–12	

Temperature of reaction chamber: 51°C.
[a] The rate of syringe pumps was kept at 8 μl min^{-1}.
[b] The TFA was collected for conversion.

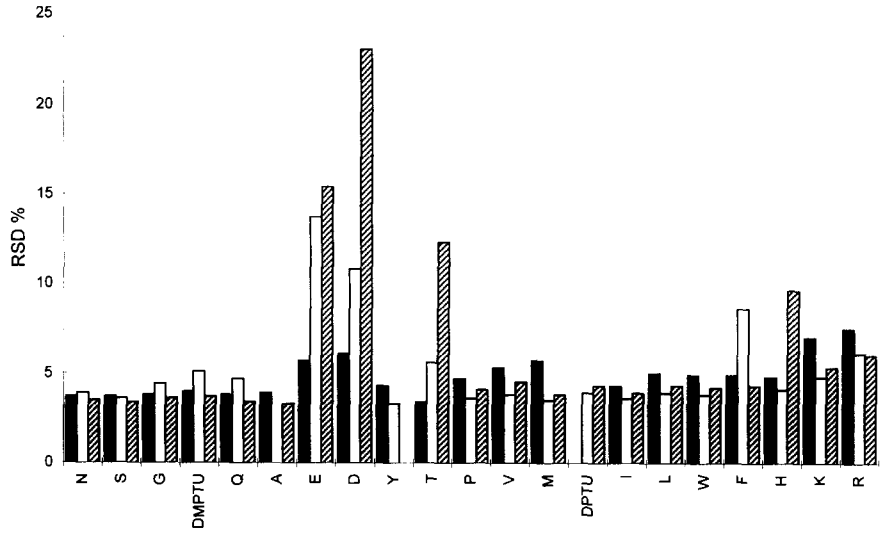

Fig. 2. Comparison of relative standard deviation (RSD) values of migration times of PTH-amino acids relative to (■) DPTU, (□) PTH-A, and (▨) PTH-Y.

2.5. Separation and identification of PTH-amino acids

The MECC-TOAD instrument and the details of the separation conditions used for the determination of PTH-amino acids have been described elsewhere [21,22]. Briefly, separation of the PTH residues from Edman degradation cycles was achieved by using a preconditioned 40 cm long fused silica capillary (50 μm i.d., 185 μm o.d.) and separation buffer containing 10.7 mM sodium phosphate, 1.8 mM sodium tetraborate, and 25 mM SDS at pH 6.7. The sample, dissolved in 1 μl of the internal standard PTH-Y, was injected hydrodynamically ($\Delta h = 4$ cm for 12 s) and the separation was carried out at 9 kV. The migration times were normalized either to the internal standard PTH-Y or to the by-product DPTU. The identification of a PTH residue from Edman degradation was obtained by matching the normalized migration time of the residue with that of the standard mixture of 19 PTHs, DPTU and DMPTU.

3. Results and discussion

3.1. PTH-amino acid identification by MECC-TOAD

We have previously demonstrated that the MECC-TOAD for the separation and detection of PTH-amino acids offers the advantages of fast and complete separation within 10–11 min and mass detection limits of less than 1 fmol [22]. Nine replicates of analyses of the standard mixture (19 PTH-amino acids, DMPTU and DPTU) were conducted over a period of 8 h. The same vial of separation buffer was used for all analyses. The relative migration time of the PTH-amino acids to that of PTH-A, or PTH-Y, or DPTU were calculated from the electropherograms. The RSD values of the relative migration times from the nine replicates are presented in Fig. 2. When the migration times of PTH amino acids were determined relative to PTH-A, the RSD values for most of the components were less than 4% except those of PTH-E, PTH-D and PTH-F, for which the RSDs were 14, 11, and 8%, respectively. Similar results were obtained when PTH-Y was used

to correct for migration time. RSD values of the relative migration times for most of the components were about 4%, but those of PTH-E, PTH-D, PTH-T and PTH-H were higher than 10%. Although PTH-E and PTH-D have larger shifts in migration time compared with other PTHs, their migration order does not change under the given conditions. The migration time of the components relative to DPTU gave the most consistent RSD values for all the PTH amino acids, mostly below 5%. DPTU is a common by-product from Edman degradation and thus, a convenient internal standard for migration time matching. However, this by-product peak is occasionally eliminated when small amounts of coupling reagents are used. Also, the unknown concentration of DPTU excludes its use as a standard for quantitation of the PTH amino acid obtained in each cycle. Therefore, it is necessary to use a second internal standard which gives a double check on the migration time for identification and makes calculation of yields possible. In this study, PTH-Y was used as the internal standard because its stock solution was stable at −20°C for over 1 year.

Normalization of migration times to an internal standard demonstrates that the identification of the PTH-amino acids by CE analysis can be as reliable as that with HPLC. The reproducibility of migration time from CE was generally below 1% when the running buffer was frequently replenished [22], whereas the reproducibility of migration time from HPLC is about 0.5% [24]. The above CE runs gave relatively higher RSD values than routine analysis we did because the above runs were intentionally carried out using the same buffer over 8 h to observe the extreme variation of migration time. In addition, MECC-TOAD determination is about four times faster and mass detection limits are about 1000 times lower than those of HPLC [22,24].

3.2. Design of miniaturized sequencer

We and others [13,15] have observed that reduction of the amount of reagents used in Edman degradation is necessary in order to minimize the background peaks. However, delivery of a few μl of reagent using most adsorptive or covalent sequencing instruments [11–15] is difficult because the requirements of valves to control the delivery of reagents. The use of valves substantially increases dead volume and also complicates the electronics and software for controlling the valves in the sequencer. To overcome these problems and deliver sub μl amounts of reagent, we designed a unique, valveless microsequencer that uses syringe pumps instead of gas pressurization to deliver reagents (Fig. 1). The Teflon tubing sleeves used to connect the inlet capillaries to the syringe pumps did not require ferrules and nuts to secure them. Combined with the elimination of valves in the liquid flow path, this design minimized the overall dead volume of the system. The desired reagents and solvents were accurately and reproducibly delivered to the reaction chamber. In addition to the present sequencer design being very simple, it is also economical.

The amount of PITC required for each Edman degradation cycle was less than 4 μl, as shown in Table 1. Therefore, a 250 μl syringe contained enough PITC for 62 cycles. Commercial sequencers can typically perform about 40 cycles after which the identification of PTH-amino acid residue becomes ambiguous in the HPLC analysis. Thus, there is no need to refill the syringes during repetitive sequencing cycles on the same polypeptide.

Fused silica capillaries were used in the plumbing system, instead of the usual Teflon tubing [12,13,15], because of their facile connection to both the syringes and the reaction chamber. Six narrow-bore capillaries (200 μm o.d.) could easily fit inside the wide-bore capillary reaction chamber, which would not have been possible with Teflon tubing. Fused silica capillaries are also less permeable to oxygen than Teflon. The syringe-pump-based design allowed delivery of reagents and solvents through individual flow paths, directly to the sample membrane. With this configuration, the problem of side reactions taking place along the flow path was eliminated.

We previously reported [23] that a few μl of reagent was easily lost to the walls or vaporized inside the valves and along the Teflon flow path when argon was used to push reagents to the reaction chamber. Unfortunately, excess amount of liquid were used in order to deliver enough reagent to the reaction chamber, which caused

severe side-reactions. By-products were very large and interfered with the MECC separation of the PTH-amino acid residues. This problem was eliminated using the present reaction chamber assembly, as illustrated in Fig. 1A. The distance between the inlet ends of the TFA, NMM and PITC delivery lines and the membrane was about 2 mm. An aliquot of 1 μl reagent gave a 4.5 mm long plug in the 750 μm i.d. reaction chamber. When the plug of reagent reached the membrane, it quickly wet the membrane, indicating that 1 μl of reagent was sufficient for complete wetting. This is essential to obtain high yields in the coupling and cleavage reactions. Therefore, up to 2 μl of reagents delivered to the reaction chamber using syringe pumps would be sufficient for coupling PITC to the polypeptide sample, which is demonstrated in the following section.

3.3. Edman degradation

The performance of the syringe-pump-based microsequencer was evaluated by sequencing myoglobin and insulin chain B, covalently attached to the Sequelon-DITC and Sequelon-AA membranes, respectively. An initial set of sequencing experiments was performed on 33 pmol of Sequelon-DITC-myoglobin (Millipore evaluation standard). Because the protein N terminus and lysyl residues were covalently attached to the DITC-membrane, the first PTH amino acid from Edman degradation was not analyzed. The concentration of the expected amino acid from each cycle was calculated based on the peak height of the product calibrated against that of the internal standard PTH-Y; consequently, the picomoles of the product in 1 μl of solution was obtained. The pseudo-initial yield (cycle 2) was 76% and the repetitive yield was 87% from 33 pmol of myoglobin. No internal standard was used for the analysis of PTH-D from cycle 4, so the yield of cycle 4 was not quantified. The yields of PTH amino acid obtained from 18 cycles of sequencing 22 pmol of Sequelon-DITC-myoglobin were 64% for cycle 2 and 90% for repetitive yield. PTH-W from cycle 7 and PTH-K from cycle 16 were not detected. This may be due to degradation of these products during conversion. We have successfully identified these products in other sequencing experiments when the conversion is carried out in 5% aqueous TFA at 65°C.

Insulin chain B was covalently attached to Sequelon-DITC and Sequelon-AA membranes by following the directions from the Millipore kits. A 26 pmol sample of Sequelon-AA-insulin chain B was subjected to four cycles of sequencing. The yields of cycles 1, 2, 3, and 4 were 33, 32, 26, and 25%, respectively, giving an average repetitive yield of 90%. The sequence analysis of 37 pmol Sequelon-DITC-insulin chain B gave yields of about 17% in each of the first four cycles and over 90% repetitive yield. These results were in agreement with the MilliGen® Sequencer user's manual which states that the initial yield in solid phase sequencing varies from 30 to 60% and the repetitive yield is over 90%.

The electropherograms representing the results of sequencing 11 cycles of 33 pmol Sequelon-DITC-myoglobin are shown in Fig. 3. It is noteworthy that only 1–2 nl of the 1 μl sample (0.1%) was injected for identification by MECC-TOAD. The PTH residues were positively identified by using the migration times normalized to the 19-PTH amino acid standard. Four major by-products, DPTU, U1, U2 and U3, were observed. DPTU, U1 and U3 were completely separated from the PTH amino acids. However, U2 eluted close to PTH-R. Both U2 and U3 had somewhat variable migration times. It was observed that an increased level of background peaks appeared when the reagents were left inside the syringes at room temperature for several days. In Fig. 3, cycles 5–10 were performed on the same day, 3 days after the first four cycles were completed. Cycle 11 was carried out 7 days after the first four cycles. A comparison of the background peaks for degradation cycles done under the same conditions but on different days showed increased background with old reagents. In the 4–5 min. region (Fig. 3), background peaks progressively increased with time after loading the syringes with reagents.

A number of preliminary studies were conducted to reduce the background peaks. One of the important factors investigated was the amount of each reagent used in coupling and cleavage. To

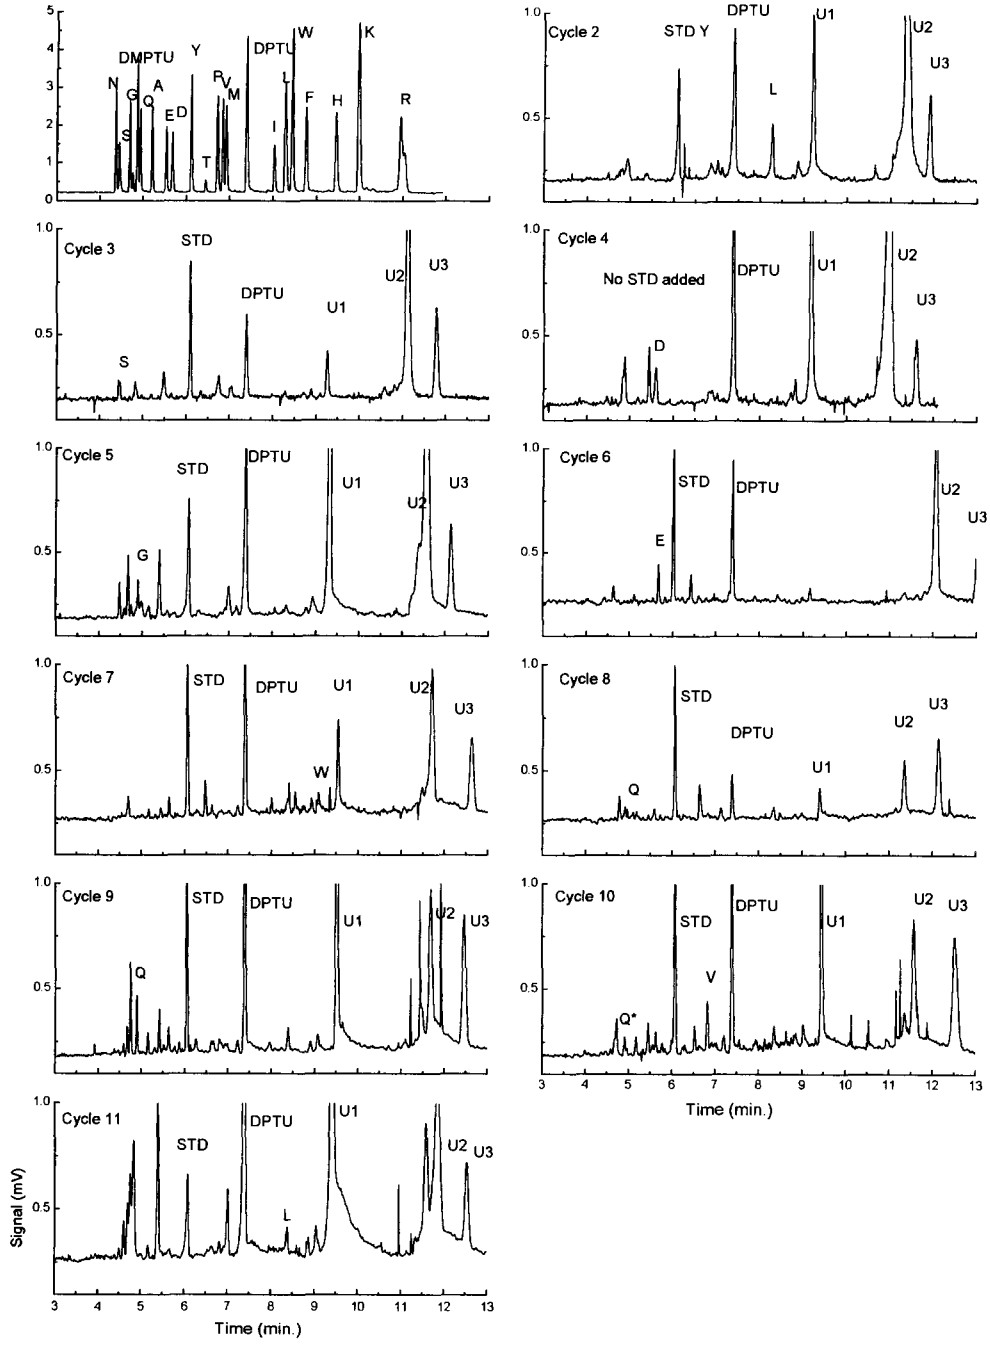

Fig. 3. Original electropherograms showing sequencing results of 33 picomoles of Sequelon-DITC-myoglobin.

minimize the volumes of liquid delivered, a microscope was used to observe how much reagent was necessary to completely wet the membrane. As mentioned in the previous section, as little as 1 μl of PITC or NMM completely wet the membrane (about one fourth of the commercial 8 mm disk). As expected, reduction of the amounts of PITC and NMM used for Edman degradation resulted in lower background peaks. In Fig. 3, the DPTU and U1 peaks in cycles 6–8 were significantly reduced compared with those in other cycles because only 1 μl of PITC and NMM was used for each coupling reaction, compared with 2–4 μl of PITC and NMM that was used in the other cycles.

During the experiments, it was found that more than 8 min of flushing with argon at 5 psig was necessary to completely remove the residual TFA vapor from inside the reaction chamber after ATZ amino acid extraction. However, if 1 μl of NMM is used to neutralize residual TFA followed by 1 min argon, the level of by-products DPTU and U1 are reduced, as demonstrated in cycles 2 and 3 of Fig. 3. In addition, the overall cycle time is reduced. Nevertheless, the pre-flush with NMM did not significantly change the amounts of the other two by-products, U2 and U3.

The amount of TFA used for cleavage and extraction produced different levels of background peaks. Examples from sequencing 22 pmol of Sequelon-DITC-myoglobin are presented in Fig. 4. Cycles 2 and 6 were performed under similar conditions, the only difference being 12 μl (4 μl × 3) of TFA were used for extraction in cycle 6 compared with 6 μl (2 μl × 3) of TFA used in cycle 2. Reduced background peaks were observed when 50% less TFA (cycle 2) was used for extraction. Precise control of the amount of coupling and cleavage reagents can lead to a clean electropherogram. The conditions used for cycle 15 shown in Fig. 4 are summarized in Table 2. Reduced amounts of PITC and NMM were used for coupling, and less TFA was used for cleavage and extraction. In addition, 2 μl of TFA was used to quickly flush the membrane before cleavage (step 14), resulting in a clean electropherogram for cycle 15. However, it is important to note that flushing with TFA before cleavage must be completed within a few seconds, because cleavage takes place almost immediately when the acid reaches the membrane. The idea is to remove by-products that persist after solvent washes but before the cleavage reaction. We found that this step, like all steps in each cycle, must be precisely controlled. As expected, the yield for cycle 15 was lower than those from previous cycles, presumably due to the loss of the product during the flushing and incomplete extraction. This timing precision implies that automation of the sequencer and precise control of the wash and extraction processes and temperature could improve the yield further.

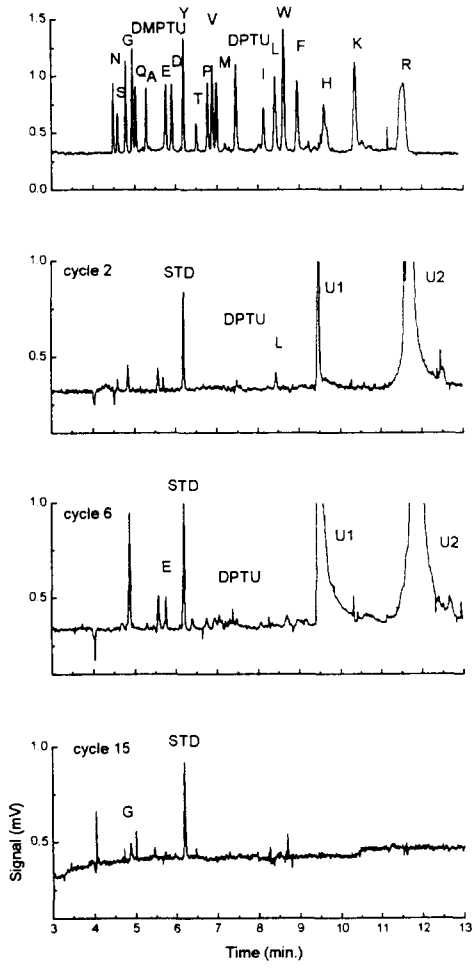

Fig. 4. Comparison of the background peaks from cycles 2, 6, and 15 of 22 picomoles Sequelon-DITC-myoglobin sequenced under different conditions, described in the text.

[a] and [b] same as Table 1.

The potential of the syringe-pump-based microsequencer in sequence analysis of < 10 pmol levels of polypeptides was explored. A standard, 8 pmol Sequelon-DITC-myoglobin, was sequenced using the conditions in Table 2. The residues from cycle 5 and cycle 10 were positively identified, but determination of the residues from other cycles was difficult due to the low percentage of product that could be analyzed. For example, a cycle yield of 65% represents 5 pmol PTH amino acid, but only 5 fmol is injected into the MECC-TOAD system. Further advances in on-line injection of the degradation products are necessary to achieve femtomole sequencing levels.

4. Conclusion

We have developed a miniaturized syringe-pump-based microsequencer. Its performance is demonstrated by sequencing 8–37 pmol of myoglobin and insulin chain B covalently bound to Sequelon membranes. To our knowledge, this is the smallest volume sequencer and the first to be constructed with a reaction chamber made from fused silica capillary and valveless delivery of reagents. The instrument can deliver solvents and reagents directly to the reaction chamber so that side reactions can be minimized. The elimination of background peaks was demonstrated with precise control of the amounts of reagents, the wash and the extraction processes. The advantages of the new design include simplicity and economy in both construction and operation of the sequencer.

The syringe-pump-based sequencer can deliver extremely small amounts of TFA for cleavage and subsequent extraction, resulting in the elimination of the evaporation step between extraction and conversion of the ATZ amino acids. While we currently rely on off-line conversion of the ATZ to PTH derivative, we are developing a system with on-line conversion. The on-line system will generate PTH amino acids in a much smaller volume, which is compatible with direct injection into our CE analysis system.

From our experience, covalent sample attachment is more suitable for ultra-sensitive sequencing of proteins and peptides than adsorptive methods, when Edman degradation is carried out in a capillary-sized reaction chamber. Since many samples for sequencing are presented as electroblots [4,25], it is essential to make the syringe-pump-based sequencer compatible with protein electrotransfer techniques. In combination with on-line conversion and on-line MECC-TOAD analysis, the miniaturized microsequencer should provide a 10–100-fold improvement in polypeptide sequencing sensitivity.

Abstract

Applicability of the nitromethane selective quenching rule for discriminating between alternant versus nonalternant polycyclic aromatic hydrocarbons (PAHs) is examined for 58 representative PAH solutes dissolved in micellar *N*-hexadecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate and in micellar *N*-dodecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate solvent media. Results of measurements show that zwitterionic surfactants can be considered, for the most part, as providing a polar solubilizing media as far as the nitromethane selective quenching rule is concerned. Nonalternant PAHs that contain electron donating methoxy- and hydroxy-functional groups (and methyl-groups to a much lesser extent) are noted exceptions. © 1997 Elsevier Science B.V.

Keywords: Fluorescence quenching; Micellar solvent media; Nitromethane selective quenching rule; Zwitterionic surfactants

1. Introduction

This study continues a systematic examination of the effect that solvent media and substituent functional group has on the ability of nitromethane to selectively quench fluorescence emission of alternant polycyclic aromatic hydrocarbons (PAHs). Emission intensities of nonalternant PAHs are for the most part unaffected by nitromethane addition. Published studies [1–8] involving over 63 PAHs have identified dibenzo[hi,wx]heptacene, benzo[k]fluoranthene and naphtho[2,3b]fluoranthene as among the few exceptions to the so-called nitromethane selective quenching rule in the PAH6 benzenoid, fluorenoid, fluoranthenoid and 'methylene-bridged' cyclopenta-PAH subclasses. More recent measurements [9,10] revealed that nitromethane quenched fluorescence emission of all eighteen acenaphthylene- and acephenanthrylene-derivatives studied thus far which is completely contrary to what would be expected based upon the fact that the solutes are listed as 'textbook' examples

PII S0039-9140(96)02084-X

of nonalternant PAH molecules. The unusual fluorescence quenching behavior of the acenaphthylene- and acephenanthrylene-derivatives results from the molecules' fixed double bond in the five-membered ring. The double bond is alkenic in nature, rather than aromatic as one might believe. This observation is confirmed by independent NMR coupling measurements [11–14].

Breymann et al. [7] attributed nitromethane's selectivity to an electron/charge transfer reaction whereby an electron is transferred from the excited PAH fluorophore to nitromethane, which acts as an electron acceptor. From a strictly thermodynamic point-of-view, it is conceivable that the extent of quenching could be altered simply by changing the electronic nature of the surrounding solvent media in order to either stabilize or destabilize the positive charge (or partial positive charge) that is temporarily formed on the polycyclic aromatic hydrocarbon. Micellar solutions provide a very convenient means to introduce ionic character, and still have a solvent media capable of solubilizing the larger, hydrophobic PAH solutes. Anionic surfactants could perhaps stabilize a positive charge on the PAH ring system, whereas cationic surfactants would tend to inhibit fluorescence emission quenching by nitromethane.

The above ideas were borne out in two preliminary studies [15,16] involving micellar sodium dodecylsulfate (SDS), sodium dodecanoate (SDD, also called sodium laurate), tetradecyltrimethylammonium bromide (TTAB, also called myristyltrimethylammonium bromide) and cetyltrimethylammonium bromide (CTAB) solutions. Nitromethane quenching selectivity was lost in only the anionic SDS and SDD solutions. Except for benzo[k]fluoranthene, dibenzo[b,k]-fluoranthene, dibenz[a,e]acephenanthrylene and naphtho[2,3b]fluoranthene, emission intensities of the eleven nonalternant PAHs studied were for the most part not significantly affected by nitromethane addition in the case of the cationic surfactant solvent media. These four PAHs are known exceptions to the nitromethane selective quenching rule. Earlier studies further documented that the presence of micellar aggregates was a necessary condition for the anionic headgroup charge to affect the quenching mechanism. At SDS and SDD molar concentrations below the cmc, nitromethane quenching selectivity was again observed.

While our earlier studies did suggest that the anionic versus cationic headgroup plays an important role in the observed loss of quenching selectivity, we did not explore what happens when both types of charges are present in the micelle. In this communication we report the fluorescence behavior of 25 alternant and 33 nonalternant polycyclic aromatic hydrocarbons in micellar *N*-hexadecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate (SB-16, also called palmityl sulfobetaine) and *N*-dodecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate (SB-12, also called lauryl sulfobetaine) solvent media as a function of added nitromethane concentration. Zwitterionic surfactants are neutral compounds. The two formally charged substituent groups are separated by intervening atoms and are generally not electronically conjugated with each other. The resulting micelle's conformational structure is determined to a large extent by the electrostatic energy of interaction between the charged substituent groups and the internal energy of the ion bridge/tether. For aliphatic ion bridge structures the all-trans conformation must have the lowest internal energy [17], but in this conformation the distance between oppositely charged substituents is large. The distance may be reduced by rotating the bonds within the ion bridge to the less favorable gauche conformation.

2. Experimental

Micellar solutions of *N*-hexadecyl-*N*,*N*-dimethyl-3-ammonio-1-propane-sulfonate (Sigma, circa 5.0×10^{-3} M) and *N*-dodecyl-*N*,*N*-dimethyl-3-ammonio-1-propanesulfonate (Sigma, circa 1.0×10^{-2} M) were prepared by dissolving the surfactant in doubly de-ionized water. Dibenz[e,l]acephenanthrylene, 3-methoxydibenz[e,l]acephenanthrylene and 3-methoxyindeno[1,2,3hi]chrysene (see Fig. 1 for molecular structures) were synthesized and purified by procedures described elsewhere [18]. Synthetic refer-

ences and/or commercial suppliers for the remaining 55 PAH solutes contained in Tables 1 and 2 are listed in our earlier papers (for a single source listing see Tucker [19]). Stock solutions were prepared by dissolving the solutes in dichloromethane, and were stored in closed amber glass bottles in the dark to retard any photochemical reactions between the PAH solutes and dichloromethane solvent. Carbon tetrachloride and chloroform (to a much lesser extent) are reported to react with polycyclic aromatic hydrocarbons via a hypothesized concerted transannular addition with free radical formation [20–25]. Small aliquots of each stock solutions were transferred into test tubes, allowed to evaporate, and diluted with the micellar solvent media of interest. All solutions were ultrasonicated, vortexed and allowed to equilibrate for a minimum of 24 h before any spectrofluorometric measurements

[a] Unless otherwise indicated, only 1 small 50 μl and 100 μl drops of 'neat' nitromethane was added to 10 ml of dissolved PAH solution.

[b] % Reduction $= 100 \times (F_{initial} - F_{final})/F_{initial}$; where $F_{initial}$ refers to the corrected PAH emission intensity prior to nitromethane addition and F_{final} is the corrected emission intensity after nitromethane addition.

[c] Because of the large primary inner-filtering correction only one small 25 μl drop of nitromethane was added to 10 ml of dissolved PAH solution.

were made. Experimental results were unaffected by longer equilibration times.

Absorption spectra were recorded on a Milton Roy Spectronic 1001 Plus and a Hewlett-Packard 8450 A photodiode-array spectrophotometer in the usual manner. The fluorescence spectra were measured on a Shimadzu RF-5000U spectrofluorimeter with the detector set at high sensi-

tivity. Solutions were excited at the wavelengths listed in Tables 1 and 2. Fluorescence data were accumulated in a 1 cm^2 quartz cuvette at 23°C (ambient room temperature) with excitation and emission slit width settings of 15 and 3 nm, respectively. The fluorescence spectra represent a single scan which was then solvent blank corrected and verified by repetitive measurements.

Emission intensities associated with the quenching measurements were corrected for primary inner-filtering artifacts and self-absorption arising from the absorption of excitation radiation by nitromethane and the PAH solute, respectively, according to the following expression [26–28]:

$$f_{prim} = F^{corr}/F^{obs} = 2.303A(y-x)/[10^{-Ax} - 10^{-Ay}] \quad (1)$$

which differs slightly from the approximate form [29]

$$f_{prim} \approx 10^{0.5A} \quad (2)$$

In the above equations F^{corr} and F^{obs} refer to the corrected and observed fluorescence emission signal, respectively, A is the absorbance per cm of pathlength at the excitation wavelength, and x and y denote distances from the boundaries of the interrogation zone to the excitation plane. Several of the PAHs have excitation wavelengths in the 300–320 nm spectral region and a few drops of nitromethane gave solutions having appreciable absorbances. Computational procedures and interrogation zone dimensions are discussed in greater detail elsewhere [3–5,30,31]. Every effort was made to work at solution absorbances of A $cm^{-1} \leq 0.95$ ($f_{prim} \leq 3.0$), where Eqs. (1) and (2) are valid. Secondary inner-filtering corrections were not necessary as nitromethane is 'optically transparent' in most of these PAH emission ranges.

3. Results and discussion

Tables 1 and 2 summarize our fluorescence quenching measurements for 25 alternant and 33 nonalternant polycyclic aromatic hydrocarbons dissolved in micellar SB-12 and micellar SB-16 solvent media. Experimental results are reported in the last columns as the percent reduction in the original fluorescence emission intensity observed after the addition of nitromethane. As indicated in the table footnotes, numerical entries correspond to either 25 μl, 50 μl or 100 μl of neat quenching agent added to circa 10 ml of solution. All emission intensities used in the computations were corrected for primary inner-filtering and solute self-absorption as discussed in the last paragraph of the Experimental section. Estimated nitromethane molar concentrations are as follows: 0.044 M (25 μl), 0.088 M (50 μl) and 0.176 M (100 μl). Molar concentrations are calculated using an average droplet mass of 0.0270 g obtained by weighing 25 individual Eppendorf pipette droplets of nitromethane, which ranged in size from 0.0267–0.0275 g. Uncertainties in the percent reductions are believed to be ± 2% (or better) based upon replicate measurements for select solutes.

Readers should note that acenaphthylene- and aceanthrylene-derivatives are listed in Table 1 as alternant PAHs. Classification of aromatic molecules as alternant versus nonalternant PAHs depends upon the nature of the aromatic ring system. Earlier quenching studies [9,10] labelled aceanthrylene- and acephenanthrylene-derivatives as nonalternant PAHs assuming that the C=C double bond in the cyclopenta-ring was aromatic. NMR coupling measurements [11–14] show that the double bond is alkenic, and should not have been considered as part of the aromatic ring system when the molecules were initially classified as nonalternant PAHs. Placement of these seven acenaphthylene- and aceanthrylene-derivatives in Table 1 as alternant PAHs is consistent with the C=C double bond in the cyclopenta-ring being nonaromatic in nature.

Careful examination of Tables 1 and 2 reveals that nitromethane quenches the fluorescence emission of all 25 alternant PAH6 benzenoids and alkylated derivatives, in accordance with the nitromethane selective quenching rule. Similar behavior is observed for both zwitterionic surfactant solutions. No special significance is given at the present time to the slightly larger percent reductions observed in the SB-12 micelle solution as such differences may result simply from the size of

the added nitromethane droplet and/or differences in the nitromethane partitioning behavior between the micellar phase(s) and the bulk aqueous solution. More interesting quenching behavior is observed in the case of the 35 nonalternant fluoranthenoid and fluorenoid compounds. Five of the parent nonalternant PAHs, benzo[k]fluoranthene, naphtho[2,3b]fluoranthene, naphtho[1,2b]fluoranthene, benzo[b]fluoranthene and dibenz[e,l]acephenanthrylene are quenched by nitromethane in both micellar solvent medias. The first two compounds have been previously noted to be exceptions to the nitromethane selective quenching rule [3,6,32], and their behavior here is not totally unexpected. (Note: naphtho[1,2b]fluoranthene was considered to be 'borderline' case in our initial quenching study [3], and its behavior is also in agreement with earlier findings). What is unexpected, however, is the large number of methyl- and methoxy-nonalternant PAH derivatives that are quenched in zwitterionic solutions.

Rationalization of why nitromethane quenches the fluorescence emission of nonalternant PAHs (particularly the methyl- and methoxy-derivatives) dissolved in the zwitterionic surfactant solutions must take into account the fact that most of the fluorophore molecules reside somewhere within the micellar interior. Polycyclic aromatic hydrocarbons, especially the larger multi-ring ones, are extremely hydrophobic and they have very limited aqueous solubilities. In several earlier solvent polarity probe studies, we noted that it was impossible with our Shimadzu spectrofluorimeter to determine meaningful emission intensity ratios for coronene, methylcoronene, 1,2-dimethylcoronene and other larger PAHs because of extremely weak fluorescence signals [33,34]. We even substituted neat acetonitrile for the recommended aqueous-acetonitrile solvent media (20:80 by volume) in our quenching studies [35] in order to solubilize the larger PAHs. The large increase in emission intensity that is observed in the micellar SB-12 and micellar SB-16 solvents results from the enhanced PAH solubility, combined with inability of oxygen to effectively quench PAH molecules residing inside the micellar pseudophase.

Excited-state lifetimes of PAHs are on the order of nanoseconds, [36,37] and the micelle-to-aqueous pseudophase transfer rate is on the order of μs (micelle residence times being several μs [38,39]). Any hypothesized quenching mechanism must have the PAH molecule residing somewhere within the interior of the micelle during the electron transfer. Exciplex formation and/or a significant change in the basic quenching mechanism is unlikely as we failed to observe new band(s) in any of the recorded emission and absorption spectra.

To gain better insight into actual location of the dissolved PAH inside the micelle and the role that solvent polarity has upon presumed charge transfer quenching mechanism, we examined fluorescence behavior of alternant and nonalternant PAHs dissolved in *n*-heptane and cyclohexane in the presence of nitromethane. These measurements are summarized in Table 3 as the percent reduction in the original fluorescence emission signal observed after the addition of either 25 μl or 50 μl of 'neat' nitromethane to 10 ml of solution. Nitromethane has a limited solubility in hydrocarbon solvents. Even at the 50 μl addition of nitromethane the calculated mole fraction concentration of $X_{\text{nitromethane}} \approx 0.0095$ in cyclohexane is still three times less than the published solubility ($X_{\text{nitromethane}} \approx 0.030$) in cyclohexane at 25°C [40]. Experimental solubility data could not be found for nitromethane in *n*-heptane; however, Marsh [41] reported both excess enthalpies and excess volumes for miscible nitromethane + *n*-hexane mixtures at 25°C up to $X_{\text{nitromethane}} = 0.03526$, which is still 2–3 times larger than the 50 μl quenching study. *n*-Hexane and *n*-heptane are saturated hydrocarbons differing by a single CH_2-group. Nitromethane should have similar solubility in both alkanes. Moreover, we did not see any cloudiness in the solutions after shaking, and the measured absorbances doubled when the aliquot size was increased from 25 μl to 50 μl of nitromethane. These observations also indicate that the solubility limit was not exceeded.

Careful examination of Table 3 reveals that nitromethane no longer selectively quenched fluorescence emission of alternant PAHs. Emis-

[a] Unless otherwise indicated, only one small 25 μl drop of 'neat' nitromethane was added to 10 ml of dissolved alternant PAH solution, and one small 50 μl drop of 'neat' nitromethane was added to 10 ml of dissolved nonalternant PAH solutions.
[b] % Reduction $= 100 \times (F_{initial} - F_{final})/F_{initial}$; where $F_{initial}$ refers to the corrected PAH emission intensity prior to nitromethane addition and F_{final} is the corrected emission intensity after nitromethane addition.
[c] Because of the large primary inner-filtering correction only one small 25 μl drop of nitromethane was added to 10 ml of dissolved PAH solution.

sion signals of perylene, coronene, benzo[ghi]perylene, anthanthrene, benzo[a]pyrene and naphtho[2,3g]chrysene were for all practical purposes unaffected by nitromethane, as were signals of all ten nonalternant PAHs studied. Even in the case of pyrene, benzo[e]pyrene and anthracene where sizeable quenching was observed, the percentage reduction in emission intensity was still significantly less than was observed in our initial study [5] involving the much more polar 'neat' acetonitrile and binary aqueous-acetonitrile (20:80 by volume) solvent mixtures.

Results of these measurements suggest that dissolved PAHs must reside somewhere within a fairly polar region of the zwitterionic micelles, other-wise, one would not observe the large percentage reductions in emission signals that are given in Table 1. Nitromethane and the PAH fluorophore must be situated in fairly close proximity to each other in order for electron transfer to effectively occur. Nitromethane, because of its very limited solubility in saturated hydrocarbons, resides in the polar region(s) of the micelle. The close proximity requirement then places the solubilized PAH solutes in a fairly polar region within the micelle. Experimental I/III band emission intensity ratios for pyrene (I/III $\approx$ 1.06), benzo[ghi]perylene (I/III $\approx$ 1.02) and coronene (I/III $\approx$ 0.55) dissolved in SB-12 and SB-16 also indicate a moderately polar molecular environment around the solubilized PAH probe molecule. Much smaller ratios of I/III $\approx$ 0.58 for pyrene [42], I/III $\approx$ 0.38 for benzo[ghi]perylene [43] and I/III $\approx$ 0.12 for coronene [44] would be expected if

the PAH were solubilized in an entirely hydrocarbon-like micellar region. Similarly, we believe that nonalternant PAHs also reside in a polar molecular environment within the micelle. The above argument seems reasonable as a search of the published chemical literature [45–51] reveals that most authors conclude that the site of solubilization of aromatic probes is close to the micelle surface in the so-called palisade layer.

We rationalize the experimental quenching data in zwitterionic solutions in terms of earlier observations involving anionic and cationic surfactants. Presence of micellar aggregates is a necessary condition for the anionic substituent's negative charge to affect the quenching mechanism [16]. Micelles may either provide a favorable geometry for electron transfer to occur with concurrent stabilization of the developing positive charge on the PAH, and/or increase the local concentration of nitromethane around the solubilized PAH solute molecule. The positively charged tetraalkylammonium substituent is anchored to the anionic substituent by $-CH_2CH_2CH_2-$ tethers. In close proximity to the dissolved PAH and nitromethane molecules, the tetraalkylammonium substituent would be in a position either to 'fix' the nitro-group in a conformation unfavorable for electron transfer or to interact with the PAH's aromatic π-cloud, pulling electron density toward the cation and away from any surrounding nitromethane quencher molecules. Both types of cationic interactions should discourage electron transfer from the excited PAH fluorophore to nitromethane, which acts as the electron acceptor. Almgren et al. [50] invoked weak specific interaction between the solubilized PAH and the cationic head group to explain large differences between the maximum solubilities of pyrene (and other PAHs) in anionic micelles versus micelles of tetraalkylammonium cationic surfactants. Two published papers [50,52] have used the change in the I/III band emission intensity in pyrene's fluorescence spectrum to calculate the equilibrium constant for presumed pyrene-tetraalkylammonium association complexes. Proton and ^{13}C NMR data [53,54] have also been used as experimental evidence to support PAH-tetraalkylammomium group interactions in both homogeneous and heterogeneous solvent media.

In zwitterionic surfactant solutions the solubilized polycyclic aromatic hydrocarbon can conceivably interact with both charged substituent groups. Fluorescence quenching data in Tables 1 and 2 suggest that zwitterionic surfactants can be considered, for the most part, as providing a polar solubilizing media as far as the nitromethane selective quenching rule is concerned. Nonalternant PAH solutes that containing electron donating methoxy- and hydroxy-functional groups (and to a much lesser extent methyl-groups) are noted exceptions. We believe that the increased quenching and loss of nitromethane selectivity results because the surfactant's positively-charged tetraalkylammonium substituent interacts with the lone electron pairs on the oxygen atoms, rather than with the aromatic π-electron cloud. There would then be sufficient electron density for complete/partial electron transfer to nitromethane which acts as the electron acceptor. Depending upon the PAH's molecular structure, the anionic sulfonate group might still be favorably situated so as to stabilize any developing charge on the PAH aromatic ring system that might occur.

Dissimilar fluorescence quenching behavior in micellar anionic, cationic, zwitterionic and nonionic solvent media is important from an analysis standpoint. Cationic and nonionic surfactants would be the solvent medias of choice if one wished to use nitromethane as a selective fluorescence quenching agent to simplify observed emission spectra. A possible application would involve the chromatographic separation of unknown PAH mixtures with fluorescence detection. With trace nitromethane added to the micellar mobile phase one would observe reduced fluorescence emission signals from alternant PAHs which might facilitate resolution or quantification of co-eluting solutes.

Received 6 May 1996; received in revised form 26 August 1996; accepted 26 August 1996

Abstract

A luminescence spectrometric method was developed for the determination of ultra trace amounts of europium (down to 1×10^{-13} M) in high purity lanthanum, praseodymium and dysprosium oxides. This is based on the enhanced luminescence of europium-thenoyltrifluoroacetone (TTA)-dibenzo-18-crown-6 (DBC)-Triton X-100 in the presence of terbium. The fluorescence intensity is linear with europium concentration in the range 1×10^{-11}–1×10^{-6} M under the recommended conditions. The optimized procedure is successfully utilized for the determination of ultratrace amounts of europium in lanthanium, praseodymium and dysprosium oxides. © 1997 Elsevier Science B.V.

Keywords: Luminescence spectrometry; Rare earth oxides; Ultra trace quantities

1. Introduction

High purity individual rare earth oxides are increasingly used as major components in refractive index lenses and fibre optics (La_2O_3), lasers (Y_2O_3), phosphor (YVO_3) and magnetic bubble memory films (Gd_2O_3) [1,2]. The electrical and magnetic properties of these materials are influenced by the levels of contaminating foreign trace elements particularly other lanthanides. It is therefore important that such contaminants at trace levels be identified and quantified [3].

Various luminescence methods described for the determination of traces of lanthanides in high purity rare earth oxides are reviewed elsewhere by us [3] but these are not sensitive. Enhanced luminescence was observed during a study of Eu-TTA-1,10-phenanthroline-surfactant system in the presence of terbium and this allows the determination of 10^{-11}–10^{-8} M of europium with a detection limit of 10^{-13} M [4,5]. Unfortunately, 10 fold amounts of La, Ce, Pr, Nd, Ho, Er, Yb, Y and Lu interfere in the determination of 10^{-9} M of Eu [5]. This paper describes similar phenomenon observed during a study of Eu-TTA-dibenzo-18-crown-6 surfactant system in the presence of terbium which enables the determination of 10^{-11}–10^{-6} M of europium with a detection limit of 10^{-13} M. On the other hand, in the present procedure 10^3 fold amounts of lan-

thanum, praseodymium and dysprosium do not interfere in the determination of 10^{-8} M europium enabling us in the determination of ultra-trace amounts of europium in high purity lanthanum, praseodymium, dysprosium and their mixtures of oxides.

2. Experimental

2.1. Apparatus

A LS-50-B luminescence spectrometer (Perkin Elmer) was used. An ELICO LI-120 digital pH meter was used for pH adjustment.

2.2. Reagents

Standard solutions (1×10^{-3} M) of lanthanides were prepared by dissolving the oxides (99.9%) in dilute hydrochloric acid. Working solutions were prepared by dilution with distilled water. Aqueous 1×10^{-2} M solutions of TTA and dibenzo-18-crown-6 (DBC) in acetonitrile were used. The concentration of non-ionic surfactant, Triton X-100 solution was 1% (w/w). The buffer solution was 0.3 M ammonium acetate. All the reagents used were of analytical grade.

2.3. Procedure

To a 25 ml volumetric flask, solutions were added in the following order. Standard solutions of Eu^{3+} and Tb^{3+}, TTA, Dibenzo-18-crown-6, buffer and surfactant solutions. The mixture was diluted to 25 ml with distilled water and allowed to stand for 10 min. The fluorescence intensity was measured in a 1 cm quartz cell at excitation and emission wavelengths of 371 and 614 nm, respectively.

3. Results and discussion

The emission spectra of the systems investigated are as shown in Fig. 1. The emission spectra of Eu-TTA-DBC-Triton X-100 in the presence and absence of terbium are similar to each other and

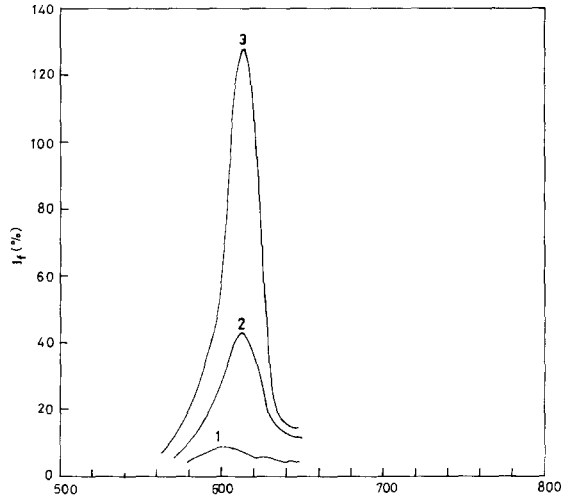

Fig. 1. Emission spectra: (1) Eu-TTA-DBC-Triton X-100; (2) Tb-TTA-DBC-Triton X-100; and (3) Eu-Tb-TTA-DBC-Triton X-100. Conditions: 1.0×10^{-4} M DBC, 3×10^{-2} M ammonium acetate, 5×10^{-2}% Triton X-100.

show the emission spectra of Eu^{3+}. The maximum excitation wavelength (not shown in Fig. 1) is 371 nm and the maximum emission wavelength is 614 nm. However, the intensity of Eu-Tb-TTA-DBC-Triton X-100 is 1–2 orders of magnitude stronger than that of the system without terbium.

The effect of terbium concentration on the fluorescence intensity of the europium system is

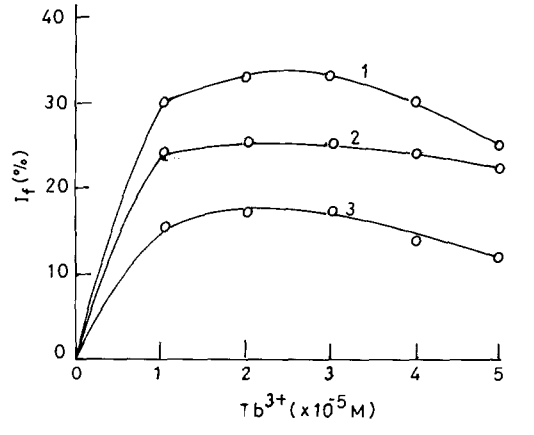

Fig. 2. Effect of terbium concentration. Europium concentration: (1) 1×10^{-8} M; (2) 1×10^{-9} M; and (3) 1.0×10^{-10} M. Conditions: 1.0×10^{-4} M TTA, 1.0×10^{-4} M DBC, 3×10^{-2} M ammonium acetate, 5×10^{-2}% Triton X-100.

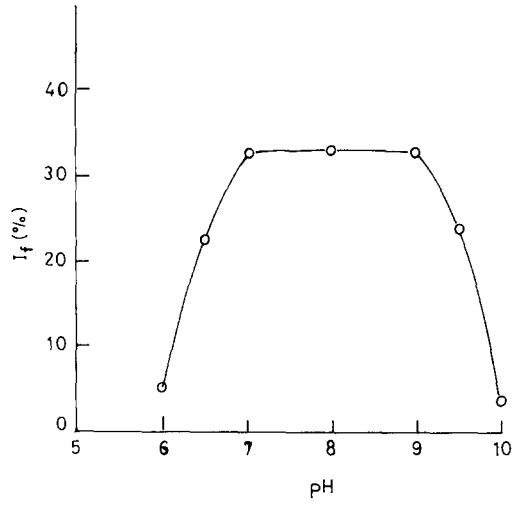

Fig. 3. Effect of pH on Eu-Tb-TTA-DBC-Triton X-100 system. Conditions: 1.0×10^{-8} M Eu^{3+}, 2.0×10^{-5} M Tb^{3+}, 1.0×10^{-4} M TTA, 1×10^{-4} M DBC, 5×10^{-2}% Triton X-100.

shown in Fig. 2. For 1×10^{-9} M Eu^{3+} the fluorescence intensity reaches a maximum at 1.5×10^{-5} M, Tb^{3+}, whereas in the range of 1×10^{-8}–1×10^{-10} M of Eu^{3+} the maximum fluorescence intensity occurs in the range $1.5–2 \times 10^{-5}$ M. Fig. 3 shows the effect of pH on the fluoresence intensity in the presence of terbium. The greatest fluorescence intensity occurs over the pH range 7.0–9.0. The type of buffer also effects the fluorescence intensity. Under the general conditions used for Fig. 3 at pH 7 ammonium acetate and hexamine-HCl buffers gave the same fluorescence intensity but ammonia–ammonium chloride reduced the intensity (by 10%) and citrate and phosphate buffers quenched the fluorescence completely. Thus, ammonium acetate ($> 10^{-3}$ M) was chosen for further use. The effects of TTA, DBC and Triton X-100 on the fluorescence intensity of Eu-Tb system were examined. The concentration ranges that gave greatest intensity were 7×10^{-5}–1.5×10^{-4} M TTA, $> 10^{-5}$ M DBC and 2.0–10.0×10^{-2}% (w/w) Triton X-100.

The nature of crown-ether was found to have strong influence on the fluorescence intensity of Eu-Tb system. DBC gave nine-fold higher fluorescence intensity compared with dicyclohexyl-18-crown-6 though enhanced luminescence for europium was observed in the presence of terbium in latter crown ether also. DBC was used in subsequent studies.

The fluorescence intensity of Eu-Tb system is a linear function of the concentration in the range 1×10^{-11}–1×10^{-6} M under the recommended conditions. The sensitivity is thus, two orders of magnitude better than that of Eu-TTA-DBC-Triton X-100 system. The detection limit (for an SNR value of 3) is 1.5×10^{-13} M, which is about four orders of magnitude less than that of the Eu-TTA-DBC-Triton X-100 system.

The effect of lighter and middle lanthanides on the fluorescence intensity of Eu-Tb system were studied. At 1×10^{-8} M europium, 10^{-5} M amounts of lanthanum, praseodymium and dysprosium oxides do not interfere. However, *Y* and heavy lanthanides were found to interfere at concentrations $> 10^{-7}$ M. Table 1 shows the results of the determination of europium in certain commercial high purity rare earth oxides and their mixtures.

3.1. Enhancement mechanism

Fig. 2 shows that there is no constant mole ratio between Eu^{3+} and Tb^{3+} in the Eu-Tb-TTA-DBC-Triton X-100 system. Fig. 4 shows that the absorption spectrum of this system is similar to that of the system without terbium. These results show that terbium does not form a new compound with the Eu-TTA-DBC-Triton X-100. It should also be noted that the enhancement effect occurs only in aqueous phase in the presence of surfactants and not in organic solvents (e.g., benzene, *n*-butanol, cyclohexane and TBP).

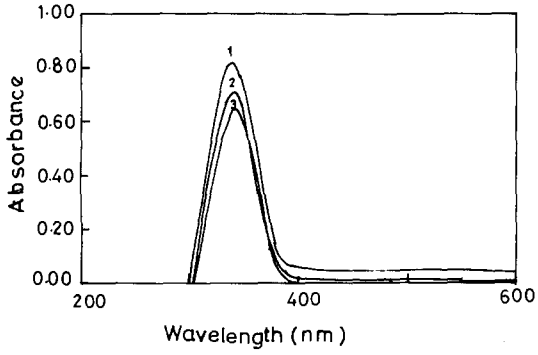

Fig. 4. Absorption spectra: (1) Eu-Tb-TTA-DBC-Triton X-100 system; (2) Tb-TTA-DBC-Triton X-100 system; and (3) Eu-TTA-DBC-Triton X-100 system. Conditions: 1×10^{-7} M, Eu^{3+}, 2.0×10^{-5} M Tb^{3+}, 1.0×10^{-4} M TTA, 1.0×10^{-4} M DBC, 3×10^{-2} M ammonium acetate, 5×10^{-2}% Triton X-100.

The excited singlet states of TTA in these complexes undergo a radiationless transiton to their triplet states. Europium can be excited both by intramolecular energy transfer as suggested by Crosby et al. [6], from the excited triplet state of TTA in the Eu-TTA-1,10-phenanthroline by Tb-benzoic acid due to the wrapping effect [7]. On the other hand, the enhancement in the Eu-TTA-dibenzoylpyridinium ion by yttrium was attributed to the energy transfer from yttrium complex to europium complex [8]. Because the concentration of terbium complex is much greater than that of the europium complex (in the present case) in the Triton X-100 solution, the enhancement effect was a result of two mechanisms, one of which was the wrapping effect of Tb complexes over Eu complexes and the other was intermolecular energy transfer from terbium to europium [9]. Triton X-100 also plays an important role in the dissolution of both complexes and their protection against collision with solvent (water) molecules, which would cause loss of energy.

Received 30 April 1996; received in revised form 27 August 1996; accepted 28 August 1996

Abstract

Ternary mixtures of Bromocresol Green (BCGH), Benzethonium Chloride (BZ^+Cl^-), and Quinine (Q) in dichloromethane (CH_2Cl_2 for ratios $1:\geq 1:\geq 1$ ($BCGH_2$:BZ^+Cl^-:Q) generate species $BCGH^-BZ^+$, BZ^+BCG^--H-Q) and $BCG^{2-}(BZ^+)_2$ in chemical equilibrium; whose thermodynamic parameters are determined. A new method to study ternary mixtures in a non-polar solvent has been given and other amines (A) and quaternary ammonium compounds (QAC) instead of Q and BZ^+Cl^- have also been researched. Species $BCGH^-BZ^+$, and $BCG^{2-}(BZ^+)_2$ are ion associates of 1:1 and 1:2 (dye:BZ^+Cl^-) stoichiometry and species BZ^+BCG^--H-Q presents a hydrogen bond, being of 1:1:1 (dye:BZ^+Cl^-:Q) stoichiometry. The Vis-VU, IR and ^{1}H-NMR spectra of the associates suggest that they are in nature resonance hybrids. A new and fundamental equation which governs extraction of any 1:1:1 associate is deduced and checked experimentally, showing that its extraction depends on the high capacity of the amine to accept hydrogen bonds and the high extractability of the ammonium ion. Extraction of the 1:1:1 associate using different amines and ammonium ions is studied both, experimentally and by the new equation, checking that the 1:1:1 associate containing Q and BZ^+ is selectively extracted due to the fact that Q has a high hydrophobicity and high capacity to form hydrogen bonds and species BZ^+Cl^- has a high ion-associability. Selective extraction of this 1:1:1 associate is useful for quantitative determination in complex mixtures of ammonium ions of high ion associability as BZ^+Cl^-. © 1997 Elsevier Science B.V.

Keywords: Extraction global equation; Ternary associates spectroscopy; Ternary associates theory; Thermodynamic equilibria

1. Introduction

Several methods have been published for the quantitative determination of amines and quaternary ammonium ions, in which acid dyes form colored ion-pairs extractable from the aqueous solution with organic solvents [1–5]. The extract is used spectrophotometrically to determine a trace component in the ion-pair, which is generally of 1:1 stoichiometry (dye:amine or dye:ammonium). A review of this type of analytical methods and of the used ion-association reagents was also published [6]. However, these analysis methods are unspecific. This is a disad-

PII S0039-9140(96)02086-3

vantage and therefore extraction of an 1:1:1 associate (dye:ammonium:quinine) using a diprotic acid dye such as Bromocresol Green ($BCGH_2$) and Quinine (Q) in order to determine quaternary ammonium compounds (QAC) with an enhanced selectivity was proposed [7]. Quinine was only used for enhancing the extractability and selectivity of the 1:1:1 associate, which was identified as the species responsible for the visible absorption band of the extract used for the quantitative determinations; but neither nature of the 1:1:1 species nor the causes for the selective extraction were fully clarified. These problems are now studied for the first time by means of new experimental results and theoretical equations.

At a first stage, ternary mixtures in a single dichloromethane phase of a sulphonphthalein dye, $BCGH_2$, Benzethonium Chloride, BZ^+Cl^-, and Q, in different proportions are investigated for the first time finding new associates of different composition and nature. A new and simple method to study equilibria of three components in a nonpolar solvent from spectrophotometric measurements is now put forward since the known methods were put forward in an aqueous medium [8–10]. Absorption peaks, P, molar absorptivities, ϵ, equilibrium constants, K, and thermodynamic parameters of the complexes obtained in these ternary mixtures are compared with the same data obtained for complexes in $BCGH_2$-Q binary mixtures. Through the comparison between the obtained results in binary and ternary mixtures (P, ϵ, K, etc.), this paper provides new evidences which can be helpful in deciding the controversial points regarding the nature, composition and absorption peaks of the ternary and binary compounds. From this information, it is established why Q can be used for enhancing the selectivity and extractability of some QAC. This paper shows, for the first time, the nature and physicochemical properties of the 1:1:1 associates described in extraction studies using Vis-UV, IR and ^{1}H-NMR data, justifying its importance from an analytical point of view. Resonance of associates is also proposed for the first time to explain some details of the nature of associates obtained in ternary mixtures and their analytical applications.

At a second stage, extraction of associates in ternary mixtures of a sulphonphthalein dye, $BCGH_2$, Benzethonium Chloride, BZ^+Cl^-, and Q, is carried out in dichloromethane/water systems. Extraction of $BCGH_2$-Q and $BCGH_2$-benzethonium binary mixtures is also carried out to compare the associates extracted in the two kinds of mixtures. Then, a new equation, which combines the results of equilibrium among associates in dichloromethane of the first stage and those of extraction of the second one is deduced and checked experimentally using both, data in literature and our own data. This equation demonstrated the importance of studies of formation of ternary associates in the organic phase for extraction studies for the first time from a quantitative point of view and it suggests that extraction of the 1:1:1 ternary associate is a global process of the processes that occur in both phases.

2. Experimental

2.1. Apparatus

All vis-VW spectrophotometric measurements were made on a Perkin–Elmer Lambda 5 spectrophotometer, with a B. Braun AG models Frigomix 1.495 and thermomix 1.441 thermostat with a ± 0.2°C accuracy). Quartz cells of 1 cm with Teflon stoppers were also used. A Radiometer Copenhagen PHM64 Research pH meter was used with a combined electrode for the pH measurements. The electrode was calibrated with standard buffer solutions of pH = 4.00 and pH = 7.03 at 293.16 K unless otherwise stated; the precision of the measurements was of ± 0.01. The ^{1}H-NMR spectra were recorded on a Bruker AM-60 Spectrometer with $CDCl_3$ as solvent. The IR spectra were made on a Perkin-Elmer 298 IR spectrophotometer with potassium bromide pellets. The KBr has been previously dried in an oven at 200°C. All calculations were made with an IBM compatible computer. Some of the substances were dissolved with the help of a Selecta ultrasons ultra sound apparatus.

2.2. Reagents

The reagents used were CH_2Cl_2 (Probus HPLC, with $< 0.02\%$ water content), methanol (Probus HPLC), $BCGH_2$ (Merck), atropine, tropine, homatropine, methylatropine, tetramethylammonium chloride, tetraethylammonium, chloride (Sigma), Q, benzethonium chloride and proton sponge (Fluka-Chemie). All the solid materials were of analytical grade and all amines were used as free bases without further purification after storage in a desiccator with phosphorous pentoxide.

3. Results and discussion

3.1. Absorption spectra, composition and equilibrium constants of associates in dye-quaternary ammonium compound-amine ternary mixtures

This section and the following provide a new method to study the associates obtained in ternary mixtures in a single nonpolar phase. Also an attempt will be made to give an interpretation of the results of the experimental data (as for example the use of the Job's method with three reagents or when a reagent and the product show the same absorption maximum, etc.) and of the calculated constants from these data (as for example molar absorptivities, equilibrium constants and thermodynamic parameters, etc.).

Ternary mixtures of $BCGH_2$, BZ^+Cl^-, and Q, when the concentrations are in the order $[BCGH_2] = [BZ^+Cl^-] \leq [Q]$, that is to say, proportions $1{:}1{:} \geq 1$ ($BCGH_2$:BZ^+Cl^-:Q), present in dichloromethane, CH_2Cl_2, two new absorption bands with maxima at 415 and 630 nm which pass through an isosbestic point as can be seen in Fig. 1A. Also the $BCGH_2$-Q binary mixture shows two absorption bands but with maxima at 415 and 547 nm and an isosbestic point as shown in Fig. 1B. Therefore, the ternary mixture gives an absorption band at 630 nm which does not appear in the binary mixture. Job's method was used to deduce the stoichiometry of the products responsible for the new absorption bands. Job's method for the binary mixture has been carried out by measuring the absorbance at 415 and 547 nm of different proportions of 10^{-4} M solutions of $BCGH_2$ and 10^{-4} M of Q, such that $[BCGH_2] + [Q] = 10^{-4}$ M. The absorbance of these solutions are plotted against the molar fractions of the dye as shown in Fig. 2. The concentrations used in the Job's method for the ternary mixture were identical but differ in that here, the dye has been initially mixed with an equimolar concentration of BZ^-Cl^-. The concentration of this third component has been ignored for the dye molar fraction calculations as could be observed in Fig. 2 where, moreover, it can be seen that curves at 415 nm are identical for both binary and ternary mixtures. The plots in Fig. 2 suggest 2:1 and 1:2 stoichiometries ($BCGH_2$:Q) for the binary mixtures measured at 415 and 547 nm. Accordingly, in the binary mixture the three following processes are assumed as reactions Eqs. (1)–(3); where $BCGH_2$ is the free dye, Q

$$BCGH_2 + Q \rightleftarrows BCGH^-QH^+ \quad (1)$$

$$BCGH^-QH^+ + Q \rightleftarrows QH^+BCG\ \ H-Q \quad (2)$$

$$BCGH^-QH^+ + BCGH_2 \rightleftarrows (BCGH^-)_2QH_2^{2+} \quad (3)$$

quinine base, $(BCGH^-)_2QH_2^{2+}$ and $BCGH^-QH^+$ are the ion associates of 2:1 and 1:1 stoichiometry. The QH^+BCG^--H-Q associate shows a hydrogen bridge and it is of 1:2 stoichiometry (dye:Q). Eqs. (1)–(3) were previously studied from data in binary mixtures [11]. The same stoichiometries of $BCGH_2$ to Q have also been obtained for the ternary mixtures at 415 and 630 nm as can be seen in Fig. 2. The fact that the stoichiometric relation does not vary in the ternary mixture while the absorption maximum does, could be interpreted as follows: in the binary mixture, Eqs. (1) and (2) for absorption at 547 nm and Eqs. (1) and (3) for absorption at 415 nm would justify the observed stoichiometries, and the peaks at 415 and 547 nm would be assigned to the $(BCGH^-)_2QH_2^{2+}$ and QH^+BCG^--H-Q species (Fig. 1B). On the other hand, in the ternary mixture, four processes should be assumed. The first one is given by Eq. (1) and the rest by the following equations:

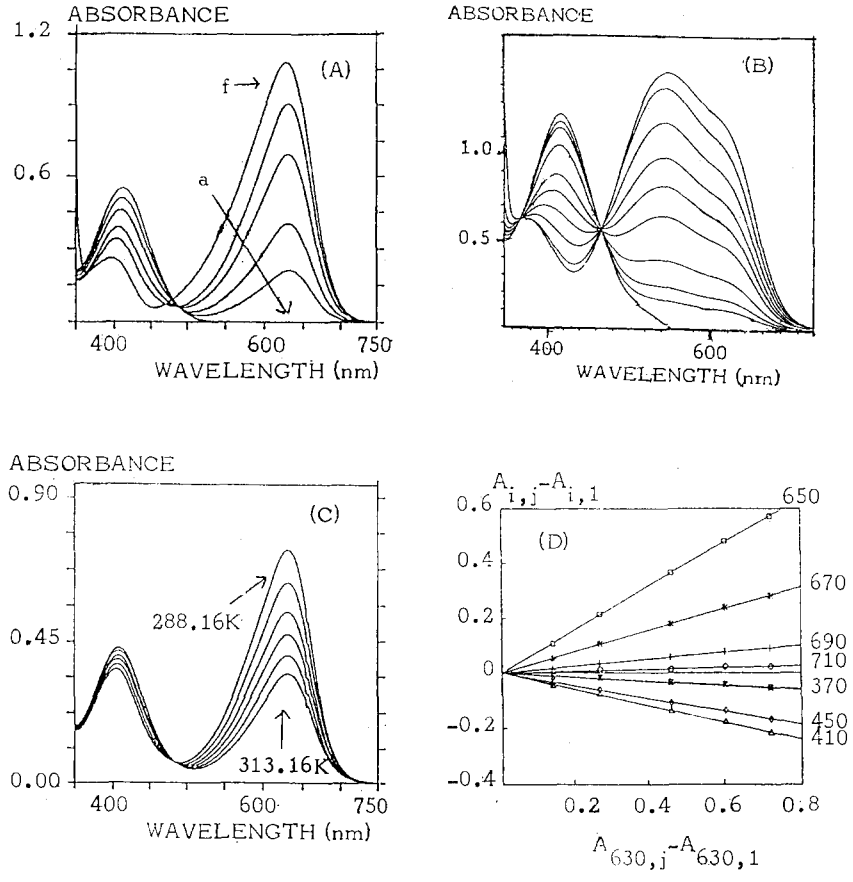

Fig. 1. (A) Visible-ultraviolet spectra of CH_2Cl_2 solutions of Bromocresol Green, $BCGH_2$, 3×10^{-5} M; Benzethonium Chloride, BZ^+Cl^-, 3×10^{-5} M and different concentrations of Quinine, Q, 3 (curve a), 4, 5, 8, 120 and 5000×10^{-5} M (curve f). T = 293.16 K. (B) Visible-ultraviolet spectra of CH_2Cl_2 solutions of $BCGH_2$, 6.6×10^{-5} M and different concentrations of Q, 6.6, 7.7, 8.3, 9.4, 11.8, 14.0, 17.02, 32, 37.9 and 60×10^{-5} M. T = 288.16 K. (C) Visible-ultraviolet spectra of CH_2Cl_2 solutions of $BCGH_2$, 3.4×10^{-5} M; BZ^+Cl^-, 3.4×10^{-5} M and Q, 6.8×10^{-5} M at 288.16, 293.16, 298.16, 303.16, 308.16 and 313.16 K. (D) Coleman's method for two species whose sum of concentrations is constant from the spectral data in Fig. 1A. The numbers correspond to the wavelength, *i*, of the row of the matrix which has been resolved graphically according to Coleman.

$$BCGH^-QH^+ + BZ^+Cl^- \rightleftarrows BCGH^-BZ^+ + Cl^-QH^+ \quad (4)$$

$$BCGH^-BZ^+ + Q \rightleftarrows BZ^+BCG^- - H - Q \quad (5)$$

$$Cl^-QH^+ + BCGH_2 \rightleftarrows BCGH^-Cl^-QH_2^{2+} \quad (6)$$

where Cl^-QH^+ is Q hydrochloride (colourless). Eqs. (1), (4) and (5) justify the 1:2 stoichiometry at 630 nm of the ternary mixture; since the products of Eq. (4) contain dye (species $BCGH^-BZ^+$) and Q (species Cl^-QH^+) in a 1:1 ratio and Eq. (5) consumes one more molecule of Q thereby justifying the 1:2 stoichiometry. As Eqs. (1) and (4) are quantitative [11] (the latter will be shown later), in proportions 1:1: ≥ 1 ($BCG:BZ^+Cl^-:Q$), species $BCGH_2$ and $BCGH^-QH^+$ do not exist in the ternary mixture; therefore, only Eq. (5) will be present in the solution and species $BCGH^-BZ^+$ and BZ^+BCG^--H-Q will justify the absorption maxima at 415 and 630 nm in Fig. 1A. Eqs. (1), (4) and (6) justify the 2:1 stoichiometry at 415 nm in ternary mixtures since the products of Eq. (4) contain dye (species $BCGH^-BZ^+$) and Q (species Cl^-QH^+) in a 1:1 ratio and Eq. (6) con-

sumes one more molecule of dye thereby justifying the 2:1 stoichiometry. The fact that the curve at 415 nm in Fig. 2 is identical for binary and ternary mixtures is justified by identical absorption spectra of $(BCGH^-)_2QH_2^{2+}$, $BCGH^-BZ^+$, $BCGH^-Cl^-QH_2^{2+}$ species (see next paragraph) as well as identical values of equilibrium constants for Eqs. (3) and (6) since in both reactions the same nitrogen of Q and the same proton of the dye are neutralized [11]. Similarly, in ternary mixtures in an excess of dye ($[BCGH_2] > [BZ^+Cl^-] = [Q]$) only Eq. (6) will be present in the solution together with $BCGH^-BZ^+$ species generated by Eq. (4). Eq. (4) is a reaction of ionic exchange, Eq. (5) is the formation of a hydrogen bridge between OH in $BCGH^-BZ^+$ and amino nitrogen in Q, and Eq. (6) is a neutralization reaction whose study was carried out in [11] from dye-Q hydrochloride binary mixtures.

As Eq. (4) is complete, curve 'a' in Fig. 1A, where the three reagents ($BCG:BZ^+Cl^-:Q$) are in a 1:1:1 ratio, is assigned to the $BCGH^-BZ^+$ species generated in Eq. (4). The molar absorptivity of the $BCGH^-BZ^+$ ion pair determined from absorbance value at 415 nm of $BCGH_2$-BZ^+Cl^--Q mixtures in proportions 1:1:1 was $19\,800 \pm 700$ $l \times mol^{-1}\ cm^{-1}$ at 293.16 K. This value is similar

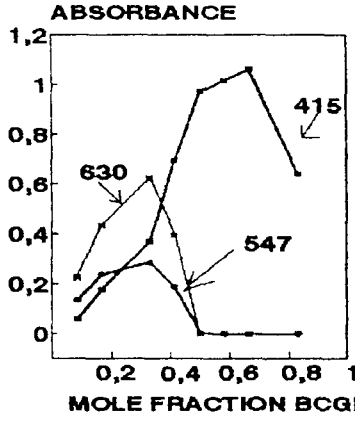

Fig. 2. Continuous variation plots between $BCGH_2$ and Q for the binary mixture ($BCGH_2$-Q: $[BCGH_2] + [Q] = 10^{-4}$ M) at 415 and 547 nm and for the ternary mixture ($BCGH_2$, BZ^+Cl^-, Q: $[BCGH_2] + [Q] = 10^{-4}$ M and $[BCGH_2] = [BZ^+Cl^-]$) at 415 and 630 nm. T = 293.16 K.

to that given before for species $BCGH^-QH^+$ and to those of $BCGH^-$ajmalineH$^+$ and $BCGH^-$homatropineH$^+$ in the same solvent [12] (CH_2Cl_2). Therefore, this value corresponds to the molar absorptivity of the $BCGH^-$ anion in this solvent, ϵ_{BCGH^-} since the cation only acts as the stabilizer of $BCGH^-$ in the nonpolar solvent. Obviously, this value is also similar to that of the molar absorptivity of $BCGH^-Cl^-QH_2^{2+}$ species and it is half the $(BCGH^-)_2QH_2^{2+}$ species determined in [11].

Ternary mixtures corresponding to Fig. 1A, in proportions $1:1:\geq 1$ ($BCGH_2$:BZ^+Cl^-:Q), are cut in an isosbestic point; therefore Eq. (5) is an equilibrium. Fig. 1C shows the displacement of this equilibrium with temperature. Fig. 1D is the Coleman's test [13] from Fig. 1A, which clearly shows two absorbent species whose sum of concentrations is constant in agreement with the already established. An identical result is obtained when the Coleman's test is applied to the spectral curves in Fig. 1C. Eq. (5) satisfies the following prerequisites: (a) is an 1:1 addition reaction; (b) the reagents do not absorb at the maximum absorption of the addition compound; and (c) the addition compound follows Beer's Law. Therefore, the iterative Rosseinsky's method [14], making use of a computer program in TURBOBASIC described previously in [11,12] was used to calculate $K_{BZBCG\text{-}H\text{-}Q}$ ($K_{BZBCG\text{-}H\text{-}Q} = [BZ^+GCG^-\text{-}H\text{-}Q]/[BCGH^-BZ^-][Q]$) of Eq. (5) and the molar absorptivity of BZ^+BCG^--H-Q, $\epsilon_{BZBCG\text{-}H\text{-}Q}$. These constants at several temperatures together with the thermodynamic parameters of Eq. (5) are presented in Table 1. The $\epsilon_{BZBCG\text{-}H\text{-}Q}$ value in Table 1 from equilibrium data is similar to that obtained in curve 'f' on Fig. 1A when a strong excess of Q is added. This suggests that Eq. (4) is highly displaced to the right as indicated before. As Eqs. (1) and (2) also satisfy prerequisites a, b and c; the same method to calculate K_{BCGHQH} (Eq. (1)) and $K_{QHBCG\text{-}H\text{-}Q}$ (Eq. (2)) was used. The K_{BCGHQH} value ($K_{BCGHQH} = [BCGH\ QH^+]/[BCGH_2][Q]$), was $10^{10.82}$ $l \times mol^{-1}$ at 298.16 K. The $K_{QHBCG\text{-}H\text{-}Q}$-value, ($K_{QHBCG\text{-}H\text{-}Q} = [QH^+BCG^-\text{-}H\text{-}Q]/[BCGH^-QH^+][Q]$), molar absorptivity for QH^+BCG^--H-Q, $\epsilon_{QHBCG\text{-}H\text{-}Q}$, and thermodynamic parameters for Eq. (2) are also

presented in Table 1. By analogy with Eq. (2) which was studied in [11], Eq. (5) is the formation of a hydrogen bridge and BZ^+BCG^--H-Q species is a 1:1:1 associate because contains dye, Q and ammonium cation in that ratio. Data in Table 1 for QH^+BCG^--H-Q and BZ^+BCG^--H-Q species suggest some interesting points. So, the previous discussion suggests that the two species are Hydrogen Bonded Complexes (HBC) and an ordinary HBC will not show [15–17], a) high K and $\Delta H°$-values (see Table 1); high visible peak (630 nm) and high molar absorptivity (Table 1). Resonance hybrid of the hydrogen-bonded structure in a later section (see Scheme 1) could be responsible for these results which indicate that this type of HBC is very stable.

Reactions of the type (2) and (5) were also carried out using other amines (A) and QAC following the same methods given for Q and benzethonium. The $K_{AHBCG\text{-}H\text{-}A}$-values using different amines together the absorption maximum

of every one of the AH^+BCG^--H-A associates (λ_{max}) the $K_{BZBCG\text{-}H\text{-}A}$ values corresponding to associates formation of type BZ^+BCG^--H-A (in these cases λ_{max} is always 630 nm) are given in the upper part of Table 2. It can be seen that the 1:1:1 associate (species BZ^+BCG^--H-A) is always more stable than the 1:2 associate (species AH^+BCG^--H-A) and that the increase from $K_{AHBCG\text{-}H\text{-}A}$ to $K_{BZBCG\text{-}H\text{-}A}$ is related to λ_{max}. So, the increase maximum ($K_{BZBCG\text{-}H\text{-}A} = 5K_{AHBCG\text{-}H\text{-}A}$) is obtained with Q of $\lambda_{max} = 547$ nm, the lowest wavelength of all the amines, and with proton sponge of $\lambda_{max} = 630$ nm, the highest one, there is no increase ($K_{AHBCG\text{-}H\text{-}A} = K_{BZBCG\text{-}H\text{-}A}$). In a later section will be shown the double nature Hydrogen Bond Complex (HBC)-Ion Associate of this type of associates and as the character HBC increases when decreases λ_{max}. With proton sponge there is no increase because it can not form hydrogen bonds with the dye due to its particular structure [15,16], so that in this case Eqs. (2) and (5) are two neutralizations, which explains the low values of $K_{AHBCG\text{-}H\text{-}A} = K_{BZBCG\text{-}H\text{-}A} = 19\ 1 \times mol^{-1}$. The increase from $K_{AHBCG\text{-}H\text{-}A}$–$K_{BZBCG\text{-}H\text{-}A}$ in the HBC means that $BCGH^-BZ^+$ shows more ability than $BCGH^-AH^+$ species to form a hydrogen bridge through OH-phenol with the amine. Since the component dye is the same in the two associates (BCG^--H-Q), this must be due to the different nature of the cation (AH^+ or BZ^+). So, the positive charge in molecular structure of benzethonium cation, BZ^+, is buried or sterically hindered which would lead to an increase in the planarity of the dye ring system and to an easier formation of the hydrogen bridge (also this would explain the bathochromic effect when QH^+ is replaced by BZ^+). On the other hand, in AH^+ the positive charge is exposed to the molecular surface of the cation which could decrease the planarity of the dye ring system giving an associate with a lower λ_{max} and would make the formation of the hydrogen bridge more difficult. Moreover, the two protons in $BCGH^-AH^+$ could interchange which would make the formation of a hydrogen bridge with another Q molecule more difficult. This proton interchange is not possible in the $BCGH^-BZ^+$ species.

In Table 2 (upper part), it can be seen that ability to form hydrogen bonds, measured by $K_{AHBCG\text{-}H\text{-}A}$ or $K_{BZBCG\text{-}H\text{-}A}$ value, is related to the amine basicity which, could be measured by its pK_{AH^+} value in water. However, structure is also important since Q is less basic than atropine and homatropine in water and it has a higher capacity to form a hydrogen bridge; and proton sponge is the more basic of all amines and can not form hydrogen bonds. On the other hand, $K_{QACBCG\text{-}H\text{-}Q}$-

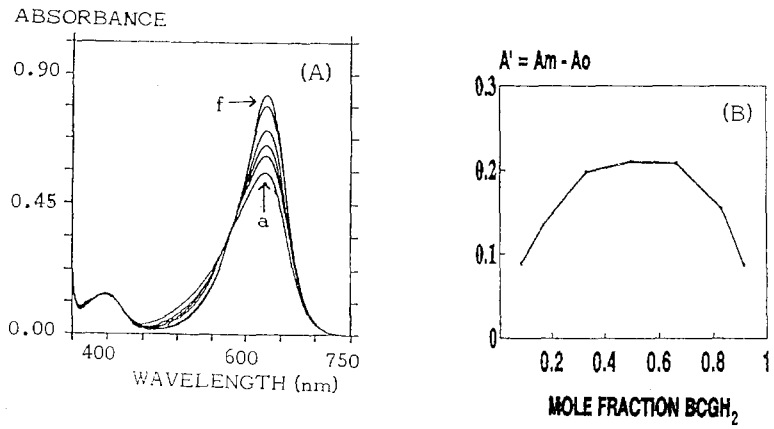

Fig. 3. (A) Visible-ultraviolet spectra of CH_2Cl_2 solutions of $BCGH_2$, 1.5×10^{-5} M; Q 2×10^{-3} M and different concentrations of BZ^+Cl^-, 1.5 (curve a), 4.5 (b), 10.4 (c), 23.7 (d), 79.4 (e), 150.2×10^{-6} M (curve f). T = 288.16 K. (B) Continuous variation plot for the reaction of BZ^+ BCG-H-Q with BZ^+Cl^-, in CH_2Cl_2. T = 288.16 K.

values with various ammonium ions using Q are also given in Table 2 (lower part). It can be seen that the highest increase from $K_{QHBCG\text{-}H\text{-}Q}$ – $K_{QACBCG\text{-}H\text{-}Q}$ is obtained when QAC is benzethonium (five times). This is consistent with the fact that the positive charge in molecular structure of BZ^+ is stronger buried or sterically hindered than in the other ammonium ions.

3.2. Ternary mixtures in an excess of benzethonium chloride

Until now, only one benzethonium cation, BZ^+, has been taking part in the described complexes. This is due to the fact that the anterior experiments have been carried out with an equimolar concentration of $BCGH_2$ and BZ^+Cl^-. In order to obtain and study in solution the $BCG^{2-}(BZ^+)_2$ ion associate, a ternary mixture of ratios $1{:}1{:}\gg 1$ ($[BCGH_2] = [BZ^+Cl^-] \ll [Q]$), at a concentration of Q sufficient to ensure the complete formation of BZ^+BCG^--H-Q species by Eq. (5), was registered (curve 'a' in Fig. 3A). To avoid the side reaction of the solvent due to the excess of Q [18], this solution was freshly prepared every time. Then increasing amounts of BZ^+Cl^- were added to the solution and the spectrum registered each time BZ^+Cl^- is added (b–f in Fig. 3A). These spectra showed an increase in absorbance at 630 nm while the maximum wavelength of absorption remained unvariable. This absorbance increase is attributed to the presence of a new species in the solution, the $BCG^{2-}(BZ^+)_2$ ion associate which, although with the same maximum wavelength as BZ^+BCG^--H-Q, has a higher molar absorptivity, and $\epsilon_{BCG(BZ)_2}$. This new species is formed after the breaking of the hydrogen bridge of the BZ^+BCG^--H-Q species as suggested by Eq. (7).

$$BZ^+BCG^- - H - Q + BZ^+Cl^- \rightleftarrows BCG^{2-}(BZ^+)_2 + Cl^-QH^+ \quad (7)$$

To demonstrate that in proportions $1{:}>1{:}\gg 1$ ($[BCGH_2] < [BZ^+Cl^-] \ll [Q]$), Eq. (7) is present in the solution. Job's method was used, following the guidelines explained in a previous paper [19] which takes into account the complete overlapping of the band of the reagent, BZ^+BCG^--H-Q, and the product, $BCG^{2-}(BZ^+)_2$. In accordance with the instructions given there [19], the Lambert-Beer can be expressed here as $A' = A_m - A_0 = x\ (\epsilon_{BCGBZ_2} - \epsilon_{BZBCG\text{-}H\text{-}Q}) = x\epsilon'$. A_m is the experimental absorbance of the system given by Eq. (7); A_0 is the absorbance due to the BZ^+BCG^--H-Q species this being equal to the total (or initial) dye concentration, $C^0_{BCGH_2}$, in the experiment multiplied by the molar absorptivity of the BZ^+BCG^--H-Q species ($A_0 = \epsilon_{BZBCG\text{-}H\text{-}Q}\ C^0_{BCGH_2}$. A_0 is equally to the absorbance found in a previous identical experiment where the species

BZ^+Cl^- is excluded; 'x' is the concentration of the products of Eq. (7), $\epsilon_{BCG(BZ)_2}$ the molar absorptivity of $BCG^{2-}(BZ^+)_2$ and $\epsilon_{BZBCG\text{-}H\text{-}Q}$ the molar absorptivity of the BZ^+BCG^--H-Q species. The difference between and $\epsilon_{BCG(BZ)_2}$ and $\epsilon_{BZBCG\text{-}H\text{-}Q}$ is the ϵ' value. To determine the stoichiometry of BZ^+BCG^--H-Q to BZ^+Cl^-, solutions of $BCGH_2$-BZ^+Cl^- and excess of Q (being $C^0_{BCGH_2} = C^0_{BZCl} \ll C^0_Q$ the BZ^+BCG^--H-Q species is generated immediately) were mixed with solutions of BZ^+Cl^-, such that $[BZ^+BCG^-\text{-H-Q}] + [BZ^+Cl^-] = 5.6 \times 10^{-5}$ M and their absorbances, A_m, measured at 630 nm. The stoichiometric balance of BZ^+BCG^--H-Q–BZ^+Cl^- was determined by plotting A′ values against the mole fraction of the $BCGH_2$ (equal to mole fraction of BZ^+BCG^--H-Q) as can be seen in Fig. 3B. The stoichiometry was always 1:1, which demonstrates that Eq. (7) is present in the solution.

Isoosbestic point in Fig. 3A and Coleman's test as used before suggest that Eq. (7) is a chemical equilibrium. The equilibrium constant of Eq. (7), $K_{BCG(BZ)_2} = [BCG^{2-}(BZ^+)_2]\,[Cl^-QH^+]/[BZ^+BCG^-\text{-H-Q}]\,[BZ^+Cl^-]$ and the molar absorptivity of the new ion associate could also be determined simultaneously from the values of the corrected absorbance, A′, and the concentrations of the reagents following an iterative method previously given for reactions of type $A + B \rightleftarrows C + D$, where A and C are exclusively absorbent [19]. The $K_{BCG(BZ)_2}$, ϵ' and thermodynamic parameters from the plot of $\ln K_{BCG(BZ)_2}\epsilon'$ against 1/T, the van't Hoff alternative plot [20,21], are given in Table 1 together with statistical indices. From ϵ' values in Table 1, $\epsilon_{BCG(BZ)_2} = 52\,000 \pm 4000$ l mol^{-1} cm at 298.16 K, was calculated being similar to that obtained by displacing Eq. (7) to the right with an strong excess of BZ^+Cl^- (curve 'f' in Fig. 3A). This last spectrum corresponds to the $BCG^{2-}(BZ^+)_2$ species. As the absorption peak and molar absorptivity of this species are similar to those of BCG^{2-}(ammonium$^+$)$_2$ using other ammonium ions, such as tetrabutylammonium or tetrapentylammonium (and to those of the BCG^{2-} anion in water [22]); thus, spectrum of $BCG^{2-}(BZ^+)_2$ species in CH_2Cl_2 is only due to the BCG^{2-} anion and ammonium ion only acts as the stabilizer of BCG^{2-} in the nonpolar solvent. Data on Table 1 suggest that $BCG^{2-}(BZ^+)_2$ species is not very stable and enthalpy and enthropy changes are similar to those usually observed in the ordinary ion-association formation reactions [16,17].

3.3. Resonance, nature and structure of associates

This section attempts to go further into this matter using new spectral data as such as IR and H^1-NMR spectra and also information from literature.

Resonance of associates, in particular that of the QH^+BCG^--H-Q and BZ^+BCG^--H-Q species, must be introduced to explain some of their properties of great analytical importance which were shown in the previous sections. Canonical resonance structures of $BCGH^-$ and BCG^{2-} anions in dichloromethane ($BCGH^-QH^+$, $BCGH^-BZ^+$, $BCGH^-Cl^-QH_2^{2+}$, $(BCGH^-)_2QH_2^{2+}$ and $BCG^{2-}(BZ^+)_2$ species) could be similar to those described in literature for both anions in water [29] because in dichloromethane cations of ion associates only act as the stabilizer of the anions as discussed before. So, visible absorption for $BCGH^-$ ion associates in dichloromethane would be mainly due to an one-sided quinonoid ring system and absorption for $BCGH^{2-}$ ion associates would be due to symmetrical structures with two alternative quinonoid rings as in water. These symmetrical ones are always more stable than the asymmetrical ones which would justify the peak at higher wavelength and the higher molar absorptivity of BCG^{2-} ion associates, (630 nm, $\epsilon_{BCG^{2-}} = 52\,000 \pm 4000$ l × mol^{-1} cm^{-1} at 298.16 K (Section 3.2) in dichloromethane, compared with that of the $BCGH^-$ anion (415 nm and $\epsilon_{BCGH^-} = 19\,500 \pm 500$ l × mol^{-1} cm^{-1} at 298.16 K) in the same solvent. The IR (KBr-disc) and H^1-NMR ($CDCl_3$) peaks of $BCGH^-QH^+$, $BCGH^-BZ^+$, $BCGH^-Cl^-QH_2^{2+}$, $(BCGH^-)_2QH_2^{2+}$ and $BCG^{2-}(BZ^+)_2$ associates are in agreement with the nature before assigned to these species. These associates were obtained at solid state by direct precipitation in water at pH = 1.5 and after recrystallized following a similar method to that

described previously [24] ($BCG^{2-}(BZ^{+})_2$ associate was obtained at pH = 9). So, IR spectra of associates containing Q show an absorption peak at 2580 cm^{-1} being similar to that shown by Q hydrochloride which according to literature [25] is assigned to ^{+}NH (quinuclidine). Therefore, the nitrogen of associates of Q is guaternary and they are ion associates in agreement with that previously discussed. The IR peak at 3480 cm^{-1} assigned to O–H in $BCGH_2$ or to $BCGH^{-}$ associates (KBr-disc) disappears in the $BCG^{2-}(BZ^{+})_2$ spectrum suggesting the presence of BCG^{2-} in the species and, therefore, confirming that it is in nature an ion associate, also in agreement with that previously discussed. Identical confirmation for associates nature containing Q was obtained by the ^{1}H-NMR spectra since these associates presented peaks at 3.20 (quartet), 2.03 (broad singlet) and 1.27 (broad triplet) ppm which are similar to those to the hydrogens of quinuclidine in Q hydrochloride [25]. This also suggests that the nitrogen of these associates is quaternary and that the hydrogen is completely transferred from the dye to Q.

Vis-UV absorption peaks and molar absorptivities in CH_2Cl_2 of ternary associates ($QH^{+}BCG^{-}$-H-Q, $BZ^{+}BCG^{-}$-H-Q and $BCG^{2-}(BZ^{+})_2$) are summarized in Table 3. These data justify the nature assigned to each and every of these species. Species $QH^{+}BCG^{-}$-H-Q, $BZ^{+}BCG^{-}$-H-Q have similar molar absorptivity but lower than that of BCG^{2-} anion (or $BCG^{2-}(BZ^{+})_2$ species), therefore, they do not contain the BCG^{2-} anion; they have a hydrogen bond. Different absorption peaks of $QH^{+}BCG^{-}$-H-Q and $BZ^{+}BCG^{-}$-H-Q associates in Table 2 could be explained by the different nature of the cation (QH^{+} or BZ^{+}). When a more polar solvent is used (acetone or ethanol) absorption peak and molar absorptivity of $QH^{+}BCG^{-}$-H-Q increases until it reaches that of the BCG^{2-} anion, in agreement with that in more polar solvents BCG^{2-} anion should be present. When this last experiment is carried out with $BZ^{+}BCG^{-}$-H-Q only molar absorptivity increases to reach that of the BCG^{2-} anion. Although species $BZ^{+}BCG^{-}$-H-Q (a 1:1:1 associate) is a HBC it has its peak at the same wavelength as the BCG^{2-} anion, so that their canonical resonance structures must contain both, BCG^{2-} anions and hydrogen bonds as shown in Scheme 1. Bottom left structure shows a BCG^{2-} anion and the other three structures show a HBC. This suggests that $BZ^{+}BCG^{-}$-H-Q species is of complex nature. As $\epsilon_{BCG^{2-}}$ is approximately equal to $2\epsilon_{BZBCG\text{-}H\text{-}Q}$ $BZ^{+}BCG^{-}$-H-Q species is mainly a HBC, although in a less proportion than $QH^{+}BCG^{-}$-H-Q species whose absorption peak and $\epsilon_{QHBCG\text{-}H\text{-}Q}$ indicate a purer hydrogen bond. Species $QH^{+}BCG^{-}$-H-Q is also of complex nature since its spectrum shows a shoulder at 630 nm in addition to the peaks at 415 and 547 nm as it can be seen in Fig. 1B, however, it is in a much higher proportion than $BZ^{+}BCG^{-}$-H-Q species a HBC (their canonical resonance structures are similar to those in Scheme 1 but substituting BZ^{+} by QH^{+}). Resonance hybrid of the H-bonded structure of the two ternary associates could justify their particular physicochemical properties as discussed before. An additional and complementary explanation for the batho- and hyperchromicity of associates containing BZ^{+} against to those containing QH^{+} (see Table 3) is that the substitution of BZ^{+} by QH^{+} increases the planarity of the dye ring system as explained in the previous section.

To obtain further information of the bond nature of ternary associates in $QH^{+}BCG^{-}$-H-Q and $BZ^{+}BCG^{-}$-H-Q species their ^{1}H-NMR spectra in $CDCl_3$ were recorded using TMS as an internal reference. Species were obtained in $CDCl_3$ by Eqs. (2) and (5). Peaks of hydrogens of quinuclidine in Q hydrochloride according to literature [25] appear at 3.20 (quartet), 2.03 (broad singlet) and 1.27 (broad triplet) ppm and peaks of Q free base appear at 3.00 (quartet), 1.75 (broad singlet). Peaks of ternary associates, obtained by

Table 3
Visible absorption maxima, λ_{max}, and molar absorptivities, ϵ, of ternary associates in CH_2Cl_2

Associate	λ_{max} (nm)	ϵ(L·mol^{-1} cm^{-1})
$QH^{+}BCG^{-}$-H-Q	547	26000 ± 2000
$BZ^{+}BCG^{-}$-H-Q	630	27000 ± 3000
$BCG^{2-}(BZ^{+})_2$	630	52000 ± 4000

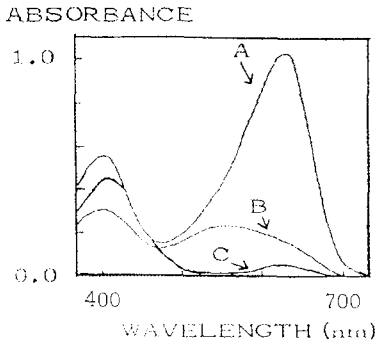

Fig. 4. Visible absorption spectra of dichloromethane phase of after extracting 100 ml of aqueous phase at pH = 8.4 with 10 ml of CH_2Cl_2 (CH_2Cl_2 reference). (A) Aqueous phase: $[BCGH_2] = 1.5 \times 10^{-4}$ M, $[BZ^+Cl^-] = 4 \times 10^{-6}$ M and $[Q] = 1.4 \times 10^{-5}$ M. (B) $[BCGH_2] = 1.5 \times 10^{-4}$ M and $[Q] = 1.4 \times 10^{-5}$ M. (C) $[BCGH_2] = 1.5 - 10^{-4}$ M and $[BZ^+Cl^-] = 4 \times 10^{-6}$ M. T = 293.16 K.

Eqs. (2) and (5) at 283.16 K, to increase the formation of these associates ($\Delta H°$ is negative), are close to those of Q hydrochloride suggesting that the amino nitrogen is almost quaternary so that a strong hydrogen bonding would probably be involved.

3.4. Extraction of associates in dichloromethane/water systems and its relation with the process in each phases

The present theory on extraction of ternary associates [7,26–28] cannot explain the relation between the extraction process and the processes which occur in each phase. In the following discussion an attempt will be made to deduce an equation which combines all the processes and to check it experimentally from our data and by the use of the data from literature.

Absorption spectra of dichloromethane phase after extracting from an aqueous phase containing a binary mixture ($BCGH_2$-Q or $BCGH_2$-BZ^+Cl^-) and a ternary mixture ($BCGH_2$-BZ^+Cl^--Q) at pH = 8.4 (ionic strength = 0.1) are presented on Fig. 4. Curve 'C' on this figure, corresponding to the $BCGH_2$-BZ^-Cl^- binary mixture, shows two peaks with maxima at 415 and 630 nm. If extraction of this mixture is carried out at pH = 4.7 then only absorption at 415 nm would be observed [1]. On the other hand, at pH = 12 only absorption at 630 nm will appear [26]. Spectra of the dichloromethane phase at pH = 4.7 and 12 are similar to those of the $BCGH^-BZ^+$ and $BCG^{2-}(BZ^+)_2$ species obtained in previous sections. Therefore, curve 'C' in Fig. 4 corresponds to a mixture of the two species in the dichloromethane phase. Similarly, curve 'B' corresponds to a mixture of $BCGH^-QH^+$ and QH^+ BCG^--H-QH species. The spectrum corresponding to the ternary mixture on Fig. 4 (curve 'A') is similar to that of the BZ^+BCG^--H-Q species (the 1:1:1 associate) obtained before, which indicates that curve 'A' corresponds to this species. Therefore, species obtained by extraction can also be obtained by reaction in a single dichloromethane phase. This, last method makes it study easier. For example, our work confirms a 1:1:1 stoichiometry for associate extracted from ternary mixture (curve 'A') which was unclear from other extraction studies [7]. Although stoichiometry of associates in binary extraction studies was clear, this one is confirmed again in this paper by study in a single dichloromethane phase. The nature and structure of associates is also described better by this method as shown in the previous sections. Other advantages of studying associates in a single organic phase will be shown later.

The extraction constant for the Q, E_Q, in the partition experiment could be defined by Eq. (8):

$$E_Q = [Q]_{org}[H^+]/[QH^+] = k_{d(Q)}K_{QH^+} \quad (8)$$

being $[Q]_{org}$ the Q concentration in organic phase, $[H^+]$ and $[QH^+]$ are the concentrations of those species in aqueous phase in a partition experiment using only Q. The extraction constant, E_Q, is a true constant since it can also be written as the product $k_{d(Q)}K_{QH^+}$, being K_{QH^+} the second dissociation constant acid in water, w, for Q ($K_{QH^+} = [Q]_w[H^+]/[QH^-]$) and $k_{d(Q)}$ its partition coefficient defined by $k_{d(Q)} = [Q]_{org}/[Q]_w$. Therefore, extraction constant, E_Q, represents a global constant of the two processes. As in literature the product $k_{d(Q)}K_{QH^+}$ (equal to E_Q) is $10^{-6.26}$ mol × l^{-1} in the dichloromethane/water system [2]; experiments of partition with only guinine were not necessary to be carried out.

The extraction constant of the $BCGH^-BZ^+$ ion pair, E_{BCGHBZ}, could be written by Eq.:

$$E_{BCGHBZ} = [BCGH^-QH^+]_{org}/[BCGH^-][BZ^+] \quad (9)$$

where $[BCGH^-BZ^+]_{org}$ is the concentration of the ion pair in organic phase, $[BCGH^-]$ and $[BZ^+]$ are the concentrations of these species in aqueous phase. The E_{BCGHBZ} value was determined by partition experiments in dichloromethane/water systems containing dye and BZ^+Cl^- at various pH from 5 to 7, according to Schill method described for Bromothymol Blue [2]. The value obtained was $10^{8.96}$ $l \times mol^{-1}$.

Extraction constants for ternary associates (QH^+BCG^--H-Q, BZ^+BCG^--H-Q and $BCGZ^{2-}(BZ^+)_2$) into a two phase system would be

$$E_{QHBCG-H-Q} = \frac{[QH^+BCG^- - H - Q]_{org}}{[BCG^{2-}][QH^+]^2} \quad (10)$$

$$E_{BZBCG-H-Q} = \frac{[BZ^+BCG^- - H - Q]_{org}}{[BCG^{2-}][BZ^+][QH^+]} \quad (11)$$

$$E_{BCG(BZ)_2} = \frac{[BGC^{2-}(BZ^+)_2]_{org}}{[BCG^{2-}][BZ^+]^2} \quad (12)$$

where $[]_{org}$ is the concentration of the associate in organic phase and [] is the concentration of the species in aqueous phase. A very useful decomposition for $E_{BZBCG-H-Q}$ is given by the following equation:

$$E_{BZBCG-H-Q} = E_{BCGHBZ}E_Q K_{BZBCG-H-Q}K^{-1}_{BCGH} - \quad (13)$$

where $K^{-1}_{BCGH} - (K^{-1}_{BCGH} - = [BCGH^-]/[BCG^{2-}][H^+])$ is the inverse of the second dissociation acid constant of $BCGH_2$ which is [23] $10^{4.66}$ $mol \times l^{-1}$. Eq. (13) is obviously satisfied since it really corresponds to a decomposition of the extraction constant, which must be considered the global constant of all processes into the two phases. Eq. (13) shows the important and quantitative relation between the extraction process of the 1:1:1 ternary associate and that of association ($K_{BZBCG-H-Q}$) which was studied in a previous section. By this equation $E_{BZBCG-H-QH}$ was $10^{12.47}$ $l \times mol^{-1}$. An approximate calculation for $E_{QHBCG-H-Q}$ and $E_{BCG(BZ)_2}$ from data on Fig. 4 leads to, $10^{10.81}$ and $10^{4.04}$ $l \times mol^{-1}$. Therefore, $E_{BZBCG-H-QH} > E_{HBCG-H-Q} > E_{BCG(BZ)_2}$. Eq. (13) can be generalized for any dye (DH_2), amine (A) and QAC as shown in Eq. (14), which will be discussed in the next section.

$$E_{QACD-H-A} = E_{DHQAC}E_A K_{QACD-H-Q}K^{-1}_{DH} - \quad (14)$$

3.5. Analytical applications. The high extractability and selectivity of 1:1:1 associates containing Q

In the following discussion an attempt will be made to explain different extractabilities of the ternary associates from a qualitative point of view by the use of theories from literature and from a quantitative point of view by the Eq. (14) deduced before.

High extractability of BZ^+BCG^--H-Q species in comparison with the other ones in Fig. 4 for the ternary mixture at pH = 8.4 is the great analytical interest and can be explained by three factors. The first one is the high pH level at which the divalent anion, BCG^{2-}, will be present in the aqueous phase, so that extraction of associates of $BCGH^-$ (yellow associates) must be poor as shown in this figure and discussed in the last section. The second one, the different nature of the ternary associates (QH^+BCG^--H-Q, BZ^+BCG^--H-Q and BCG^{2-} $(BZ^+)_2$ species) which justifies that $E_{BCG(BZ)_2}$ value and therefore extractability of BCG^{2-} $(BZ^+)_2$ species is the lowest of the three ternary associates. So, BCG^{2-} $(BZ^+)_2$ species is in nature an ion associate of a divalent anion, therefore less extractable than QH^+BCG^--H-Q and BZ^+BCG^--H-Q species, in which the dye acts almost as monovalent (BCG^--H-Q) due to the hydrogen bridge with Q. Associates of a divalent anion are less extractable because they attach strongly water molecules by their two charges in the aqueous phase which must be released after neutralization with the two cations. The release of water molecules and extraction of the ion-associate is easier with a monovalent anion since water molecules are more weakly attached in this last case [6]. The third

factor, is the different cation in QH^+BCG^--H-Q and BZ^+BCG^--H-Q species which must justify that $E_{BZBCG\text{-}H\text{-}QH} > E_{QHBCG\text{-}H\text{-}Q}$, since they have the same anion (BCG^--H-Q). So, in benzethonium cation, BZ^+, water molecules can not approach the cationic nitrogen, because the nitrogen atom is surrounded by bulky groups therefore, according to literature this kind of cation will show high ion-associability and its ion associate with univalent anion (BCG^--H-Q) will be easily extracted. On the other hand, in protonated Q, QH^+, the charge is jutting out into water and is slightly hydrated which will hinder the extraction of its ion associate with the anion BCG^--H-Q. This explains that extractability of BZ^+BCG^--H-Q be higher than QH^+BCG^--H-Q and consequently $E_{BZBCG\text{-}H\text{-}Q} > E_{QHBCG\text{-}H\text{-}Q}$. Moreover, at pH = 8.4 (Fig. 4), extraction of QH^+BCG^--H-Q species is difficult because $[QH^+]$ will be low in aqueous phase ($pK_{QH^+} = 8.3$) and, in Eq. (10), $[QH^+BCG^-\text{-H-Q}]$ depends on $[QH^+]^2$.

Eq. (13) or Eq. (14) is the fundamental equation for extraction of any 1:1:1 associate. It shows that if the same dye and amine are used (for example $BCGH_2$ and Q); extraction of 1:1:1 species is mainly based on the high extractability of the ammonium cation (high $E_{BCGHQAC}$-value) and on the strength of the hydrogen bond between the second proton of the dye and amine ($K_{QACBCG\text{-}H\text{-}Q}$ -value in this example) since the product $E_Q K_{BCGH}^{-1}$ in Eq. (14) (A is Q and D is $BCGH_2$) is identical for all the QAC. In the lower part in Table 2 are given $E_{BCGHQAC}$ (obtained in similar way to E_{BCGHBZ}), and $K_{QACBCG\text{-}H\text{-}Q}$ and, from these constants, $E_{QACBCG\text{-}H\text{-}Q}$ values were computed by Eq. (14) using different QAC. The low $E_{QACBCG\text{-}H\text{-}Q}$ values, except when Benzethonium was used, indicated that extraction of ammonium ions of short chains as 1:1:1 associates is negligible. On the other hand, in the upper part in Table 2, extraction constants, $E_{BZBCG\text{-}H\text{-}A}$, for different amines using Benzethonium and $BCGH_2$ were also calculated by Eq. (14) (E_A and $K_{BZBCG\text{-}H\text{-}A}$ determined by the same method given for Q in previous sections). The low values of $E_{BZBCG\text{-}H\text{-}A}$ indicate that extraction of amines as 1:1:1 associates must be negligible except when Q is used. Both, not interference of amines and QAC were experimentally confirmed because spectrum of ternary mixture on Fig. 4 did not change after addition of amines and ammonium ions of Table 2 in the usual concentration ranges of the analytical methods. These results show why using Q high extractability and selectivity of 1:1:1 species containing benzethonium is obtained and they also explain why benzethonium could be quantitative determined using the two phase method without interference of some other amines and QAC [7]. This analytical method for QAC, based on extraction of a 1:1:1 species, is very important because of its enhanced selectivity since this is the main problem of this type of analytical methods in the literature [28–30].

As before mentioned, according to Eq. (14) if $BCGH_2$ is used, high extractability of an 1:1:1 species is based on high values for $K_{QACBCG\text{-}H\text{-}A}$ and $E_A = k_{d(A)}K_{AH^+}$. Q provides the best values for the three constants because Q with low pK_{QH^+} (high K_{QH^+}) has a high capacity to form hydrogen bridges (high $K_{QHBCG\text{-}H\text{-}Q}$ or $K_{BZBCG\text{-}H\text{-}Q}$ values) having, moreover, a high $k_{d(Q)}$ (Table 2). In Table 2, tropine ($pK_{AH^+} = 11.73$) has a higher $K_{AHBCG\text{-}H\text{-}A}$ value than Q but its pK_{AH^+} is much higher and its $k_{d(A)}$ is lower so that, taken into account Eq. (14), its 1:1:1 ternary associate will not be extracted (see in Table 2 its low $E_{BZBCG\text{-}H\text{-}A}$-value). Although in the future other amine with better values of the three constant than Q could be found, extraction of its 1:1:1 associate will not be selective among QAC of similar extractability (as for example Benzalkonium or tetrapentylammonium) because according to Eq. (14), $E_{QACD\text{-}H\text{-}A}$ will be similar with similar ammonium compounds. This limitation is inherent to the procedure of determination of QAC based on extraction of a 1:1:1 associate using any amine and dye. Consequently, although by this method the selectivity is enhanced, it presents the general limitation of the analytical methods based on the extraction of ion associates.

Finally, Eq. (14) also permits to study other dyes, moreover $BCGH_2$. But when K_{DH}^{-1}- increases, $K_{BZD\text{-}H\text{-}A}$ decreases and conversely; so that, according to Eq. (14), other dyes do not improve much the quantitative determination of Benzethonium (or other ions of similar ex-

tractability, such as Benzalkonium or Berberine) with $BCGH_2$. This result has been shown experimentally in extraction studies with other dyes [28].

4. Conclusions

Identical associates of a dye, ammonium salt and guinine can be obtained by association reactions in a single dichloromethane phase as by extraction in a dichloromethane/water two phase system. Nature and physicochemical properties of associates are described better from studies of association reactions in the extraction solvent as a single phase. A new method to study associates in ternary mixtures in a single dichloromethane phase is put forward and it can be used for the dye-amine-ammonium salt system. After mixing in dichloromethane $BCGH_2$, Benzethonium chloride (BZ^+Cl^-) and Q five associates can be generated: $BCGH^-QH^+$, $BCGH^-BZ^+$, $BCG^{2-}(BZ^+)_2$, QH^+BCG^--H-Q and BZ^+BCG^--H-Q (the 1:1:1 associate). The spectrophotometric properties (Vis-UV, IR, ^{1}H-NMR) suggest that the first three associates are ion associates in nature while the two last ones present a hydrogen bridge. All the associates are in nature resonance hybrids which justifies the high values of the equilibrium constants and thermodynamic parameters of associates containing a hydrogen bonding. Extraction in a two phase system must be considered a global process of the processes which occur in each of the phases. A new and fundamental equation can be deduced to govern quantitatively the relation of the global process into the two phase system with the processes in each of the two phases. This equation suggests that extraction of a 1:1:1 associate (for example BZ^+BCG^--H-Q species) is primarily based on the high ion associability of the QAC (measured for its E_{BCGHBZ}-value) and secondarily it is based on the high capacity to form hydrogen bond of the amine (its $K_{QACD\text{-}H\text{-}A}$-value) with a not too high value of its dissociation constant in water ($pK_{QH^+} = 8.3$). As Q and Benzethonium have the best values of those constants, its 1:1:1 associate is selective against the QAC of short hydrophobic chains (low ion associability) and amines in general. However, extraction of this 1:1:1 associate is not selective among QAC of similar hydrophobic chains. This is the classic limitation of the known analytical methods based on extraction of ion associates which the 1:1:1 method will not be able to surpass although in the future other amine with higher capacity to form hydrogen bridges than Q could appear.

Abstract

A quick and very sensitive method is proposed for the determination of the insecticide carbaryl, following transformation in 1-naphthol, using solid-phase fluorescence excited by a pulsed nitrogen laser and detected with a charge-coupled device. Carbaryl is hydrolized in an alkaline medium resulting in 1-naphthol. This hydrolysis product is fixed on QAE Sephadex A-25 gel at pH 11.20. The fluorescence of the gel, packed in a 1 mm silica cell, was measured directly using a solid-surface attachment. The detection limit obtained was 1.8 ng. A recovery study was carried out on several types of water samples to check the efficiency of the method. The results obtained are compared with data published in a previous paper where the LS-50 spectrofluorimeter was used. The detection and quantification limits are improved here by an order of magnitude. © 1997 Elsevier Science B.V.

Keywords: Carbaryl; Solid-phase laser-induced fluorescence; Water analysis

1. Introduction

Carbaryl (1-naphthyl-N-methylcarbamate) is one of the major active ingredients of widely applicable insecticides [1–3]. Along with its relatively short half-life various studies have indicated that both carbaryl and its hydrolysis product 1-naphthol may cause toxic effects by the inhibition of the enzyme cholinesterase and by their teratogenic character [4–6]. Consequently, the determination of carbaryl residues in natural water is clearly important. Various methods have been proposed for its determination in formulations, crops, waters and soils. They usually involve a chromatographic separation, such as TLC [7,8], GC [9,10] or HPLC [11–17], in order to avoid matrix interferences.

Molecular luminescence techniques provide very sensitive methods of analysis and several spectrofluorimetric methods have been proposed for carbaryl determination based on its native fluorescence [18–21].

The use of lasers as sources in molecular luminescence has several potential advantages over traditional non-coherent light sources [22]. Since the radiance of a laser is greater than that of the traditional blackbody sources, laser excitation increases the sensitivity of fluorometric methods,

PII S0039-9140(96)02089-9

and often improves the observed limits of detection [23]. With increasing source intensity, and the onset of saturation, an increased linear dynamic range and freedom from quenching effects can be observed. In addition, the narrow spectral width of the laser source results in slightly narrower fluorescence peaks and, therefore, in higher selectivity. Recent advantages in charge-coupled device (CCD) image detector technology have brought its application to analytical spectroscopy because they offer negligible dark current, high quantum efficiency, low readout noise, wide dynamic range, and the ability to bind photogenerated charge from multiple pixels [24–26]. CCDs are thus, the detectors of choice, in particular if the multiplex advantage can be fully exploited. This results in lower limits of detection, more rapid analysis, the opportunity to use lower power and less expensive lasers.

In this paper, we demonstrate the versatility of the solid-phase fluorescence method [27] by applying a pulsed nitrogen laser as the excitation source and a charge-coupled device camera for the fluorescence detection of carbaryl, via transformation in 1-naphthol, in natural waters. The solid-phase fluorescence combines the direct measurement of solid-surface signal using a small amount of a suitable solid support to preconcentrate the analyte. The results obtained are compared with data reported in our previous paper [28], where a LS-50 spectrofluorimeter was used.

2. Experimental

2.1. Instrumentation

Fig. 1 shows a block diagram of the system setup. A pulsed nitrogen laser (Laser Photonics, model UV-12, wavelength 337.1 nm, pulse duration 10 ns) was used to irradiate the sample at room temperature in air at atmospheric pressure. The laser was focused onto the sample with a quartz planoconvex lens with a focal length of $f = 45$ mm. The laser energy measured on the sample surface by using an energy-meter Gentec was 2 mJ. Fluorescence was collected onto the entrance slit of a triple indexable grating spectrograph (Acton Research Corporation, model SpectraPro 275, Czerny-Tuner; $F/3.8$), fitted with classically ruled gratings of 300, 600 and 1800 grooves/mm. Optical collection was performed with a glass biconvex lens with focal length of 10 cm. The spectrometer entrance slit was 15 mm high by 20 μm wide. The area of the spot of laser radiation illuminating the sample was 900 × 100 μ^2 measured by using a 6X JUNIOR SIZE COMPARATOR magnifying glass equipped with a micrometric scale. A solid-state two-dimensional charge-coupled device (CCD) (EG&G PAR, Thomson CSF, THX-31195A) was used to detect the fluorescence. The CCD consists of 512 × 512 elements each being 19 μm × 19 μm. The active area is 9.7 mm × 9.7 mm. The CCD was cooled to − 60°C by a Peltier system. When cooled to − 60°C, this detector exhibits a dark current of 10 photoelectrons pixel^{-1} s^{-1} and a readout noise of 4–5 electrons per scan. For data acquisition, the CCD system was optically triggered with a beam deflected from the laser and a fast photodiode. Operation of the detector was controlled by a personal computer with Optical Multichannel Analyzer (OMA) Spec 4000 software. The spectrometer is connected to the controlling PC by a conventional IEEE-488 general-purpose interface bus (GPIB).

For comparison to the proposed system, a commercial spectrofluorimeter was also used, the Perkin Elmer Model LS-50 equipped with a Xenon discharge lamp (20 kW), Monk-Gillieson monochromators, a Quantic Rhodamine 101

counter to correct the excitation spectra and a Gated photomultiplier. The luminescence spectrometer was interfaced with a Mitac MPC 3000F-386 microcomputer supplied with FL Data Manager software for spectral acquisition. The excitation and emission slits were both maintained at 2.5 nm. The scan rate of the monochromators was maintained at 240 $nm \cdot min^{-1}$.

A Crison 501 digital pH-meter with saturated calomel and glass electrodes and an Agitaser 2000 rotating agitator were also used.

2.2. Reagents

All reagents were of analytical-reagent grade unless stated otherwise. Stock solutions of Carbaryl (Riedel-de Haën) and 1-Naphthol (Merck) with a concentration of 100 $mg \cdot l^{-1}$ were prepared by exact weighing of the reagent and dissolution in ethanol 96% (v/v) (Panreac). Working solutions were prepared by adequate dilution with deionized water. These solutions were stored in a dark bottle at 4°C remaining stable for at least 6 months.

QAE Sephadex A-25 dextran type anion-exchange gel (Sigma) was used in the chloride form and without pre-treatment in order to avoid contamination.

2.3. Treatment of water samples

Water samples were filtered through a cellulose acetate filter (0.45 μm pore size, Millipore HAWP 04700) and collected in dark glass bottles previously cleaned with hydrochloric acid and washed with deionized water. The samples were stored at 4°C until analysis which was performed with the minimum possible delay [29].

2.4. Basic procedure for analyzing carbaryl

A 500 ml water sample containing between 0.07 and 40.0 $\mu g \cdot l^{-1}$ of carbaryl was transferred into a glass bottle, and 10 ml of 0.1 M NaOH solution and 100 mg of QAE Sephadex A-25 gel were also added. The mixture was shaken mechanically for 10 min after which the gel beads were collected by filtration under suction and packed in a 1 mm silica cell together with a small volume of the filtrate with the aid of a pipette. A blank solution containing all the reagents except carbaryl was prepared and treated in the same way as described above.

For each concentration of analyte, ten scans were taken, and the average of the peak heights was used in the calibration curve.

The measured relative fluorescence intensity (RFI) of the gel beads containing the fluorescent product was the diffuse transmitted fluorescence (DTF) emitted from the gel at the unexcited surface of the cell. The optimum angle formed between the cell plane and the excitation beam was 45° in all instances [27].

2.5. Procedure for water samples

A volume of natural water sample containing an adequate amount of carbaryl was levelled off to 500 ml with deionized water, placed in a glass bottle and 10 ml of 0.1 M NaOH solution and 100 mg of QAE Sephadex A-25 gel were added. The mixture was shaken mechanically for 10 min and then treated as described under Basic Procedure. The standard addition method was used for calibration purposes.

3. Results and discussion

3.1. Spectral characteristics

Fig. 2 compares the emission spectra of the carbaryl hydrolized-gel system taken with (a) the LS-50 spectrofluorimeter and (b) the pulsed nitrogen laser system. The excitation wavelength of 337.1 nm provided by the nitrogen laser is very close to the excitation maximum of the system located at 333 nm when the LS-50 spectrofluorimeter is used.

The differences between the spectra are worth noting. While in the Fig. 2a the emission maximum wavelength is located at 450 nm, the spectrum obtained with laser excitation (Fig. 2b) shows a shoulder at this position, but the maximum emission is now at 485 nm. This spectral shape is very similar to the phosphorescent signal

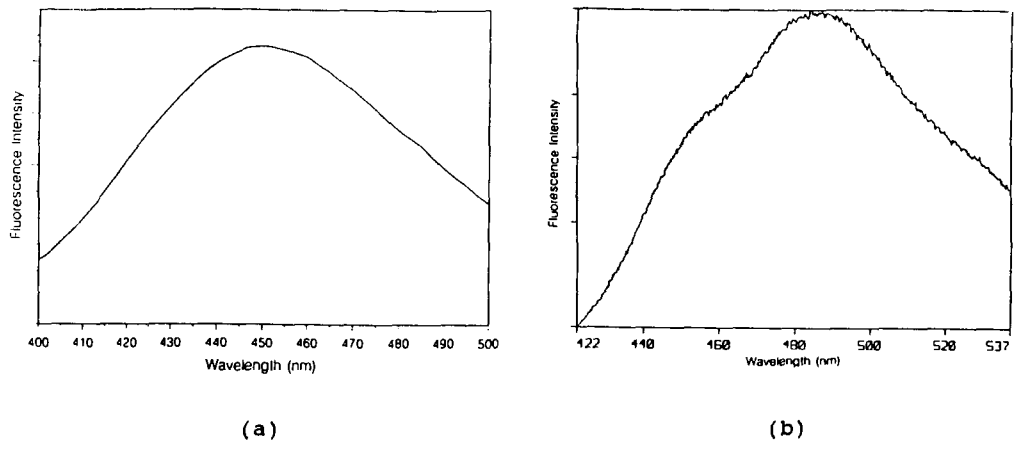

Fig. 2. Emission spectra of carbaryl hydrolized-gel system taken with (a) the LS-50 spectrofluorimeter maintaining an excitation wavelength of 333 nm and (b) the pulsed nitrogen laser system.

emitted by carbaryl and 1-naphthol using Whatman N°1 chromatography paper as the solid support [30]; however, these two compounds, in the absence of a heavy atom, show another maximum phosphorescent emission at room temperature located at 515 nm.

From a study of the half-life of the excited state of the system in the solid phase, it was concluded that the luminescence process was fluorescence because τ is lower than 10 ns, i.e., the pulse duration. Campligia et al. found phosphorescence lifetime values of 1185 ± 121 and 1083 ± 267 ms for carbaryl and 1-naphtol fixed on chromatographic paper in the absence of a heavy atom.

3.2. Experimental variables

As we reported in a previous paper [28], carbaryl shows native fluorescence in neutral and acidic media but, is not fixed on QAE Sephadex A-25 at pH values lower than 8.0. Its hydrolysis product, 1-naphthol, exhibits fluorescence in basic media only, and is quantitatively fixed on QAE-gel at pH higher than 11.0, showing fluorescence with excitation and emission maxima at 333 nm and 450 nm, respectively.

The optimum pH for the simultaneous hydrolysis and fixation of the carbaryl was found to be 11.20 fixed with an adequate volume of NaOH 0.1 M solution.

The fluorescence intensity was shown to be independent of the ionic strength, adjusted with NaOH, NaCl and $NaClO_4$ up to $1.5\ 10^{-4}$ M.

The shaking time necessary for maximum RFI development (with the hydrolysis step and fixation in the gel phase taking place simultaneously) was 10 min, remaining constant thereafter.

The addition order of the reagents did not affect the results obtained. The order used was carbaryl, buffer and gel.

As the use of a large amount of the gel lowered the RFI, only the amount required to fill the cell and facilitate handling the 100 mg was used in all measurements.

With regard to the stability of the QAE-carbaryl hydrolized system, Fig. 3 shows different spectra of the same sample taken at intervals of 10 min. The sample was constantly irradiated. The fluorescence emitted remained constant for at least 1.5 hours regardless of the radiation received.

3.3. Analytical parameters

The calibration graphs for samples treated according to the procedure described above are linear for the concentration range 0.07–40.0 $\mu g \cdot l^{-1}$ for a 500 ml sample volume. To check the linearity of the calibration standard, the lack-of-fit test [31] was applied for ten replicates of each standard.

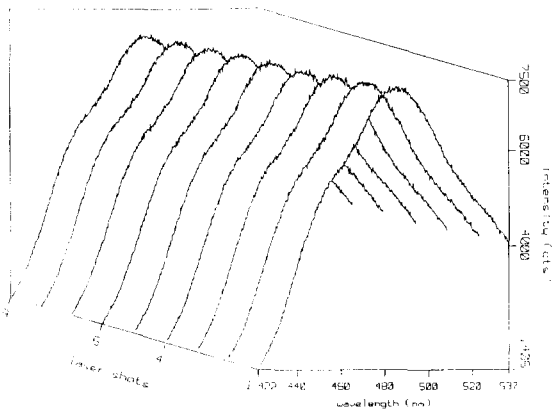

Fig. 3. Spectra of QAE-carbaryl hydrolized system taken at intervals of 10 min.

Table 1 shows the results obtained for the analytical parameters of the proposed method and those obtained previously by using a commercial LS-50 spectrofluorimeter. The precision determined as relative standard deviation (RSD) was measured for a carbaryl concentration of 10 and 30 $\mu g \cdot l^{-1}$, respectively, for each excitation system, by performing ten independent determinations.

The IUPAC detection limit ($K = 3$) and the quantification limit ($K = 10$) were calculated for 500 ml sample volume (Table 1) through 10 individual samples prepared according to the procedure without analyte in both cases. The detection limits are given in bulk concentration and amount of analyte in laser probe volume for the laser system.

It is worthy of note that the detection and quantification limits obtained in this case are one order of magnitude below those found with the LS-50 spectrofluorimeter.

Table 1
Analytical parameters obtained with a commercial spectrofluorimeter (Perkin Elmer LS-50) and the laser system

Parameters	Values found	
	Laser system	LS-50 commercial
Slope ($l \cdot \mu g^{-1}$)	651.97	6.93
Correlation coefficient	0.999	0.998
Lack-of-fit test (P-value)	0.22	—
Linear Dynamic Range ($\mu g \cdot l^{-1}$)	0.07–40.0	0.4–60.0
LOD[a] ($\mu g \cdot l^{-1}$)	0.02	0.1
LOD (ng)	1.8	—
LOQ[b] ($\mu g \cdot l^{-1}$)	0.07	0.4
RSD (%)	2.4	0.9

[b] Limit of quantification.

4. Applications to real samples

We tried to find carbaryl in ground water from the Santa María farm located near Granada and tap water from the city's supply but we did not find this insecticide above our DL.

To check the accuracy of the proposed method, a recovery study was carried out on various types of sample waters. The volume of water used was 500 ml in all instances and three determinations were required for each sample tested. Table 2 summarizes the values obtained. In all instances the values found were close to 100%.

Validation of the proposed method for natural water was also carried out, through a standard addition of carbaryl to the different types of water samples. The t-test was applied to check the similarity between the representative values of the slope of standard calibration and standard addition calibration obtained by standard additions of carbaryl to natural water samples. The statistics used [32] is calculated with the following equation:

$$t(b) = \frac{|b_S - b_A|}{s_p \sqrt{\frac{1}{\sum(c_{i,S} - \bar{C}_S)^2} + \frac{1}{\sum(c_{i,A} - \bar{C}_A)^2}}}$$

In this equation, b_A and b_s are the slopes of standard addition calibration (AC) and standard calibration (SC), respectively; s_s represents the regression standard deviation of SC; $c_{i,A}$ and $\bar{C}_A$ the concentration of added standard set used in AC and the average concentration of this set; and $c_{i,S}$ and $\bar{C}_S$ the concentration of standard set used in SC and the average concentration of the same set.

Table 2
Recovery assays of carbaryl in water samples

Water	Added ($\mu g \cdot l^{-1}$)	Found[a] ($\mu g \cdot l^{-1}$)	Recovery (%)	RSD (%)
Tap (Granada City)	1.0	0.95	95.0	2.0
	10.0	10.74	107.4	1.5
	20.0	19.50	97.5	2.8
	40.0	38.91	97.3	0.9
Ground (Santa María Farm)	1.0	1.07	107.0	3.2
	10.0	10.85	108.5	1.4
	20.0	19.16	95.8	2.7
	40.0	41.03	102.6	2.9

[a] Mean of three independent determinations.

The null hypothesis is accepted for a significance level (P value) greater than 10% (the usual value of 5% should not be used because this test is excessively robust). The Student's t and P values calculated were 0.652 and 52.6% for ground water and 0.754 and 46.5% for tap water, respectively. In both cases, $P > 10\%$; thus, we may conclude that there are no matrix effects and the method is accurate.

As already reported in the previous paper and subsequently tested following the proposed method, the usual levels of the different ions present in the waters sampled do not interfere with carbaryl recovery. The usual chlorine level in local tap water (O.6 $ng \cdot ml^{-1}$) did not produce any interference either.

Flame atomic absorption spectrometric determination of zinc after colloid precipitate flotation with hydrated iron(III) oxide and iron(III) tetramethylenedithiocarbamate as collectors

Katarina Čundeva, Trajče Stafilov *

Institute of Chemistry, Faculty of Science, St. Cyril and Methodius University, Skopje, Macedonia

Received 1 July 1996; received in revised form 28 August 1996; accepted 4 September 1996

Abstract

Colloid flotation of zinc from fresh water with a combination of two collectors, hydrated iron(III) oxide ($Fe_2O_3 \cdot xH_2O$) and iron(III) tetramethylenedithiocarbamate ($Fe(TMDTC)_3$), permits rapid separation of the precipitate before its atomic absorption spectrometric (AAS) analysis. All important parameters necessary for the successful flotation like optimal mass of collectors, pH of the medium, electrokinetic potential of the collector particle surfaces, type of tenside, induction time etc., were checked. At the optimal pH value of medium (5.5) establishing by recommended procedure, zinc was separated quantitatively (97.4–98.8%) with 5 mg Fe(III) as constitutive element of the two collectors used. The content of zinc was determined by flame atomic absorption spectrometry (FAAS). These results were compared with the results obtained by inductively coupled plasma—atomic emission spectrometry (ICP-AES). The FAAS detection limit for zinc is 9.4 $\mu g\ l^{-1}$. The proposed method is simple, rapid and applicable to the zinc separation at $\mu g\ l^{-1}$ levels from a large volume of water. © 1997 Elsevier Science B.V.

Keywords: Determination; Flame atomic absorption spectrometry; Precipitate flotation; Zinc

1. Introduction

In the recent years there has been an increased interest in the separation of trace heavy metals from large volumes of dilute aqueous solution by flotation techniques [1–10]. These techniques were developed to extend the range of analysis to trace concentration of heavy metals in natural waters by divers instrumental methods which follow the flotation [1–3]. There are reports of zinc separation by colloid precipitate flotation using hydrated metal oxides like $Fe_2O_3 \cdot xH_2O$ or $Al_2O_3 \cdot xH_2O$ as collectors [1–5] or by ion flotation with divers dithiocarbamates [6,8]. This paper is the first attempt for flame atomic absorption spectrometry (FAAS) determination of zinc after its preconcentration by colloid precipitate flotation using a combination of two colloid collectors $Fe_2O_3 \cdot xH_2O$ and $Fe(TMDTC)_3$. The same combination of collectors have been applied [9] for separation of several metals from sea water using neutron activation, but not for zinc. The necessity

PII S0039-9140(96)02095-4

of the first induction time [1,10] for a coprecipitation step of flotation with $Fe_2O_3 \cdot xH_2O$ as first collector was investigated. The improvement of the zinc preconcentration by using $Fe(TMDTC)_3$ as second collector was studied. The method developed is simple, rapid (need about 30 min) and applicable for Zn determination from a large volume of fresh water. This method can be compared with differential pulse anodic stripping voltammeter (DPASV) with hanging mercury electrode or mercury film electrode which achieve detection limits for zinc (1 $\mu g\, l^{-1}$ or less) and need short analysing time (about 15 min) [11–13].

2. Experimental

2.1. Apparatus

Apparatus employed in this work have been previously described [10]. For AAS measurements an air-acetylene flame was applied. The Zn Perkin–Elmer hollow cathode lamp was used as a primary source. Instrumental parameters are shown in Table 1. Inductively coupled plasma-atomic emission spectrometric measurements (ICP-AES) were performed by Varian spectrometer Model Liberty 110. The flotation cell used to carry out the preconcentration was a glass cylinder (4 × 105 cm) with a sintered glass disc (porosity No. 4) at the bottom to generate air bubbling.

2.2. Reagents and standards

All chemicals used for preparation of solutions, were of an analytical-reagent grade except for sodium dodecylsulfate (NaDDS) and sodium oleate (NaOL). The aqueous solutions were prepared in redistilled water.

Table 1
Optimal instrumental parameters for FAAS determination of Zn

Wavelength	213.8 nm
Spectral bandpass	2.0 nm
Lamp current	15.0 mA

Stock solution of Zn was made from $ZnSO_4 \cdot 7H_2O$ as 1 mg ml^{-1} solution. Before each investigation standard solutions were freshly prepared by diluting this stock solution. The stock solution of $FeCl_3$ (30 g l^{-1}) was made in the same way, as previously described [10]. Series of standards with concentrations of Fe ranging from 2.5 to 100 mg ml^{-1} were obtained by dilution this Fe stock solution. The diluted standards of Zn and Fe serve to investigate the optimal conditions for performing the flotation procedure, to obtain data for construction the calibration curve (concentration absorbance) and for the method of standard additions of the natural water analysis. By dissolving an appropriate quantity of ammonium tetramethylenedithiocarbamate (NH_4TMDTC) in water the stock solution was prepared as 0.1 mol l^{-1}. Before each flotation the solution of NH_4TMDTC was filtered. The 0.5% solutions of tensides used were prepared by dissolving appropriate amounts of NaDDS and NaOL in 95% ethanol. The pH of the working solutions was regulated by 0.1 mol l^{-1} solution of HNO_3 and 2.5 and 10% solutions of KOH. Solution of KCl ($c = 3.57$ mol l^{-1}) was used to adjust the ionic strength.

2.3. Flotation procedure

The recommended flotation procedure is for clear and uncontaminated fresh water. The investigated samples were tap water from the city of Skopje and water from the lake of Ohrid. Immediately after the sampling, the lake waters were filtered trough a membrane filter (0.5 mm width of pores) to remove the lake plankton. The tap water was not filtered. To prevent the possible hydrolytic precipitation a few ml of conc. HNO_3 had to be added to 1 l of natural water. The pH had to be ca. 2.8–3.

An acidified water sample (1 l) was placed in 1000 ml beaker. After adding 6 ml of KCl and 1 ml of 5 mg ml^{-1} of the $FeCl_3$ solution, the pH was adjusted to 5.5 with a solution of KOH (2.5 or 10%). The yellow-brown precipitate was stirred 5 min (a first induction time). Then to the solution with precipitate of $Fe_2O_3 \cdot xH_2O$, 2 ml of NH_4TMDTC solution were added. The precipitate changed its colour to black $Fe(TMDTC)_3$. After stirring of 15 min (a second induction time),

0.6 ml of NaDDS and NaOL alcoholic solutions were added and the contents of the beaker were transferred quantitatively into the flotation cell with the small portion of 0.1 mol l^{-1} NH_4NO_3. Air (50 ml min^{-1}) was passed from the perforated bottom of the cell for 2–3 min. Then, the glass pipette-tube was immersed into the cell through the foam layer and the water phase was sucked off. Hot 65% HNO_3 solution (10 ml) was added to the cell to destroy the scum. The solution was sucked off and collected in a volumetric flask of 25 ml. The cell and the pipette-tube were washed with 4 mol l^{-1} HNO_3 solution. The flask was filled up to the mark with the same solution and the sample was ready for FAAS measurements.

To obtain the optimal experimental parameters, like collector mass, medium pH, type of tenside, ionic strength, induction time, for zinc standard solutions of this colligend were treated by the flotation procedure and then they were tested by FAAS.

3. Results and discussion

3.1. Coprecipitation with hydrated iron(III) oxide

In the previous paper [10] two induction time of 15 min were used. The necessity of the first induction time for a coprecipitation of Zn with $Fe_2O_3 \cdot xH_2O$ as the first collector was investigated. The series of flotation were performed by addition of different Fe(III) quantities (2.5–100 mg l^{-1}) to the working solutions at a constant pH (5.5) and ionic strength (0.02 mol l^{-1}) regulated with KCl. The results of these investigations are presented in Table 2. The data show that Zn recoveries at the pH of 5.5 with 5 mg of Fe were poor (22.17–30.44%). The maximal recoveries of this colligend, under these conditions, were obtained with 100 mg Fe(III) (56.95–60.03%), but they were insufficient too. These data show that the role of $Fe_2O_3 \cdot xH_2O$ as collector in the recommended procedure with two collectors at pH 5.5 was not decisive for colligend separation from water matrix as Feng and Ryan asserted [9].

Table 2
The values of the Zn flotation recovery dependence on the iron(III) mass coprecipitating with $Fe_2O_3 \cdot xH_2O$ in the presence of 0.02 mol l^{-1} KCl at pH 5.5

Sample number	γ(Fe) mgl^{-1}	Recovery (%)	
		γ(Zn) = 1 μg ml^{-1}	γ(Zn) = 2 μg ml^{-1}

9	100	60.03	56.95

3.2. Effect of the Fe(III) tetramethylenedithiocarbamate mass on Zn recoveries

The dependence of Zn recoveries on the mass of $Fe(TMDTC)_3$ was determinated trough the mass of Fe(III), as a constitutive element of this collector. The series of flotation were performed by addition of different Fe(III) amounts (2.5–100 mg l^{-1}) to the working solutions (containing 1 and 2 mg ml^{-1} Zn) at a constant pH (5.5) and ionic strength (0.02 mol l^{-1}). The results

Table 3

9	100	96.0	98.7

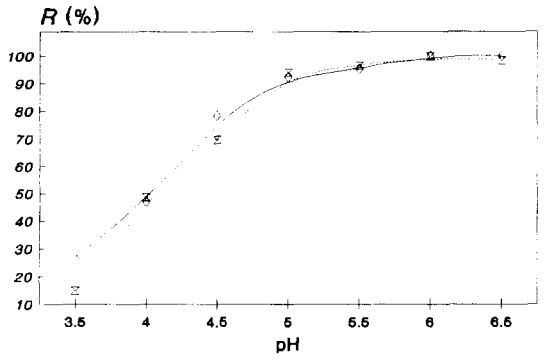

Fig. 1. Dependence of zinc flotation recovery R (%) on medium pH values in the presence of constant mass of iron(III) (5 mg), 2 ml 0.1 mol l^{-1} NH_4TMDTC solution, 0.6 ml 0.5% alcoholic solutions of tensides (NaDDS and NaOL) and KCl (0.02 mol l^{-1}) as an ionic adjuster (——◇—— $\gamma(Zn) = 1$ μg ml^{-1}; - - -x- - - $\gamma(Zn) = 2$ μg ml^{-1}).

in Table 3 and Figure 2 show that the quantitative Zn recoveries obtained after flotation with this collector at pH 5.5 using the minimum of 5 mg Fe(III) were satisfactory (97.5–98.2%). The data in Table 3 show that the leading role in the preconcentration was performed by $Fe(TMDTC)_3$ as the second collector which has better hydrophobility. That means that the first induction time can be reduced. The reducing of the first induction time had shortened the overall time for performing of the method. The different mass of colligend (25 and 50 mg) had no appreciable effect on the flotation efficiency.

3.3. Influence of pH

The influence of pH on the Zn flotability R (%) was studied at different pH values from solutions containing 25 and 50 mg of zinc with a constant mass of Fe(III) (5 mg) at constant ionic strength (0.02 mol l^{-1}). The pH was regulated within the working range of 3.5–6.5. The investigation on the pH values higher than 6.5 were not performed. Namely, at pH higher than 6.5 the collector $Fe(TMDTC)_3$ did not exist due to its hydrolysis. Fig. 1 illustrates a significant effect of pH on the zinc recoveries (95.3–100.0%) within the range of 5.5 to 6.5. The Zn recoveries within the pH range of 3.5–4.5 were poor due to hydrolysis of surfactants NaDDS and NaOL as anionits.

3.4. Choice of tenside

The particles of hydrated Fe(III) oxide had a positive electrokinetic ζ potential of 0.026 V at pH 5.5. The ζ potential of Fe(III) thetramethylenedithiocarbamate, at the same pH, was 0.046 V. According to the signs of the ζ potentials of two collectors used, they need anionits during the step of flotation. The combination of two anionits NaDDS and NaOL was shown successful. NaDDS provides a good foaming in hard water because of its soluble calcium and magnesium salts. The long chain of NaOL increases the aerofility of collector particles. When NaOL is added to the system the air bubbles attached and fixed more easily to the collector particles and the foaming is much better.

3.5. Induction time

The time necessary for incorporation of the colligend Zn in the collector precipitate is termed the induction time τ. The investigation of the relation between Zn recoveries and τ are given in Table 4. From the results, it can be concluded that the separation of colligend was quantitative over a range of 5–20 min. In practice, the first induction time of 5 min and the second induction time of 15 min were used.

3.6. Detection limit

To evaluate the detection limit of the method ten successive blank measurements were made. The FAAS detection limit of Zn is 9.04 μg l^{-1}. It was estimated as three values of the standard deviation (S.D.)($s = 3.013$ μg l^{-1}). The relative S.D. was 9.62%.

Table 4
The influence of the induction time on Zn flotation recoveries

$\gamma(Zn)$ 1 μm ml^{-1}					
τ_1 min^{-1}	5	10	5	15	15
τ_2 min^{-1}	10	10	15	15	20
R (%)	96.5	96.3	100.0	97.9	98.9

[a] Oh., water from the lake of Ohrid.[b] DH (Deutsche Härte), German degree of water hardness.[c] Sk., tap water from the city of Skopje (a source Rašče).

3.7. Analysis of natural water

The possibility of usage of FAAS were studied. The applicability of the proposed procedure has been verified by the method of standard additions. For this purpose known amounts of Zn were added to 1000 ml aliquots of lake and tap water samples. Then these were floated and tested by AAS. The recoveries of 92.2–105.5% (Table 5) show that the preconcentration and separation of this colligend is satisfactory. The results obtained by AAS were compared with the results obtained by ICP-AES determinations; the samples were concentrated by evaporation (from a volume of 1000–25 ml) of tap and lake water (Table 5). A calculation of Student's *t*-test for our results gives the values range from 2.36 for water sample from Daljan to 2.76 for sample from Ljubaništa, whereas the theoretical value (95%) of *t* was 2.78. As calculated *t* values are smaller than theoretical, there is no significative difference between the two methods.

4. Conclusion

The experimental conditions for FAAS determinations of Zn following colloid flotation preconcentration and separation with two collectors have been established. The necessity of the first induction time [1,11] for a coprecipitation step of flotation with hydrated iron(III) oxide ($Fe_2O_3 \cdot xH_2O$) as the first collector was investigated. The adding of $Fe(TMDTC)_3$ as a second additional collector, which ameliorates the flotation separation, was studied. The dithiocarbamate added increases the hydrophobility of the sublate which is the most important criterion for the successful flotation. During the air bubbling step of flotation, the collector precipitate of $Fe(TMDTC)_3$, as a compound with a better hydrophobility than $Fe_2O_3 \cdot xH_2O$, improves and facilitates the separation of the foam layer from the liquid phase processing water sample. The recommended method extends the range of conventional atomic absorption determination for zinc, simplifies the determination procedure and shortens the overall time of the experiment.

The study of complex equilibria of uranium(VI) with selenate

P. Lubal *, J. Havel

Department of Analytical Chemistry, Faculty of Science, Masaryk University, Kotlářská 2, 611 37 Brno, Czech Republic

Received 3 June 1996; received in revised form 13 August 1996; accepted 12 September 1996

Abstract

Uranyl (M)-selenate (L) complex equilibria in solution were investigated by spectrophotometry in visible range and potentiometry by means of uranyl ion selective electrode. The formation ML and ML_2 species was proved and the corresponding stability constants calculated were: $\log \beta_1 = 1.57_6 \pm 0.01_6$, $\log \beta_2 = 2.42_3 \pm 0.01_3$ ($I = 3.0$ mol l^{-1} $Na(ClO_4, SeO_4)$ (spectrophotometry) at 298.2 K. Using potentiometry the values for infinite dilution ($I \rightarrow 0$ mol l^{-1}) were: $\log \beta_1 = 2.64 \pm 0.01$, $\log \beta_2 \leqslant 3.4$ at 298.2 K. Absorption spectra of the complexes were calculated and analysed by deconvolution technique. Derivative spectrophotometry for the chemical model determination has also been successfully applied. © 1997 Elsevier Science B.V.

Keywords: Derivative spectrophotometry; Stability constants; Spectra deconvolution; Uranyl selenate

1. Introduction

Uranyl ion is linear oxocation, which starts to hydrolyse at pH higher than 2.5 for concentrations ≈ 0.1 mol l^{-1} [1,2] if no other complexing agents is present. It can be assigned according Hard and Soft Acids and Basis (HSAB) principle to hard acids therefore it tends to form more stable complexes with harder bases, such as ligands with oxygen donor atom like carbonate, sulphate, oxalate, aromatic hydroxycompounds, etc., and/or with harder halogenide anions (fluoride, chloride) and, of course, with hydroxide under the formation of polynuclear hydroxospecies) [1–3]. The affinity to oxygen is so high that the existence of a ternary polynuclear species, in uranyl-carbonate-hydroxide [4,5] and/or uranyl-sulphate-hydroxide [6] systems has been proved. The highest co-ordination number of uranyl in its compounds in solution is mostly equal to four, in solid state it is equal to six.

The complex equilibria in uranyl-sulphate system have been investigated by means of different methods (potentiometry, spectrophotometry, extraction, solubility, dialysis, ion-exchanger, calorimetry etc.) (reviewed in [2] and [3]). It is evident that in uranyl-sulphate system species ML and ML_2 are formed [3], but there are some doubts about the formation of species ML_3.

Stability constants of uranyl with selenate has not been determined as yet. As selenate is isoelectronic with sulphate, it could be suggested that the same species such as in uranyl-sulphate system will be formed. Detailed study of the interactions

of uranyl with selenate is the subject of this work. Some results of this work were preliminary reported elsewhere [7].

2. Theory

2.1. Determination of the number of light-absorbing species

Generalised form of Bouger–Lambert–Beer law can be written in matrix notation:

$$\mathbf{A} = \mathbf{EC} \tag{1}$$

where $\mathbf{A}$ is the $n_w \times n_s$ absorbance matrix, $\mathbf{E}$ is the $n_w \times n_c$ matrix of molar absorptivities, $\mathbf{C}$ is the $n_c \times n_s$ concentration matrix. Here n_w denotes the number of wavelengths, n_s means the number of solutions whose spectra have been recorded, and n_c is the number of components which absorb in chosen spectral range. The rank of the matrix, rank(**A**) (RM) is obtained from the equation

$$\text{rank}(\mathbf{A}) = \min(\text{rank}(\mathbf{E}), \text{rank}(\mathbf{C})) \leqslant \min(n_w, n_c, n_s) \tag{2}$$

Since the rank(**A**) is equal to the rank of **E** or **C**, whichever is the smaller, and since rank(**E**) $\leqslant n_c$ and rank(**C**) $\leqslant n_c$, then provided n_w and n_s equal to or greater than n_c, it will only be necessary to determine the rank of **A** and find the number of absorbing species. Also we assume that the rank(**A**) is equal to the number of linearly independent columns of **A** expressed as number of nonzero eigenvectors (it means that the concentration of one or more species can not be expressed as a linear combination of the other species in all experiments).

For calculation of RM the Simmonds–Wernimont–Kankare method [8] was applied. The second moment matrix given by formula

$$\mathbf{M} = \frac{1}{n_s}\mathbf{A}\mathbf{A}^T \tag{3}$$

is symmetric (square) matrix of order n_s and of rank n_c, rank(**M**) $\leqslant n_c$. Each element of the absorbance matrix **A** is a subject to experimental error and because of that fact, the number of nonzero eigenvalues is $\min(n_w, n_s)$. Let the eigenvalues of **M** be EV_i, matrix trace of **M**, tr(**M**), summation of the eigenvalues, and suppose that there are k independent components in the system. Then the residual standard deviation of absorbance is given by

$$s_k(A) = \frac{\text{tr}(\mathbf{M}) - \sum_{i=1}^{k} EV_i}{\sqrt{n_w - k}} \tag{4}$$

Relative variance

$$RV(\%) = \frac{EV_i}{\text{tr}(\mathbf{M})} \times 100 \tag{5}$$

Cumulative relative variance

$$CRV(\%) = \frac{\sum_{i=1}^{k} EV_i}{\text{tr}(\mathbf{M})} \times 100 \tag{6}$$

and Malinowski's indicator function IND_k by Malinowski [9]

$$IND_k = \frac{s_k(\mathbf{A})}{(n_w - k)^2} \tag{7}$$

Let the precision of the absorbance measurement be given by the S.D. of absorbance of spectrophotometer used, $s_{inst}(\mathbf{A})$. Then we may say that if $s_k < s_{inst}(\mathbf{A})$, it is probable that $n_c < k$ and Malinowski's indicator function number shows minimum value [9].

3. Experimental

3.1. Reagents

Uranyl perchlorate was prepared from solid uranyl nitrate (Lachema Brno, Czech Republic) adding slight excess of concentrated 70% (w/w) perchloric acid and evaporating almost to dryness until negative reaction for nitrate was obtained. The product was two times recrystallised from diluted perchloric acid solution. The prepared substance was dissolved in water adding slight amount of perchloric acid, which concentration was then determined by Gran transformation [10] of the alkalimetric titration. The uranyl content was determined gravimetricaly as U_3O_8 (precipitation by H_2O_2) and by 8-hydroxyquinoline [11].

Uranyl nitrate (Lachema Brno, Czech Republic) for potentiometric measurements was dissolved in acidic solution of nitric acid and the stock solution was standardised as described above.

Sodium perchlorate p.a. (Lachema Brno, Czech Republic) was purified removing traces of heavy metal ions precipitation with sodium hydroxide and the product was several times recrystallised [12].

Sodium selenate was prepared by Dr Černík from Department of Inorganic Chemistry of Masaryk University. The sample was found to be free of any selenite traces [13]. Also sodium selenate (Fluka, Switzerland) was used.

3.2. Apparatus

UV-VIS measurements were done on a one beam diode array spectrophotometer HP 8452A (Hewlett Packard, USA). The derivative spectra were computed using HP 8452A standard software.

The proton concentration of solutions was checked using combined RADELKIS OP-8080 glass electrode (MOM, Hungary), in which inner saturated potassium chloride solution was removed from the reference part of the electrode and substituted with 2.99 mol l^{-1} sodium perchlorate solution and 0.01 mol l^{-1} sodium chloride, saturated with silver chloride. The reliability of the electrode was tested measuring time stability of the potential. The electrode parameters were determined by calibrating the corresponding electrode cell titrating known amount of perchloric acid by standardised sodium hydroxide solution at given ionic strength medium. The recalculation of $-\log[H^+]$ values from measured potential was done by means of equation

$$E = E^0 + g(-\log[H^+]) + E_j \quad (8)$$

where E^0 is potential of cell at $-\log[H^+] = 0$, g is Nerstian slope given by the term 2.30259 RT/F and E_j is a junction potential. For the potentiometric measurements a digital pH-meter RADELKIS OP-208 (MOM, Hungary) was used. The uranyl concentration was measured using uranyl electrode described elsewhere [14]. As reference electrode saturated calomel electrode was used. The potentiometric titrations were carried out by an automatic titrator TTT 81 with microprocessor connected to automatic burette ABU 80 and digital pH-meter PHM 84, (all Radiometer Copenhagen, Denmark).

All experiments were carried out at ionic strength $I = 3.00$ mol l^{-1} $Na(ClO_4 + SeO_4)$ (spectrophotometry, $-\log[H^+]$ values in solutions were from 2.26 (0.0 mol l^{-1} selenate concentration) to 2.86 (0.6 mol l^{-1} selenate concentration) and sodium selenate concentration up to 0–0.03 mol l^{-1} (potentiometry, $-\log[H^+]$ adjusted to the value equal to 3.5 when hydrolysis of uranyl under the presence of selenate is negligible) and at the temperature equal to 298.2 ± 0.5 K. Hydrolysis of uranyl for concentrations used is negligible at this $-\log[H^+]$ value [2]. So, it was not necessary to take into consideration the formation of mixed hydroxo-selenate species.

3.3. Computation

For the calculations SQUAD [15], SUPERQUAD [16], SIBYLA [17] and HALTAFALL [18] programs were used running on a PC AT 386.

4. Results and discussion

4.1. The spectrophotometric study

First, kinetic stability of uranyl-selenate mixtures was tested. The absorbance of the solutions were checked during 24 h period. The change in absorbance values for the whole spectra never exceeded 0.01 absorbance unit. Thus, it was concluded, that the equilibrium is reached very fast. The solutions were stable for at least 24 h.

The absorption spectra recorded are given in Fig. 1. Experimental conditions are given therein. It is possible to observe that increasing selenate concentration absorption maxima of uranyl are shifted towards the longer wavelengths.

Rank of the absorbance matrix enables to predict the number of light-absorbing species in solution. The number of complexes formed was estimated from the first step of factor analysis of

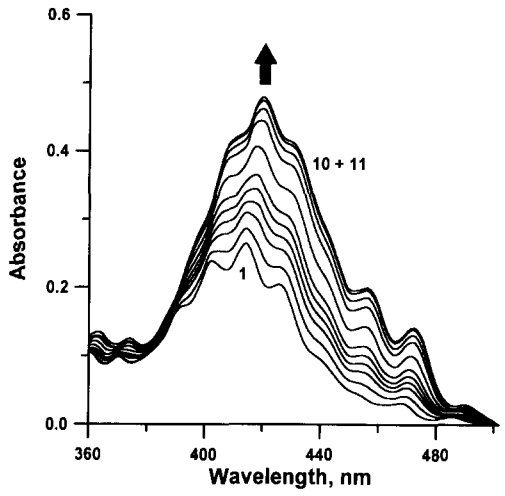

Fig. 1. Absorption spectra of uranyl at various selenate concentrations. Total concentration of uranyl $c_M = 0.0331$ mol l^{-1}. Total selenate concentration in mol l^{-1}: 1, 0.00; 2, 0.012; 3, 0.024; 4, 0.036; 5, 0.048; 6, 0.060; 7, 0.118; 8, 0.236; 9, 0.354; 10, 0.470; 11, 0.590.

absorption matrix (Principal Component Analysis) (Table 1). It follows from this analysis that there are 2–3 absorbing species formed, which is indicated by relative variance, cumulative relative variance and residual standard deviation values. Malinowski's indicator function IND_k [9] gives unreliably high number of the components. This criterion should be considered unreliable [19] in most of the cases. From low contribution of relative variance to the trace of second moment absorbance matrix we can conclude that there are three species in the solutions with different spectral properties.

Independently the formation of protonated species in $-\log[H^+]$ region 1.4–3.0 was also checked. The evidence for no formation of protonated species was found.

Therefore it was assumed, that the following equilibria take place in solution:

$$UO_2^{2+} + rSeO_4^{2-} \rightleftarrows UO_2(SeO_4)_r^{(2r-2)-} \quad (A)$$

with stability constant values

$$\beta_r = [UO_2(SeO_4)_r^{(2r-2)-}][UO_2^{2+}]^{-1}[SeO_4^{2-}]^{-r} \quad (9)$$

4.1.1. The search of the chemical model

The stoichiometry of species does not exceed 1:2 (stoichiometric ratio $r = 2$, Fig. 2). From above described facts it has been deduced, that there are only three absorbing species, i.e., stoichiometry M, ML and ML_2 in solution can be suggested.

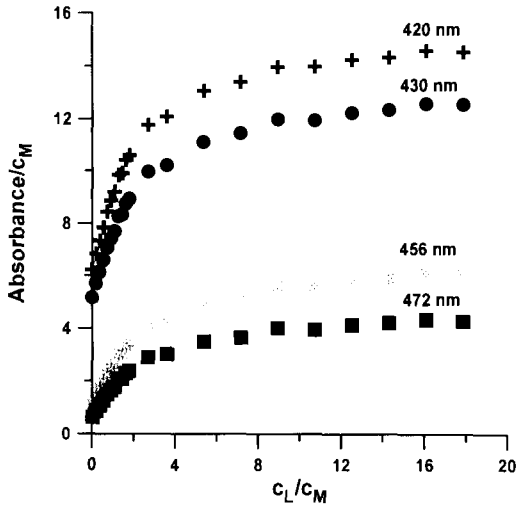

Fig. 2. Plots of absorbance vs. selenate concentration at selected wavelengths. Uranyl concentration $c_M = 0.0331$ mol l^{-1}.

Chemical model, i.e., the composition of the complexes and corresponding stability constants was searched for by the classical approach using 'trial and error' method [19].

A certain chemical model was suggested and then applying least-squares procedure of SQUAD program, minimising the sum of squares of residuals, U,

$$U = \sum_{i=1}^{n_w \times n_s} (\mathbf{A}_{exp,i} - \mathbf{A}_{calc,i})^2 = \min \quad (10)$$

where $\mathbf{A}_{exp}$ are experimental and $\mathbf{A}_{calc}$ calculated values of absorbances and the summation is done over all experimental points, number of solutions (n_s) times number of wavelengths (n_w). The program also calculates the S.D. of absorbance defined as

$$\sigma(\mathbf{A}) = \sqrt{\frac{U}{(n_s \times n_w - n)}} \quad (11)$$

where n is the number of parameters estimated. The 'best' one is that one for which is the lowest values of U and $\sigma(\mathbf{A})$ are obtained.

Several chemical models were tried. The most probable seems to be the model which consists of species M, ML and ML_2 (Table 2). The calculated molar absorptivities are given in Fig. 3.

As stability constants values show higher S.D. values computed from nonderivative spectroscopy, while lower values were found for the first up to the fourth derivative spectra Table 1 (Table 2). It is caused by similarity of spectra (Table 3), therefore the calculation of stability constants values has also been tried using derivative spectra with lower S.D. were observed for derivative spectra (Table 2). Also the choice of the wavelength values has influence on the correct stability constants values of the chemical model (Table 2).

Derivative spectra are very good alternative for the calculation of chemical model parameters (Table 2). Comparing calculated stability constants from both methods it is possible to see that results from derivative spectra have lower S.D's. The explanation is in this fact that peaks are

[b] 50 chosen wavelengths in region 360–500 nm, e.g., 360, 362, 364, 366, 370, 374, 378, 382, 386, 390, 392, 394, 398, 400, 402, 404, 408, 410, 414, 418, 420, 422, 424, 426, 428, 430, 432, 434, 436, 438, 440, 442, 444, 446, 448, 450, 454, 456, 458, 462, 466, 468, 470, 472, 474, 478, 482, 486, 490 and 494 nm.

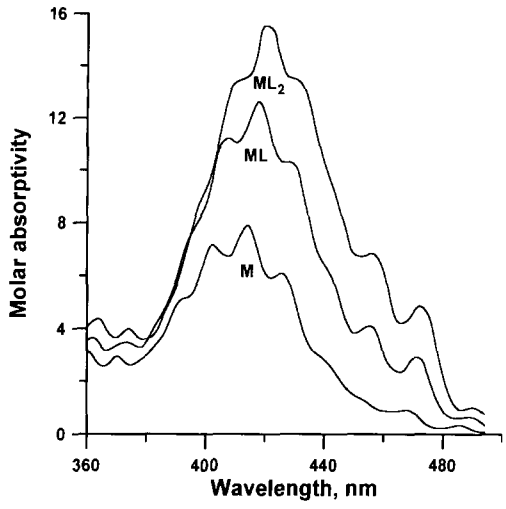

Fig. 3. Calculated spectra of individual species.

separated better to each other. On the other hand, the values of stability constants calculated by both methods are reliable because they are in region of 99.74% probability of each other confidence interval (three times S.D.) [20].

This improvement has several reasons. We can write combining mass balance equation and stability constant relationship with Bouger–Lambert–Beer law, respectively:

$$\mathbf{A}_{i,j} = \sum_{k=1}^{n} \varepsilon_{i,k}\beta_k[\mathrm{M}][\mathrm{L}]^k \tag{12}$$

for $i = 1, \ldots, n_w$ (number of chosen wavelength in measured spectra), $j = 1, \ldots, n_s$ (c_M, c_L, or pH is changed), $k = 1, \ldots, n$ (the number of complexes), $M, ML, \ldots, ML_n$.

If we differentiate over wavelength values n times, we obtain

$$\frac{\partial^n \mathbf{A}_{i,j}}{\partial\lambda^n} = \sum_{k=1}^{n} \frac{\partial^n \varepsilon}{\partial\lambda^n}\beta_k[\mathrm{M}][\mathrm{L}]^k \tag{13}$$

Choosing wavelength values in region where the position of wavelength under condition $\partial^n A_{i,j}/\partial\lambda^n = 0$ changing ligand or metal concentration, we get overdetermined system in which we can efficiently eliminate 'background'. This determination of the chemical model is more certain. At the same time respective contribution of individual species to total signal is higher for values obtained from derivative spectrophotometry than from normal spectrophotometry. This fact is already known in works concerning analytical determination of several components in mixture [21]. Second, the data are contemporaneously smoothed as it has been shown somewhere [22]. Above discussed facts all together play very important role in derivative spectra evaluation.

The distribution diagram calculated using the stability constants values as calculated (Table 2) is shown in Fig. 4.

4.1.2. Deconvolution of the spectra

The calculated spectra for each species were deconvoluted into one broad and two narrow bands of gaussian profile [23]:

$$\varepsilon_i = \varepsilon_{\max,i} \mathrm{e}^{-5.545(\lambda - \lambda_{\max,i})^2/2\sigma_i^2} \tag{14}$$

where ε_i is the calculated molar absorptivity, ε_{max} is the molar absorptivity at wavelength of the maximum molar absorptivity peak, λ is the wavelength, λ_{max} is the wavelength of the maximum absorptivity peak, and σ-half is the width of the absorption band, i.e., its width in half height of the band.

The area of spectral band is given by relationship [24,25] for so called oscillator strength

$$f_i = 1000 \ln(10)\frac{mc^2}{\pi e^2 N_A}\int_{\nu_1}^{\nu_2} \varepsilon \, \mathrm{d}\nu$$
$$= 4.315 \times 10^{-9} \int \varepsilon \, \mathrm{d}\nu \tag{15}$$

where m and e is charge and mass of electron, c is velocity of the light in vacuum, N_A is Avogadro number. We get after a simplification [24,25]

$$f_i \approx 4.60 \times 10^{-9} \varepsilon_{\max,i} \nu_{1/2} \tag{16}$$

if the band has gaussian shape with half-width $\nu_{1/2}$. After rearrangement for wavelength values in nanometers the relation Eq. (16) is equivalent to Eq. (17):

$$f_i \approx 4.60 \times 10^{-2} \varepsilon_{\max,i} \left(\frac{1}{\lambda_{\max,i} - \sigma_i} - \frac{1}{\lambda_{\max,i} + \sigma_i}\right) \tag{17}$$

This parameter is proportional probability of light absorption as quadrate of so called transition moment defined by relationships [24]

Table 3
Deconvolution of calculated molar absorptivities into three bands of Gaussian profile

Species	Band parameters	Band number			Statistical parameters	
		1	2	3	R^2	s
M	ε_{max}	2.4 ± 0.2	7.3 ± 0.1	0.6 ± 0.1		
	λ_{max} (nm)	360 (fix)	410.4 ± 0.4	467 ± 4	0.988	0.2555
	σ (nm)	34 ± 3	50 ± 2	26 ± 8		
	f_i	4.8×10^{-5}	2.0×10^{-4}	6.6×10^{-6}		
ML	ε_{max}	3.0 ± 0.2	12.0 ± 0.1	2.2 ± 0.2		
	λ_{max} (nm)	362 (fix)	416.0 ± 0.3	467 ± 2	0.991	0.3362
	σ (nm)	26 ± 4	50 ± 1	28 ± 4		
	f_i	5.5×10^{-5}	3.2×10^{-4}	2.6×10^{-5}		
ML_2	ε_{max}	3.8 ± 0.2	15.0 ± 0.1	3.6 ± 0.2		
	λ_{max} (nm)	364 (fix)	420.7 ± 0.4	467 ± 4	0.992	0.3953
	σ (nm)	24 ± 3	51 ± 1	26 ± 8		
	f_i	6.4×10^{-5}	4.0×10^{-4}	4.0×10^{-5}		

Remark: fixed values were obtained from logaritmic analysis of spectra [23].

$$P = \langle \psi_a | M | \psi_b \rangle = e\sqrt{D} \quad (18)$$

where D is so called dipole strength of electron transition between states defined wave functions Ψ_a and Ψ_b treated by means of dipole moment operator M. Those relationships connect experimental chemistry with theoretical quantum chemistry.

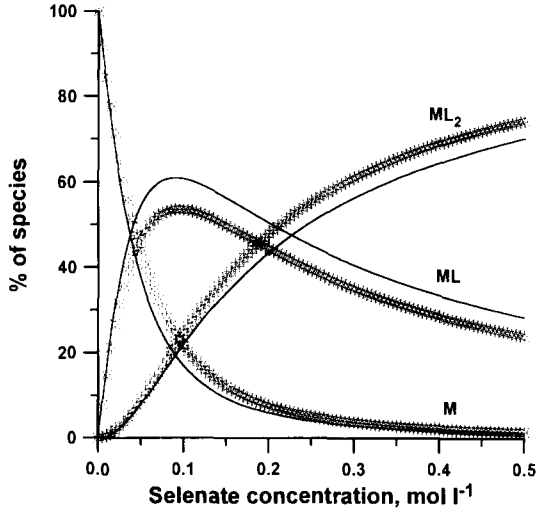

Fig. 4. Distribution diagram for uranyl-selenate complexes. Total uranyl concentration $c_M = 0.0331$ mol l^{-1}. Full drawn lines calculated for stability constants values log $\beta_1 = 1.742$ and log $\beta_2 = 2.488$. Dashed drawn lines calculated for stability constants values log $\beta_1 = 1.576$ and log $\beta_2 = 2.423$.

Also the deconvolution into the bands of studentian or lorentzian profile [23] was done, but using gaussian profile gave the best fit (Table 3). The parameters of gaussian profile show for complexes very low shift of wavelength of maximal molar absorptivity peak and higher maximal molar absorptivity value at wavelength of maximum molar absorptivity. The results are comparable with [24] where authors deconvoluted 24 (14 in VIS region and 10 in UV region) gaussian profile bands for the uranyl spectra. They represent three main bands in VIS region and also enable to calculate basic energy levels [24]. The oscillator strength values for uranyl were estimated for those three bands (Table 3) and they have been compared with literature data [1,26,27]. These values are in agreement with data found in the literature. Also increasing oscillator strength values in order M, ML and ML_2 species which can be assigned decreasing energy electron levels and therefore higher probability of electron transitions between levels.

The structures and intensities of the bands in spectrum are influenced mainly by geometry of the ligands co-ordinated to the uranyl moiety [27]. The electron transitions in the complexes are from point of view of the molar absorptivities spin allowed and Laporte forbidden [28] (for uranyl

cation it probably indicates octahedral aqua-complex $UO_2(H_2O)_6^{2+}$ in slight acid solution, of course, for complexes we suppose also deformed octaedrical structure, where two water molecules at octaeder corners are bonded less weakly than selenate or water in the square plane.

It was observed, that increasing pH up to four ($c_M = 0.0331$ mol l^{-1}, $c_L = 0.59$ mol l^{-1}), faint precipitate is formed in solution. The formed species is probably $[(UO_2)_2(SeO_4)_2(OH)_2]^{2-}$ while its charge is compensated by two sodium ions from the ionic medium (the product composition is the most probable). Uranyl ion has the most probably co-ordination number six in this compound. This hypothesis is supported by the fact that species of similar composition were proved for sulphate [6] and their formation was deduced from hydrolysis data in sodium sulphate medium [3,29]. Furthermore, products of similar composition were synthesised [30].

4.2. The potentiometric study

The equilibria in uranyl-selenate system were also investigated potentiometricaly by means of an uranyl electrode which enables to determine directly the concentration of free metal ion.

As it was already shown for uranyl electrode in [14], this one has no response in presence 0.01 mol l^{-1} sodium perchlorate as ionic medium. For 3 mol l^{-1} sodium perchlorate only constant response of uranyl electrode was observed which can be caused by the preferred formation of associate ion carrier with perchlorate than for associate with $UO_2(OH)^+$. Hence, all experiments were done without any adjustment of ionic strength in uranyl concentration region 0.1–0.5 mmol l^{-1} at $-\log[H^+]$ about 3.5 where protonation of selenate and the formation of uranyl hydrolytic polynuclear species are negligible [31]. The slope of the electrode was lower than the theoretical one given by Nerstian equation. The function of uranyl electrode is not still completely clear, there is only a hypothesis that species responsible as active carrier one of the electrode [14] is complex $UO_2(OH)^+$. The following equation was derived [14]:

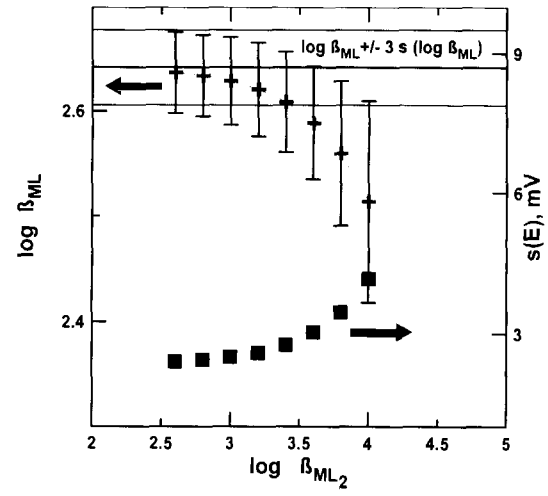

Fig. 5. The search of the chemical model from potentiometric data.

$$E = \text{const} + \frac{RT}{F} \ln a_{UO_2^{2+}} + \frac{RT}{F} \ln a_{OH^-} \qquad (19)$$

That is why the measurements were carried out at constant pH value. At lower uranyl concentration we can also assume that $a_{UO_2^{2+}} \approx c_{UO_2^{2+}}$.

It is clear from spectrophotometric results that species ML and ML_2 are formed, but it was possible to calculate from potentiometric data only stability constant for ML species ($\log \beta_1 = 2.64$). The explanation is that complexes formed are rather weak and thus even at very high ligand excess (several hundreds times over uranyl concentration) solutions are diluted and complex ML_2 is formed at low amount (maximum amount is 20% rel at very high ligand excess) in course of the ML species formation. This is detectable from calculations. Therefore the model with fixed stability constant values for species ML_2 was also tested (Fig. 5). It can be estimated from Fig. 5 and also from experimental points at very high ligand excess that stability constant value of species ML_2 does not exceed 3.4 ($\log K_2$ lower than 0.8). Both values for species ML and ML_2 are lower than for the complexes in the uranyl-sulphate system, respectively [3] (weighted average of $\log \beta(ML) = 3.1 \pm 0.1$, $\log \beta(ML_2) = 3.9 \pm 0.2$ and thus $\log K_2 = 0.8$) and this is in agreement with their protonation constants values (selenate is a weaker base than sulphate and so it should

form a little weaker complexes with the same metal ions as sulphate) and polarizability (HSAB principle).

If we consider $\log \beta_1^*$ as stability constant value at zero ionic strength (in our case 2.64) and $\log \beta_1$ (for 3 mol l^{-1} sodium perchlorate from derivative spectrophotometry measurements 1.58 ± 0.01) as stability constant value at ionic strength I_m given in molality scale (3 mol l^{-1} sodium perchlorate solution has molality 3.502 mol kg^{-1}), we can write according [3,32] the equation:

$$\log \beta_1 + 8D = \log \beta_1^* - \Delta\varepsilon I_m \quad (20)$$

where $D = A\sqrt{I_m}/(1 + 1.5\sqrt{I_m})$ is the derived Debye-Hückel term, and $\Delta\varepsilon = -\varepsilon(SeO_4^{2-}, Na^+) - \varepsilon(UO_2^{2+}, ClO_4^-)$ is obtained from interaction coefficients representing solute interactions in solution. After substitution of all known terms and value $\varepsilon(UO_2^{2+}, ClO_4^- = 0.26$ from [3] we obtain for $\varepsilon(SeO_4^{2-}, Na^+ = -0.009$. Then, from all known and calculated values the relationship Eq. (21) can be derived. This equation is suitable for the estimation of the activity coefficient in sodium selenate solution

$$\log \gamma_{\pm} = \frac{-0.51052\sqrt{3c_m}}{1 + 1.5\sqrt{3c_m}} + 2\varepsilon(SeO_4^{2-}, Na^+) \times c_m \quad (21)$$

where c_m is molal concentration of sodium selenate and additional term describes deviation from an ideal solution behaviour for 2:1 electrolyte. Comparing $\varepsilon(SO_4^{2-} = -0.12 \pm 0.06$ from [3] the solutions of sodium selenate have more ideal behaviour as electrolyte 2:1 than sodium sulphate. The relationship Eq. (21) can be used for the calculation of stability constants of the selenate with different metal ions under presence of sodium ions as supporting electrolyte.

Square wave adsorptive voltammetric determination of sunset yellow

J.J. Berzas Nevado *, J. Rodríguez Flores, M.J. Villaseñor LLerena

Department of Analytical Chemistry and Foods Technology, University of Castilla La Mancha, 13071 Ciudad Real, Spain

Received 11 April 1996; received in revised form 12 September 1996; accepted 17 September 1996

Abstract

Square wave adsorptive stripping voltammetry was used for determining trace amounts of dye Sunset Yellow (E-110) for the first time. Its adsorptive voltammetric behaviour followed by a square wave mode step was investigated at different pH media. Sunset Yellow in 0.5 M NH_4Cl/NH_3 buffer solution gave an adsorptive stripping voltammetric peak at the hanging mercury drop electrode at -0.60 V using an accumulation potential of -0.40 V. The effect of experimental parameters that affected this determination are discussed. The calibration graph to determine Sunset Yellow was linear in the range 5–90 $\mu g\ l^{-1}$, obtaining a relative standard deviation of 2.2% for a solution of 30 $\mu g\ l^{-1}$ ($n = 10$) in the same day. The determination limit was 5 $\mu g\ l^{-1}$ after 15 s of accumulation at -0.40 V. The proposed method was applied to determine this dye in several commercial refreshing drinks, which contained small amounts of this compound. Measurements were made directly over diluted solutions of commercial samples. Similar results were obtained between adsorptive stripping square-wave voltammetric values and the obtained by application of a HPLC method with spectrophotometric detection. © 1997 Elsevier Science B.V.

Keywords: Adsorptive stripping voltammetry; Chromatography; Dyes; Sunset Yellow

1. Introduction

Food colorants may often be considered simply cosmetic in nature, but the role they play in our food supply is actually very significant. Colour is the first sensory quality by which foods are judged and food quality and flavour are closely associated with colour. Consumers are conditioned to expect foods of certain colours and to reject any deviation from expectations. The psychological basis for the need for food colours is well established [1].

Colorants also play a significant role in enhancing the aesthetic appeal of food. They are very important ingredients in many convenience foods such as confectionery products, gelatin desserts, snacks and beverages, since many of these would be colourless and would thus appear undesirable without the inclusion of colorants.

The term colour additive can be applied to any dye, pigment or other substance made (artificial colorant) or obtained from a vegetable, animal, mineral or another natural source, that are capable of coloring foods, drugs or cosmetics [2].

Sunset Yellow, subject of this work, is a synthetic dye available as yellow powder that can be present in common foods (drinks, yoghurts, ice cream, sweets, etc., ...). The presence and content of this dye must be controlled because it is not totally inoccuo. Development of regulations for use of foods colorants was reviewed by Haveland-Smith [3].

Recently, we have developed spectrophotometric methods in order to determine this dye in two different binary mixtures and a ternary mixture with other two yellow colorants [4–6]. These methods were applied to several commercial products.

On the other hand, chromatographic methods have been previously used for colorant analysis in foods [7–10].

Fogg et al. have reported sensitive methods to determine several dyes (Quinoline Yellow, Tartrazine, Carmoisine, etc., ...) by means of the use of paste carbon electrode in static systems or in continuous flow systems [11–13].

Fogg et al. have also realized a theoretical and general study about the voltammetric behaviour of several synthetic colorants (reduction peak potentials and intensities) by means of DPS and DPP techniques [14,15]. Sunset Yellow was not determined in any commercial product in both cases, since the study made was almost brief and theoretical. The sensitivities reached by Fogg et al. in the analysis of some dyes in commercial samples (cosmetic and tablets coatings) were smaller than the obtained by us in soft drinks.

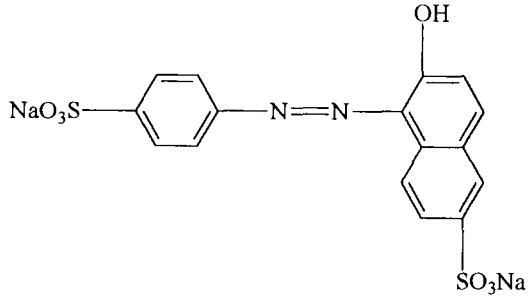
The polarographic reduction mechanism of azo-compounds has been known for some time [16,17]. The electrode process must be consistent with the mechanism that postulates a step-wise breakage of the molecule, similar to that occurring in the metabolic processes of these dyes.

$$R-N=N-R_1+4H^++4e^- \rightarrow R-NH_2+R_1-NH_2$$

where RNH_2 is sulfanilic acid and R_1NH_2 is 1-amino-2-hydroxy-6-naphthalenesulphonic acid [18].

In this work, a study of the electrochemical behaviour of Sunset Yellow (whose formula is given) has been achieved taking into account the possible adsorption of the molecule on the mercury and following the study by square wave voltammetry with a previous stripping period. The method proposed by us permits to reach a similar sensitivity than the obtained by the already mentioned DPP method and it reduces at least ten times the length of real time of analysis (27 s).

Sunset Yellow



The sensitivity of adsorptive stripping methods is obviously their greatest advantage. In the other hand, a serious drawback is the interference from other surface-active substances that may be present in the solution. In this case, competitive adsorption usually occurs and produces a decrease in the measured current or in concentrations of surface-active substances and, consequently, significant suppressions of the signal are observed. In such conditions, it is necessary to employ a suitable separation of interfering compounds. If the sample contains interfering compounds that are electrochemically active but are not adsorbed on the electrode surface, classical separation procedures will be not necessary then.

Another advantage of stripping analysis is the possibility of working with very diluted samples that produces a logical decrease of interferences in foods techniques.

The simultaneous use of adsorptive stripping techniques and square wave measurements provides a very sensitive, selective and rapid approach. The method here proposed has yielded good results in the determination of Sunset Yellow in three different commercial products: Tof

lemon and Gatorade orange (both contain E-104 (Quinoline Yellow) and E-110 (Sunset Yellow) as dyes) and in other third refreshing drink flavour orange (Product 3), which also contains two dyes: E-102 (Tartrazine) and E-110 (Sunset Yellow).

2. Experimental

2.1. Reagents

All solvents and reagents were of analytical grade unless indicated otherwise. Solutions of voltammetric study were made with deionized water (Milli-Q quality). Sunset Yellow (E-110) solution was reached from Sancolor S.A enterprise. Stock solutions had a concentration of 10 mg l^{-1}. In order to achieve all voltammetric studies following solutions were also prepared: a 0.1 M HCl solution, an $HOAc/OAc^-$ buffer solution (0.1 M and pH = 4.8), a NaH_2PO_4/Na_2HPO_4 buffer solution (0.1 M and pH = 7.7) and a NH_4Cl/NH_3 buffer solution (0.1 M and pH = 10.0). All these were prepared from suprapure reagents. Methanol (HPLC quality) was used in chromatographic analysis

Three commercial products containing Sunset Yellow were studied. These are the followings:

Refreshing drink Tof, flavour lemon: with carbonated water, sugars, lemon juice, citric acid, lemon flavoring, emulsifiers E-915 (glycerol esters) and E-414 (arabic gum), sweetenings, preservative E-211 (sodium benzoate) and dyes: E-104 (Quinoline Yellow) and E-110.

Gatorade, flavour orange: with water, glucose, saccharose, citric acid, mineral salts, natural flavorings and dyes: E-104 and E-110.

Product 3, (refreshing drink flavour orange): with carbonated water, sugars, orange juice, citric acid, orange essences, sodium benzoate, dyes E-102 (Tartrazine) and E-110 and ascorbic acid.

Ingredients above summarized are in the three cases in order decreasing of concentration.

The trade name of third product has not been given because its manufacturing enterprise want to remain anonymous.

2.2. Apparatus

Square-wave voltammograms were obtained with a Princenton Applied Research (PAR) Model 384B polarographic analyzer combined with a stand PAR Model 303 A static mercury drop electrode (SMDE), using an Ag/AgCl reference electrode, a PAR Model 305 magnetic stirrer, a TANDOM computer using 384 B software and a EPSON FX 850 printer.

The HPLC equipment used was: a SHIMADZU model SPD-M10A, with a double pump system, that permit us to work in gradient mode, and as stationary phase a chromatographic column Apex C_{18} (25 cm of length and 5 μm as particle diameter).

2.3. Procedure

The general procedure for adsorptive stripping voltammetric method was as follows: in order to achieve all voltammetric assays, 10 ml of 0.5 M NH_4Cl/NH_3 buffer solution were placed in the polarographic cell, using in all assays an accumulation potential of −0.40 V, an accumulation time of 15 s and a rest period of ten seconds, being after that scans run in the negative direction between −0.4 and −0.9 V in these conditions. Experimental and instrumental parameters that affected the process were optimized and the obtained results are the followings: NH_4Cl/NH_3 concentration = 0.5 M, t_{ac} (accumulation time) = 15 s, E_{ac} (accumulation potential) = −0.40 V, ΔE (pulse amplitude) = 50 mV, Δs (scan increment) = 4 mV, frequency = 70 Hz and electrode area = 2.5 mm^2.

All results shown in this paper were obtained at room temperature (25 ± 1°C).

The determination of Sunset Yellow in these three commercial products was also verified by HPLC using a diode-array detector with measurements at 420, 440 and 480 nm (wavelengths where the Sunset Yellow absorbance was maximum) and the stationary phase already mentioned in Section 2.2. As mobile phase we have employed a mixture of methanol and 0.1 M buffer solution NaH_2PO_4/Na_2HPO_4 (pH = 7.0) following the next gradient of concentrations.

Time (min)	Concentrations
0–2	20% methanol constant
2–5	20–100% methanol in linear gradient
5–7	100% methanol constant

The flow rate was 1.5 ml min^{-1}. In such conditions the retention time of this dye was 4.6 min.

3. Results and discussion

Firstly, a preliminary study about the adsorptive voltammetric behaviour of Sunset Yellow at different pH values (1.3, 4.7, 7.7 and 10.0) was realized for 0 and 30 s of accumulation time. In the first case (pH:1.3) there was not shown any reduction process in the checked potential range for the studied dye, whereas in the other three pH tested an only reduction peak was obtained, whose potential peak was shifted to potential more negative when the pH increased, which involves that E_p was pH dependent, (as expected for a reaction in which hydrogen ions take part in the electrochemical process), and whose intensity rose with the use of accumulation times. It was selected a value of pH 10 (NH_4Cl/NH_3 buffer) as optimum medium because the reduction peak obtained showed the highest sensitivity and the best definition.

We have chosen SWAdSV with regard DPAdSV by means of a brief investigation, in which square-wave voltammetry response was found to be very sensitive to the adsorption of Sunset Yellow on the mercury drop surface. In this study, a sample was treated in the same experimental conditions and with the most similar instrumental parameters by both techniques.

Later experiments were carried out in order to find optima chemical and instrumental conditions to determine Sunset Yellow by the technique chosen.

The selection of the optimum concentration of NH_4Cl/NH_3 buffer solution was made in order to reach the best signal over the background, subsequently, concentration of NH_4Cl/NH_3 buffer solution was varied between 0.01 and 0.50 M for a 200 μg l^{-1} Sunset Yellow solution. In Fig. 1 it is shown this experience and as it can be seen when the concentration buffer was increased between 0.01 and 0.25 M the peak response also increased, reaching a plateau between 0.25 and 0.50 M. This last concentration was chosen as optimum because it yielded the maximum peak response into the constant intensity area. The potential peak (E_p) stayed constant in all this experience.

In conditions above mentioned, the stability for a 30 μg l^{-1} solution of Sunset Yellow was tested, so, this solution seemed to be stable for two hours, which was enough to recorder all scans of an experience by SWAdSV technique, whereas for higher periods than 2 h, a decrease of the peak current associated with this reduction process was observed.

With regard to the advantageous use of nitrogen atmosphere maintained over the solution surface, parallel experiences were realized in presence and absence of N_2 showing similar results in both cases; for this reason, faster analysis could be even achieved satisfactorily by using non deoxygenated samples.

After that, it was achieved the optimization of instrumental parameters that affected the response to the adsorption phenomenon and to the

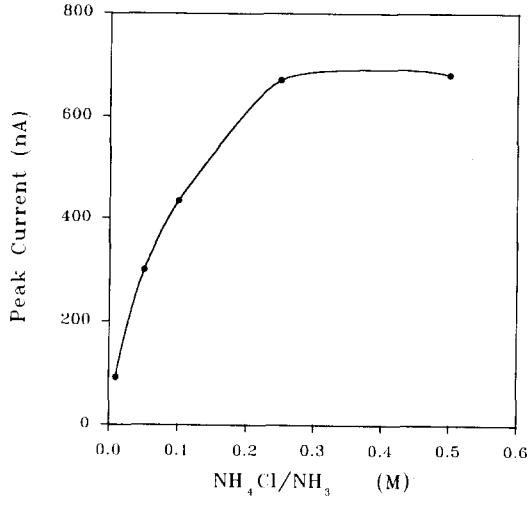


Fig. 1. Influence of NH_4Cl/NH_3 concentration over SWAdSV signal for a 200 μg l^{-1} Sunset Yellow solution. Experimental conditions: $\Delta E = 50$ mV, $\Delta s = 2$ mV, frequency = 50 Hz, electrode area = 2.5 mm^2.

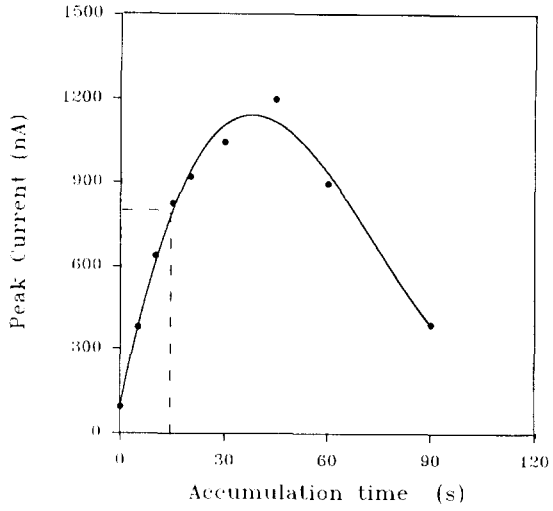

Fig. 2. Influence of accumulation time over the SWAdSV signal for a 30 μg l^{-1} Sunset Yellow solution. Experimental conditions: $[NH_4Cl/NH_3] = 0.5$ M, $E_{acc} = -0.4$ V, $\Delta E = 50$ mV, $\Delta s = 2$ mV, frequency = 50 Hz, electrode area = 2.5 mm^2.

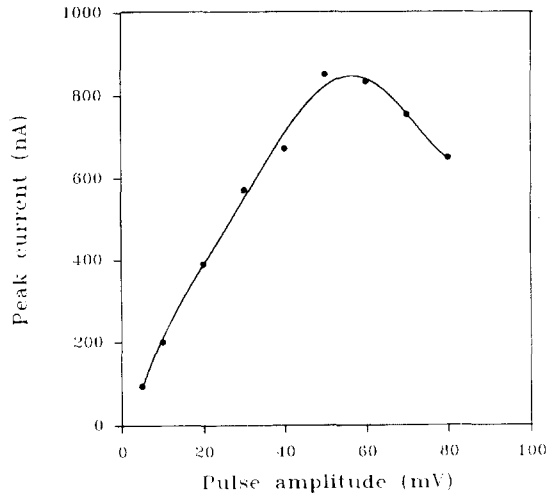

Fig. 3. Effect of pulse amplitude over the SWAdSV signal for a 30 μg l^{-1} Sunset Yellow solution. Experimental conditions: $[NH_4Cl/NH_3] = 0.5$ M, $E_{acc} = -0.4$ V $t_{acc} = 15$ s, $\Delta s = 2$ mV, frequency = 50 Hz, electrode area = 2.5 mm^2.

own technique. In all these assays a concentration of 30 μg l^{-1} of Sunset Yellow was used as suitable in order to prevent a rapid saturation of the mercury drop. Results obtained are the followings:

As optimum accumulation time (t_{acc}) it was chosen a value of 15 s because provided the largest peak current in the linearity range, whereas for accumulation times between 15 and 45 s the signal showed a not linear increase and even decreased the peak intensity for larger accumulation times as it is shown in Fig. 2. The potential of the reduction peak stayed constant for all this experience, however light shifts in E_p values to positive potentials were observed when very high accumulation times were tested. The linear relation found between I_p and t_{acc} in the range 0–15 s was the following:

$I_p(nA) = 98.33 + 54.28 t_{acc} \quad r = 0.9997 \quad n = 5$

In order to select the most suitable accumulation potential (E_{acc}) several values were tested (−0.30, −0.35, −0.40 and −0.45 V). The I_p value was independent of E_{acc} from −0.30 to −0.40 V and decreased for −0.45 V. An $E_{acc} =$ −0.40 V was selected as optimum. The variation of accumulation potential did not produce shifts in E_p values.

The influence of the pulse amplitude (ΔE) over the peak intensity was studied between 5 and 80 mV and a not linear relationship was observed in this range, being selected as optimum a value of 50 mV, because gave the largest peak intensity, decreasing the obtained signal for higher values of this parameter. In the other hand, an increase in ΔE values produced a shift in E_p to positive potentials. The effect of pulse amplitude over the peak intensity is shown in Fig. 3.

When the scan increment (Δs) was tested, the increase of this parameter (2, 4, 6, 8 and 10 mV) produced an increase in the peak intensity (Table

Table 1
Variation of I_p and E_p with Δs for the reduction process of 30 μg l^{-1} Sunset Yellow solution

Δs (mV)	E_p(V)	I_p(nA)
2	−0.57	820.3
4	−0.59	1090.4
6	−0.61	1115.1
8	−0.62	1190.5
10	−0.64	1234.3

Experimental conditions: $[NH_4Cl/NH_3] = 0.5$ M, $t_{acc} = 15$ s, $E_{acc} = -0.4$ V, $\Delta E = 50$ mV, frequency = 50 Hz, electrode area = 2.5 mm^2.

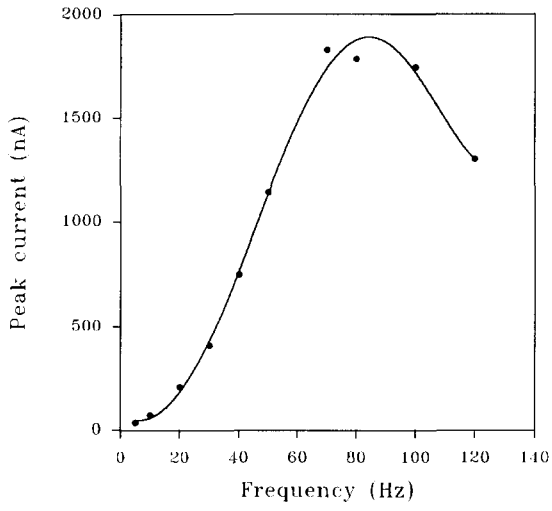

Fig. 4. Influence of frequency over the SWAdSV signal for a 30 μg l^{-1} Sunset Yellow solution. Experimental conditions = $[NH_4Cl/NH_3] = 0.5$ M, $t_{acc} = 15$ s, $E_{acc} = -0.4$ V, $\Delta E = 50$ mV, $\Delta s = 4$ mV, electrode area = 2.5 mm^2.

1), but also a distortion in this signal was observed, resulting a poorer resolution. It was concluded that an intermediate value of 4 mV was the most appropriate.

With regard to the frequency, the influence of this parameter was studied between 5 and 120 Hz, and a not linear response was obtained in this range, being selected as optimum a value of 70 Hz, because provided the largest peak current, decreasing this signal for higher values of this parameter as it is shown in Fig. 4. When frequency values were increased, E_p values showed a shift to negative potentials.

In these conditions, a very reasonable scan rate of 280 mV/s ($\Delta s \times$ frequency) was reached in this determination.

It was also tested the influence of the electrode area (1.0, 1.6 and 2.5 mm^2) over the peak current. In this experience, the increase of the size of area yielded, as expected, an increase in the peak response and did not affect the value of E_p. The size 'large' (2.5 mm^2) was considered as suitable in this experience because provided the largest intensity.

In conditions previously optimized, the repeatability of the signal was checked in the same day by measurements of a 30 μg l^{-1} Sunset Yellow solution and a relative standard deviation of 2.2% was obtained in such conditions ($n = 10$)

Once established the most suitable chemical and instrumental conditions, voltammograms at different concentrations of Sunset Yellow were recorded in such conditions in order to check the linearity range, showing an only peak at -0.60 V (Fig. 5). A calibration graph was established between 5.0 and 90.0 μg l^{-1} against their respective peak intensities, being the obtained equation:

$$I_p(nA) = 163.9 + 59.87C_s(\mu g\, l^{-1}) \quad r = 0.9994$$

$$n = 7$$

The determination limit (minimum signal measurable over the background voltammogram) reached in these conditions was 5.0 μg l^{-1}.

In Table 2 optima conditions selected by the studied technique have been summarized and also the variation range tested for each parameter.

4. Applications

The procedure for the preparation of the samples was the same in all cases: a known volume of

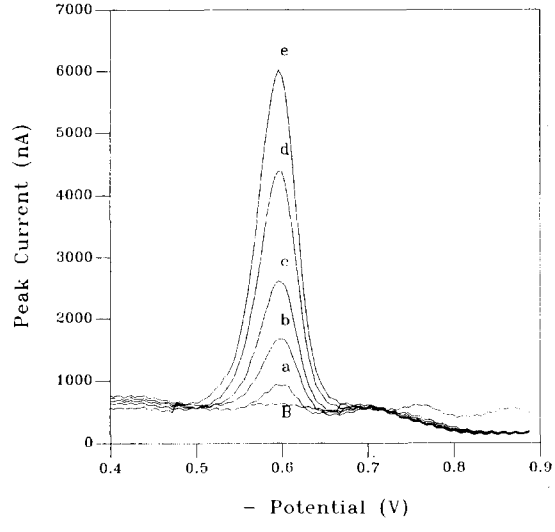

Fig. 5. Background (B) and square wave adsorptive stripping voltammograms at different concentrations of Sunset Yellow: (a) 5.0, (b) 15.0, (c) 30.0, (d) 60.0 and (e) 90.0 μg l^{-1}. Experimental conditions: $[NH_4Cl/NH_3] = 0.5$ M, $t_{acc} = 15$ s, $E_{acc} = -0.4$ V, $\Delta E = 50$ mV, $\Delta s = 4$ mV, frequency = 70 Hz, electrode area = 2.5 mm^2.

Table 2
Optima conditions to determine Sunset Yellow by SWAdSV

Parameter	Variation range	Optimum value
NH_4Cl/NH_3 concentration	0.01–0.5 M	0.5 M
Accumulation time	0–90 s	15 s
Accumulation potential	−0.30–0.45 V	−0.40 V
Pulse amplitude	5–80 mV	50 mV
Scan increment	2–10 mV	4 mV
Frequency	5–120 Hz	70 Hz
Electrode area	1.0–2.5 mm^2	2.5 mm^2
Linearity range	5.0–430.6 $\mu g\ l^{-1}$	5.0–90.0 $\mu g\ l^{-1}$

the commercial product (200, 20 and 100 μl of Tof lemmon, Gatorade lemmon and the third refreshing drink, respectively) was added in a 10 ml NH_4Cl/NH_3 0.5 M solution, which was placed in the voltammetric cell.

Standard addition method was used for determining contents of studied dye in order to avoid matrix effects. In Table 3 have been summarized the mean and standard deviations (estimated from five determinations) of results obtained in these analysis by standard additions method in each product. In Fig. 6 are shown voltammograms obtained when additions of Sunset Yellow of 10.0, 20.0 and 40.0 $\mu g\ l^{-1}$ were made over a diluted solution of commercial product Gatorade in 0.5 M NH_4Cl/NH_3.

In conditions already described in experimental section for HPLC study, three linear calibration graphs were established between 0.2 and 12.0 mg l^{-1} with slopes of 14.98, 17.43 and 31.70 arbitrary units of peak area $\times 1\ mg^{-1}$ at 420, 440 and 480 nm, respectively ($r = 0.9996$, 0.9994 and 0.9997).

Table 3
Contents ($\mu g\ l^{-1}$) of Sunset Yellow in commercial products

Refreshing drinks	SWAdSV	HPLC
Tof (lemon)	192 ± 4[a]	200 ± 5
Gatorade (lemon)	5790 ± 116	—
Refreshing drink (orange)	2142 ± 42	1960 ± 39

— Already explained in Section 4.
n (number of determinations) = 5.
[a] Mean ± S.D.

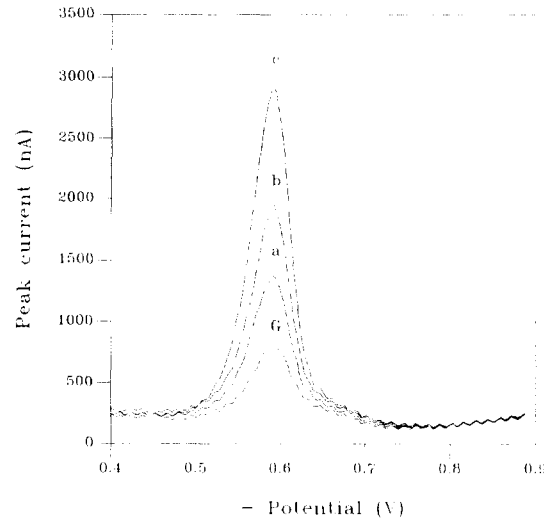

Fig. 6. Square-wave voltammograms of Gatorade (G) and standard additions of Sunset Yellow of (a) 10.0, (b) 20.0 and (c) 40.0 μg^{-1}. Experimental conditions: $[NH_4Cl/NH_3] = 0.5$ M, $t_{acc} = 15$ s, $E_{acc} = -0.4$ V, $\Delta E = 50$ mV, $\Delta s = 4$ mV, frequency = 70 Hz, electrode area = 2.5 mm^2.

Chromatographic results are also summarized in Table 3 and as it can be seen these results are in accordance with the obtained by voltammetric method. Sunset Yellow was not determined in Gatorade product by HPLC because voltammetric and chromatographic studies were achieved in different time periods, so when we realized chromatographic analysis this product had varied its composition and Sunset Yellow had been replaced by β-Carotene (E-160 a)

In the other hand, the presence of dye Quinoline Yellow in the composition of commercial products Tof and Gatorade did not involve interferences in the voltammetric determination of Sunset Yellow because in chemical conditions established Quinoline Yellow did not give reduction peaks at potentials where Sunset Yellow was reduced.

With regard to Tartrazine (Product 3), this colorant produced small interferences in the determination of studied dye, because gave a current peak at potentials (−0.61 V) very nearly to the Sunset Yellow (−0.60 V), which produced small differences between chromatographic and voltammetric results, (as it is shown in Table 3), that

could be due to the possible contribution of Tartrazine over voltammetric signal of Sunset Yellow, nevertheless, for similar concentrations, Sunset Yellow had a higher tendency than Tartrazine to be absorbed in the surface drop electrode in the accumulation step and consequently higher possibilities to be reduced in the cathodic run, showing higher peak currents. The presence of small amounts of Sunset Yellow restrain the Tartrazine signal corresponding to higher concentrations. In order to quantify this behaviour seven samples of different concentration ratios (Sunset Yellow: Tartrazine) were tested from ratios 4:1 to 1:10. It was observed a great contribution of Tartrazine over the analytical signal of Sunset Yellow (25–250%) from ratios 1:1 to 1:10, whereas in the other tested ratios there was not this interference.

5. Conclusions

Adsorptive stripping square-wave voltammetry is an useful technique to determine Sunset Yellow in commercial refreshing drinks. The sensitivity and accuracy of the method allowed in the determination of Sunset Yellow, and the relatively short accumulation times and inexpensive instrumentation are some of advantages provided by this technique.

We advise the proposed method using standard addition method measurements (in order to prevent matrix effect), taking into account good results obtained, the speed of the determination in analysis (very short length of real time analysis: 27 s), the simplicity of treatment of the sample (measurements have been made directly over a diluted solution of commercial product) and higher sensitivities reached in commercial applications with regards to other techniques [18] in the determination of contents of the studied dye in complex matrix as foods.

Satisfactory results and small values of standard deviations obtained in the determination of the dye in these three commercial products are an indication of the applicability of this method in other beverages and foods that contain this dye.

Inhibition of the enzyme phosphoenolpyruvate-carboxylase (PEPC) by different pollutants

Kathrin Stein *, Gerd Ohlenbusch

Institute of Inorganic and Analytical Chemistry, Technical University of Clausthal, Paul-Ernst-Str. 4, 38678 Clausthal-Zellerfeld, Germany

Received 1 April 1996; received in revised form 10 September 1996; accepted 17 September 1996

Abstract

The inhibitory effect of different pollutants on the enzyme phosphoenolpyruvate-carboxylase was investigated. For this enzyme, different procedures are described for determining the activity of the enzyme. Determination of the presence of the enzymatically-formed oxaloacetate was found to be more suitable for this purpose because of the higher sensitivity compared with that of the enzymatically-formed phosphate. In order to detect possible inhibitors of this enzyme, inhibition tests were carried out with different pesticides and metal ions. The enzyme activity was decreased by ziram, ferbam and pentachlorophenol. Of the tested metal ions, the enzyme reacts very sensitively to mercury ions, however cobalt, lead, zinc and copper also showed an inhibition effect. © 1997 Elsevier Science B.V.

Keywords: Heavy metal ions; Inhibitors; Pesticides; Phosphoenolpyruvate-carboxylase (PEPC)

1. Introduction

In routine analysis of drinking water, sewage and soil, a larger part of the samples proved to be non-polluted. Using traditional instrumental analysis methods for this is very expensive. Thus, biochemical analysis procedures have received more and more attention in the last few years. Enzymes may be used as powerful instruments to detect hazardous substances in food and even in environmental substances. Enzyme inhibition tests are part of this methodology. Screening tests can be carried out with these kinds of samples. The polluted ones can be separated from the non-polluted ones, so that only the actual polluted samples must be examined with the more exact, but also more expensive, instrumental methods. This can significantly cut costs and save time. The enzyme inhibition test is especially well suited as a screening test. Here, the fact that the activity of enzymes is selectively inhibited by certain pollutants is explored. The intensity of the inhibition correlates with the concentration of the pollutant. It is necessary to be able to use a variety of inhibition tests to screen different pollutants. With respect to the enormous multiplicity of enzymatic reactions it seems possible to design enzymatic screening tests for nearly each substance of interest [1]. Therefore it is very important to find enzyme-inhibitor-systems with environmental rele-

* Corresponding author.

PII S0039-9140(96)02107-8

vance. The interest on such screening tests for pesticides is very high. A well examined example is the acetylcholinesterase inhibition test, which has been available on the market for a longer time. Organophosphorous acid esters and *N*-methyl carbamates can be detected in water samples. Another example is the inhibition of the enzyme aldehyde dehydrogenase, dithiocarbamates used as fungicides inhibit this enzyme [2]. By using microtiterplates, the time needed to carry out enzyme inhibition tests is reduced tremendously, since up to 96 tests can be carried out simultaneously. Thus, sample preparation is the most time consuming step. Another pollutant of great interest is the herbicide atrazine, which is given as a possible inhibitor of the enzyme phosphoenolpyruvate carboxylase by Wiegand-Rosinus et al. [3]. Therefore the inhibition behaviour of phosphoenolpyruvate carboxylase is experimentally examined. We could not measure an inhibition of this enzyme by atrazine. To determine other inhibitors of the enzyme, the inhibition test is carried out with the pesticides ferbam, ziram, aldrin, heptachlor, aldicarb, carbofuran, parathionethyl and pentachlorophenol, which are choosen as examples of different chemical structures (normally the inhibition depends on the chemical structure), and the metal ions mercury, thallium, aluminium, nickel, chromate, cobalt, lead, zinc and copper (the activity of a lot of enzymes is inhibited by heavy metal ions).

The activity of enzymes can be determined by measuring the products formed after the enzymatic reaction. The enzyme phosphoenolpyruvate carboxylase acts as catalyst in the following reaction:

$$PEP + HCO_3^- \xrightarrow{PEPC} OAA + P_i$$

PEP, phosphoenolpyruvate; PEPC, phosphoenolpyruvate carboxylase; OAA, oxaloacetate; P_i, inorganic phosphate.

Some authors described the determination of CO_2 or bicarbonate with the use of phosphoenolpyryvate decarboxylase in buffer solutions, food or animal tissues, plasma or serum. All these applications malate dehydrogenase was used to measure the formed oxaloacetate [4–7]. Instead of a coupled enzymatic reaction the formed products could be measured photometrically. This is more suitable for an inhibition test, because of the possible influence of the investigated inhibitors on the second enzymatic reaction. For the photometric determination of inorganic orthophosphate, a large number of different procedures are described [8–14]. In this work, the phosphate reacts with molybdate-vanadate solution, and the formed molybdato-vanadato-phosphate complex is measured at a wavelength of 405 nm [8,11]. Oxaloacetate can be measured photometrically as well. The diazonium salt, fast violet B, forms a red complex with oxaloacetate, which could be measured photometrically at 490 nm [15].

2. Experimental

2.1. Apparatus

Microtiterstrip reader (Behring EL 301), MaxiSorp-microtiterstrips (Nunc Ltd.), pH-meter E 603 (Metrohm).

2.2. Reagents

For all solutions bi-distilled water was used.

2.2.1. Activity measurement by determining the enzymatically formed phosphate

$KHCO_3$ (MicroSelect, Fluka); solution: 50 mg are dissolved in 25 ml water. $MgCl_2 \cdot 6H_2O$ (p.a., Merck); solution: 51 mg are dissolved in 25 ml water. HCl (p.a., Riedel-de Haën); 37%. Tris–(hydroxymethyl)–aminomethane (TRIS) (p.a., Merck); solution: 6 mg TRIS are dissolved in water, the pH is adjusted to 8.6 with HCl (1 mol l^{-1}) and filled to 50 ml. Cofactor solution: 4 ml $KHCO_3$ solution, 2 ml $MgCl_2 \cdot 6H_2O$ solution and 1 ml TRIS solution are mixed. Nitric acid, Baker; 70–71%. Ammoniumvanadate (p.a., Riedel-de Haën); solution: 25 mg ammoniumvanadate are dissolved in hot water, 0.2 ml concentrated nitric acid are added and the mixture is filled to 10 ml with water. Sulphuric acid (p.a., Merck); 95–97%. Ammoniummolybdate-tetrahydrate (p.a., Merck); solution: 1 g ammoniummolybdate is dissolved in approximately 50°C warm water, 1 ml concen-

trated H_2SO_4 is added and the mixture is filled with water to 10 ml. Reagent solution: 3 ml each of freshly made ammoniummolybdate and ammoniumvanadate solution are mixed.

Phosphoenolpyruvate-carboxylase (E.C. 4.1.1.31) (suspension of the enzyme from corn in 2.4 mol l^{-1} ammonium sulphate solution, 10 mmol l^{-1} phosphate buffer (pH 7), 1 mmol l^{-1} biotin, 5 mmol l^{-1} dithiothreitol and 1 mmol l^{-1} phenylmethylsulfonylfluoride; 8.1 mg protein ml^{-1}; 2.4 U mg^{-1} protein),(Sigma); solution (750 U l^{-1}): 38.6 µl enzyme suspension was diluted with 961.4 µl water.

Phosphoenolpyruvate tricyclohexylaminsalt (PEP) >98%, (Fluka); stock solution: 93.1 mg PEP are dissolved in 2 ml water. For getting the substrate curve solutions in the concentration range from 1×10^{-1} to 1.34×10^{-3} mol l^{-1} the stock solution is diluted adequately. For the following inhibition test 46.6 mg PEP was dissolved in 2.5 ml water. Acetonitril (p.a., Riedel-de Haën).

2.2.2. Activity measurement by determining the enzymatically formed oxaloacetate

TRIS; solution (1 mol l^{-1}): 1.2114 g TRIS are dissolved in 10 ml water. $MgCl_2 \cdot 6H_2O$ (p.a., Merck); solution (0.2 mol l^{-1}): 40.6 mg are dissolved in 10 ml water. $KHCO_3$ (MicroSelect, Fluka); solution (0.4 mol l^{-1}): 40.1 mg are dissolved in 10 ml water. Triton X-100 (alkylphenylpolyethylenglycol) (SERVA); solution (1%): 1 ml is dissolved in 100 ml water. Fast violet B (FVB) standard (Fluka); solution (6 g l^{-1}): 30 mg FVB are dissolved in 5 ml Triton X-100-solution. The solution must be prepared freshly every day. Oxaloacetic acid 99%ig (Fluka); solution (2.5 mmol l^{-1}): 330 mg oxaloacetic acid are dissolved in 100 ml water. TRIS buffer: 0.5 ml TRIS solution and 0.5 ml $MgCl_2$ solution are mixed and filled with water to 7 ml. Subsequently the pH is adjusted to 8 with HCl (1 mol l^{-1}) and filled with water to 10 ml. Enzyme solution: 10.3 µl enzyme suspension are diluted with 989.7 µl water. Phosphoenolpyruvate tricylcohexylaminsalt (PEP) (Fluka); solution: 20 mg PEP are dissolved in 200 µl $MgCl_2$ solution (0.2 mol l^{-1}), 200 µl TRIS buffer (1 mol l^{-1}) and 100 µl $KHCO_3$ solution (0.4 mol l^{-1}). Subsequently, the pH is adjusted to 9 with HCl (1 mol l^{-1}) and filled with water to 2 ml.

2.2.3. Inhibitors

Pentachlorophenol (PCP), (AccuStandard Ehrenstorfer, Augsburg); stock solution (1 g l^{-1}): 10 mg PCP are dissolved in 10 ml methanol. Sample solutions are prepared by adequately diluting with water in the concentration range from 2 mg l^{-1} to 100 mg l^{-1}. Ferbam (Ehrenstorfer, Augsburg); 84% stock solution (0.84 l^{-1}): 10 mg Ferbam are dissolved in 10 ml acetonitril. Sample solutions are prepared by diluting adequately with water in the concentration range from 1.05 mg l^{-1} to 84 mg l^{-1}. $HgNO_3$ (p.a., Fluka); standard solution (1 g l^{-1} Hg^{2+}): 161.8 mg $HgNO_3$ are dissolved in 100 ml nitric acid. All other used pesticides, Ehrenstorfer, Augsburg, all other tested heavy metal stock solution 1 g l^{-1}, Merck.

3. Procedure

3.1. Activity measurement by determining the enzymatically formed phosphate

For determining the substrate curve, 70 µl cofactor solution, 40 µl PEP solution and 40 µl enzyme solution are poured in the wells of the microtiter strip. After 13 min enzymatic reaction time, 30 µl reagent solution are added. Photometric measurements are carried out after another 2 min at 405 nm against the reagent blank containing water instead of PEP solution.

3.2. Determination of the inhibition using photometric phosphate determination

For inhibition tests, 70 µl cofactor solution, 80 µl standard solution (inhibitor) and 40 µl enzyme solution (750 U l^{-1}) are poured in the wells of the microtiter plate. After an incubation period of 30 min, in which the inhibition reaction takes place, 40 µl PEP solution are added, and after another 30 min of reaction time, 30 µl reagent solution are added. After 2 min, photometric measurements are carried out at 405 nm against reagent blank. 100% activity is determined using water instead of the inhibitor solutions. The inhibition was calculated as follows:

$$I[\%] = \frac{A_0 - A_i}{A_0} 100\%$$

A_0, absorption of the non-inhibited reaction; A_I, absorption of the inhibited reaction; I, inhibition.

3.3. Activity measurement by determining the enzymatically formed oxaloacetate

For determining the complex formation rate between FVB and enzymatically formed oxaloacetate, the following volumes of solutions are poured into the wells: 60 μl buffer, 40 μl oxaloacetic acid, 60 μl water and 90 μl FVB solution. After the addition of the FVB solution, the absorption is determined photometrically at intervals of 1 min at 490 nm against reagent blank, containing water instead of oxaloacetate.

3.4. Determination of the inhibition using photometric oxaloacetate determination

For inhibition tests, 100 μl inhibitor solution and 30 μl enzyme solution are poured in the wells of the microtiter plate. After 30 min incubation period, 30 μl PEP solution are added and after another 30 min reaction time, 30 μl FVB solution are added. The absorption is measured 15 min later at 490 nm against reagent blank, containing water instead of PEP solution. 100% activity is determined using water instead of inhibitor solution.

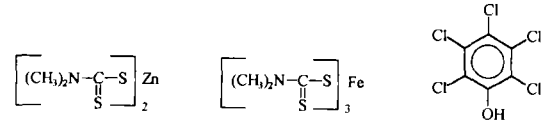
4. Results and discussion

4.1. Determining the enzymatic activity by means of photometric phosphate determination

In the acidic pH range, which is necessary for photometric phosphate determination, the enzyme denatures immediately and forms very fine flakes, but in the concentration range from 0.5 to 5 μmol l^{-1} phosphate a linear relationship between absorption and concentration (regression coefficient: $r = 0.996$) is observed at this acidic pH.

For the development of the inhibition tests, the optimal substrate concentration has to be determined. For this, a substrate curve is measured by determining the absorbance at different substrate concentrations (Fig. 1). Normally, the substrate concentration at the beginning of the steady state range should be chosen for the inhibition test [16]. Here, a small fluctuation in the substrate concentration (e.g., due to pipetting deviation) does not lead to larger deviations of the absorption. In this case, with a substrate concentration of 6 mmol l^{-1}, a compromise was chosen. This concentration is not in the steep increase section of the substrate curve. A sufficiently high signal is observed, and the costs for the expensive substrate phosphoenolpyruvate are not yet too high. From the Lineweaver–Burk plot, the Michaelis constant is determined to be $K_M = 4.1$ mmol. This value matches well with the value given in the literature (approximately 1 mmol) [17].

By using atrazine no inhibition effect could be observed at concentrations up to 100 mg l^{-1}. Since the possible inhibition mechanism is not known, a series of other pesticides are tested regarding their inhibition to this enzyme. An inhibition effect on the enzyme is observed for the fungicides ziram, ferbam and pentachlorophenol.



ziram ferbam pentachlorophenol

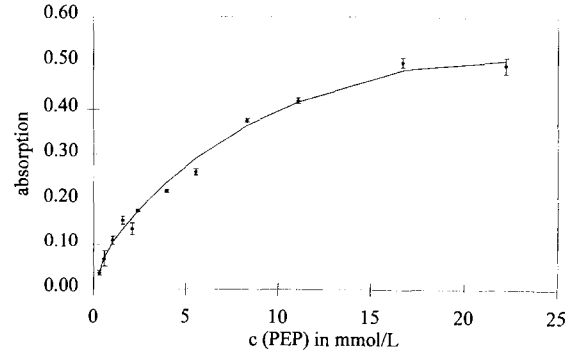


Fig. 1. Substrate curve for phosphoenolpyruvate (PEP) (mean values from $n = 5$ measurements).

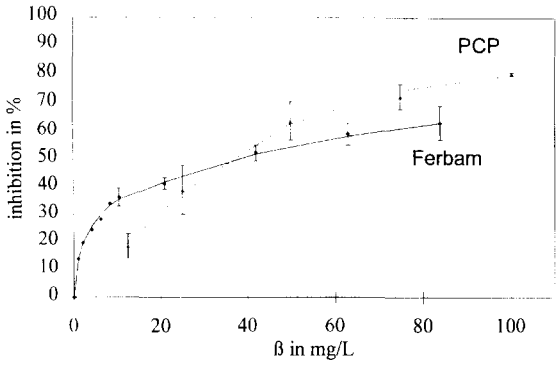

Fig. 2. Inhibition caused by pentachlorophenol (mean values from $n = 3$ measurements) and by ferbam (for $c > 20$ mg/l: mean values from $n = 3$ measurements) (photometric phosphate determination).

For the other investigated pesticides (aldrin, aldicarb, atrazine, azinphosethyl, carbofuran, heptachlor and parathionethyl), no inhibition effect could be measured up to concentration of 100 mg l^{-1}.

The inhibition curve was determined for ferbam and PCP (Fig. 2). Often the 10% inhibition value is given as a detection limit. Under this not optimised condition 10% inhibition was observed at 7.5 mg l^{-1} PCP and below 1 mg l^{-1} ferbam. Since the inhibitors are dissolved in organic solvents the influence of the solvent was investigated. 10% of methanol leads to a decrease in activity of 25%, but 10% of DMSO leads to an inhibition of the enzyme of 20%. In contrast to this, the solvent acetonitrile leads only to a little increase in enzyme activity. The weak amounts of solvents in the sample, which influence likewise the activity of the enzyme, were mathematically considered at the evaluation by measuring the influence of the solvent and substracted rsp added this inhibition rsp activation caused by the solvent from the measured total inhibition rsp the measured activation was taken into account determining the not inhibited activity. Since it is well known, that enzymes can be inhibited by heavy metal ions, the suspicion is obvious, that the inhibition caused by ferbam is developed by the iron ion of the molecule. Therefore, an inhibition test with $FeCl_3 \cdot 6H_2O$ solution is carried out. The concentration of the iron ions is the same as the iron concentration in the solution of 100 mg l^{-1} ferbam. With this iron solution, however, no inhibition of the enzyme could be observed. Therefore, the observed inhibition of the ferbam solution is caused by the ferbam molecule itself, and not by the iron ion.

4.2. Determination the enzymatic activity by means of oxaloacetate detection

Years ago Norris et al. described a method using FVB for the oxaloacetate determination formed by phosphoenolpyruvate carboxylase [15]. In determining the enzyme activity by means of the oxaloacetate concentration after 15 min the oxaloacetate is almost completely transformed with the Fast Violet B (FVB). For the following measurements, the absorption is measured 15 min after addition of the FVB solution (Fig. 3). Because of the inhibition effect of FVB itself [15], it must be added at the end of the enzymatic reaction. The absorption in the investigated concentration range from 10 to 500 µmol l^{-1} oxaloacetate showed a very good linearity (regression coefficient: $r = 0.9999$). Because of the higher sensitivity of the photometric oxaloacetate determination compared with the phosphate determination weaker enzyme concentrations can be used. This way, the detection limit of the inhibitor is improved. As shown in the inhibition curve of Fig. 4, 20 mg l^{-1} PCP cause almost 100% inhibition of the enzyme, while at determination of the enzymatic activity by means of measuring the

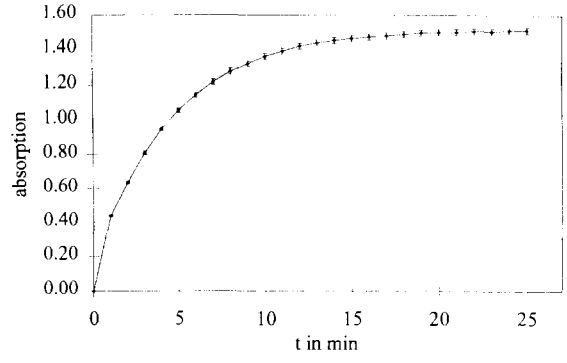

Fig. 3. Formation rate of the diazonium colour complex (mean values from $n = 3$ measurements).

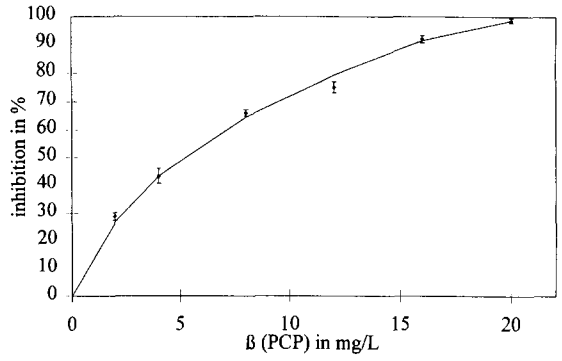

Fig. 4. Inhibition caused by pentachlorophenol (mean values from $n = 2$ measurements) (photometric oxaloacetate determination).

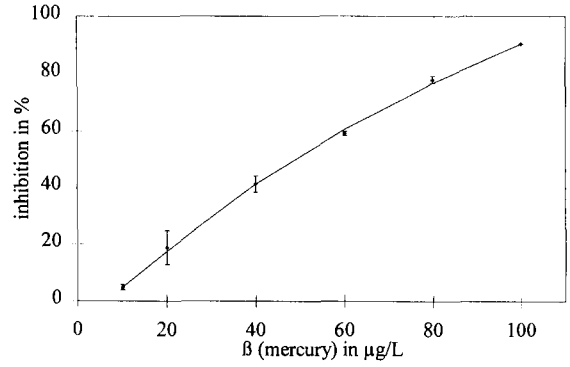

Fig. 5. Inhibition caused by mercury(II)-ions (mean values from $n = 2$ measurements) (photometric oxaloacetate determination).

enzymatically formed phosphate with 100 mg l^{-1} PCP, an inhibition of only 80% is observed (compare Fig. 2).

The mercury(II) ion is a very strong inhibitor for phosphoenolpyruvate carboxylase, as it is for a lot of other enzymes. As shown by the inhibition curve in Fig. 5, Hg(II) could be detected in the µg l^{-1} concentration range (10% inhibition for 15 µg l^{-1} Hg(II)). Analogously, the inhibition effect of other heavy metal ions were investigated. At concentrations of 1 mg l^{-1} thallium, aluminium, nickel and chromate, no inhibition was observed. However, cobalt (< 10% inhibition at 1 mg l^{-1}), lead (< 10%), zinc (27%) and copper (54%) are also inhibitors of this enzyme.

5. Prospect

In this work the determination of the enzymatic formed oxaloacetate was found to be more suitable for a phosphoenolpyruvate inhibition test, because of its higher sensitivity, which results in a higher sensitivity to the inhibitors examined. The described investigations are basic points for the optimisation of the inhibition test under the view of the further application, e.g., determination of PCP in extracts of leather, wood or cotton, determination of Hg^{2+} ions in natural waters, extracts from soil or food and so on, which will be done at the time. Such inhibitions test are a tool in the field of the analysis with the respect to the effect of pollutants on the environment.

Short communication

Detection and semiquantitative determination of bismuth(III) in water on immobilized and plasticized polyurethane foams with some chromogenic reagents

M.S. El-Shahawi*[1], R.S. Al-Mehrezi

Department of Chemistry, Faculty of Science, UAE University, P.O. Box 17551, Al-Ain, United Arab Emirates

Received 7 November 1995; revised 16 April 1996; re-revised 17 May 1996; accepted 22 May 1996

Abstract

Polyurethane foams immobilizing 1,2-di-(2-fluorophenyl)-3-mercaptoformazan (F_2H_2Dz) and dithizone (H_2Dz) have been used for the detection of bismuth(III) in water via batch, dynamic and pulsated column modes of extraction. The detection limits of bismuth(III) with the F_2H_2Dz- and H_2Dz-immobilized foams were found to be 0.01 and 0.02 $\mu g\ ml^{-1}$ respectively. Lower concentrations ($\leqslant 1$ ppb) of bismuth(III) were also detected by employing dynamic and pulsated columns packed with plasticized tri-*n*-butylphosphate and F_2H_2Dz-immobilized reagent foams. The electronic spectra and partition coefficients of the reagents H_2Dz and F_2H_2Dz and their bismuth(III) chelates in chloroform and in polyurethane foams have been determined. Bismuth (V) was also detected by the proposed procedure after prior reduction to bismuth(III) with sulphur dioxide at pH < 1. The effect of diverse ions on the detection of 1 μg of bismuth(III) was critically investigated using F_2H_2Dz-immobilized foam. © 1997 Elsevier Science B.V.

Keywords: Bismuth(III); Chromogenic reagents; Polyurethane foams

1. Introduction

Various reagents have been used for the detection, extraction and spectrophotometric determination of bismuth(III) [1]. Most of these reagents suffer from limitations, e.g. long extraction period, low stability of the compounds formed, low tolerance limit, critical pH and interferences [1,2].

Open cell polyurethane foams have been successfully used for the extraction and collection of various species in aqueous media [3]. Foams loaded with dithizone and other chromogenic reagents (chromofoams) have been reported for the sensitive detection and semiquantitative determination of some metal ions, including bismuth(III), employing batch and column extraction modes [4–9].

There has been no study of the use of 1,5-di(2-fluorophenyl)-3-mercaptoformazan agent in the detection and proconcentration of bismuth(III)

and other metal ions in aqueous solution employing polyurethane foams. Thus, the present paper describes the use of the immobilized and plasticized 1,5-di-(2-fluorophenyl)-3-mercaptoformazan (F_2H_2Dz) and dithizone (H_2Dz) polyurethane foams for the sensitive and selective detection and the semiquantitative determination of traces of bismuth(III) in aqueous media.

2. Experimental

2.1. Reagents and materials

All the reagents used were of analytical-reagent-grade unless otherwise specified. An open cell polyether type polyurethane foams (bulk density 30 kg m^{-3}) was supplied by Greiner K.G. Schaumstoffwerk (Kremsmunster, Austria). The foam material (cubes with 0.5 cm sides) was washed and dried as previously described [10]. A stock solution containing 1 mg ml^{-1} of bismuth(III) was prepared by dissolving the appropriate amount of bismuth(III) nitrate pentahydrate in deionized water acidified with a few drops of 0.5 M nitric acid and standardized by EDTA titration. A bismuth(III) solution (100 μg ml^{-1}) was also prepared by dissolving 0.123 g of bismuthic acid in 100 ml of 0.5 M KOH [11]. Tri-*N*-butylphosphate (TBP; BDH) was used without further purification. A series of standard bismuth(III) and (V) solutions was prepared by dilution with water acidified with a few drops of nitric acid.

The reagent F_2H_2Dz was prepared by the nitroformazyl method [12,13]. This reagent and the H_2Dz (Merck) solutions were prepared by dissolving 10 mg of each reagent separately in 50 ml of chloroform. The F_2H_2Dz- and H_2Dz-loaded foams were prepared by mixing the dried foam cubes with F_2H_2Dz and H_2D-2 solutions (10 ml g^{-1} dry foam) respectively and stirring for 10 min. The reagent-loaded foam cubes were then squeezed and dried as reported [10]. Plasticized F_2H_2Dz and H_2Dz foams were prepared by mixing the dried foam cubes with F_2H_2Dz and H_2Dz (0.1% w/v) in TBP respectively, stirring for 15 min and then drying [10].

2.2. Apparatus

A Shimadzu UV 2101 PC UV–visible scanning spectrophotometer and a Shimadzu FTIR-8101 Fourier transform infrared spectrophotometer were used for recording the IR and electronic spectra of the reagents and their bismuth(III) complexes in chloroform and in parallelepiped polyurethane foam. An Orion pH-meter, glass

[a] Data were obtained from Ref. [4].

columns (16 cm height × 5 mm i.d.) and medical syringes (100 ml capacity) as pulsating columns were used.

2.3. General procedures

2.3.1. Batch experiment

One of the immobilized reagent or plasticized TBP–reagent foam cubes was shaken with 3–5 ml of the bismuth(III) aqueous solution (pH < 4) for 2 min. The colour of the reagent foam changed from green to orange–brown and to orange with H_2Dz and F_2H_2Dz respectively. The colour that developed on the foam cube was taken as evidence for the detection of bismuth(III).

2.3.2. Column experiments

1 g of the F_2H_2Dz or H_2Dz-loaded or plasticized reagent–TBP foams was packed in a glass column by the vacuum method of foam column packing [14]. 250 ml of the bismuth(III) solution of optimum pH was allowed to pass through the foam column at a flow rate of 2–3 ml min^{-1}. The coloured foam bed produced was used for the detection of bismuth(III) ions.

2.3.3. Pulsating column experiments

50 ml of the bismuth(III) solution of suitable pH was transferred to a 100 ml medical syringe. The solution was then compressed and released with one cube of F_2H_2Dz-immobilized or plasticized F_2H_2Dz–TBP foam. An orange colour on the foam cube was then observed after 25 successive pulses.

3. Results and discussion

Table 1 summarizes the IR data for the regions of interest in the spectra of the solid reagents H_2Dz and F_2H_2Dz and their solid complexes of bismuth(III) in a potassium bromide disc. The reagents F_2H_2Dz and H_2Dz and their bismuth(III) complexes were characterized by IR spectral [15–17] (Table 1) and elemental analysis. The electronic spectra of the reagents and bismuth(III) complexes in chloroform and in parallelepiped polyurethane foams are also given in Table 1 and Fig. 1. The electronic spectra of the bismuth(III) complexes in chloroform (Fig. 1A) and in polyurethane foams (Fig. 1B) have well-defined bands at 489–490 and 478–487 nm respectively and a broad shoulder of low intensity at 270–360 nm. The introduction of fluorine atoms at the C-2 position of the phenyl radicals of H_2Dz leads to small bathochromic shifts of both of its bands (632 and 454 nm → 615 and 448 nm respectively) for H_2Dz. The position of λ_{max} for the bismuth(III) complex of F_2H_2Dz in chloroform underwent similar shifts (Table 1) as compared with the bismuth(III) complex of H_2Dz. The relative molar absorptivities in chloroform of the two absorption bands of F_2H_2Dz and its bismuth(III) complex were similarly affected by the introduction of fluorine atoms compared with H_2Dz and its bismuth(III) complex (Table 1).

3.1. Detection and semiquantitative determination of bismuth(III) with F_2H_2Dz

Bismuth(III) forms orange–red and orange–

Table 3
Detection of 1 μg of bismuth(III) with F_2H_2Dz-immobilized polyurethane foams in the presence of some interfering ions

Foreign ions	Compound added	Tolerance limit	Note
Cd^{2+}	$CdBr_2$	$1:1 \times 10^4$	Add a few crystals of sodium sulphite
Fe^{2+}	$FeSO_4$	$1:1 \times 10^4$	Add 1 ml of NaF (1 M)
Fe^{2+}	$FeCl_3$	$1:1 \times 10^4$	Add 1 ml of NaF (1 M)
Ni^{2+}	$NiCl_2 \cdot 4H_2O$	$1:1 \times 10^3$	Add a few drops of KCN (1 M)
Au^{3+}	$AuCl_3$	$1:1 \times 10^3$	Add a few crystals of sodium sulphite and adjust pH to $\simeq 1$
MnO_4^-	$KMnO_4$	$1:1 \times 10^3$	Add one crystal of sodium azide
Mn^{2+}	$MnSO_4$	$1:1 \times 10^4$	Add bromine water and boil the solution
Hg^{2+}	$HgCl_2$	$1:1 \times 10^4$	Add one crystal of ascorbic acid
Pd^{2+}	$Pd(NO_3)_2$	$1:1 \times 10^3$	Add one crystal of NaF or thiourea
Cr^{3+}	$CrCl_3 \cdot 6H_2O$	$1:1 \times 10^3$	Add H_2O_2 and boil the solution
Ag^+	$AgNO_3$	$1:1 \times 10^3$	Add a few crystals of KCNS
Zn^{2+}	$ZnSO_4$	$1:1 \times 10^3$	Adjust the pH of the aqueous solution to <2 with HNO_3 (1 M)
Oxalate	$H_2C_2O_4 \cdot 2H_2O$	$1:1 \times 10^3$	Add bromine water and boil the solution
VO_3^-	NH_4VO_3	$1:1 \times 10^3$	Add 1 ml of NaF (1 M)

brown complexes [12, 18] with F_2H_2Dz and H_2Dz in acidic aqueous solution ($pH < 5.2$) respectively. These reactions were tried with foam immobilized with F_2H_2Dz and H_2Dz and plasticized reagent–TBP foam for the detection and semiquantitative determination of bismuth(III) in aqueous solution.

On shaking one cube of the unloaded foam with the mixed test solution of $Bi(F_2HDz)_3$ in a test tube at $pH < 4$ for 2–3 min as little as 0.10 ppm bismuth(III) was easily detected. The sensitivity of the test was significantly improved by immobilizing or plasticizing the foam cubes with the reagent F_2H_2Dz. On shaking one cube of the immobilized F_2H_2Dz foam and one cube of the plasticized F_2H_2Dz–TBP with 2–3 ml of the test aqueous solution of bismuth(III) concentrations as low as 0.01 and 0.005 ppm were easily detected respectively. The relatively high available surface area of the foam cube acts as an efficient collector for the bismuth(III) ions present in the aqueous solution at low concentration. In addition, it is easy to observe the characteristic red colour of the reaction product on/in the thin membranes of the foam material. The TBP plays a dual purpose [5] as it acts as an efficient non-volatile solvent for the reagent F_2H_2Dz and as a plasticizer for the plastic foam itself. This enhances the permeability of the foam material and the rate of sorption of bismuth(III) ions from the aqueous solution on the plasticized reagent foam. A comparison between these results (Table 2), those reported with the usual spot test [19] and those of Hamza et al. [4] employing H_2Dz-loaded foam shows that the F_2H_2Dz-immobilized foam and platicized F_2H_2Dz-TBP foam methods are much more sensitive for the detection of bismuth(III) than H_2Dz and other chelating agents [4, 19].

The colour density on the foam cubes was found to depend on the concentration of the bismuth(III) ions. Thus, semiquantitative determination of bismuth(III) was achieved by comparison of the colour of the plasticized F_2H_2Dz-TBP foam cube with a standard colour scale prepared from 0.01, 0.05, 0.1, 0.5, 1 and 10 ppm bismuth(III) solutions under the same experimental conditions.

The proposed F_2H_2Dz-loaded and plasticized F_2H_2Dz–TBP foams were easily packed in the column mode producing a foam bed suitable for the detection of bismuth(III) present in an extremely dilute aqueous solution. Concentrations

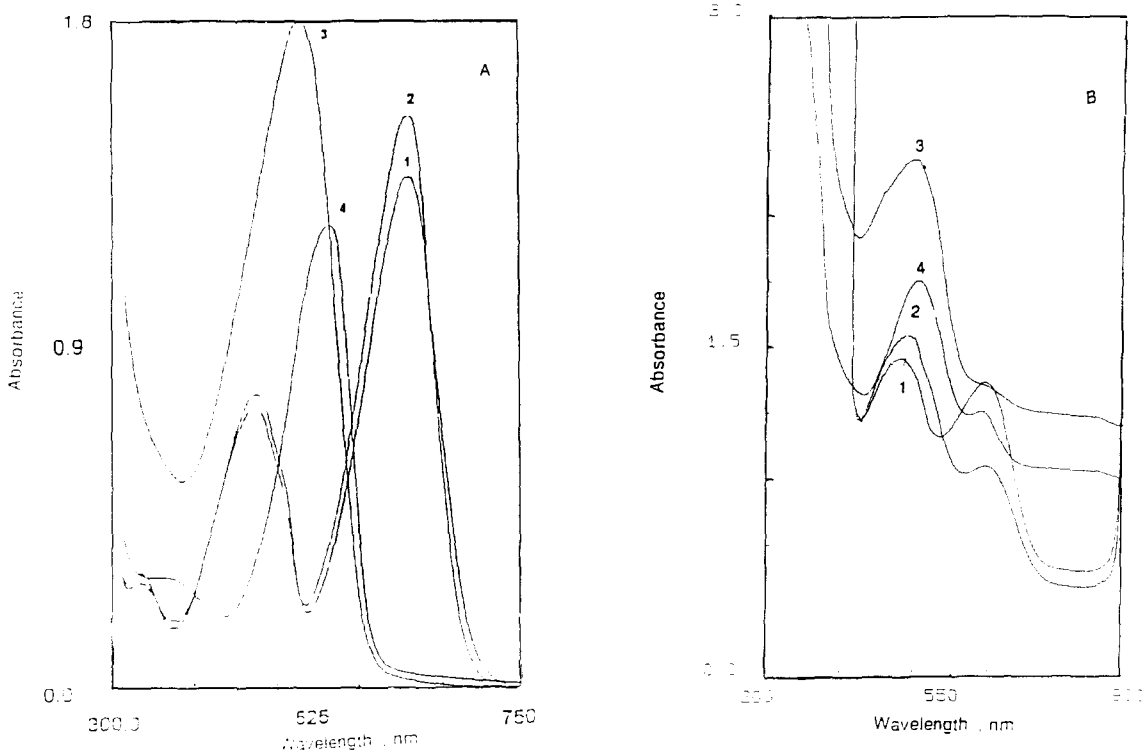

Fig. 1. Electronic spectra of (1) F_2H_2Dz, (2) H_2Dz, (3) $Bi(F_2HDz)_3$ and (4) $Bi(HDz)_3$ in chloroform (A) and in polyurethane foam (B).

as low as 5 and 1 ppb of bismuth(III) in aqueous solution were easily detected with F_2H_2Dz-loaded and plasticized F_2H_2Dz–TBP foams respecively. The length of the coloured zone was found to be proportional to the bismuth(III) concentration in the aqueous phase (Fig. 2). Thus, semiquantitative determination of bismuth(III) in extremely dilute solutions was found to be possible using a standard colour covering the range 5–80 ppb and employing F_2H_2Dz-loaded foam.

The proposed F_2H_2Dz-loaded and plasticized F_2H_2Dz–TBP foam cubes were used in a medical syringe for the detection of bismuth(III). As little as 5 ppb of bismuth(III) was easily detected after 25 successive pulses with F_2H_2Dz-loaded and plasticized F_2H_2Dz–TBP foams. Semiquantitative determination was also found to be possible with standards of 5, 10, 15, 20 and 25 ppb bismuth(III) solution by comparison of the colour of the foam cubes at a constant number of pulses $\geqslant 25$.

3.2. Determination and semiquantitative determination of bismuth(III) with H_2Dz foam

The use of H_2Dz allows the detection of as little as 0.02 ppm bismuth(III) in aqueous solution by shaking one cube of H_2Dz-loaded foam or plasticized H_2Dz–TBP foam with the test solution. These data are in good agreement with the data reported by Hamza et al. [4]. As little as 5 ppb of bismuth(III) was easily detected in aqueous solution by H_2Dz-loaded and plasticized H_2Dz–TBP foam columns at a flow rate of 2–3 ml min^{-1}. The semiquantitative determination of bismuth(III) with immobilized foams was found to be possible in the concentration range 1–30 ng ml^{-1} (Fig. 2).

The results obtained with F_2H_2Dz were much better thatn those obtained with H_2Dz. The higher acidity of F_2H_2Dz ($pK_a = 4.05$) and the higher extraction constant of its bismuth(III) complex ($\log K_{ex} = 11.41$) compared to the values

for H_2Dz ($pK_a = 4.7$) [20] and its $Bi(HDz)_3$ complex ($\log K_{ex} = 9.8$) may partially account for this behaviour. The distribution ratios of $Bi(F_2HDz)_3$, ($\log D = 4.1$) and $Bi(HDz)_3$ ($\log D = 3.8$) in the thin membrane of the polyurethane foam may also play significant roles in the preconcentration. Similarly, the fluorine atom at the ortho position of the phenyl moiety of H_2Dz was found to increase the partition coefficient of F_2H_2Dz between CCl_4 and H_2O to 2.1×10^4 compared to 1.1×10^4 for H_2Dz [21,22] in the same two-phase system. The partition coefficient of $Cu(F_2HDz)_2$ between CCl_4 and H_2O was found to be 1.53×10^5 [21], compared to 7.3×10^4 for $Cu(HDz)_3$ (calculated from the stability constants data of Ref. [23]).

Bismuth (V) was also detected by the proposed method after prior reduction to bismuth(III).

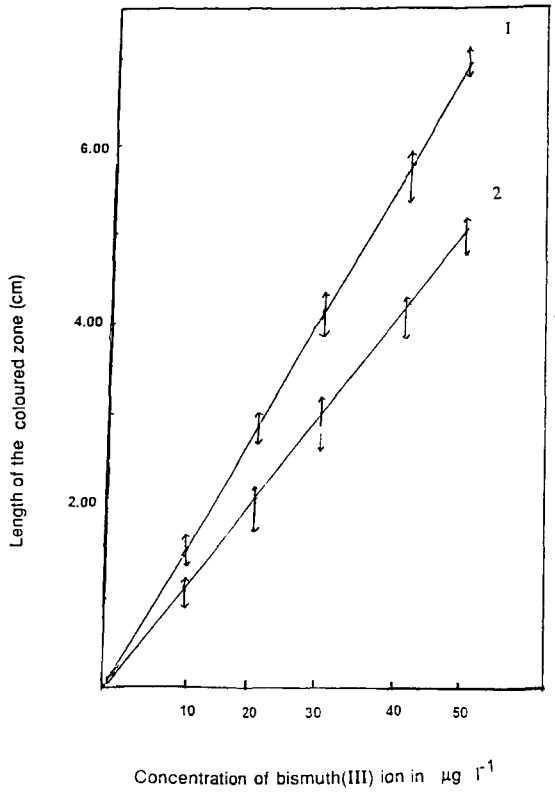

Fig. 2. Relationship between the length of the coloured zone (cm) on the immobilized (1) F_2H_2Dz, (2) H_2Dz, foam columns and the concentration of bismuth(III) in ppb.

Sodium sulphite (1%) in acid media was found to be the most convenient reducing agent, where the unreacted sulphur dioxide was easily removed by boiling. As little as 0.02 ppm of bismuth (V) was easily detected in batch mode after reduction to bismuth(III) followed by shaking this solution with plasticized F_2H_2Dz–TBP foams.

3.3. Interference study

Elimination of interferences in the detection of bismuth(III) in water employing the F_2H_2Dz-loaded foam was considered to be a prime importance. Thus, the selectivity of the proposed batch F_2H_2Dz-loaded foam method for the detection of bismuth(III) in the presence of diverse ions was critically investigted. It was possible to detect 1 μg of bismuth(III) in the presence of up to 1 mg of the following ions: Li^+, Ca^{2+}, Ba^{2+}, Mg^{2+}, Sr^{2+}, Al^{3+}, NH_4^+, Mn^{2+}, Zn^{2+}, SO_4^{2-}, NO_3^-, Br^-, Cl^-, VO_3^-, WO_4^{2-}, SO_3^{2-}, BrO_3^-, NO_2^-, NO_3^-, ClO_4^-, SeO_3^{2-}, SeO_4^{2-}, SbO_2^-, AsO_2^-, acetate, citrate, tartrate, ascorbate, phosphate and chromate. In the presence of some other ions ($\leqslant 0.01$ mg) which interfered seriously with the proposed method, simple modifications were made to the aqueous sample solution to eliminate their interferences, affording unambiguous and sensitive detection of bismuth(III) as given in Table 3.

3.4. Application of the proposed method

The feasibility of the method for the detection of bismuth in sea and waste water samples was also examined. A water sample (0.2 l) acidified with 0.1 mol l^{-1} nitric acid was allowed to pass through a 0.45 μm Millipore filter, and then 10 ml of 1×10^{-3} mol l^{-1} disodium salt of EDTA and 10 ml of 1×10^{-3} mol l^{-1} NaF were added. The reaction mixture was allowed to stand for 15 min and then 1 ml of sodium sulphite solution and 5 ml of concentrated HCl were added. The solution was boiled to dryness, diluted with 20 ml of distilled water and the pH was then adjusted to 9–10 with ammonia follwed by the addition of 10 ml of 2% (w/v) sodium diethyldithiocarbamate (NaDDC). The $Bi(DDC)_3$ complex produced was

then extracted by shaking with 10 ml of xylene [24]. Back extraction of bismuth(III) was achieved with 5 ml of concentrated HNO_3 and finally the pH of the solution was adjusted to 3–5. Negative results for the detection of bismuth in sea and waste water with batch immobilized-F_2H_2Dz foam were obtained while with a column packed with F_2H_2Dz foam it was possible to detect bismuth(III) in the concentration range 10–20 ppb in seawater. This concentration range was detected by flameless atomic absorption spectrometry to be 12 ± 2 ppb bismuth.

An attempt was made to demonstrate the utility of the method for the quantitative collection of bismuth(III) at $3 < pH < 5$ with a column packed with F_2H_2Dz foam. 100 ml of a 10 μg ml^{-1} aqueous solution of bismuth(III) was precolated through a foam column (12 cm height × 1.5 i.d.) packed with F_2H_2Dz foam at 1–2 ml min^{-1}. Analysis of the effluent solution by atomic absorption spectrometry showed quantitative collection (95–98%) of bismuth(III) on the foam column with a standard deviation σ of 1.30.

4. Conclusion

This article has demonstrated the possible use of plasticized or immobilized polyurethane foams for the sensitive and selective detection and quantitative collection of bismuth(III) in water at extremely low concentrations. Elimination of the interference of diverse ions in the detection of bismuth in water by the proposed procedure is of prime importance. Much work still remains to be done on improving the selectivity and utility of the method for the direct determination of bismuth(III), or bismuth (V) after prior reduction, either by direct solid phase spectrometry on parallelpiped polyurethane foams or by elution of the $Bi(F_2HDz)_3$ chelate from the packed foam column with a selective eluting agent.

Abstract

Previously, thiols have been determined indirectly by cathodic stripping voltammetry (CSV) after accumulation as their mercury and copper(I) salts. Following a previous report of the first use of the catalytic nickel peak (for the determination of cysteine), this paper reports the first use of the catalytic cobalt peak in CSV (for the determination of 2-mercaptobenzothiazole (MBT)): only a very ill-defined catalytic cobalt peak had been observed previously with cysteine, and was unreported. MBT is accumulated at pH 4 (Britton–Robinson buffer) as its cobalt(II) complex at -0.1 V, and is then determined indirectly by observing the reduction of the cobalt(II) in the complex at -0.95 V, i.e., with a much lowered overpotential: hydrated cobalt(II) is reduced at -1.2 V. The peak is catalytic because the thiol released on reduction of the complex complexes further cobalt ions and causes their reduction. The detection limit for the determination of MBT was calculated to be 2.5×10^{-9} M (3σ) using an accumulation time of 1 min. The sensitivity is about three times that obtained with the corresponding catalytic nickel peak. © 1997 Elsevier Science B.V.

Keywords: Catalytic cobalt peak; 2-Mercaptobenzothiazole; Thiols

1. Introduction

Mercury is oxidized more readily, i.e., at a less positive potential, in the presence of complexants or precipitants for mercury(I) or -(II). In this way, thiols can be accumulated as their mercury salts and can be determined by monitoring the reduction of the complexed mercury ions during a cathodic potential sweep. An accumulation potential in the region of $+0.2$–0 V is usual [1]. In the presence of copper(II), many thiols can be accumulated as their copper(I) complexes, and can be determined by monitoring the reduction of the copper(I) in the complex during a cathodic sweep. An accumulation potential in the region of -0.1

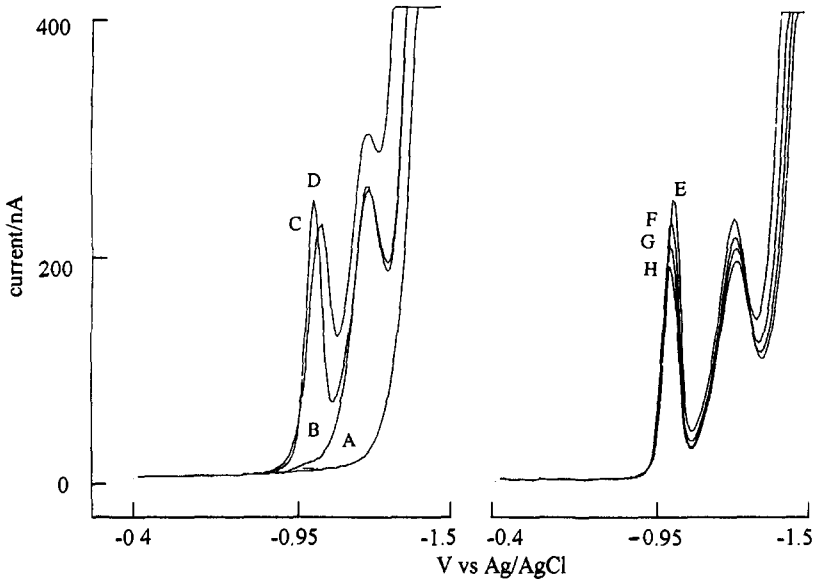

Fig. 1. Effect of pH on the CSV of MBT in the presence of cobalt(II) in Britton–Robinson buffer. Accumulation potential = −0.40 V; accumulation time = 60 s; MBT concentration = 1.2×10^{-7} M; cobalt(II) concentration = 3.4×10^{-4} M. (a) pH 3.1 buffer only; (b) pH 3.1 buffer plus cobalt only; (c)–(h) buffer plus cobalt(II) plus MBT. pH: (c) 3.1; (d) 3.6; (e) 4.0; (f) 4.3; (g) 4.5; (h) 4.7.

V is necessary [1]. Recently, we reported the first use of the catalytic nickel peak in cathodic stripping voltammetry (CSV) [2–6]. Hydrated nickel(II) is reduced at about −1.0 V, but nickel(II) in complexes of thiols such as cysteine [2], penicillamine [5] and glutathione [3] is reduced at about −0.6 V owing to the reduced overpotential. This latter peak is catalytic because the thiol released on reducing the complexed nickel(II) is free to complex further nickel(II) ions and to cause their reduction. In the case of cysteine, penicillamine and glutathione, however, the peak is relatively small. More recently, 2-mercaptobenzothiazole (MBT) was shown to give a much larger catalytic nickel peak when determined by CSV in this way [7].

The catalytic cobalt wave has been studied mechanistically in polarography [8], including studies of cobalt complexes of thiols and selenium analogues [9–13]. More interest has been shown polarographically in the catalytic hydrogen evolution process, which occurs in the presence of cobalt, and which gives a peak at a more negative potential than the catalytic cobalt peak [13]. We observed the catalytic cobalt peak in the CSV of cysteine at pH 7 in a brief excursion from our main study with nickel [2], but the peak was very ill-defined and was not reported. Here we report the first recorded use of the catalytic cobalt peak in CSV, in the determination of MBT.

Derivatives of MBT are used extensively as accelerators in the vulcanization of rubber [14]. MBT is also used as a corrosion inhibitor in antifreezes based on ethylene glycol. Because of its widespread use, MBT has been detected in many environmental samples, including waste waters. Liquid–liquid extraction and HPLC have been used to determine MBT and its derivatives [15], as have polarography and voltammetry [13,16]. Goyal and Kumar [16] studied the oxidation of MBT at a pyrolytic carbon electrode: a platinum ring-disc electrode was used to determine MBT in ethylene glycol samples at 3×10^{-4} – 6×10^{-2} M levels. Calusaru [13] showed that by forming the cobalt(II)–MBT complex, MBT could be determined polarographically at 1×10^{-6} – 1×10^{-5} M levels using the catalytic hydrogen peak produced by the complex. The method described here would need to be tested for its suitability for application to any of these sample types.

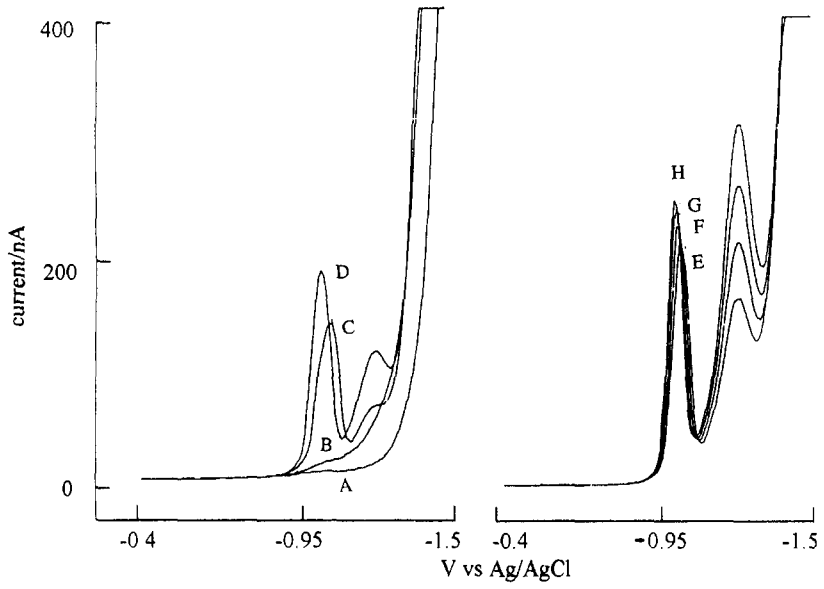

Fig. 2. Effect of cobalt(II) concentration on the CSV of MBT in the presence of cobalt(II) in pH 4 Britton–Robinson buffer. Accumulation potential = −0.40 V; accumulation time = 60 s; MBT concentration = 1.2×10^{-7} M. (a) Buffer only; (b) buffer plus MBT only; (c)–(h) buffer plus MBT plus cobalt(II). Cobalt(II) concentration: (c) 0.85; (d) 1.7; (e) 2.55; (f) 3.40; (g) 4.24; (h) 5.1×10^{-4} M.

2. Experimental

Cathodic stripping voltammetry was carried out with a Metrohm 646/647 VA processor, using a multi-mode electrode in the hanging mercury drop electrode (HMDE) mode. The three-electrode system was completed by means of a glassy carbon auxiliary electrode and an Ag/AgCl (3 M KCl) reference electrode. All potentials are quoted relative to this reference electrode. Differential-pulse voltammetry was carried out with a pulse amplitude of 50 mV, a scan rate of 10 mV s^{-1} and a pulse interval of 1 s.

Stock solutions of MBT (Aldrich) in methanol (3×10^{-3} M) were prepared fresh every 3 days. More dilute solutions were prepared daily by diluting these solutions with methanol. Standard cobalt(II) solutions were prepared daily by diluting standard solutions (Spectrosol, BDH). Britton–Robinson buffer was prepared by dissolving boric acid (2.47 g), orthophosphoric acid (2.7 ml) and glacial acetic acid (2.3 ml) in water and diluting to 1 l. Appropriate volumes of this solution were adjusted to the required pH with sodium hydroxide solution (3 M).

The general procedure used to obtain cathodic stripping voltammograms was as follows: a 20 ml aliquot of buffer was placed in the voltammetric cell and the solution was purged with nitrogen for 6 min with the stirrer on. After an initial blank run, the required volumes of MBT and cobalt solutions were added by means of a micropipette. After forming a new mercury drop, accumulation was effected for the required time at the predetermined accumulation potential whilst the solution was stirred. The small mercury drop size was used on the Metrohm 647 VA stand. At the end of the accumulation period, the stirrer was switched off and after 10 s had elapsed to allow the solution to become quiescent a negative-going potential scan was initiated. When further volumes of MBT solution or reagents were added, the solution was deoxygenated for a further 20 s before producing further voltammograms.

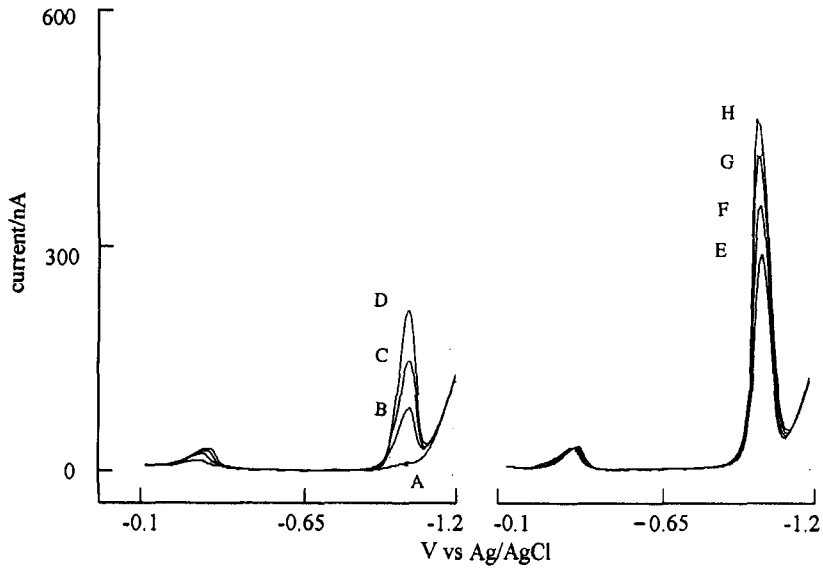

Fig. 3. Cathodic stripping voltammograms obtained for producing a calibration graph for the determination of MBT in pH 4.0 Britton–Robinson buffer. Accumulation potential = −0.10 V; accumulation time = 60 s; cobalt(II) concentration = 2.55×10^{-4} M; MBT concentration = (a) 0; (b) 0.3; (c) 0.6; (d) 0.9; (e) 1.2; (f) 1.5; (g) 1.8; (h) 2.1×10^{-7} M.

3. Results and discussion

Typical cathodic stripping voltammograms for MBT based on accumulation of the cobalt(II) complex are shown in Figs. 1–3. The effect of pH on the catalytic cobalt peak is shown in Fig. 1. pH 4.0 is optimum, giving a well defined peak of maximum height with good separation from the diffusion-controlled hydrated cobalt(II) peak. Cathodic stripping voltammograms showing the effect of cobalt(II) concentration are shown in Fig. 2. The catalytic peak is clearly seen to be well formed and approaching its maximum height at cobalt(II) concentrations of about 2.55×10^{-4} M, and this concentration of cobalt was usually used subsequently in determining MBT; above this concentration of cobalt the peak continues to increase slightly. The hydrated cobalt(II) diffusion peak, which is much smaller than the catalytic peak at relatively low cobalt(II) concentrations, increases in size when excess of cobalt(II) is added. Cathodic stripping voltammograms obtained for producing a calibration graph are shown in Fig. 3 for 2.55×10^{-4} M cobalt(II); the sensitivity would be increased slightly if a slightly higher concentration of cobalt(II) were used. Calibration graphs obtained with 1 min accumulation, including that using the voltammograms shown in Fig. 3, were rectilinear from 3×10^{-8} to 2.7×10^{-7} M MBT. The standard deviation of the signal at 3×10^{-8} M was 2.8% ($n = 8$). From this, the detection limit was calculated to be 2.5×10^{-9} M (3σ, $n = 8$): the sensitivity (2.4 nA for 1 nmol l^{-1}) is about three times that obtained with the corresponding catalytic nickel peak. With longer accumulation times, well defined peaks could be obtained with more dilute MBT solutions, a 7×10^{-9} M MBT solution producing a peak current of 75 nA for a 5 min accumulation. An accumulation time of 60 s, however, was normally used. The effect of accumulation time on peak height at higher concentrations (1.2×10^{-7} M MBT and 2.55×10^{-4} M cobalt(II)) had been studied. The peak height increased regularly (but sub-linearly) with increasing accumulation time up to about 6 min, when the unit increase with time became small. Peak currents for accumulation times of 0, 60, 120, 180, 360, and 480 s were 60, 206, 324, 420, 588, and 644 nA, respectively.

This work was carried out as part of a larger study of indirect CSV methods for determining thiols and other compounds, and is the first reported use of the catalytic cobalt peak in CSV. The appropriate choice of methods involving the accumulation of thiols as mercury, copper(I), nickel and cobalt salts and complexes seems to depend on the particular thiol that is being determined. Thus, MBT is poorly determined as its mercury salt, and is better determined as its copper(I), nickel or cobalt salts or complexes. Cysteine can be determined voltammetrically as its nickel complex but has not been determined successfully as its cobalt complex so far. Trimercapto-*s*-triazine (TMT), which is used to remove heavy metals from effluents, gives excellent mercury(II), nickel and cobalt peaks, but gives no peak with copper(II), presumably owing to formation of colloidal copper(II) TMT (to be published elsewhere). Studies on the CSV of a range of thiols, and other compounds that can be determined indirectly this way, are continuing, in order to establish what factors govern whether complexes and salts are accumulated from solution or not. The possibility is also being considered of the use of accumulation of such complexes and salts at screen-printed electrodes for use in sensor devices.

Short communication

Cathodic stripping voltammetric determination at a hanging mercury drop electrode of the environmental heavy metal precipitant trimercapto-*s*-triazine (TMT)

Abstract

Trimercapto-*s*-triazine (TMT) is available commercially for precipitating heavy metals in effluents prior to discharge and for recovering silver and copper. The TMT content of an effluent for discharge is normally monitored down to about 2 ppm by means of its UV absorption at 285 nm. Indirect cathodic-stripping voltammetric methods of determining TMT at sub-ppb levels in standard solutions are reported here. These methods might prove suitable for the determination of TMT in effluent at levels lower than is currently possible. TMT can be accumulated and determined indirectly at pH 9.0 as its mercury salt down to sub-ppb levels. Accumulation is made at 0 V and the mercury TMT reduction peak is at −0.47 V. Alternatively, by adding nickel(II), TMT can be determined optimally at pH 7.8, using the catalytic nickel peak at −0.73 V and accumulating between −0.10 and −0.60 V: at this pH the HgTMT peak at −0.47 V is small. At slightly higher pH (pH 8.6) the nickel TMT complex can be accumulated directly at −0.40 V, but at this pH, however, a slightly increased sensitivity can be achieved by accumulating TMT as its mercury salt, at −0.1 V in the presence of nickel(II), the nickel TMT complex being formed during the potential sweep on the release of the TMT when the mercury salt is reduced. Unlike many other thiols TMT is not accumulated as its copper(I) salt on addition of copper(II) to the solution. © 1997 Elsevier Science B.V.

cipitation of divalent heavy metals and silver from aqueous solutions. It is used in the treatment of effluent before discharge and in the recovery of metals, e.g. copper and silver, from electroplating and photographic baths and from electrical components (see Degussa literature).

A few years ago we were pleased to provide initial information on the voltammetric determination of heavy metals in samples provided by chemists at Powergen who were assessing the suitability of the technique for analysis of effluent from the Flue Gas Desulphurisation plant being installed at Ratcliffe on Soar Power Station. This plant, now in operation, removes sulfur dioxide from the flue gases. This is done by means of a limestone slurry, which is converted first into calcium sulfite, and then, through the injection of air, to calcium sulfate (gypsum), which is sold for plasterboard production and other purposes. Small concentrations of heavy metals enter the system from the limestone or the coal, via the flue gases: these are removed from the effluent initially with lime and then with TMT15.

Trade literature from Degussa gives methods for the determination of TMT. At higher levels (e.g. in TMT15), TMT can be determined acidimetrically by potentiometric titration with hydrochloric acid. At lower levels, e.g. in treated effluent, it can be determined by means of its UV absorption at 285 nm. Typical dosage levels of TMT15 are reported to be 50–100 ml per cubic meter of effluent (ie. 7.5–15 ppm TMT). Calibration graphs are constructed from 1–10 ppm TMT using standard TMT solutions prepared in water having a similar salt composition to the effluent as high salt levels are reported to cause a reduction in the absorbance at 285 nm.

General studies are being made in our laboratories of the indirect determination of thiols by cathodic stripping voltammetry [1–7]. In particular the first use of nickel and cobalt catalytic reduction peaks in CSV have been reported [1,7]. Comparisons are being made of the use of accumulation and determination of the mercury, copper(I), nickel and cobalt salts of thiols. In this communication we report on the cathodic stripping voltammetry of TMT in standard solutions using these methods, and give some indication of possible interference from heavy metals, including copper and nickel, in the determinations.

2. Experimental

Cathodic stripping voltammetry was carried out with a Metrohm 646/647 VA Processor, using a multi-mode electrode in the HMDE mode. The three-electrode system was completed by means of a glassy carbon auxiliary electrode and an Ag/AgCl (3M KCl) reference electrode. All potentials are quoted relative to this reference electrode. Differential-pulse voltammetry was carried out with a pulse amplitude of 50 mV, a scan rate of 10 mV s^{-1} and a pulse interval of 1 s.

Samples of TMT15 were kindly provided by Powergen. Stock solutions of TMT (1.2×10^{-2} M) were prepared fresh every week: more dilute solutions were prepared daily by diluting these solutions. Standard copper(II), nickel(II) and other heavy metal solutions were prepared daily by diluting standard atomic absorption solutions from various manufacturers. Britton Robinson buffer (BRB) was prepared by dissolving boric acid (2.47 g), orthophosphoric acid (2.7 ml) and glacial acetic acid (2.3 ml) in water and diluting to 1 l. Appropriate volumes of this solution were adjusted to the required pH with sodium hydroxide solution (3 M).

The general procedure used to obtain cathodic stripping voltammograms was as follows: a 20 ml aliquot of buffer was placed in the voltammetric cell and the solution was purged with nitrogen for 6 min with the stirrer on. After an initial blank run, the required volumes of TMT and metal solutions were added by means of a micropipette. After forming a new mercury drop, accumulation was effected for the required time at the predetermined accumulation potential whilst the solution was stirred. The small mercury drop size was used on the Metrohm 647 VA stand. At the end of the accumulation period the stirrer was switched off and after 10 s had elapsed to allow the solution to become quiescent a negative-going potential scan was initiated. When further volumes of TMT solution or reagents were added the solution was deoxygenated for a further 20 s before producing further voltammograms.

3. Results

Typical cathodic stripping voltammograms of TMT at pH 2–9.4 are shown in Fig. 1. At the lower pH values (pH < about 7.5) two peaks are observed, which may be attributed to the reduction of mercury(II)-TMT. The smaller second peak is absent at higher pH values. There is a shift in the potential of the main peak from −0.1 to −0.47 V over this pH range, and the peak height reaches a maximum value at about pH 9.0. This pH was used subsequently. Calibration graphs were very reproducible, but were rectilinear up to 7×10^{-7} M when a disproportionate increase of peak current was obtained, followed by a levelling off of the current. At this time we have no explanation for the disproportionate increase in current, although it may be associated with the accumulation of different layers of HgTMT. The final levelling off of the current is normally owing to saturation of the surface of the drop. The limit of detection (three standard deviations) was calculated to be 5×10^{-9} M.

The addition of copper(II) removed the mercury TMT peak: a 7-fold excess of copper(II) eliminated the peak completely. No peak indicating the accumulation of copper(I) TMT was observed (see Fig. 2). Addition of cadmium also removed the mercury TMT peak, and small peaks

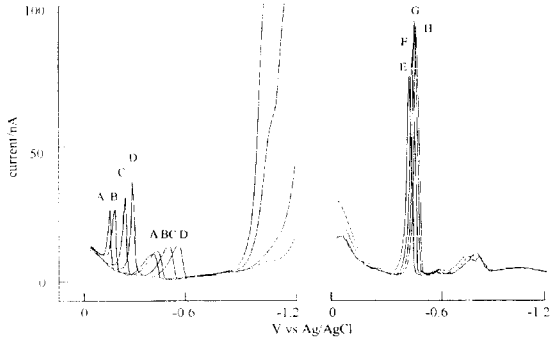

Fig. 1. The effect of pH on cathodic stripping voltammograms of TMT at a hanging mercury drop electrode. Accumulation potential, 0.0 V; accumulation time, 60 s; TMT concentration, 2.4×10^{-7} M. pH = A, 2.15; B, 2.50; C, 3.59; D, 4.44; E, 8.15; F, 8.69; G, 9.06; H, 9.41.

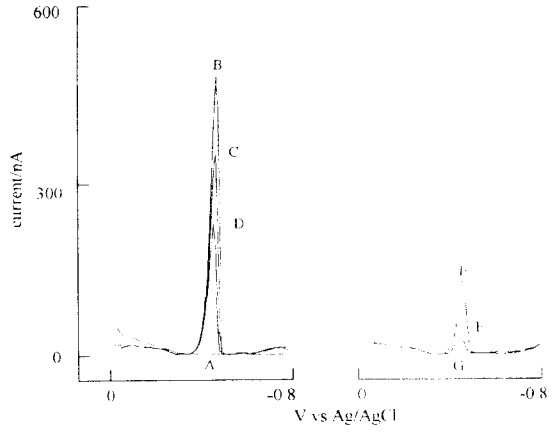

Fig. 2. Interference of copper(II) in the determination of TMT. Accumulation potential, 0.0 V; accumulation time, 60 s; TMT concentration, 2.4×10^{-7} M. pH = 9.0. Copper(II) concentration: A, 0 (buffer only); B, 0 (buffer + TMT only); C, 3.14; D, 6.28; E, 9.44; F, 12.6; G, 15.7×10^{-7} M.

became evident between −0.6– −0.8 V indicating some small accumulation of a cadmium TMT species (not shown). Lead, cobalt and zinc did not interfere at this pH: there was no sign of a catalytic cobalt peak but the possibility of its appearing at lower pH values needs to be investigated.

On the addition of a high concentration (e.g. 5×10^{-4} M) of nickel(II) the catalytic nickel peak of NiTMT appeared at −0.73 V in addition to the HgTMT peak at −0.47 V, when accumulation was effected at −0.1 V at pH 8.6. This indicates that TMT is accumulated still as HgTMT at −0.1 V, but is converted to NiTMT when the TMT is released when the HgTMT is reduced at −0.47 V during the potential scan. TMT can be accumulated directly at −0.4 V, but with a slightly reduced sensitivity. The optimum pH for the production of the catalytic nickel peak is slightly lower (pH 7.8) than for the production of the peak of the mercury salt: at this pH the mercury peak is very small, even when accumulation is effected at −0.20 V. Typical cathodic stripping voltammograms obtained for producing a calibration graph for the determination of TMT as its nickel complex with an accumulation time of 60 s are shown in Fig. 3.

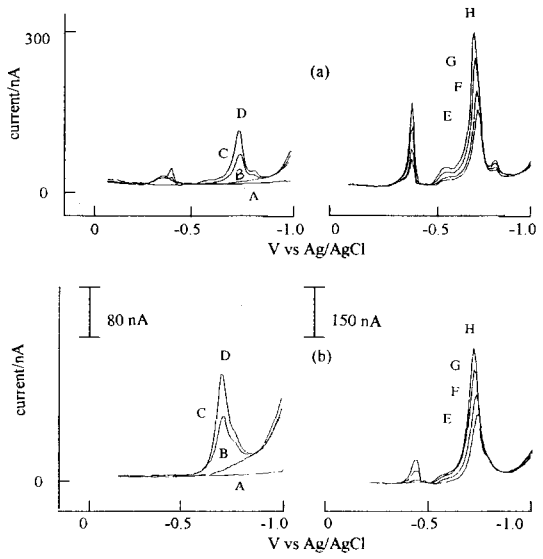

Fig. 3. Cathodic stripping voltammograms obtained for producing a calibration graph for the determination of TMT as its nickel complex (a) at pH 8.6 and (b) at pH 7.8. Accumulation potential, (a) -0.1 V and (b) -0.2 V; accumulation time, 60 s. Nickel(II) concentration: 5.1×10^{-4} M. TMT concentration: A, 0 (buffer only); B, 0 (buffer + Ni only); C, 0.3; D, 0.6; E, 0.9; F, 1.2; G, 1.8; H, 2.4×10^{-7} M.

4. Discussion

The values of the solubility products for M_3TMT_2 are quoted in the Degussa literature as being 1.0×10^{-18} (nickel) and 1.3×10^{-31} (copper(II)). This explains why the nickel CSV method can be applied but not the copper(I) method. The nickel salt/complex is sufficiently soluble for the nickel method to be applied, whereas addition of copper(II) to a TMT solution of about 1×10^{-7} M causes precipitation, or initially a colloidal solution of the copper(II) salt, which does not allow accumulation of the copper(I) salt at the electrode surface.

Determinations of the trace metals remaining after TMT treatment of effluent are made by well-established stripping voltammetric methods after UV irradiation to destroy TMT remaining in the effluent (J.A. Lees, Private communication and [8]). The trace metals remaining in the effluent could be present as dissolved or colloidal TMT complexes. The CSV methods described in this communication will determine free TMT and soluble TMT complexes that can be accumulated as Hg_3TMT_2 (solubility product $= 1.4 \times 10^{-47}$), but apparently not colloidal TMT complexes.

Book reviews

Handbook of Sensors and Actuators, Volume 2, Solid State Magnetic Sensors, by C.S. Roumenin, Elsevier, Amsterdam, 1994, xiii + 417 pp., US$148.50. ISBN 0-444-89401-2.

One of a series of handbooks on sensors and actuators, this book is intended to be of use to scientists and engineers interested in using miniature sensing elements to detect and measure magnetic fields. The author's aim is to present the overall progress made in the field of magnetotransducers, to summarise the scientific achievements, and to provide a handbook for researchers and engineers interested in solid-state magnetosensors.

After introducing the principles and technologies used to measure magnetic fields, the background theory of the Hall effect, magnetoresistance, magnetodiode and related effects, and coherent phenomena associated with superconductivity in condensed matter—including the principles of operation of the incredibly sensitive SQUIDs (Superconducting Quantum Interference Devices)—are dealt with in detail. The characteristics of solid-state magnetic field sensors and methods for their determination are summarised.

About half the book is devoted to an extensive review of developments associated with the various classes of miniature magnetosensor: Hall sensors (first developed about 100 years ago) and magnetoresistors; magnetodiode sensors; bipolar magnetotransistors (whose characteristics have greatly improved, although the theory of their action is incomplete) and related sensors; SQUID sensors (both DC and RF). Factors such as the choice of materials and geometry are considered, and the implications for fabricating and packaging the sensors in single-chip form are made clear.

The functional approach to the construction of magnetosensors, which has lead to the invention of multisensors, gradiometers and vector magnetometers, is described. The incorporation into the circuit environment of solid-state sensors as electronic devices is considered, including biasing and signal processing circuitry, flip-flop based sensors, interfacing with digital systems, and a discussion of improvements that may be made to solid-state magnetosensors are surveyed. In addition to accurate measurement of d.c. and a.c. magnetic fields, electrical quantities and a variety of non-electrical and non-magnetic quantities may be measured. Useful appendices on magnetic terms and units, and important quantities and constants used in this area, are included.

Physical Properties of Polymers Handbook, edited by J.E. Mark, American Institute of Physics, New York, 1996, xv + 723 pp., £95.00. Also available from Oxford University Press. ISBN 1-56396-295-0.

This is the third volume from the AIP series in Polymers and Complex Materials. The books in the series are designed to help those who concentrate on one type of complex material to gain an insight from systematic expositions of other mate-

rials with analogous microstructural complexities, and to keep up with experimental and theoretical advances occurring in disciplines other than their own. The first two volumes were *Statistical Physics of Macromolecules* and, *Biomimetics: Design and Processing of Materials.*

The large multi-authored text is divided into 10 parts and contains 52 chapters. Properties emphasised are those that are most relevant to physical chemistry and chemical physics, so that the more synthetic-organic topics such as the polymerization process and the chemical modification of polymers are not included. The first part of the book concentrates on Structure and is followed by a Theory section containing topics such as scaling and fractal dimension, computational parameters and rotational isomeric state models. Part 3, the largest in the book, deals with Thermodynamic properties such as heat capacities, thermal conductivities, glass temperatures, solubility parameters and many others. The small (29 pages) Spectroscopy section contains information on NMR, IR and, Neutron and X-ray scattering. Part 5 covers Mechanical Properties such as impact behaviour and viscoelasticity and includes chapters on adhesives and gels. Part 6 deals with Crystallinity and morphology and contains, for example, chapters on densities, unit cell information and crystallization kinetics. The 6 chapters of Part 7 concentrate on Electro-Optical and Magnetic Properties such as electrical conductivity, electroluminescence and the refractive index. Part 8 contains details of Responses to Radiation, Heat and Chemical Agents such as flammability, degradation and pyrolysability. The chapter on synthetic biodegradable polymers for medical applications is an overview of general interest, with many useful references for further reading. Part 9 of the book deals with surface and interfacial properties, acoustic properties and permeability of polymers to gases and vapors. Finally, part 10 lists a number of definitions, units and conversion factors.

The many figures, tables and equations are of high quality, numerous references are included and the extensive indexing enables information to be located easily. Overall, this handbook succeeds in collating useful information on polymer properties and deserves a place in science libraries as well as in the numerous laboratories involved with polymer activities.

Practical Surface Analysis, Volume 2—Ion and Neutral Spectroscopy, edited by D. Briggs and M.P. Seah, Second edition, Wiley, Chichester, 1992, xvi + 738 pp., £50.00. ISBN 0-471-96498-0.

My favourable opinion of the hard-back version of this book, reviewed in Talanta, 1993, 40, 1995, remains unchanged even though the book is no longer up-to-date. The paper-back version will be welcomed by under- and post-graduate students because it is a relatively cheap, highly valuable book. Research supervisors will also welcome this version, for their highly-prized, hardback version need no longer be 'borrowed' by their students.

Mass Spectrometry in the Biological Sciences, edited by A.L. Burlingame and S.A. Carr, Humana, Totowa, New Jersey, 1996, xii + 570 pp., $145.00. ISBN 0-89603-340-6.

This book contains 26 chapters written by leading practitioners in 'biological mass spectrometry' and is based on the 3rd International Symposium for Mass Spectrometry in the Health and Life Sciences; held in San Francisco in 1994.

I place Biological Mass Spectrometry in inverted commas because this is a book that has been largely written by mass spectrometerists and concentrates (mostly) on the changes offered by biopolymers in their quest to work at ever higher mass and with increasingly involatile and intractable molecules. I do not mean to be overly critical on this point, but there are a lot of other areas in the biosciences that are benefitting from the application of mass spectrometry. Some of these rely on new application of 'old' technology, but others are a direct result of recent develop-

rials with analogous microstructural complexities, and to keep up with experimental and theoretical advances occurring in disciplines other than their own. The first two volumes were *Statistical Physics of Macromolecules* and, *Biomimetics: Design and Processing of Materials.*

Properties emphasised are those that are most relevant to physical chemistry and chemical physics, so that the more synthetic-organic topics such as the polymerization process and the chemical modification of polymers are not included. The first part of the book concentrates on Structure and is followed by a Theory section containing topics such as scaling and fractal dimension, computational parameters and rotational isomeric state models. Part 3, the largest in the book, deals with Thermodynamic properties such as heat capacities, thermal conductivities, glass temperatures, solubility parameters and many others. The small (29 pages) Spectroscopy section contains information on NMR, IR and, Neutron and X-ray scattering. Part 5 covers Mechanical Properties such as impact behaviour and viscoelasticity and includes chapters on adhesives and gels. Part 6 deals with Crystallinity and morphology and contains, for example, chapters on densities, unit cell information and crystallization kinetics. The 6 chapters of Part 7 concentrate on Electro-Optical and Magnetic Properties such as electrical conductivity, electroluminescence and the refractive index. Part 8 contains details of Responses to Radiation, Heat and Chemical Agents such as flammability, degradation and pyrolysability. The chapter on synthetic biodegradable polymers for medical applications is an overview of general interest, with many useful references for further reading. Part 9 of the book deals with surface and interfacial properties, acoustic properties and permeability of polymers to gases and vapors. Finally, part 10 lists a number of definitions, units and conversion factors.

The many figures, tables and equations are of high quality, numerous references are included and the extensive indexing enables information to be located easily. Overall, this handbook succeeds in collating useful information on polymer properties and deserves a place in science libraries as well as in the numerous laboratories involved with polymer activities.

Practical Surface Analysis, Volume 2—Ion and Neutral Spectroscopy, edited by D. Briggs and M.P. Seah, Second edition, Wiley, Chichester, 1992, xvi + 738 pp., £50.00. ISBN 0-471-96498-0.

My favourable opinion of the hard-back version of this book, reviewed in Talanta, 1993, 40, 1995, remains unchanged even though the book is no longer up-to-date. The paper-back version will be welcomed by under- and post-graduate students because it is a relatively cheap, highly valuable book. Research supervisors will also welcome this version, for their highly-prized, hardback version need no longer be 'borrowed' by their students.

Mass Spectrometry in the Biological Sciences, edited by A.L. Burlingame and S.A. Carr, Humana, Totowa, New Jersey, 1996, xii + 570 pp., $145.00. ISBN 0-89603-340-6.

This book contains 26 chapters written by leading practitioners in 'biological mass spectrometry' and is based on the 3rd International Symposium for Mass Spectrometry in the Health and Life Sciences; held in San Francisco in 1994.

I place Biological Mass Spectrometry in inverted commas because this is a book that has been largely written by mass spectrometerists and concentrates (mostly) on the changes offered by biopolymers in their quest to work at ever higher mass and with increasingly involatile and intractable molecules. I do not mean to be overly critical on this point, but there are a lot of other areas in the biosciences that are benefitting from the application of mass spectrometry. Some of these rely on new application of 'old' technology, but others are a direct result of recent develop-

ments in mass spectrometry. As an inorganic mass spectrometerist I feel duty bound to mention that a section on inductively coupled plasma mass spectrometry and more on the measurement and application of stable isotope tracers (organic and inorganic) would have been useful additions.

Space does not permit an in-depth review of every chapter and it is hard to single out individual contributions from the text that is of such consistently high quality. However, to give a flavour of the contents I have selected a handful for special mention: Designing TOF/MS for the Future (R. Cotter et al), The Role of Fourier Transform Ion Cyclotron Resonance MS in Biological Research—New Developments and Applications (R.D. Smith et al), MALDI-TOF MS in the Quest for Novel Antibiotics (P. Tempst et al), Approaches to the Practical Use of Recognition Studies (A.M. Lawson et al) and Applications of Accelerator MS in Tocicology: A Highly Sensitive Tool for Low-Level Isotope Measurement (K.W. Turtletaub and J.S. Vogel). In addition to these there were chapters on DNA Sequencing, IR-MALDI MS of Proteins, Capillary LC/Electrospray MS and Tandem LC/MS in Drug Biotransformations.

This book is a must for all MS laboratories with an interest in biological applications. No one can fail to be impressed by the massive strides that have been made in the development and application of MS over the past decade. Equally no one can be in any doubt that we are only at the beginning of a most exciting phase of collaboration with our bioscience colleagues.

Thin-Layer Chromatography: Reagents and Detection Methods, Volume 1b by H. Jork, W. Fuk, W. Fischer and H. Zimmer, VCH, Weinheim, 1994, xvi + 496 pp., £81.00. DM 198.00. ISBN 3-527-28205-X.

This volume is part of a series. Volume 1, which covers Physical and Chemical Detection Methods, is to be published in three Volumes (Volumes 1a, 1b and 1c). Volume 2 will be concerned with Biochemical and Biological Detection Methods. The particular volume under review deals with Activation Reactions, Reagent Sequences and Reagents.

Volume 1a is divided into three parts. Part 1 covers, in 137 pages, Specific Detection Methods and involves (i) Activation Reactions, (ii) Reagents for the Recognition of Functional Groups and (iii) Reagent sequences. Activation Reactions are subdivided into Photochemical, Thermochemical and Electrochemical Activation Reactions. Each method is briefly described with listings of examples where the methods have been successfully used. In addition a number of more detailed procedures, e.g. for the detection of testosterone, are provided. The section on Reagents for the Recognition of Functional Groups is a short section (11 pages) and essentially provides a list of reagents for the detection of specific functional groups, e.g. aldehydes, amines etc. The third section of Part 1 (*ca* 80 pages) covers Reagents Sequences, which involve the use of combinations of such reactions as electrophilic substitutions, oxidations and reductions, azo couplings, metal complexations etc. for the detection of specific compounds or families of compounds. An example of a reaction sequence involves the sequential addition of (i) cerium(IV) sulphate/sodium arsenite/sulphuric acid, (ii) methylene blue and (iii) ammonia vapour for the detection of iodide ions and organoiodine compounds. For each quoted recipe, the preparation of all the necessary reagents, the method of application and, where known, the underlying chemistry are detailed.

The major part (Part II, with over 300 pages) of this Volume is an alphabetical listing of reagents and their uses for the detection of specific types of compounds. For each reagent listed, the formula, the preparation of reagent solutions, the method of application, the chemical reactions undergone, the compounds detected and examples of tested procedures are all generally given.

The excellent index at the end of this Volume covers not only Volume 1a but also Volume 1b. The book is truly a mine of useful information. It clearly has a place in all chemistry libraries and is highly recommended by this reviewer.

NATO Advanced Research Workshop on Biosensors for Direct Monitoring of Environmental Pollutants in Field

Smolenice (Slovakia)
4–8 May 1997

Scientific Programme
Trends of analytical methodology for determination of indoor and outdoor pollutants. DNA, biological recognition and receptor based sensors, biosensors for in field uses, ground water analysis and remote sensing, biosensors for environmental pollutants based on non-aqueous systems, micromachining, industrialization and market aspects of biosensors for environmental pollutants.

Organizing Committee
D.P. Nikolelis (Greece), M. Trojanowicz (Poland), G.G. Guilbault (Ireland), U.J. Krull (Canada), J. Wang (USA), M. Mascini (Italy).
Local Organizing Committee
V. Tvarozek, T. Hianik, D. Donoval, I. Novotny, M. Snejdarkova.

Applications for participation should be sent to:
Dr. D.P. Nikolelis (Director NATO ARW), Laboratory of Analytical Chemistry, Chemistry Department, Athens University, Panepistimiopolis-Kouponia, 15771 Athens, Greece. Fax: +301 723 1608.

Chemistry, Energy and the Environment 3

Hotel Palácio, Estoril, Portugal 25–28 May 1997

The workshop will cover modern trends in the development of chemistry for energy storage and energy conservation processes, its contribution to environmental protection, alternative options on the central roles to be played by chemistry in the energy industry and their relevance to society, and several aspects on Energy and New Technologies, as well as Energy and The Environment. The aim is to promote the exchange of information and ideas between scientists in industry, academia and government and to provide a forum for people dealing with these problems from around the world.

Workshop topics will include:

- Chemistry—friend or foe of the environment?
- Catalysis in the service of the environment.
- The challenge of the environmentally-friendly production of energy.
- Hydrogen as an energy source.
- Nuclear waste.
- Renewable energy water production processes.
- Energy sources for 2000 and beyond.
- Electrochemical decontamination.

Call for papers:

Authors are invited to submit titles of papers covering any of the above topics, and/or related topics. These titles should reach CAC Sequeira, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal.

Further information write to:

César Sequeira, Institute Superior Técnico, 1096 Lisboa Codex, Portugal. Tel./fax: +351 1 7783594

First Symposium 'In Vino Analytica Scientia' Applications of Analytical Chemistry to Wines, Alcohols and Spirits

University of Bordeaux-2: 12–14 June 1997

Under the Patronage of: Federation of European Chemical Societies (Analytical Chemistry Division and Food Chemistry Division), Société Française de chimie (Division de Chimie Analytique) and Office International de la Vigne et du Vin.
Ecole Européenne de Chimie Analytique (EECA) will organise the *1st Symposium 'In Vino Analytica Scientia'* (Applications of Analytical Chemistry to Wines, Alcohols and Spirits) at the University of Bordeaux-2, the 12, 13, 14 June 1997, with the Vinexpo Exhibition.The official languages will be English and French with simultaneous translation.

This international meeting of researchers, oenologists and professionals will take stock of the latest benefits of Analytical Chemistry in the improvement of both products and processes.

Scientific Programme:
- Constituents of grapes, wines and spirits
- Chemical and biochemical reactions
- Contaminants and traces
- Flavours and sensory analysis
- Chemical and biochemical sensors
- Quality and authenticity of products

Invited Speakers:
V. Cheynier (F), M. Forina (I), G. Friedbacher (A), A. Mosandl (D), P. Schreier (D), G.R. Scollary (AUS), J.R. da Silva (P), H.K. Sivertsen (N), M. de la Torre Borona (E), J. Vercauteren (F), J.C. Villetaz (CH), J. Wang (USA)

Presidium:
Honorary President: P. Ribéreau-Gayon
Presidents: R. Kellner, W. Pfannhauser

Scientific Committee:
Chairman: C.J. Ducauze
F. Bandion (A), Al. Bertrand (F), M. Comtat (F), J. Empis (P), M. Karayannis (GR), R. Lobinski (F), G.J. Martin (F), M.-H. Merle (F), B. te Nijenhuis (NL), A.C. Noble (USA), A. Rapp (D), D.N. Rutledge (F), J.C. Sapis (F), G.R. Scollary (AUS), M. Valcarcel (E), H.H. Widmer (CH), P.G. Zambonin (I)

Tenth International Conference on Partitioning in Aqueous Two-phase Systems, Advances in the Principles and Applications of Separation Science in Biotechnology, Cell Biology and Environmental Recovery
Reading, UK
10–15 August 1997

This will be the 10th International Conference on Partitioning of Proteins, Metal Ions and Biological Particles in Aqueous Two-phase Systems. Theoretical, predictive, applied and engineering aspects of this emerging technology, which has found important applications, will be presented and discussed.

The conference will provide a focus for presentation and debate on developments and major issues in the principles and applications of separation science in biotechnology, cell biology and environmental ion recovery. It is expected that the meeting will be a forum for interdisciplinary debate with active participation of academics and industrial colleagues.

Abstracts of papers and posters for presentation at the conference are invited. Original contributions on any aspect of the following themes will be welcome:

- physicochemical properties of proteins important in bioseparations; interactions between liquid phase components and proteins
- modelling partitioning; thermodynamics
- prediction of partitioning of macromolecules and metal ions
- applications of partitioning; separation of enzymes and recombinant proteins
- studies of phase separation and development of new polymers
- biomedical applications; partitioning of cells, organelles and plasma membranes
- novel and complementary techniques

Authors intending to submit papers should send a title and 200–300 word abstract to the SCI Conference Secretariat to arrive no later than Friday, 1 February 1997.

For further details contact:

SCI, Society of Chemical Industry, 14/15 Belgrave Square, London SW1X 8PS; Tel.: +44 171 2353681; fax: +44 171 2357743; e-mail: conferences@chemind.demon.co.uk

Twenty-Eighth Annual International Symposium On Environmental Analytical Chemistry

Geneva, Switzerland 2–5 March 1988

The aim of this 28th Symposium is to actively encourage progress in methods, instrumentation, applications and to facilitate the transfer of know-how in different fields. It is targeted at scientists, analysts, manufacturers, end-users and post-graduate students.

Tentative main topics of the Symposium:
- Analyzing trace polar products in the environment
- New extraction, separation and instrumental techniques
- Chiral separations in environmental analysis
- Micro-Total analysis Systems (TAS)
- In situ measurements and speciation
- Quality assurance issues for environmental analysis for harmonization within EC and non-EEC countries
- Environmental and Education
- Other topics

All topics will be introduced in plenary lectures and invited research lectures followed by brief research presentations and posters. An exhibition of scientific equipment will also be organised. A short course on Sample Handling and Analysis of Organic Pollutants will be organised in Archamps, France, 27–28 February 1988.

For further details contact:
Mrs. M. Frei-Husler, IAEAC Secretariat, Postfach 46, CH-4123 Allschwil 2, Switzerland. Tel.: +41 61 4812789; fax: +41 61 4820805.

Properties and analytical application of room temperature phosphorescence of 1-bromonaphthalene induced by *p*-octylpolyethylene glycol phenylether in aqueous *β*-cyclodextrin solution

Xinzhen Du *, Yong Zhan, Yunbao Jiang, Xianzhi Huang, Guozhen Chen

The Research Laboratory of SEDC of Analytical Science for Material and Life Chemistry, Department of Chemistry, Xiamen University, Xiamen 361005, People's Republic of China

Received 28 March 1996; received in revised form 8 July 1996; accepted 12 July 1996

Abstract

Intense room temperature phosphorescence of 1-bromonaphthalene (1-BrN) induced by *p*-octylpolyethylene glycol phenylether was studied in aqueous *β*-cyclodextrin solution. The mode of inclusion complex formation was approached. The optimal conditions were obtained. Interferences of foreign substances with phosphorescence were examined. The phosphorescence intensity is proportional to the concentration of 1-BrN in the range $0 \sim 5.18$ μg ml^{-1}. The recovery is 90–102% and the relative standard deviation is less than 4.5%. The proposed method is simple and convenient. © 1997 Elsevier Science B.V.

Keywords: 1-Bromonaphthalene; *β*-Cyclodextrin; *p*-Octylpolyethylene glycol phenylether; Phosphorescence

1. Introduction

Micelle-stabilized room temperature phosphorescence (MS-RTP) and cyclodextrin-induced room temperature phosphorescence (CD-RTP) have been proposed for analytical purposes in the eighties [1–5]. Good spectral selectivity was obtained because a majority of organic species do not show phosphorescence at room temperature and the substrates have little or lower background emission in the proximity of the phosphorescence wavelength. For MS-RTP, deoxygenation is needed for the attainment of RTP. However, oxygen removal from micellar solutions by the nitrogen-purging technique results in plentiful bubbles. It has an effect on the precision of analysis. For CD-RTP of polycyclic aromatic hydrocarbons (PAHs) without an internal heavy atom, a bromonated alkane or alcohol was required as an external heavy-atom perturber, sometimes combined with deoxygenation by nitrogen [6–9]. Although no bubbles appear, a phosphoroscope was required for phosphorescence measurements because serious emulsification of the solutions causes strong scattering lights.

* Corresponding author.

PII S0039-9140(96)02048-6

Bromonated naphthalenes are a series of interesting compounds which normally exhibit weaker fluorescence than their parent naphthalene due to their internal heavy atom effect [10,11]. In the presence of acetonitrile or an alcohol, the intense RTP of 1-bromonaphthalene (1-BrN) has been observed from aqueous cyclodextrin solutions without deoxygenation on a conventional spectrofluorimeter [12–15]. Since the microcrystals of the inclusion complex containing an alcohol absorb onto the inner walls of glassware, the phosphorescence intensity is usually unstable at a fixed concentration of phosphors. In this work, *p*-octylpolyethylene glycol phenylether (OP), a detergent, was employed for the attainment of stable phosphorescence. It can induce intense RTP of 1-BrN in aqueous β-cyclodextrin (β-CD) solution like an alcohol and enables the complex precipitate to disperse in solution due to the complex with the polar head group of OP. As a result, the accuracy and the precision were improved. Furthermore, the interaction of OP with β-CD and 1-BrN and the potential application were also discussed.

2. Experimental

2.1. Reagents

1-BrN, purchased from Shanghai Reagent Co., was distilled under reduced pressure. A solution of 200.7 μg ml^{-1} 1-BrN was prepared by dissolving it in 2.33×10^{-2} mol l^{-1} OP solution in an ultrasonic bath. β-CD, purchased from Suzhou Gourment Factory, was dissolved in distilled water and recrystallized three times. OP was purchased from Shanghai Reagent Co. and was used as received. Twice demineralized water was distilled.

2.2. Apparatus

All steady-state luminescence spectra were performed on a Hitachi 650-10S fluorescence spectrophotometer equipped with a 150 W xenon lamp as the excitation light source. Excitation and emission slits of 3 nm were employed. The scan speed of the monochormators was maintained at 240 nm min^{-1}. The quartz cell was washed with ethanol to guarantee the thorough cleaning of organic species that absorb onto the inner walls of the glassware. It was carefully washed with distilled water prior to use.

2.3. General procedures

An aliquot of 2.33×10^{-2} mol l^{-1} OP solution containing 1-BrN was transferred into a 10 ml volumetric flask and an appropriate amount of β-CD was added. After dilution to the mark with water, the samples were allowed to stand for at least 45 min. The samples were introduced into the cell, which was later capped with a Teflon stopper. The RTP signal was monitored at 492 nm when the samples were excited at 290 nm.

3. Results and discussion

3.1. RTP spectra of a ternary inclusion complex

In aqueous solution, 1-BrN exhibits weak fluorescence with an excitation wavelength of 277 nm and emission wavelength of 337 nm. Upon addition of β-CD to the solution, the fluorescence intensity slightly increases due to the formation of the β-CD:1-BrN inclusion complex but no RTP appears. In the presence of both β-CD and OP, 1-BrN gives rise to intense phosphorescence emission at 492 nm and 525 nm at room temperature in aerated aqueous solution, accompanied by the emulsification of the solution. The excitation wavelength redshifts to 290 nm (see Fig. 1). These phenomena suggest that OP has a significant effect on the microenvironment surrounding 1-BrN because phosphorescence is highly sensitive to the properties of environment. A favorable microenvironment is provided in the apolar cavity of β-CD upon addition of OP. It is reasonable to attribute the appearance of RTP to the formation of a ternary complex among β-CD, 1-BrN and OP.

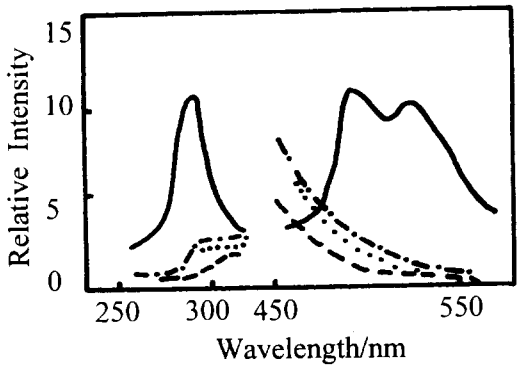

Fig. 1. RTP spectra of inclusion complexes. OP (•-•), β-CD + OP(•••), 1-BrN + OP(– – –) and β-CD + 1-BrN + OP(——). 1-BrN: 20.70 μg ml^{-1}; β-CD: 8.0×10^{-3} mol l^{-1}; OP: 2.33×10^{-3} mol^{-1} l^{-1}. Photomultiplier, gain: 1.0. Slit width: 3 × 3 mμ.

3.2. Effect of β-CD on RTP

The influence of β-CD on the RTP of 1-BrN was examined at a fixed concentration of 1-BrN and OP. As shown in Fig. 2, the phosphorescence is too weak to be observed at a β-CD concentration below 1.0×10^{-3} mol l^{-1} in the presence of 2.33×10^{-3} mol l^{-1} OP. Subsequently, the phosphorescence intensity rapidly increases with the increasing concentration of β-CD. Although the higher β-CD concentration results in more intense RTP, β-CD of 8.0×10^{-3} mol l^{-1} was used in the experiment due to the limit of its solubility in water.

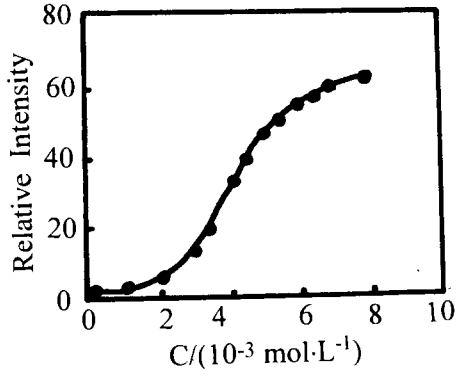

Fig. 2. Dependence of RTP on β-CD concentration. 1-BrN: 20.70 μg ml^{-1}; OP: 2.33×10^{-3} mol l^{-1}.

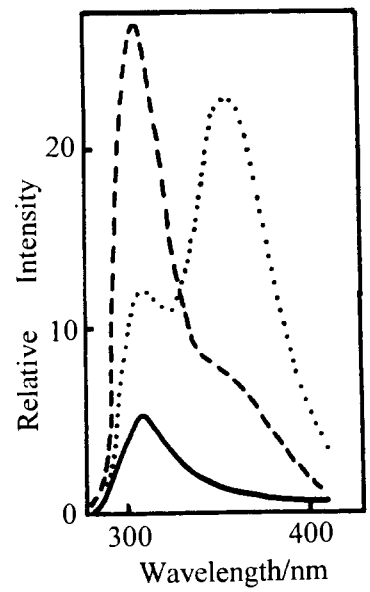

Fig. 3. Fluorescence spectra of OP. OP(•••); β-CD + OP(– – –) and β-CD + 1-BrN + OP(——). 1-BrN: 20.70 μg ml^{-1}; β-CD: 8.0×10^{-3} mol l^{-1}; OP: 2.33×10^{-3} mol l^{-1}.

3.3. Effect of OP on RTP

OP is a nonionic detergent with a *tert*-octyl group as its hydrophobic part and a polyethylene glycol group as its hydrophilic one. It contains ether groups, a phenyl group and a hydroxyl group. Surface tension measurements suggest that the micelles are not present in aqueous solution containing excess β-CD since the β-CD molecule includes an OP molecule. Fig. 3 shows the fluorescence spectra from a micellar solution of OP in the absence and presence of excess β-CD. The fluorescence at 307 nm ($\lambda_{ex} = 287$ nm) and 360 nm ($\lambda_{ex} = 297$ nm) can be attributed to the OP monomer and OP aggregates, respectively.

Upon addition of OP to the solution containing 1-BrN and 8×10^{-3} mol l^{-1} β-CD, RTP can be observed at 1.54×10^{-4} mol l^{-1} OP. This is accompanied by the slight emulsification of the solution, in which the micelles are not present in aqueous solution due to the inclusion of β-CD with OP. As shown in Fig. 4, the addition of more OP to the solution leads to more intense RTP. In the presence of 2.33×10^{-3} mol l^{-1} OP, the phosphorescence maximum is obtained. Since OP

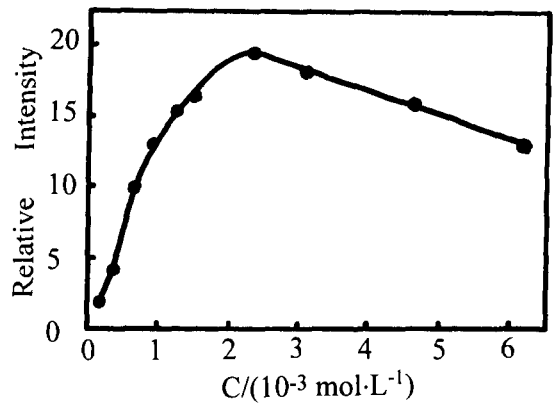

Fig. 4. Dependence of RTP on OP concentration. 1-BrN: 20.70 μg ml^{-1}; β-CD: 8.0×10^{-3} mol l^{-1}.

is an amphiphilic molecule, the complex precipitate homogeneously disperses in aqueous solution. Consequently, the phosphorescence intensity appears stable and good precision was achieved. After the highest phosphorescence intensity, a further increase in OP concentration results in a decrease in the phosphorescence intensity. RTP completely disappears and the solutions become transparent in the presence of more than 1.24×10^{-2} mol l^{-1} OP (more than 8.0×10^{-3} mol l^{-1}). The spectral changes indicate that the complex has completely dissociated. In terms of the surface tension of the solutions, the micelles occurs in the presence of excess OP. Since the spectral properties of 1-BrN in the solutions are similar to those of 1-BrN in the micellar solution of OP, it is possible that the 1-BrN molecule transfers from the β-CD cavity to the micellar core.

The phosphorescence enhancement upon addition of OP indicates that OP is also a micorenvironment regulator in the apolar cavity of β-CD like an alcohol. The hydrocarbon part of OP is incorporated into the apolar cavity of β-CD through the hydrophobic interaction. This result is analogous to those reported by Park and Song [16] and Li and Purdy [17]. By the Benesi–Hildebrand method [18], the stoichiometry of the 1:1:1/β-CD:1-BrN:OP complex was obtained with phosphorescence measurements. The apparent inclusion constant was estimated as 1.80×10^{-5} mol^{-2} l^2, which is much greater than the value of 720 mol^{-1} l of the β-CD:1-BrN complex. On the other hand, it is seen from Fig. 3 that the ternary complex formation results in a greatly decreased fluorescence of OP at 307 nm. One plausible explanation is that 1-BrN and the phenyl ring of OP locate close to each other in the cavity and 1-BrN seriously quenches the fluorescence of OP due to its external heavy-atom effect. For this reason, most of water molecules in the cavity are replaced by the 1-BrN molecule and the hydrocarbon part of the OP molecule. The rotation of the 1-BrN molecule in the cavity is restricted and the

RSD relative standard deviation.

rigidity of the 1-BrN molecule is promoted. Furthermore, the longer phosphorescence lifetime of 1-BrN (3.62 ms) also indicates that the excited triplet state of the 1-BrN molecule in the β-CD cavity is shielded from efficient triplet state quencher oxygen molecules in the solution to some extent. As a result, the probability of a radiationless transition greatly decreases and the phosphorescence intensity dramatically increases.

3.4. Interferences of foreign species

Interferences of other PAHs with the RTP of 1-BrN were studied. Under our experimental conditions, the PAHs examined do not phosphoresce but show strong fluorescence at room temperature. For the determination of 4.14 μg ml^{-1} 1-BrN, 9-fold amounts of anthracene and an equivalent amount of chrysene do not interfere, and 3.7-fold amounts of biphenyl and an equivalent amount of fluorene result in a decrease by 10% in the phosphorescence intensity. Equivalent amounts of phenanthrene and acenaphthene reduce the phosphorescence intensity by 15%. Three-fold amounts of naphthalene and an equivalent amount of 1-naphthol reduce the phosphorescence intensity by 25%.

3.5. Analysis of synthetic samples

A linear relationship between the phosphorescence intensity and 1-BrN concentration was examined. In the range $0 \sim 5.18$ μg ml^{-1}, the phosphorescence intensity is proportional to the concentration of 1-BrN. The straight line has a regression equation of $I_p = 3.355C + 5.703$ and a regression coefficient of 0.9994. Based on a signal-to-noise ratio of three, the limit of detection was estimated as 4.04 ng ml^{-1}. The analytical results of synthetic samples are listed in Table 1. The recovery is 90–102% and the precision is good ($n = 11$). It is suitable for the determination of 1-BrN in a mixture of PAHs.

Received 21 March 1996; received in revised form 16 July 1996; accepted 22 July 1996

Abstract

Four simple and sensitive spectrophotometric methods (A–D) for the assay of cisapride in pure and dosage forms based on the formation of chloroform soluble ion-associates under specified experimental conditions are described. Four acidic dyes, namely, Suprachen Violet 3B (SV 3B, method A), Erioglaucine A (EG-A, method B), Naphthalene Blue 12 BR (NB-12BR, method C) and Tropaeolin 000 (TP 000, method D) are utilized. The extracts of the ion-associates exhibit absorption maxima at 595, 640, 620 and 500 nm for methods A, B, C and D, respectively. Beer's law and the precision and accuracy of the methods are checked by the UV reference method. The results are reproducible with an accuracy of ± 1.0%. The methods are found to be suitable for the determination of cisapride in the presence of the other ingredients that are usually present in dosage forms. © 1997 Elsevier Science B.V.

Keywords: Cisapride; Ion-associates; Spectrophotometry

1. Introduction

Cisapride (CPD) is a gastrointestinal stimulant agent, effective in the relief of gastrointestinal or esophagus disorders and in the promotion of gastric emptying of a gastrointestinal motility [1]. It is a prokinetic agent believed to facilitate acetylcholine release from the myenteric plexus of the gut [2]. It is chemically known as (±) *cis*-4-amino-5-chloro-*N*-[1-[3-fluorophenoxy)propyl]-3-methoxy-4-piperidyl]-2-methoxy benzamide. The drug is official in the British Pharmacopoeia [3]. Literature mentions only a few methods such as fluorimetry [4], high performance liquid chromatography [5,6], thin layer chromatography [7] and a fluorescent polarization immunoassay method [8] for its determination in biological fluids and dosage forms. Although spectrophotometric methods are the instrumental methods of choice commonly used in industrial laboratories, no colorimetric method has been reported so far for the determination of cisapride. Therefore, the need for a fast, low cost and selective method is obvious, especially for routine quality control analysis of pharmaceutical products containing cisapride.

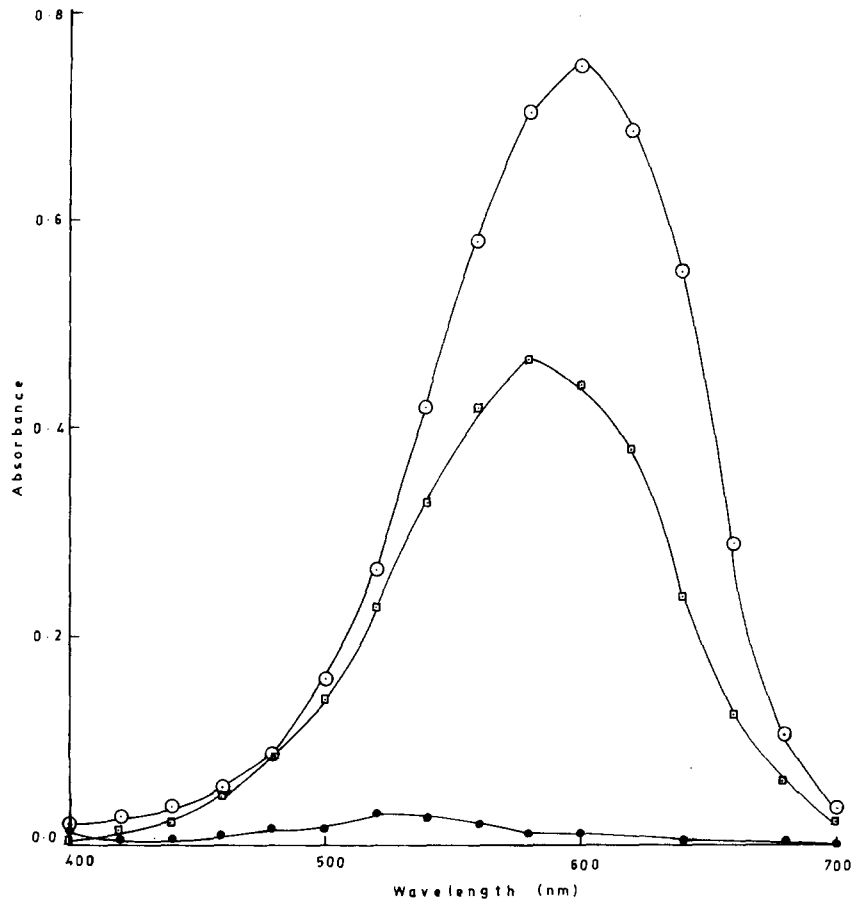

Fig. 1. Absorption spectra of the CPD-SV3B system (⊙——⊙) (concentration of CPD: 6.43×10^{-5} M; SV3B: 9.26×10^{-4} M), aqueous SV3B (□——□) (aqueous SV3B: 2.77×10^{-4} M), and reagent blank vs. chloroform (●——●).

As the extraction spectrophotometric procedures are popular for their sensitivity and selectivity in the assay of drugs [9,10], the technique was therefore utilized in the present work for the estimation of cisapride. A thorough literature survey of the extraction spectrophotometric determination of drugs reveals that many acid dyes belonging to azo [11–19], amino anthroquinone [20–22], indigoid [14,15], triphenylmethane [14,15,23] and sulphopthalein [14,24] are studied in the determination of compounds exhibiting basic properties (e.g. amines, quaternary ammonium compounds, heterocyclic compounds). In continuation of these studies, the present paper describes four simple and sensitive extraction spectrophotometric methods for the determination of cisapride, based on its tendency to form chloroform extractable ion-association complexes with acidic dyes belonging to different chemical classes, namely, Suprachen Violet 3B, SV 3B (amino anthroquinone; method A), Erioglaucine A, EG-A (triphenyl methane; method B), Naphthalene Blue 12BR, NB-12BR (diazo; method C) or Tropaeolin 000, TP 000 (monoazo; method D) under specified experimental conditions by exploiting the basic nature of the drug molecule.

2. Experimental

2.1. Instruments

A Milton Roy Spectronic 1201 UV-visible spectrophotometer and a Systronic 106 digital spectrophotometer with 1 cm matched quartz cells were used for all the absorbance measurements. An Elico LI 120 digital pH meter was used for pH measurements.

2.2. Reagents

All reagents and chemicals used were of analytical or pharmacopoeial grade purity and doubly distilled water was used throughout.

2.2.1. Dye solutions

Aqueous solutions of SV 3B (0.2% W/V, Chroma, Stuttgart, Germany), EG-A (0.4% W/V, Gurr, High Wycombe, Bucks, UK), NB-12BR (0.2% W/V, BDH, Poole, UK) and TP 000 (0.2% W/V, Fluka, Switzerland) were prepared by dissolving the required amount in doubly distilled water. The solutions were washed with chloroform to remove the chloroform-soluble impurities and the residual solvent was removed by bubbling with nitrogen.

2.2.2. Buffer solutions

The glycine–HCl buffer solutions (pH 1.3 for methods A, B and pH 1.5 for method C) were prepared [25].

2.3. Preparation of standard drug solution

A 1 mg ml^{-1} stock solution of cisapride was prepared by dissolving 100 mg of the drug in 100 ml of chloroform. Working standard solutions were obtained by appropriate dilution of the stock solution with the same solvent (50 μg ml^{-1}, for methods A, C, D and 10 μg ml^{-1}, for method B).

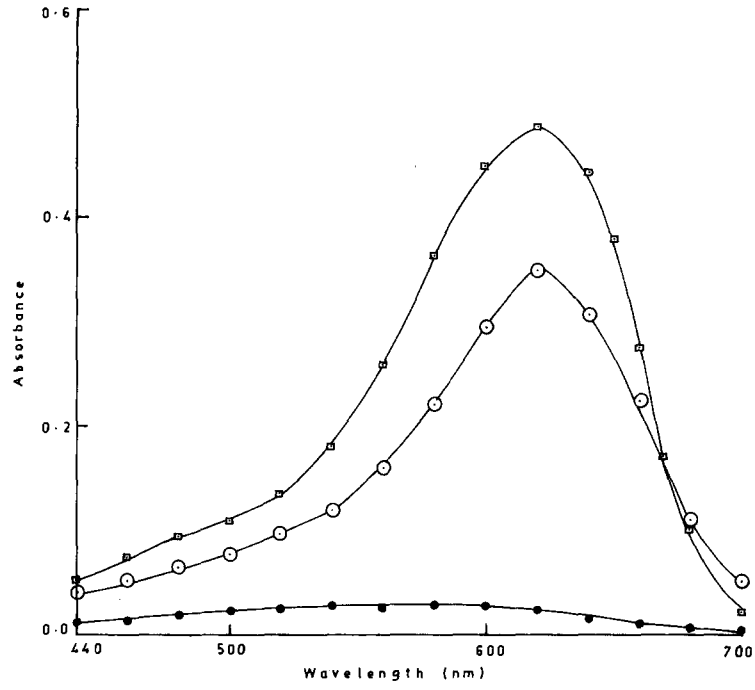

Fig. 3. Absorption spectra of the CPD-NB 12BR system (⊙——⊙) (concentration of CPD: 2.14×10^{-5} M; NB-12BR: 2.11×10^{-4} M), aqueous NB-12BR (□——□) (aqueous NB-12BR: 1.90×10^{-5} M), and reagent blank vs. chloroform (●——●).

2.4. Recommended procedures

2.4.1. Methods A and B

Aliquots of standard CPD solution (0.5–8.0 ml; 50 μg ml^{-1}, method A or 0.5–6.0 ml; 10 μg ml^{-1}, method B) were placed in a series of 125 ml separating funnels. A volume of pH 1.3 buffer solution (6.0 ml for method A or 10.0 ml for method B) and 2.0 ml of SV 3B solution (method A) or 5.0 ml of EG-A solution (method B) were added. The total volume of the aqueous phase in each separating funnel was adjusted to 10.0 ml and 15.0 ml with distilled water for methods A and B, respectively. A requisite volume of chloroform was added to each funnel to make the organic layer up to 10.0 ml and contents were shaken for 2 min. The two phases were allowed to separate, the separated chloroform layer was dried over sodium sulphate and the absorbance was measured at appropriate λ_{max} (595 nm, method A or 640 nm, method B) against the corresponding reagent blank within the stability period (1 min–3 h, method A or 1–30 min, method B). The amount of CPD was computed from the respective calibration curves.

2.4.2. Methods C and D

Aliquots of standard CPD solution (0.5–4.0 ml; 50 μg ml^{-1}, method C or 1.0–5.0 ml; 50 μg ml^{-1}, method D) were placed in a series of 125 ml separating funnels. Then 5.0 ml of pH 1.5 buffer and 1.0 ml of NB-12BR solutions (for method C) or 6.0 ml of 0.1 M HCl and 2.0 ml of TP 000 solutions (for method D) were added to each separating funnel. The total volume of the aqueous phase was adjusted to 15.0 ml and 10.0 ml with distilled water for methods C and D, respectively. A requisite volume of chloroform was added to each funnel to make the organic layer 10.0 ml and the contents were shaken for 2 min. The two phases were allowed to separate, the separated chloroform layer was dried over sodium sulphate and the absorbance was measured at appropriate λ_{max} (620 nm, method C or 500 nm,

method D) against the corresponding reagent blank within the stability period (1–30 min; method C or 1 min–2 h; method D). The amount of CPD was computed from the respective calibration curves.

2.5. Analysis of pharmaceutical formulations

A portion of pharmaceutical preparation (tablets, chewable tablets and suspension) equivalent to 100 mg of active ingredient was extracted with chloroform (3 × 20 ml) and filtered if any insoluble portion was left. The combined chloroform extract was made up to 100 ml with the same solvent to obtain a solution of 1 mg ml^{-1}. The stock solution was further diluted to provide the working standard solutions and these were analyzed as described under the procedure for bulk samples.

3. Results and discussion

Conditions under which the reaction of CPD with each dye fulfils the essential analytical requirements were investigated. All the experimental conditions studied were optimized at room temperature (25 ± 3°C) and were established by varying one parameter at a time [26] and observing its effect on the absorbance of the coloured species.

In the preliminary experiments, in view of developing methods of analysis suitable for assaying small quantities of CPD, several acidic dyes such as Alizarin Red S, Suprachen Violet 3B, Fast Green FCF, Erioglaucine A, Orange II, Tropaeolin 000, Alizarin Violet 3B, Naphthalene Blue 12 BR, Bromocresol Green and Bromopyragallol Red were tested at various pH ranges as the colour producing agents by a dye salt partition technique. Different organic solvents such as benzene, chloroform, carbontetrachloride, ethyl acetate, dichloromethane and methyl isobutyl ketone were tested for the extraction of the ion-association complex formed between the CPD and each dye. The criterion for the best dye was the highest absorbance value of the complex in the organic phase at the wavelength of maximum absorbance [10]. The above studies reveal that four dyes namely SV 3B (Cl No. 60730), EG-A (Cl No. 42090), NB-12 BR (Cl No. 20500) and TP 000 (Cl No. 14600) gave better results than the other dyes. These dyes also gave low absorbance for the reagent blank. Chloroform was suggested as the solvent of choice for the extraction of the coloured complex with respect to maximum stability.

Figs. 1–4 shows the absorption spectra of the ion-association complexes of CPD with the four dyes, extracted into chloroform and of the reagent blank, obtained as described in the procedure. The spectra are very similar in shape to the absorption spectrum of an aqueous solution of the respective dye, indicating that these ion-association complex spectra show the characteristics λ_{max} (595 nm, method A; 640 nm, method B; 620 nm

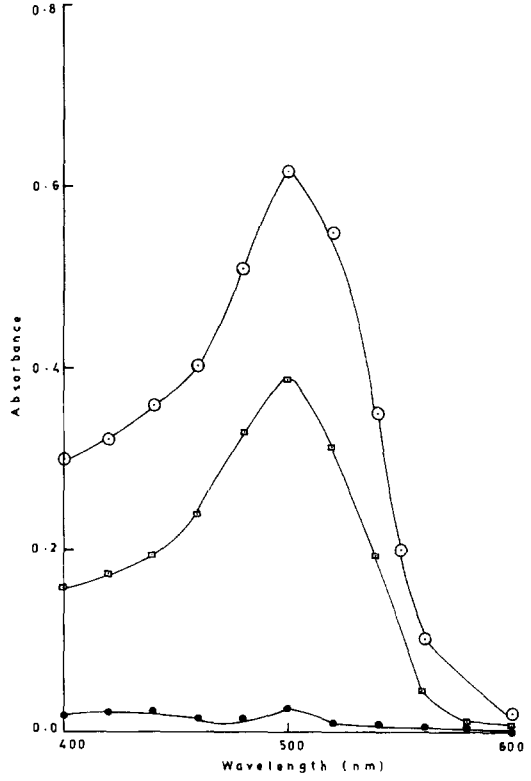

Fig. 4. Absorption spectra of the CPD-TP 000 system (⊙——⊙) (concentration of CPD: 3.21×10^{-5} M; TP 000: 1.14×10^{-3} M and HCl: 6.0×10^{-2} M), aqueous TP 000 (□——□) (aqueous TP 000: 2.28×10^{-5} M; HCl: 2.4×10^{-2} M) and reagent blank vs. chloroform (●——●).

[a] $Y=a+bC$ where C is the concentration in μg ml^{-1} and Y is absorbance units.
[b] Six replicate samples (concentrations of 30, 3, 10 and 15 μg ml^{-1} of pure drug for methods A, B, C and D, respectively.

method C; and 500 nm, method D) values of the respective dye itself.

In order to establish the optimum pH range (for methods A, B and C) or acid strength (for method D), the CPD was allowed to react with the respective dye in aqueous solution buffered between pH 1.0–10.0 (methods A, B and C) or in dilute HCl ranging from 0.05–1.5 M (method D) and the complex formed was extracted into chloroform for absorbance measurement. The results show that a quantitative extraction was produced between pH 1.1–1.5 (methods A and B), 1.4–1.8 (method C) or with an acid strength of 0.08–0.12 M HCl (method D). All subsequent studied were carried out at pH 1.3 (for methods A and B) and pH 1.5 (for method C) or 0.1 M HCl (for method D). The pH was adjusted using a glycine–HCl buffer solution (this buffer was chosen on account of its elevated complexing ability, which could be of use in overcoming interferences). The volume of this buffer added (4–10 ml) had no effect in methods A, B and C, respectively. A 6.0 ml portion of 0.1 M HCl solution was found to be optimal in method D. The minimum shaking time was determined by varying the shaking time from 1–10 min; although 1 min was sufficient, prolonged shaking had no adverse effect on the extraction and 2 min was selected for this study. A ratio of 1:1 (for methods A and D) or 2:3 (for methods B and C) of organic to aqueous phases was required for efficient extraction of the coloured species and lower reagent blank reading. It was found that better reproducibility and a lower reagent blank were achieved if the dye was purified by extraction with chloroform initially.

3.1. Analytical data

The optical characteristics such as the Beer's law limits, molar absorption coefficient, Sandell's sensitivity, regression equation and correlation coefficient obtained by linear least squares treatment [27] of the results for the systems involving cisapride with the mentioned dyes are presented in Table 1. The precision of each method was tested by estimating six replicates of CPD within Beer's law limits. The percent standard deviation and the percent range of error at 95% confidence limit are given in Table 1.

In order to confirm the utility of the proposed methods, they were applied to the estimation of CPD in various pharmaceutical formulations and

the results are presented in Table 2. The results obtained by the proposed and UV reference (which is developed in our laboratory, showing characteristic λ_{max} at 308 nm in methanol medium) methods for the dosage forms were compared statistically by means of F- and t-tests and were found not to differ significantly. As an additional check of accuracy of the proposed methods, recovery experiments were performed by adding a fixed amount of the CPD to the preanalysed formulation and the results are also summarized in Table 2.

3.2. Chemistry of the ion-association complex

Cisapride being basic in nature forms an ion-association complex with the acidic dye which is extractable into chloroform. The stoichiometric ratio of the dye to drug was determined by the slope ratio method [28] and found to be 1:1 (for methods A and D), 1:3 (for method B) or 1:2 (for method C). The quantitative measure of the effect of complexation on acid–base equilibrium is most likely to be interpretable in terms of electronic, steric and other effects of complexing. The possible structure of the ion-association complex in each instance was established based on the analogy reports for similar types of molecules with acidic dyes and was further confirmed by slope-ratio studies. The protonated nitrogen (positive charge) of the drug molecule in acid medium is expected to attract the oppositely charged part (negative charge) of the dye and behave as a single unit being held together by electrostatic attraction as given in Scheme 1.

4. Conclusion

A significant advantage of an extraction spectrophotometric determination is that it can be applied to the determination of individual compounds in a multicomponent mixture. This aspect of spectrophotometric analysis is of major interest in analytical pharmacy since it offers distinct possibilities in the assay of a particular component in a complex dosage formulation. In the present study, cisapride was determined successfully as a pure compound as well as a component in representative dosage formulations. The ingredients usually present in the dosage forms of cisapride did not interfere in the proposed methods. Thus, the proposed methods are simple, rapid with reasonable precision and accuracy when compared with many of the reported methods and offer advantage in that only a small amount of drug or dosage formulation (even 0.5 μg ml^{-1}) is enough for analysis.

Acknowledgements

The authors are thankful to Sun Pharmaceutical Industries (Bombay, India) for their generous gift sample of cisapride and the authorities of Andhra University for providing research facilities.

Received 29 April 1996; received in revised form 12 July 1996; accepted 22 July 1996

Abstract

The formation and dissociation rates of some transition metal(II) and lanthanide(III) complexes of the 1,7,13-triaza-4,10,16-trioxacyclooctadecane *N',N'',N'''*-triacetic acid (**1**) and 1,7,13-triaza-4,10,16-trioxacyclooctadecane-*N',N'',N'''*-trimethylacetic acid (**2**) have been measured by the use of stopped-flow and conventional spectrophotometry. Experimental observations were made at 25.0 ± 0.1°C and at an ionic strength of 0.10 M KCl. The complexation of Zn^{2+} and Cu^{2+} ions with **1** and **2** proceeds through the formation of an intermediate complex (MH_3L^{+*}) in which the metal ion is incompletely coordinated. This may then lead to a final product in the rate-determining step. Between pH 4.68 and 5.55, the diprotonated (H_2L^-) form is revealed to be a kinetically active species despite its low concentration. The stability constants (log $K_{MH_3L^{+*}}$) and specific base-catalyzed rate constants (k_{OH}) of intermediate complexes have been determined from the kinetic data. The dissociation reactions of **1** and **2** complexes of Co^{2+}, Ni^{2+}, Zn^{2+}, Ce^{3+}, Eu^{3+} and Yb^{3+} were investigated with Cu^{2+} ions as a scavenger in acetate buffer. All complexes exhibit acid-independent and acid-catalyzed contributions. The buffer and Cu^{2+} concentration dependence on the dissociation rate has also been investigated. The metal and ligand effects on the dissociation rate of some transition metal(II) and lanthanide(III) complexes are discussed in terms of the ionic radius of the metal ions, the side-pendant arms and the rigidity of the ligands. © 1997 Elsevier Science B.V.

Keywords: Alkanoic acid complexes; Lanthanide; Transition metal

1. Introduction

In recent years there has been a growing interest in the development of macrocyclic polyaza-polycarboxylate ligands which can be used as contrast agents for magnetic resonance imaging (MRI) [1,2] and as NMR shift probes for biological systems [3] by forming metal chelates of high thermodynamic and kinetic stability [4]. The kinetic behavior of the Ln^{3+} ions with DOTA (1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-te-

PII S0039-9140(96)02052-8

traacetic acid) and TETA (1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraaceticacid) differs considerably from that of the first-row transition metal ions, since the DOTA and TETA complexes of Ni^{2+} and Cu^{2+} formed relatively quickly as demonstrated by Kasprzyk and Wilkins [5]. Macrocyclic polyazapolycarboxylate ligands have some additional features including cavity size, steric factors, conformation and preorganization which affect the rates of formation and dissociation for their complexes. Formation kinetics on the lanthanide complexes of NOTA (1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetic acid) and DOTA have been investigated and the formation of intermediates ($LnHNOTA^{+*}$ and LnH_2DOTA^{+*}) was proposed, followed by reorganization in the rate-determining step to the final product [6,7]. The size effect of Ln^{3+} ions on the formation rate of Ln^{3+} complexes was not pronounced as observed for the dissociation reactions of these chelates [6,7]. Additional studies on the dissociation kinetics of lanthanide complexes of macrocyclic polyazapolycarboxylate, triaza-crown-alkanonate and DTPA-bis(amide) ligands were also reported [8–13]. In these studies, the dissociation of the complexes occurred via both acid-independent and acid-assisted pathways and the dissociation rates varied with the size of metal ions and the ligand topology.

The main objective of this research is to determine the formation and dissociation rates of some divalent and trivalent metal complexes with various macrocyclic triazatrioxa ligands with acetate and methylacetate groups as *N*-pendant arms (Fig. 1). We intend to investigate the effect of the cavity size and rigidity of the macrocycle as well as pendant arms effects on the kinetic properties of these complexes.

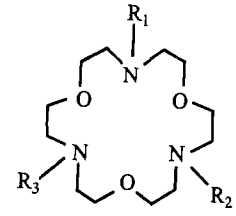
2. Experimental

2.1. Chemicals and reagents

1,7,13-Triaza-4,10,16-trioxacyclooctadecane trihydrobromide was prepared by the previous procedure [14]. Ligands 1,7,13-triaza-4,10,16-trioxacyclooctadecane-*N*,*N*′,*N*″-triacetic acid (**1**) and 1,7,13-triaza-4,10,16-trioxacyclooctadecane-*N*,*N*′,*N*″-trimethylacetic acid (**2**) were synthesized according to the method of Martell et al. [15]. The ligands were characterized by ^1H NMR, mass spectrometry and elemental analysis (1: found: C, 39.76; H, 6.06; N, 7.63%; $C_{18}H_{33}N_3O_9 \cdot 3HCl$ requires C, 39.68; H, 6.11; N, 7.71%. 2: found: C, 42.85; H, 6.78; N, 7.06 %; $C_{21}H_{39}N_3O_9 \cdot 3HCl$ requires C, 42.97; H, 6.70; N, 7.16%). The stock solutions of $CoCl_2$, $NiCl_2$, $CuCl_2$, $ZnCl_2$, $CeCl_3$, $EuCl_3$ and $YbCl_3$ were prepared from solid samples (Aldrich, 99.9%). The concentrations of the sample solutions were determined by EDTA titration using Murexide or xylenol orange as indicators. The concentrations of **1** and **2** stock solutions were determined by titration against a standardized $CuCl_2$ solution using Murexide as an indicator. Potassium chloride was used to control the ionic strength in all kinetic studies. All solutions were made in deionized water. All other chemicals were reagent grade and were used without further purification.

2.2. Measurements

The pH values of the sample solutions were measured with a Beckman combination electrode and Beckman Model ϕ 71 pH meter. The H^+ ion concentrations were calculated from the measured pH values in acetate buffer solution of 0.10 M (KCl) ionic strength by the procedures reported previously [16]. Kinetic measurements were car-



1. $R_1 = R_2 = R_3 = CH_2COOH$

2. $R_1 = R_2 = R_3 = CHCOOH$ (with CH_3)

Fig. 1. Structure of the triaza-crown-alkanoic acids.

ried out on a Hi-Tech stopped-flow spectrophotometer interfaced with a scientific data acquisition system and a UVIDEC-610 spectrophotometer at 25.0 ± 0.1°C with the use of a Lauda RM6 circulatory water bath.

The formation reactions of Zn^{2+} complexes were studied in slightly buffered solutions (0.01 M acetic acid/sodium acetate) by monitoring the pH decrease (0.05–0.17 pH unit) with bromocresol green ($4.6 < pH < 5.2$, observation wavelength 615 nm) as an indicator [5]. The reaction of Cu^{2+} with **2** was studied by monitoring the formation of complex directly at 260 nm. The data agreed well with some runs using the indicator method [5]. The concentration of the indicator was 2.0×10^{-5} M, while that of the acetate buffer varied between 5.0×10^{-3} and 2.0×10^{-2} M, independent of the reaction rate. The concentration of the ligands was 2.0×10^{-4} M, while that of the Cu^{2+} and Zn^{2+} ions was varied between 4.0×10^{-4} and 4.0×10^{-3} M.

The dissociation reactions of the complexes were studied in acidic solutions in the presence of excess Cu^{2+} ions. Under these conditions, a dissociation reaction takes place and the progress of the exchange may be monitored by the formation of copper complexes at 270 nm. The Cu^{2+} ion was used as a scavenger of free ligands. The complex concentration in the reaction mixtures was 5.0×10^{-5} M, while that of the Cu^{2+} ion was varied between 2.0×10^{-4} and 1.0×10^{-3} M. The buffer solutions were made by using a constant acetate ion concentration and varying the concentration of acetic acid necessary for attainment of the desired pH.

3. Results and discussion

3.1. Formation kinetics

The formation rate of Zn(**1**), Cu(**2**) and Zn(**2**) complexes in the presence of excess metal ion can be given as

$$d[ML^+]\,dt^{-1} = k_{obs}[L]_T \quad (1)$$

where $[L]_T$ is the total concentration of the free ligand and k_{obs} is a pseudo-first-order rate constant. At a given pH 4.64–5.55, the values of k_{obs} increased with increasing $[M^{2+}]$ and the plot of the k_{obs} values against $[M^{2+}]$ gave a saturation curve, as found for the formation of Ln(NOTA) [6] and Ln(DOTA)$^-$ [7]. The relationship between k_{obs} values and $[M^{2+}]$ can be described [17] by

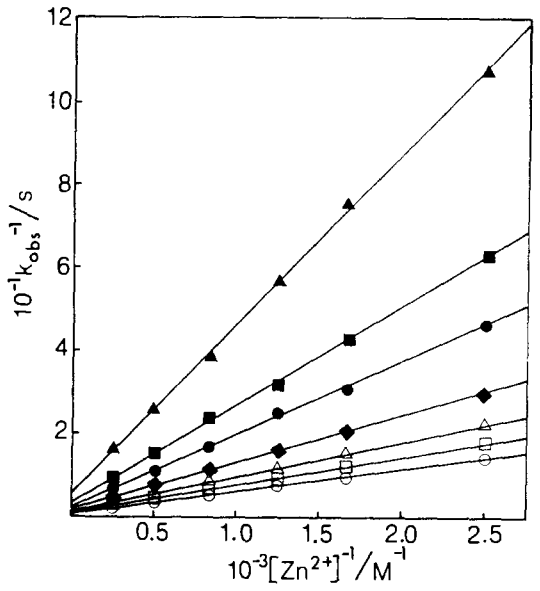


Fig. 2. Plots of k_{obs}^{-1} vs $[Zn^{2+}]^{-1}$ for the formation kinetics of Zn(**2**) at different pH values. [**2**] = 2.0×10^{-4}M; [OAc^-] = 0.01 M; $T = 25.0 \pm 0.1$°C; $I = 0.10$ M (KCl); pH = 4.68(○), 4.89(□), 5.04(△), 5.26(◆), 5.37(●), 5.45(■), 5.55(▲).

$$k_{obs} = \frac{k_1 K[M^{2+}]}{1 + K[M^{2+}]} \quad (2)$$

where K is the equilibrium constant characterizing the formation of the intermediate and $k_1$is the rate constant of the intermediate to product in the rate-determining step. Plots of $1/k_{obs}$ against $1/[M^{2+}]$ lead to straight line as show in Fig. 2. The values of k_1, K and the second-order rate constant $k_2 = k_1 K$ were deduced from Eq. (2) and are summarized in Table 1. The present work shows no significant variation in the values of K with various pH. The protonated forms of **1** and **2** could contribute to the complexation kinetics of M^{2+} ions between pH 4.64 and 5.55. The concentrations of protonated ligands were computed with the use of ligand protonation constants. (Protonation constants (log K_i) in 0.10 M KCl and 25.0 ± -

	5.43	4.92×10^1	8.27×10^2	4.07×10^4

0.1°C are 9.57, 8.15, 7.67, 2.05 and 1.07 for **1** [15] and 9.70, 9.18, 7.27, 3.86 and 2.94 for **2**, which were calculated by fitting the potentiometric data to the PKAS program [18]). In this pH range, the species H_3L is at a high concentration (81.99–99.62%) while H_2L^- is at a low concentration (0.07–1.42%).

The stability constant of the intermediate $(MH_3L^+)^*$ can be calculated from the value of K at a given pH, using known protonation constants of the ligands by Eq. (3)

$$K_{(MH_3L^+)^*} = K(1 + (K_3[H^+])^{-1} \quad (3)$$

The calculated stability constants of three intermediate complexes $(MH_3L^+)^*$, summarized in Table 2 along with the literature value [19], are relatively pH-independent over most of the pH range examined. The stability constants of the intermediate here are about one order of magnitude higher than those for the corresponding monoacetate and monomethylacetate complexes [20]. This suggests that the M^{2+} ion is coordinated with more than one carboxylate oxygen in the intermediate formation. A similar result is also observed for the formation of $Ln(N_3O_2Ac)$

(1,4,10-traiza-7,13-dioxacyclopentadecane-*N*,*N*′,*N*″-triacetic acid) [12]. The intermediate of the Cu(**2**) complex has a larger stability constant than that of the Zn(**2**) complex. This fact may be attributed to the thermodynamic stability ($\log \beta_{Cu(2)} = 13.45$ vs. $\log \beta_{Zn(2)} = 13.00$). (The stability constant was obtained from the experimental data with the aid of the BEST program [18]. Values were obtained in 0.10 M (KCl) at 25.0 ± 0.1°C). The stability constants for intermediates of Zn(**1**) and Zn(**2**) are not significantly different, and are about one order of magnitude lower than the value of $K_{ZnH_2L^{+*}}$ found previously for $Zn(N_3O_2Ac)$ [19].From the kinetic data, the second-order rate constant k_{H_nL} also represents $(k_1K)_{H_nL}$. If one species is markedly more reactive than all others, the second-order rate constant could be obtained from the following expression [5]

$$k_2 = k_{H_nL}(1 + (K_{H_{(n+1)}L})^{-1}[H^+])^{-1} \quad (4)$$

Table 2

[a] Ref. [19].

where $K_{H_{(n+1)}L}$ is the protonation constants of **1** and **2**. From the plots of k_2 against $(1+(K_{H_{(n+1)}L})^{-1}[H^+])^{-1}$, the second-order rate constants for the H_2L^- and H_3L species are collected in Table 2. Despite their very low concentration in the pH range observed, the H_2L^- species appears to be kinetically much more reactive than the H_3L species (except for the Zn(**1**) reaction), even though the latter is the major component in solution [21]. These experimental results show differences from those reported by Kumar and Tweedle [4], where H_3L and H_2L^- are the predominant species due to the difference in the basicities of ligands. The low reactivity of the H_3L form may be assigned to the formation of trizwitterionic forms of **1** and **2**. The three $N-H^+$ groups in the 18-membered cycle of H_3L probably hinder the rearrangement of the intermediate complex into the final chelate product due to the electrostatic repulsion with the incoming metal ion.

The value of k_1, the rate of rearrangement of the intermediate, was increased with increasing pH as shown in Table 1. This implies that the rearrangement of the intermediate complex into the final chelate product is catalyzed by the OH^- ion. This observation is consistent with the previously reported works [4,12,19]. Fig. 3 shows that the plot of k_1 as a function of $[H^+]^{-1}$ gives a linear line. An expression consistent with this functional dependence is given by Eq. (5) [4]

$$k_1 = k_{H_2O} + k_{OH}K_W[H^+]^{-1} \quad (5)$$

where k_{H_2O} and k_{OH} are the water and hydroxide-catalyzed rate constants of the rearrangement of the intermediate. The k_{OH} values calculated form the slope of the straight line in Fig. 3 and Eq. (5) ($\log K_W = 13.78$) are listed in Table 2. The values of second-order rate constants for proton transfer (k_{OH}) are diffusion controlled. This may be attributed to the low basicity of nitrogen express as macrocyclic ligands [4]. A significant contribution from the base form of the buffer is not expected, since the concentration of buffer used in the present work is low. The k_{OH} value of Zn(**2**) is about two orders of magnitude smaller than that of Zn(**1**). This indicates that the substitution of three methyl groups on the acetate pendant arms of **1** makes the ligand more rigid [22,23]. On the other hand, the hydroxide-catalyzed dissociation rate of Cu(**2**) is about 30 times faster than that of Zn(**2**). Probably the cavity size (18-membered cycle) of **2**, which is too large for the Cu^{2+} ion, plays a major role in the metal complex formation reaction. Similar results reported that the formation rates of alkaline earth complexes of DOTA were increased with decreasing ionic size [5].

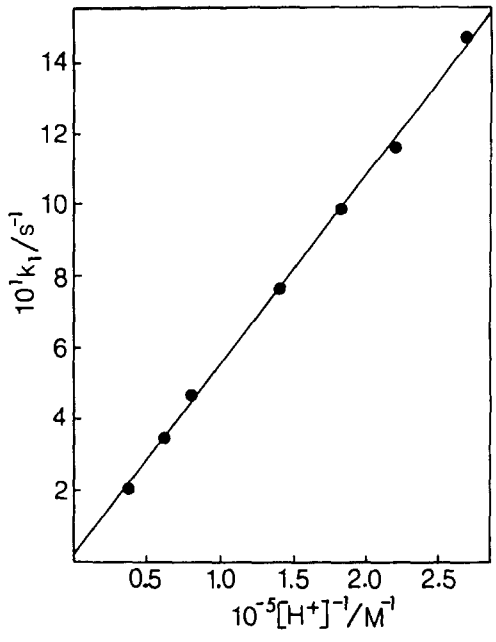

Fig. 3. Plots of k_1 vs. $[H^+]^{-1}$ for the formation kinetics of Zn(**2**) at 25.0 ± 0.1°C and $I = 0.10$ M (KCl).

3.2. Dissociation kinetics

The rates of the dissociation reactions for some transition and lanthanide complexes of **1** and **2** have been measured between pH 4.07 and 5.18. In the presence of excess Cu^{2+} ions, the rate of exchange may be expressed as

$$-d[ML]\,dt^{-1} = k_{obs}[ML] \quad (6)$$

where k_{obs} is a pseudo-first-order rate constant. The values of k_{obs} for **1** and **2** complexes were found to be independent of $[OAc^-]$ but dependent on $[Cu^{2+}]$. The dependence of k_{obs} on $[Cu^{2+}]$ is illustrated in Fig. 4 at different pH values. The data in Fig. 4 indicate that the dissociation rate of complex is proportional to $[Cu^{2+}]$. The small

positive intercepts along the ordinate of these data plots indicate that $[Cu^{2+}]$-independent dissociation also occurs. Thus, the data can be described by

$$k_{obs} = k_d + k_{Cu}[Cu^{2+}] \quad (7)$$

where k_d and k_{Cu} are the functions of acidity, $[H^+]$. Fig. 5 shows that k_d is proportional to $[H^+]$, while k_{Cu} is proportional to $[H^+]^{-1}$. On the basis of these results, the overall rate of dissociation reaction can be expressed as

$$-d[ML]\,dt^{-1} = k_d[ML] + k_H[ML][H^+] + k_{Cu}[ML][Cu^{2+}] + k_{CuH-1}[ML][Cu^{2+}][H^+]^{-1} \quad (8)$$

The rate constants (k_d, k_H, k_{Cu} and k_{CuH-1}) calculated from the experimental data are presented in Table 3. As can be seen, the first and second terms in Eq. (8) are responsible for the dissociative pathway of the Cu^{2+}-independent mode. The

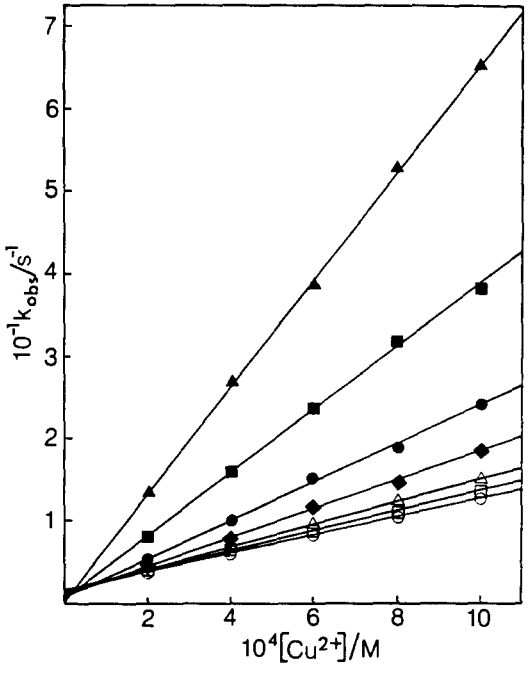

Fig. 4. Plots of k_{obs} vs. $[Cu^{2+}]$ for the dissociation kinetics of Eu(**1**) at different pH values. [Eu(**1**)] = 5.0×10^{-5} M; $[OAc^-]$ = 0.01 M; $T = 25.0 \pm 0.1$°C; $I = 0.10$ M (KCl); pH = 4.08(○). 4.17(□), 4.27(△), 4.40(◆), 4.64(•), 4.91(■), 5.18(▲).

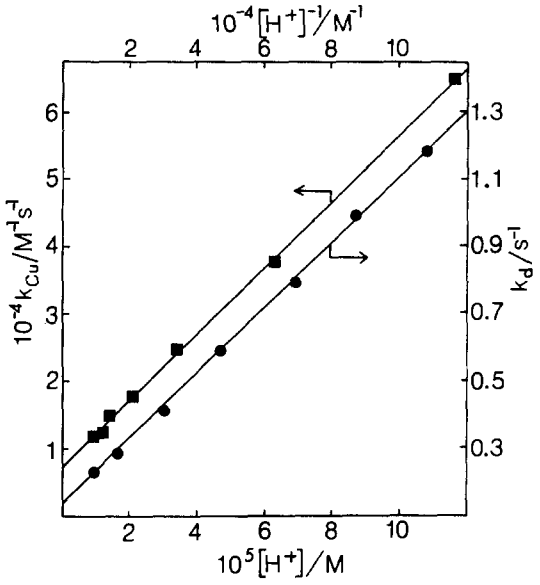

Fig. 5. Plots of k_d vs. $[H^+]$ and k_{Cu} vs $[H^+]^{-1}$ for the dissociation kinetics of Eu(**1**). [Eu(**1**)] = 5.0×10^{-5} M; $[OAc^-]$ = 0.01 M; $T = 25.0 \pm 0.1$°C; $I = 0.10$ M (KCl).

rate-determining step involves the loss of metal ion from the complexes and the rapid reaction of the released ligand with Cu^{2+} ion. Eq. (8) also represents the associative pathway of the Cu^{2+}-dependent mode, which is composed of the direct attack of the Cu^{2+} ion on partially dissociated M–L and the $[H^+]^{-1}$ dependence. $[H^+]^{-1}$ behavior can be interpreted by the existence of the attack of hydrolyzed copper species ($CuOH^+$) on M–L, even though the investigated pH is not higher. k_{CuOH^+} is therefore obtained by the expression.

$$k_{CuH-1} = k_{CuOH^+}\beta_{CuOH^+} \quad (9)$$

where β_{CuOH^+} ($= k_{CuOH^+}K_W$) is a stability constant (i.e. 2.0×10^{-8}) [9].

Table 3 gives a summary of the rate constants for dissociation of various metal complexes of **1** and **2**. A comparison of the rate constants k_d and k_H of the transition metal and lanthanide complexes of **1** and **2** demonstrates the order $Co^{2+} > Ni^{2+} > Zn^{2+}$ and $Ce^{3+} > Eu^{3+} > Yb^{3+}$, respectively. Both rate constants are significantly affected by metal ionic size. An increase in the cation radius from Co^{2+} to Zn^{2+} leads to an

increase in kinetic stability probably because the Zn^{2+} ion fits into a ligand somewhat better than the Co^{2+} and Ni^{2+} ions. However, the consistent decrease in the dissociation rates of **1** and **2** complexes from Ce^{3+} to Yb^{3+} parallels the thermodynamic stability of these complexes with decreasing ionic size or increasing charge density of Ln^{3+} ions. The dissociation rates of **1** complexes were found to be faster than those of **2** complexes. This indicates that the substitution of three methyl groups on the acetate pendant arms of **1** increases the rigidity of the macrocycle, yielding a complex with even greater kinetic stability. A methyl substitution in other polyazapolycarboxylate ligands has also been observed to increase the inertness of their resulting complexes [22–24]. An acid-catalyzed dissociation rate of Eu(**1**) is about four orders of magnitude faster than that of Eu(N_3O_2Ac), even though **1** has the increased ring size (18-membered cycle) compared with N_3O_2Ac (15-membered cycle). This may be attributed to the decrease of macrocycle rigidity by the flexibility of **1** and the mismatch caused by the large cavity size.

Abstract

This paper describes a comparative study of the microwave induced plasma (MIP) and the stabilized capacitive plasma (SCP) for halide determinations. The MIP is generated in a Beenakker cavity TM_{010} using a tangential flow torch and the SCP consists of a 27.12 MHz discharge sustained in a liquid-cooled, fused silica tube surrounded by two annular electrodes. Both discharges are operated in helium at atmospheric pressure and detection was carried out by Atomic Emission Spectrometry (AES). The halides (I^-, Br^-, Cl^-) are converted to volatile halogens by continuous flow generation based on chemical oxidation and on-line separation from the aqueous phase, via a gas–liquid separator, to be finally introduced into the plasma. The different factors affecting the emission intensity of the volatile halogens generated are compared for both discharges and the analytical performance characteristics are also evaluated. Detection limits of 17 ng ml^{-1}, 24 ng ml^{-1} and 55 ng ml^{-1} are obtained for the determination of Cl^-, Br^-, and I^-, respectively, in the ultraviolet-visible (UV-VIS) region using the MIP-AES and 45 ng ml^{-1}, 135 ng ml^{-1} and 400 ng ml^{-1} for Cl^-, Br^-, and I^- with the SCP-AES. Lines in the near infrared (NIR) region were also evaluated for the SCP-AES detection; improvements in detection limits higher than 30 times were observed in the NIR region as compared with the UV-VIS with detection limits in the NIR of 1.4 ng ml^{-1} for Cl^-, 3 ng ml^{-1} for Br^- and 13 ng ml^{-1} for I^-. © 1997 Elsevier Science B.V.

1. Introduction

Different plasma sources, using He as the discharge gas, have been proposed as sensitive means for halogen detection by Atomic Emission Spectrometry (AES) such as inductively coupled plasmas [1], glow discharges [2], furnace atomic non-thermal excitation spectrometry [3], etc. Among those, the microwave induced plasmas MIPs, owing to their high electronic temperature, offer particularly good analytical sensitivity for

the analysis of non-metals such as the halogens [4–6]. However, the limited thermal energy available in the *commonly used low-power* MIPs (< *150 W*) leads to difficulties with sample desolvation, restricting the real-life use of these discharges to gas phase sample introduction, as in gas chromatography where MIP-AES has become a popular detector [7–9].

More recently, the stabilized capacitive plasma (SCP) has attracted special attention and interest for non-metal excitation using He as plasma gas [10–12]. This plasma has also been evaluated as a gas chromatographic detector [12] and good results (in terms of sensitivity, chemical and spectral interferences) were observed for non-metals in this particular application of SCP-AES.

Alternative means of gas phase sample introduction to MIPs and SCPs for total halogens analysis include chemical [13–17] or electrothermal [11–18] volatilization of halides.

Using chemical volatilization, by on-line chemical oxidation to the corresponding halogen with an adequate oxidant ($KMnO_4$ or H_2O_2) in acid media, we have investigated the comparative analytical performances of both low power plasma for halide analysis: the MIP-AES generated in a Beenakker cavity and the SCP-AES device. Analytical figures of merit and discussion on excitation characteristics observed with both plasma systems are given. Finally, the application of both detection systems to the *determination* of chloride in real water samples is described.

2. Experimental

A block diagram of the experimental set-up used is shown in Fig. 1. Details of the sample introduction system, the plasma components and the spectrometric equipment are described below.

Table 1
Optimum sample and oxidant flow rates

Halogen	Oxidant flow (ml min^{-1})	Sample flow (ml min^{-1})	H_2SO_4 (ml min^{-1})
Chlorine	0.12	4.5	—
Bromide	0.12	4.5	—
Iodine	2.1	2.1	2.1

2.1. Sample introduction system and procedure

Sample solutions were prepared in 7.5 M H_2SO_4 when analyzing bromide or chloride. In order to prevent any chemical oxidation of iodide to volatile iodine by sulfuric acid, the iodide samples were prepared in aqueous medium. For on-line oxidation of samples containing chloride or bromide a solution of 0.05 M $KMnO_4$ in concentrated H_2SO_4 was pumped to the sample stream. For iodide the dissolved samples were mixed on-line with two solutions: one of 3 M H_2SO_4 and the second one containing 3 M H_2O_2. Flow rates of samples and reagents selected in the continuous system are given in Table 1. The generated volatile halogen passed through a gas–liquid separator consisting of a glass tube (2 cm i.d. and 6.5 cm long) where the gas–liquid sample mixture interacted with a smooth flow of He which passes through a glass-frit membrane (Fig. 2). The liberated halogen vapour was stripped off continuously by the carrier-gas stream of He, while residual moisture was removed by bubbling through a desiccator flask filled with concentrated H_2SO_4. The dried gaseous mixture is then introduced directly into the plasma discharge (see Fig. 1) for atomization and excitation.

2.2. Plasma–AES equipment

The components of the two plasma systems used are listed in Table 2 and have been described in detail elsewhere [10,19]. The Beenakker cavity of the MIP was mounted on a translation stage (Oriel Corp.) over an optical bench so that the vertical and horizontal positions could be adjusted within a reproducibility of better than 0.02 mm. A Tangential Flow Torch (TFT) was used as the discharge tube [19–21]. It consists of two coaxial alumina ceramic capillaries (2.5 mm i.d., 4 mm o.d., 30 mm long, and 1 mm i.d., 2 mm o.d., 60 mm long, respectively) positioned in a fitting holder for the addition of a tangential gas flow. Reflected power was kept all time at values lower than 3 W. The plasma was viewed axially and imaged 1:1 on the entrance slit of the monochromator using a fused silica lens.

The SCP is a 27.12 MHz discharge in helium at atmospheric pressure [10,12]. The discharge is sustained in a water-cooled, fused silica tube surrounded by two annular electrodes. The outer surface of the tube is efficiently cooled to a temperature below 100°C by a thin film of fast flowing water. The light emitting region is a disused filament in the centre of the tube at a length of about 20 mm symmetrical to the electrodes. The emitted light from the SCP is collected "end-on" but, in contrast to the MIP detection, an optical fibre, directly mounted on the torch in order to direct the spectral emission to the slit of the spectrometer, was used for the SCP.

Helium (99.999%) was chosen as plasma gas because of its high excitation energy. In the case of the SCP a dopant gas addition of 0.03% O_2 was used.

2.3. Reagents

All the reagents used in this study were of analytical reagent grade and high-purity water (Milli-Q Water) was used throughout.

Stock solutions of iodide, bromide and chloride (1000 μg ml^{-1}) were prepared by dissolving the corresponding potassium halides (dried previously at 110°C) in Milli-Q water. Calibration standard solutions were prepared by serial dilution of the stock solutions in Milli-Q water for I^- and in 7.5 M H_2SO_4 for Br^- and Cl^-.

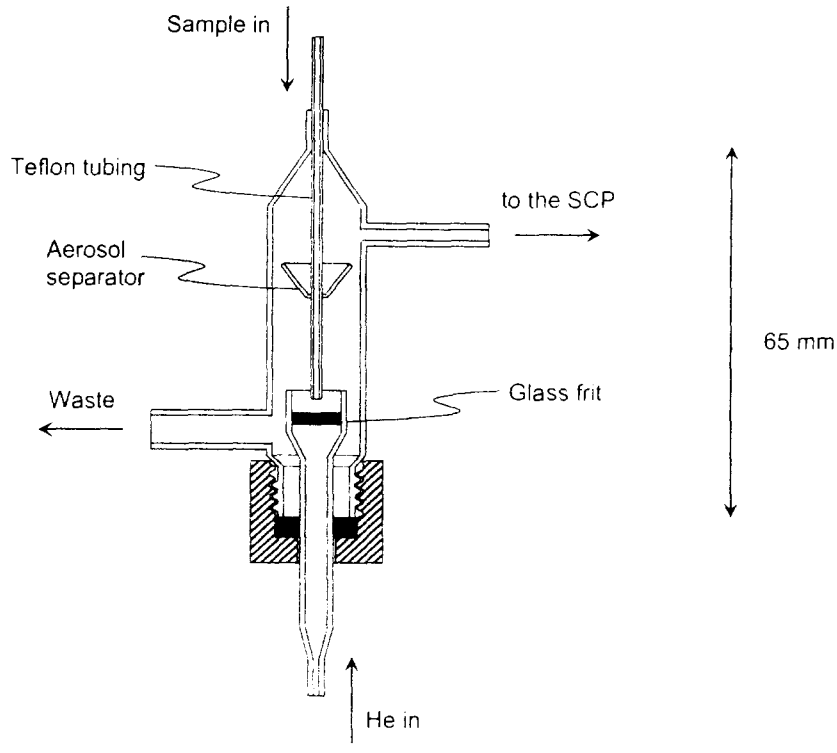

Fig. 2. Diagram of the gas–liquid separator.

2.4. Real sample analysis

To check the applicability of the technique, the chloride content of some commercial mineral waters, tap water, and groundwaters was analyzed. Samples were prepared using sulfuric acid at a final concentration of 7.5 M H_2SO_4. The calibration was carried out using synthetic standard solutions prepared in 7.5 M H_2SO_4.

For method validation, the determination of chloride in the same real water samples was also carried out by ion chromatography using an ion chromatograph (Dionex Corporation) with suppressed conductivity detection.

3. Results and discussion

In order to obtain maximum analyte emission, both chemical generation and plasma excitation parameters were examined and individually optimized for each halide. These parameters included plasma variables (flow rates of the gases forming the plasma and microwave power) and also the conditions for continuous chemical halogen generation and halogen stripping from the liquid phase; flow rates of the liquid samples and of the individual oxidation reagents, type of gas–liquid separator, etc.

The optimization studies were carried out following a univariant search and using the ratio I_N/I_B (where I_N is the background-corrected net analyte emission intensity and I_B the background emission intensity) as the analytical parameter to be maximized.

3.1. Wavelength selection

There are several emission lines lying in the UV-VIS and NIR regions which have been recommended for halogen determined by Plasma-AES at atmospheric pressure [13–18,22]. The emission lines selected offering the best signal to background ratios with our detection systems are

collected in Table 3 for both SCP and MIP detectors (in this latter case only UV-VIS detection was available).

3.2. Effect of plasma parameters

The effect of microwave forward power in the Beenakker cavity was studied for each continuously generated halogen as explained in the Section 2, in the range 75–100 W. The results obtained have been plotted in Fig. 3. As can be seen, the plots are very similar for the three analytes under study; consequently the observed effect of microwave forward power does not seem to be dependent on the energy of the high lying state of the excited analyte (29 eV for the Cl 479.45 nm ionic line, 26.11 eV for the Br 470.48 nm ionic line, and 6.95 eV for the I 206.16 nm atomic line) or the spectral region (UV for iodine and VIS for bromine and chlorine) for the power values investigated.

Table 3
NIR and UV-VIS wavelengths (nm) investigated

Halogen	SCP		MIP
	UV-VIS	NIR	UV-VIS
Cl	479.45	837.59	479.45
Br	470.48	827.24	470.48
I	206.16	973.17	206.16

The commercial SCP-AES instrument used here works at a fixed value of 140 W, hence, it was not possible to evaluate the effect of the radiofrequency power in our experiments.

The observed influence of plasma carrier flow rate on analytical signals (I_N/I_B) of halogens in

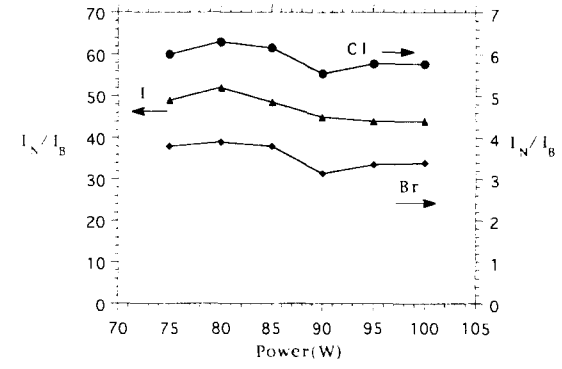

Fig. 3. Effect of the microwave forward power on the determination of chloride by MIP-AES.

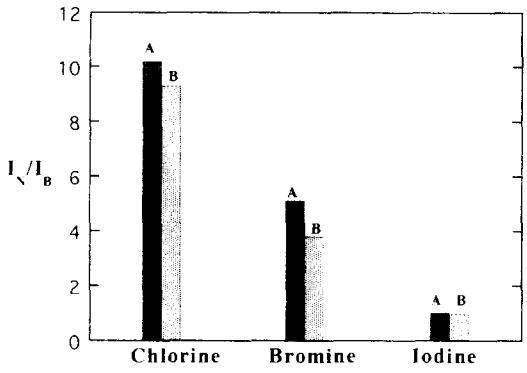

Fig. 4. Influence of sample He flow rates for the two plasmas on the observed analytical signal (net signal over background, I_N/I_B):(a) SCP; (b) MIP.

the SCP and the MIP is plotted in Fig. 4(a) and 4(b) for each of the three halogens. Over the range of flow rates evaluated, no noticeable changes in the background emission were observed. Interestingly, different behavior was noticed in the two plasmas studied; in the SCP (Fig. 4(a)) it can be observed that the optimum plasma gas flow rate is quite dependant upon the type of analyte: for chlorine optimum flow rates were in the region of 20–40 ml min^{-1}, for bromine in the region 40–70 ml min^{-1} and for iodine the optimum was in the range 120–150 ml min^{-1}. These results could be rationalized in terms of volatility: Cl_2 is lighter, and so more volatile than bromine and iodine; being easier to transport by the carrier gas, the use of higher flow rates will just dilute the volatilized analyte and decrease its residence time in the plasma. The heavier iodine needs higher flows of carrier gas for its transport [14] while bromine would show an intermediate transport behavior (see Fig. 4(a)). The optimization results of carrier gas flows using the MIP-AES system (Fig. 4(b)) indicated a much smaller effect of residence time of analytes in this plasma. It seems that the TFT used for MIP generation requires a minimum carrier gas flow for efficient transport (e.g. around 60–70 ml min^{-1}) but it is much less sensitive to the use of higher flow rates (210 ml min^{-1} was the maximum flow rate tested). In any case, the volatility effect is still noticeable as iodine needs higher flows for optimum transport/atomization/excitation than the other halogens. The effect of the tangential gas flow in the torch, at the flow rates under study (70–230 ml min^{-1}) was not critical for chlorine or bromine excitation; however, for iodine a gradual improvement in sensitivity was observed by increasing the tangential flow rate from 70 to 180 ml min^{-1}.

Table 4 collects the finally selected conditions for the plasma operating parameters in the SCP and the MIP for the analysis of the three halides.

3.3. Halogen generation conditions

In order to establish optimum conditions for on-line generation of chlorine, the $KMnO_4$ concentration and flow rates of $KMnO_4/H_2SO_4$ and of the sample were varied and the corresponding plasma emission signals from a 10 μg ml^{-1} solution of chloride were recorded following the general procedure. Selected optimum conditions are collected in Table 1 and in the Section 2.

The continuous on-line bromine generation has been carried out previously in our laboratory using ClO^- as oxidant [17]. However, 0.05 M $KMnO_4$ plus concentrated H_2SO_4 was selected here, thus allowing the possibility of performing a simultaneous determination of both chloride and bromide (for iodine analysis $KMnO_4$ cannot be

Table 4

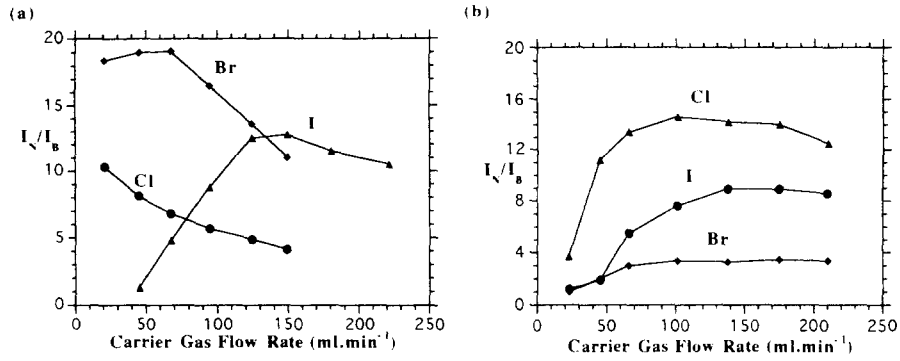

Fig. 5. Comparison of two gas–liquid separator designs using the SCP-AES detection system for the determination of halides. A: GLS depicted in Fig. 2 (experimental conditions as stated in Table 3); B: GLS described in [16] (He flow-rate 70 ml min^{-1} for Cl^- analysis; 70 ml min^{-1} for Br^- analysis; 150 ml min^{-1} for I^- analysis).

used because it transforms iodide into non-volatile IO_3^-).

The influence of the gas–liquid separator (GLS) device was also studied in the SCP-AES detector by comparing the design shown in Fig. 2 and a GLS described previously in the literature [16,23]. As can be seen in Fig. 5 significantly higher analytical signals were obtained for the three halogens using the GLS of Fig. 2 which was then selected for further experiments.

3.4. Comparative analytical performance characteristics

Analytical performance characteristics were evaluated for chloride, bromide and iodide determinations with the MIP (UV-VIS emission lines) and SCP (UV-VIS and NIR emission lines) detectors using the optimum experimental conditions. The linear ranges, the detection limits (calculated as the concentration of analyte producing a net signal equal to three times the standard deviation of the background emission intensity), and the precisions (expressed as relative standard deviation for ten replicators) observed for the three elements in both discharges are summarized in Table 5. While in the UV-VIS region the delectability of halogens is clearly better using the MIP-AES, using the NIR atomic emission lines in the SCP provided the best detection limits observed, demonstrating the usefulness of this spectral region for halogen determinations. The comparatively poor precision obtained for iodine at 206.16 nm in the SCP has already been reported [24].

3.5. Interference studies

The chemical generation and separation of volatile molecular halogen avoids most of the possible interferences which could affect plasma detection. However, matrix interferences may occur in the halogen chemical generation process itself.

The effect of different salts on the generation of chlorine using the MIP-AES detector was studied in this work. The results have been compiled in Table 6 which shows that no effect was observed from ions such as F^-, NO_3^-, PO_4^{3-}, CrO_4^{2-} even at ratios of 500:1 (maximum level tested). However, anions consuming oxidant (such as I^-, SCN^- or $C_2O_4^{2-}$) interfere, but increasing the flow of oxidant or the oxidant concentration used would improve significantly the tolerance ratio to those potential interferences.

A study of interferences in the analysis of iodide by MIP-AES has been carried out elsewhere [25], using a "surfatron" as the MIP cavity. The effect of some common salts that might accompany iodide in real samples was tested and the results showed that this determination was very selective.

No spectral interference was observed at any of the emission lines under study in both plasmas. It has been reported that the atomic line I(I) at 973.17 nm could be overlapped by phosphorus

Table 5
Analytical performance characteristics

emission [24]. However, phosphorus is not a source of spectral interference in our method since no volatile phosphorus species are formed with the proposed system.

3.6. Real sample analyses

The optimized method was tested in real analysis for the determination of chloride in mineral waters using MIP-AES. The real sample measurements for SCP-AES (tap water, groundwaters) were carried out using a flow injection (FIA) mode for halogen generation [26]. The results observed with both detectors are collected in Tables 7 and 8. As can be seen, good agreement was observed with results for the same samples obtained by ion chromatography, which validates the proposed methodologies.

4. Conclusions

This comparative study of two different inexpensive plasmas as excitation sources confirms the feasibility of highly sensitive halide determinations by resorting to continuous halogen generation as the sample introduction approach. For the case of the emission lines evaluated in the UV-VIS region, better detection limits were obtained with the MIP than with the SCP, however, it has also to be noted that different light collection systems were used for both detectors and that could give rise to slight modifications in the detection limits. The NIR region offers particular advantages as shown by SCP results. This calls for further exper-

Table 7
Results of the determination of chloride in mineral waters by MIP-AES

iments using the MIP as excitation source and NIR lines for detection.

It is worth noting that the determination of chloride was the most sensitive of the three halogens assayed with both detectors. Finally, the use of the same oxidant mixture for Cl^- and Br^- analysis provides the possibility for simultaneous determination of both elements with a multichannel detector.

Flow injection spectrophotometric determination of cyanide by the phenolphthalin method

Amin T. Haj-Hussein *

Chemistry Department, Yarmouk University, Irbid, Jordan

Received 11 June 1996; received in revised form 29 July 1996; accepted 30 July 1996

Abstract

The phenolphthalin method for the determination of cyanide has been modified and adapted to a continuous flow system based on the flow injection principle. Aqueous cyanide samples are injected into a carrier stream (0.001 M NaOH), which is then merged with the combined reagent stream of phenolphthalin and carbonate buffer (pH 10.3), and the mixture is passed through an on-line cupric sulfide packed column. The resulting phenolphthalein (the oxidized form of phenolphthalin) is measured in a flow-through spectrophotometer at 552 nm, to determine the cyanide content. The chemical factors and flow injection analysis (FIA) variables influencing the system are discussed. The calibration graph is linear from 0.6 to 4.3 ppm cyanide. At a sampling rate of about 70 samples h^{-1} with 50 μl sample injections, precision was about 1% relative S.D. © 1997 Elsevier Science B.V.

Keywords: Flow injection; Phenolphthalin; Spectrophotometry; Cyanide

1. Introduction

The phanolphthalin method [1–4], is based on the oxidation of phenolphthalin to phenolphthalein by cyanide in the presence of copper. This method was once very widely used in cyanide analysis but has yielded to the generally superior methods based on the Konig reaction [2,5]. Robbie [4] studied the method extensively and found that the color intensity produced is significantly dependent on the amount of alkali, and the color fades if more alkali is added. He reported also that the color formed increases due to the slow spontaneous conversion of excess phenolphthalin reagent as the solution stands. Thus, the conventional phenolphthalin method requires an immediate measurement of the color produced [4], or addition of a stabilizing reagent after color development [6]. Even experienced analysts very often fail to obtain reproducible results manually. The adaptation of such a method to a continuous system seems therefore justified. Flow injection analysis (FIA) [7] is now a well established technique for carrying out automatic wet chemical analysis in a rapid and efficient way. In this paper the adaptation of the phenolphthalin method for the determination of cyanide to the FIA system is described. Since the residence time is short and can be kept constant, the color instability problem was solved and reproducible results were ob-

PII S0039-9140(96)02056-5

tained. Also the intensity of the color produced, which is significantly dependent on the pH of the medium, was controlled by using a carbonate buffer continuously pumped into the FIA system. Furthermore, the copper required in this FIA method was produced in situ using an on-line cupric sulfide packed column. So, the inconvenience of using the phenolphthalin-$CuSO_4$ reagent (prepared fresh daily in the conventional method) was eliminated. The proposed FIA method has the advantages of stability of reagents, reproducibility, sensitivity and rapidity of determination, and is a quantitative technique.

2. Experimental

2.1. Reagents

All chemicals used were of analytical reagent grade, unless otherwise specified; all solutions were prepared with deionized water.

2.1.1. Cupric sulfide

This was prepared by adding a solution of 0.01 M sodium sulfide to a solution of 0.01 M cupric sulfate up to nearly the equivalent point, leaving a slight excess of the latter. The precipitate, CuS, was filtered, washed with water and dried.

2.1.2. Phenolphthalin solutions

These were phenolphthalin in 3 vol.% ethanol prepared by dissolving the calculated amount of phenolphthalin (Sigma, 95%) in 3.0 ml absolute ethanol, and diluting to 100 ml with water. Phenolphthalin solutions of concentrations 0.5×10^{-4}, 1.0×10^{-4}, 2×10^{-4}, 3.0×10^{-4} and 4.0×10^{-4} M, were prepared. All solutions are stable for 2 weeks or more without precipitation occurring, except for the 4.0×10^{-4} M solution which is stable only for a day at room temperature.

2.1.3. Buffer solutions

The carbonate, phosphate and ammonia buffer solutions were prepared as previously described [8]. Carbonate buffer solutions of 0.025, 0.050, 0.10 and 0.30 M $NaHCO_3/NaCO_3$ at pH 10.3 and 0.2 M at pH 9.5, 10.0, 10.3, 10.6, 11.0, and 11.3 were prepared. The phosphate buffer solutions were 0.20 M Na_2HPO_4/Na_3PO_4 at pH 9.5, 10.0, 10.5, 11.0, and 11.3. The ammonia buffer solutions were 0.20 M NH_4Cl/NH_3 at pH 9.5, 10.0, 10.3, 10.6 and 11.0. The pH of these buffers were adjusted to the required value with NaOH or HCl. All pH measurements were made using a Metrohm Herisau (Type E 520) pH meter equipped with a combined Metrohm AG 9100 electrode.

2.1.4. Sodium hydroxide dilution solution, 1.0×10^{-3} M NaOH

This was prepared by dissolving 0.04 g NaOH in 1 l of water.

2.1.5. Standard cyanide solutions

Stock cyanide solution was prepared by dissolving the calculated amount of potassium cyanide (BDH, 96%) in sodium hydroxide dilution solution, and the solution was standardized using the Liebig method [9]. A stock standard solution of 0.03846 M (1000 ppm) was prepared. Working standards in the range 3.8×10^{-6}–3.8×10^{-4} M (0.1–10 ppm) cyanide were prepared by successive dilution of the stock solution with sodium hydroxide dilution solution. Because cyanide solutions are very reactive and unstable, these solutions were stored in closed, dark bottles in a cool place.

2.1.6. Interfering ions/solutions

Solutions of diverse ions were prepared from the sodium or potassium salts of the anions and chlorides of the cations. In each case the appropriate amount of foreign ion and standard cyanide solution was introduced into a 25 ml volumetric flask and made up to 25 ml with sodium hydroxide dilution solution.

2.2. Apparatus

The schematic of the manifold for this study is shown in Fig. 1. The carrier and reagent solutions were delivered by a four-channel RAININ (Rabbit) peristaltic pump operated with Tygon tubing. Sample solutions were injected manually into the carrier stream using a Rheodyne six-bore injector

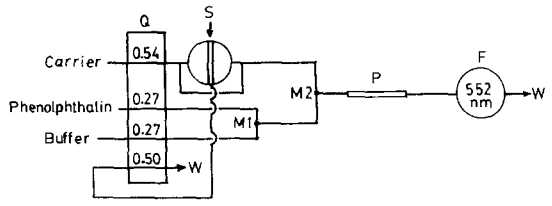

Fig. 1. Manifold for FIA spectrophotometric determination of cyanide. The internal diameter of the microline tubing was 0.51 mm. The abbreviations represent the following: S, point of injection; Q, flow rate (ml min^{-1}); M1 and M2, confluence points; P, packed column; F, flow-through cell; W, waste.

(Type 50). A Varian DMS 100 UV-visible spectrophotometer equipped with a 10 mm Hellma-type flow cell (Model QS 178.012) was used as detector and was connected to a linear 1200 chart recorder. Tubing, made of Microline (0.51 mm i.d.) was used throughout. The confluence points were KEL-F polymer tees. Press-to-fit connections made of silicone rubber tubing were used for the entire manifold.

2.3. Microcolumn construction

The body of the on-line column (Fig. 2) was a 6.0 cm long glass tube (1.4 mm i.d. and 4.0 mm o.d.). An on-line filter (polyethylene porous bed, 4.0 mm in diameter, 2.0 mm thickness) was fixed by 3.0 mm i.d. Tygon tubing at both ends of the column. The column was packed with 80 mg of crushed cupric sulfide particles of appropriate grain size (about 0.8–1.2 mm). A thick-walled silicone rubber tube of 0.51 mm i.d. was inserted at both ends of the Tygon tubing to minimize the dead volume.

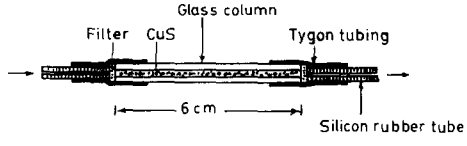

Fig. 2. Design of the microcolumn for the on-line FIA/spectrophotometric system.

2.4. FIA

The flow system illustrated in Fig. 1 was used. The reagent stream contains phenolphthalin and carbonate buffer. Since a mixture of these two components is not stable, because alkali tends to cause the phenolphthalin to convert to the phenolphthalein form [4], they are mixed in the FIA system at point M1. Different volumes in the range 25–100 μl of cyanide sample solutions were continuously pumped through the sample loop, and then injected in the carrier stream (0.001 M NaOH solution). The carrier stream, containing the sample zone, was merged with the premixed reagent stream of phenolphthalin and carbonate buffer at confluence point M2. The combined stream was passed through the CuS packed column (the distance between M2 and the packed column was reduced to about 3 cm to avoid excessive dispersion of the sample solution) in which the phenolphthalin is oxidized to phenolphthalein, and directed to the flow-through cell of the spectrophotometer (the distance between the packed column and the flow cell was reduced as much as possible, to about 25 cm, in order to secure limited dispersion of the color produced). The absorbance of phenolphthalein was monitored at 552 nm. The output of the spectrophotometer was registered on the chart recorder. When the baseline was reached, another slug of sample could be injected.

3. Results and discussion

Determination of cyanide by this FIA/spectrophotometric method is based on the measurement of the absorbance of the red color of the phenolphthalein produced in an alkaline solution. Absorbance measurements were performed using the manifold shown in Fig. 1. The absorption spectrum for phenolphthalein at pH 10.3 (carbonate buffer) obtained by injecting a standard cyanide solution (1.5×10^{-4} M) is shown in Fig. 3. The curve exhibits a band with maximum absorption at 552 nm which was used as the optimum wavelength for studying the chemical factors and the FIA variables influencing the system.

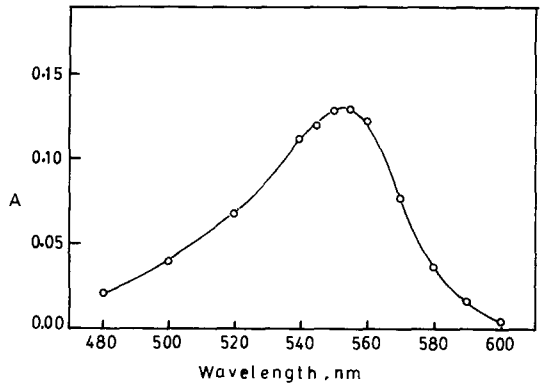

Fig. 3. Absorption spectrum of phenolphthalein at pH 10.3 with the manifold shown in Fig. 1. Carrier, 1.0×10^{-3} M NaOH; phenolphthalin concentration, 3.0×10^{-4} M; carbonate buffer concentration, 0.20 M; cyanide concentration, 1.5×10^{-4} M; injection volume, 50 μl.

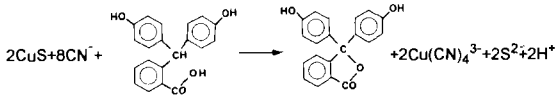
3.1. Optimization of chemical factors

Cyanide solutions readily dissolve CuS forming the colorless tetracyanocuprate(I) ions [10]. Thus, in the presence of cyanide, copper acquires powerful oxidizing characteristics owing to the formation of extremely stable cuprocyanide complexes. Under these conditions phenolphthalin is oxidized to phenolphthalein (red in alkaline medium). Accordingly, the heterogeneous chemical reaction in this FIA system can be represented by the following redox equation:



Considering this redox reaction, several chemical factors had to be optimized to achieve reproducible results. These include pH of the reaction medium, buffer concentration and phenolphthalin concentration.

3.1.1. pH

In this FIA system, two consecutive processes are affected by variation in the pH of the reaction medium. The first process is the oxidation of phenolphthalin to phenolphthalein. The second one is the color change of the phenolphthalein (indicator) formed, which is believed to be due to structural change, including the production of quinonoid and resonance forms [9]. By increasing the pH of the medium, the tendency to form phenolphthalein in the redox process is enhanced and subsequently the intensity of the red color is increased. But if the reaction is carried out in highly alkaline solution, the red color first produced disappears owing to a further structural change [9]. Therefore, the pH of the reaction medium should be carefully controlled to achieve reproducible results. To determine the optimum pH value, three different alkaline buffer solutions were examined. The results are shown in Fig. 4. Ammonia buffer was not suitable because it formed an intense blue color of mixed amine complexes of copper(II), which absorbs at the peak of the absorption band of phenolphthalein. Phosphate buffer was not satisfactory owing to the low absorbance values obtained, which decreases the sensitivity of the method. The most suitable buffer was carbonate, which had the advantage in that it's maximum absorbance value at

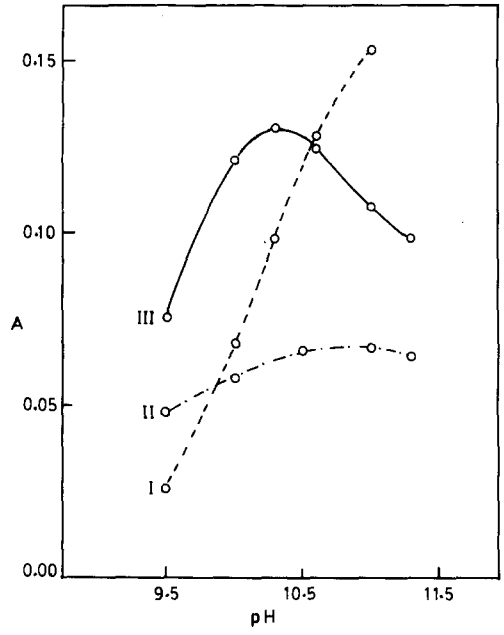


Fig. 4. Effect of buffer pH on the determination of cyanide with the manifold shown in Fig. 1. The buffer solutions used were 0.20 M ammonia buffer (I), 0.20 M phosphate buffer (II), and 0.20 M carbonate buffer (III). Wavelength, 552 nm; other conditions as given in Fig. 3.

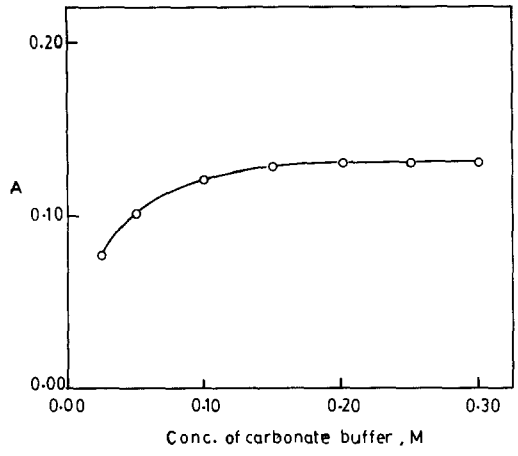

Fig. 5. Effect of carbonate buffer (pH 10.3) concentration. Wavelength, 552 nm; other conditions as given in Fig. 3.

pH 10.3 decreases the opportunity for interferences from some cations in water samples that may form hydroxide precipitates at higher pH values. Furthermore, the solubility of CuS varies with the pH of the medium. In a previous work [11], it was found that the solubility of CuS was negligible at pH > 9.2. Consequently, carbonate buffer of pH 10.3 was selected for use.

3.1.2. Carbonate buffer concentration

The effect of carbonate concentration (pH 10.3) was determined using a standard cyanide solution (1.5×10^{-4} M) and phenolphthalin solution (3.0×10^{-4} M). The absorbance values at 552 nm were measured in the concentration range 0.025–0.30 M carbonate buffer solution. Fig. 5 shows that the absorbance of phenolphthalein formed is dependent on the carbonate buffer solution, and a concentration of 0.20 M is necessary for the development of maximum absorbance.

3.1.3. Phenolphthalin concentration

The effect of phenolphthalin concentration was determined using a concentration of 1.5×10^{-4} M cyanide and 0.20 M carbonate buffer (pH 10.3). The absorbance values at 552 nm were measured in the concentration range 0.5×10^{-4}–4.0×10^{-4} M phenophthalin solutions. Fig. 6 shows that the absorbance of phenolphthalein formed is dependent on the phenolphthalin concentration. The concentration of 3.0×10^{-4} M was chosen because it is much more stable than a 4.0×10^{-4} M solution, and this quantity of phenolphthalin is enough to allow a complete cyanide reaction.

3.2. Optimization of FIA variables

3.2.1. Sample volume injection

The injection volume has a significant effect on peak height, sensitivity, range of linearity and sampling rate [7]. The peak height was found to increase with the injected sample volume (Fig. 7). The range of linearity of cyanide concentrations was found to decrease as the sample volume increased (Fig. 7), and tailing became larger, thus lowering the sampling rate. At a flow rate of 1.08 ml min^{-1}, it was found that the sampling rate decreased from 80 to 40 samples h^{-1} as the injection volume increased from 25 to 100 μl. A 50 μl sample loop was selected.

3.2.2. Flow rate

The signal increased about 9% when the flow rate was changed from 1.08 to 1.6 ml min^{-1}. The higher the flow rate, the higher the peak, but the reproducibility was poor when the flow rate exceeded 1.08 ml min^{-1}. Moreover the flow rate has a significant effect on the residence time and dispersion [7]. Thus, to reduce dispersion, the

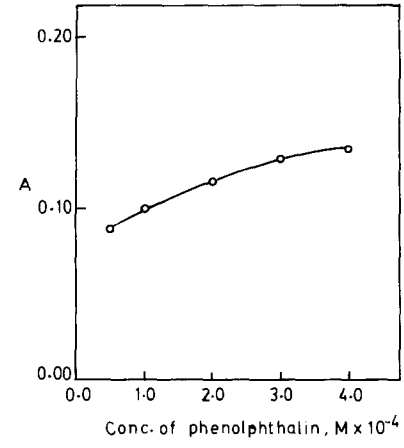

Fig. 6. Effect of phenolphthalin concentration. Wavelength, 552 nm; other conditions as given in Fig. 3.

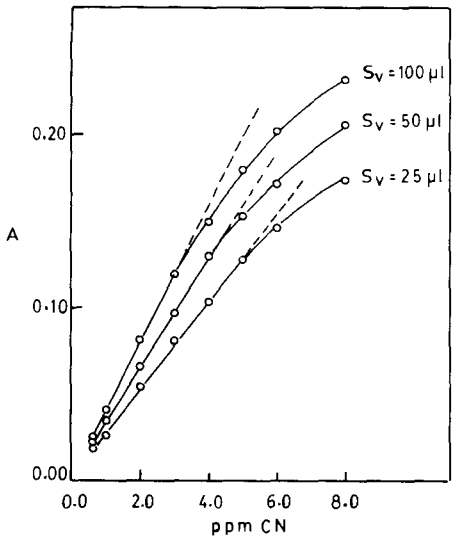

Fig. 7. Effect of injection volume on the determination of cyanide with the manifold shown in Fig. 1. Wavelength, 552 nm; other conditions as given in Fig. 3.

pumping rate should be decreased which results in an increase in the residence time. In this system, a high reproducibility of measurements with a reasonable sampling rate were achieved at a flow rate of 1.08 ml min^{-1}. At this flow rate, the average sampling rate with 50 µl sample injections was around 70 samples h^{-1}.

3.2.3. System characterization

The flow system in Fig. 1 was used for preparing the calibration graph. Standard cyanide solutions were injected from a sample loop of 50 µl. At a flow rate of 1.08 ml min^{-1}, with 50 µl sample injections, the calibration graph (Fig. 7) is linear in the range 0.6–4.3 ppm cyanide. The resulting linear calibration graph has a regression coefficient of 0.999. The detection limit of cyanide, defined as the concentration that gives a signal three times the S.D. of the background signal, was 0.1 ppm. For successive injections of standard cyanide solution (3.9 ppm) the precision of the method was found to $< 1\%$ relative S.D.

3.3. Interference study

In order to apply the proposed FIA determination of free cyanide to natural waters, the effect of foreign substances was examined. In each case, the solution was made to contain 0–200 ppm foreign ion and 4 ppm CN and the recommended procedure followed thereafter. A 2% relative error in the determination of cyanide was considered permissible. The following ions showed no interferences at concentrations of 200 ppm: Ca^{2+}, Mg^{2+}, Cl^-, $HClO_3$-, SO_4^{2-}, NO_2^-, NO_3^-, and F^-. This indicates that the major constituents, in amounts larger than those normally found in natural waters, have no effect on the determination of cyanide by the proposed method.

However, it is known that the phenolphthalin method is sensitive to foreign oxidizing materials. Childs and ball [12] reported that ferricyanides and aqueous solutions of halogens give similar color, because of direct oxidation of phenolphthalin. Moreover, it is reported [13] that oxidizing agents, such as chlorine, decompose most cyanides, also oxidized products of sulfide convert CN^- to SCN^--rapidly, and aldehydes convert cyanide to cyanohydrin. Therefore, in order to apply the proposed FIA method for the determination of total cyanide in waters and waste waters, all known interferences should be eliminated. Oxidizing agents and sulfides can be removed by special procedures, and most other interfering substances removed by distillation [13].

3.4. Application of method

The method was evaluated by recovery studies using cyanide-free natural water samples, obtained from a drilled well (Al-Husn, Jordan) more than 300 m deep. The samples were only filtered to remove possible interference from suspended

Table 1
Recovery results from cyanide determination in spiked water samples

Set Number	Amount of CN (ppm)		Recovery (%)
	Added	Found[a]	
1	2.00	2.03	101.5
2	3.00	2.98	99.3
3	4.00	3.95	98.7

[a] Each value represents the mean of five determinations.

particles. Various amounts of cyanide stock solution were introduced into 25 ml volumetric flasks along with 5 ml water samples. The volume in each flask was made up to 25 ml with sodium hydroxide dilution solution, and the recommended procedure followed thereafter. Five samples and three standards were determined at each cyanide concentration chosen for the study. Average values for the absorbances of standards were used in constructing a calibration curve from which sample absorbances were converted into ppm cyanide found. The results are summarized in Table 1. The recoveries varied from 98.7 to 101.5% (mean 99.8%).

4. Conclusion

A sensitive and reasonably fast FIA/phenolphthalin procedure for the determination of cyanide is developed. The incorporation of a cupric sulfide packed column provides a simple means of producing the copper required in the FIA system. Also, the use of carbonate buffer (pH 10.3) offers the advantage of controlling the intensity of the color produced and decreases the interfering effects of some cations in water samples. The calibration graph is linear in the range 0.6–4.3 ppm of cyanide when using a sample volume of 50 μl. The detection limit is found to be 0.1 ppm cyanide.

Although some FIA spectrophotometric methods [14–16] for the determination of cyanide based on the Konig reaction reported lower limits of detection, the detection limit obtained by the proposed method is considered to be within the sensitivity range of the best colorimetric methods known for cyanide determination [17]. Moreover, the proposed method is quite economical in comparison. However, the most important features of this FIA system are its simplicity, ease of automation, stability of reagents and high precision and sampling frequency.

Received 12 February 1996; received in revised form 26 April 1996; accepted 8 August 1996

Abstract

A sequential injection analysis (SIA) assembly for the atomic absorption determination of Fe(III) in natural waters is proposed. Iron is preconcentrated on a microcolumn packed with a chelating resin (Chelex 100) that is inserted in the manifold. The sample is passed through the column and the iron retained by the resin is subsequently eluted with 2 M HNO_3. The proposed SIA system affords automatic preconcentration, elution, detection of Fe(III), data acquisition and treatment. When 9 ml of iron solution containing 0.4 or 1 mg l^{-1} was passed through the resin, the retention efficiency was 93.1 ± 0.6 and 7.4 ± 3.0% respectively, and when 27 ml of iron solution of 0.2 mg l^{-1} was preconcentrated, the retention was 8.4 ± 2.9%. The detection limits thus achieved is 12 μg l^{-1} when 9 ml of sample are preconcentrated and 6 μg l^{-1} for 27 ml. © 1997 Elsevier Science B.V.

1. Introduction

Sequential injection analysis (SIA) was developed by Růžička and co-workers in 1990 and has been studied by several groups with regards to its theoretical foundation and potential applications [1–6]. Whereas in flow injection analysis (FIA) the samples are injected into a continuous flow, in SIA the sample and reagent zones are first sequentially aspirated and stacked into a channel and then the flow is reversed in order to transport them into the detector. For this purpose, a multiposition selector valve has been used as distributor and either a sinusoidal flow pump [3,6], specially designed for SIA, or a peristaltic pump [5] as liquid drives.

SIA methodology has important advantages over conventional FIA. Thus, the instrumental set-up is much more flexible (a given assembly can be used to implement various determinations with little alteration); the experimental components un-

* Corresponding author. E-mail: vcerda@p01.uib.es

dergo little wear; hydrodynamic variables can be controlled by straightforward means; the manifold does not have to be changed if flow parameters or injection volumes are modified; the analyte/reagent ratio can readily be optimized in order to ensure sensitive responses with substantially decreased reagent consumption; and reaction times can be prolonged with no detriment to the dispersion.

The aim of the present work was to study the feasibility of combining SIA methodology and on-line preconcentration of metals using a column packed with a chelating resin (Bio-Rad Chelex 100) and its subsequent determination by atomic absorption spectrophotometry. For this purpose, we chose the determination of Fe(III) in natural waters.

In preconcentration by sorbent extraction with a flow injection system, a chelating agent is added to the sample solution. The metal chelates thus formed are preconcentrated in an appropriate column and subsequently eluted with an organic solvent. By making the correct selection of a suitable chelating agent and eluent, numerous advantages can be achieved. On-line preconcentration techniques in flow injection, when combined with atomic absorption spectrometry, have provided a sensitive and rapid method for the analysis of trace elements [7–23].

Olsen et al. [7] developed an FIA system including a Chelex 100 column for the determination of Cd, Pb, Cu and Zn in sea water. They employed two different procedures for this purpose. One uses two injection valves that are serially arranged with the resin column. One valve is employed to inject 1 ml of sample, which is later preconcentrated, and the other to inject 180 μl of 2 M HNO_3 to elute the metals. Such a simple assembly does not allow the pH of samples acidified with HNO_3 for preservation to be adjusted. The second procedure involves injecting the sample into a water stream that is subsequently merged with ammonium acetate and passed through a coil and then through the resin column. The ensuing method allows Pb concentrations down to 10 ng ml^{-1} and cadmium and zinc down to 1 ng ml^{-1} to be determined at a rate of 30–60 samples h^{-1}.

Hirata et al. [8] reported a procedure for the determination of seven heavy metals including Fe(III) by use of an automated on-line column preconcentration system for flow injection atomic absorption spectrometry. The resin used, Muromac A-1, is similar to Chelex 100 and contains an iminodiacetic group.

Di and Davey [9] proposed a flow injection on-line preconcentration system, combined with graphite furnace atomic absorption spectrometry, for the determination of gold in ores samples. An α-aminopyridine resin was used. The reported detection limit was 0.065 μg l^{-1} of gold.

Hartenstein et al. [24] used a Chelex 100 column in an FIA manifold for the multielement ICP-AES determination of barium, beryllium, cadmium, cobalt, copper, manganese, nickel and lead. The sensitivity is increased by a factor of 20 relative to conventional aspiration of samples.

2. Experimental

2.1. Reagents

All reagents used were analytical-grade chemicals. A stock standard solution containing 1000 mg l^{-1} Fe(III) was prepared by dissolving the required amount of metallic iron in HNO_3 and diluting to volume with distilled water. Working-strength solutions containing 0.012–20 mg l^{-1} Fe(III) were made from the stock solution by dilution and adding 1:1000 HNO_3 to pH 3–3.5, where retention on the column and solution stability were maximal.

The column eluent, 2 M HNO_3 was of analytical grade and purchased from Merck.

The chelating resin (Chelex 100, 50–100 mesh) was obtained from Sigma.

Finally, 0.2 M acetic–acid acetate buffers of pH 3, 4, 5 and 6 and 0.2 M formic–acid formate buffers of pH 2, 3, 4 and 5 were prepared using NaOH for pH adjustment.

2.2. Apparatus

Fig. 1 depicts the automated assembly used for the proposed SIA determination. It consisted of

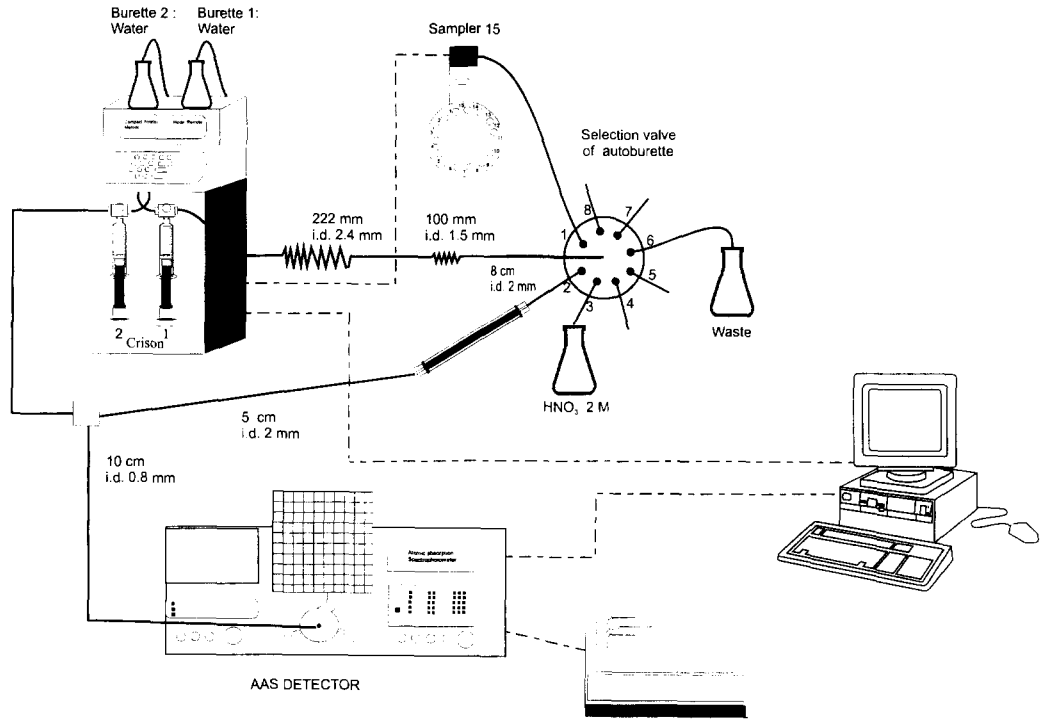

Fig. 1. Instrumental set-up used for the SIA preconcentration and determination of Fe(III).

the following elements: (1) an automated Compact Titrator from Crison (Alella, Barcelona, Spain) that was controlled via a PC and equipped with an autosampler; the titrator includes two 10 ml burettes that can be used simultaneously and an eight-way switching valve; (2) an IBM Personal System 2 computer that was used for instrumental control and data acquisition and processing; (3) a Crison 15 autosampler holding up to 15 samples of 100 ml each; (4) a Perkin-Elmer Model 703 atomic absorption spectrophotometer equipped with a standard air-acetylene burner and an iron hollow-cathode lamp (Table 1); (5) a Perkin-Elmer Plasma 2000 ICP spectrophotometer; and (6) a model 939 atomic absorption spectrometer furnished with a Model 90 graphite furnace and an FS 90 autosampler, all from Unicam.

The software package GFLOW[1], developed by the authors' group, was used to control the instrumentation and acquire and process data. The software allows one to select the desired operating sequence, viz. aspirating or propelling a preset reagent volume by means of either burette, con-

trolling the pumping rate in order to adjust the flow-rate, switching between the channels, using any of the samples on the autosampler, etc. This endows the process with high flexibility in the mixing of reagents or samples and controlling their flow through different components.

2.3. Preparation of the microcolumn

The column consisted of a 55 mm × 2.5 mm i.d. × 10 mm o.d. methacrylate cylinder on the ends of which two small circles of filter-paper were attached.

After one of the microcolumn ends had been stoppered, the resin was loaded with the aid of a syringe, up to 45 mm of the column length. Because Chelex 100 contracts and expands with changes in pH, the resin should be in contracted form (viz. in an acidic medium such as 2 M HNO_3) prior to filling. Also it should be kept in de-ionized water when not in use.

The same column was used in all the experimental work without any significant alteration.

2.4. Procedure

As can be seen in Fig. 1, burette 1 was connected via an in-out valve to a bottle containing distilled water or to the eight-way switching valve by which reagents or samples were aspirated or propelled. The burette was connected to the switching valve via two Teflon coils. The coil lying closer to the burette, with a volume of about 10 ml, prevented samples and reagents from reaching the burette. That lying closer to the switching valve, with a 5 ml volume, was used to intercalate the different reagents or samples for delivery to the manifold.

Burette 2 also was loaded with distilled water that was then propelled to a T-piece where it merged with channel 2 from the switching valve, which was used to elute the sample retained on the Chelex 100 column. The simultaneous use of the two burettes allowed one to be employed to aspirate the different solutions (sample, eluent) and the other to propel water to the nebulizer, thereby achieving a virtually continuous solution supply, as required by an air-acetylene atomic absorption spectrophotometer. This would have been impossible with a single burette.

The flow-rate of the stream fed to the nebulizer was set at 6.5 ml min^{-1}, which was appropriate for a flame atomic absorption application, taking into account that the sample was aspirated into the flame via a conventional pneumatic nebulizer.

Channel 1 of the switching valve was used to aspirate samples and channel 3 to aspirate nitric acid, which was propelled to channel 2 in order to elute the retained Fe. Channel 6 led to waste and channels 4, 5, 7 and 8 were not used.

Before the process was started, the two burettes and channels were loaded with the required reagents. For this purpose, an appropriate volume of each reagent was aspirated and then propelled to waste.

The operating conditions employed are summarized in Table 2. Briefly, a clean-up step (a–c) was used where the sample was aspirated and sent to waste in order to fill the length of tubing between the sampler and channel 1 with sample. In step c, burette 2 was filled with 2 ml of water, which left a free capacity of 10 ml for the operations involved in the subsequent steps. Because burette 1 was simultaneously used to sweep the sample to waste, no solution reached the nebulizer during this step. However, the effect on the flame was minimal since the step duration was considerably decreased by the high pumping rates used. These steps (a–c) were only implemented with each sample changeover.

Then, 9 ml of sample were aspirated through channel 1 (step d) and a volume of 9.8 ml was propelled to channel 2 (i.e. to the preconcentration column, step e). This was followed by a burette equilibration step (f). Nitric acid (2 M) was aspirated through channel 3 (step g) and on to the detector in order to elute the sample retained on the column (step h). Note that burette 2 was always on and that while burette 1 aspirated the solution, burette 2 propelled water to the detector in order to feed the nebulizer with a continuous flow.

At the end of step h, the two burettes were in the same position as at the start of step d. From there, the operating sequence was continued in order to perform new injections of the same sam-

Table 2
Procedure using the preconcentration column

[a] P. Ch. = propulsion towards the stated channel; P.T. = propulsion towards the T-piece; A. Ch. = aspiration from the stated channel; A.E.B. = aspiration from the external bottle.

ple. At each sample changeover, the programme was restarted from step a.

In order to compare the sample concentration efficiency of the Chelex 100 column, the column was removed and experiments were repeated. For this purpose, the method summarized in Table 3 was used. Essentially, it involved cleaning and filling of the sample channel (steps a–c), followed by switching of the valve to position 1 and aspiration of 1 ml of sample (step d), and back to position 2 to propel 3 ml of sample to the detector (step e). Finally, the burette was equilibrated (step f) in order to restart the cycle (injection of the sample) from step d. Each new sample was processed from step a.

It should be noted that, because the solutions containing Fe(III) were only transported to the detector, thus undergoing little dispersion, their injection resulted in very slow baseline restoration unless the propelling flow-rate was markedly increased. This was the solution adopted for the system including no column. Also, because this experiment was carried out for comparison with the method using the pre-column, the manifold was simplified by suppressing the water stream from the second burette.

[a] See Table 2.

2.5. Sample conditioning

When natural waters were sampled, 10 ml of concentrated hydrochloric acid (Merck, Suprapur) per litre of sample solution were immediately added. The samples were filtered if necessary. For the digestion, 25 ml of nitric acid (Merck, Suprapur) were added to 250 ml of sample and boiled until the volume was ca. 50 ml. Finally an appropriate volume of NH_3 (Merck, Suprapur) was added to obtain pH 3–3.5. The final volume was adjusted to 100 ml with distilled water.

3. Results and discussion

3.1. Optimization of experimental variables

3.1.1. Influence of flow-rate

Variable flow-rates of sample through the column were tried in order to investigate their effect on Fe(III) retention. No change was observed below a flow-rate of 6.5 ml min^{-1}. Experi-

ments were carried out by using 9 ml of a 0.2 mg l^{-1} standard solution at 6.5, 3.0, 2.0, 1.8 and 1.4 ml min^{-1}. The highest flow-rate tried 6.5 ml min^{-1}, was adopted for subsequent experiments.

3.1.2. Influence of the inner diameter of the preconcentration column

Experiments were conducted with 9 ml of a 0.2 ppm standard and columns of 1.5, 2, 2.5, 3 and 3.5 mm i.d. The peak absorbances varied very little with the column inner diameter. In any case, the 2.5 mm i.d. column provided better reproducibility (the RSD was 5.8, 6.0, 2.8, 5.3 and 3.2% for the 1.5, 2, 2.5, 3 and 3.5 mm i.d. columns respectively), which it is probably due to poorer resin packing in the columns of smaller inner diameter.

3.1.3. Influence of nitric acid concentration

Most reported applications of Chelex 100 use 2 M HNO_3 as the eluent for metal preconcentration and in all our preliminary experiments were conducted with this eluent. This section deals with the effect of changing the nitric acid concentration of Fe(III) elution and hence on the absorbance signal. For this purpose, we used 1 ml of 0.5, 1.0, 1.5, 2.0, 3.0 and 4.0 M HNO_3 and 9 ml of 0.4 mg l^{-1} Fe(III) standard, each experiment being repeated five times.

The absorbance increased with increasing HNO_3 concentration up to 2 M, above which it remained constant. We therefore adopted a 2 M HNO_3 concentration as it ensured adequate analytical signals and complete elution of Fe(III).

3.1.4. Influence of pH

The amount of metal absorbed by the Chelex 100 resin is a function of pH. As a rule, absorption below pH 2 is very low but increases sharply between pH 2 and 4, and usually peaks at pH 4. The recommended pH for Fe(III) retention varies among samples; thus sea water is adjusted to pH < 8 [24], pH 5–5.5 [25] or even pH 1.6 [26], depending on the accompanying metals in the sample.

We performed tests at various pH values using Fe(III) standards in order to check whether iron retention by the resin changed with pH. The standards were supplied with a known, constant amount of buffer. The pH values were adjusted with either a formic acid–formate buffer of pH 2, 3, 4 or 5, or an acid–acetic acetate buffer of pH 3, 4, 5 or 6. Tests were conducted with 9 ml of a 0.2 mg l^{-1} standard. The results showed that higher signals were obtained at pH 3–3.5 and dropped at pH 6. Therefore, pH 3.5 was chosen for both standards and samples. Finally, the use of a few ml of 1:1000 HNO_3 was found to result in no appreciable alteration of the signal, so this solution was subsequently employed for pH adjustment as it was easier to prepare and ensured greater stability of standards and samples.

3.1.5. Regeneration of the column

Quigley and Vernon [27] recommended periodic recycling of Chelex 100 resin to its NH_4^+ form. Kingston et al. [25] flushed the resin previously in order to convert it into the NH_4^+ form and then with water to remove excess ammonia. Olsen et al. [7] used a similar procedure, except that they employed ammonium acetate as carrier in an FIA system.

We studied the effect of using the column in the NH_4^+ rather that the H^+ ion form on Fe(III) retention. For this purpose, 2 ml of 0.05 M ammonium acetate was passed at the end of the cycle, followed by 2 ml of water, in order to remove completely excess ammonium ions, otherwise iron(III) hydroxide would have precipitated and the absorbance signal would have been diminished as a result. The results obtained showed that the signal was not altered by this regeneration operation; in fact, the signal obtained at a given Fe(III) concentration was the same whether the resin was used in the H^+ or the NH_4^+ form.

3.2. Calibration graph and reproducibility

The linear range and reproducibility for the proposed method were determined under the above described optimal conditions. To this end, Fe(III) solutions with concentrations in the range 0.01–1.2 mg l^{-1} were used in triplicate injections of 9 ml each. The calibration graph was linear between 0.05 and 1.2 mg l^{-1} Fe(III), and conformed to the equation absorbance = 0.319 [Fe(III) (mg l^{-1})] + 0.007, with $r = 0.999$. The

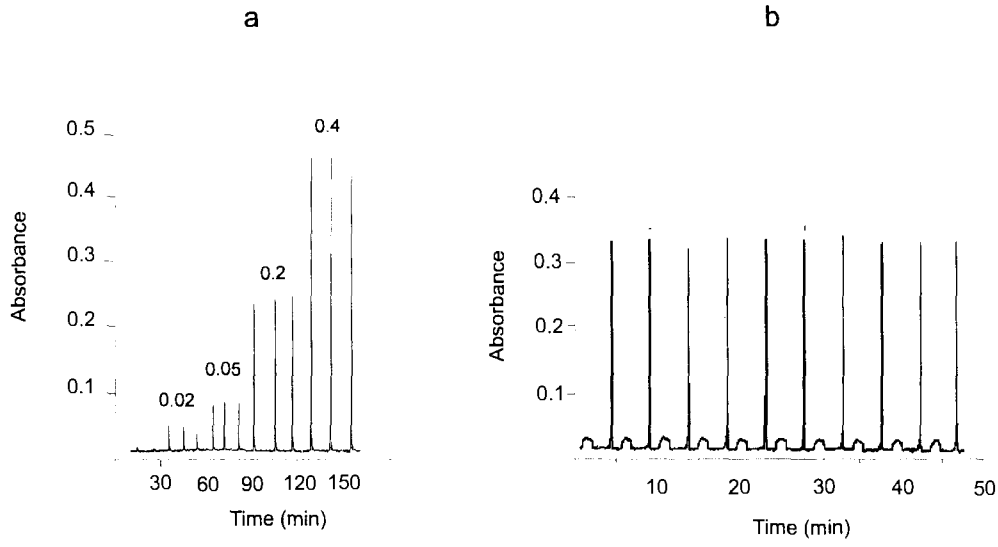

Fig. 2. (a) Calibration performed with 27 ml of standards containing 0.02, 0.05, 0.2 and 0.4 mg l^{-1} Fe(III), following preconcentration on Chelex 100. $[HNO_3] = 2$ M. (b) Study of the reproducibility of the preconcentration column by use of 9 ml of a 1 mg l^{-1} standard. $[HNO_3] = 2$ M.

detection limit, 0.012 mg l^{-1}, was calculated as $3\sigma_b/S$, where σ_b is the standard deviation for 10 measurements of the blank and S is the sensitivity of the method, calculated as the slope of the calibration graph. The RSD obtained for 10 cycles using 9 ml injections of a 1 mg l^{-1} concentration was 4% (Fig. 2(b)). In this figure, the small secondary peaks are due to the unretained Fe(III).

Since increasing the sample volume passed through the column could theoretically improve the detection limit, we used a volume of 27 ml (3×9 ml owing to the volume constraint of the burette, 10 ml). A new calibration graph was constructed using standards of 0.02–0.4 mg l^{-1} (Fig. 2(a)), the linear portion of which conformed to the equation absorbance = 1.153 [Fe(III (mg l^{-1})) + 0.013 with $r = 0.999$. The detection limit was 0.006 mg l^{-1} and the reproducibility 4.8% (RSD).

In order to compare the proposed system with another excluding the Chelex 100 column (i.e. with no preconcentration) a new calibration graph was constructed from 1 ml injections of Fe(III) concentrations of 1, 5, 10, 15 and 20 mg l^{-1}. The calibration curve conformed to the equation absorbance = 0.0112 [Fe(III) (mg l^{-1}) + 0.022, with $r = 0.980$ (Fig. 3(a)). The reproducibility, calculated from 10 cycles replicates using 1 ml of a 10 mg l^{-1} standard, was 2% (RSD) (Fig. 3(b)). The detection limit was calculated as in the previous experiments and was 0.08 mg l^{-1}.

A comparison of the different calibration curves reveals that the methods which concentrate 9 and 27 ml of sample give a slope 28 and 103 times higher than that with no preconcentration, respectively. Such high slopes testify to the efficiency of the concentration procedure.

3.3. Efficiency of the column

The efficiency of the microcolumn was estimated by first calculating the theoretical amount of Fe (in μg) that it should be able to retain based on its dimensions (4.5 × 2.5 mm i.d.) and retention capacity (0.4 mequiv M^{2+} ml^{-1} resin). Therefore, the theoretical amount of Fe that the resin should retain was 21 000 μg, so there should be no saturation problems.

We then calculated the retention efficiency of the column packed with Chelex 100 (5.5 cm × 2.5 mm i.d.) from the following equation:

$$E\ (\%) = \frac{C_s - C_w}{C_s} \times 100$$

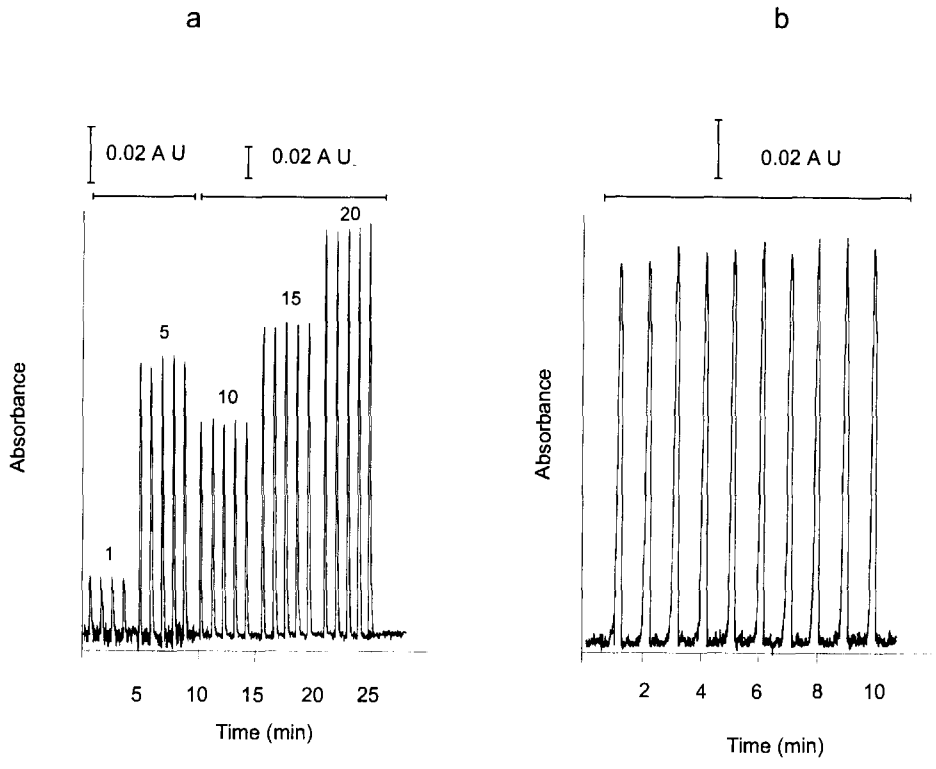

Fig. 3. (a) Calibration performed with 1 ml of standards containing 1, 5, 10, 15 and 20 mg l^{-1} Fe(III), with no preconcentration. (b) Study of the reproducibility by use of 1 ml of a 10 mg l^{-1} Fe(III) standard, with no preconcentration.

where C_s is the analyte concentration in the sample prior to passage through the column and C_w the concentration of unretained analyte. Both were referred to the same volume.

In order to calculate the efficiency, several preconcentration cycles were performed as described above. A 9 ml volume of iron solution containing 0.4 or 1 mg l^{-1} of iron was passed through the resin. The eluted fraction (9.8 ml) was acidified with HNO_3 and made up to 10 ml. Then 2 M HNO_3 was passed through the column to collect a new fraction (5 ml) that was made up to 10 ml with distilled water. The iron concentrations in the two fractions, C_w and C_s, were determined by ICP-AES. As can be seen from the results (Table 4), the retention efficiency was $93.1 \pm 0.6\%$ for the 0.4 mg l^{-1} solution and $7.4 \pm 3.0\%$ for the 1.0 mg l^{-1} solution, i.e. the resin was more effective with low iron concentrations, which was an advantage in view of the intended application.

We calculated the column efficiency for the method in concentrating 27 ml of sample, using the same procedure as above. The results obtained are given in Table 4. The sample was a standard solution containing 0.2 mg l^{-1} of iron; a volume of 27 ml was passed through the column, so an amount of 5.4 μg was loaded, which led to a theoretical concentration of 0.54 mg l^{-1} after elution with 2 M HNO_3 and dilution to a final volume of 10 ml. The retention efficiency thus obtained was $78.4 \pm 2.9\%$.

We also calculated the retention efficiency for Fe(II) ion, concentrating 27 ml of standard solution of 0.2 mg Fe(II) l^{-1}. The column efficiency turned out to be $71.7 \pm 3.7\%$, similar to that for Fe(III).

3.4. Application to real samples

The proposed method was applied to the determination of iron in various water samples using

Table 4
Study of the retention efficiency of the column

Sample	Sample No.	Concentration (mg l^{-1})		Mean	Efficiency (%)
		Theoretical (C_s)	Found (C_s-C_w)

SIA with atomic absorption spectrophotometry after concentration of 27 ml of the sample using the Chelex 100 resin. The sample was treated with nitric acid as described above to convert all types of Fe into soluble Fe(III).

Three public supply waters of different origins and one water from a well were studied. The results thus obtained were compared with those provided by electrothermal atomic absorption spectrometry (ETAAS). Table 5 indicates that the results obtained by SIA were satisfactory.

Table 5
Determination of Fe(III) in real samples

[b] Well water.

4. Conclusions

This paper has demonstrated that SIA is useful for the preconcentration of metal ions by use of Chelex 100 resin. The proposed iron determination features good reproducibility and sensitivity. The ensuring method is suitable for the fully automatic determination of Fe(III) in drinking water.

Among other advantages, the same assembly can be used for other determinations with minimal reagent consumption. Also, the SIA assembly is highly robust; its components undergo very little wear, so they can be used for months without replacement.

Finally, Table 6 summarizes the analytical figures of merit for the three methods tested (without a column, with a column and 9 ml of sample and with a column and 27 ml of sample). As can be seen, the detection limit obtained with the resin and 27 ml of sample was roughly 15 times lower and the slope (sensitivity) was 100 times higher than when no preconcentration was applied. On the other hand, the reproducibility was lower,

Table 6
Analytical parameters of methods with and without preconcentration using a Chelex 100 column

Parameter	Without concentration	Concentration of 9 ml sample	Concentration of 27 ml sample
Detection limit (mg l^{-1})	0.088	0.012	0.006
Reproductibility (RSD) (%)	2.0	4.0	4.8
Sensitivity, slope of calibration graph (AU l mg^{-1})	0.011	0.319	1.153

Solvent extraction separation of iron(III) and aluminium(III) from other elements with Cyanex 302

H.S. Ajgaonkar, P.M. Dhadke *

Inorganic Chemistry Laboratory, Department of Chemical Technology, University of Bombay, Matunga, Bombay 400 019, India

Received 5 February 1996; received in revised form 29 July 1996; accepted 8 August 1996

Abstract

A rapid method was developed for the solvent extraction separation of iron(III) and aluminium(III) from other elements with Cyanex 302 in chloroform as the diluent. Iron(III) was quantitatively extracted at pH 2.0–2.5 with 5×10^{-3} M Cyanex 302 in chloroform whereas the extraction of aluminium(III) was quantitative in the pH range 3.0–4.0 with 10×10^{-3} M Cyanex 302 in chloroform. Iron(III) was stripped from the organic phase with 1.0 M and aluminium(III) with 2.0 M hydrochloric acid. Both metals were separated from multicomponent mixtures. The method was applied to the separation of iron and aluminium from real samples. © 1997 Elsevier Science B.V.

Keywords: Cyanex 302; Aluminium(III); Iron(III); Solvent extraction

1. Introduction

Organophosphorus acids and their esters and oxides have been widely used for the purification and separation of various metals such as Cu(II), Co(II), Ni(II), Zn(II), Cd(II) and lanthanides [1,2]. The quantitative extraction of iron(III) from 0.5 M nitric acid was possible with 0.1 M mono(2-ethylhexyl)phosphoric acid in hexane [3]. The extraction of iron(III) with di-*n*-butylthiophosphoric acid was incomplete from 0.2 M hydrochloric or sulphuric acid solutions [4]. However, the extraction of aluminium(III) with di-*n*-butyldithiophosphoric acid and di(2-ethylhexyl)dithiophosphoric acid has been reported [5]. Numerous studies have been carried out on the extraction of iron(III) from hydrochloric and sulphuric acid media with di(2-ethylhexyl)phosphoric acid (HDEHP) with kerosene as a diluent [6,7]. Extraction of aluminium from a weakly acidic medium with concentrated solution of HDEHP in kerosene was carried out [8]. The extraction of aluminium(III) was possible from sulphuric acid solution using HDEHP [9]. The mechanism of extraction of Ti(IV) and Al(III) by HDEHP in kerosene was also investigated [10]. The same group also studies the extraction of Al(III) from formic acid solution with the same reagent [11]. The extraction of Fe(III) from KSCN with tri-*n*-butylphosphate (TBP) and Al(III) from HCl with TBP (100%) has been reported [12,13]. The extraction of iron(III) and aluminium(III) involving tri-*n*-butylphosphine

PII S0039-9140(96)02063-2

sulphide was not quantitative from HCl solutions [14].

Organothiophosphinic acids were recently introduced as extractants [15]. The most important among them is bis(2,4,4-trimethylpentyl)monothiophosphinic acid (Cyanex 302). It was first used for the extraction of zinc from sulphate solution containing calcium [16]. Several applications of this reagent to the extraction of various metals such as Cu(II), Cd(II), Ag(I), Ni(II), Zr(IV), Th(IV), Sc(III) and Pd(II) have been reported [17–20]. However, systematic investigations on the solvent extraction of iron(III) and aluminium(III) with Cyanex 302 are lacking. This paper presents an account of such investigations.

2. Experimental

2.1. Apparatus and reagents

A Systronics MK VI combined electrode digital pH meter and a GBC model 911 A UV–visible spectrophotometer with 10 mm Corex quartz cuvettes were used.

Cyanex 302 (Cytec Industries, USA) was used as received. A stock solution of iron(III) was prepared by dissolving 8.634 g of $(NH_4)Fe(SO_4)_2 \cdot 12H_2O$ in 1 l of distilled water containing 5.0 ml of sulphuric acid and a stock solution of aluminium(III) by dissolving 2.920 g of $Al_2(SO_4)_3 \cdot 16H_2O$ in 250 ml of distilled water containing a few drops of sulphuric acid. The solutions were standardized volumetrically (Fe(III)) and gravimetrically (Al(III)) [21] and contained 1496.6 μg ml^{-1} of Fe(III) and 1000 μg ml^{-1} of Al(III). Working standard solutions containing 40 μg ml^{-1} of Fe(III) and 10 μg ml^{-1} of Al(III) were prepared by appropriate dilution of the stock solutions.

2.2. Procedure

Aliquots of solutions containing iron(III) and aluminium(III) were taken and the pH was adjusted to 2.0 for iron(III) and 4.0 for aluminium(III) with dilute sulphuric acid and ammonia solution. The total volume was made up to 10 ml. The solutions were then transferred into separating funnel, 10 ml of Cyanex 302 solution in chloroform of appropriate concentrations were added and the solutions were shaken for about 8 min. The two phases were allowed to settle and separate. The metals were stripped from the organic phase with 1.0 M hydrochloric acid (iron(III)) and 2.0 M hydrochloric acid (aluminium(III)). The metals in the aqueous phase were determined spectrophotometrically at 480 nm as the complex with potassium thiocyanate for iron(III) [21] and at 520 nm with aluminon for aluminium(III) [22]. The concentrations of metals were calculated from the calibration graphs.

3. Results and discussion

3.1. Effect of pH

The effect of pH on the percentage extraction of iron(III) and aluminium(III) by Cyanex 302 in chloroform was studied in the range 0–5.0. As shown in Fig. 1, the extraction of iron(III) was quantitative in the pH range 2.0–2.5 and that of aluminium(III) in the pH range 3.0–4.0. Since most of the time pH was adjusted with acetate

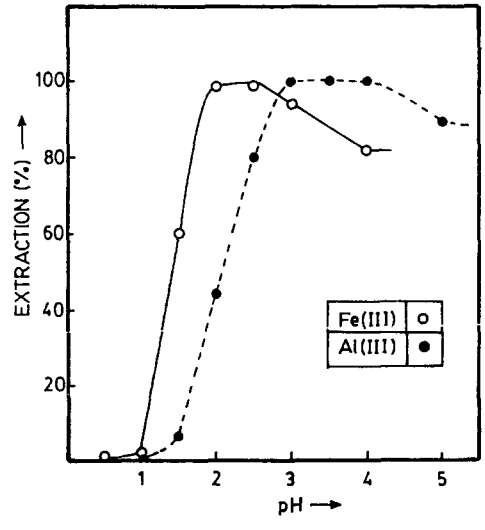

Fig. 1. Effect of pH on the extraction of iron(III) and aluminium(III). Fe(III), 50 μg; Al(III), 15 μg.

Table 1
Effect of Cyanex 302 concentration

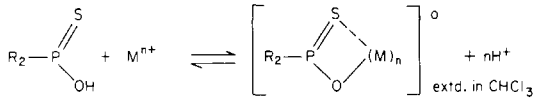
30.0	399	99.7	–	–
50.0	399	99.7	999	99.9
100.0	—	—	999	99.9

buffer, neither metal was hydrolysed. No perceptible precipitation of aluminium(III) or iron(III) was observed at pH > 2.5 and pH > 4.0, respectively. This was because ammonium acetate–acetic acid buffer was used, which prevents the hydrolysis of both ions. Hence all subsequent extractions of iron(III) were carried out at pH 2.0 and those of aluminium(III) at pH 4.0. The mechanism of extraction is as follows:



where M = Fe or Al, $n = 3$ and R = 2,4,4-trimethylpentyl.

3.2. Effect of Cyanex 302 concentration

Iron(III) and aluminium(III) were extracted with various concentration of Cyanex 302 ((0.1–100) × 10^{-3} M) (Table 1). The extraction of iron(III) was quantitative with 5×10^{-3} M Cyanex 302 and that of aluminium(III) with 10×10^{-3} M Cyanex 302. A decrease in the concentration of Cyanex 302 gave lower *D* values for both iron(III) and aluminium(III).

3.3. Effect of diluents

Various polar and non-polar solvents were tested as diluents for the extraction of iron(III) and aluminium(III) with 5×10^{-3} and 10×10^{-3} M Cyanex 302, respectively. The extraction of iron(III) was quantitative with chloroform, toluene, xylene, carbon tetrachloride and hexane as diluents but benzene and cyclohexane proved to be poor diluents. The extraction of aluminium(III) was quantitative with chloroform, carbon tetrachloride, hexane, cyclohexane and benzene but xylene and toluene proved to be poor diluents. Owing to clear phase separations, chloroform was preferred as the diluent for both metal ions (Table 2).

Table 2
Effect of various diluents

Diluent	Dielectric constant	Iron(III)		Aluminium(III)	
		D	Extraction (%)	*D*	Extraction (%)
Chloroform	4.80	399	99.7	999	99.9
Carbon tetrachloride	2.00	399	99.7	999	99.9
Hexane	1.90	39	97.5	999	99.9
Cyclohexane	2.02	9.0	90.0	999	99.9
Benzene	2.20	19.0	95.0	999	99.9
Xylene	2.28	65.6	98.5	9.16	90.1
Toluene	2.23	399	99.7	8.46	89.4

3.4. Effect of stripping agents

The organic phases were extracted with various mineral acids of different concentrations to strip both metals into the aqueous phase (Table 3). All mineral acids were effective for the quantitative stripping of iron(III) and aluminium(III). For practical purposes we preferred 1.0 M hydrochloric acid for iron(III) and 2.0 M hydrochloric acid for aluminium(III) because they facilitate the direct spectrophotometric determination of both metal ions.

3.5. Effect of metal ion concentration

Iron(III) and aluminium(III) were extracted with concentrations ranging from 5–60 μg ml^{-1} for Fe(III) and from 0.5–3.5 μg ml^{-1} for Al(III). The system adhered to beer's law in the ranges 5–50 μg ml^{-1} for Fe(III) and 0.5–3.0 μg ml^{-1} for Al(III). Higher concentrations of the metals can be extracted with high concentrations of the reagent.

3.6. Effect of period of equilibration

The solutions were shaken for periods ranging from 2–20 min. the extraction of iron(III) was quantitative with an 8 min period of equilibration and that of aluminium(III) with 6 min. Therefore, equilibrium periods of 8 min for iron(III) and 6 min for aluminium(III) were adopted.

3.7. Nature of the extracted species

The composition of the extracted species was ascertained for both metals by plotting log *D* against log Cyanex 302 concentration at a fixed pH. For iron(III) the slope was 3.0 (Fig. 2) and for aluminium(III) the slope was 1.1 (Fig. 3). This shows that the probable compositions of the extracted species are [Fe(Cyanex 302)$_3$ SO_4] and [Al(Cyanex 302)HSO_4^-].

3.8. Separation of iron(III) and aluminium(III) from diverse ions

The effect diverse ions on extraction of iron(III) and aluminium(III) was studied. The tolerance limit was set as an error of ±2% in absorbance measurements. In the extraction of iron(III) the alkali and alkaline earth metals showed no interference up to 50 μg ml^{-1}. Metals such as Ni(II), Cr(III), Tl(III), Pb(II), Cd(II), As(III) and Zn(II) did not interfere in the range 5–100 μg ml^{-1}, but ions such as V(V), Ru(III), Os(VIII), Al(III), Mo(VI) and Hg(I) interfered to a large extent. Noble metals such as Pt(IV) and Au(III) showed no interference up to 25 μg ml^{-1}. The interference of Cu(II) was removed by extracting Cu(II) with 8×10^{-2} M Cyanex 302 at pH 1.0 prior to the extraction of iron(III). Iron(III) was also separated from Co(II) and Mn(II) by first extracting iron(III) followed by the extraction of both metals.

During the extraction of aluminium(III), alkali and alkaline earth metals were tolerated up to 75

Table 3

μg ml^{-1}. Transition metals such as Co(II) and Ni(II) did not interfere up to 37.5 μg ml^{-1} and Mn(II) and Cr(III) showed no interference up to 35 μg ml^{-1}. Metals such as Zn(II), V(V), Ru(III), Os(VIII), Fe(III), Be(II), Pd(II) and Mo(VI) showed strong interference even at low concentrations. The interference of Cu(II) was removed by extracting Cu(II) prior to the extraction of aluminium(III). In both cases the cations used were invariably in the form of chloride or nitrate, which are water soluble.

Anions such as chloride, bromide, iodide, sulphate, sulphite, nitrate, nitrite, thiocyanate, phosphate and thiourea were tolerated up to 20 and 30 μg ml^{-1} for iron(III) and aluminium(III), respectively. At such low concentrations iron(III) and aluminium(III) were not precipitated as iodide or phosphate, respectively. Oxalate and EDTA interfere strongly in both metal extractions. In the case of anions generally the sodium salts were used whereas in the case of oxy anions such as molybdate the corresponding ammonium salts were used.

	Ni(II)	10	2.0	Unextracted	–	99.9

[a] Extraction was carried out in the presence of ammonium sulphate as a salting-out agent.

3.9. Separation of iron(III) and aluminium(III) from multicomponent mixtures

Various metals showed different extents of extraction at different pH values and concentrations of Cyanex 302. Such differences were fully exploited to devise a different separation by resorting to a technique selective for extraction at different pH values with varying concentration of Cyanex 302. Copper and chromium were separated from iron(III) and aluminium(III) by first extracting these elements, followed by the extraction of iron(III) and aluminium(III), whereas cobalt(II) and manganese(II) were separated by first extracting iron(III) and aluminium(III) followed by the extraction of other elements. Magnesium and nickel were not extracted under these conditions. The details of separation are presented in Tables 4 and 5.

3.10. Application to analysis of real samples

The utility of the proposed approach was tested by analysing ores, alloys (ilmenite, monel metal, steel) and pharmaceutical samples such as Impheron injection and Fecontin F tablets for iron(III) and Digene and Siloxogene tablets for aluminium(III) (Table 6). A known weight of sample of ore or alloy was treated with acids and evaporated to dryness. The samples were again disintegrated with perchloric acid and evaporated to dryness, then the residue was dissolved in water and diluted to a known volume. The reaction with acids was invariably carried out in hood to prevent spillage and explosion. Heating was carried out slowly on a sand-bath with appropriate precautions.

Iron(III) was extracted from the diluted sample solution using the proposed method. In the case of monel metal, Cu(II) was removed by first extracting the sample with Cyanex 302 followed by extraction of iron(III), whereas with EN 36A (steel) and ilmenite ore iron(III) was extracted using the proposed method. Metals such as titanium, nickel and manganese were not extracted under these conditions.

Aluminium(III) was extracted from the pharmaceutical samples such as Digene and Siloxogene tablets using the proposed method. The experimental results 99.2 mg for Digene tablets and 99.4 mg for Siloxogene tablets showed good agreement with the certified values of 100 mg for both samples.

Table 5
Separation of aluminium(III) from multicomponent mixtures

Sample no.	Mixture	Amount taken (μg ml^{-1})	pH	Cyanex 302 extractant concentration (M)	Diluent	Recovery (%)
1	Cu(II)	5	1.0	0.08	Xylene	99.1
	Al(III)	1.5	4.0	0.01	Chloroform	99.8
	Co(II)[a]	2.5	7.5	0.0075	Toluene	98.9
2	Cu(II)	5	1.0	0.08	Xylene	98.7

	Co(II)[a]	2	7.5	0.0075	Toluene	98.9
5	Al(III)	2.5	4.0	0.01	Chloroform	99.7
	Co(II)	2.5	7.5	0.0075	Toluene	99.1
	Mg(II)	2.5	7.5	Unextracted	–	99.9

[a] Extraction was carried out in the presence of ammonium sulphate as a salting-out agent.

4. Conclusion

The proposed separation methods are simple, rapid and selective and compare favourably with existing methods. The extraction of Fe(III) and Al(III) was possible with very low concentrations of the reagent compared with other methods. Large amounts of diverse ions were tolerated and the various elements were separated at microgram concentrations. The overall time required for extraction and determination is less than 20 min and the concentration of stripping agent required is very low.

Abstract

Amberlite XAD-7 resin coated with dimethylglyoxal bis(4-phenyl-3-thiosemicarbazone) (DMBS) was prepared and applied to the preconcentration of platinum(II) and palladium(II) from aqueous solution. Platinum(II) and palladium(II) were collected quantitatively on resin coated with the reagent (DMBS-XAD-7) from acidic solution in the presence of iodide ion by a bach method. The metal ions were then easily eluted from DMBS-XAD-7 as their DMBS chelates with a small volume of *N,N*-dimethylformamide. This collection and elution method was applied to the simultaneous determination of platinum(II) and palladium(II) by reversed-phase high-performance liquid chromatography with spectrophotometric detection using an ODS column and acetone–water as the mobile phase. The proposed method was applied to the determination of the metals in commercially available samples. © 1997 Elsevier Science B.V.

1. Introduction

High-performance liquid chromatographic (HPLC) methods for the separation and determination of metal ions as their chelate compounds have been widely developed in recent years [1–12]. Dithiosemicarbazone compounds have also been applied to the separation of metal chelates by HPLC because of the formation of kinetically inert metal chelates [13–15]. The dithiosemicarbazones, however, have the disadvantage of low solubility in common solvents except *N,N*-

PII S0039-9140(96)02064-4

dimethylformamide and dimethyl sulfoxide. Therefore, it is difficult to use these compounds in preconcentration methods such as solvent extraction.

In trace metals, preconcentration or separation of the analytes from a matrix is frequently a necessity. The use of supports loaded with chelating reagents is particularly convenient because it is easy to prepare such resins. Therefore, preconcentration and separation methods for trace metal ions have been developed by using various supports coated with a large number of cheating reagents [16–23]. We have also prepared Amberlite XAD resins loaded with dithiosemicarbazone compounds and applied them to the collection of metal ions from aqueous solution [24]. In this process, the metal ions collected on the resin were readily eluted as their dithiosemicarbazone chelates with a small volume of *N,N*-dimethylformamide. Based on the results, the determination of trace mercury by reversed-phase HPLC with spectrophotometric detection after collection on and elution from Amberlite XAD-7 coated with dimethylglyozal bis(4-phenyl-3-thiosemicarbazone) (DMBS) has been developed [25].

In this work, we found that the collection of platinum(II) on Amberlite XAD-7 coated with DMBS (DMBS–XAD-7) was accelerated dramatically in the presence of iodide ion. Based on this result, we tried to develop a method for the simultaneous determination of platinum(II) and palladium(II) by reversed phase HPLC with spectrophotometric detection after collection on and elution from DMBS-XAD-7.

2. Experimental

2.1. Reagents and apparatus

Dimethylglyoxal bis(4-phenyl-3-thiosemicarbazone) (DMBS) was synthesized as reported in the literature [26] and the reagent solution was prepared by dissolving it in *N,N*-dimethylformamide (DMF).

Amberlite XAD-7 resin (acrylic ester type, bead size 250–850 μm), purchased from Rohm and Haas, was washed successively with 5 mol dm^{-3} hydrochloric acid, distilled water and methanol and then dried at 40°C for 24 h in a vacuum drying oven.

Standard palladium(II) and platinum(II) solutions (1 mg cm^{-3}) were prepared by dissolving 0.1667 g of palladium(II) chloride (Wako Pure Chemicals, Osaka, Japan) and 0.2128 g of potassium tetrachloroplatinate(II) (Wako Pure Chemicals) in 10 cm^3 of 5 mol dm^{-3} nitric acid diluting to volume in a 100 cm^3 volumetric flask. The palladium(II) solution was standardized by titration with EDTA and the platinum(II) solution by spectrophotometry with tin(II) chloride, and were further diluted as required. Other chemicals used were of analytical or HPLC grade.

All absorbance measurements were made with a Hitachi U-2000 spectrophotometer. A Hitachi–Horiba Model $F\text{-}7_{AD}$ pH meter was used for all pH measurements. HPLC was performed at room temperature with a Hitachi Model L-6200 system, L-4200 UV–visible detector and D-2500 chromato-integrator. The column used was an ERC-ODS 1282 (250 × 6 mm i.d.) (ERC, Japan).

2.2. Preparation of the resin loaded with DMBS

Amberlite XAD-7 resin (25 g) was mixed with 50 cm^3 of 0.01 mol dm^{-3} DMBS in solution DMF and the mixture was stirred at room temperature for 2 h. The resin loaded with DMBS was filtered off, washed with water and dried at room temperature for 48 h at 50°C in a vacuum drying oven.

2.3. Standard procedure

To a solution containing up to 1 μg of palladium(II) and 2 μg of platinum(II) in a 50 cm^3 screw-capped glass bottle, 0.2 cm^3 of 1 mol dm^{-3} potassium iodide solution and 0.2 cm^3 of 1 mol dm^{-3} nitric acid solution were added to make a 0.01 mol dm^{-3} (pH 2), then the volume was made up to 20 cm^3 with water. An amount of DMBS-XAD-7 was added and the mixture was shaken for 30 min. The solution was filtered through a polyethylene column (65 × 9 mm i.d.) fitted with a porous polyethylene disk of 20 μm pore size, and then platinum and palladium were eluted from the

resin as their DMBS chelates with 1 cm^3 of DMF. A 10 mm^3 volume of the solution was injected into the HPLC system.

2.4. Analysis of real samples

To 0.01 g of each sample in a Teflon beaker a mixture of 2.5 cm^3 of hydrochloric acid and 2.5 cm^3 of nitric acid was added and the beaker was heated at 150°C on a hot-plate until the solution evaporated to dryness. This procedure was repeated several times until decomposition occurred. After cooling, the residue was dissolved in 50 cm^3 of 0.5 mol dm^{-3} nitric acid. The platinum and palladium in each sample was determined by the proposed method.

3. Results and discussion

3.1. Complexation and spectrophotometric properties

Chelate formation of platinum(II) and palladium(II) with DMBS was examined in 80:20 (v/v) DMF-water because of the low solubilities of DMBS and its metal chelates in aqueous solution. Platinum(II) and palladium(II) formed 1:1 chelates with DMBS. The absorbtion spectra of Pt(II) and Pd(II)-DMS chelates are shown in Fig. 1. The absorption maxima and molar absorption coefficients (ε, dm^{-3} mol^{-1} cm^{-1}) of their metal chelates were 442 nm for planinum ($\varepsilon = 25\,000$) and 430 nm for palladium ($\varepsilon = 24\,000$). Palladium(II) reacted quantitatively with DMBS at room temperature, but it was necessary to heat for quantitative chelate formation of platinum(II) with DMBS for 20 min at 80°C.

3.2. Collection and elution behavior of platinum(II) and palladium(II) on the reagent-loaded resin

The total amount of DMBS loaded on the reagent-loaded resin was 22.9 μmol g^{-1} and the capacity of copper(II) for the DMBS-loaded resin was 21.0 μmol g^{-1} [24]. These results indicated that DMBS formed a 1:1 chelate with copper(II)

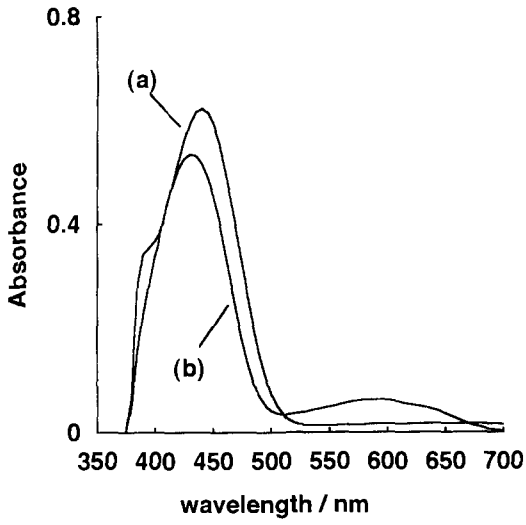

Fig. 1. Absorption spectra of (a) Pt– and (b) Pd–DMBS chelates in 80:20 (v/v)DMF-water. $[Pt^{2+}] = 2.4 \times 10^{-5}$ mol dm^{-3}; $[DMBS] = 2.0 \times 10^{-4}$ mol dm^{-3}; reference, reagent blank.

[26]. Platinum(II) was not collected quantitatively on the reagent-loaded resin within a shaking time of 60 min (Fig. 2, no other ligands) owing to the slow chelate formation with DMBS as described in the previous section. In order to accelerate the

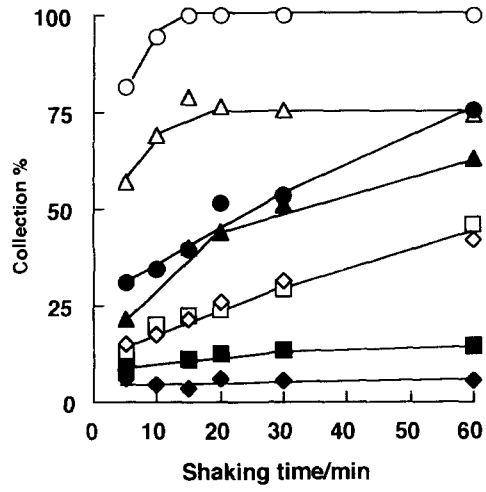

Fig. 2. Effect of shaking time on the collection of planinum(II) in the presence of some ligands. (○) I^-; (△) SCN^-; (▲) Br^-; (□) Cl^-; (■) NO_2^-; (◇) hydroxylammonium chloride; (◆) thiourea; (●) no other ligands.

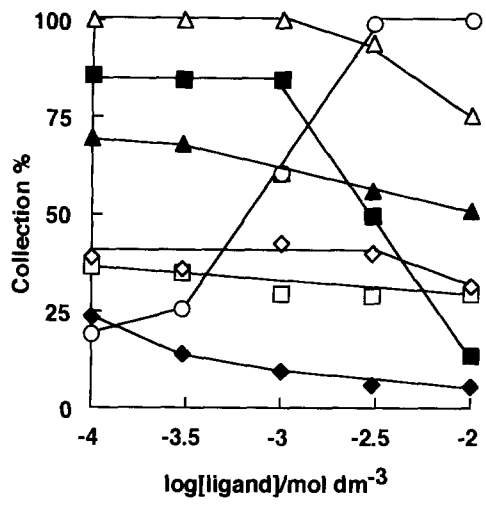

Fig. 3. Effect of ligand concentration on the collected of platinum(II) [Pt] = 2 μg/20 cm^{-3}; [HNO_3] = 0.01 mol dm^{-3}; DMBS–XAD-7 = 0.1 g; shaking time = 30 min. (○) I^-; (△) SCN^-; (▲) Br^-; (□) Cl^-; (■) NO_2^-; (◇) hydroxylammonium chloride; (◆) thiourea.

reaction between the DMBS on the resin and platinum(II) in solution, the effects of the shaking time and of the ligand concentrations on the collection were examined in the presence of various ligands. As shown in Fig. 2, iodide ion accelerates the collection of platinum(II) on the resin decreased with increasing ligand concentration for all ligand systems except iodide ion, as shown in Fig. 3. Quantitative collection takes place at higher concentrations in the presence of iodide ion, at lower concentrations in the presence of thiocyanate ion. In the case of chloride and bromide ions, the predominant species in solution can be estimated to be $Pt(II)L_n^{m-}$ ($L = Cl^-$ or Br^-, $n = 3$ or 4 and $m = -1$ or -2) at 1×10^{-2} mol dm^{-3} of the ligands from their known stability constants [27]. It may be suggested that higher order complexes of platinum(II) form with increasing ligand concentration and the percentage collection on the resin is low for the ligand systems except iodide ion, although the stability constants of platinum(II) with thiocyanate, nitrite, hydroxlammonium chloride and thiourea are unknown. The accelerated process with iodide ion cannot be explained in detail. A further study using other ligands is required to clarify the accelerated process.

The collection of palladium(II) on the resin was not particularly by iodine ion affected in the concentration range above 5×10^{-3} mol dm^{-3}. The concentration of iodide ion for the collection of both metal ions was adjusted to 0.01 mol dm^{-3}. The optimum pH conditions were determined in the presence of iodide ion. Platinum(II) and palladium(II) were found to be optimally collected from aqueous solution in the pH range 0–4 (Fig. 4). Quantitative collection of the metal ions was could not be achieved owing to hydrolysis at higher pH values. In this study, the optimum pH of the solution for collection was adjusted to 2 by adding 5 mol dm^{-3} nitric acid to make a 0.01 × mol dm^{-3} solution. A 100-fold concentration of platinum and palladium simultaneously could be achieved under these conditions.

3.3. Chromatographic conditions

We have investigated on the separation behavior of some platinum(II) and palladium(II) dithiosemicarbazone chelates by reversed-phase HPLC with an ODS column [15]. The elution peaks of the metal dithiosemicarbazone chelates on the chromatogram were not successfully separated by using methanol–water or acetonitrile–water mobile phases. The resolved separation of

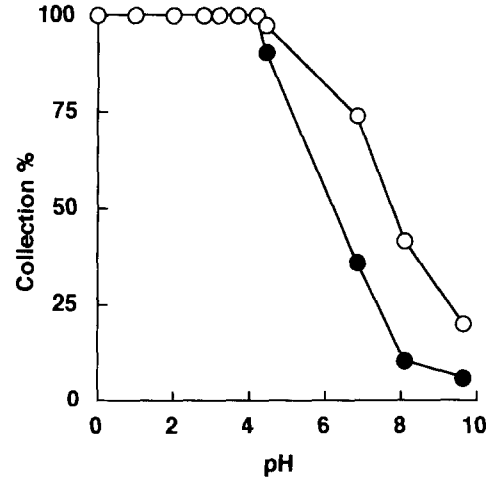

Fig. 4. Effect of pH on the collection. (○) [Pt] = 2 μg/20 cm^{-3}; (●) [Pd] = 1 μg/20 cm^3; [KI] = 0.01 mol dm^{-3}; DMBS–XAD-7 = 0.1 g; shaking time = 30 min.

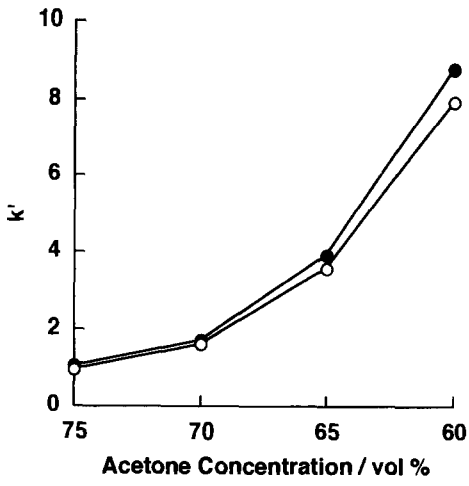

Fig. 5. Relationship between capacity factor (k') of (○) Pt- and (●) Pd–DMBS, and acetone concentration in the mobile phase. Each mobile phase contained 1×10^{-3} mol dm^{-3} CH_3COONa and 1×10^{-4} mol dm^{-3} EDTA.

platinum(II) and palladium(II) chelates was achieved by using acetone–water as the mobile phase. The effect of the acetone content in the mobile phase on the retention behavior of platinum(II) and palladium(II)–DMBS chelates was studied, and the results are shown in Fig. 5. The retention increased as the aqueous component in the mobile phase increased. The optimum composition of the mobile phase was 65:35 (v/v) acetone–water, and sodium acetate was added at 1×10^{-3} mol dm^{-3} because this addition led to reproducibility of the elution peaks and stability of the baseline on the chromatogram. To avoid contamination with metal ions through contact between the eluent and metal parts of the HPLC apparatus, EDTA was also added at 1×10^{-4} mol dm^{-3}. A typical chromatogram is shown in Fig. 6. Their elution peaks were identified with 80:20 (v/v) DMF–water containing DMBS or the DMBS chelates. The most suitable detection wavelength was 425 nm.

3.4. Calibration

Calibration graphs were constructed by the standard procedure. The calibration graphs were linear over the range 0–2 μg for platinum and 0–1 μg for palladium. $C_{Pt}(\mu g) = [H(\mu V) + 27.04]/966.60$ and $C_{Pd}(\mu g) = [H(\mu V) - 18.80]/1640.80$, where H is the peak height at 425 nm on the chromato-integrator. The detection limits as signal-to-noise ratio of 3:1 were 65 ng for platinum and 10 ng for palladium.

3.5. Effect of diverse ions

The effect of Cu and Hg, which were also collected on the resin in acidic medium, and some precious metal ions was on the determination of both metal ions was examined. The tolerance limit was taken as being the amount causing an error of ±3% in the peak heights for platinum and palladium alone on the chromatogram. For the determination of 1 μg of platinum and 0.5 μg of palladium, Cu and Hg were tolerated at levels up to 20 μg and Au, Ag, Rh, Ru and Ir up to 40 μg. The recovery of platinum decreased more with the above amounts of Cu, Hg and Ag owing to competitive reactions with DMBS on the resin, Ni, Zn, Cd and Pb, which were collected on the resin in alkaline medium, did not interfere at levels up to 500 μg. Common anions such as chloride and sulfate ions did not interfere at levels up to 1000 μg.

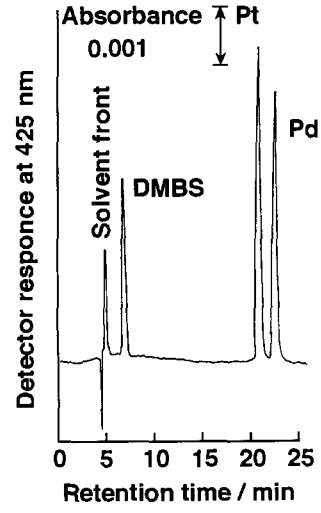

Fig. 6. Chromatogram of Pt- and Pd-chelates Pt = 2 μg; Pd = 1 μg; mobile phase = 65:35 (v/v) acetone–water containing 1×10^{-3} mol dm^{-3} CH_3COONa and 1×10^{-4} mol dm^{-3} EDTA; flow-rate 1 cm^3 min^{-1}; sample size = 10 mm^3.

[b] Purchased from Nilaco, Japan.

4. Application

The proposed method was applied to the determination of platinum and palladium in commercially available dental alow and platinum–palladium wire and the results are given in Table 1. The results obtained with the proposed method were in good agreement with the indicated value for each sample.

The proposed method can be applied to the determination of platinum and palladium in the samples with other components such as dental alloy and with different concentrations of metal ions such as platinum–palladium wire.

Determination of thiosulfate at the 10^{-6} M level by its oxidation with iodine in an organic phase and spectrophometric measurement of triiodide

Tomozo Koh *, Tatsuo Sugimoto, Masahiro Matsui, Yasuyuki Miura

Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka 259-12, Japan

Received 4 March 1996; received in revised form 6 August 1996; accepted 9 August 1996

Abstract

A highly sensitive method is proposed for the determination of thiosulfate based on the oxidation of aqueous thiosulfate (100 or 200 ml) by iodide in 4 ml of carbon tetrachloride. The excess of iodine was extracted into 8 ml of aqueous iodide solution as triiodide to be measured spectrophotometrically; the thiosulfate could therefore be indirectly highly concentrated and determined selectively. The side-reaction of thiosulfate in a large volume of solution with the hypoiodite formed from the iodine in carbon tetrachloride could be compensated for by adding a certain amount of extra thiosulfate. A linear calibration graph with a negative slope was obtained over the concentration ranges 1.1×10^{-7}–1×10^{-5} M (12 ppb–1.12 ppm) for 100 ml of thiosulfate solution and 6×10^{-8}–5×10^{-6} M (6.7 ppb–0.56 ppm) for 200 ml of thiosulfate solution. The proposed method was successfully applied to the determination of various amounts of thiosulfate in hot-spring and lake-water samples. © 1997 Elsevier Science B.V.

Keywords: Iodine oxidation; Spectrophotometry; Thiosulfate; Water

1. Introduction

A mixed solution of standard iodate and an excess amount of iodide has proved to be an excellent primary standard solution for iodine [1], because the mixture is extremely stable and a standard iodine solution can be readily prepared by the addition of acid, in which the following reaction proceeds to stoichiometric completion:

$$IO_3^- + 8I^- + 6H^+ \rightarrow 3I_3^- + 3H_2O \quad (1)$$

Ozawa [2] has proposed a method for the determination of thiosulfate based on its oxidation with the iodine produced from the mixture of standard iodate and iodide:

$$2S_2O_3^{2-} + I_2 \rightarrow S_4O_6^{2-} + 2I^- \quad (2)$$

followed by spectrophotometric measurement of the excess amount of triiodide. This method has been extensively used for the determination of polythionates and further for the determination of polythionates in mixtures, where the thiosulfate formed from the polythionates by their cyanolysis

PII S0039-9140(96)02065-6

[3] and sulfitolysis [4–7] was measured. However, iron(III) interfered considerably in the determination of thiosulfate, even when present at a concentration as low as 1 ppm, because of its oxidation of the iodide in the triiodide. Therefore, for the determination of thiosulfate in real samples, the iron(III) present has to be removed by separation of a cation-exchange column [8,9]. Further, the method [2] using aqueous triiodide is limited by its sensitivity. Recently, a new reaction of thiosulfate [10] in the presence of a large amount of formaldehyde with iodine in an organic phase was studied in detail and used for the determination of thiosulfate, this method has advantages over the former method in terms of sensitivity and selectivity, but polythionates interfere in the determination of thiosulfate.

In this study, we developed a selective and sensitive method for the determination of thiosulfate, in which aqueous thiosulfate in 100 or 200 ml of solution reacts with iodine in 4 ml of carbon tetrachloride. The excess of iodine is then extracted into an aqueous iodide solution as triiodide and the triiodide formed is measured spectrophotometrically at 350 nm. The proposed method is free from interferences from iron(III) and other sulfur species, including polythionates and is at least 10- or 20-fold more sensitive than a conventional method using aqueous triiodide. This method was applied successfully to the determination of thiosulfate in the presence of large amounts of iron(III), sulfide and sulfite in hot-spring and lake-water samples.

2. Experimental

2.1. Reagents and apparatus

All of the reagents used were of analytical-reagent grade and were used as received. Doubly distilled water was used throughout. An approximately 0.1 M thiosulfate solution was prepared by dissolving sodium thiosulfate pentahydrate in oxygen-free water containing a small amount of sodium carbonate (0.01%, w/v) as a stabilizer. This solution was standardized by iodimetry 1 week after preparation. Working standard thiosulfate solutions (in 0.01%, w/v, Na_2CO_3) were prepared by appropriate dilution with oxygen-free water. An approximately 0.05 M iodine solution was prepared by dissolving a known amount of iodine in carbon tetrachloride. A 10 ml volume of this solution was pipetted into a 200 ml conical beaker containing 10 ml of water and then standardized against a standard thiosulfate solution by iodimetry; the beaker was shaken during the titration and the disappearance of the purple color due to iodine in the organic phase was taken as the end-point of the titration. Working standard solutions were prepared by suitable dilution with carbon tetrachloride. Standard solutions of 5×10^{-2} and 1.5×10^{-5} M iodine in carbon tetrachloride were stable for up to 2 and 1 week, respectively, after preparation.

A Shimadzu Model UV-160A recording spectrophotometer with 10 mm quartz cells was used for all absorbance measurements. An Iwaki Model KM shaker was used to promote both the reaction of iodine with thiosulfate in the two different phases and the extraction of the iodine in carbon tetrachloride into the aqueous phase as triiodide.

2.2. Recommended procedure

Place 100 ml of solution containing up to 1×10^{-5} M thiosulfate and 2 ml of 10 M sulfuric acid in a 300 ml separating funnel. For samples containing sulfide and sulfite, bubble nitrogen through the solution at a flow-rate of 400 ml min^{-1} for 20 min [10] in order to remove completely the sulfide and sulfite. Allow the mixture to stand for at least 10 min after bubbling, then add 1.5 ml of 1×10^{-4} M thiosulfate and 4 ml of 1.5×10^{-4} M iodine in carbon tetrachloride and shake the funnel for 2 min to allow the iodine to react with the thiosulfate in the aqueous phase. Transfer an exactly given volume of the organic phase into another 50 ml separating funnel and add 5 ml of 1 M potassium iodide (in 0.04%, w/v, Na_2CO_3). After introducing nitrogen into the funnel at a flow-rate of 250 ml min^{-1} for 2 min to displace the air, add 3 ml of 1.2 M acetic acid and shake the funnel for 1 min to extract the excess iodine into the aqueous phase as triiodide [10].

Measure the absorbance of the aqueous phase at 350 nm using 10 mm quartz cells. An iodine-free reagent blank was subtracted from all the absorbances measured in the procedure.

3. Results and discussion

3.1. Calibration

A series of standard solutions (100 ml) of thiosulfate were treated as described in Section 2.2. After the reaction of thiosulfate with the iodine in carbon tetrachloride, the excess iodine was extracted into an aqueous iodide solution as triiodide, and the triiodide formed was measured spectrophotometrically. Hence the absorbance for the triiodide should decrease with increase in the concentration of thiosulfate. As can be seen in Fig. 1, the calibration graph obtained for thiosulfate coincided exactly with that obtained for

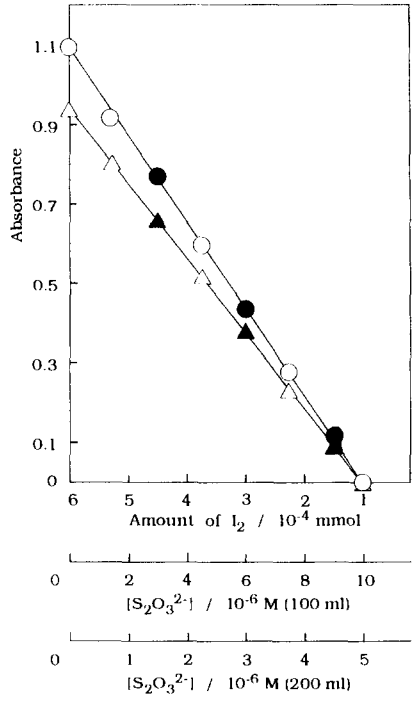

Fig. 1. Calibration graphs for thiosulfate and iodine. ○, $S_2O_3^{2-}$ in 100 ml of solution; ●, I_2 (expected) by using 100 ml of water; △, $S_2O_3^{2-}$ in 200 ml of solution; ▲, I_2 (expected) by using 200 ml of water.

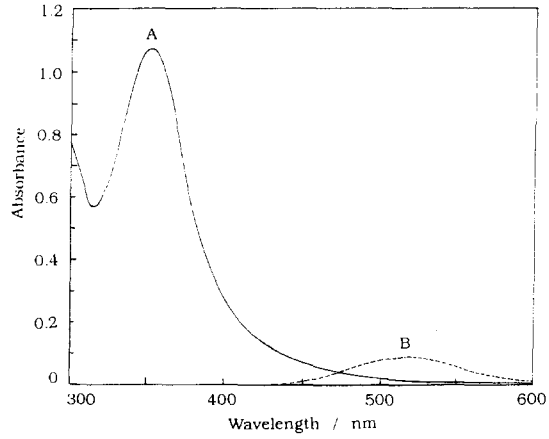

Fig. 2. Absorption spectra of the reagent blank and the iodine in carbon tetrachloride. A 4 ml volume of 1.5×10^{-4} M iodine solution in carbon tetrachloride was used. A, reagent blank measured as triiodide in 8 ml of solution; B, iodine in 4 ml of carbon tetrachloride.

iodine (expected graph) by using a series of standard solutions (4 ml of carbon tetrachloride solutions) of iodine and 100 ml water (in place of 100 ml of thiosulfate solution) in the procedure. In this instance, the amount scale for iodine is drawn in the opposite direction to scale for the thiosulfate concentration; the absorbance for 1×10^{-4} mmol of iodine reached zero in the procedure, because some iodine was consumed by the thiosulfate added. Even when 200 ml of thiosulfate solution were used to which 4 ml of 10 M sulfuric acid were placed, the calibration graph obtained for thiosulfate agreed well with that for iodine, demonstrating that the reaction of thiosulfate with iodine in carbon tetrachloride proceeded to stoichiometric completion according to Eq. (2). The difference between the calibration graph for 100 ml of thiosufate solution and that for 200 ml of thiosulfate solution is due to the difference in the amount of the iodine dissolved in water. The proposed method could be applied to the determination of thiosulfate in the concentration ranges 1.1×10^{-7}–1×10^{-5} M (12 ppb–1.12 ppm) for 100 ml of thiosulfate solution and 6×10^{-8}–5×10^{-6} M (6.7 ppb–0.56 ppm) for 200 ml of thiosulfate solution. The precision was determined from 11 replicate results obtained for a 100 ml aliquot of a 6.0×10^{-6} M standard thiosulfate

solution; the mean concentration of thiosulfate was found to be 6.0×10^{-6} M, with a standard deviation of 3.4×10^{-8} M (3.9 ppb) of $S_2O_3^{2-}$ and a relative standard deviation of 0.58%.

3.2. Absorption spectra

Fig. 2 shows the absorption spectra of the reagent blank (A) obtained in the procedure and of a solution of 1.5×10^{-4} M iodine in carbon tetrachloride (B). The reagent blank was obtained as follows. A 4 ml volume of 1.5×10^{-4} M iodine solution in carbon tetrachloride was shaken with a solution containing 100 ml of water, 2 ml of 2 M sulfuric acid and 1.5 ml of 1×10^{-4} M thiosulfate, then the iodine in carbon tetrachloride (its absorption spectrum shown in Fig. 2 (B)) was extracted into 8 ml of an aqueous solution of iodide as triiodide. The absorption spectrum (A) of the reagent blank has a much higher maximum absorption at 350 nm than that (B) of a solution of 1.5×10^{-4} M iodine in carbon tetrachloride which has its maximum absorption at 520 nm. Therefore, the excess iodine for the reaction with thiosulfate was measured as triiodide [10] at 350 nm in the procedure.

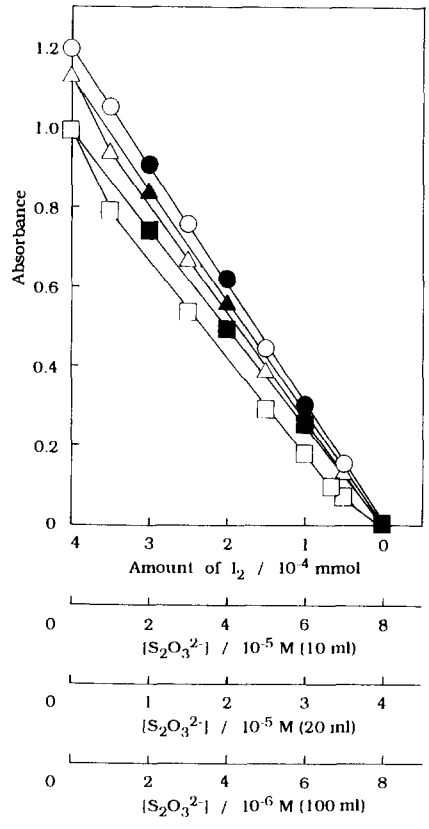

Fig. 3. Calibration graphs obtained for thiosulfate by using 10, 20 and 100 ml of thiosulfate solution. A 4 ml volume of 1×10^{-4} M iodine solution in carbon tetrachloride was used. ○, $S_2O_3^{2-}$ in 10 ml of solution; ●, I_2 (expected) by using 10 ml of water; △, $S_2O_3^{2-}$ in 20 ml of solution; ▲, I_2 (expected) by using 20 ml of water; □, $S_2O_3^{2-}$ in 100 ml of solution; ■, I_2 (expected) by using 100 ml of water.

3.3. Reaction of thiosulfate with iodine in carbon tetrachloride

Before 4 ml of iodine solution in carbon tetrachloride were added to an aqueous thiosulfate solution in the procedure, a strong acid (sulfuric acid) had to be added in order to prevent the iodine from transferring into the aqueous phase; an oxonium ion concentration range 0.3–1.3 M proved sufficient. Hence, 1 ml of 2 M H_2SO_4, 2 ml of 2 M H_2SO_4 and 2 ml of 10 M H_2SO_4 were used, for 10, 20 and 100 ml volumes of thiosulfate solution, respectively. Each 10 ml of solution of a series of amounts of standard thiosulfate was allowed to react with 4 ml of 1×10^{-4} M iodine in carbon tetrachloride by shaking the separating funnel, and the excess iodine was measured spectrophotometrically as triiodide according to the procedure. The resulting graph is shown in Fig. 3.

The calibration graph for thiosulfate was in good agreement with that obtained for iodine (expected graph) by using a series of standard solutions (4 ml) of iodine in carbon tetrachloride and 10 ml of water. However, when the volume of thiosulfate solution was increased to 20 and 100 ml, the calibration graph obtained for thiosulfate deviated negatively from the expected graph; the larger the volume of thiosulfate solution, the greater the calibration graph deviated, as shown in Fig. 3. This deviation can be attributed to partial oxidation of thiosulfate to oxidation states higher than that of tetrathionate ion (see Eq. (2)), by the hypoiodite ion formed as a result of the hydrolysis of the iodine transferred even into a strongly acidic medium. In order to eliminate the

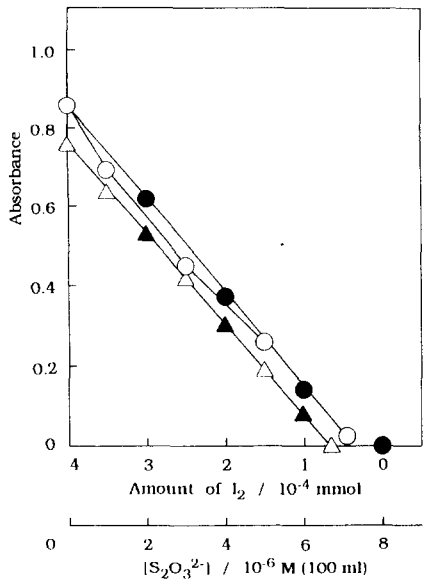

Fig. 4. Compensation for the side-reaction of thiouslfate in 100 ml of iodine solution in carbon tetrachloride. A 4 ml volume of 1×10^{-4} M iodine solution in carbon tetrachloride was used. ○, $S_2O_3^{2-}$ in 100 ml of solution plus 0.5 ml of 1×10^{-4} M $S_2O_3^{2-}$; ●, I_2 (expected) by using 100 ml of water plus 0.5 ml of 1×10^{-4} M $S_2O_3^{2-}$; △, $S_2O_3^{2-}$ in 100 ml of solution plus 1 ml of 1×10^{-4} M $S_2O_3^{2-}$; ▲, I_2 (expected) by using 100 ml of water plus 1 ml of 1×10^{-4} M $S_2O_3^{2-}$.

effect of this side-reaction from the determination of thiosulfate, an attempt was made to add thiosulfate for reaction with the hypoiodite. When 0.5 ml of 1×10^{-4} M thiosulfate solution was added to a solution containing 100 ml of up to 7.1×10^{-6} M thiosulfate solution and 2 ml of 10 M sulfuric acid, the calibration graph for thiosulfate approached the expected graph more closely (Fig. 4). Fig. 4 also shows that the calibration graph agreed completely with the expected graph when 1 ml of 1×10^{-4} M thiosulfate solution was used additionally. In the procedure, 1.5 ml of 1×10^{-4} M thiosulfate solution and accordingly 4 ml of a carbon tetrachloride solution of 1.5×10^{-4} M iodine, higher than 1×10^{-4} M, were used to compensate for the side-reaction between the iodine in carbon tetrachloride and the thiosulfate in samples. The iodide ion in the aqueous phase proved not to bring about any measurable change in either the reagent blank or the absorbance of thiosulfate in amounts up to 3000 μg. This means that the amount of iodide ion (19 μg) transferred into the aqueous phase as a result of the reaction of iodine with the thiosulfate added to compen-

[a] Corrected for four determinations.

sate for the side-reaction is too small to form triiodide; the equilibrium constant [11] for the following reaction:

$$I^-(aq) + I_2(org) \rightleftharpoons I_3^-(aq) \quad (3)$$

is not high, but is $10^{0.99}$ at 20°C when the organic solvent is carbon tetrachloride.

When sulfide and sulfite were removed from thiosulfate by bubbling nitrogen through the sample solution, a considerably higher absorbance was unexpectedly obtained, this higher absorbance was thought to be caused by the fact that the following hydrolysis reaction of iodine:

$$I_2 + H_2O \rightleftharpoons HIO + H^+ + I^- \quad (4)$$

is substantially depressed in an oxygen-free medium. The oxygen dissolved in water was also removed together with the sulfide and sulfite when the sample solution was purged with nitrogen. However, the higher absorbance continued to decrease gradually with time and eventually reached a normal value in 10 min. Hence the mixed solution purged with nitrogen had to be allowed to stand for at least 10 min as in the procedure.

3.4. Effects of foreign ions

A 100 ml volume of solution containing 67.3 μg of thiosulfate (6×10^{-6} M) and various amounts of foreign ions was treated as described in the procedure. The results are given in Table 1. In a previous method based on the oxidation of thiosulfate with aqueous triiodide [2], copper(II), iron(III), nitrite and iron(II), which oxidize iodide and reduce iodine, interfered in the determination of thiosulfate when present in amounts similar to

that of thiosulfate. In the proposed method, copper(II) and iron(II) were tolerated in amounts of up to 10 000 μg and both of iron(III) and nitrite up to 1000 μg. Iron(III) and lead(II) were tolerated in amounts of up to 10 000 μg when masked by the addition of 2 ml of 0.2 M EDTA solution and nitrite up to 10 000 μg when decomposed by the addition of 2 ml of 0.5 M amidosulfuric acid solution. All polythionates of tri-, tetra-, penta- and hexathionate were tolerated in amounts of up to 10 000 μg. Further, both sulfite and sulfide could be completely removed in amounts of up to 5000 μg from thiosulfate by bubbling nitrogen through the solution according to the procedure. Iodide did not interfere with the determination of thiosulfate in amounts of up to 3000 μg and arsenate up to 100 μg. The other ions listed in Table 1 were tolerated in amounts as high as 10 000 μg with an error of less than 2%.

3.5. Application to real samples

In order to remove the sulfite and sulfide in real samples, nitrogen was bubbled, according to the procedure, through 150 ml of solution containing 120 or 60 ml of the samples, a known amount of thiosulfate and 3 ml of 10 M sulfuric acid. A 25 ml aliquot of the solution from which the sulfite and sulfide had been removed was transferred into a 300 ml separating funnel and the volume was adjusted to 100 ml; in this instance the original samples were to be diluted to 5- or 10-fold, respectively. A 100 ml of mixed solution was treated according to the procedure, in which 2 ml of 0.2 M EDTA solution were added for both hot-spring C and lake-water samples, containing large amounts of iron(III). The thiosulfate content was determined using the standard additions method. The results are summarized in Table 2. The results obtained for the samples diluted to 5- and 10-fold the original volume were in good agreement with each other.

Potential matrix interferences from unknown species in real samples were investigated by adding known amounts of thiosulfate to the sample solutions. The recoveries ranged from 99.2 to 100.8% with an average of 100.4%, which is adequate for the analysis of environmental samples.

Second-order data by flow injection analysis with spectrophotometric diode-array detection and incorporated gel-filtration chromatographic column

Iben Ellegaard Bechmann

Department of Chemistry, Technical University of Denmark, DK-2800 Lyngby, Denmark

Received 24 April 1996; received in revised form 29 July 1996; accepted 29 July 1996

Abstract

A flow injection analysis (FIA) system furnished with a gel-filtration chromatographic column and with photodiode-array detection was used for the generation of second-order data. The system presented is a model system in which the analytes are blue dextran, potassium hexacyanoferrate(III) and heparin. It is shown that the rank of the involved sample data matrices corresponds to the number of chemical components present in the sample. The PARAFAC (parallel factor analysis) algorithm combined with multiple linear regression and the tri-PLS (tri-linear partial least-squares regression), which allows unknown substances to be present in the sample, are implemented for FIA systems and it is illustrated how these three-way algorithms can handle spectral interferents. The prediction ability of the two methods for pure two-component samples and also the predictions ability in the presence of unknown interferents are satisfactory. However, the predictions obtained by tri-PLS are slightly better than those obtained using PARAFAC regression algorithm. © 1997 Elsevier Science B.V.

1. Introduction

Data structures produced by analytical chemical systems in general and by flow injection analysis (FIA) systems in particular can be divided into classes reflecting the complexity of the data, ranging from scalars, vectors and matrices to higher order data structures. More than 90% of the papers published in analytical chemical journals are based on zeroth-order data structures [1]. This simple data structure arises when only one measurement per sample is recorded. A set of calibration samples thus gives a vector. The measurement can be a variety of signals, e.g. potential, current, absorbance or, as often used in FIA, the height (or area) of the sample peak. The use of zeroth-order data requires that the measured signal is absolutely selective and additionally that the signal is a known function (e.g. linear) of the concentration of the analyte. If the selectivity assumption is not fulfilled for all samples, an improvement can be achieved by using first-order data structures [1], which gives the possibility of detecting outlying samples. First-or-

PII S0039-9140(96)02066-8

der data, where each sample gives rise to a vector and a set of calibration samples hence yields a matrix, can be obtained in two ways in FIA: (1) by recording the actual measurement (e.g. the absorbance at a given wavelength) as a function of time; and (2) by recording multiple measurements at a given time (e.g. the UV/VIS spectrum at the peak maximum). The condition for employing first-order data is that the responses are linear and additive for all analytes.

The number of FIA papers published on first-order data using two-way data analytical methods for instance partial least-squares (PLS) regression is increasing [2–5]. From a multivariate chemometric point of view, second-order data structures [1], where each sample gives rise to a matrix and a set of calibration samples to a cube, are, however, much more interesting because these data make it possible not only to detect outlying samples but also to determine correct analyte concentrations even though the analytical signal is not selective. This has been called the second-order advantage [1]. Second-order data can be achieved, for instance, by scanning multiple wavelengths at multiple times. The majority of papers published concerning second-order data in FIA rely on spectrophotometric diode-array detection [6,7]. The condition for optimal use of second-order data is that the data structure is bilinear, which means that the responses are linear and additive for all analytes and that no co-elution of analytes is allowed. This bilinear data structure is found in chemical systems obeying the Lambert–Beers law and where the analytes are separated in time by a column, e.g. in chromatographic systems combined with a photodiode-array detector.

In this work, a flow injection system with an incorporated gel-filtration chromatographic column and a UV/VIS photodiode-array detector was used for the generation of second-order data. In an earlier paper [8], the application of a gel-filtration chromatographic column in a FIA system for enzymatic determination of formaldehyde in aqueous fish extracts was reported. In that work, the purpose of providing the FIA system with a gel-filtration chromatographic column was on-line removal of the protein fraction of the extract prior to the enzymatic analysis. The purpose of this work was partly to improve the possibilities of the application of gel-filtration chromatographic columns in FIA and partly to illustrate the general advantages of using second-order FIA data, especially in cases where unknown spectral interferents are present. In that context, attention is drawn to an early paper [9] where the resemblance of flow injection analysis with chromatographic systems in general is discussed further. The system presented here is a model system where the analytes blue dextran, potassium hexacynoferrate(III) and heparin were chosen to illustrate the benefit of the methodology used. The data structure produced by the FIA system is a bilinear data structure, where each sample produces a 76 (times) × 188 (wavelength) matrix. Among the most common methods used for second-order calibration are unfolding methods, where the calibration cube is unfolded to an ordinary matrix which is then treated by standard two-way methods (e.g. PLS). In the case of response matrices where each chemical component gives rise to a matrix of rank one, the rank annihilation factor analysis (RAFA) method [10] or the general rank annihilation method (GRAM) can be used [10,11] for the prediction of correct analyte concentration in presence of spectral interferents.

In this paper, the tri-linear parallel factor analysis (PARAFAC) algorithm [12–14] and the newly developed tri-linear partial least-squares regression (tri-PLS) [15] are implemented for FIA systems. PARAFAC is a generalization of PCA to higher order data arrays, but there are some important differences between the two methods. Tri-PLS is a generalization of the ordinary two-way PLS methods. A short description of the two methods is given in Section 3. Compared with the unfolding methods, the multi-linear models are much simpler because they use fewer parameters.

2. Experimental

2.1. Apparatus

2.1.1. FIA system

The FIA system used in the experiments was a simple one-line FIA system. All tubing employed

was PTFE (0.5 mm i.d.) and the carrier stream was propelled by an Ismatec MS-4 Reglo peristaltic pump. The sample (50 μl) was aspirated into the valve by the same pump. The carrier stream was pumped through a gel-filtration chromatographic column (HiTrap Desalting; Pharmacia, Uppsala, Sweden). The detector was a TIDAS (Zeiss J and M Analytische Mess- und Regeltechnik, Germany) photodiode array spectrophotometer furnished with a 8 μl flow cell. A 12-port injection valve (made in this laboratory) was used for injection of the sample. The photodiode array starts scanning 20 s after injection and continues for a further 75 s at 1.0 s intervals. The wavelength range recorded in each scan is 220–594 nm (every 2 nm). Injection of one sample thus, generates a data matrix containing 76 × 188 absorbances. An example of the data structure produced by injection of 50 μl sample is depicted in Fig. 1.

2.1.2. Gel-filtration column

The column used in this work was a HiTrap desalting column (Pharmacia) of dimensions 25 × 16 mm i.d. The column is filled with Sephadex G-25 Superfine and has a fractionation range between 1000 and 5000 Da. This column shows a significantly better separation of low and high molecular weight substances than the Sephadex G-25 column used in the previous work [8], which was packed in this laboratory and consisted of a piece of PVC into with was machined a tubular cavity of 52 × 3.3 mm i.d. When not in use, the column reactor was stored filled with a 20% (v/v) ethanol solution in a refrigerator at 5°C to prevent microbiological growth.

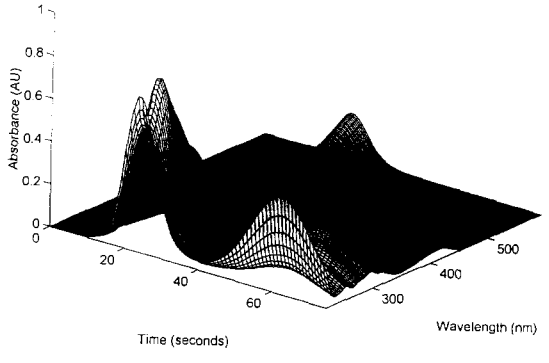

Fig. 1. Three-dimensional plot of the data matrix corresponding to injection of a mixture of blue dextran and $K_3Fe(CN)_6$.

Table 1
Concentrations of blue dextran and $K_3Fe(CN)_6$ for nine calibration samples

Sample	Blue dextran (mg ml^{-1})	$K_3Fe(CN)_6$ (mg ml^{-1})
C1	0.00	0.00
C2	2.65	0.00
C3	5.30	0.00
C4	0.00	0.80
C5	2.65	0.80
C6	5.30	0.80
C7	0.00	1.60
C8	2.65	1.60
C9	5.30	1.60

2.2. Reagents

The samples use in the model system were made from stock solutions of a high molecular weight substance (Blue dextran, Mw $\approx 10^6$ g mol^{-1}; Sigma) and a low molecular weight substance (potassium hexacyanoferate(III), Mw = 329.2 g mol^{-1}; Merck) in degassed, distilled Millipore-filtered water containing 0.9% NaCl. The stock solutions, which contained 26.5 g l^{-1} blue of dextran and 1.62 g l^{-1} of potassium hexacyanoferrate(III), were diluted with 0.9% NaCl solution for the preparation of samples. A solution of heparin (Tinzaparine, MW $\approx$ 4000 g mol^{-1}) containing 10 g l^{-1} was used in some of the test samples as an interfering component.

2.3. Programs

Data collection and control of the pump and valve were performed by a software package from J&M Analytische Mess- und Regeltechnik (Germany). All calculations were preformed in Matlab ver. 4.0 for Windows (Math Works), partly by use of PARAFAC and multi-linear PLS algorithms available from the Internet at http://newton.foodsci.kvl.dk/foodtech.html (R. Bro and C.A. Andersson).

3. Theory

3.1. Data structure

The data structure produced by the FIA system is a bilinear data structure, where each sample produces a J (times) $\times$ K (wavelength) matrix. If all responses are linear and no noise is present, the rank of the measured response matrix will be equal to the number of chemical substances present in the sample. However, the true rank of the sample matrix is often not determinable because of real data contain non-linearities and noise. For this reason, it is necessary to determine a pseudo-rank instead. In the present work, principal component analysis (PCA) [10] is used for this purpose. In this context the rank equals the number of principal components which is necessary to explain 99% of the variance in the response matrix. The dimension of the three-way calibration data array, $\mathbf{X}$, is $I \times J \times K$, where I is the number of samples in the calibration set. The pre-processing of this kind of raw data is more complicated than in the two-way case. In this work no centering and no scaling were used in the PARAFAC models. The data arrays used for tri-PLS are centered by unfolding the data array to a $I \times JK$ matrix and then mean center the unfolded matrix. No scaling was used.

3.2. PARAFAC

PARAFAC performs a tri-linear decomposition of the data array, $\mathbf{X}$, and can be regarded as a generalization of the bilinear PCA. In PARAFAC the tri-linear model of $\mathbf{X}$ is found to minimize the sum of squares

$$\left(\sum e_{ijk}^2\right)$$

in the model

$$x_{ijk} = \sum_{f=1}^{F} a_{if} b_{jf} c_{kf} + e_{ijk}$$

where x_{ijk} is an element in $\mathbf{X}$ ($i = 1, ..., I$, $j = 1, ..., J$, and $k = 1, ..., K$), a are the scores, b and c are loadings in the model and F is the number of factors. In contrast to PCA, the number of factors to be included in the PARAFAC model must be determined before the modelling.

A very obvious advantage of PARAFAC over PCA is the uniqueness of the solution. The loadings in a spectral bilinear PCA model reflect the pure spectra of the analytes measured, but it is not possible without external information actually to find the pure spectra. In the data used for the PARAFAC model represent a second-order data structure, the true analyte spectra can often be found directly, if only the concentrations vary independently pairwise and no spectra are linearly dependent on any of the others. In this work, PARAFAC is used for prediction purposes by

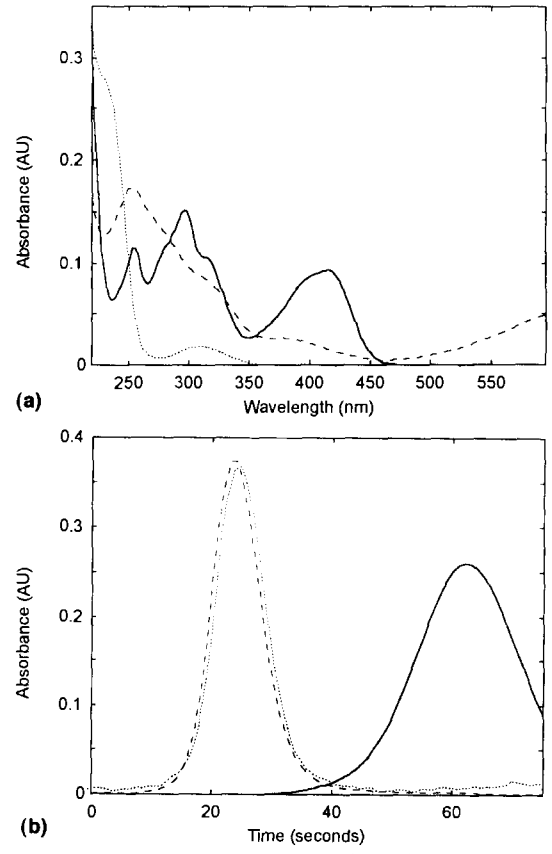

Fig. 2. (a) Normalized pure spectra of the three components. Dash line, blue dextan; solid line, $K_3Fe(CN)_6$; Dotted line, heparin. (b) Normalized concentration profiles calculated by alternating regression on each of the pure sample matrices. Lines as in (a).

following the strategy of principal component regression (PCR) [10]. The scores from the PARAFAC model are used for the predictions using multiple linear regression.

3.3. Tri-PLS

The tri-linear PLS is a natural extension of the ordinary bi-linear PLS method. By the tri-linear decomposition in tri-PLS the calibration cube **X** is decomposed into a set of rank-one cubes describing **X** in some optimal sense. This does not mean, however, that the part of **X** relevant for describing the dependent variables (the analyte concentrations) has to be of rank one. One advantage of tri-PLS over PARAFAC is the incorporation of the dependent variables (the analyte concentrations) in the decomposition of the measured calibration cube, which might stabilize the predictive model. The theory of multi-linear PLS can be found elsewhere [15].

4. Results and discussion

The samples used for calibration consisted of mixtures of the two analytes, blue dextran and potassium hexacyanoferrate(III). The samples were prepared as a two-factor, three-level factorial design, i.e. the calibration set consisted of nine samples. The compositions of the calibration samples are given in Table 1.

An independent test set of 12 different test samples was prepared. To illustrate how the PARAFAC and the tri-PLS algorithms handle spectral interferents, some of the test samples in addition contained heparin.

The pure spectra and the concentration profiles of blue dextran, potassium hexacyanoferrate(III) and heparin are shown in Fig. 2(a) and (b), respectively.

The spectra and time profiles are found by resolution of each of the three data matrices measured on pure standards using the alternating least squares (ALS) algorithm [10]. From Fig. 2(b), it is seen that the time profiles of the dextran and the $K_3Fe(CN)_6$ differ owing to different resolution times on the gel-filtration column. The resolution times of heparin and dextran are almost the same owing to their molecular weights of close to 4000 Da and higher than 5000 Da, respectively. In the current application, the exclusion limit of the column is apparently about 4000 Da and not 5000 Da as specified by Pharmacia. The spectral characteristics of the three components, however, are different. The data structure obtained by injection of a pure mixture of blue dextran and $K_3Fe(CN)_6$ is thus, expected to be a bilinear second-order data structure.

A PARAFAC model with two components should give the right solution since there are two

analytes in the calibration set. The spectral loadings of a two-component PARAFAC model are shown in Fig. 3(a) and the corresponding time loadings are shown in Fig. 3(b). From comparison with Fig. 2(a) and (b), it is seen that the model estimates precisely both the pure spectra and the time profiles of the two analytes.

The PARAFAC model was validated by test set validation with the nine samples in a calibration set and 12 other samples in a test set. For the predictions of analyte concentrations in the test samples, a regression model was made from the scores of the two-component PARAFAC model. For comparison, the results of using a tri-PLS model with two PLS components were also calculated. The true concentrations and the concentrations predicted by PARAFAC for the 12 test samples are given in Table 2 together with the concentrations predicted by tri-PLS. The pseudo-rank determined by PCA of the measured data matrices for the 12 test samples is also given in Table 2.

The rank of a sample matrix containing only one substance equals one and the rank of a sample matrix containing two substances equals two, and analogously with three substances. This indicates that an FIA system furnished with a gel-filtration column acts as expected of a chromatographic system.

It appears that the prediction of $K_3Fe(CN)_6$ concentrations in the presence of heparin in general is better than the predictions for dextran in the presence of heparin. This can be explained by the almost identical resolution profiles of the two high molecular weight substances used. Comparing the predicted and actual concentrations obtained by applying the two methods on the 12 test samples, the root mean square error of prediction (RMSEP) can be calculated. The RMSEP for the prediction of dextran is 0.03 mg ml^{-1} and that for $K_3Fe(CN)_6$ is below 0.01 mg ml^{-1}. The predictions obtained by tri-PLS are slightly better than those obtained by PARAFAC, but both the PARAFAC and the tri-PLS algorithms give satisfactory predictions in the presence of unknown chemical interferents. However, tri-PLS does not possess the uniqueness properties of PARAFAC and it is therefore not possible without external information actually to find the pure spectra of the analytes. If the investigated samples contain specific chemical components of interest, the PARAFAC algorithm might therefore be preferable.

Acknowledgements

The author thanks Professor Elo H. Hansen for valuable comments and suggestions. Rasmus Bro is thanked for helpful comments and for placing the Matlab m-files for PARAFAC and tri-PLS on the Internet. The Danish Ministry of Agriculture and Fisheries is acknowledged for financial support. This work was performed in collaboration with the Danish Institute for Fisheries Research, Department of Seafood Research.

Porphyrins as ligands for trace metal analysis by high-performance liquid chromatography

Zhihong Shi, Chengguang Fu *

Research Centre of Physical and Chemical Analysis, Hebei University Baoding, 071002, People's Republic of China

Received 16 April 1996; received in revised form 5 August 1996; accepted 15 August 1996

Abstract

The role of porphyrins in the determination of metal ions by high-performance liquid chromatography (HPLC) is examined. In assessing the current status of the area, recent advances and developments are discussed and future potential is pointed out. © 1997 Elsevier Science B.V.

Keywords: High-performance liquid chromatography; Porphyrin ligands; Trace metal analysis

1. Introduction

High-performance liquid chromatography (HPLC) has been mainly used as a technique for the separation of organic solutes and its leading position in this role remains unchallenged. Although as early as 1972 Huber et al. [1] had accomplished the separation and determination of metal ions by HPLC, related research work in this field did not provoke interest until the 1980s. Rapid improvements in HPLC methodology and the application of superior metal chelate systems have significantly enhanced the potential usefulness of HPLC for the separation and determination of metal ions. Many reagents have been successfully used as ligands to form metal chelates pre-column, in situ or post-column, such as pyridylazo [2–4], thiazolylazo [5], 8-hydroxyquinoline [6], complexones [7], diethyldithiocarbamate [8] and β-diketones [9].

Several reviews have been published on the determination of metal ions with organic chelating reagents by HPLC [10–14]. The present paper stresses applications of porphyrins as ligands to the separation and determination of metal ions by HPLC.

It is well known that a porphyrin is a kind of highly sensitive chromogenic reagent. Porphyrins and their metal chelates generally exhibit characteristically sharp and intense absorption in the visible region. The band at about 400–500 nm, which is called the Soret band, shows the most intense absorption. Molar absorptivities of the order of 10^5 are often recorded.

The Soret band is regarded as the band of choice for the spectrophotometric determination of metalloporphyrins. If a porphyrin reacts easily and quantitatively with a metal ion, the porphyrin

PII S0039-9140(96)02068-1

must be useful as a sensitive spectrophotometric reagent for the determination of metal ions. Many porphyrins, including lipophilic and water-soluble types, have been synthesized and used for the spectrophotometric determination of metals [15–20].

However, there is a major problem in utilizing a porphyrin for the spectrophotometric determination of metals: the Soret bands of porphyrins and their metal chelates overlap so closely that the determination of a certain metal ion often suffers serious interference from other metals. When the method is applied to practical samples, a complicated separation procedure is often needed. Therefore, the simultaneous determination of different metals is rarely effective.

To solve the above problems, HPLC is the best choice. Considering the remarkably high stability of metal porphyrin chelates and the similarity of the chelates' absorbance, a porphyrin is an ideal chelating reagent for the determination of metal ions by HPLC. In addition, the intense color of the chelates should permit selective detection in the visible region of the spectrum.

The authors have attempted here to include all the work reported on the application of porphyrins to the HPLC determination of metal ions. Related high-performance thin-layer chromatographic (HPTLC) studies are also covered. It is hoped only that this review will introduce readers not familiar with this area to its potential usefulness.

2. Application of porphyrins in the determination of metal ions by HPLC

In general, there are two types of HPLC separation of metalloporphyrins: the separation of different porphyrin complexes of a certain metal ion and the separation of metalloporphyrins with respect to their central metal ions. The HPLC separations of the naturally occurring porphyrins and metalloporphyrins are examples of the former type of separation [21–23] and the determination of trace metals as their porphyrin chelates by HPLC belongs to the latter type. The latter type of HPLC separation is more difficult because each metal ion is surrounded by a bulky macrocyclic porphyrin structure to which various organic functional groups are further bonded. The difficulty in the separation of metalloporphyrins increases with increase in the chemical similarity of the central metal ions.

From the literature, it seems that the porphyrins which have been employed as ligands for the separation and determination of trace metals by HPLC can be classified into the following three groups: (i) porphyrins with no substituents; (ii) porphyrins with substituents at positions 5, 10, 15 and 20 (see Fig. 2 and Table 1); and (iii) porphyrins with substituents on the pyrrole rings.

2.1. Porphyrins with no substituents

21*H*,23*H*-porphine (H_2P) is the simplest synthetic porphyrin (Fig. 1). H_2P and its metal chelates are not soluble in water.

Wakui et al. [24] reported the HPTLC and HPLC behavior of several metal complexes of H_2P. The chromatographic mobility of H_2P and its Ni(II), Cu(II), Zn(II) and Pd(II) complexes were investigated by HPTLC on an octadecyl-bonded silica gel plate with various polar organic solvents. The mobility generally decreased according to the central metal ion of the complex in the order $Zn(II) > H_2P > Ni(II) > Pd(II) > Cu(II)$. According to the R_f data obtained for H_2P and its metal complexes from the HPTLC study, methanol is a good choice of eluent for the separation of these metal porphyrin complexes. The HPLC separation of H_2P and its four metal complexes was achieved on a LiChrosorb RP-18 column using methanol or acetonitrile as mobile phase and the eluates were detected at 390 nm. With acetonitrile, the retention time of every compound was shorter than that observed with

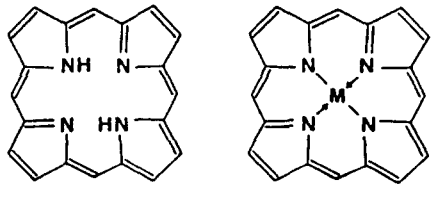

Fig. 1. H_2P (left) and complex with divalent metal M (right).

Table 1
Porphyrins with substituents at positions 5, 10, 15 and 20

Name	Abbreviation	Substituents	Solubility in water
meso-Tetraphenylporphine	TPP		Insoluble
meso-Tetrakis(*p*-tolyl)porphine	TTP		Insoluble
meso-Tetrakis(3-bromophenyl)porphine	*m*-BrTPP		Insoluble
meso-Tetrakis(4-hydroxyphenyl)porphine	THPP		Slightly soluble
meso-Tetrakis(*N*-methyl-4-pyridyl)porphine	T(4-MPy)P		Slightly soluble
meso-Tetra(4-carboxyphenyl)porphine	TCPP		Soluble
meso-Tetra(*p*-sulfophenyl)porphine	$TPPS_4$		Soluble
meso-Tetrakis(3-bromo-4-sulfophenyl)porphine	*m*-$BrTPPS_4$		Soluble
meso-Tetrakis(4-methoxyl-3-sulfophenyl)porphine	$T(4\text{-}MOP)PS_4$		Soluble

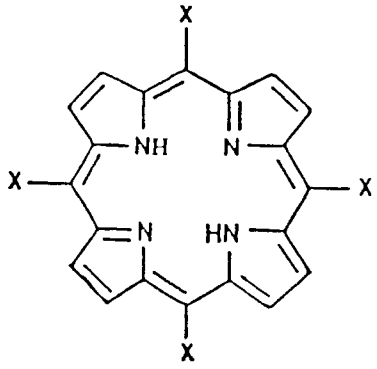

Fig. 2. The general structure of porphyrins. Substituents at the positions marked X are numbered 5, 10, 15 and 20.

methanol. However, the resolution between NiP, PdP and CuP was insufficient. It was shown that the metal complexes left the column without undesirable changes. It is unfortunate that the authors did not apply their work to the quantitative determination of metal ions.

2.2. Porphyrins with substituents at positions 5, 10, 15 and 20

The general structure of these porphyrins is shown in Fig. 2 and substituents are listed in Table 1.

In Fig. 2, substituents at the positions marked *X* are numbered 5, 10, 15 and 20. For example, the porphyrin where all four *X*s are phenyl groups is 5, 10 15, 20-tetraphenylporphine; this compound also has the trivial names meso-tetraphenylporphine and $\alpha,\beta,\gamma,\delta$-tetraphenylporphine.

2.2.1. TPP

TPP is one of the typical synthetic water-insoluble porphyrins. In 1975, Hui et al. [25] reported on the TLC behavior of the TPP chelates of manganese, iron, cobalt, nickel, copper, zinc, rhodium, cadmium, mercury and lead on silica gel and alumina. Good separations can be deduced from the published R_f data. Saitoh et al. [26] studied the HPTLC behavior of TPP and its chelates of Mg(II), Ni(II), Cu(II), Zn(II), Cd(II), Mn(III) and Fe(III). Cellulose and silica gel were chosen for normal-phase distribution and two kinds of alkylated silicas were chosen for reversed-phase distribution. These HPTLC studies clarified that the reversed-phase separation mode on an octadecyl-bonded silica gel coupled with a non-aqueous mobile phase is a good choice for the separation of complexes of divalent metals with TPP. Since metal TPP chelates are relatively insoluble in water and methanol, conventional reversed-phase systems using an aqueous mobile phase would not be effective in this case.

In a later paper, Saitoh et al. [27] described the HPLC behavior of TPP and its nine metal chelates on a C_{18}-bonded stationary phase. The retention of the chelate depends on its central metal ion, increasing in the order Zn(II) < V(IV) < Fe(III) < Mg(II) ≈ Cd(II) ≈ (H_2TPP) < Ni(II) = Pd(II) < Cu(II) < Mn(III).

A common mobile phase used in reversed-phase HPLC is methanol–water, whereas from the retention data for the TPP compounds obtained by Saitoh et al. we can see that methanol is not suitable for their rapid HPLC separation because of the considerable retention. It can be predicted that much larger retention volumes will be observed with methanol–water than with methanol alone. Acetonitrile is not useful for similar reasons, if it is used alone. Ethanol, acetone and *N*,*N*-dimethylformamide give relatively small retention volumes for the TPP compounds. Taking account of the solubility of the TPP compounds, the viscosity and the cost, acetone is considered to be the most convenient eluent.

The chelates of Mg(II), V(IV), Ni(II), Cu(II), Zn(II) and Pd(II) were separated in about 8 min using a LiChrosorb RP-18 column (250 × 4 mm i.d. 7 μm), with acetone–acetonitrile (40:60, v/v) as mobile phase at a flow-rate of 1 ml min^{-1}; the eluates were detected at 420 nm.

In order to extend the applicability of HPLC to the porphyrin complexes of trivalent metals, Suzuki et al. [28] studied the specific retention behavior of metal(III) TPP chelates in non-aqueous reversed-phase HPLC. The authors attributed the exceptionally large retention observed for MnTPPCl and CoTPPCl to the dissociation of the complexes in the mobile phase and the adsorption of the cationic metal TPP complexes on

the unmodified surface silanol sites on the reversed-phase column packing material. Any undesirable large retention could be suppressed by the addition of NH_4Cl to the mobile phase. It is interesting that the retention of MnTPPCl and CoTPPCl decreases dramatically with an increase in the concentration of NH_4Cl added to the mobile phase: a linear relationship between log k′ and log [NH_4Cl], with the slope of about -1, was observed for these two metal (III) complexes in the concentration range of NH_4Cl from 2.5×10^{-4} to 1.3×10^{-2} mol l^{-1}. The retention of the trivalent Mn, Fe and Co complexes of MTPPCl type can be controlled by regulating the NH_4Cl concentration in the ethanolic mobile phase. The successful separation of Mn(III), V(IV), Fe(III) and Ni(II) complexes of TPP has been accomplished by the use of ethanol containing 2.57×10^{-3} mol l^{-1} NH_4Cl as mobile phase.

It is known that the complexes of TPP with rare earths (REs) are considerably less stable than those of other metals, e.g. Fe(II), Fe(III), Ni(II) and Cu(II), owing to the large ionic radii of the RE(III) ions (> 100 pm at coordination number > 6) compared with the best fit (64 pm) for the hole in N-4 moiety of porphyrin [29]. The suppression of undesirable decomposition of the complexes in the chromatographic process is the prime requisite for the successful HPLC separation of RE-porphyrins.

Suzuki et al. [30] successfully developed RE–TPP complexes on an octadecyl-bonded silica TLC plate with a developing solvent containing both acetylacetone and diethylamine. The complexes showed high stability during the separation process.

In a later study Saitoh et al. [31] examined the feasibility of reversed-phase HPLC for the separation of the complexes of TPP with 12 rare earths, viz. Y(III), Nd(III), Sm(III), Eu(III), Gd(III), Tb(III), Dy(III), Ho(III), Er(III), Tm(III), Yb(III) and Lu(III), which have very similar chemical properties. All these RE–TPP complexes can be chromatographed with high stability in their migration process along the column with a methanol–water mixture containing a small amount of acetylacetone and an amine as mobile phase. The elution sequence for the RE complexes depends on the amine added to the mobile phase. The amine functions as a base which promotes the dissociation of Hacac to $acac^-$ ion, and accordingly the mixed ligand complex RE(TPP)(acac) is stabilized. Amines, particularly the mixed ligand complex RE(TPP)(acac) is stabilized. Amines, particularly di-*n*-alkylamines, also function as hydrophobic neutral ligands with which an RE–TPP can form an adduct complex, and accordingly the retention is enhanced. The effect of the latter function depends on the amine used, which is explained in terms of a steric effect of the alkyl moiety in the amine molecule. The Nd, Gd, Tb, Dy, Ho, Er and Lu complexes are successfully separated in 15 min, as shown in Fig. 3.

It appears that Saitoh et al.'s study will be useful in porphyrin chemistry where the separation or purification of RE–TPP complexes is required. However, when the method is applied to the determination of RE(III) ions by HPLC in aqueous samples, the development of a successful procedure for the quantitative formation of RE–TPP complexes is still urgently needed.

Little work has been done on the quantitative determination of trace metals. The scheme for the determination of metals has two essential points: quantitative chelation of the metal–TPP complexes at the microgram level and separation and measurement of the metal chelates within a short time. Reversed-phase HPLC is known to be a

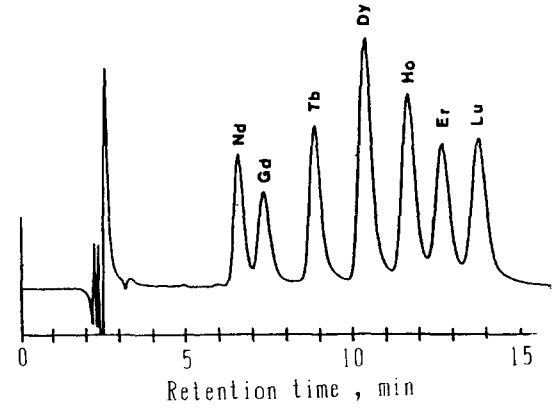

Fig. 3. HPLC separation of RE–TPP complexes. Column, TSK Gel ODS-80TM (150 × 4.6 mm i.d., 5 μm); mobile phase, methanol–water–Hacac–TEA (90:10:0.5:0.68, v/v); flow-rate, 0.8 ml min^{-1}; detection at 555 nm.

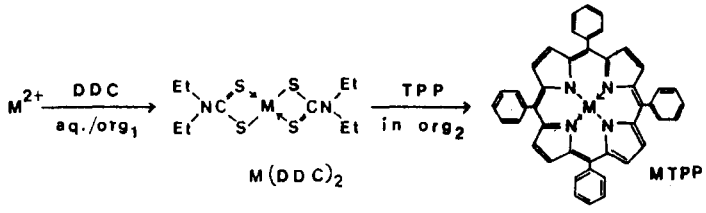
promising technique for the separation of several metal–TPP chelates. Accordingly, the most urgent need is to establish a suitable procedure for the preparation of these chelates. Several methods are available for the preparation of metal porphyrin chelates [32]. However, these are useful on a preparative rather than an analytical scale and the quantitative nature of the reaction has been little studied. Saitoh and Suzuki [33] described procedures for the quantitative formation of TPP chelates of Ni(II), Cu(II) and Zn(II) and the simultaneous determination of these metals in NBS SRM bovine liver. The metal ions were extracted as their diethyldithiocarbamate (DDC) chelates from an aqueous solution into carbon tetrachloride. The extract, after removal of the solvent, was treated with TPP in benzyl alcohol at 140°C for 60 min. Quantitative conversion of the DDC chelate into the TPP chelate was obtained over the range 0.25–4.5 μg of each metal by use of 3 μmol of TPP. The conversion procedure may be demonstrated as follows:



Saitoh and Suzuki's extraction step with DDC not only facilitates metal–TPP chelate formation but also pre-separates the metal ions of interest from a complicated real sample. However, the extraction and conversion procedure is complicated and time-consuming. Accordingly, a high level of operator skill is required to minimize the loss of metal ions during the sample preparation procedure. It appears that an easier procedure for the formation of metal–TPP chelates is needed.

After the extraction and conversion step, TPP and its Ni(II), Cu(II) and Zn(II) chelates were separated on a LiChrosorb RP-18 column (250 × 4 mm i.d. 7 μm) with acetone–acetonitrile (40:60, v/v) as the mobile phase. The flow-rate was 1.3 ml min^{-1} and the eluates were detected at 412 nm.

Liu and Huang [34] reported another feasible procedure for the quantitative formation of TPP chelates with Cu(II), Pb(II), Zn(II) and Cd(II). First, the metal ions reacted with TPP in *N,N*-dimethylformamide (DMF) at 100°C for 25 min with solid NaOH as catalyst. After the solution had cooled to room temperature, pure benzene was used to extract the MTPP chelates from the DMF solution.

The HPLC separation was achieved on a Micropak MCH-5 column (150 × 4 mm i.d.). The mobile phase was methanol–water–chloroform (94:1:5, v/v) and the eluates were detected at 425 nm. The detection limits were 0.04 ng for Cd(II), 0.16 ng for Pb(II), 0.20 ng for Cu(II) and 0.005 ng for Zn(II). The method was applied to the determination of metal ions in electroplating waste liquor and tin alloy.

From the papers that have been published on the HPLC of TPP chelates, we can see that most research work has been focused on the retention behavior of the chelates from theoretical viewpoints. As the TPP reagent is insoluble in water, the quantitative formation of the TPP chelates is difficult to achieve. Thus the application of the HPLC determination of metal ions with TPP as chelating reagent is limited.

2.2.2. TTP

Kobayashi et al. [35,36] investigated the migration behavior of metal–TTP complexes in HPTLC systems with cellulose, silica gel and octadecyl-bonded silica gel thin layers. Although the central metal atom is small in size relative to the porphyrin molecule and accordingly it is surrounded by the large cyclic organic structure of porphyrin, the mobility of metal–TTP complexes depends considerably on the central metal ion. It is considered that the central metal of a TTP complex influences the π-electron system of the metalloporphyrin with which the polar adsorbent

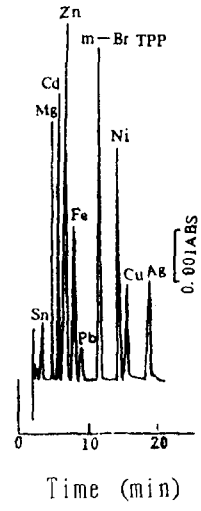


Fig. 4. Chromatogram of metal–*m*-BrTPP complexes. Column, YQG-C_{18} (150 × 5 mm i.d., 5 μm); mobile phase, methanol–acetonitrile (65:35, v/v); flow-rate, 1.0 ml min^{-1} and 3.0 ml min^{-1} after Pb has eluted; detection at 420 nm; sensitivity, 0.05 a.u.f.s; injection volume, 20 μl containing 10 ng Mg and Zn, 55 ng Cd and Fe, 65 ng Sn, 80 ng Ni, 85 ng Pb, 130 ng Cu and 145 ng Ag.

interacts. From the work of Kobayashi et al., we can conclude that a C_{18}-silica plate with a non-aqueous eluent is more convenient and effective for the separation of metal-TTP complexes.

On the basis of the HPTLC studies, Kobayashi et al. [37] successfully separated the TTP complexes of Mg, VO, Ni, Cu, Zn and Pd in about 10 min on a LiChrosorb RP-18 column (250 × 4 mm i.d., 7 μm) with acetone–acetonitrile (70:30, v/v) as mobile phase at a flow-rate of 1 ml min^{-1}; detection was achieved at 420 nm.

The above work has further confirmed the feasibility of the reversed-phase separation mode using a non-aqueous solution as mobile phase for the separation of metal chelates with water-insoluble porphyrins.

2.2.3. *m*-BrTPP

Cheng et al. [38] synthesized *m*-BrTPP and for the first time used it as chelating reagent for the reversed-phase HPLC separation and determination of Sn, Mg, Cd, Zn, Fe, Pb, Ni, Cu and Ag with a non-aqueous mobile phase. The chromatogram is shown in Fig. 4. This method can determine more metal ions than any other HPLC method using porphyrins as chelating reagents. It is unfortunate that these authors did not apply their method to the determination of metal ions in practical samples.

2.2.4. THPP

Igarashi et al. [39] described the simultaneous determination of small amounts of Cu(II) and Zn(II) with THPP by HPLC. The chelation procedure is as follows: place a sample solution containing up to 2.0 μg of Cu(II) and Zn(II) in a 100 ml round-bottomed flask and add 5 ml of ethanol, 1 ml of pH 8.0–8.5 buffer solution and 5 ml of 5×10^{-5} mol l^{-1} THPP ethanol solution. Heat and reflux the mixture for 10 min and allow to cool to room temperature, then dilute to 25 ml with water.

The metal chelates were separated on a Radial Pak C_{18} column (100 × 8 mm i.d.) with ethanol–water (75:25, v/v) as mobile phase; the eluates were detected at 420 nm. The method was successfully applied to the determination of Cu and Zn in tap water; 0.70 ppb of Cu(II) and 91. 5 ppb of Zn(II) were detected.

As THPP is slightly soluble in water, the quantitative formation of the MTHPP complexes can be easily performed in aqueous solution. The HPLC determination can be achieved using the conventional reversed-phase mode.

2.2.5. TMPyP

Igarashi et al. [40] reported on the simultaneous determination of Cu(II), Zn(II) and Pd(II) by HPLC with TMPyP as chelating reagent. The recommended procedure is as follows: place a sample solution containing up to 2.0 μg of metal ions in a 50 ml beaker and add 1 ml of 1×10^{-4} mol l^{-1} TMPyP solution and 2 ml of buffer solution (pH 5.0–7.0). Boil the mixture for 30 min, allow to cool to room temperature and then dilute to 25 ml with water.

Separation was performed on a Radial Pak column (silica, 100 × 8 mm i.d.). The mobile phase was H_2O-CH_3COOH (1:1, v/v) containing 0.35 mol l^{-1} of sodium dodecy sulfate (SDS) at a flow-rate of 1.0 ml min^{-1}; the eluates were detected at 430 nm. The peak height calibration

curves for these metal ions were linear in the range 0–0.08 μg ml^{-1}.

2.2.6. TCPP

Igarashi et al. [41] described the simultaneous determination of small amounts of Cu(II), Zn(II), Co(II) and Mn(II) with water-soluble TCPP by reversed-phase HPLC. The procedure is as follows: prepare a sample solution containing up to 1.6 μg of Cu(II), Zn(II), Mn(II) and Co(II) in a 25 ml amber-colored volumetric flask, then add 2 ml of 1×10^{-4} mol l^{-1} TCPP, 0.25 ml of 1 mol l^{-1} pyridine solution, 0.5 ml of 0.1 mol l^{-1} sodium tetraborate buffer solution (pH 9.3) and 1 ml of 1×10^{-4} mol l^{-1} mercury(II) solution. Leave to stand at room temperature for 30 min and dilute to 25 ml with water.

For HPLC, the mobile phase was a 1:1 (w/w) mixture of acetonitrile and acetic acid–sodium acetate buffer solution (pH 3.5) at a flow-rate of 0.5 ml min^{-1}. The column was a Merck CGC glass cartridge of LiChrosorb RP-18 (150 × 3.2 mm i.d., 5 μm). The absorbance was measured at 420 nm. The peak height calibration curves for these metal ions were linear over the range of 4×10^{-8}–1×10^{-6} mol l^{-1}. The method was applied to the determination of Cu(II), Zn(II) Co(II) and Mn(II) in water.

2.2.7. $TPPS_4$

Xu et al. [42] used $TPPS_4$ as a chelating reagent and proposed a new method for the rapid separation and determination of trace amounts of Cu(II), Zn(II), Fe(II) and Mn(II) by reversed-phase ion-pair HPLC. The chelation procedures are as follows: place 0–0.6 ml of standard solution containing Cu(II), Zn(II), Fe(II) and Mn(II) at concentrations of 10 μg ml^{-1} in a 25 ml amber-colored volumetric flask, add 3.0 ml of 1.4×10^{-4} mol l^{-1} $TPPS_4$, 5.0 ml of acetate buffer (pH 4.1), 1.0 ml of 0.01% beryllium II and 2.0 μg of Hg(II) and dilute the solution to 15 ml with water. Heat the solution for 45 min in boiling water, allow it to cool to room temperature and dilute to 25 ml with water.

The chelates were separated on a LiChrosorb RP-18 column (200 × 4.6 mm i.d., 5 μm). The mobile phase was acetonitrile–water (40:60, v/v) containing 8 mmol l^{-1} tetrabutylammonium bromide (ion-pair reagent) and 10 mmol l^{-1} acetic acid-sodium acetate buffer (pH 4.1). The eluates were detected at 420 nm. The chromatogram is shown in Fig. 5.

The authors claimed that the detection limits for Mn, Zn, Cu and Fe were 3.6, 0.93, 0.70 and 1.8 ppb, respectively. This method was successfully applied to the determination of Cu, Zn, Fe and Mn in a standard sample of peach leaves and the analytical results were in agreement with standard reference values.

Similar work was done by Leiet al. [43]. The chelation reaction of $TPPS_4$ with Cu(II), Co(II), Mn(II) and Zn(II) was optimized by catalyzing it with Hg(II) and in the presence of pyridine. For the HPLC separation of the metal ions, the authors employed benzyltriethylammonium chloride as counter ion. They proposed a rapid method for the determination of Cu(II), Co(II), Mn(II) and Zn(II) within 12 min. The detection limits were 0.42, 0.28, 0.23 and 0.09 ppb for Cu, Co, Mn and Zn, respectively.

These authors found that the peak of $CoTPPS_4$ was not good and overlapped that of $MnTPPS_4$ when pyridine was not added to the mobile phase.

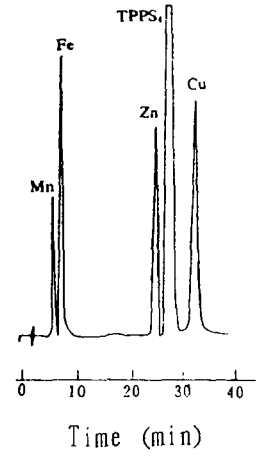

Fig. 5. Chromatogram of $TPPS_4$ and its metal chelates. Column, LiChrosorb RP-18 (200 × 4.6 mm i.d., 5 μm); mobile phase, acetonitrile–water (40:60, v/v), containing 8 mmol l^{-1} TBABr and 10 mmol l^{-1} HOAc–NaOAc buffer (PH 4.1); flow-rate, 1.0 ml min^{-1}; detection at 420 nm; sensitivity, 0.002 a.u.f.s; injection volume, 10 μl.

It was deduced that pyridine participates in the pre-column chelation process. Adding pyridine to the mobile phase can suppress the breakaway of pyridine from $CoTPPS_4$ and make the peak of $CoTPPS_4$ sharp and separated from that of $MnTPPS_4$.

In subsequent papers, Lei and co-workers applied the method to the determination of Cu(II) and Zn(II) in peanuts [44] and Mn(II), Zn(II) and Cu(II) in tea [45].

2.2.8. *m-BrTPPS*$_4$

Xu et al. [46] synthesized a new water-soluble porphyrin reagent, *m*-$BrTPPS_4$, and successfully used it as a pre-column chelating reagent for the determination of Mn(II), Fe(III), Zn(II), Pd(II) and Cu(II) by reversed-phase ion-pair HPLC.

The complexes were quantitatively formed according to the following procedure: add 3 ml of 1.5×10^{-4} mol l^{-1} *m*-$BrTPPS_4$, 5.0 ml of 1.0 mol l^{-1} acetate buffer (pH 4.1), 1.0 ml of 0.01% (w/w) beryllon II and 2.0 μg of Hg(II) to a sample containing Cu(II), Zn(II), Pd(II), Mn(II) and Fe(II), dilute the mixture to about 15 ml and heat the solution in boiling water for 45 min.

For HPLC analysis, a LiChrosorb RP-18 column (200 × 4.6 mm i.d. 5 μm) was employed. The mobile phase was CH_3CN-H_2O (45:55, v/v) containing 2.0 mmol l^{-1} tetrabutylammonium bromide and 10 mmol l^{-1} acetate buffer (pH 5.0), at a flow-rate of 1.0 ml min^{-1}. The detection wavelength was 420 nm. The authors claimed that the limits of detection (20 μl injected) were 160 pg for Mn, 79 pg for Fe, 70 pg for Pd, 36 pg for Cu and 31 pg for Zn.

Xu and co-workers also used *m*-$BrTPPS_4$ as a chelating reagent. For the quantitative determination of metal ions by reversed-phase HPLC, they used tetraethylammonium iodide (TEAI) as counter ion. This method was applied to the determination of trace amounts of Co(II), Zn(II) and Cu(II) in river water [47], tangerine skin and purple rice [48].

2.2.9. *T(4-MOP)PS*$_4$

Xu et al. [49] published a reversed-phase ion-pair HPLC method for the determination of Co(II), Zn(II) and Cu(II) in tangerine skin and purple rice with $T(4\text{-MOP})PS_4$ as pre-column chelating reagent. The chelation procedure was performed as follows: add 0–3.0 μg of Co(II), Zn(II) and Cu(II), 3.0 ml of $T(4\text{-MOP})PS_4$, 2.0 ml of pH 4.0 buffer, 1.0 ml of 0.2% hydroxylamine and 1.0 ml of 0.03% 8-hydroxyquinoline-5-sulfonic acid to a 10 ml colorimetric tube and heat the tube in boiling water for 12 min. A Zorbax ODS column (150 × 4.6 mm i.d., 5 μm) was used with acetonitrile–water (31:69, v/v) containing 0.040 mol l^{-1} TEAI and 0.020 mol l^{-1} HOAc-NaOAc buffer (pH 6.0) as mobile phase at a flow-rate of 1.0 ml min^{-1}. The column temperature was 40°C and the eluates were detected at 418 nm. The complexes and porphyrin were separated within 12 min. The authors claimed that the detection limits for Co, Zn, and Cu were 0.12, 10.12 and 0.35 ng, respectively.

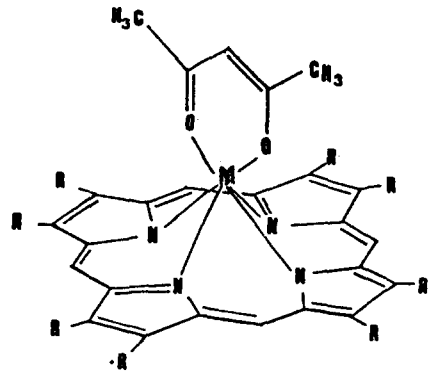

Fig. 6. Structural formula of RE(OEP)(acac) (R = ethyl).

2.3. *Porphyrins with substituents on the pyrrole rings*

2.3.1. *Octaethylporphyrin*

Octaethylporphyrin (OEP) is a kind of water-insoluble porphyrin which has been frequently used as a model porphyrin similarly to TPP in studies relating to porphyrins. In OEP, eight ethyl groups are bonded to eight β-pyrrole positions.

Shibata et al. [50] studied the reversed-phase HPLC behavior of the complexes of OEP with 11 trivalent REs viz., Y, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu, on an octadecyl-bonded silica gel column. The complexes were prepared in the form of RE(OEP)(acac) as shown in Fig. 6.

All these complexes can be eluted without decomposition with a methanol–water mixture that contains a small amount (about 1%) of acetylacetone (Hacac) and an amine. A amine added to the mobile phase with a small amount of Hacac functions as a base which enhances the stability of the RE(OEP)(acac) complexes and accordingly suppresses their undesirable adsorption on the stationary phase material. The second useful function of the amine is with regard to the selectivity and the elution sequence for the RE-OEP complexes. The retention selectivity depends on the amine used. The effect of dialkylamines in particular on the retention sequence of RE-OEP complexes is different from that for RE–TPP complexes [30].

OEP has not been used for the quantitative determination of rare earth elements owing to the difficulty of chelate formation. More research work should be focused on the quantitative formation and determination of RE–OEP complexes.

2.3.2. Hematoporphyrin IX (Hp)

Hp is well known as the first porphyrin to be isolated from natural materials. Hp and its metal complexes have been of increasing interest from the medical point of view because of their usefulness in the diagnosis and chemotherapy of malignant tumors [51–53]. The general structure of a metal (II)–Hp complex (MHp) is illustrated in Fig. 7.

Suzuki et al. [54] described the behavior of Hp and its complexes with Ni(II), Cu(II) and Zn(II)

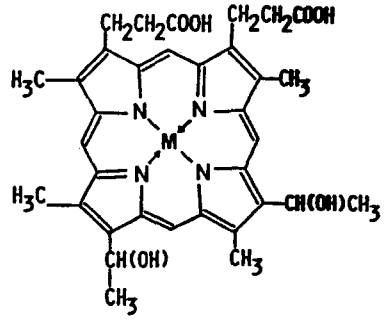

Fig. 7. Structural formula of a metal(II)–hematoporphyrin IX complex.

in a reversed-phase system. These four compounds were successfully separated within about 8 min on a Lichrosorb RP-18 column (250 × 4 mm i.d.) with methanol–phosphate buffer (pH 3) (85:15, v/v) as the mobile phase, at a flow-rate of 1 ml min^{-1}. The elution of the compound was monitored spectrophotometrically at 398 nm. The retention order was ZnP < (Hp) < NiP < CuP. This metal order with respect to the increase in retention is comparable with those observed for metal complexes of porphyrins more hydrophobic than Hp, such as TPP, TTP and porphine, on LiChrosorb RP-18 column with a non-aqueous polar mobile phase.

It was suggested that the retention order of the central metals of the metal porphyrin complexes shown above would be valid for various metalloporphyrins irrespective of whether the porphyrin ligand contains hydrophobic functional groups. It is unfortunate that the authors did not apply their method to the quantitative determination of metal ions.

3. Conclusions

Because of the widespread occurrence and biological importance of metalloporphyrins in plants and animals, the chemistry of these compounds are of interest to workers in a variety of fields. Porphyrins are attractive from the analytical point of view because of their very high molar absorbance. The main problem in utilizing a porphyrin as a chelating reagent for the HPLC determination of metal ions is that the formation of the metal chelates is often difficult. To enhance the rate of metalloporphyrin formation, the following procedures have been employed: (i) heating; (ii) the use of reducing agents such as hydroxylamine and ascorbic acid; (iii) addition of an aromatic heterocyclic base such as pyridine and imidazole; (iv) the use of a substitution reaction with cadmium or mercury porphyrins; (v) the use of porphyrins with substituents at the pyrrole nitrogens; and (vi) the introduction of functional groups binding metal ions in the vicinity of the porphyrin nucleus.

Among the porphyrin compounds, the water-insoluble type are relatively easy to synthesize in reasonable yields. As they are not soluble in water, the preparation of metal chelates cannot be accomplished in aqueous solution and complicated extraction procedures are often needed. Moreover, the porphyrins and their metal chelates are not easy to separate using the conventional reversed-phase HPLC mode. From papers that have been published on the separation of water-insoluble metalloporphyrins, we can see that non-aqueous reversed-phase HPLC has been employed by most workers.

Water-soluble porphryins are relatively difficult to synthesize and the yields are much lower, but their solubility in water makes it easy to prepare metal chelates in aqueous solution and the metal chelates can be separated by ion-pair reversed-phase HPLC. However, water-soluble porphyrins are usually synthesized by binding hydrophilic groups with water-insoluble porphyrins, thus making the molecule large and difficult to separate on a normal column.

To solve the above problems, more research work should be conducted. The following are the aspects that should be addressed in the future:

(i) study of easier procedures for the preparation and purification of porphyrins;

(ii) synthesis of new porphyrins which have superior chromatographic properties and high sensitivities;

(iii) study of new methods for the quantitative formation of metal porphyrin chelates, with special attention to the quantitative reaction of water-insoluble porphyrins with metal ions in aqueous solution;

(iv) extension of HPLC to the determination of more metals as their porphyrin chelates;

(v) application of porphyrins to speciation studies;

(vi) application of published methods to the determination of metal ions in practical samples; and

(vii) enhancement of the application of HPLC to the separation and determination of naturally occurring complexes.

Renewable liquid film-based electrochemical sensor for gaseous hydroperoxides

Huiliang Huang, Purnendu K. Dasgupta *

Department of Chemistry and Biochemistry Texas Tech University, Lubbock, TX 79490-1061, USA

Received 16 July 1996; received in revised form 16 August 1996; accepted 16 August 1996

Abstract

Electrochemical sensors for hydroperoxides based on thin flowing films were investigated. The sensor is composed of two segments of Nafion tubing put on a silver wire. A small portion of the silver wire is exposed and is chloridized to function as the reference electrode. One Nafion segment has a Pt-wire coil wrapped on it to function as the counter electrode and the other has a similar Pt-Rh wire coil that functions as the working electrode. A collection solution flows as a thin film on the sensor surface and also functions as the collection medium. Hydrogen peroxide and cumene hydroperoxide were examined as test compounds. The former can be oxidatively determined with a Pt-Rh electrode over a large range (ppb–ppm) without any significant influence of relative humidity. By using a technique to stop the liquid flow, the sensitivity can be further improved. Cumene hydroperoxide, an industrially important hydroperoxide, can be determined easily with a relative precision of better than 5% in the vapor phase over simulated process reaction mixtures containing percentage levels of the analyte by reduction on a Pd electrode. The sensor is simple and inexpensive to fabricate and requires only a suitably equipped personal computer for operation. © 1997 Elsevier Science B.V.

Keywords: Electrochemical sensor; Hydroperoxides; Renewable liquid film

1. Introduction

In recent years, we have been fascinated by utility of small liquid drops and thin films for sample collection in biphasic systems, such as the collection of a gaseous analyte or solvent extraction, with analysis either in situ or on-line [1–7]. While much of this work has focused on the use of optical detectors, is was realized from the inception [1] that electrochemical detection should provide a very powerful means of in situ detection in these systems. Liquid drops and films have had a long history in electrochemistry in particular, the recognition that falling drops continuously provide a highly reproducible and renewable surface led to the dropping mercury electrode (DME) [8]. The invention of the DME ushered in the modern era of instrumental analytical methods and resulted in the 1959 Nobel Prize in Chemistry, the first related to instrumental analysis [9].

The DME itself operates best in the analytical concentration range 10^{-3}–10^{-5} M. Below an analyte concentration of 10^{-5} M, the background current becomes comparable with the diffusion

PII S0039-9140(96)02069-3

current due to the analyte, thus restricting any further improvement in the limits of detection (LODs) in classical polarography. On the other hand, if a renewable liquid film is made to cover conventional metallic electrodes, it may be possible to determine much smaller analyte concentrations in the liquid. Mercury film electrodes, for example, have been extensively used to improve sensitivities and detection limits over those attainable with conventional solid electrodes [10–14], although the stability of such electrodes may be a problem [15]. Looking at more conventional liquids for forming a film for electrochemical sensing, if the liquid film is of suitable composition, such a film can be used for the collection of gaseous analytes, with the film serving as a miniature sampler/preconcentrator. If the analytes collected into the film are electroactive, electrochemical sensing would be simple and attractive.

Hydrogen peroxide is an important atmospheric oxidant [16] and we have been interested in the atmospheric measurement of H_2O_2 for some time [17,18]. Hydrogen peroxide is also used as a sterilizing agent in bioreactors and for safety reasons it is desirable to have a means for monitoring residual concentrations after sterilization has been completed. Hydroperoxides (of which H_2O_2 is the simplest member) are reactive oxidants that are electroactive. Some organic peroxides are also industrially important as polymerization initiators and cross-linking agents, dicumenyl peroxide (DCP) being particularly important [19]. DCP is typically produced from cumene hydroperoxide ($CumHO_2$). A typical reactor mixture may contain an aromatic alcohol (such as phenylpropan-2-ol) or phenol, a ketone such as acetone or acetophenone and cumene. $CumHO_2$ itself may also be used for the radical polymerization of methacrylates [20] and the acid hydrolysis of $CumHO_2$ to yield acetone and phenol is a major means of production of the latter two compounds, necessitating the use of $CumHO_2$ in quantities of many thousands of kilograms [21]. In a typical industrial application, it may be desirable to control the concentration of $CumHO_2$ at the levels below 10%. Rather than sampling the complex liquid mixture, monitoring the vapor phase in the reactor is an attractive alternative for monitoring the $CumHO_2$ content. Electrochemical sensors for H_2O_2 are well known [22]. In the present work, we explored the utility of a renewable film-based electrochemical sensor for measuring hydroperoxides from low ppb levels of gaseous H_2O_2 to vapor phase $CumHO_2$ present in percentage levels over the liquid.

2. Experimental

2.1. Reagents and materials

A stock solution of 1 M H_2O_2 was prepared from 30% H_2O_2 (Fisher) and standardized by iodimetry [23]. Lower concentrations of H_2O_2 were prepared fresh daily from this stock solution. Nafion tubing (dry dimensions 1 mm o.d., 0.8 mm i.d.) was obtained from Perma-Pure Products (Toms River, NJ, USA). Non-conductive epoxy adhesive was obtained from Decon (Danvers, MA, USA). Platinum, palladium, platinum/rhodium (30%) and silver wires were obtained from Aesar (Ward Hill, MA, USA).

2.2. Instrumentation

Fig. 1 shows a computerized electrochemical analyzer consisting of a potentiostat and a current to voltage converter. An LF353N (National Semiconductor) dual BiFET operational amplifier (A1 and A2) integrated circuit forms the basis of a potentiostat to provide a constant potential for conventional amperometry or a pulsed potential for pulsed amperometry. The A3 amplifier functions as a current to voltage converter to monitor the sensor current. The reference electrode R, the counter electrode C and the working electrode W in the electrochemical sensor S are connected to the non-inverting input of A2, the output of A1 and the inverting input of A3, respectively. The rotary switch P selects the feed back gain resistor (10 KΩ–10 MΩ). An 80486 class PC operating at 33 MHz is interfaced with the electronic circuit via a 12-bit A/D–D/A board (Flash-12 high speed analog and digital I/O card, Strawberry Tree, Sunnyvale, CA, USA) for controlling instru-

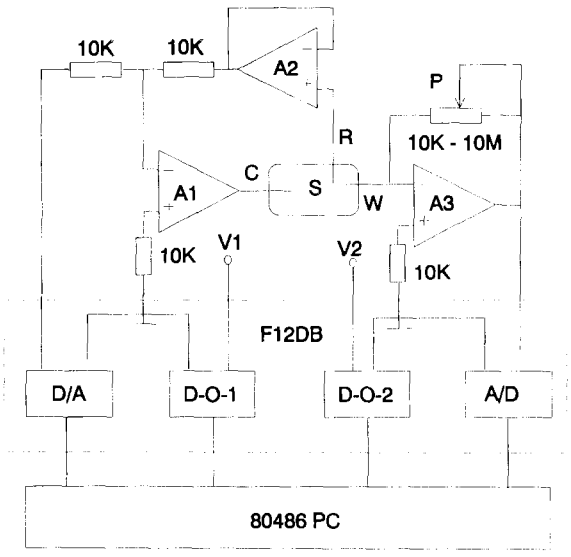

Fig. 1. PC-based electrochemical detection system. A1–A3 = FET-input operational amplifier; S = sensor (C, R, W = counter, refernece and working electrodes); F12DB = Flash-12 and daughter board housing D/A and A/D units and digital output-controlled relays (D-O-1, D-O-2) that govern valves V1 and V2.

ment operation and data acquisition. The digital to analog converter (D/A) can generate a constant voltage for amperometric measurements or any desired pulsed waveform for pulsed amperometric measurements. The analog to digital converter (A/D) acquires data from the A3 output. The digital outputs D-O-1 and the D-O-2 provide independent means for controlling valves V1 (see Fig. 2) and V2 (valve for stopping liquid flow, see below). Instrument control and operation are conducted by software written in-house in C and available from the authors on request. The operational details are given below.

2.3. Test arrangement

The sampling manifold and test gas generation device (reactor–simulator) are shown in Fig. 2. All gas flows are metered by mass flow controllers (Model FC-280, Tylan General, Torrance, CA, USA). Compressed house air is fed through a pressure regulator and purified by column C, containing sequential beds of silica gel and activated carbon. The pure air flow is then divided into three streams. One stream, metered through M4 (maximum 500 cm^3 min^{-1}), flows into the gas generator. For H_2O_2, the gas generator is a length of porous hydrophobic membrane immersed in H_2O_2 solution of known concentration; the exit gas is in Henry's law equilibrium with the solution. Details of such an H_2O_2 source are given elsewhere [24]. The exit H_2O_2 concentration is readily computed from published Henry's law data for H_2O_2.

To test the feasibility of monitoring $CumHO_2$ in a reactor that may typically contain 49% phenol, 23% acetone, 15% cumene and 3% $CumHO_2$ by weight, we mimicked this composition in the generating liquid except that acetontirile was substituted for cumene. The amount of $CumHO_2$ was varied by varying the $CumHO_2$ and acetonitrile content, maintaining a constant amount of phenol and acetone. Approximately 150 ml of this liquid was put in a 500 ml capacity Erlenmeyer flask, with the air inlet tube located 1 cm above the liquid surface and the exit tube 1 cm below the silicone-rubber stopper. The gaseous $CumHO_2$ output from this source was stable, but the exact gas phase concentration was not determined.

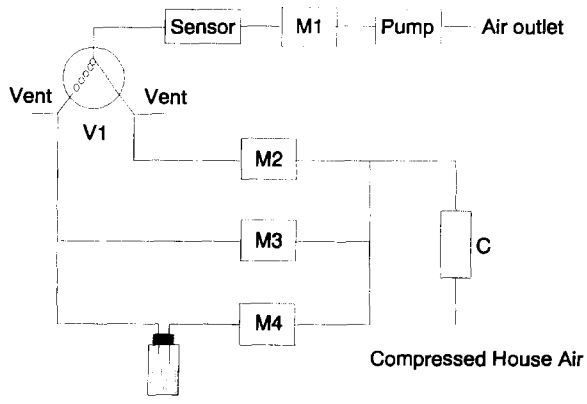

Fig. 2. C = silica gel/activated carbon column for air pruification; M1-M4 = mass flow controllers (M1 controls sampling rate, M2 controls zero (pure) air flow, M3 controls dilution air (may be partially humidified, see text) and M4 controls flow through the test gas generator (depicted as a bottle)); V1 = three-way PFA Teflon solenoid valve.

The exit gas from the generator is diluted by pure dry air metered by M3. The gas concentration generated in the merged stream is thus controlled by choosing an appropriate flow-rate ratio of M4 and M3. The humidity of the test gas was varied by dividing the stream after M3 into two parts and putting a controlled amount through a water bubbler, then recombining the wet and dry streams before addition to the gas generator output. The humidity of the final mixture was measured by a capacitance-type relative humidity probe.

Either the test gas stream or the purified air metered by M2 is selected by three-way perfluoroalkoxy (PF) Teflon valve V (Flouroware, Chaska, MN, USA) to be sampled by the sensor. The gas is aspirated by the air pump P at a flow-rate determined by M1 (1 l min^{-1}, unless stated otherwise). All remaining flow streams are vented.

2.4. Sensor fabrication

Fig. 3 shows the sensor construction. Two 15 mm long segments of Nafion tubing are slipped over a 1 mm diameter silver wire, leaving a 1.5 mm segment of bare silver surface exposed between the two tube segments. The exposed silver is anodically chloridized for 10 min in a solution of 0.01 M HCl. This functions as the reference electrode (RE). A 0.2 mm diameter platinum wire is coiled on to one segment of the Nafion tubing to function as the counter electrode (CE) and a 0.25 mm diameter Pt/Rh (30% Rh) or a Pd wire (127 μm) is coiled on to the other, downstream, segment of the Nafion tubing to function as a working electrode (WE). The assembly is then put into a polypropylene T-fitting T1 (3/32 in 1.8 mm i.d.), leaving the working electrode exposed outside the bottom end of the fitting. Epoxy adhesive is then liberally applied to cover up the top end of the fitting with the electrode connections protruding. Liquid (see below) is pumped by a syringe pump (Model 341, Sage Instruments) through the tee arm and flows as a thin film on the surfaces of the CE, the RE and the WE, forming eventually a drop at the tip of the sensor that periodically falls. The sensing arm of T1 is inserted through a hole drilled into another, larger, tee T2 (6.5 mm i.d.), directly on the top of the vertical arm of the latter. The sample gas enters through both the horizontal arms of T2, connected to a common inlet. The sample is aspirated concurrent to the liquid flow, first coming directly in contact with the film covering the WE. (Because the incoming sample gas directly contracts the bottom Nafion segment, it is advantageous to have the working electrode located on this segment. If the sensor

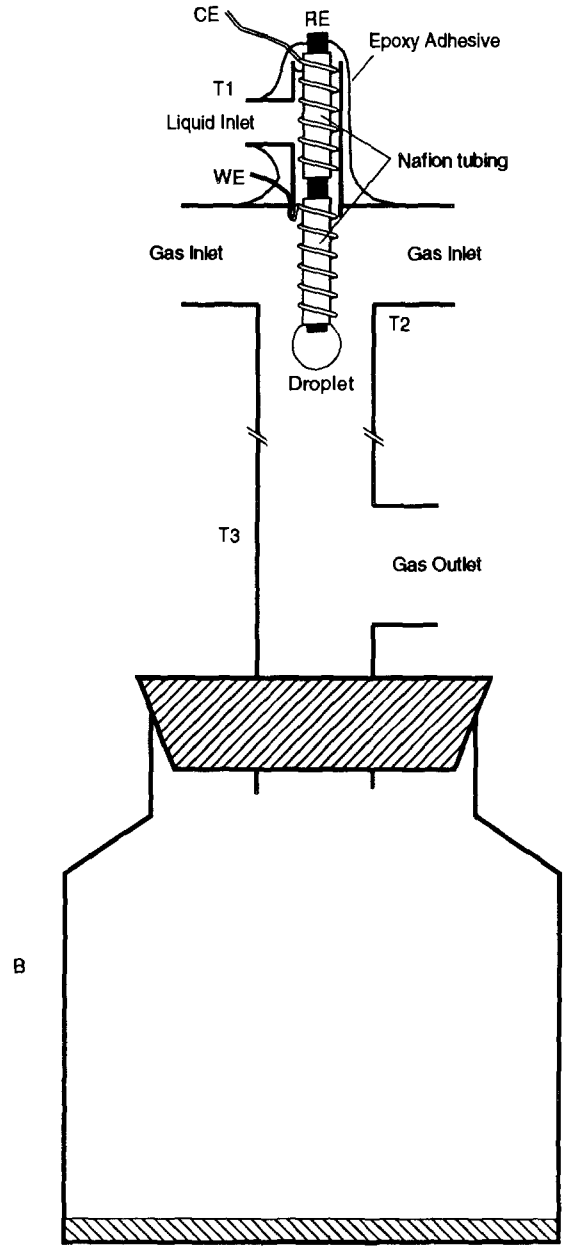

Fig. 3. Sensor arrangement. T1 = sensor tee; RE = reference electrode; CE = counter electrode; WE = working electrode; T2 = gas inlet tee (connected to V1, Fig. 2); T3 = gas outlet tee (connected to M1, Fig. 2); B = waste bottle.

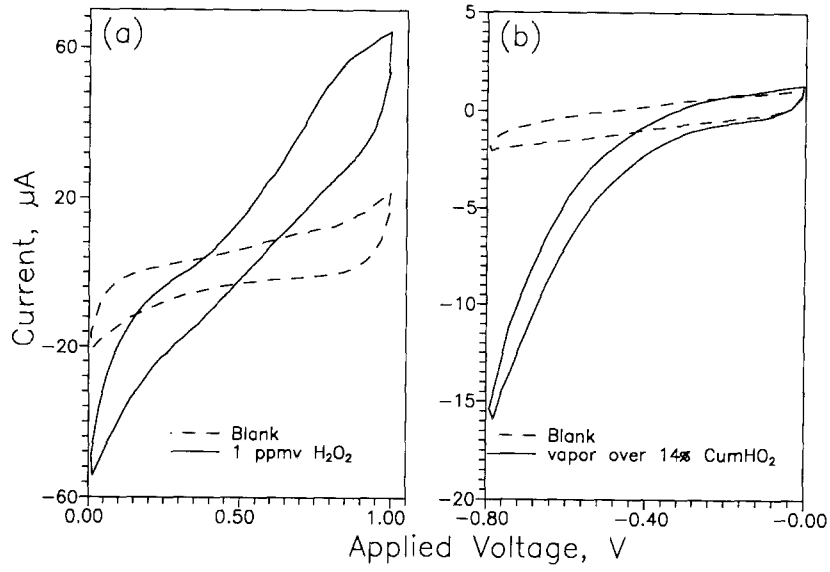

Fig. 4. Cyclic voltammograms of gas phase (a) H_2O_2 and (b) $CumHO_2$. Sensor construction and film composition are indicated in the text. Liquid and gas flow-rates are 15.3 μl min^{-1} and 1 l min^{-1}, respectively.

assembly were to be placed further down T1 such that the entering sample gas first contacts the top Nafion segment, the working electrode would be best placed on the top segment). Following a short length of connecting PFA tubing, the gas exits at the bottom through another tee T3 while waste liquid is collected in a bottle B.

3. Results and discussion

3.1. Sensor parameters

H_2O_2 can be determined either by oxidation to O_2 or reduction to water, while other hydropeoxides are determined by reduction. In atmospheric samples, to avoid interference from other concurrently present oxidants, H_2O_2 is preferably determined by oxidation. Sensor parameters that are readily selected include the choice of the electrode material, the film-forming solution and the nature of the reference electrode. In the present work, many combinations of the sensing and counter electrode materials were investigated. For the oxidation of hydrogen peroxide, the best working electrode was found to be Pt/Rh (30% Rh), while Pd was found to be the best electrode material for the reductive determination of $CumHO_2$. Regarding the choice of a reference electrode, a silver/silver chloride electrode is convenient, inexpensive and easily miniaturized. A minimum concentration of chloride is necessary for the electrode to maintain a constant reference potential; this can be accomplished by incorporating some constant concentration of chloride in the film-forming solution.

As a suitable sink for H_2O_2, water itself is sufficient. To promote the formation of a smoothly flowing film, a surfactant such as Triton X-100 (TX-100), 0.3% in concentration, is effective. Thus, for H_2O_2, we use a solution of 0.3% Triton X-100 and 1 mM HCl, the latter providing for a stable reference potential.

Unlike H_2O_2, $CumHO_2$ is very poorly soluble in water. Several water-miscible organic solvents such as acetonitrile, dimethylformamide, dimethyl sulfoxide, ethylene glycol and glycerol, in mixtures with water and salt solutions, were investi-

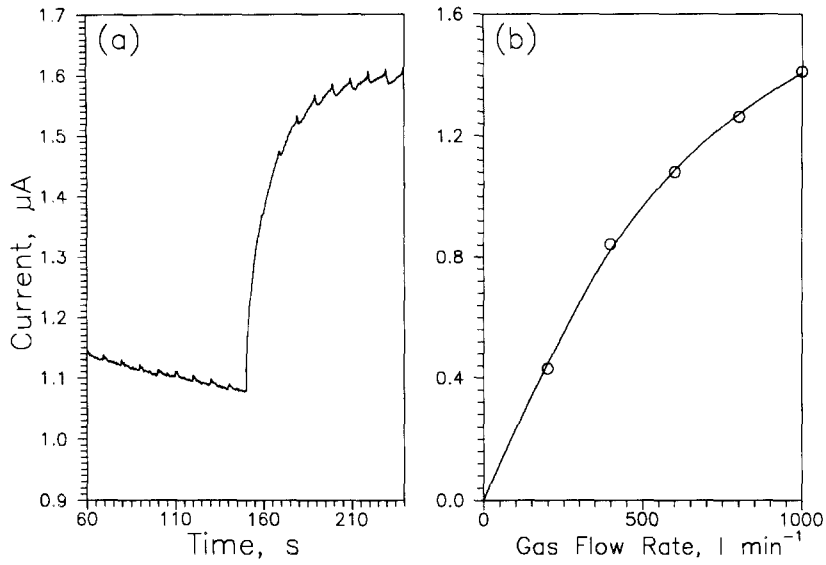

Fig. 5. (a) Sensor output during the sampling cycle, ca. 20 ppbv H_2O_2, flow-rates as in Fig. 4; (b) dependence of the signal on the gas flow-rate, liquid flow-rate 15.3 μl min^{-1}. The solid line is the best fit to Eq. (3).

gated. The best results were obtained with a 30% glycerol–70% saturated $CaCl_2$ solution for monitoring $CumHO_2$. The $CaCl_2$ serves as a humectant.

Fig. 4(a) shows the cyclic voltammogram obtained when 1 ppmv H_2O_2 is sampled in a flowing film of TX-100-HCl. A current plateau is reached above 0.86 V. An applied potential of 0.95 V was therefore chosen for the oxidative determination of H_2O_2. We did not notice any significant interference from common atmospheric gases under these conditions; NO_2 and HCHO produce a response but only when present at very high (ppm) levels, not relevant to ambient air studies.

Fig. 4(b) shows the cyclic voltammogram obtained when $CumHO_2$ is sampled. In this case, the cathodic current continues to increase with increasing cathodic potential within the range tested and never reaches a plateau. Since increasing the cathodic potential much further increases the background current significantly, a potential of −0.80 V was chosen for the reductive determination of $CumHO_2$. All potentials reported are relative to the Ag/AgCl reference electrode in the sensor. Since the two film-forming solutions have different chloride activities, the reference potential is not the same in the two cases.

3.2. Hydrogen peroxide

3.2.1. Sampling cycle and data acquisition

For H_2O_2, valve V1 (Fig. 1) was programmed to switch continuously between zero air and the sample gas for periods of 2.5 and 1.5 min, respectively, thus resulting in a sampling cycle of 4 min. No data were acquired for the first minute, allowing the system to attain a stable zero air response. The background current was then acquired for the next 1.5 min (Fig. 5(a)), at the end of which the valve was switched to the sample gas. The current rose to a stable plateau value over the next 30–60 s and the value for the 210–240 s period was taken to be the sample current. The valve was then switched back to zero air and the cycle repeated. During each sampling cycle, the temporal electrochemical protocol involves pretreating the electrode for 5 s at −0.1 V and then maintaining it at the sensing potential of +0.95 V for the remaining 235 s. The results were interpreted either in terms of current (averaged current

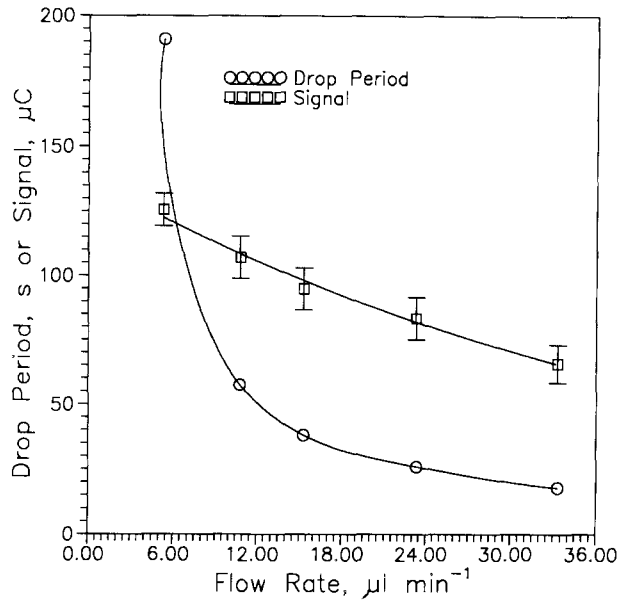

Fig. 6. Decrease in drop period and analytical signal with increasing liquid flow-rate. The collected sample is diluted.

during 210–240 s, less the averaged background current over 120–150 s) or charge (integrated charge in μC, less the background, over the same periods as above). There was no significant difference in the quality of the results using either approach.

3.2.2. Signal dependence on gas flow-rate

With 200 ppbv H_2O_2, the gas flow-rate was varied from 200 to 1000 ml min^{-1}, at a constant liquid flow-rate of 15.3 μl min^{-1}. The analytical signals increased with increasing the gas flow-rate, as shown in Fig. 5(b). When a gas is collected by diffusion to the walls of a tube, the collected fraction f is related to the flow-rate Q by an exponential relationship of the type [25]

$$1 - f = a\, e^{-b/Q} \quad (1)$$

Although the present geometry is not exactly the same, an equation of the same general form should be applicable to the present case. Consider that the total amount of the analyte collected is the product of the flow-rate Q and the collection efficiency f and the analytical signal S should be linearly related to this product, hence

$$f = kS/Q \quad (2)$$

where k is a proportionality constant. Eqs. (1) and (2) can be transposed to the form

$$S = Q(1 - a\, e^{-b/Q})/k \quad (3)$$

The solid line in Fig. 5(b) is the best fit of the experimental data to Eq. (3). The numerical values also suggest that at the lowest sampling rate tested of 200 ml min^{-1}, the collection efficiency is nearly 95%. In other experiments, a gas flow-rate of 1 l min^{-1} was used, except where stated otherwise.

3.2.3. Dependence on liquid flow-rate

With 200 ppbv H_2O_2 sampled at 1 l min^{-1}, the liquid flow-rate was varied from 5.3 to 33.3 μl min^{-1}. The analytical signals and the drop period decrease with increasing liquid flow-rate, as shown in Fig. 6. Both the analytical signal and the drop period are approximately linearly related to

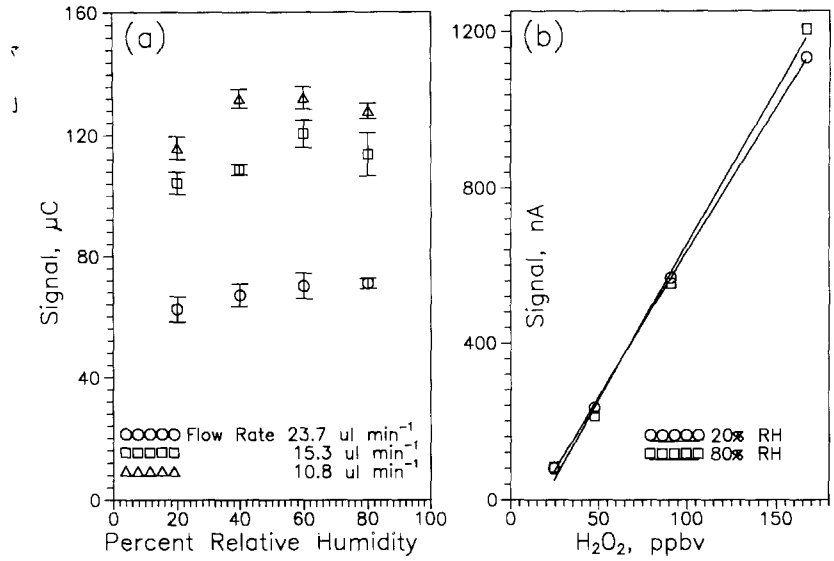

Fig. 7. Effect of relative humidity: (a) signal for 167 ppbv H_2O_2 at three different liquid flow-rates at four different RH levels; (b) calibration plots at 20 and 80% RH showing insignificant difference in slope.

the reciprocal of the liquid flow-rate. At high liquid flow-rates, the linear relationship holds well, but at low liquid flow rates, the signal or the drop period begins to increase more than linearly with decreasing flow-rate, as evaporative losses become important. Unless stated otherwise, a liquid flow-rate of 15.3 μl min^{-1} was used in the experiments.

3.2.4. Effects of relative humidity (RH)

The effects of RH on aqueous drop- or film-based sensors can be very important [1,4]. The present sensor showed no major dependence on RH. Fig. 7(a) shows signals obtained at four different relative humidities for a 167 ppbv H_2O_2 sample at three different liquid flow-rates. At the highest liquid flow-rate (lowest signal levels), the effect of evaporation is the least prominent and the signal is essentially constant over the RH range tested. Even at the other liquid flow-rates, the scatter in the data is larger but there is no consistent RH effect. A calibration plot was conducted at 20 and 80% RH over the range 24–167 ppb H_2O_2. These data (Fig. 4(b)) show virtually identical calibration plots, with no significant difference between the calibration slopes.

3.2.5. Analytical range

The sensor was calibrated for its response in the range 12–200 ppbv H_2O_2. The response was linear with concentration and followed the equation

$$\text{signal}(\mu C) = 0.42[H_2O_2, \text{ppbv}] + 13.66 \quad (r^2 = 0.9988) \quad (4)$$

Based on experiments conducted at 12 ppbv H_2O_2, the estimated LOD at a signal-to-noise ratio of 3 is ≤ 2 ppbv. Although atmospheric H_2O_2 levels frequently exceed this value, it would be desirable to improve upon this LOD for routine use. In the same manner that a hanging mercury drop electrode or an electrode bearing a thin mercury film provides better analytical sensitivity than that attainable with a DME, by stopping the liquid flow during sampling to form a stationary film (and thereby to increase the analyte concentration), one can dramatically improve the sensitivity. Stopped-flow experiments were conducted using gravity-induced liquid flow (at

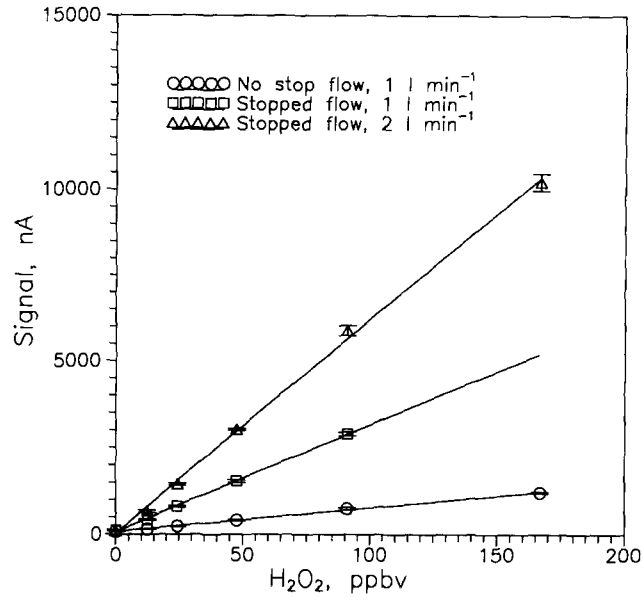

Fig. 8. Improvement in sensitivity by using stopped flow, especially at high gas sampling rates. (○) Response under conventional conditions, gas sampling rate 1 l min^{-1}; (□) response with the liquid flow stopped; (△) response under stopped-flow conditions with a gas sampling rate of 2 l min^{-1}.

ca. 50 μl min^{-1}) during the zero air sampling period and stopping the liquid flow altogether by means of a solenoid valve (V2 in Fig. 1) when the test gas was sampled. Fig. 8 shows calibration plots (at 50% RH) for: (i) normal conditions, liquid flow and gas flow 15.3 μl min^{-1} and 1 l min^{-1}, respectively, sensitivity 6.9 nA $(ppbv)^{-1}$; H_2O_2; (ii) stopped liquid flow, gas flow 1 l min^{-1}, sensitivity 31.2 nA $(ppbv)^{-1}$; and (iii) stopped liquid flow, gas flow 2 l min^{-1}, sensitivity 61.8 nA $(ppbv)^{-1}$. There is nearly an order of magnitude increase in sensitivity on going from operating mode (i) to (iii). The long-term stability of the sensor was studied with 167 ppbv H_2O_2. Over a ca. 8 h period (108 measurements), the relative standard deviation (RSD) was 2.7% under experimental mode (i) above, obviously, this includes not only the imprecision of the sensor but also that of the source output and all the other associated flow/temperature control systems. The measurement precision was slightly worse for experimental protocol (iii): over a period of ca. 10 h ($n = 137$), the RSD was 4.7%.

3.3. Cumene hydroperoxide

In this case, the output of the gas generator was continuously monitored using an electrochemical protocol in which the sensor was alternately cleaned at a potential of +0.1 V for 0–5 s and then maintained at the sensing potential of −0.8 V for 5–−95 s. The current was recorded for the period 65–95 s during each cycle. The response of the sensor to the $CumHO_2$ content of the simulated reaction mixture was highly linear:

$$\text{signal}(\mu C) = 10.54 \pm 0.18[CumHO_2, \%] + 33.79 \pm 1.46 \quad (r^2 = 0.9984) \qquad (5)$$

The precision of the data also indicated that such would readily provide a means for process

monitoring of $CumHO_2$ in a reactor at the 2.5% level with a relative precision of better than 5%.

4. Conclusion

We have demonstrated that in situ electrochemical sensing is a simple and sensitive complement to the drop- or film-based collection of analyte gases and vapors. The technique is obviously not limited to any given electrochemical sensing technology, or to any particular collection liquid. It should be possible to extend the approach to any biphasic system, e.g. in a liquid–liquid system where the film-forming liquid is different from and is immiscible with the liquid constituting the analyte matrix. In general, we believe that this general concept has great potential utility for the sensing of gases.

The ionic product of water in concentrated tetramethylammonium chloride solutions

P. Sipos *, I. Bódi [1], P.M. May, G.T. Hefter

Abstract

The ionic product of water, $pK_w = -\log[H^+][OH^-]$ has been determined in aqueous solutions of tetramethylammonium chloride over the concentration range of 0.1–5.5 M at 25°C using high-precision glass electrode potentiometric titrations. pK_w data relating to aqueous potassium and sodium chlorides at ionic strengths up to 5 M are markedly lower than the tetramethylammonium chloride results. These differences are almost certainly due to weak associations between potassium and (especially) sodium and hydroxide ions. © 1997 Elsevier Science B.V.

Keywords: Ionic product; Tetramethylammonium chloride solutions; Water

1. Introduction

Tetraalkylammonium salts, such as tetramethylammonium chloride (TMACl) are widely utilised as background electrolytes for solution speciation studies, mostly in bioinorganic chemistry and in the study of ion-selective electrodes [1]. This is because the tetraalkylammonium cations are expected to have little complexing ability. This 'inertness' makes them suitable as background electrolytes for studying interactions such as ion-pairing which despite being weak, can be of considerable importance in concentrated electrolyte solutions.

Thermodynamic characterisation of highly concentrated aqueous electrolytes is of interest in understanding and simulating the behaviour of seawater, geological brines and many industrial process streams [2,3]. Of all the reactions in aqueous solution the ionization of water

$$H_2O = H^+_{(aq)} + OH^-_{(aq)}$$

is undoubtedly the most important. Accurate values of the ionic product of water, $pK_w = -\log[H^+][OH^-]$, are essential for determining formation constants of most other reactions especially those occurring at relatively high pH. As noted in a recent paper from our laboratories [4] the value of pK_w tends to be rather poorly characterized at very high ionic strengths in most electrolyte solutions.

Osmotic coefficients for aqueous solutions of different alkylammonium salts at 25°C have been systematically measured over a wide range of concentrations [5–7], whereas the corresponding pK_w data are scarce. As a minor part of a theoretical study [8], Lucas compared measured and calculated pK_w data in aqueous TMACl but provided almost no details about the experimental technique employed. Anderegg [9] has reported pK_w 14.11 at 20°C corresponding to 13.96 at 25°C in 1 M (TMACl) which is significantly different from that of Lucas (13.88). These observations clearly indicate a need for the systematic measurement of pK_w in TMACl over a range of ionic strength. Accordingly this paper describes the determination of the ionic product of water by glass electrode potentiometry in aqueous TMACl solutions over the concentration range 0.10–5.50 M at 25°C.

2. Experimental

2.1. Materials

TMACl (Sigma-Aldrich, 97% pure) was used as received for some experiments (see below) or was recrystallised from dry analytical grade ethanol and dried in vacuo at room temperature. The titrant was either NaOH (made from pellets, analytical grade, Ajax, Australia) or TMAOH (nominally 25 w/w% aqueous solution, analytical grade, Sigma-Aldrich). The carbonate content of the base solutions was minimised by adding solid CaO (0.5 g, analytical grade, Ajax) to the titrant solution (250 ml) which contained the necessary amount of NaOH or TMAOH (~ 0.1 M) and TMACl. The solution was agitated for at least 48 h in an airtight Pyrex glass container and then filtered on a supported membrane filter (0.45 μm). The calcium content of the solutions was measured and checked by ICP AES and was found to be less than 1 ppm. Gran-analyses of the glass electrode potentiometric titrations indicated that the resulting base solutions were practically carbonate free (accounting for less than 0.2% of the total alkalinity). The acid solutions were prepared from commercial volumetric ampoules (BDH Convol).

2.2. Apparatus and procedure

The ionic product of water in TMACl was determined by potentiometric titration of HCl (0.0400 M) dissolved in TMACl ($c - 0.04$)M with both TMAOH and NaOH (0.1 M) in TMACl (c). Measurements were performed at ionic strengths of $0.10\ \text{M} \leq c \leq 5.50$ M. At $c < 0.50$ M the measurements were of poor reproducibility (probably due to unsteady liquid junction potentials between the salt bridge and the test solutions) so these results should be regarded as less reliable than the values at $c \geq 0.50$ M. Nevertheless, even at these low ionic strengths the trend of the curve is reasonably consistent with both our other data and the values for NaCl and KCl media. The titrations were performed using glass (Metrohm, model 6.0101.000) and Ag/AgCl electrodes (of in house construction [10]) in a standard jacketed glass cell using the high precision automated titration system previously developed in our laboratories [10–12]. The solutions were blanketed by high purity nitrogen delivered through a carbon dioxide trap and a presaturator containing the TMACl concentration of interest. The burettes (calibrated precision 0.1%) were Metrohm 665 Model Dosimat units driven by an IBM microcomputer. All volumetric glassware was grade 'A' and calibrated. The cell emf was measured to ± 0.1 mV by high impedance digital voltmeters of in-house construction, connected to the computer. The temperature in the cells was maintained at 25.0 ± 0.02°C by use of a circulator thermostat (Heto Model 04 PT 623). Temperatures were periodically checked with a calibrated ITS 90 platinum resistance thermometer.

The titrations involved measuring the potential of a cell that may be represented schematically as (at the beginning of the titration)

$$\text{Ag|AgCl(s)|NaCl(aq)(5 M)}\,\|_{E_{j1}}\,\text{NaCl(aq)(5 M)}\,\|_{E_{j2}}$$

$$\text{HCl(0.04 M), TMACl}(c - 0.04)\text{M|GE}$$

where GE represents a hydrogen ion responsive glass electrode and E_{j1} and E_{j2} are liquid junction potentials. Following considerations previously presented [4], the relationship between the cell potential and the hydrogen ion concentration at 25°C is

where $E^{0\prime}$ is the formal cell potential.

3. Results and discussion

The titrations were carried out over the pH range of 1.5–12.0. At least 4 and usually 8, titrations were performed at each individual ionic strength. The titration curves were evaluated by means of the ESTA library of computer programmes [13–15]. Computer simulation of the titration data routinely consisted of the following steps.

(1) Calculation of Gran-plots for a given group of titrations gave the base concentration (which was then used without further optimisation), the estimated level of carbonate (or other weak acid or base) contamination and the general condition of the electrochemical cell (in terms of linearity of the plots), in this way the best sets of data were selected.

(2) Least-squares analyses of the emf data given by Eq. (1) were then carried out with respect to either the values of the potential (to obtain an estimate of the formal potential) or of the concentration of the H^+ ions (to obtain an estimate of pK_w), the results of these optimisations are summarised in Table 1 and Fig. 1.

(3) Simulations were carried out to calculate the likely magnitude of the real errors in the equilibrium constants using our standard Monte Carlo error analysis (Table 1).

Initial titrations using TMACl and TMAOH as supplied, revealed two artifactual protonation steps in the pH-range of 6–10 associated with ill-defined equivalence points. These effects became larger as the ionic strength increased and presumably correspond to minor amounts of sec-

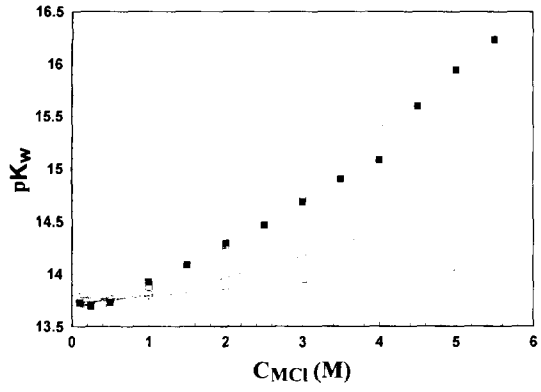

Fig. 1. The ionic product of water, pK_w, as a function of the ionic strength: tetramethylammonium chloride (■: present data; □, Ref. [8]). NaCl (△, Ref. [4]) and KCl (○, Ref. [4]).

ondary and/or tertiary amine impurities that are expected to be the main contaminants in quaternary ammonium compounds. Recrystallization of the TMACl eliminated the main discrepancy (the 'extra' inflexions virtually disappeared). Subsequent Gran-analyses showed that minor proton active substances (accounting for up to 0.5% of the total alkalinity) were still present. These most probably stem from the TMAOH stock solution and resulted in pK_w values with relatively high standard deviations and objective functions (Table 1). As purification of TMAOH stock solution is experimentally difficult, we decided to use NaOH instead. Although this means that a small fraction ($< 5\%$) of the tetramethylammonium cations is exchanged for sodium ions, this has no practical effect on pK_w particularly at higher ionic strengths. With NaOH as the titrant, the least squares analyses yielded pK_w values with acceptable standard deviations and objective functions (Table 1). It is noteworthy that at $c > 3$ M these characteristics become progressively worse, although still acceptable. This is almost certainly because even repeated recrystallization is unable to sufficiently lower trace impurities and also because of increasing experimental difficulties associated with the manipulation of the highly viscous TMACl solutions. In spite of these complications, there are grounds for confidence that the results are not adversely affected by any significant systematic error since the calculated equilibrium constants (pK_w) and their internal standard deviations are practically the same regardless of the objective function used (ESTA2B tasks OBJT or OBJE) [14].

It is noteworthy that pK_w data relating to aqueous potassium and sodium chlorides at ionic strengths up to 5 M[4] are markedly lower than either of these TMACl results (Fig. 1). These differences are almost certainly due, at least in part, to the weak association between K^+ and (especially) Na^+ and OH^- [2,4,16].

Determination of trace amounts of dipyridamole by stripping voltammetry using a Nafion modified electrode

Zhenhui Wang *, Hongzhong Zhang, Shuping Zhou

Department of Chemistry, Henan Normal University, Xinxiang 453002, China

Received 14 March 1996; received in revised form 26 August 1996; accepted 27 August 1996

Abstract

This paper presents a new method for determination of dipyridamole by anodic stripping voltammetry using a Nafion modified glassy carbon electrode. The stripping peak current was proportional to the concentration of dipyridamole over the range of 1.0×10^{-9}–8.0×10^{-8} M in (pH 1.7) Britton–Robinson buffer with 1 min accumulation. The detection limit has been estimated as 8.0×10^{-11} M with 4 min accumulation. The method has been successfully applied to the determination of dipyridamole in human serum. © 1997 Elsevier Science B.V.

Keywords: Anodic stripping voltammetry; Dipyridamole; Nafion modified electrode

1. Introduction

Dipyridamole[2,6-Bis(diethanolamino)-4,8-di-piperidinopyrimido-(5,4-d)pyrimidine] is a dilatation agent of coronary artery used for the treatment of angina pectoris and myocardial infarction.

Various methods have been employed for the determination of dipyridamole, including spectrotrophotometry [1,2] high-performance liquid chromatography [3,4] and polarography [5]. Zeng et al. have studied the determination of dipyridamole by adsorptive cathodic stripping voltammetry with a hanging mercury drop electrode [6]. The detection limit is 1.0×10^{-9} M with a 5 min preconcentration. However, the electroanalytical method for this drug with a non-mercury electrode has not yet been reported up to now.

This paper describes the determination of trace amounts of dipyridamole in human serum by anodic stripping voltammetry with a Nafion modified glassy carbon electrode. The Nafion film shows an excellent natural barrier to interferences from negatively charged compounds. So, this method exhibits its high sensitivity and selectivity in comparison with the pioneer work [6]. The detection limit of 8.0×10^{-11} M has been estimated with 4 min preconcentration. In addition, the regeneration of the electrode surface is quite easy, and the environmental pollution caused by mercury is also avoided.

2. Experimental

2.1. Apparatus

A Model 79-1 voltammeter (Jinan No. 4 Radio Fctory) equipped with a X-Y recorder (LZ3-104) was used for electroanalytical measurements at a scan rate of 100 mv s^{-1}. A three-electrode system comprises a Nafion glassy carbon working electrode, platinum counter-electrode and Ag-AgCl (saturated KCl) reference electrode. Stirring was performed using a Model Gsp-76-02 magnetic stirrer. Voltammetric studies were performed with a PAR 174A polarography.

2.2. Reagents

A stock standard solution of dipyridamole in ethanol (1.0×10^{-2} M) was prepared and keep in brown volumetric flask. Dipyridamole working standard solutions were prepared daily by serial dilution of the stock standard solution.

Nafion were purchased from Aldrich. The Nafion stock solution was 0.05% absolute ethanol solution.

Trichloroacetic acid: 20% aqueous solution.

All reagents were of analytical-reagent grade quality. Deionized distilled water was used throughout to prepare solutions.

2.3. Preparation of modified electrode

The glassy carbon electrodes (GCE) having a geometric area of 0.126 cm^2 were used to prepare the Nafion modified electrode. The modified procedure was in the following.

The glassy carbon working electrode was polished with 0.05 μm α-alumina particles, ultrasonicated in absolute ethanol and de-ionized distilled water, respectively, and allowed to dry in air. The electrode was then coated with 4 μl of 0.05% (V/V) Nafion solution to cover the electrode surface, dried by infrared lamp. A uniform film was formed over the entire surface. The modified electrode was rinsed with de-ionized distilled water, and then cyclic scanned between 0.0 and + 1.0 V in Britton–Robinson (B.R. pH = 1.7) buffer solution for a few times before use.

2.4. Procedure

A 10 ml volume of (pH = 1.7) B.R. buffer solution containing a suitable amounts of dipyridamole was added to the sample cell. The Nafion modified electrode was kept at the desired accumulation potential for a given time period, while the solution was stirred at about 400 rpm throughout the entire period. The stirring was then stopped and the solution was allowed to rest for 30 s, after which a positive-going scan was initiated at 0.0 V (scan rate 100 mv s^{-1}). The scan was terminated at + 1.0 V, and the second derivative voltammogram was recorded.

2.5. Renewal of electrode surface

After each electrochemical measurement, the electrode was cycled two times between 0.0 and + 1.0 V in B.R. buffer to renew the electrode surface. There should be no peaks in the potential scan range, otherwise the regeneration must be repeated.

2.6. Serum treatment

Pipette 0.50 ml of human serum containing dipyridamole into a 5 ml centrifugal tube, add 0.50 ml of water and 1.00 ml of 20% trichloroacetic acid, mix thoroughly and stand for 2 min centrifuge at 4000 rpm in a high speed centrifuge, transfer 0.10 ml of centrifugal solution on superior layer, then follows the procedure described above.

3. Results and discussion

3.1. Second derivative voltammograms

The derivative technique is a significant advance in linear-sweep voltammetry. The higher the derivative order, the larger the peak current. Therefore, the sensitivity of using second-derivative stripping voltammetry is higher than that of conventional stripping methods [7].

Fig. 1 shows the second-derivative voltammograms for dipyridamole at 4.0×10^{-8} M level

Fig. 1. Second derivative voltammograms for 4.0×10^{-8} M of dipyridamole in B.R. (pH = 1.7) buffer. Accumulation potential: 0.0 V. Accumulation time: 80 s; (a) Nafion modified GCE; (b) GCE.

after 60 s preconcentration at 0.0 V from a stirred B.R. buffer. A larger stripping peak (peak a), which increased linearly with increasing of dipyridamole content, was found at +0.75 V measured with the Nafion modified electrode, and a smaller stripping peak (peak b) was appeared at the similar potential with a bare glassy carbon electrode under the same conditions. The results indicate that the Nafion film enhance the preconcentration of dipyridamole on the electrode surface.

Table 1 shows the results for determination of three concentration levels of dipyridamole with Nafion modified electrode (MGCE) and bare glassy carbon electrode (GCE), respectively.

It can be seen from Table 1 that the lower the determined concentration, the greater the difference of the peak currents. Contrasted the peak currents determined on Nafion modified electrode with the unmodified one, the former greatly improves the sensitivity for determination of trace amounts of dipyridamole.

The effect of the volume of Nafion which added to GCE surface on the peak height was studied. The results showed that the presence of 4 μl 0.05% of Nafion was sufficient for obtaining the maximum current. However, the stripping current is too small to be useful as using a bare glassy carbon electrode for determination of this drug (Fig. 1, curve b). The reproducibility and stability of the electrode were examined in ten parallel determinations. For 4.0×10^{-8} M of dipyridamole with a preconcentration time of 60 s, the relative standard deviation was 3.72%. The result indicates that the Nafion modified glassy carbon electrode has a good reproducibility and stability. The electrode lasted for 1 week at least before it needed remodifying.

3.2. Cyclic voltammetry

In order to understand the electrochemical process occurring on modified electrode, cyclic voltammetry of the system was carried out. Fig. 2 shows the repetitive cyclic voltammograms for dipyridamole stirring accumulation the analyte for 60 s gave a large anodic peak. No peak was observed on the cathodic branch, indicating irre-

Table 1
Comparison results

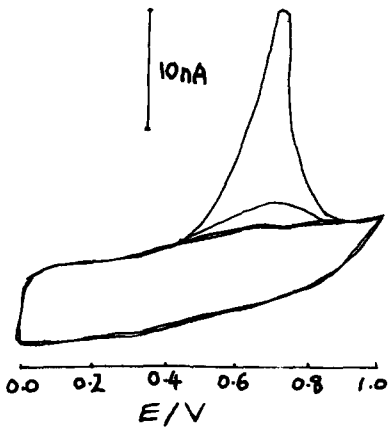

Fig. 2. Cyclic voltammograms for 4.0×10^{-8} M of dipyridamole recorded continuously at the Nafion modified electrode in B.R. (pH 1.7) buffer scan rate 100 mv s^{-1}; accumulation time: 60 s.

versibility of the oxidation. A rapid decrease in the anodic peak was observed in subsequent scans, such behaviour indicated the analyte which accumulated on the Nafion modified electrode surface rapid stripping.

3.3. Selection of experimental conditions

Various supporting electrolytes, such as HCl, H_2SO_4, HNO_3, H_3PO_4, HCl-NaAc, tartaric acid–tartarate, citric acid–citrate, NaOH and B.R. buffer solution were tested in order to optimize the response for dipyridamole at a Nafion modified electrode. The anodic stripping peak of dipyridamole was not found in alkaline and neutral medium. A well-defined and sensitive anodic stripping peak was appeared at $+0.75$ V when B.R. buffer was used as electrolyte. No reduction peak was obtained in the similar experimental conditions.

The solution pH has a strong effect on the stripping response (Fig. 3). For example, increasing the pH from 1.4 to 1.7 results in a sharp increase in the peak current. Further increasing the pH beyond 1.8, a rapid decrease in the response was observed. Therefore, a B.R. buffer solution (pH = 1.7) was selected for maximum sensitivity.

The stripping peak current of dipyridamole is affected by the preconcentration potential. Experiments showed that the peak current was increased with negative shifting of the start potential in the range $+0.4$–0.0 V. The stripping currents appeared stable values as the accumulation potential varied between 0.0 and -0.4 V. As the accumulation potential was beyond -0.4 V, the current signal was depressed, immediately. The selected accumulation potential was 0.0 V.

The stripping peak current increased linearly with increasing accumulation time up to 80 s for 2.0×10^{-8} M of dipyridamole. As the time longer than 90 s, the increment of peak current showed a deviation from linearity, indicating that complete coverage of the Nafion modified electrode was gradually being achieved. The choice of optimum accumulation time depends on the range of concentration studied, and requires a compromise between sensitivity and speed. The chosen accumulation time was 60 s for all further studies. The stripping signal was also affected by surfactants. Experiments proven that cation and neutral surfactants strongly depressed the peak current. The effect of cation surfactant, such as cetyltrimethylammonium bromide (CTMAB) was greater. However, the presence of a suitable amounts of anion surfactant did not affect the stripping signal. It can be deduced that protonated dipyridamole exists as cation form in solution.

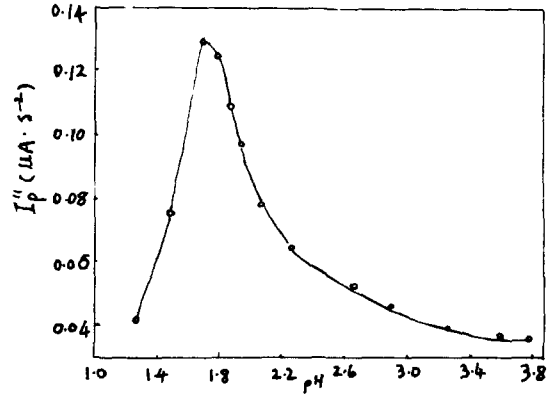

Fig. 3. Reltionship between stripping signal and pH values for 2.0×10^{-8} M of dipyridamole. Other conditions as in Fig. 1.

Table 2
Analytical results[a]

Determined values in human serum (μg/ml)	R.S.D. (%)	Added (μg)	Found (μg)	Recovery (%)
3.78	4.76	0.80	0.81	101
		0.80	0.82	103
		1.60	1.58	98.8
		1.60	1.67	104
		2.40	2.32	96.7

[a] The data were checked identical with the results determined by HPLC ($n = 5$).

3.4. Calibration graph

The serum sample pretreatment step is required owing to high protein content in human serum. In addition, the loss of determined dipyridamole is unavoidable in the process of serum treatment. So it is necessary to prepare the calibration graph in human serum, and the following procedure was described elsewhere [8].

Under the optimum conditions described above, the linear range of peak current versus the concentration of dipyridamole is $1.0 \times 10^{-9} \sim 8.0 \times 10^{-8}$ M (accumulation 1 min) with a correlation coefficient of 0.9998 and a slope of 6.9 nA per 10^{-9} M. the detection limit has been estimated as 8.0×10^{-11} M with 4 min accumulation.

3.5. Effect of foreign ions

Foreign ions were added together with 4.0×10^{-8} M of dipyridamole as in the recommended procedure. Measurement of the stripping signal for each solution was repeated three times and the average values of the three stripping currents were obtained. The relative error was less than $\pm 5\%$. The results showed that 20 000-fold excess of Na^+; 1000-fold excess of K^+; 2500-fold excess of Zn^{2+}; 1200-fold excess of Mg^{2+}; 1000-fold excess of Pb^{2+}; 500-fold excess of Ca^{2+}, Al^{3+}; 200-fold excess of Fe^{3+}, Se (IV); 100-fold excess of Cu^{2+}; 3000-fold excess of Cl^-; 2000-fold excess of PO_4^{2-}; 75-fold excess of I^-; 120-fold excess of gelatin; 1700-fold excess of ascorbic acid; 17-fold excess of albumin; 4-fold excess of dopamine; 16-fold excess of dopamine hydrochloride; 3-fold excess of nor-adrenaline; 9-fold excess of perphenazine; 12-fold excess of DL-tyrosine and DL-serine did not have a substantial effect on the determination of dipyridamole.

3.6. Application

The proposed method was applied to the determination of trace amounts of dipyridamole in human serum. The determination was performed by the standard-addition method. The determination results and recoveries of known amounts of dipyridamole added to serum sample were given in Table 2.

4. Conclusion

The anodic stripping voltammetry at a Nafion modified glassy carbon electrode has been shown to be suitable for the determination of trace amounts of dipyridamole in human serum. The sensitivity is significantly enhanced by accumulation of the drug on the modified electrode surface. Compared with the pioneer work [6], this method not only increases the sensitivity of assay the drug, but also reduces the pollution caused by mercury.

The preconcentration mechanism of dipyridamole at a Nafion modified glassy carbon electrode is probable a cation exchange process between the protonated dipyridamole and the active group of Nafion. The electro-oxidation mechanism is not fully understood. Studies are continuing on the mechanism of the oxidation reaction.

Estimation of cephalosporin antibiotics by differential pulse polarography

G.V. Subba Reddy, S. Jayarama Reddy *

Department of Chemistry, S.V. University, Tirupati-517 502, India

Received 28 May 1996; received in revised form 27 August 1996; accepted 27 August 1996

Abstract

Differential pulse polarographic (DPP) method of determination of cephalosporins has been developed based on the electrochemistry of the azomethine group in the drugs in universal buffers of pH 2.0–12.0. Quantitative measurements were successful in the concentration range of 1.0×10^{-5} M–2.5×10^{-8} M, the lower concentration representing the detection limit by DPP. The described procedure has been applied for the determination of these drugs individually in pharmaceutical formulations and urine samples as well as for simultaneous determination in a single run. © 1997 Elsevier Science B.V.

Keywords: Azomethine; Cephalosporin; Polarographic

1. Introduction

Cephalosporins are widely used in clinical therapy for the treatment of severe infections, because of their convenient antibacterial activity, β-lactamases resistance and pharmacokinetic properties [1–5]. Ceftazidime is known to be not metabolised in body and excreted 80–90% unchanged in active form in urine. Chromatographic [6,7] and spectrophotometric [8] method of determination of cephalosporins has been reported. Electrochemical techniques [9–11] have been widely used for the determination of azomethine containing compounds. In view of the known electroactivity of cephalosporins, application of electroanalytical methods also acquires importance due to their simplicity, selectivity and accuracy in this type of compounds. DPP has been widely used over the years to determine the drugs in pharmaceutical preparations and body fluids [12–19].

Cephalosporins such as Ceftazidime (I), Ceftizoxime (II) and Ceftriaxone (III) having the same >C=N– group with the different environment which have extensive use as antibiotics have not been determined electrochemically.

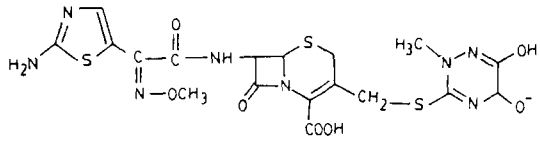
II



III

This communication describes a simple and rapid technique for the determination of the compounds I–III using DPP.

2. Experimental

The compounds (I–III) were obtained from Glaxo India Limited, Bombay. All chemicals used were AnalaR grade reagents. Stock solutions were prepared by dissolving the required quantity of the compound/pharmaceutical formulations in 100 ml pure methanol for getting a concentration of 1 mM (10^{-3} M). The desired concentrations of solutions were prepared by diluting the stock solution with the supporting electrolyte. The supporting electrolytes were prepared by from 0.05 M citric acid, 0.2 M boric acid and 0.1 M tri sodium orthophosphate over the pH range of 2.0–12.0. Aliquots of solutions diluted with supporting electrolyte and deoxygenated with oxygen free nitrogen for 15 min prior to measurements. Urine samples were analysed for drugs without any prior digestion or extraction.

Metrohm E506 polarecord connected to E612 VA-Scanner was used for differential pulse Polarographic experiments. The three electrode assembly consisted of a dropping mercury electrode of an area 0.0324 cm^2 as working electrode and a platinum foil as the auxiliary electrode. pH measurements were made using Elico L1 digital pH meter. All measurements were carried out at 25 ± 1°C.

3. Results and discussion

From the experimental results obtained by DPP, the reduction of the azomethine functional group in all the cephalosporins under investigation is found to proceed in a single step with a four electron addition in pH 2.0–12.0 of universal buffer system. The total number of electrons involved in the reduction process was calculated from the results obtained with millicoulometry [20] and found to be four [21]. The probable general half-reaction is given in: (Scheme 1).

As the pH of the buffer system increased, the peak potentials are found to be shifted towards more negative values within the range of − 0.564– − 1.34 V. In basic buffers of pH > 8.0, the reduction of azomethine is difficult due to non-availability of protons and it is not useful for analytical purpose. The investigated compounds were found to exhibit well resolved peaks which are suitable for the analysis in pH 4.0 and 6.0.

The electrode process for all the three electroactive species are found to be free from adsorption and diffusion controlled in nature which is confirmed through the linear plots of i_m vs. concentration, i_m versus $t^{2/3}$ passing through origin.

3.1. Analysis

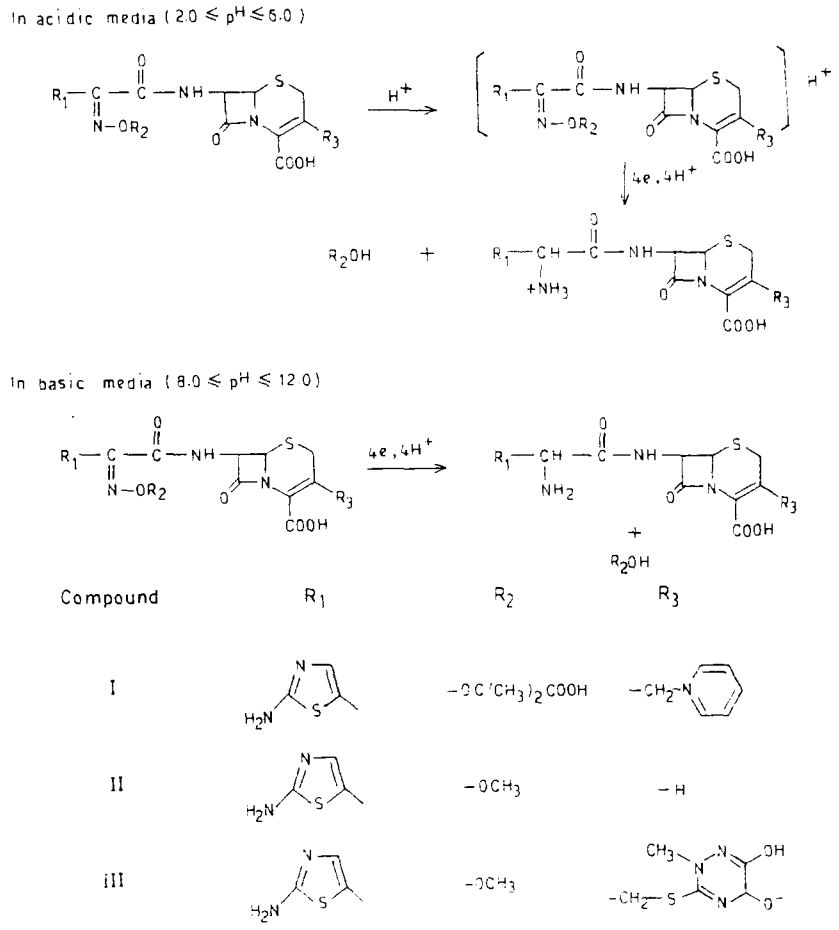
Standard addition and calibration methods were employed for quantitative estimation of the compounds in pharmaceutical formulations and in urine samples. The peak currents vary linearly with the concentration of the drug over the range 1.25×10^{-5} M to 2.5×10^{-8} M with the slope of 0.03 and lower detection limit of 2.4×10^{-8} M. The correlation coefficient and standard deviation were 0.996 and 1.04, respectively. The lower detection limit was calculated using the expression

$$dl = 3\ S.D.\ m^{-1}$$

where S.D. = standard deviation, m = slope of calibration plot.

3.2. Recommended analytical procedure

Standard solutions of the investigated compounds (1.0×10^{-5} M) were prepared in pure



Scheme 1.

methanol. In polarographic cell, 1 ml of standard solution was transferred and made up with 9 ml of the supporting electrolyte (pH 4.0) and then deoxygenated with nitrogen gas for 10 min. After recording the polarogram small increments (0.2 ml) of standard solutions were added and polarograms were recorded after each addition under the similar conditions. The optimum conditions for the determination of cephalosporins in pH 4.0 was found to be a drop time of 2 s, a pulse amplitude of 60 mV and applied potential of -0.608 V, -0.65 V, and -0.72 V with the relative S.D. and correlation coefficient for 10 replicants 1.44, 1.58 and 1.34%, and 0.989, 0.996, 0.954 for I, II, III, respectively. The described analytical procedure was used for the determination of the Ceftazidime, Ceftizoxime and Ceftriaxone in its pharmaceutical formulations.

Tablet and injection formulations containing a nominal 100 mg of any compounds under investigation in a total mass approximately 300 mg were analysed in order to examine the applicability of the method. Not less than 10 tablets/injections were thoroughly ground and mixed. Portions equivalent to 5, 10, 15, 20 and 25 mg of compound were accurately weighed, dissolved in pure methanol and transferred in to 10 ml calibrated flasks. A 0.5 ml aliquot of the clear supernant liquid was diluted to 10 ml with the supporting electrolyte and subjected to polarography. The amount of the compound in portion of the sample taken was calculated by reference to the calibra-

	10.0	09.98	99.92	0.016

tion plot. The assay results for the formulations in pH 4.0 are given in Table 1.

In order to determine, the amount of a particular drug in urine sample, calibration plots constructed in accordance with the limits at which the unchanged drugs are excreted are employed. Different amounts of I were added to a fixed volume of urine. Aliquots of these spiked urine samples were diluted with the supporting electrolyte and the polarograms recorded. The calibration plots ranging from 2.4 to 60 ng ml^{-1} was linear passing through the origin. Using the same procedure calibration plots were constructed for II and III. Using the calibration plot ranging from 2.4 to 60 ng ml^{-1} compound I was determined in urine. The analysis of numerous samples indicates a relative S.D. of 2.0% at the lowest concentration and 1.5% at concentration 8 ng ml^{-1} and higher. II and III were determined in urine with the same concentration range and the relative S.D. at the lowest concentration were 1.48 and 1.46%, respectively. Typical differential pulse polarogram of Ceftriaxone in urine sample is given in Fig. 1.

Further the method is selective for simultaneous determination of cephalosporins because of wide separation in their E_m values (Fig. 2). The wide range of concentrations over which the drugs can be determined indicates great utility of the method. The determinations of higher concentrations in pharmaceutical formulations are possible. The proposed supporting electrolyte permits high sensitivity in polarographic quantitative determination of these compounds. The method is sensitive enough to measure concentrations as low as those encountered after therapeutic dosage.

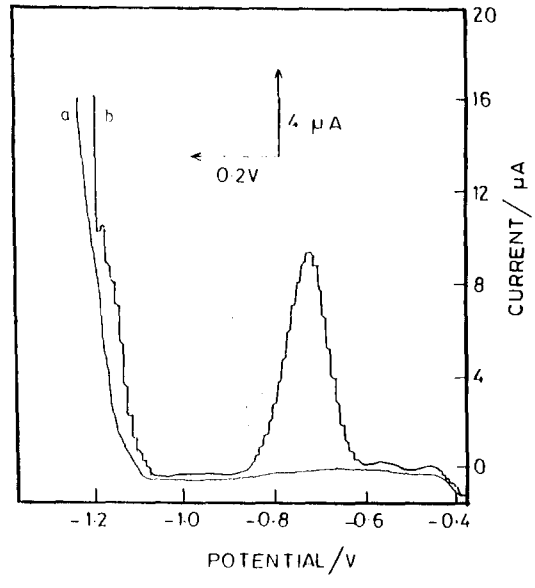

Fig. 1. Typical differential pulse polarogram of ceftriaxone in urine sample in pH 4.0. Concentration = 20 ng ml^{-1}; drop time = 2 s; and pulse amplitude = 60 mV. a = Urine blank + buffer, b = ceftriaxone in urine + buffer.

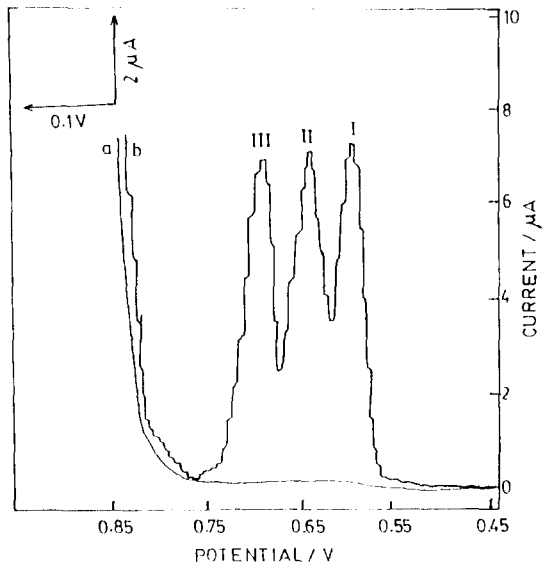

Fig. 2. Typical differential pulse polarogram of 0.01 mM I + 0.01 mM II + 0.01 mM III (I = Ceftazidime, II = Ceftizoxime and III = Ceftriaxone) in pH 4.0. Drop time = 2 s; and pulse amplitude = 60 mV. a = Blank solution, b = [I + II + III] + buffer.

Abstract

Rapid and accurate binary mixture resolution of chlorpheniramine maleate–noscapine hydrochloride and chlorpheniramine maleate-guaiphenesin, was performed. Derivative spectrophotometry, by the zero-crossing measurements, was used due to the drugs closely overlapping absorption spectra. Neither sample pretreatment nor separation were required. Linear calibration graphs of first derivative values at 268.0 and 261.0 nm for chlorpheniramine-maleate-noscapine hydrochloride and at 273.2 and 261.0 nm for chlorpheniramine-guaiphenesin were obtained vs. concentration with negligible intercept on the y-axis. Thus, the derivative spectrophotometry method was applied to the determination of these drugs in binary mixtures obtaining selectivity, accuracy and precision. © 1997 Published by Elsevier Science B.V.

Keywords: Binary mixture; Chlorpheniramine maleate; Noscapine hydrochloride; Guaiphenesin

1. Introduction

Chlorpheniramine maleate (1) is an alkylamine derivative with the actions and uses of the antihistamines [1]. It is one of the most potent antihistamines and causes a moderate degree of sedation. It is used alone or with noscapine hydrochloride (2) [2] and guaiphenesin (3) [3] for the symptomatic treatment of coughs due to acute or chronic bronchitis and bronchial allergic conditions, Fig. 1. Bronchodilation has been produced by nebulized chlorpheniramine in children with asthma. Adverse effects have been reported: smell and taste alterations; thrombocytopenic purpura; and progressive left-sided facial dyskinesia [4]. Chlorpheniramine maleate in compound preparations cannot be directly determined by conventional spectrophotometric methods because of the significant overlapping in the spectra. The derivative technique in UV-vis spectrophotometry offers a powerful approach for the enhancement of sensitivity and specificity. It has frequently been em-

PII S0039-9140(96)02083-8

ployed to overcome the problem of interference due to irrelevant spectral overlapping, which may be caused either by substances other than analytes or by excipient matrices commonly present in pharmaceutical formulations. In derivative spectroscopy, the conventional spectrum is rapidly and simply transformed to a function of its first derivative ($dA/d\lambda$), by an analogue or digital device as the spectrum is scanned. Consequently, fine structural features are sharpened to give improved resolution of overlapping peaks and potentially greater sensitivity. The main advantages and limitations of this technique have been described by O'Haver et al. [5].

Derivative spectrophotometry on the basis of zero-crossing measurements has been employed for the simultaneous determination of substances of clinical interest [6–8] and rapidly gained applications in the fields of pharmaceutical analysis, biochemistry, analytical chemistry and clinical chemistry [9,10].

The described first derivative UV spectrophotometric method is simple, direct and accurate and has been applied to determine chlorpheniramine maleate, noscapine hydrochloride and guaiphenesin, in the synthetic chlorpheniramine-noscapine and chlorpheniramine-guaiphenesin mixtures.

2. Experimental

2.1. Reagents

Stock chlorpheniramine maleate solution, 558.86 μg ml^{-1}, prepared by dissolving chlorpheniramine maleate (Sigma Chemical Products) in water.

Stock noscapine hydrochloride solution, 1954.5 μg ml^{-1} prepared by dissolving 2 (Sigma Chemical Products) in water.

Stock guaphenesin solution, 1070.0 μg ml^{-1}, prepared by dissolving 3 (Sigma Chemical Products) in water. The stock solutions were kept refrigerated at about 4°C, in the dark. Solutions of the desired concentration were obtained by diluting the stock solutions to volume with water. All experiments were performed with solvent grade Milli-Q-water (Millipore Corporation).

2.2. Apparatus

Ordinary and derivative spectrophotometric analyses were performed on a Shimadzu UV-vis Spectrophotometer UV-160 A with standard 1.0 cm quartz cuvettes. The UV-160 A is a microcomputer-controlled double-beam recording spectrophotometer which has the following features: this very compact instrument combines a monochromator, keyboard, CRT and graphic printer; it permits various spectral processing such as the expansion/compression of spectra, peak-pick, derivative, smoothing, data storage and arithmetic calculation between spectra.

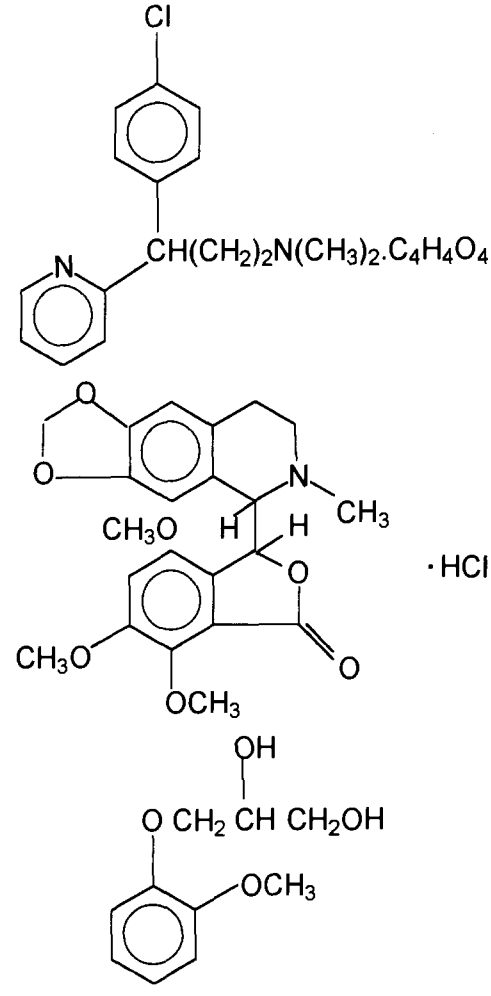

Fig. 1. Structural formulae of chlorpheniramine maleate (1), noscapine hydrochloride (2) and guaiphenesin (3).

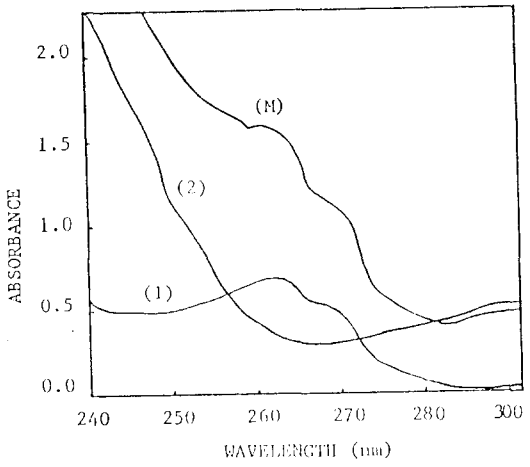

Fig. 2. Absorption spectra of chlorpheniramine maleate (1) 45.2 μg ml^{-1}, noscapine hydrochloride (2) 91.6 μg ml^{-1} and their 1:1 mixture (M), in distilled water.

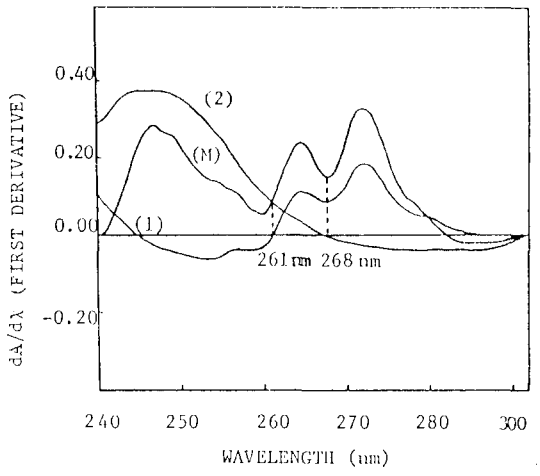

Fig. 4. First derivative spectra of chlorpheniramine maleate (1), noscapine hydrochloride (2) and their 1:1 mixture (M).

Absorption spectra of samples were recorded at a scan speed of about 480 nm min^{-1} between 230–300 nm for 1–2 mixtures and 220–320 nm for 1–3 mixtures.

The first derivative spectra were recorded with a $\Delta\lambda = 7.2$ nm.

2.3. Sample preparation and procedure

Samples (5 ml) were prepared in 8 ml test tubes containing 20.0–160.0 μg ml^{-1} of 1, 20.0–140.0 μg ml^{-1} of 2, and 20.0–140.0 μg ml^{-1} of 3 or their binary mixtures.

The absorption spectra of the samples were recorded against a reagent-blank (water). The calibration graphs were constructed on the chart paper against the corresponding concentrations. The absolute values of the derivative were obtained by a zero-crossing technique with measurements at 268.0 nm for 1 and 261.0 nm for 2 in the 1–2 mixtures and 273.2 nm for 1 and 261.0 nm for 3 in the 1–3 mixtures, respectively.

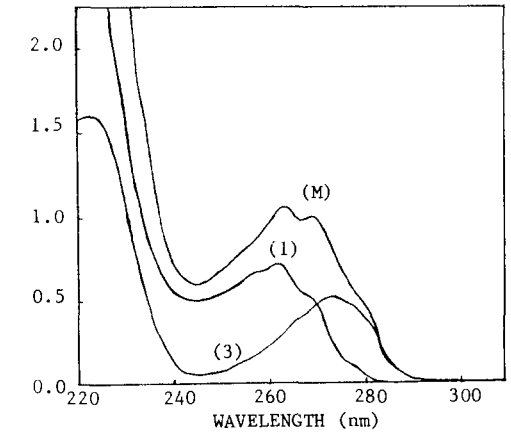

Fig. 3. Absorption spectra of chlorpheniramine maleate (1) 50.1 μg ml^{-1}, guaiphenesin (3) 43.9 μg ml^{-1} and their 1:1 mixture (M), in distilled water.

2.4. Sample analysis

The proposed method was applied to the determination of 1–2 or 1–3 in synthetic mixtures of different proportions, using the calibration graphs.

3. Results and discussion

Fig. 2 shows the closely overlapping absorption spectra of 1 (45.2 μg ml^{-1}) and 2 (91.6 μg ml^{-1}) together with M, a mixture of both compounds, in the region of 240–300 nm.

Similar behavior was observed for compounds 1 and 3 (Fig. 3).

This fact makes it extremely difficult to determine 1 in the presence of noscapine hydrochloride or guaiphenesin by conventional UV spectrophotometry. This problem has been solved satisfactorily by derivative spectrophotometry. When derivative UV spectra were recorded, sharp bands of large amplitudes of chlorpheniramine maleate were produced which may offer more selective identification and specific determination of this drug.

Fig. 4 shows the first derivative spectra of 1, 2 and their mixture, M. Fig. 5 shows the first derivative spectra of 1, 3 and their mixture, M. The zero-crossing value for 1 appears at 261.0 nm; for 2 at 268.0 nm and for 3 at 273.2 nm, respectively. From among these wavelengths, these values were selected as optima to determine 1 and 2 and 1 and 3 in their mixtures.

In order to test the mutual independence of the analytical signals of 1 and 2 or 1 and 3 compounds, the following experiments were performed.

Five calibration graphs were constructed from the first derivative signals by measuring at 268.0 nm for standard samples containing between 20.0 and 160.0 μg ml^{-1} of 1, in the absence of noscapine hydrochloride (p_0) and in the presence of 83.3 μg ml^{-1} (p_1), 105.8 μg ml^{-1} (p_2), 128.7 μg ml^{-1}

LOD (the lower limits of detection) = 0.031 μg ml^{-1}.
C 1: chlorpheniramine maleate concentration.

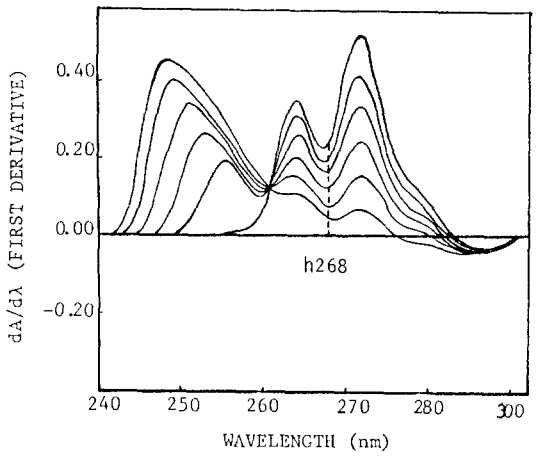

Fig. 6. A series of first derivative spectra with concentration of chlorpheniramine maleate varied from 23.8 to 140.5 μg ml^{-1} at a constant concentration of noscapine hydrochloride (129.0 μg ml^{-1}).

(p_3) and 164.1 μg ml^{-1} (p_4) of noscapine hydrochloride. The 'p' terms (p_0, p_1, p_2, p_3 and p_4) represent the calibration graphs corresponding to five sample series of chlorpheniramine maleate. The lower limits of detection (LOD) were calculated (Table 1).

Fig. 6 exhibits a series of first derivative spectra where the concentration of 1 is increased from 23.8 to 140.5 μg ml^{-1} at a constant concentration of noscapine hydrochloride (129.0 μg ml^{-1}). The experiments showed that the height at 268.0 nm

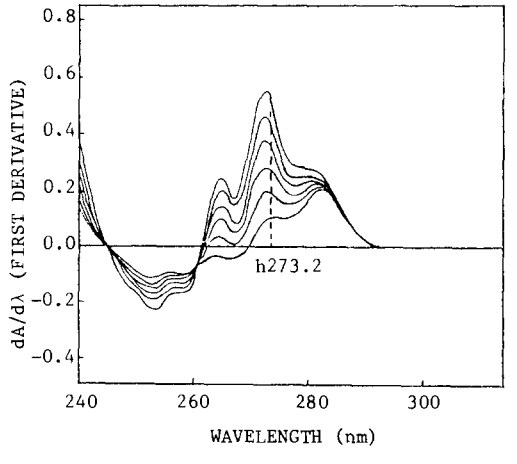

Fig. 7. A series of first derivative spectra with concentration of chlorpheniramine maleate varied from 24.9 to 146.0 μg ml^{-1} at a constant concentration of guaiphenesin (44.0 μg ml^{-1}).

($h_{268.0}$) was proportional to the chlorpheniramine maleate concentration.

It can be verified (Fig. 6) that all curves which contain the same concentration of noscapine hydrochloride converge to an abcissa value corresponding to the zero-crossing wavelength of the chlorpheniramine maleate (261.0 nm).

Similarly, five calibration graphs were prepared from the first derivative signals by measuring at 261.0 nm for standard samples containing between 20.0 and 300.0 μg ml^{-1} of 2, in the absence of 1 (q_0) and in the presence of 23.4 (q_1), 46.5 (q_2), 67.6 (q_3) and 90.1 μg ml^{-1} (q_4) of chlorpheniramine maleate. The 'q' terms (q_0, q_1, q_2, q_3 and q_4) represent the calibration graphs corresponding to five sample series of noscapine hydrochloride (Table 2).

Since, experiments with compounds 1 and 3 were performed at 273.2 and 261.0 nm for the determination of these compounds in their mixtures. Fig. 7 exhibits a series of first derivative spectra where the concentration of 1 is increased from 24.9 to 146.0 μg ml^{-1} at a constant concentration of guaiphenesin (44.0 μg ml^{-1}). The experiments showed that the height at 273.2 nm ($h_{273.2}$) was proportional to the chlorpheniramine maleate concentration.

It can be verified (Fig. 7) that all curves which contain the same concentration of guaiphenesin converge to an abcissa value corresponding to the zero-crossing wavelength of the chlorpheniramine maleate (261.0 nm).

The calibration graphs were constructed from the first derivative signals by measuring at 273.2 nm for standard samples containing between 20.0 and 120.0 μg ml^{-1} of 1, in the absence of guaiphenesin (p_0) and in the presence of 24.2 μg ml^{-1} (p_1), 65.3 μg ml^{-1} (p_2), 85.7 μg.

ml^{-1} (p_3) and 106.0 μg ml^{-1} (p_4) of guaphenesin. The 'p' terms (p_0, p_1, p_2, p_3 and p_4) represent the calibration graphs corresponding to five sample series of chlorpheniramine maleate (Table 3).

Similarly, five calibration graphs were prepared from the first derivative signals by measuring at 261.0 nm for standard samples containing between 20.0 and 120.0 μg ml^{-1} of 3, in the absence of 1 (q_0) and in the presence of 36.1 (q_1), 65.4 (q_2), 80.2 (q_3) and 115.3 μg ml^{-1} (q_4) of chlorpheni-

ramine maleate. The 'q' terms (q_0, q_1, q_2, q_3 and q_4) represent the calibration graphs corresponding to five sample series of guaiphenesin (Table 4).Tables 1–4 show the results of the statistical analysis of the experimental data for chlorpheniramine maleate, noscapine hydrochloride and guaphenesin, respectively. The linearity of the calibration graphs and the conformity of the systems to Beer's law are proven by the high value of correlation coefficients of regression equations. The lower limits of detection (LOD) were calculated by the expression LOD = 3 Sb/b [11].

The traditional Vierodt's method [12] was also applied, which involves the use of two simultaneous equations, for the determination of chlorpheniramine and guaiphenesin in unknown mixtures, with previous construction of four calibration graphs (absorbance vs. concentration). The results obtained were of poor accuracy and reproducibility with errors higher than 2%, if the ratio of guaiphenesin to chlorpheniramine maleate and noscapine hydrochloride to chlorpheniramine maleate is greater than one. This is due to close overlapping of the absorption spectra of the compounds.

Thus, the use of the first derivative spectrophotometry permits to eliminate the problem of closely overlapping spectra [13]. This method was applied for resolving the determination of clorpheniramine maleate-noscapine hydrochloride and clorpheniramine maleate-guaiphenesin in synthetic mixtures of different proportions. The results obtained are summarized in Table 5. In addition, the relative standard deviations (RSD) for five determinations at each concentration level are satisfactorily low (0.25–0.81%) and indicate the good reproducibility of the proposed method.

A rigorous analysis of the results indicated that the presence of one of the components does not interfere with the determination of the other.

Prior sample preparation, such as solvent extraction or column chromatography, is not necessary for the analysis of formulations containing mixtures of these compounds. Elimination of these steps saves considerable analysis time. It is worthy of mention that no expensive or toxic solvents or reagents are used.

Table 4

Received 10 June 1996; received in revised form 27 August 1996; accepted 27 August 1996

Abstract

A new method using a surface acoustic wave (SAW)/conductance sensor has been described in this paper for rapid determination of ribonuclease (RNase) and microanalysis of heparin. The assay of RNase is based on the change in conductance of the solution caused by enzymatic reaction between ribonucleic acid (RNA) and RNase and the analysis of heparin is based on its inhibitory action on RNase. A linear relationship between frequency response and enzyme concentration is obtained and the detection limit of RNase is evaluated to be 0.17 μg ml^{-1}. The recovery of the sensor system ranges from 95.8 to 105.0%. The inhibition of heparin is a competitive one and the possible inhibition mechanism is discussed. The kinetic parameters and inhibition parameters are estimated. The calibration graph is rectilinear for ≤ 8 μg ml^{-1} of heparin and the detection limit is 0.1 μg ml^{-1}. The influence of pH value on the inhibition of RNase by heparin has been investigated and the effects of Ca^{2+}, Mg^{2+} are also discussed. © 1997 Elsevier Science B.V.

Keywords: Heparin; Microanalysis; Ribonuclease; Surface acoustic wave

1. Introduction

The ribonuclease (RNase) is important in the anabolism and catabolism of ribonucleic acid (RNA) of the cytoplasm and nucleus. Various qualitative [1,2] and quantitative [3,4] assays for RNase activity have been described. Most utilize the differential solubility in acid or ethanol of the substrate and product of enzyme digestion. Heparin, a polymer of glucosamine and uronic acids, possess wide biological activities. It is important as a blood anticoagulant and is of clinical significance [5]. It has been widely used in medicine and pharmacology. The normal physiological concentration of heparin in human plasma is 9 μg dl^{-1} [6]. Several reports have covered the structure, function and quantitation of heparin [7,8]; up until now the main method to determine heparin is using its chromogenic substrates [9]. Heparin can greatly inhibit the enzymatic reaction of RNA/RNase and the inhibitory action is used to determine heparin in this paper. Although cur-

rently available methods are fairly sensitive, many are time-consuming and require harsh analytical conditions [10]. The present investigation was prompted by the need to develop more reliable, simple and less time-consuming methods for quantitative analysis of heparin. In this paper, a new liquid-purpose SAW/conductance sensor system has been described to rapid determination of RNase and microanalysis of heparin.

This new type of SAW/conductance sensor system proposed in our laboratory recently [11,12] is composed of a 61 MHz SAW resonator and a pair of parallel platinum electrodes. The frequency of the SAW/conductance sensor can be measured within ± 1 Hz. The device is based on the principle that oscillation is only generated and supported when the sum of the phase angles of a loop circuit containing resistive, capactive and inductive elements in series with an amplifier and a SAW device is a multiple of 2π rad and the loop gain is greater than 1. If any element in the circuit imparts a phase delay change, the oscillation frequency will change. Therefore, it can response to any changes in the physical/chemical properties of the medium between two electrodes as they cause variations in the loop parameters. By analysing the frequency shift response much information about the liquid system can be obtained.

For such a SAW/conductance sensor system, frequency shifts (ΔF) are related to the change of the electrolyte conductance (ΔK): $\Delta F = a\Delta K + b$. Here, a and b are constants depending on the SAW device, amplifier circuit and experimental conditions. So, the frequency of the SAW/conductance sensor shifts according to the conductance change of the substrate solution caused by enzymatic reaction between RNA and RNase, and it is possible to correlate the enzymatic reaction rate with the frequency change. This is the fundamental principle for the RNase determination in this study.

The proposed SAW/conductance sensor has some advantages. One advantage over more conventional oscillator circuit is the high frequency, stability and narrow band-width obtainable with SAW oscillators versus other crystal-controlled and RC/RLC/LC circuits. Another advantage is that the interferences caused by mass, viscoelastic or electroacoustic properties can be avoided. Only the alternation of conductance in test solution can produce the frequency shift of the sensor. We also found that in a medium conductivity region, the higher the conductivity, the higher the sensitivity of the SAW/conductance sensor system. So, the SAW system seems more attractive than the normal a.c. conductometry and a.c. impedance measurement. In addition, the SAW/conductance sensor is advantageous in its rapid determination, simplicity in construction and low noise levels. Since there is no report on SAW devices applied to RNA/RNase reaction and the analysis of heparin, in this paper, the SAW/conductance sensor has been successfully applied in enzymatic analysis of RNase and microanalysis of heparin.

2. Experimental

2.1. Apparatus

The experimental set-up was same as described in the previous paper [11,12]. The 61 MHz SAW resonator used in this study was manufactured on an Y,Z-cut lithium niobate piezoelectric crystal and the whole SAW device was sealed for protection against atmosphere with an epoxide lid. Without touching the solution directly, the device was electrically connected to a pair of parallel platinum electrodes, which were set in the 5 ml detection cell. During the experiments, the detection cell was placed in an air-bath thermostating equipment in which the temperature was monitored and controlled by a WMZK-01 temperature controller (Medical Instrument Co., Shanghai). The temperature was thermostated at 25 ± 0.2°C throughout the experiments. The solution in the cell was stirred with a magnetic stirrer at a constant stirring rate 6.5 V d.c. power was delivered to the circuit board (self-made) by an adjustable dual-track d.c. power supply. A universal frequency counter (Model SC-7021, Iwatsu) was used to measure the oscillation frequency of the SAW resonator at a resolution of 1 Hz and data were collected at 6 points min^{-1}.

2.2. Materials and reagents

All reagents were of analytical grade or better. Doubly distilled water was used throughout. Working buffer was 2.0 mM Tris–HCl at pH 7.0. RNase [EC 3.1.27.5] and heparin sodium (140 units mg^{-1}) were obtained from Shanghai Biochemical Products Institute and Hunan Chemical Products Institute, respectively. RNA extracted from *E. coli* was supplied by Hunan Agriculture University. The method of extracting RNA was a convenient one according to the literature [13]. The RNA extract was measured spectrophotometrically in absorbancy at 230, 260 and 280 nm, and the concentration of RNA was evaluated to be 8.2 mg ml^{-1}.

2.3. Procedures

The detection cell was filled with 5 ml of the RNA, or RNA and heparin (in 2.0 mM Tris–HCl buffer, pH 7.0) under magnetic stirring and the stable frequency of the SAW/conductance sensor was measured (F_0). Then, a small volume of the enzyme solution was transferred into the cell and the enzyme catalyzed reaction was started. Changing with the time, the resulted frequency shift was recorded as $\Delta F = F - F_0$, where F was the frequency after adding the enzyme solution. A frequency shift versus time graph was obtained and the initial response rate was calculated from its initial linear section. Then, an initial response rate versus RNase concentration calibration curve was constructed and a linear relationship between initial response rate and RNA concentration was also obtained. All experiments were repeated more than three times and the average value was used for calculation. The experiments were performed at 25 ± 0.2°C.

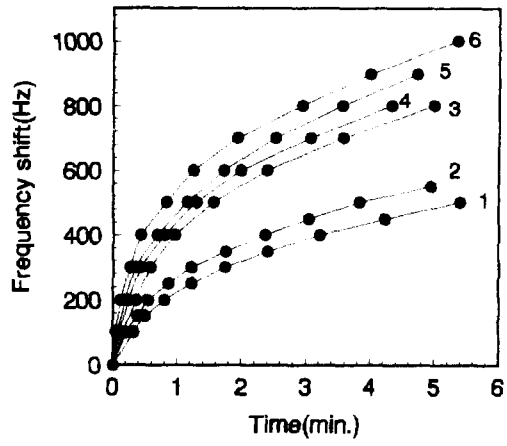

Fig. 1. Frequency response curves (frequency shift vs. time) corresponding to 15 μg ml^{-1} RNase and different concentration of RNA (μg ml^{-1}): (1) 16.5; (2) 32.9; (3) 65.9; (4) 98.8; (5) 131.7; and (6) 164.6.

3. Results and discussion

3.1. Estimation of kinetic parameters

Keeping the concentration of RNase constant at 15 μg ml^{-1}, the RNA concentration was

Table 1
Recovery determined with the SAW/conductance sensor system

Enzyme (μg ml^{-1})		V_0 (Hz min^{-1})	Recovery (%)	Mean (%)	R.S.D. (%)
Added	Found				
1.3	1.29	69	99.4

5.2	5.36	198	103.0		
7.8	8.19	280	105.0	100.1	2.4
10.4	10.29	388	98.8		
11.7	11.53	435	98.6		
13.0	12.97	475	99.7		

Experimental conditions: 165 μg ml^{-1} RNA, pH 7.0, 25°C.

ranged from 16.5 to 165 μg ml^{-1} to obtain a typical Michaelian curve. The experimental data is given in Fig. 1. The initial rate can be calculated from its initial linear section and the results show a linear relationship between the RNA concentration and the initial rate. A corresponding regression equation was described as follows: $V_0 = 3.3[RNA] + 9.2$ ($r = 0.993$, $n = 6$), where the RNA concentration was expressed in μg ml^{-1} and V_0 in Hz min^{-1}. According to the Lineweaver–Burk equation, the K_m value was estimated to be 2.6 mg ml^{-1} for RNA and a corresponding maximum initial rate (V_{max}) was 9973 Hz min^{-1}.

3.2. Assay of the enzyme concentration

At a fixed substrate concentration, the initial rate of an enzyme-catalyzed reaction is directly proportional to the concentration of that enzyme [14]. In this experiment, the substrate RNA was kept constant at 165 μg ml^{-1} and the enzyme concentration was in the range up to 13 μg ml^{-1} of RNase, at 25°C and pH 7.0. A correlation of $V_0 = 34.5[E] + 24$ ($r = 0.998$, $n = 7$) is obtained, where V_0 refer to the initial rate (in Hz min^{-1}) and $[E]$ to the concentration of the RNase solution (in μg ml^{-1}). Under our experimental condition, the detection limit of RNase is evaluated to be 0.17 μg ml^{-1} based on three times the signal-to-noise ratio (S/N = 3).

The average recoveries for RNase shown in Table 1 ranged from 95.8 to 105.0%. The data were obtained with seven different experiments and each obtained value was the mean of three measurements.

3.3. Inhibition action of heparin upon RNase

We have observed that heparin shows an inhibitory action on RNase activity. When heparin is introduced into a solution containing RNase and RNA, the enzymatic activity decreases by the concentration of heparin present in the solution. This process provided a possibility for detecting or assaying extremely low concentration of a wide range of heparin by comparing the alternation of the RNase-catalysed reaction rate which is followed by the SAW/conductance sensor. As shown in Fig. 2, the frequency response of the sensor decreases evidently when heparin is present.

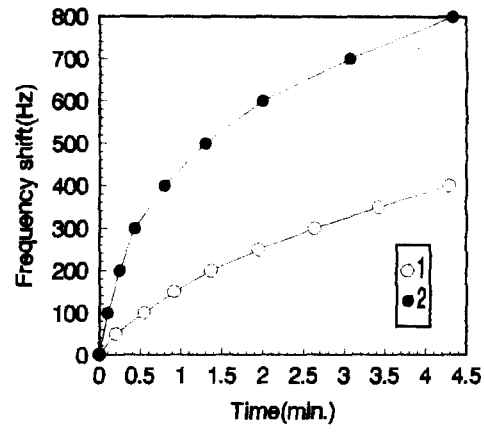

Fig. 2. Influence of heparin on the frequency response curves: (1) in the presence of 4 μg ml^{-1} heparin; and (2) in the absence of heparin. RNA concentration: 98.8 μg ml^{-1}; RNase concentration: 13 μg ml^{-1}.

The effect of substrate concentration on the inhibitory action of heparin has been investigated and the results are shown in Table 2. From the data, we can observe that the effect of the inhibitor depends on the substrate concentration. The higher the substrate concentration, the lower the inhibition. These results have implied that the inhibition is a competitive one.

Table 2
The effect of substrate concentration on the inhibitory action of heparin

Heparin concentration (μg ml^{-1})	RNA concentration (μg ml^{-1})	Inhibition (%)
8	98.8	97.7
	164.6	91.9
	247.0	84.3
4	98.8	61.0
	164.6	54.7
	247.0	45.8

The experimental conditions: 18 μg ml^{-1} RNase, pH 7.0, 25°C.

I_{50} (μg ml^{-1})			3.7			

The experimental conditions: 13 μg ml^{-1} RNase, pH 7.0, 25°C.

3.4. The possible inhibition mechanism of heparin

Heparin is a natural polysaccharide and resembles RNA in some respects. Because of this structural similarity the heparin can compete for the same binding-site on the enzyme. The enzyme-bound inhibitor then either lacks the appropriate reactive group or it is held in an unsuitable position with respect to the catalytic-site of the enzyme or to other potential substrate for a reaction to take place. In either case a dead-end complex is formed, and the inhibitor must dissociate from the enzyme and be replaced by a molecule of substrate before a reaction can take place at that particular enzyme molecule. So, the inhibition mechanism of heparin can be described as follows:

$$\begin{array}{ccccc} \mathbf{E} + \mathbf{S} & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & \mathbf{ES} & \xrightarrow{k_2} & \mathbf{E} + \mathbf{P} \\ -\mathbf{I} \Big\| \Big\downarrow +\mathbf{I} & & & & \\ \mathbf{EI} & & & & \end{array} \quad (1)$$

The dissociation constant K_i, which is also called the inhibitor constant, is expressed as:

$$K_i = \frac{[E][S]}{[ES]} = \frac{[E][I]}{[EI]} \quad (2)$$

By using the steady-state assumption, the following expression can be derived:

$$V_0 = \frac{V_{max}[S_0]}{[S_0] + K_m(1 + [I_0]/K_i)} \quad (3)$$

where V_0 and V_{max} are the initial rate and intrinsic maximum rate of the RNase-catalysed hydrolysis reaction of RNA respectively, $[S_0]$ and $[I_0]$ are the initial concentration of substrate RNA and inhibitor heparin respectively. K_m is intrinsic Michaelis constant.

Eq. (3) has the same form as the Michaelis–Menten equation. The only difference being that K_m has been increase by a factor $(1 + [I_0]/K_i)$. So, the apparent Michaelis constant $K'_m = K_m(1 + [I_0]/K_i)$ and V_{max} is unchanged ($V'_{max} = V_{max}$).

The Lineweaver–Burk equation in the presence of heparin will be:

$$\frac{1}{V_0} = \frac{K'_m}{V'_{max}} \frac{1}{[S_0]} + \frac{1}{V'_{max}} \quad (4)$$

The calculated kinetic parameters (apparent kinetic parameters, K'_m and V'_{max}; intrinsic kinetic parameters, K_m and V_{max}) and inhibition parameters (inhibitor constant, K_i; inhibitor concentration necessary to produce 50% inhibitor, I_{50}) are summarized in Table 3, which are measured under the following conditions: 13 μg ml^{-1} RNase, 2.0 mM Tris–HCl buffer, pH 7.0 and 25°C.

3.5. Relationship between frequency response and heparin concentration

Under the present experimental conditions (98.8 μg ml^{-1} RNA, 13μg ml^{-1} RNase, 2.0 mM Tris–HCl, pH 7.0, 25°C), the calibration curve of initial rate or inhibition ratio against heparin concentration was linear for ≤ 8 μg ml^{-1} (Fig. 3). They are also described by the following regression equation:

$$V_0 = -49.8[\text{heparin}] + 388.4 \quad (5)$$

$$P = 12.0[\text{heparin}] + 6.1 \quad (6)$$

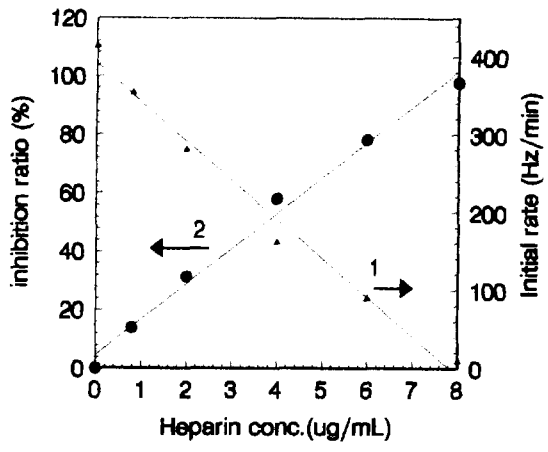

Fig. 3. Calibration graphs for heparin with SAW/conductance sensor: (1) initial rate against inhibitor heparin concentration; and (2) inhibition ratio against inhibitor heparin concentration. Experimental conditions: 13 μg ml^{-1} RNase, 98.8 μg ml^{-1} RNA, pH 7.0 and 25°C.

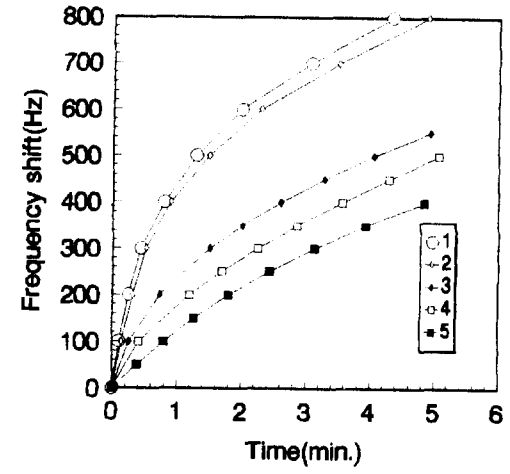

Fig. 4. Influences of Ca^{2+} and Mg^{2+}. (1) In the absense of Ca^{2+} or Mg^{2+}. (2) 2×10^{-4}M Ca^{2+}. (3) 2×10^{-4}M Mg^{2+}. (4) 2×10^{-4}M Ca^{2+} plus 2 μg ml^{-1} heparin. (5) 2×10^{-4}M Mg^{2+} plus 2 μg ml^{-1} heparin. 98.8 μg ml^{-1} RNA and 13 μg ml^{-1} RNase were selected for this measurement.

where V_0 is initial rate calculated in Hz min^{-1}, [heparin] in μg ml^{-1} and P refers to inhibition ratio (%). The regression coefficient is -0.989 ($n = 6$). The detection limit is 0.1 μg ml^{-1} or 0.014 units ml^{-1} of heparin. The standard deviation is 2.7% for four determinations of 2 μg ml^{-1} heparin.

3.6. The effect of pH on the inhibition of RNase by heparin and the influences of Ca^{2+}, Mg^{2+}

The pH value can affect the inhibition ratio of heparin and the results are shown in Table 4. The experimental conditions are: 98.8 μg ml^{-1} RNA, 13 μg ml^{-1} RNase, 4 μg ml^{-1} heparin, at 25°C. The data indicate that heparin has a minimum inhibitory effect on RNase between pH 7.5 and 8.5.

Table 4
The effect of pH on the inhibition of RNase by heparin

pH value	V_i (Hz min^{-1})	V_u (Hz min^{-1})	Inhibition (%)
6.0	145	406	64.3
6.5	148	403	63.3
7.0	161	414	61.1
7.5	248	417	40.5
8.0	290	413	29.8
8.5	252	405	37.8

V_i refers to the inhibited initial rate and V_u refers to the uninhibited initial rate.
Experimental conditions: 98.8 μg ml^{-1} RNA, 13 μg ml^{-1} RNase, 4 μg ml^{-1} heparin at 25°C.

The influences of Ca^{2+} and Mg^{2+} have also been investigated (98.8 μg ml^{-1} RNA, 13 μg ml^{-1} RNase, 2 μg ml^{-1} heparin, pH 7.0 and 25°C). The results are shown in Fig. 4. Although Ca^{2+} or Mg^{2+} can inhibit RNase, the inhibitory effect are greatly increased when Ca^{2+} plus heparin or Mg^{2+} plus heparin is added.

3.7. Comparison of the SAW-sensing method with other methods

Since the SAW/conductance sensor can respond to the conductance change of the substrate solution caused by enzymatic reactions and this is really a conductance measurement, a comparative study was carried out of the SAW/conductance sensor and the conductimetric method. The experimental conditions were the same as above. The detection limit of the conductimetry was 1.1 μg ml^{-1} of heparin and the detection limit of the

Table 5
Comparison of methods for analysing heparin

Method	Detection limit of heparin	Reference
Chemiluminescent method	90 μg l^{-1}	[5]
High-performance liquid-chromatographic-mass-spectrometric method	1 μg ml^{-1}(in plasma) 0.2 μg ml^{-1}(in urine)	[15]
Thrombin-clotting-time technique	0.05 unit ml^{-1} (in plasma)	[16]
Conductimetry	1.1 μg ml^{-1}	This paper
SAW method	0.1 μg ml^{-1} or 0.014 unit ml^{-1}	This paper

SAW-sensing method was only 0.1 μg ml^{-1} of heparin. So, the proposed SAW-sensing method was much more sensitive than the conductimetric one. A comparison of the SAW-sensing method with previously reported techniques [5,15,16] is given in Table 5. The sensitivity of both the SAW method and the overall method are good. Taking into consideration the advantages of the SAW/conductance sensor system (rapid determination, simplicity in operation and enough sensitivity), it appears to be an efficient techniques for the assay of enzyme and microanalysis of heparin.

Gas chromatography–mass spectrometric determination of fthalide and heptachlor epoxide in environmental samples

Tameo Okumura, Yoshinori Nishikawa, Hitoshi Yamamoto, Hiroe Konishi

Environmental Pollution Control Center, 1-3-62, Nakamichi, Higashinari-ku, Osaka City 537, Japan

Accepted 30 August 1996

Abstract

Methods were developed to determine traces of 4,5,6,7-tetrachlorophthalide (fthalide) and 1,4,5,6,7,8,8-heptachloro-2,3-epoxy-2,3,3a,7a-tetrahydro-4,7-methanoindene (heptachlor epoxide) in environmental samples such as river water, sediment and fish. The samples were cleaned up by using convenient disk type solid phase extractors and cartridges and analyzed by GC/MS with selected ion monitoring. Fthalide and heptachlor epoxide in water samples could be determined in the range 0.1–0.3 ng ml^{-1} with relative standard deviations (RSDs) of 1.0–4.8%. The estimated detection limits were 0.020–0.031 ng ml^{-1}, 5.1–7.3 ng g^{-1} and 2.7–4.2 ng g^{-1} in water, sediment and fish samples, respectively. The recoveries were 96–103, 99–101, 66–85 and 67–77% with RSDs of 4.3–10.2, 2.4–2.5, 4.6–5.2 and 2.1–3.8% in river water, sea water, sediment and fish samples, respectively. © 1997 Elsevier Science B.V.

Keywords: Fthalide; Gas chromatography; Heptachlor epoxide; Mass spectrometric

1. Introduction

A large number of chemicals have so far been found in the environment, increasing with progress in industrial science and improvement in living. Accurate information is necessary on environmental pollution due to hazardous agents so as to take appropriate measure to avoid actual damage. The Japan Environmental Agency has surveyed to check the safety of the chemical agents distributed in the environment. So far, our laboratory has developed GC/MS–selected ion monitoring (SIM) methods [1–6] to determine some of the chemical listed by the Japan Environmental Agency.

4,5,6,7-Tetrachlorophthalide (fthalide) and 1,4,5,6,7,8,8-heptachloro-2,3-epoxy-2,3,3a,7a-tetrahydro-4,7-methanoindene (heptachlor epoxide), used as fungicide or insecticide, are selected as target compounds in the priority list. GC/MS–SIM allows the identification and the determination of the target compounds [7–9]. GC–electron capture detection (ECD) is also able to determine them because of their several chlorine atoms [10,11]. However, GC-ECD is problematic due to various kinds of interfering substances coexisting in actual samples. The final results of the analysis might thus be subject to considerable errors with an insufficient clean-up procedure, even if the analysis is made using sensitive and sophisticated detection systems. Recently, solid phase extraction systems have been developed using a cartridge [12–15] or a filter disk [8,15–19] instead of the solvent extraction in a separatory funnel.

PII S0039-9140(96)02097-8

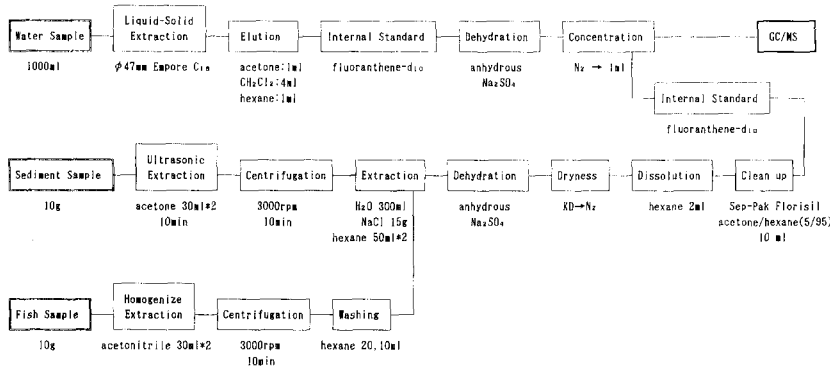

Fig. 1. Flow scheme for the determination of fthalide and heptachlor epoxide in the environmental samples.

This paper reports a convenient method to determine fthalide and heptachlor epoxide in water, sediment and fish samples at sub ng ml^{-1} or low ng g^{-1} levels. The samples are enriched and cleaned up by using a filter disk followed by capillary–GC/MS–SIM analysis.

2. Experimental

2.1. Reagents and apparatus

Fthalide ($C_8H_2Cl_4O_2$) and heptachlor epoxide ($C_{10}H_5Cl_7O$) of pesticide standards grade, and hexane, acetone, dichloromethane, acetonitrile, methanol, anhydrous sodium sulfate, sodium chloride of pesticides grade were obtained from Wako (Osaka, Japan). [$^2H_{10}$] Fluoranthene (fluoranthene-d_{10}) as an internal standard was from MSD Isotopes (Montreal, Canada). Solid phase extraction disk C_{18} (SPED-C18) for water samples was a 47 mm diameter Empore disk (3 M, from GL Science, Tokyo, Japan). The disk was washed with 10 ml of acetone and 10 ml of dichloromethane, and then conditioned with 10 ml of methanol and 10 ml of pure water before use. Glass fiber filter GF/C (47 mm d., Whatman, UK) and high density glass beads (3 M Filter Aid 400) were used on the disk to achieve smooth filtration in the case that water samples contain a lot of suspended substances. Se-Pak Florispil cartridges (Waters, Milfor, MA) for clean-up of sediment and fish samples were prewashed with 10 ml of hexane before use.

A Branson (Shelton, CT, USA) B-220 ultrasonic extractor and a Poly Toron PT10-30 homogenizer were used to extract analytes from sediment and fish samples, respectively. A Tomy Seiko LC06-SP (Tokyo, Japan) centrifuge was employed for phase separation of sediment and fish samples.

2.2. Gas chromatography–mass spectrometry

Employed were a Hewlett-Packard (Avondale, PA, USA) HP 5790 GC and a Nihondenshi (Tokyo, Japan) JEOL-DX303 MS equipped with DA-5000 data processing system. The analytical column was Ultra-2 crosslinked 5% phenyl methylsilicone (25 m × 0.32 mm i.d., 0.52 μm film thickness). The GC temperature program was as follows: initial temperature was 70°C and increased at 20°C min^{-1}–270°C. The temperature of the injector, transfer line and ion source were 250°C respectively. The carrier gas was helium at the following rate of 61 cm s^{-1} (column head pressure, 7.5 psi). The mass spectrometer was operated at 70 eV of ionization energy and 300 μA of ionization current in the electron-impact mode using scan or SIM. Monitor ions (m/z) for fthalide, heptachlor epoxide and their internal standard were as follows: fthalide; 242.9 (for quantitative determination), 244.9 (for qualitative determination), heptachlor epoxide; 352.8 (Quantification), 354.8 (Identification), fluoranthene-d_{10} (internal standard); 212.0.

Table 1
Degradation of fthalide and heptachlor epoxide at pH 5, 7 and 9

Compound	pH[a]	Conc. (mg l^{-1})	Recovery (%)		
			After 1 h	After 5 days	
				Dark	Light
Fthalide	5	0.096	112	113	—
	7	0.096	122	32	12
	9	0.096	118	1	—
Heptachlor epoxide	5	0.095	84	96	—
	7	0.095	87	100	88
	9	0.095	99	97	—

[a] pH 5: 65 mM-KH_2PO_4. pH 7: 65 mM-KH_2PO_4/65 mM-Na_2HPO_4 (4/6). pH 9: 65 Mm-Na_2HPO_4.

2.3. Analytical procedure

The clean-up and enrichment of environmental samples is outlined in the flow chart in Fig. 1. A 1000 ml volume of water sample was passed through the SPED-C18 by using an aspirator or a suction pump. Glass fiber filters and/or high density glass beads (10 g) were preferable to use on the disk in the case that the sample contains much suspended material. The pesticides adsorbed on the disk were eluted with 1 ml of acetone, 4 ml (in case of using the glass beads, 6 ml) of dichloromethane and 1 ml of hexane in that order. A 0.5 ml volume of internal standard solution (fluroanthene-d_{10}, 1 μg ml^{-1} in acetone) and 4 g (in case of using the glass fiber filter, 6 g) of anhydrous sodium sulfate were added to the eluate. As it is difficult to dehydrate polar solvent such as acetone and dichloromethane with anhydrous sodium sulfate, 1 ml of hexane was added to acetone–dichloromethane mixed solvent in order to lower polarity. Completion of the dehydration could be recognized by transparency of the eluent. The eluent was evaporated to 1 ml under a nitrogen stream, and 2 μl of the aliquot was analyzed by GC/MS.

Sediment (10 g) was mixed with 30 ml of acetone and stirred. The muddy suspension made was placed in a ultrasonic extractor for 10 min and then centrifuged at 3000 rpm for 10 min. The acetone extract was then removed. After twice repeating the procedure, the acetone extracts were combined and put into a separator funnel. A 300 ml volume of pure water and 15 g of NaCl were placed into the funnel. The solution was extracted twice with 50 ml of hexane. The organic phase was combined, dehydrated with anhydrous sodium sulfate, concentrated to 3–5 ml by a Kuderna-Danish evaporative concentrator and further evaporated to dryness under a nitrogen stream. The residue was dissolved with 2 ml of hexane, poured into the Sep-Pak Florisil cartridge, washed with 10 ml of hexane and then eluted with 10 ml of acetone/hexane (5/95). The internal standard was added to the eluate. The eluate was evaporated to 1 ml and then 2 μl of aliquot was analyzed by GC/MS.

Fish tissue (10 g) was homogenized, extracted with 30 ml of acetonitrile and centrifuged at 3000 rpm for 10 min. The extraction was performed twice. The acetonitrile phase was combined and washed with 20 ml and then with 10 ml of hexane. Followed procedures were similar to those employed for sediment sample.

3. Results and discussion

3.1. Degradation test

Degradation of fthalide and heptachlor epoxide was investigated at pH 5, 7 and 9 for 1 h and 5 days. Table 1 shows that fthalide degraded under neutral (pH 7) and alkaline (pH 9) conditions

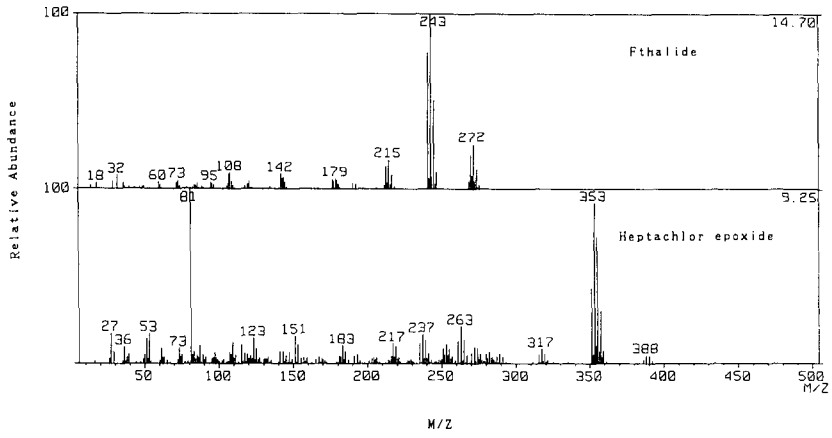

Fig. 2. GC/MS spectra of fthalide and heptachlor epoxide.

after 5 days. Fthalide is a cyclic ester, so it probably undergoes alkaline-catalyzed hydrolytic cleavage. On the other hand, heptachlor epoxide was stable under the pH conditions investigated and even stable in sunlight at pH 7.

3.2. Mass spectra, GC/MS–SIM chromatograms and calibration

The mass spectra of fthalide and heptachlor epoxide are shown in Fig. 2. The ions monitored for quantitative determination and identification were selected for optimum selectivity and sensitivity.

Typical GC/MS–SIM chromatograms of fthalide and heptachlor epoxide standards are shown in Fig. 3. Their retention time was 9–10 min at this analytical conditions.

The calibration graph for the compounds was obtained by plotting the concentration ratio (X) of the analyte to the internal standard against the corresponding peak area ratio (Y). An example is shown in Fig. 4. Excellent linearity was obtained in the calibration graphs by using five different concentrations. The equations of calibration for fthalide and heptachlor epoxide were $Y = 0.183\ X$ and $Y = 0.165\ X$ with correlation coefficients of 0.998 and 0.996, respectively.

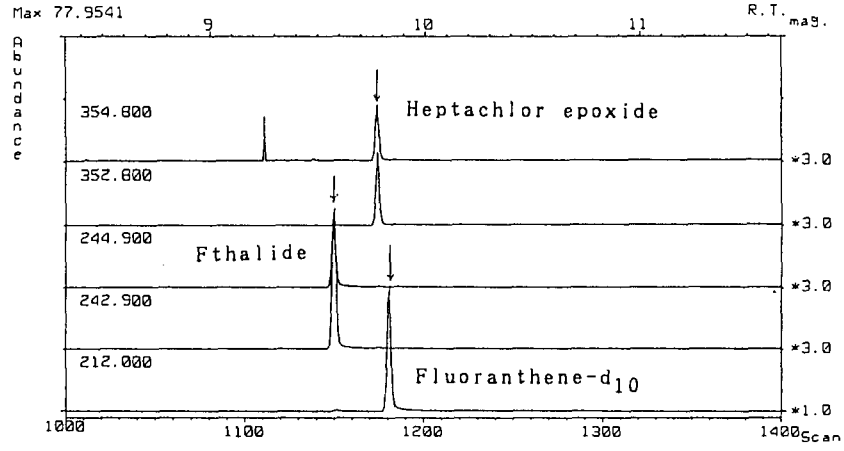

Fig. 3. Typical GC/MS–SIM chromatograms for the standards. R.T. = Rentention time in min; mag = magnitude; fthalide (m/z at 242.9 and 244.9), heptachlor epoxide (m/z at 352.8 and 354.8) fluroanthene-d_{10} (internal standard, m/z at 212.0).

[a] Detection limits of the water (DL_w) sample were calculated from the sensitivity of response estimating standard deviation as follows: $D = t(n-1, 0.05)\sigma/\sqrt{n}(dC/dR)$. $DL_w = 3\bar{D}$, where D is detection power at trace concentration of the compounds (three different concentration in this experiment). $\bar{D}$ is the average value of D calculated from different concentration (DL_w were defined as three times of the detection power). $t(n-1, 0.05)$ is the t-distribution at 95% reliability. σ is the standard deviation of the response, n is the number of replicates. C is the concentration of the compounds and R is the response (the peak area ratio of analyte to internal standard).

[b] For sediment and fish samples, detection limits ($DL_{s\&f}$) were calculated from the following equation. $DL_{s\&f} = t(n-1, 0.02)Sc$, where $t(n-1, 0.02) = 3.143$ ($n=7$) is the t-distribution at 98% reliability and Sc is the standard deviation of the seven replicate analyses.

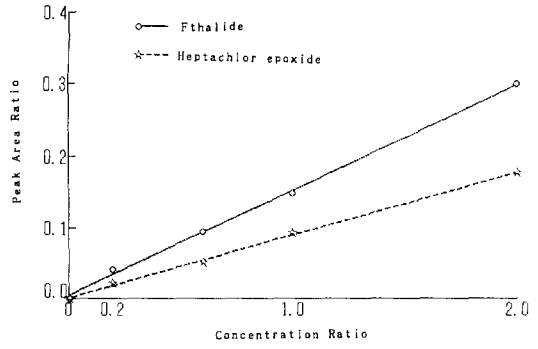

Fig. 4. Typical calibration graphs for fthalide and heptachlor epoxide. X-axis = concentration ratio (analyte/internal standard), Y-axis = peak area ratio (analyte/internal standard).

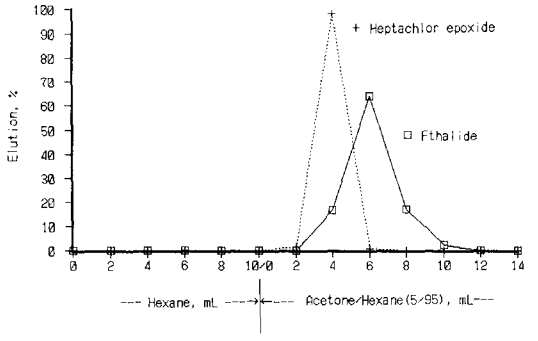

Fig. 5. Typical eluation patterns of fthalide and heptachlor epoxide on Sep-Pak Florisil cartridge. Eluent = acetone/hexane (5/95).

3.3. Solid phase disk extraction

Solid phase extraction depends on the principle of partition or adsorption of organic compounds on a solid non-polar material. The solid materials were used in a column or a cartridge at the early applications. Filter disk recently developed is most appropriate for extraction of pollutants from an environmental water sample. This technique is superior to conventional liquid–liquid extraction because it causes no emulsification, uses only small volume of extraction solvents and produces rapid procedure with less labour. The use of membrane extraction disks provide excellent recoveries for pesticides analysis even when a water sample is passed fast and small volume of an eluent is employed.

3.4. Clean-up procedure of Sep-Pak Florisil

The clean-up of sediment and fish extracts was carried out by using a Sep-Pak Florisil cartridge. Fig. 5 shows typical elution patterns of fthalide and heptachlor epoxide with hexane and acetone/hexane (5/95) as eluents. The chemicals were not eluted with 10 ml of hexane, but completely eluted with 10 ml of acetone/hexane (5/95).

3.5. Analytical precision and detection limits

Table 2 reports analytical precision and detection limits for fthalide and heptachlor epoxide in water, sediment and fish samples throughout the analytical procedures. Fthalide and heptachlor epoxide in water samples were determined in the range 0.1–0.3 ng ml^{-1} levels with relative standard deviations (RSDs) of 1.0–4.8%. Detection limits (DL_W) of water samples were calculated from the sensitivity of the response estimation

Table 3
Recovery of fthalide and heptachlor epoxide added to the environmental samples

	Sample	Sample vol.	Added (ng)	Recovery (%)	Number of sample (n)	RSD (%)
Fthalide	River water	1000 ml	500	96	4	10.2
	Sea water	1000 ml	500	99	4	2.4
	Sediment	10 g	500	66	7	4.6
	Fish	10 g	500	77	7	2.1
Heptachlor epoxide	River water	1000 ml	500	103	4	4.3
	Sea water	1000 ml	500	101	4	2.5
	Sediment	10 g	500	85	7	5.2
	Fish	10 g	500	67	7	3.8

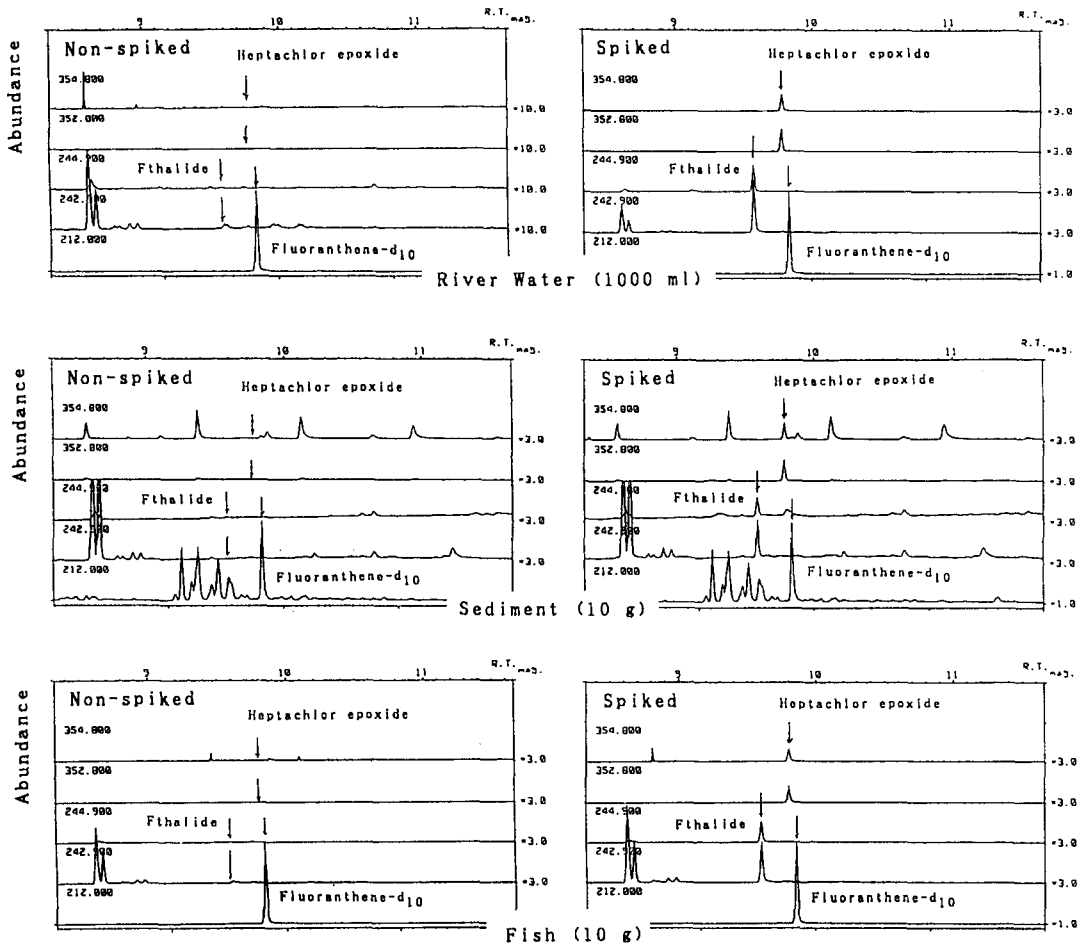

Fig. 6. Determination of fthalide and heptachlor epoxide in non-spiked and spiked river water (1000 ml, Okawa River), sediment (10 g Tokyo Bay) and fish (10 g, pearch in Osaka Bay) samples.

standard deviation. DL_W of fthalide and heptachlor epoxide were 0.020 and 0.031 ng ml^{-1} for 1000 ml of water samples, respectively. For the sediment and fish samples, detection limits (DL_S and DL_f) were calculated from the standard deviation of the seven replicated analyses. DL_S and DL_f were 2.7–5.1 and 4.2–7.3 ng g^{-1} for 10 g of samples, respectively.

3.6. Recovery test

Analyte recovery was investigated for 1000 ml of river water, 1000 ml of sea water, 10 g of sediment, and 10 g of fish samples, spiked with 500 ng of fthalide and heptachlor expodie. Table 3 shows their recovery from these environmental samples.

Fthalide and heptachlor epoxide were recovered in the range 96–103% with RSDs of 2.4–10.2% from the river and the sea waters. The recoveries of the chemical were 66–85% with RSDs of 2.1–5.2% from sediment and fish samples. The chromatograms of the chemical are shown in Fig. 6, as to non-spiked and spiked river water, sediment and fish samples.

4. Conclusions

The GC/MS–SIM method, involving SPED-C18 extraction of Sep-Pak Florisil clean-up pretreatment, are useful for routinely determining fthalide and heptachlor epoxide in the environmental samples at sub ng ml^{-1} or low ng g^{-1} levels.

Abstract

A study of the transport of Cd^{2+} ions through a tri-*n*-octylamine(TOA)—sorbital monooleate (Span 80)—oxylene liquid membrane has been performed with varying concentrations of HCl, KI, TOA, Span 80 and NaOH in the feed, membrane and stripping solutions. Maximum transport was observed at 0.01 M KI, 0.025 M HCl, 0.015 M TOA, 3% (w/v) Span 80 and 0.025 M NaOH. With this system, cadmium could be completely separated from Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cr^{3+} and Mn^{2+}. The transport mechanism of this metal ions through the membrane has been discussed. © 1997 Elsevier Science B.V.

Keywords: Cadmium; Emulsion liquid membrane; Metal ions; Stripping solution

1. Introduction

The emulsion liquid membranes (ELM) are the subject of widespread investigation [1–4] as a potential method of separation and preconcentration for both technical and analytical purposes, because of their advantage of high efficiency and low expense. Tri-*n*-octylamine (TOA) has been studied as emulsion liquid membrane mobile carrier to separate metal ions [5–8], but it has not applied for the separation of cadmium from other metal ions, and no transport studies has been made. TOA is an important extractant and can complex with CdI_4^{2-} ions [8].

In this paper, an emulsion liquid membrane with TOA as mobile carrier will be studied for the transport of cadmium. Various parameters influencing the transport of cadmium across the membrane have been optimized to separated cadmium from Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cr^{3+} and Mn^{2+}, and the transport mechanism of this metal ion has been discussed.

2. Experimental

2.1. Reagents

A standard (1 mg ml^{-1}) solution of cadmium was prepared from metal cadmium (99.99%), and distilled, deionized water. TOA (analytical grade) was obtained from Fluka. Sorbital monooleate (Span 80; chemical grade) was obtained from Tianda Experimental Factory (Tianhing, People's

PII S0039-9140(96)02098-X

Republic of China). A 0.1 M solution of TOA and a 3% (w/v) solution of Span 80 in oxylene were used in this work.

2.2. Apparatus

The following instruments were used: a motor-driven emulsifier (range 0–6000 rev min^{-1}); motor-driven stirrers (range 0–600 rev min^{-1}); and a model 722 spectrophotometer (Shanghai Analytical Instrument Factory, People's Republic of China).

2.3. Procedures

2.3.1. Preparation of ELM

Solutions, 20 ml portions, of TOA and Span 80 in oxylene were emulsified at a stirring speed of 2000 rev min^{-1}. Stripping solution was added at a rate of 20 ml min^{-1} until the volume ratio of organic membrane solution to stripping solution was 1:1. The solution was then stirred continuously for 15 min to obtain a stable while ELM.

2.3.2. Transport of metal ions

Then 2 ml of ELM was added to small beakers containing 10 ml metal ion feed solutions and the contents stirred at 200 rev min^{-1} for a given transfer time; the phases were allowed to separate. Clear feed solution was pippetted into a 25 ml volumetric flask and analyzed for the amount of cation remaining.

2.3.3. Determination of cadmium [9]

3 ml of 5×10^{-4} M 4-(2-Pyridylazo) resorcinol (PAR) alcohol solution was added to 5 ml of 0.1 M $Na_2B_4O_7 \cdot 10H_2O$ buffer solution in a 25 ml volumetric flask containing cadmium ions, after diluting to the mark the absorbance was read at 495 nm against the reagent blank.

In separation experiment, the concentration of cadmium as well as other cations was determined by inductively-coupled plasma atomic emission spectrometry (ICP-AES).

3. Results and discussion

3.1. The effect of KI, KBr, KCl and KSCN in the feed solution

TOA is called liquid anion-exchanger. Only in the form of anions, can cadmium associate with TOA and transport into stripping phase, so it is very important of the ability of different anions associating with cadmium. With a suitable acid concentration of the feed solution, an increase in the concentration of KI increased the extraction of Cd^{2+}, 0.01 M KI resulted in complete transport of Cd^{2+}, and Cd^{2+} transported into the stripping solution in the form of CdI_4^{2-}. If KI was replaced by KBr and KSCN in turn, the extraction of Cd^{2+} decreased. According to Ref [10], Cd^{2+} can form a 1:4 complex with I^-, Br^- and SCN^-, the logarithm of its accumulating stability constant ($\log \beta_4$) is respectively, 5.35, 2.93 and 2.91. This shows that the more stable the anion complex, the higher the extraction of Cd^{2+} is (see Fig. 1).

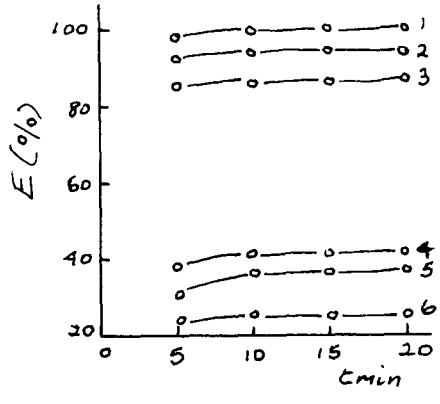

Fig. 1. The effect of KI, KBr, KSCN concentration in the feed on the percent extraction of Cd^{2+}. Feed phase: 50 μg ml^{-1} Cd^{2+} + 0.01 M HCl + agents:1- 0.01 M KI, 2- 0.005 M KI, 3- 0.05 M KBr, 4- 0.01 M KBr, 5- 0.05 KSCN, 6- 0.01 M KSCN; stripping phase: 0.025 M NaOH; and membrane phase: 3% (w/v) Span 80 + 0.015 M TOA + oxylene.

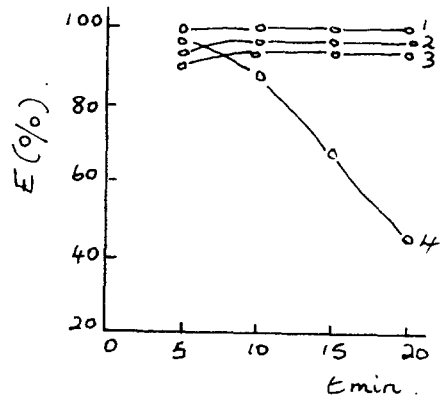

Fig. 2. The effect of HCl concentration in the feed on the percent extraction of Cd^{2+}. Membrane phase: 0.015 M TOA + 3% (w/v) Span 80 + oxylene; stripping phase: 0.05 M NaOH; and feed phase: 100 μg ml^{-1} Cd^{2+} + 0.010 M KI + HCl(M): 1- 0.01–0.025, 2- 0.05, 3- 0.1, 4- 0.005.

3.2. The effect of hydrochloric acid concentration in the feed

The relationship between the concentration of hydrochloric acid in the feed solution and extraction of cadmium is shown in Fig. 2. An acid concentration of 0.025 M was found to be the best for Cd^{2+} transport. The H^+ concentration in the feed solution was measured and it was found that with transport of cadmium into the stripping phase, the H^+ concentration in the feed solution decreased. This proved that H^+ transport into the stripping phase also occurs. In the presence of HCL and KI in the feed solution, the transport process of cadmium through an ELM is illustrated by the following equations

1. TOA (shown as R_3N) in the membrane phase reacts with hydrochloric acid in the feed phase.

$$\underset{\text{(membrane)}}{R_3N} + H^+ + \underset{\text{(feed)}}{Cl^-} = \underset{\text{(membrane)}}{R_3NH^+Cl^-}$$

2. In the feed, CdI_4^{2-} exchanges with Cl^- of $R_3NH^+Cl^-$ in the membrane phase.

$$\underset{\text{(feed)}}{CdI_4^{2-}} + 2\underset{\text{(membrane)}}{R_3NH^+Cl^-} = \underset{\text{(membrane)}}{(R_3N)_2CdI_4} + 2\underset{\text{(feed)}}{Cl^-}$$

3. NaOH in the stripping solution reacts with $(R_3NH)_2CdI_4^{2-}$ to strip cadmium into the stripping solution

$$\underset{\text{(membrane)}}{(R_3HN)_2CdI_4} + 2\underset{\text{(feed)}}{Cl^-} = \underset{\text{(membrane)}}{R_3N} + \underset{\text{(feed)}}{CdI_4^{2-}} + 2H_2O$$

The expected mechanism of cadmium transport in the present case is shown in Fig. 3. Cd^{2+} and H^+ were transported from the feed solution to the stripping solution where H^+ was neutralized by NaOH. The transport of H^+ along a concentration gradient supplied the energy for the transport of cadmium against a concentration gradient. It was discovered that the decrease of H^+ in the feed solution was more than that of cadmium. This was due to the formation of $R_3NH^+Cl^-$-type species and transport into the stripping phase. At an HCl concentration in the feed of >0.05 M, more Cl^- competed with CdI_4^{2-} to associate with protonated TOA, the extraction of cadmium decreased. When the concentration of HCl was <0.005 M, transport of cadmium abruptly decreased with time. This is because less H^+ is available to protonate R_3N, and precipitation of Cd^{2+} as $Cd(OH)_2$ blocks the transport of cadmium. In Fig. 4, it is also found that the transport of cadmium can be completed in 5 min, this is because extraction and back-extraction occur simultaneously, and the degree of dispersion of the ELM in the feed solution is high [11].

3.3. The effect of concentration of NaOH in the stripping solution

The NaOH in the stripping solution functioned as a back-extractant. When the composition of emulsion was fixed an increase in the hydroxyl

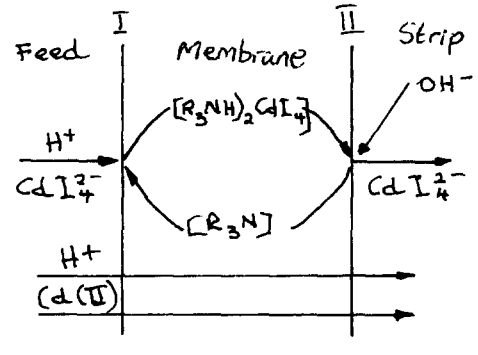

Fig. 3. Possible scheme for CdI_4^{2-} transport from HCl solution to NaOH solution through TOA-Span 80-oxylene liquid membranes.

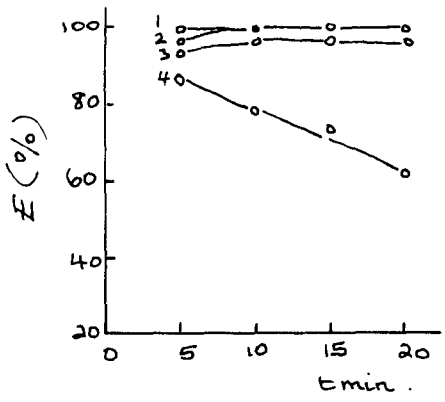

Fig. 4. The effect of NaOH concentration in the stripping phase on the percent extraction of Cd^{2+}. Feed phase: 50 μg ml^{-1} Cd^{2+} + 0.01 M KI + 0.01 M HCl; membrane phase: 3% (w/v) Span 80 + 0.15 M TOA + oxylene; and stripping phase: NaOH (M): 1- 0.01, 2- 0.025, 3- 0.05, 4- 0.1.

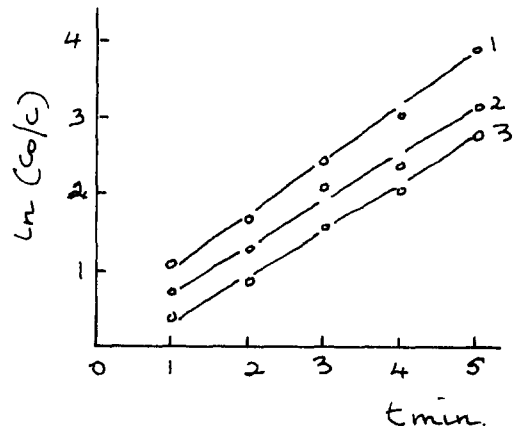

Fig. 5. The kinetic curve line of transport of Cd^{2+}. Feed phase: 50 μg ml^{-1} Cd^{2+} + 0.01 M KI + 0.01 M HCl; membrane phase: 3% (w/v) Span 80 + 0.015 M TOA + oxylene; and stripping phase: NaOH (M):1- 0.01, 2- 0.025, 3- 0.05.

ions results in faster decomposition of the cadmium complex and removal of protons from the amine molecules, thus resulting in higher extraction. However, it has been observed that above a concentration of 0.1 M NaOH, the extraction of cadmium decreased (see Fig. 4). This may be because the CdI_4^{2-} precipitated $Cd(OH)_2$ at higher NaOH concentration and clogged the membrane. This can be proved by found white $Cd(OH)_2$ precipitation in the stripping solution after demulsification.

The maximum extraction was obtained in different stripping solution at 0.01–0.1 M NaOH (shown in Fig. 4). In the experiment, 0.025 M NaOH was selected. When the concentration of NaOH was 0.01, 0.025 and 0.05 M, by changing transfer time (from 1 to 5 min) measured the natural logarithm of the ratio of initial concentration (C_0) to given time concentration (C) of cadmium the kinetic curve can be obtained (see Fig. 5). $\ln C_0/C \sim t$ curve line is a good straight line, they are (1) $\ln C_0/C = 1.103 \times 10^{-2}t + 0.4260$, $R = 0.9940$; (2) $\ln C_0/C = 1.008 \times 10^{-2}t + 0.1222$, $R = 0.9909$; (3) $\ln C_0/C = 1.012 \times 10^{-2}t - 0.3550$, $R = 0.9949$ respectively, this shows that transport of cadmium is near kinetic pesudo-first-order reaction. The transport rate constant of Cd^{2+} was 0.01103 s^{-1}, 0.01008 s^{-1} and 0.01012 s^{-1}, they are similar. This shows that the transport rate of Cd^{2+} was controlled only by $(R_3NH)_2CdI_4$ concentration on the feed-side interface, the concentration of hydroxyl ions in the stripping solution did not interfere. Its kinetic equation are illustrated by the following equation

$$-\mathrm{d[Cd(II)]} = k[(R_3NH)_2CdI_4]\,\mathrm{d}t$$

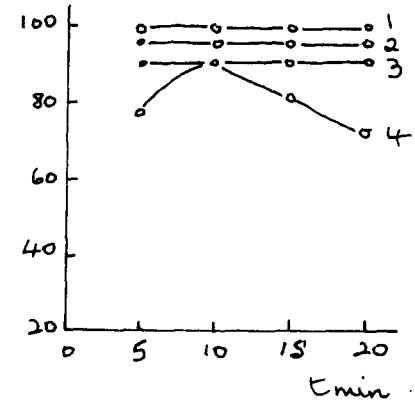

Fig. 6. The effect of TOA concentration in the membrane phase on the percent extraction of Cd^{2+}. Feed phase: 50 μg ml^{-1} Cd^{2+} + 0.01 M KI + 0.01 M HCl; stripping phase: 0.025 M NaOH; and membrane phase: 3% (w/v) Span 80 + TOA (M): 1- 0.015, 2- 0.01, 3- 0.0075, 4- 0.005.

Table 1
Separation of Cd^{2+} from mixed solution of co-ions

Initial amount of each ion (μg ml^{-1})	Percent extraction						
	Fe	Mn	Cr	Zn	Co	Ni	Cd
10.0	0	0	2	2	0	0	96.4
50.0	0	0	1	0	0	2	96.0
100	1	0	1	0	2	2	95.0

Feed phase: 50 μg ml^{-1} Cd^{2+} + 0.01 M KI + 0.01 M HCl; membrane phase: 3% (w/v) + Span 80 + 0.015 M TOA + oxylene; stripping phase: 0.025 M NaOH; and transfer time: 10 min.

3.4. The effect of the concentration of TOA

The effect of the concentration of TOA (mobile carrier) in the organic phase on the extraction of cadmium is shown in Fig. 6. The optimum concentration range of TOA was 0.015–0.02 M. A decrease of the concentration of TOA decreased the extraction of cadmium, this proved that the extraction of cadmium was controlled only by the concentration of $(R_3NH)_2CdI_4$ in the membrane phase. When the concentration of TOA was < 0.005 M, the transport of cadmium would decrease with transfer time, the reason was that less H^+ was transported into the stripping solution by TOA, cadmium precipitated $Cd(OH)_2$ (like curve line 4 in Fig. 2). In experiment 0.015 M TOA was selected for a rapid and complete transport of cadmium.

3.5. The effect of the concentration of surfactant

Both the stability of the emulsion and the viscosity of the liquid membrane were altered by the proportion of surfactant in the organic phase. An increase in the concentration of Span 80 (surfactant) increased the stability of the emulsion; however, the extraction of cadmium decreased. When the concentration of Span 80 was less than 2% (w/v) in the organic phase, the ELM was easy to break as transfer time increased. A concentration of 3% (w/v) in the organic phase resulted in good extraction and stability.

3.6. The effect of other reagents in the feed

When 0.05 M KNO_3, K_2SO_4, $KClO_4$ and $KClO_4$ were added to above system in turn, the results shown that NO_3^-, SO_4^{2-} and Cl^- did not interfere the transport of cadmium, but ClO_4^- was larger anion, associated with TOA more easily, it would form R_3NHClO_4 and repress the transport of cadmium. 0.05 M $KClO_4$ made the extraction of cadmium decrease 15%.

3.7. Separation of cadmium from other ions

Under suitably conditions, transports of Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+} and Cr^{3+} were studied in the mixed solution. Results for the competitive transport of cadmium and other common cations are shown in Table 1. (Note that the data of Table 1 comes from ICP, all other data are from colorimetric measurements.) Selective transport of cadmium was excellent and the transports of Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+} and Cr^{3+} were found to be negligible.

The TOA-Span 80-oxylene liquid membrane is feasible to separate cadmium from Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+} and Cr^{3+}, specifically from Zn^{2+}. Because character of Zn^{2+} is similar to that of Cd^{2+}, quantitative separation of Cd^{2+} from Zn^{2+} is significant.

4. Conclusion

In this paper, transport of cadmium through TOA-Span 80-ocylene ELM was studied. The mechanism of transport of cadmium was discussed and presented in Fig. 3, it is based on the association of metal anions (CdI_4^{2-}) with protonated TOA molecules at the feed-side interface, diffusion through the membrane, decomposition of the comples at the strip-solution-side membrane interface under alkaline condition, and back-diffusion of TOA molecules. The optimum condition of transport has been found and are 0.01 M KI and 0.025 M HCl in the feed solution, 0.015 M TOA and 3% (w/v) Span 80 in the liquid membrane, and 0.025 M NaOH in the stripping solution. It is concluded that this method can be applied for the separation of cadmium from Zn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+} and Cr^{3+} or as a preconcentrating step for measuring cadmium. Small amounts of carriers are involved and the extraction efficiency is high.

Development and application of new ion-exchange techniques for the separation of the platinum group and other siderophile elements from geological samples

M. Rehkämper *, A.N. Halliday

Department of Geological Sciences, The University of Michigan, Ann Arbor, MI 48109-1063, USA

Received 6 February 1996; received in revised form 4 October 1996; accepted 8 October 1996

Abstract

Two new anion-exchange techniques have been developed for the separation of the platinum group elements Ru, Pd, Ir, Pt and the siderophile metals Re, Ag, Zn and Cd from geological samples following a NiS fire assay digestion procedure. Both methods are simple and permit the isolation of these elements in sufficient purity for quantitative analysis by isotope dilution-inductively coupled plasma mass spectrometry (ID-ICPMS) at yields of 75–95%. The high affinity of the considered elements to anion exchange resins allows the use of small (1.25 ml) columns even for the processing of 5–10 g sized silicate rock samples. Following fire assay digestion and dissolution of the NiS buttons in aqua regia, the samples are loaded onto the resin bed as solutions in 1 M HCl. After elution of the bulk sample matrix with dilute HCl and HNO_3, Zn and Cd are stripped from the column using 0.8 M HNO_3. Small amounts of bromine water are added to the dilute mineral acids for the stabilization of strongly retained Ir(IV). Following this, the ion-exchange techniques permit the sequential elution of Ag, Re and the PGE using 11 M HCl, 8 M HNO_3 and 13.5 M HNO_3. The ion-exchange methods have been applied to separation of Ru, Pd, Re, Ir and Pt from the geological reference material SU-1a prior to concentration measurements by ID-ICPMS. Our analytical results are in good agreement with previously published data for this sample and display an external reproducibility (based upon repeat dissolutions) of approximately 2–10% for the elements considered in this study. © 1997 Elsevier Science B.V.

1. Introduction

Abundance measurements for the platinum group elements (PGE) in natural samples such as waters, rocks, sediments and extraterrestrial materials have received particular attention in recent years and are of relevance to a wide range of geo- and cosmochemical studies. Reliable concentration data for the PGE in meteorites and terrestrial samples provide constraints for theories on the accretion of the Earth, core formation and the origin of the Moon and are of importance in mineral exploration, environmental research, sedimentary studies and the identification of impact craters.

Inductively coupled plasma mass spectrometry (ICP-MS) has become a preferred method of elemental trace analysis in geochemistry and, being characterized by excellent detection limits, is ideally suited for the determination of PGE abundances [1–3]. The precision and accuracy of standard ICP-MS techniques that use absolute signal intensities to determine elemental concentrations are, however, generally inferior to isotope dilution (ID) measurements for the same elements by thermal ionization mass spectrometry. Significant improvements, particularly for low-abundance elements such as the PGE, can be achieved by a combination of ID with ICP-MS [4,5]. A chemical separation of the elements of interest is desirable for high-precision ID analysis in order to increase analytical sensitivity and eliminate isobaric interferences from other elements and their oxides [5,6]. Following full spike-sample equilibration during sample dissolution, the preconcentration procedure need not be quantitative, however, and this permits the use of relatively simple separation techniques [7].

The new multiple collector inductively coupled plasma mass spectrometer (MC-ICPMS) at the University of Michigan combines the ionization efficiency of a plasma source with the superior peak shapes and improved transmission of a magnetic sector mass spectrometer [8,9]. The instrument permits isotopic composition and ID concentration measurements to be performed by static multiple collection with Faraday cups at a level of precision and accuracy hitherto not achievable by ICP-MS [10]. This paper summarizes our recent efforts in the development of new ion-exchange procedures for the separation of the PGE, Re and other siderophile elements from geological samples prior to concentration measurements by isotope dilution MC-ICPMS.

A number of ion-exchange techniques for the separation of the PGE from geological samples have been published in the past. These procedures, however, were not considered to be fully adequate for our purposes since they are generally characterized by one or more of the following drawbacks: (1) they achieve only a group separation of the PGE from rock samples with no separation of the elements from one another [11–13]; (2) they only consider the separation of one or two of the PGE [14–16]; (3) they use unnecessarily large resin columns and/or large volumes of eluent [17,18]; or (4) they require the use of acids or reagents (such as $HClO_4$ or thiourea) that are difficult to purify or remove from effluent fractions by evaporation [19,20].

In this study we have developed two new anion-exchange separation schemes that permit the sequential isolation of the PGE Ru, Pd, Ir, Pt and the siderophile elements Re, Ag, Zn and Cd from geological samples following sample digestion by the NiS fire assay technique. This dissolution procedure is commonly used in the analysis of rocks for PGE abundances since it achieves the complete digestion of resistant, PGE containing phases and ensures full spike-sample equilibration for isotope dilution concentration measurements. The new ion-exchange methods are characterized by simplicity, high elemental yields and require relatively small volumes of reagents. While the procedures have been developed and used for the processing of 5–10 g sized geological samples, they can easily be adapted to the treatment of larger or smaller samples.

2. Experimental

2.1. Apparatus

The inductively coupled mass spectrometer employed in this study was the new VG Elemental Plasma 54. Since this instrument has recently been described in detail elsewhere [8,9], only a brief introduction is given here. The Plasma 54 is a new type of ICP-MS instrument that combines a conventional inductively coupled plasma (ICP) source with a multiple collector magnetic sector mass spectrometer. Following extraction of the ions generated in the Ar-plasma, a d.c. quadrupole lens system and an electrostatic analyzer are used to focus the ion beam before entering the magnetic sector analyzer. The collector assembly consists of nine Faraday cups and a Daly detector with ion counting for the measurement of small ion beams. Sample delivery was performed with a peristaltic pump and a Fisons Instruments Mistral

high efficiency nebulizer, operated at an uptake rate of approximately 0.15–0.20 ml min^{-1}. The ion-source consisted of a Fassel-type ICP torch and a solid-state radio frequency generator, operating at 1.35 kW. The nebulizer, auxiliary and coolant Ar-flows were set at approximately 0.9, 1.5 and 13 ml min^{-1}, respectively.

2.2. Materials and reagents

The acids used in this study were purified by subboiling distillation in quartz stills. 18 MΩ-grade water from a Millipore purification system was used throughout. Saturated bromine water was prepared by the equilibration of approximately 5 ml of high-purity bromine (99.998%, Alfa-AESAR) with approximately 100 ml of purified water in a 125 ml Teflon bottle. Sodium tetraborate (Alfa-AESAR, 99.5%, anhydrous), sodium carbonate (Fluka, 99.5%, anhydrous), as well elemental Ni (Alfa-AESAR, 99.996%) and S (Alfa-AESAR, 99.999%) were used as obtained, without further purification.

All ion-exchange separations were performed using quartz-glass columns (inner diameter 6 mm) fitted with acid-cleaned quartz-wool plugs for the support of the resin bed. The columns were filled with 1.25 ml of Bio-Rad AG1X8 (200–400 mesh) anion-exchange resin to a bed height of approximately 4.4 cm.

The standard reference material SU-1a, obtained from the Canadian Centre for Mineral and Energy Technology (CANMET), was used for all experiments performed in this study. The bulk material of SU-1a constitutes a Ni-Cu-Co ore from the Sudbury region (Canada) and consists of 23% chlorite, 12–16% of each of quartz, feldspar, mica and amphibole and less than 4% of each of calcite, siderite, pyrrhotite, pentlandite and chalcopyrite [21]. This sample was chosen for the present study since certified reference concentrations and/or high-quality ICP-MS literature data are available for the PGE. Additionally, it is well suited for elution experiments because it is characterized by relatively high precious metal abundances (Table 3) and, since the mineralogy of SU-1a is predominantly silicate, the results are expected to be valid for silicate rocks in general [22].

2.3. Nickel sulfide fire assay digestion

Sample digestion was performed using the nickel sulfide fire assay digestion technique [23,24]. The fusion charge composition was chosen in accordance with the results of a detailed study conducted by Paukert and Rubeska [25]. Powder splits, 5–10 g sized, of the sample SU-1a were weighed directly into 50 ml Coors fireclay crucibles. To this were added 6 g sodium tetraborate, 3 g sodium carbonate, 500 mg nickel powder and 400 mg sulfur for every 5 g of rock sample present. The fusion charges were then thoroughly mixed in the crucible and fluxed in a muffle furnace for 75 min at 1000°C.

Following cooling, the NiS beads were removed from the crucibles, placed into 15 ml Savillex beakers with screw cap lids, and refluxed with 6 ml of concentrated (11 M) HCl for approximately 24 h on a hotplate. Concentrated (13.5 M) HNO_3, 2 ml, were then added and the beakers placed back on the hotplate for a further 24 h. After this step the beads were generally completely dissolved. If an undissolved residue still persisted, however, the solutions were evaporated to incipient dryness and the residue was again refluxed with 4 ml of freshly prepared aqua regia for approximately 24 h.

Following complete dissolution of the NiS buttons in aqua regia and evaporation of the solutions to dryness, 5–10 ml of 1 M HCl and 500–1000 μl of saturated bromine water (this mixture is abbreviated as 1 M HCl + 10% Br_2 hereafter) were added to the samples. The beakers were placed on a hotplate with lids closed for at least 12 h and the solutions then dried completely.

2.4. Ion-exchange separation

Approximately, 1.25 ml of fresh anion-exchange resin were transferred as a slurry into a quartz column and the resin bed was cleaned and equilibrated prior to use with the following reagents: 20 ml of 0.8 M HNO_3 (elution of Zn, Cd), 10 ml 11 M HCl (elution of Ag and Ru), 25 ml 13.5 M HNO_3 (elution of residual Ru and Re, Pd, Pt, Ir), 40 ml 6 M HCl (reconversion of the resin into the chloride form), 4 ml 1 M HCl +

10% Br_2, backwash with 1 M HCl + 10% Br_2, 2 × 2 ml 1 M HCl + 10% Br_2 (equilibration of the resin prior to sample loading).

Samples prepared as described above were dissolved in 5–10 ml of 1 M HCl + 10% Br_2 for 24 h on a hotplate prior to ion-exchange chemistry. Centrifugation of the sample solutions before loading of the columns was not necessary because clear solutions, with no undissolved residue, were obtained in all cases during this study. Following loading of the solutions onto the columns, sample elution was initially performed using a variety of different procedures and acids in an effort to determine the best separation conditions. Effluent fractions with volumes of 2–10 ml were collected in Teflon beakers for the determination of elemental concentrations and dried down at low heat on a hotplate. After the development of satisfactory separation protocols had been completed, the reliability and performance of these techniques were further verified and documented by additional elution experiments. One of the optimized ion-exchange procedures ('Method 1', see Section 3.1) was finally used for the separation of Re and the PGE Ru, Pd, Ir, Pt prior to ID concentration measurements by MC-ICPMS.

2.5. Analysis of ion-exchange fractions from elution experiments

Prior to analysis, the dried effluent fractions were redissolved in approximately 60 μl of aqua regia and dried down slowly to a volume of approximately 5 μl. This residue was then taken up in 2–5 ml of H_2O, and the solutions thus obtained were analyzed by MC-ICPMS.

The absolute signal intensities for each element and fraction was measured using either a Faraday cup (concentrations > 1 ppb) or the Daly detector (concentrations < 1 ppb), depending on the abundance of the analyte in the respective fraction. The following isotopes, chosen for the absence of isobaric interferences, were used in these measurements: ^{66}Zn, ^{99}Ru, ^{105}Pd, ^{107}Ag, ^{111}Cd, ^{185}Re, ^{189}Os, ^{191}Ir and ^{195}Pt. Matrix induced signal suppression was monitored and corrected for by the addition of U to the sample solutions.

Elution curves, based upon the relative signal intensities of each element in the different fractions, were constructed with these data. The accuracy of this semiquantitative procedure is estimated to be ± 10%. This was judged to be adequate for the construction of elution curves and no effort was made to employ a more accurate, but time consuming, measurement and calibration technique.

2.6. Isotope dilution concentration measurements

Enriched stable isotopes of ^{99}Ru, ^{105}Pd, ^{185}Re, ^{191}Ir and ^{198}Pt from the Oak Ridge National Laboratory were used to determine the concentrations of these elements in the standard reference material SU-1a. The preparation and calibration of the spike solutions will be described in detail in a forthcoming publication. It should be mentioned, however, that the ^{99}Ru and ^{191}Ir spike solutions have hitherto been calibrated only against gravimetric standard solutions prepared from $(NH_4)_2RuCl_6$ and $(NH_4)_2IrCl_6$, respectively. Any deviation of the composition of the employed compounds from perfect stochiometry will thus result in systematic errors in the calibration of the tracer solutions. Until the calibration of the spike solutions is further verified using gravimetric standard solutions prepared from the pure metals, the analytical results presented in this paper for Ru and Ir are considered to be provisional only. Any errors are unlikely to be larger than approximately 5%, however.

For isotope dilution analyses appropriate aliquots of the tracer solutions were added directly to the sample powders in the fireclay crucibles prior to the fire assay digestion. The samples were then digested as described above and an optimized ion-exchange procedure ('Method 1'; see Section 3.1) was used for the separation of Ru, (Re, Pd) and (Pt, Ir) fractions from the sample solutions. Following collection, the three precious metal fractions were evaporated to complete dryness on a hotplate, dried again with approximately 30 μl of concentrated HNO_3 and then redissolved in an appropriate volume of H_2O (generally approximately 5–20 ml) for analysis. All isotope dilution concentration measure-

ments were performed by static multiple collection using Faraday cups only. While the (Re, Pd) fractions were split into two parts prior to analysis (because Re and Pd must be analyzed sequentially with different collector positions due to the large mass difference between these elements), Pt and Ir were determined simultaneously with the same Faraday cup configuration. Further details of the measurement procedures (e.g., choice of isotopes monitored, collector configurations, mass discrimination correction, detection limits, etc.) are outside the scope of this paper and will be described in detail in a further publication.

3. Results and discussion

3.1. Elution experiments

A variety of different organic and mineral acid types and elution procedures were initially tested to find an optimal separation protocol for the PGE and other siderophile elements from geological samples following a NiS fire assay digestion. These experiments led to the development of two optimized anion-exchange separation procedures that are suitable for the isolation of Zn, Cd, Ag, Re, Ru, Pd, Ir and Pt from 5 to 10 g sized silicate rock samples. The experimental details of the two new elution protocols are summarized in Tables 1 and 2.

Table 1
Elution sequence of ion-exchange procedure 'Method 1' for the separation of Zn, Cd, Ag, Re and the PGE Ru, Pd, Ir and Pt from geological samples

Eluent	Volume (ml)	Eluted
Sample solution in 1 M HCl + 10% Br_2	~5–10	Bulk matrix
0.5 M HCl + 10% Br_2	2	Bulk matrix
0.8 M HNO_3 + 10% Br_2	0.5	Bulk matrix
0.8 M HNO_3 + 10% Br_2	5	Zn, Cd
11 M HCl	2	Ag
11 M HCl	10	Ru
8 M HNO_3	10	Pd, Re
13.5 M HNO_3	14	Ir, Pt

Table 2
Elution sequence of ion-exchange procedure 'Method 2' for the separation of Zn, Cd, Ag, Re and the PGE Ru, Pd, Ir and Pt from geological samples

Eluent	Volume (ml)	Eluted
Sample solution in 1 M HCl + 10% Br_2	~5–10	Bulk matrix
0.5 M HCl + 10% Br_2	2	Bulk matrix
0.8 M HNO_3 + 10% Br_2	0.5	Bulk matrix
0.8 M HNO_3 + 10% Br_2	5	Zn, Cd
8 M HNO_3	10	Ru, Re
13.5 M HNO_3	14	Pt, Ir
11 M HCl	2	Ag
11 M HCl, 13.5 M HNO_3	8, 5	Pd

Figs. 1 and 2 display the different elution patterns of the siderophile elements for the new ion-exchange methods. Plotted in these figures are the normalized elemental signal intensities for each fraction and element on a relative scale from 0–1000. An arbitrary value of 1000 was assigned to the fraction of each element that displayed the highest signal intensity in each experiment, permitting a direct visual comparison of the results for the two ion-exchange separation methods.

Both separation procedures use the same ion-exchange columns (see Section 2.2) and the same acids (see Tables 1 and 2) for loading of the sample solutions (5–10 ml 1 M HCl + 10% Br_2) and the initial rinse (2 ml 0.5 HCl + 10% Br_2, 0.5 ml 0.8 M HNO_3 + 10% Br_2). The rationale behind this choice of mineral acids is that the major cationic constituents of the sample solution (particularly Ni^{2+}, but also Fe^{3+}) are virtually unretained on the anion-exchange resin under these conditions [26–29]. Therefore only small columns are required for the processing of the NiS beads derived from approximately 5 to 10 g sized silicate rock samples. Additionally, small eluent volumes suffice to achieve a nearly quantitative elution of the bulk sample matrix. An oxidant must be added to the dilute HCl and HNO_3 eluents, however, to ensure efficient retention of Ir. On-column reduction of the Ir(IV) present in the sample solutions will otherwise lead to the formation of virtually unretained Ir(III). A number of oxidizing agents such as Ce(IV), H_2O_2 or chlorine

gas are recommended for this purpose in the literature [29]. In this study, saturated bromine water was used as the oxidant, since this achieves reliable oxidation of Ir, introduces no cations (such as Ce) that may form interfering isobars [5] and is conveniently prepared, purified and handled.

Following these initial steps, Zn and Cd are quantitatively stripped from the resin by elution with 5 ml of 0.8 M HNO_3 + 10% Br_2 (Figs. 1 and 2). The other siderophile elements considered in this study are not removed from the column. This was initially somewhat surprising in the case of Ag, since published distribution coefficients and separation procedures predict that Ag should be eluted from the column by 0.8 M HNO_3 [26,30]. No significant amounts of Ag could be detected in the 0.8 M HNO_3 + 10% Br_2 effluent fractions,

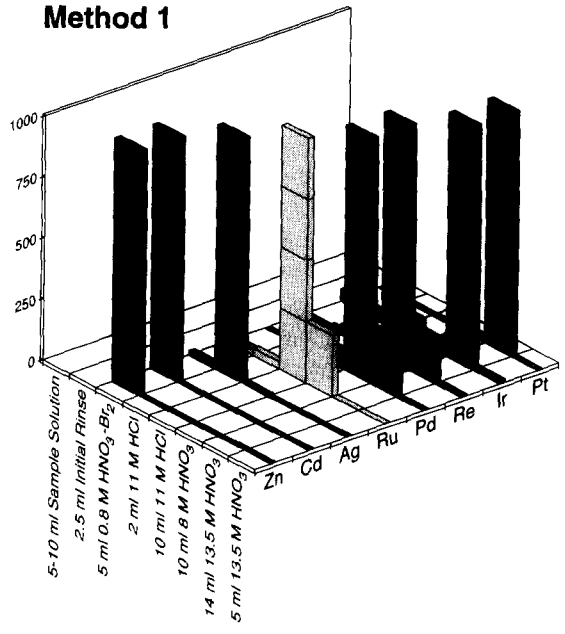

Fig. 1. Elution of Zn, Cd, Ag, Re and the PGE Ru, Pd, Ir and Pt during anion-exchange separation of standard rock SU-1a using 'Method 1'. Plotted are the normalized signal intensities for each element and effluent fraction on a scale of 0–1000. For each element the data are normalized by assigning an arbitrary value of 1000 to the signal intensity of the fraction that displays highest intensity. Effluent fractions with no data where not analyzed. 2.5 ml Initial rinse = 2 ml 0.5 M HCl + 10% Br_2 followed by 0.5 ml 0.8 M HNO_3 + 10% Br_2 (see Table 1).

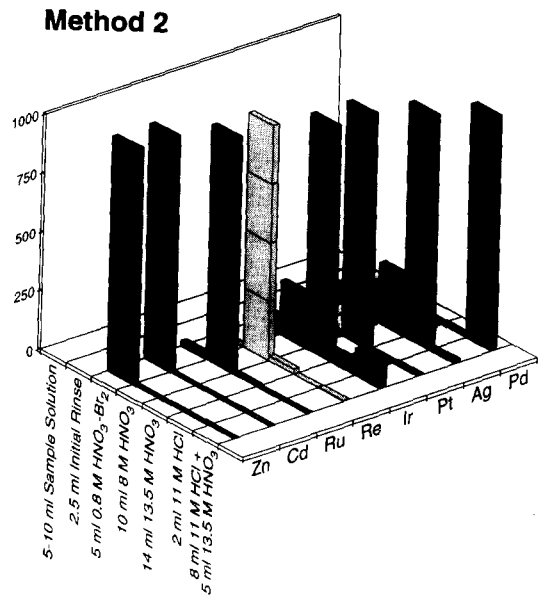

Fig. 2. Elution of Zn, Cd, Ag, Re and the PGE Ru, Pd, Ir and Pt during anion-exchange separation of the standard rock SU-1a using 'Method 2'. The figure displays the normalized elemental signal intensities (on a scale of 0–1000) for each element and effluent fraction. Normalized signal intensities were obtained with the same procedure used in Fig. 1. Effluent fractions with no data where not analyzed. 2.5 ml Initial rinse = 2 ml 0.5 M HCl + 10% Br_2 followed by 0.5 ml 0.8 M HNO_3 + 10% Br_2 (see Table 2).

however. This is most likely due to complex formation of Ag with trace amounts of Br^- in the eluent or with residual Cl^- present in the resin bed [30]. Since the elution protocols of the two new ion-exchange procedures are different after these initial steps, the two methods will be discussed separately in the following.

Ion-exchange procedure Method 1 (Table 1 and Fig. 1) continues with the elution of Ag and Ru using 2 and 10 ml of 11 M HCl, respectively. Addition of bromine water to the 11 M HCl eluent for the stabilization of Ir(IV) is not necessary, because significant amounts of Ir were not detected in the respective effluent fractions (Fig. 1) and is not desirable in any case, since this will lead to the elution of Re, as was demonstrated in additional experiments. The column yield for Ru is only marginally improved if larger volumes of 11 M HCl are used for the recovery of this

element. Additionally, this will result in increased losses of Re and Pd by premature elution.

In the next step of Method 1, Pd and Re are eluted from the anion-exchange column using 8 M HNO_3. With this acid, 10 ml are generally sufficient to achieve a yield of greater than approximately 85–90% for both elements (Fig. 1). Previous publications suggested using hot (approximately 80–100°C) nitric acid for the elution of the PGE from anion-exchange resins [5,31]. While no temperature controlled column was available for this study, the 8 M HNO_3 eluent was heated to a temperature of approximately 90°C prior to introduction of the acid into the column reservoir. Additional separation experiments confirmed that this procedure achieves a somewhat more efficient elution of Pd than use of 8 M HNO_3 at room temperature.

Although only small amounts of Ir and Pt are eluted from the resin with up to 20 ml of hot 8 M HNO_3, these elements can be efficiently stripped from the column with concentrated (approximately 13.5 M) nitric acid. While approximately 8–10 ml of 13.5 M HNO_3 are sufficient for the elution of Pt, approximately 10–15 ml are required for near-quantitative removal of Ir (Fig. 1). Elution with further 13.5 M HNO_3 leads to no significant improvements in elemental recovery for these metals (Fig. 1). The efficiency of the Pt, Ir elution is nearly identical for acids introduced into the column at approximately 90°C or at room temperature.

While ion-exchange procedure Method 2 (Table 2 and Fig. 2) uses the same acids as Method 1 (Table 1) they are applied in a different order to obtain a different elemental elution sequence. This can be of significance, e.g., to achieve a separation of Pd from Ru, which is not possible with Method 1. Following loading of the sample solutions, the initial rinse and the elution of Zn and Cd (which are identical to Method 1), Method 2 involves the elution of Ru and Re with 8 M HNO_3 at approximately 90°C. While the Ru recovery of this technique is somewhat better than for Method 1, significant amounts of Ir were eluted prematurely during this step and this could not be prevented even by the addition of bromine water to the eluent (Fig. 2). Significant amounts of Pd, however, were not detected in this effluent fraction. This result is somewhat surprising, since the same acid (8 M HNO_3) is used in Method 1 for the recovery of Pd.

Method 2 continues with the elution of Ir and Pt using 14 ml of 13.5 M HNO_3 (Fig. 2). Significant amounts of Ag accompany these elements in this procedure, however. The main Ag and Pd fractions are hereafter rinsed from the column using 2 ml of 11 M HCl and 8 ml of 11 M HCl followed by 5 ml of 13.5 M HNO_3, respectively (Fig. 2). Again the behavior of Pd was unexpected since only small amounts of this element were eluted from the resin in Method 1 with 12 ml of 11 M HCl. The reasons for the different ion-exchange properties of Pd in Methods 1 and 2 are not fully understood, but they are probably related to either complex-forming reactions of Pd with Cl^- and NO_3^- or different oxidation states of the cation (Pd^{2+} vs. Pd^{4+}) on the resin.

While our new ion-exchange techniques have hitherto only been applied to the separation of the PGE and other siderophile metals from 5 to 10 g sized geological samples they can easily be applied to the processing of even larger samples, through the use of larger resin beds and proportionally larger reagent volumes.

3.2. Elemental yields

The elution curves of Figs. 1 and 2 permit a rough, semiquantitative estimate of the elemental yield for the column chemistry. This is possible by comparing the signal intensity of, e.g., Ru in the main Ru fraction with the sum of the signal intensities of Ru in the all of the collected fractions. This estimate, however, is based upon the assumption that Ru is not eluted from the column in effluent fractions that are not analyzed and that no fraction of the element remains bound on the column after completion of the ion-exchange separation.

The semiquantitative results obtained by this procedure (estimated accuracy $\pm$ 10%) suggest that both methods generally achieve chemical yields of greater than approximately 80% for all considered elements with the exception of Ru in Method 1 (approximately 70%) and Ag and Ir in

Table 3
Re and PGE concentrations (in ppb) from this study and the literature for the geological reference material SU-1a

Element	MC-ICPMS this study	1σ	RSD (%)	n	Certified values [21]	ICP-MS Ref. [3]
Ru	54.4	1.6	2.9	4		44 ± 4
Pd	354	15	4.3	5	370 ± 30	327 ± 27
Re	40.9	1.4	3.4	5		14 ± 6
Ir	31.3	0.7	2.2	5		24 ± 2
Pt	370	41	11.1	5	410 ± 60	367 ± 40

$1\sigma = 1$ standard deviation; RSD = relative standard deviation; n = number of individual determinations, based upon repeat dissolutions. The certified values [21] are quoted with the $\pm 95\%$ confidence interval. Data of Ref. [3] are shown with 1σ external precision.

Method 2 (approximately 65%). No significant amounts of Os were detected in any of the ion-exchange fractions separated from reference material SU-1a. This indicates that Os is lost from the sample solutions as volatile OsO_4 during the dissolution of the NiS buttons with aqua regia.

After Method 1 was chosen for the separation of the PGE and Re from geological samples prior to concentration measurements by MC-ICPMS, the elemental yields of the analytical procedure were determined more rigorously. For this purpose two 5 g splits of a granitic rock sample (with negligible PGE concentrations and a known Re abundance) were doped with approximately 1 μg each of Re, Ru, Pd, Ir and Pt. The samples were then digested using the NiS fire assay technique and elemental fractions of Ru, (Re, Pd) and (Pt, Ir) were separated from the solutions of the NiS buttons using the ion-exchange procedure Method 1. After evaporation of the fractions to dryness, these were spiked with precisely weighed aliquots of stable isotope tracer solutions, refluxed for approximately 24 h on hotplate with 4 ml of aqua regia to ensure spike-sample equilibration and dried down again. The elemental yields of the complete analytical procedure were then determined by isotope-dilution analysis of the fractions with the Plasma 54. The results of the ID measurements are in good agreement with the semi-quantitative data obtained from the evaluation of the elution curves and indicate total procedural yields of approximately 85–95% for Re, Pd, Ir and Pt and of approximately 70–75% for Ru.

The high procedural yields for the PGE and Re also demonstrate that these elements are nearly quantitatively extracted into the NiS buttons during the fire assay sample digestion. In the case of Re, this result is in contradiction to reports of other investigators [3,32]. Our data, however, are further confirmed by the analyses of two fire assay fusion glasses from reference sample SU-1a, with both glass samples being characterized by negligible Re concentrations.

3.3. Isotope dilution analyses

The concentrations of Re and the PGE Ru, Pd, Ir and Pt were determined in five (four in the case of Ru) separate powder splits of the geological reference material SU-1a by isotope dilution measurements with the Plasma 54. The analytical results of these analyses are summarized and compared with certified reference values and other literature data in Table 3. The 1 σ external precision obtained by our technique varies between approximately 2 to 5% for all elements considered in this study, except Pt. The comparatively low precision of our Pt data (approximately 11%) is due to just one anomalously low result. Exclusion of this 'outlier' (Pt concentration 303 ppb) from the dataset results in a mean concentration of 387 ppb Pt for SU-1a, with a relative standard deviation of 5%. Since the other elemental concentration data of this particular sample split showed no irregularities, we suggest that the single outlier of our Pt dataset is due to the inhomogeneous distribution of a Pt-rich phase in the sample powder and is not caused by an analytical error such as incomplete spike-sample equilibration. This interpretation is supported by the fact that the previ-

ously published Pt data for reference material SU-1a (Table 3) are also characterized by relatively large analytical uncertainties in comparison to the results for other elements.

The new MC-ICPMS data are in excellent agreement with previously published values for the high-concentration elements Pt and Pd (Table 3). No certified reference concentrations are available for the elements Ru, Re and Ir, but our results are significantly higher than the ICP-MS data of Jackson et al. [3]. In the case of Re, this is probably due to incomplete recovery and loss of this element during the sample preparation procedure of Jackson et al. [3], as indicated by these authors in their publication. The discrepancies for Ru and Ir, where our data are approximately 20% higher compared with the results of Jackson et al. [3], are unlikely to be due solely to errors in the calibration of the spike solutions or blank problems. The total procedural blank of our analytical procedure was carefully monitored throughout and was found to be insignificant ($< 1\%$) for all elements considered in this study. Consequently no blank correction was applied to the analytical results. The excellent analytical precision that was obtained for the PGE as well as Re furthermore demonstrates that full spike-sample equilibration was routinely achieved during sample digestion, ruling out another potential pitfall. Since our isotope dilution technique does not require full elemental recovery during sample digestion and ion-exchange chemistry, we suggest that the differences in the concentrations are not a result of our analytical procedure but are due to other factors such as heterogeneity of the sample powders.

Acknowledgements

Der-Chuen Lee, Marcus Johnson, John Christensen and the other members of the RIGL team provided valuable technical assistance and advice. Becky Lange is thanked for making her lab and furnace available for these studies. The constructive comments of two anonymous reviewers were highly appreciated and led to significant changes and improvements in the manuscript. This research was supported by grants from DOE, NASA and NSF.

Abstract

The application of the ratio spectra derivative and partial least-squares methods to the simultaneous determination of atrazine and its degradation product desethylatrazin-2-hydroxy is presented. When the different methods are applied to the determination of these products in ground waters, PLS method gives the best results due to the presence of interfering substances with overlapping spectra. © 1997 Elsevier Science B.V.

Keywords: Atrazine; Derivative spectra; Desethylatrazin-2-hydroxy; Ground waters; Partial least squares; Ratio spectra derivative; Spectrophotometry

1. Introduction

Triazine herbicides, developed in the early 1950s [1], have been used for nearly 20 years in agriculture all over the world. Due to filtration through soil, atmospheric deposition or surface run-off most of these triazine herbicides have been reported as common contaminants in aquatic environments, including rivers, lakes, estuaries, rain water and both surface and ground waters [2–8].

Investigation of the impact of the agricultural non-point source concentration necessitates the development of rapid and accurate methods for the determination of these pesticides. Common multimethods are mainly based on gas chromatography with selective detection using electron capture, nitrogen–phosphorous, flame photometric detectors and mass selective detector. Other chromatographic techniques used in pesticide analysis are reversed-phase high performance liquid chromatography (RP–HPLC) with UV-Vis or diode array detectors and thin layer chromatographic methods [9–16]. Antibody-based assays represent an effective alternative to chromatographic methods, but discrimination of chemically similar structures is usually inferior to instrumental analysis [17,18]. However, these techniques are considerably time-consuming and expensive. UV-

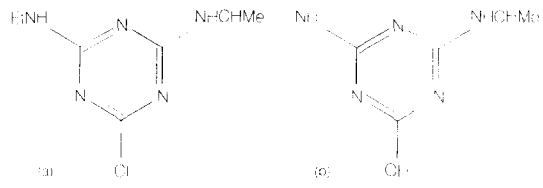

Fig. 1. (a) Atrazine; (b) desethylatrazin-2-hydroxy.

Vis analysis offers a fast and reliable method to obtain information about the distribution of these pesticide residues in waters. Furthermore, costs for UV-Vis determinations are far below of other instrumental methods.

The European Union (EU) has imposed rigid limits for pesticides in drinking water. So the maximum level allowed for a single pesticide is 0.1 μg l^{-1} while for a pesticide and its degradation products a limit of 0.5 μg l^{-1} has been established [19,20]. Although the use of UV-Vis methods do not allow to determine these pesticides for the established limits, these can be reached using the enrichment procedures described in the literature for *s*-triazines and their metabolites, such as liquid–liquid extraction [21] and solid-phase extraction (SPE) [22,23].

UV-Vis quantitation methods traditionally used involve measuring the analyte absorbance at a given wavelength. However the analyte of interest is often accompanied by other compounds absorbing in the same spectral region. In these cases, spectral overlapping is a serious limitation and requires resolution by mathematical procedures such as derivative techniques or multivariate statistical analysis, in this way, partial least squares, PLS, have been successfully applied to spectroscopic data [24–26]. Recently PLS has been applied to electroanalytical techniques, such as indirect voltametric of differential pulse polarographic (DPP) [27,28].

Considering that in real environment situations, the atrazine (Fig. 1a) degrades and the dealkylated and the hydroxylated metabolites are formed, [29,30] the present paper reports different quantitation methods such as zero crossing, ratio spectra derivative and PLS for the determination of atrazine and a hydroxy-dealkylated degradation product, desethylatrazin-2-hydroxy (Fig. 1b) in ground water samples.

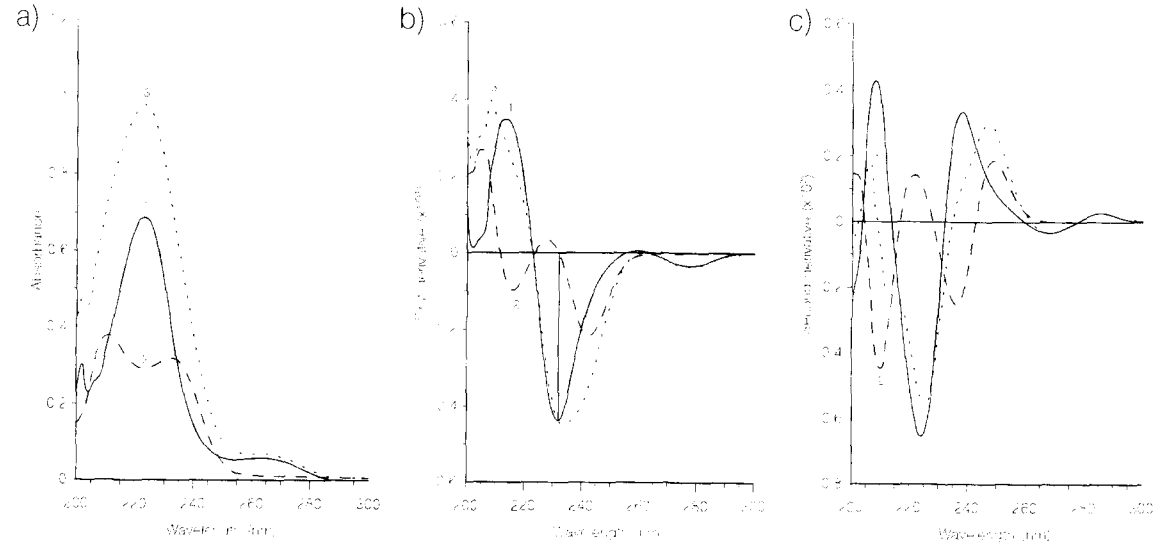

Fig. 2. Absorption spectra of (1) atrazine, 2 μg ml^{-1}, (2) desethylatrazin-2-hydroxy and (3) their mixture: (a) zero-order spectra, (b) 1st derivative spectra, and (c) 2nd derivative spectra.

2. Experimental

2.1. Reagents

Stock solutions, 100 μg ml^{-1} of atrazine (AT) and desethylatrazin-2-hydroxy (DAH) (Riedel-de Haën, Seelze Germany) were prepared in methanol. The pH of the working solutions was adjusted to pH = 5.8 with 1 ml of 0.1 M acetic/acetate buffer solution and the final percentage of methanol was 8% v/v. The ionic strength was maintained constant at 0.25 M with $NaClO_4$.

All reagents used were of analytical reagent grade and water deionized.

2.2. Apparatus

All absorption spectra were acquired on a Hewlett–Packard HP-8452A diode array spectrophotometer, furnished with a quartz cell of 1 cm path length, coupled on a Hewlett–Packard Vectra ES Computer equipped with a Hewlett–Packard Think Jet printer.

Absorption spectra were recorded and processed with the aid of the spectrophotmeter's bundled software. A PC/AT 46 computer provided with a mathematical coprocessor, equipped with the Unscrambler II [31] software package was used for the statistical treatment of the data and the application of multivariate methods.

A PHM 84 Radiometer digital pH meter equipped with a combined glass calomel electrode, was used to measure pH.

A Swinny Stainless 13 mm (Millipore) equipped with cellulose 0.45 μm filter (Millipore) was used to filter ground water samples.

2.3. Procedures

2.3.1. Zero crossing method

To 25 ml calibrated flasks were added 2.5 ml of 2.5 M $NaClO_4$ solution, 1 ml of acetic/acetate pH = 5.8 buffer solution, atrazine and desethylatrazin-2-hydroxy both in the range 25–150 mg, enough methanol to obtain a final composition of 8% v/v and made up to volume with deionized water.

To determine atrazine in presence of desethylatrazin-2-hydroxy first derivative of the spectra were obtained and calibration graph was prepared at the zero-crossing point ($\lambda_{AT} = 232$).

2.3.2. Ratio spectra derivative

To determine atrazine, the adsorption spectra of the solutions (prepared as in Section 2.3.1) were recorded between 200–350 nm and divided by the standard spectrum of a 2 μg ml^{-1} desethylatrazin-2-hydroxy solution. From the ratio spectra thus obtained, first derivatives were calculated. The concentration of atrazine is proportional to the amplitude at 216 nm.

To determine desethylatrazin-2-hydroxy, the adsorption spectra of the solutions were recorded between 200–350 nm and divided by the standard spectrum of a 2 μg ml^{-1} atrazine solution. From the ratio spectra thus obtained, first derivatives were calculated. The concentration of desethylatrazin-2-hydroxy is proportional to the amplitude at 236 nm.

2.3.3. PLS method

Eleven solutions were prepared for the corresponding multivariate calibration used to apply PLS-1 method. The optimized calibration matrix calculated by application of the PLS-1 method was then applied to analyze the 1st and 2nd derivative spectra of the samples in the range 240–280 nm.

2.3.4. Procedure to determine atrazine and desethylatrazin-2-hydroxy in ground waters

Ground waters from mountain sources were filtered and spiked with variable amounts of atrazine (50–125 mg) and desethylatrazin-2-hydroxy (50–150 mg) and analyzed according to the procedures outlined above.

3. Results and discussion

Fig. 2a shows the absorption spectra corresponding to atrazine, desethylatrazin-2-hydroxy and a mixture of them, at pH = 5.8, methanol-water 8% v/v and I = 0.25 M. The absorption maxima for atrazine are at 226 nm and 264 nm, and

no changes were observed in the spectra in the pH range 1–11. the absorption maxima for desethylatrazin-2-hydroxy are situated at 212 and 234 nm. In this case, at the same operatory conditions, the adsorption spectra are slightly influenced by variations of pH. It was observed that pH = 5.8 offers the best conditions to study the mixture of both pesticides.

3.1. Zero-crossing method

The adsorption spectra of desethylatrazin-2-hydroxy is completely overlapped with the spectrum of atrazine (Fig. 2a) and thus the determination of atrazine in presence of desethylatrazin-2-hydroxy, or vice-versa, can not be carried out by direct absorbance measurements. Fig. 2b shows the first derivative adsorption spectra of solutions of both pesticides and of their mixture. It can be seen that in spite of the overlapped O-order spectra of these compounds, the zero-crossing method could be suitable to obviate that problem. To quantitate atrazine in presence of desethylatrazin-2-hydroxy, the measurements were made at the zero-crossing point of desethylatrazin-2-hydroxy, at 212 and 232 nm. The best results were obtained at 232 nm (Table 1). However, the quantitation of desethylatrazin-2-hydroxy, in presence of atrazine at 256 nm zero-crossing point of atrazine is not satisfactory. Although the second derivative spectra of atrazine and desethylatrazin-2-hydroxy (Fig. 2c) produce some zero-crossing points for both pesticides that could permit their quantitation, the corresponding calibration graphs at 212 and 232 and 216, 228 and 242 nm for the quantitation of atrazine and desethylatrazin-2-hydroxy, respectively, do not allow good results. Similar results are obtained with higher order derivative spectra.

Thus, the zero-crossing method using first derivative spectra can only be used to quantitate atrazine in presence of desethylatrazin-2-hydroxy (Tables 1 and 2).

3.2. Ratio spectra derivative method

In the ratio spectra derivative method, overlapping of the spectra in a certain region is actually desirable because in division of spectrum by another, the error increases when one of absorbance approaches zero [32]. Fig. 3a shows the ratio spectra derivative of different amounts of atrazine, first derivative of the spectra of atrazine standard solutions divided by the standard spectrum of a 2 μg ml^{-1} solution of desethylatrazin-2-hydroxy. The first derivative amplitude at any given wavelength is proportional to the atrazine concentration, and the wavelength corresponding to the maximum at 216 nm was selected. Fig. 3b shows the ratio spectra derivative for different standard solutions of desethylatrazin-2-hydroxy, using the spectrum of a 2 μg ml^{-1} solutions of atrazine as the divisor. In this case, the optimum results were obtained at 236 nm.

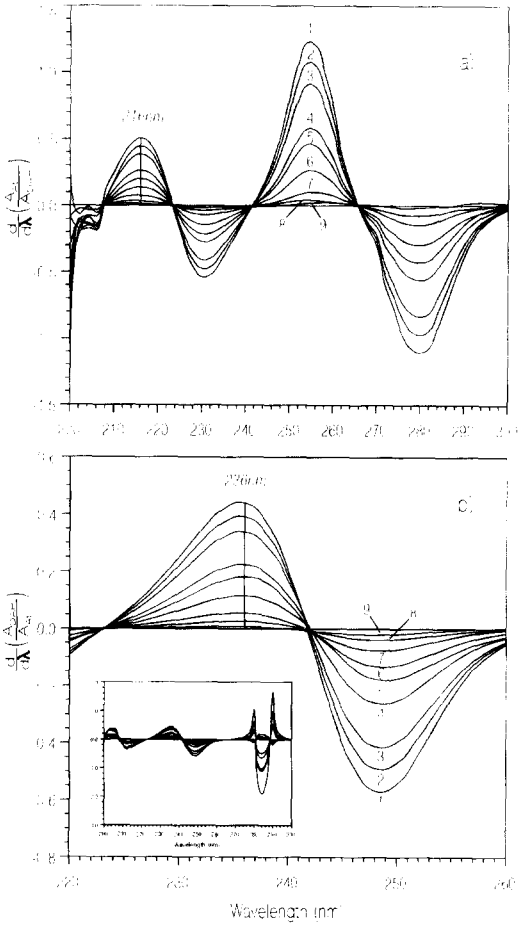

Fig. 3. First derivative of the ratio spectra of (a) atrazine, (b) desethylatrazin-2-hydroxy, using a 2 μg ml^{-1} divisor, solutions: (1–9) 0.2–8 μg ml^{-1}.

The ratio spectra derivative method allow to use different concentrations as the divisor to obtain the calibration graphs Thus, to quantitate atrazine, concentrations of desethylatrazin-2-hydroxy in the range 0.2–8.0 μg ml^{-1} were used and in order to minimize the standard error of the estimations and a concentration of 2 μg ml^{-1} of DAH was selected as divisor, Fig. 4. Similarly, a 2 μg ml^{-1} solution of atrazine was selected as divisor to quantitate desethylatrazin-2-hydroxy, Fig. 4.

Once the optimum working conditions has been established, calibration graphs were obtained at 216 nm (AT) and 236 nm (DAH), and showed that the proposed method is applicable over the ranges 0.30–8.0 μg ml^{-1} for atrazine and 0.22–8.0 μg ml^{-1} for desethylatrazin-2-hydroxy. The detection limit was calculated as the intercept of the calibration graphs plus three times the estimated standard deviation. The results obtained are included in Table 1. As can be seen, the corresponding r^2 values, which are an indication of the quality of the fitting of the data to the straight line, were higher than 0.9995.

To check the precision of the method, the signals for eleven replicates, containing 2 μg ml^{-1} of atrazine and 2 μg ml^{-1} of desethylatrazin-2-hydroxy were measured. The statistical parameter obtained for the simultaneous determination of both herbicides are shown in Table 2.

The proposed method was applied to several synthetic binary mixtures of atrazine and desethylatrazin-2-hydroxy in the range 1.0–6.0 μg ml^{-1}. The results obtained are summarized in Table 3.

3.3. Partial least squares method

Partial least-squares (PLS) modeling is a powerful multivariate statistical tool that has been successfully applied to quantitative analysis in spectrophotometric methods. PLS is a mathematical procedure that simultaneously includes spectral intensities at multiple selected wavelengths and allows to extract full useful complementary information from all of the spectra data, thus improving the quantitative analysis of mixtures.

It is also well known [33,34] that the quality of the results obtained in multi-component analysis from extensively overlapping spectra depends on the wavelength selection and the spectral mode used. PLS-1 and -2 types have been described. The difference between both types is that PLS-1 performs the optimization of the number of factors for only one component at a time and PLS-2 calculates the number of factors on all the components simultaneously and one pondered number of factor is optimized.

A training set of eleven representative binary mixtures, Table 4, of atrazine and desethylatrazin-2-hydroxy was prepared and the absorption spectra were recorded under the selected experimental conditions.

The PLS-1 method was applied to the quantitation of atrazine and desethylatrazin-2-hydroxy using first and second derivative adsorption spectra respectively, in the range 240–280 nm. By application of the PLS-2 algorithm no better results were obtained.

After the data were autoscaled to the mean value of the variables, the selection of the optimum number of factors in the PLS algorithm as to model the system without overfitting the concentration data, was carried out using the cross-validation method leaving out one sample at a time. Validation variance parameter was used to select the optimum number of factors, Table 5. In this sense, for atrazine the number of factors that minimizes the residual variance (optimal model) were two, corresponding to the local minimum. For desethylatrazin-2-hydroxy, two factors were selected also, because a higher number of factors does not minimize significantly the residual variance and could produce a overfitted model.

The root mean square difference (RMSD), which indicates the average error in the analysis and (R^2) which is an indication of the quality of fit of all the data to straight line were calculated.

$$\mathrm{RMSD} = \left[\frac{1}{N}\sum_{i=1}^{N}(\hat{x}_i - x_i)^2\right]^{1/2}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{N}(x_i - \hat{x}_i)^2}{\sum_{i=1}^{N}(\bar{x}_i - x)^2}$$

where N is the total number of samples, $\hat{x}_i$ = predicted concentration, x_i = standard concentration and $\bar{x}$ = mean of true concentrations. The results are summarized in Table 6.

The calibration model was applied to a series of synthetic mixtures, Table 3, and the analytical precision of the optimized model was evaluated by using the relative error of prediction (REP).

Table 4

0.03592	0.9993	0.04325	0.9990

Values of 1.93 and 2.49% for atrazine and desethylatrazin-2-hydroxy, respectively, indicate that the model proposed is satisfactory.

3.4. Determination of atrazine and desethylatrazin-2-hydroxy in ground water

When working on synthetic mixture, no significant advantages are found in the application of the different methods developed. Because of this, for the analysis of ground waters samples only the ratio spectra derivative and PLS-1 methods, were applied to the simultaneous determination of atrazine and desethylatrazin-2-hydroxy. Spiked samples were prepared from ground waters coming from mountain sources in the highest part of Orotava Valley (Tenerife, Canary Islands), in order to be sure that they were not contaminated with the named herbicides.

The results obtained are shown in Table 7. As can be seen the results obtained by application of ratio spectra derivative method gives such errors, specially for atrazine, that it can not be applied to the determination of these herbicides, in ground water samples. These results can be justified on the basis of the absorption spectra of the ground water, which show a maximum probably due to the presence of humic acids and related compounds, Fig. 5, overlapping those of the analytes.

However, when the PLS-1 method was applied to the first and second derivative spectra of the samples in the range 240–280 nm, as stated above, all the spiked samples of ground water were correctly resolved, Table 7.

4. Conclusions

A comparative study of the utilization of zero-crossing method, ratio spectra derivative and PLS approaches for the determination of mixtures of atrazine and desethylatrazin-2-hydroxy in ground waters samples has been carried out. These methods gave good results when applied to the resolution of synthetic binary mixtures. However, derivative methods are not suitable for the resolution of mixtures of both pesticides in ground waters samples due to the presence of spectral

Abstract

In this paper a study of the electrocatalytic oxidation of propylgallate (PG) by using a polypyrrole electrode modified with tetrasulfonate nickel (II) phthalocyanine complex (Pt/PPy/NiPcTs) was carried out. Several parameters of this polymeric electrode, such as: (a) its stability in hydroorganic solution, by using an indium tin oxide (ITO) electrode and spectrophotometry; and (b) its thickness using electrochemical techniques, have been studied. In addition, several parameters affecting the PG voltammetric peak, such as pH, methanol/water ratio, potential scan rate and analyte concentration, were considered. Finally, the developed method was applied to the determination of PG in spiked potato flakes and cornflakes, showing its validity. © 1997 Elsevier Science B.V.

Keywords: Antioxidant; Nickel phthalocyanine; Polypyrrole electrode

1. Introduction

During the last decade, numerous and considerable advances concerning the development of polymeric materials in order to prepare redox complex modified electrodes with electrocatalytic properties, have been carried out. In this sense we can underline the work of Lyons [1] where an interesting theoretical review of electrocatalysis using electroactive polymers, electroactive composites and microheterogeneous systems was made. These electrodes have permitted the enhancement of the selectivity and sensitivity of many interesting electroanalytical reactions and the use of conducting polymer films in amperometric biosensors [2] and in potentiometric sensors [3].

Electrochemical synthesis of polymeric films has been carried out by different authors [4–8], showing that both the rate and the extension of the polymerisation process, as well as the physicochemical properties of the polymer, can be controlled, by a careful selection of experimental conditions.

From an electroanalytical point of view, one of the compounds more widely used for electrode modification is pyrrole, mainly due to the important amount of counterions incorporated during the electropolymerisation step [9–11]. Moreover, polypyrrole is easily synthesised from different solvents, such as acetonitile [12–14] or water [4,5].

One of the counterions used for the modification of polypyrrole electrodes is the nickel (II) phthalocyanine tetrasulfonate complex (NiPcTs) [15], which allows us to take advantage of the electrocatalytic properties of this type of molecules. Examples of electron transfer reactions catalysed by these polymeric films electrodeposited on a solid electrodes can be found in the review of Cox [16] and Leidner [17]. Food products, mainly those containing a high amount of fat, can be involved in degenerative processes which can produce an important loss of their nutritional value (for example oxidative degeneration of vitamins), the appearance of an unpleasant smell or even the formation of toxic compounds [18]. Consequently, in order to keep the food quality, several antioxidant compounds [18]. Consequently, in order to keep food quality, several antioxidant compounds are added to food products. Antioxidants act against lipidic oxidation by means of different mechanisms.

An important group of oxidants is that of phenolic compounds, which can be either natural compounds or synthetic substances. Regarding synthetic antioxidants, one can consider, among other, the following: TBHQ (tert-butylhydroquinone), BHA (tert-butylhydroxyanisole), BHT (tert-butylhydroxytoluene), PG (propylgallate) and OG (octylgallate).

The use of these synthetic antioxidants is limited by the legislation of different countries [19] and their toxicity studies have been reported [20,21]. As other food additives, their inclusion in the corresponding positive catalogue implies an exhaustive evaluation of the ingestion risks in order to establish the admissible daily dose (ADD). The latter is the daily amount of antioxidant with no toxic effect in animals and is expressed in mg kg^{-1} of animal weight and divided by a security factor, usually 100.

The electrochemical methods used for the determination of antioxidant are numerous and they have been summarised in the review of Mannino and Wang [22]. It is important to emphasize that the electroanalytical methods are very useful for the determination of organic compounds, due to their sensitivity, selectivity and accuracy, as well as to the important information on the electrochemical mechanisms which sometimes are comparable to those taking place in metabolic processes in living organisms. In this sense, we can mention the reviews of Bersier and Bersier [23,24], and Kalvoda [25].

In this paper, a study of the anodic electrocatalysis of propylgallate at a nickel (II) phthalocyanine polypyrrole electrode deposited on a Pt wire is carried out. The stability of the modified electrode in the analytical solution used (Britton–Robinson 0.1 M) was checked by using a spectrophotometric method. Several analytical and electrochemical parameters have been considered and the characteristics of the developed method for the determination of PG established. This method has been applied to several commercial food products, such as spiked potato flakes and cornflakes.

2. Experimental

2.1. Reagents

Sodium nickel (II) phthalocyanine tetrasulfonate, NiPcTs, (Aldrich); sodium p-toluenesulfonate, TsNa, (Fluka); pyrrole (Merck); propylgallate (Riedel de Häen); boric acid (Merck); acetic acid (Merck); orthophosphoric acid (Panreac); sodium hydroxide (Panreac); methanol (Merck); aluminium oxide (Metrohm 6.2802.000); sodium dichromate (Panreac). All reagents were of analytical grade. Ultrapure water was obtained from a Barnstead System.

2.2. Instrumentation

Potentiosatat AUTOLAB PSTAT 10 ECO-CHEMIE (Holland) using the GPES software; spectrophotometer UV-Visible PU 8700, Unicam

(UK); ultrasonic bath P-Selecta (Spain). Mechanical stirrer vibromatic 384 P-Selecta (Spain); rotary vacuum evaporator Büchi (Italy); thermostatic bath P-Selecta (Spain).

2.3. Electrodes

Ag/AgCl/KCl (sat) reference electrode; Pt wire (home made) auxiliary electrode; Pt electrode, 0.076 cm^2 (Metrohm); optically transparent Indium and Tin oxide (ITO) electrodes (5 × 0.8 cm).

3. Procedure

3.1. Electrogeneration of modified polypyrrole electrodes

In all cases, modified polypyrrole electrodes were prepared by chronoamperometry at constant potential (0.8 V vs. Ag/AgCl/KCl (sat) for 60 s) from an aqueous solution onto an ITO or Pt substrate. The working electrode was polished on a polishing cloth with alumina and then cleaned by ultrasonication prior to use. Monomer solutions containing pyrrole (0.1 mol l^{-1}) and NiPcTs (10^{-4} mol l^{-1}), or pyrrole (0.1 mol l^{-1}) and TsNa ($4 \cdot 10^{-4}$ l^{-1}), were deoxygenated with nitrogen for 10 min prior to use.

3.2. Treatment of commercial food samples

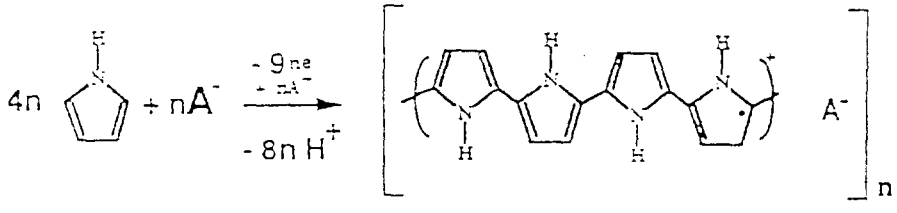
A procedure similar to that proposed by King [26] was followed for the determination of PG in spiked potato flakes. The sample was powdered in an agate mortar. Then, 1 g of this sample, to which 100 μl aliquot of a 0.5 mol l^{-1} PG standard solution in methanol was added, was placed in a 20 ml centrifuge tube. Extraction was carried out with three 5 ml portions of a 50% v/v water:methanol mixture. The tube was mechanically shaken for 5 min, and after centrifugation at 5000 r.p.m. for 12 min, all the extracts were combined in a 100 ml vessel of a rotary vacuum evaporator, and concentrated up to a final volume of 3 ml. This extract was transferred into a 25 ml volumetric flask, and then diluted to the mark with a Britton–Robinson buffer solution of pH 1.05. This solution, with a PG theoretical concentration of $2.0 \cdot 10^{-3}$ mol l^{-1}, was transferred to the electrochemical cell, where PG was voltammetrically determined using the standard additions method (10 μl of a 0.5 mol l^{-1} PG standard solution were added, and the Britton–Robinson solution degassed, each time).

To modify the pH, maintaining the other parameters, a Britton–Robinson solution was employed. Therefore, to vary the pH, a 2 mol l^{-1} NaOH solution was added to the Britton–Robinson solution in sufficient amount to reach the necessary pH values.

All the experiments were carried out at constant temperature (20°C).

4. Results and discussion

Electrochemical polymerisation provides a simple means of incorporating counterions A^- into polypyrrole, according to Eq. 1.



eq.1.

It was found that our NiPcTs could be incorporated directly into poplypyrrole using this method. Polymer growth could be initiated from an aqueous solution containing just the pyrrole monomer and the NiPcTs. When the platinum electrode in monomer solution was subjected to a 800 mV potential step a chronoamperometric response was observed, as shown in Fig. 1, similar to that previously described by other workers in galvanostatic experiments [27,28]. In this figure we can see that, after a great increase of the anodic current density at the potential jump, the current density decreased quickly, but 1 s after the potential step the current density rose again. As NiPcTs is the only other species present, it must be incorporated as the anion (A^-) in the polymer structure.

In order to achieve charge balance, the polymer reduction process in the analyte solution must be accompanied by immigration of cations from Britton–Robinson solution or immigration of anions from polypyrrole electrode. The relatives rates of these competitive processes will determine the outcome. These rates can in principle be understood in terms of diffusion coefficients and partition coefficients. In this way one might rationalize the difference between a conventional PP^+/X^- and our PP^+/NiPcTs where X^- is a more little and faster diffusing species than NiPcTs. So it's reasonable to think that the cations from Britton–Robinson solution move in and out of the polymer

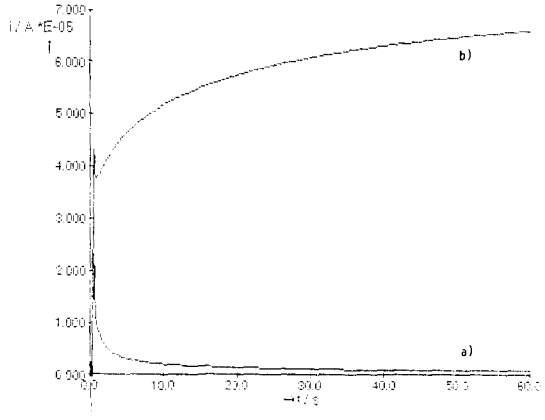


Fig. 1. Chronoamperometric response of a Pt electrode maintained to a constant potential potential of 800 mV during 60 s in 10^{-3} mol l^{-1} NiPcTs in water solution: (a) without pyrrole; and (b) with 0.1 mol l^{-1} pyrrole.

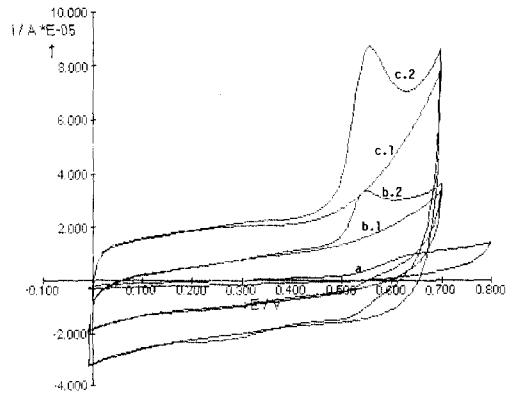

Fig. 2. Cyclic voltammograms obtained in a Britton–Robinson 0.1 mol l^{-1} solution (pH = 1.0; 5.6% methanol; $v = 100$ mV s^{-1} at different working electrodes: (a) WE Pt: with $2 \cdot 10^{-4}$ mol l^{-1} PG; $E_p = 0.631$ V, Ip = 1.87 μA; (b) WE Pt/PPy/Ts: without (I) and with (II) $2 \cdot 10^{-4}$ mol l^{-1} PG; $E_p = 0.554$ V, $I_p = 13.07$ μA; and (c) WE pt/PPy/NiPcTs: without (I) and with (II) $2 \cdot 10^{-4}$ mol l^{-1} PG; $E_p = 0.547$ V, $I_p = 38.29$ μA.

to provide charge compensation and the NiPcTs tends to stay in the reduced film [29].

4.1. Catalytic effect

In order to ascertain if PG is electrocatalytically oxidised at the Pt/PPy/NiPcTs electrode, voltammograms of PG were obtained in a Britton–Robinson 0.1 M solution of pH 1.05 (control solution), at different working electrodes: Pt, Pt/PPy/Ts and Pt/PPy/NiPcTs, where Ts is p-toluenesulphonate, a counterion with no electrocatalytic properties. These voltammograms are displayed in the Fig. 2. As can be seen the best results were obtained when working with a Pt/PPy/NiPcTs electrode, showing a higher PG peak intensity and demonstrating that an electrocatalytic effect is produced (Fig. 2 curve c.2).

It is necessary to remark that the cyclic voltammogram produced, when using a Pt/Ppy/NiPcTs electrode in pure (blank) electrolyte, show a high background current. The electrochemical reaction of the polypyrrole film in the supporting electrolyte was previously mentioned; this polypyrrole reaction is quite sensitive to the nature of the electrolyte and of the counterion incorporated into the polymer, since it involves movements of ions in and out

of the film. A. Díaz et al. [30] describe that the observed background currents are dependent on the potential region, the polarity of the solvent, the sweep rate and perhaps the nature of counterions incorporated. But the large background observed do not interfere with the electrochemical measurements using cyclic voltammetry. No signal of Ni(II) oxidation is produced because NiPcTs is an example of a redox inactive transition metal phthalocyanines [31].

4.2. Spectrophotometric control of the polymer stability

In order to verify that the NiPcTs film remained adsorbed onto the Pt electrode, a series of polymeric electrodes modified with NiPcTs were prepared on transparent Indium and Tin oxide (ITO) electrodes in the conventional way described in experimental section. The presence of the modifier onto these electrodes was studied by using molecular absorption spectroscopy. The spectra were compared with those recorded with NiPcTs in Britton–Robinson solution and the following results were obtained:

4.2.1. Study of the stability of the ITO/PPy/NiPcTs electrostatic finding in aqueous media

We have prepared several polypyrroles on ITO as mentioned above. These electrodes were subjected to the following spectrophotometric tests: (a) molecular absorption spectra of a freshly prepared electrode introduced into the control solution; (b) molecular absorption spectra of the control solution in which the polymer modified electrode was immersed for 15 min; and (c) molecular absorption spectra of the control solution in which the polymer modified electrode was immersed for 30 min. These experiments were carried out at three different pH values: 1.0, 7.20 and 11.30. The spectra of pH 1.05 are shown in Fig. 3 showing the others pH similar spectra. From these, it can be deduced that the polymer did not leak into the control solution.

The absorption spectra recorded after rinsing the electrodes with water are compared with those of the NiPcTs dissolved in Britton–Robinson solution at corresponding pH values, showing both a similar absorption spectrum. So we can conclude that the NiPcTs are retained by polypyrrole film, owing to electrostating binding. Because of the incorporation into the polymer films, a red shift of a few nanometers is observed for the Soret band. This red shift can likely be attributed to the aggregation and stacking of NiPcTs molecules in the polymer [32,33].

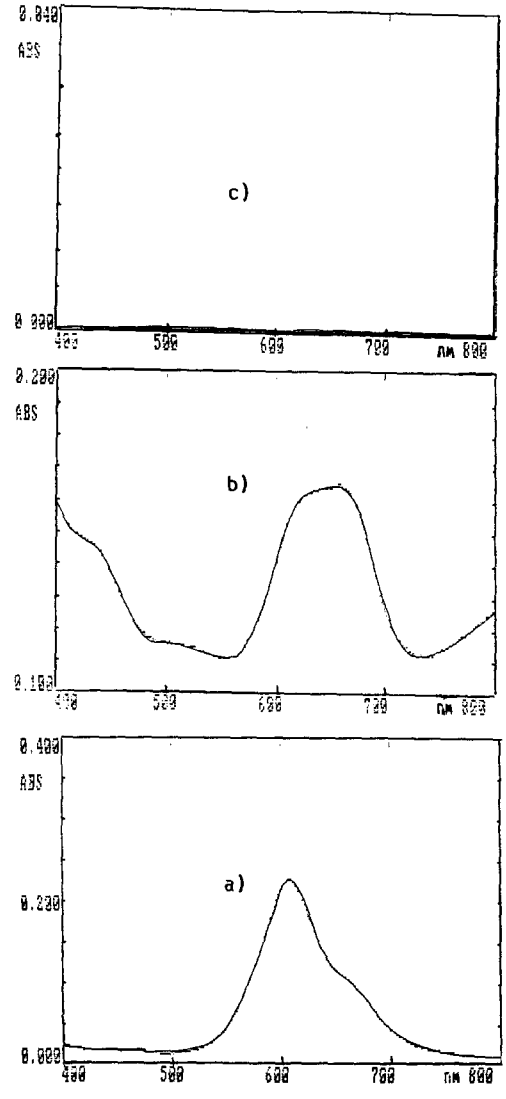

Fig. 3. Molecular absorption spectra of: (a) NiPcTs dissolved in a Britton–Robinson 0.1 mol l^{-1} solution of pH 1.05 (control solution); (b) an ITO/PPY/NiPcTs electrode freshly prepared; and (c) the control solution in which the polymer modified electrode was immersed for 30 min.

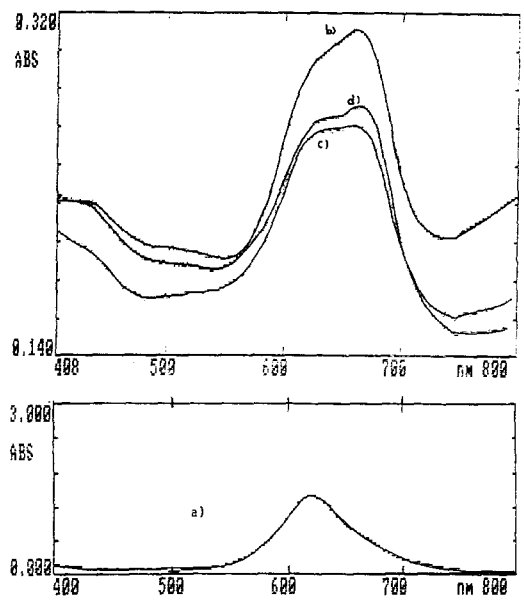

Fig. 4. Molecular absorption spectra of (a) NiPcTs solution in Britton–Robinson 0.1 mol l^{-1} solution; (b) ITO/PPy/NiPcTs electrode freshly prepared; (c) ITO/PPy/NiPcTs electrode after anodic pretreatment for 50 s at 0.9 V in Britton–Robinson 0.1 mol l^{-1} solution; and (d) ITO/PPy/NiPcTs electrode after cathodic pretreatment for 50 s at −0.1 V in Britton–Robinson 0.1 mol l^{-1} solution.

4.2.2. Study of the stability of the ITO/PPy/NiPcTs electrostatic binding after several oxidation–reduction cycles

Several experiments with the ITO/PPy/NiPcTs electrodes in Britton–Robinson 0.1 M solution were achieved with: (i) recently prepared electrode; (ii) after an anodic pretreatment at 0.9 V during 50 s; and (iii) after a cathodic pretreatment at −0.1 V during 50 s. The obtained spectra are plotted in Fig. 4.

In this figure it can be observed that the polypyrrole electrode immersed in the control solution retains its activity after a cathodic pretreatment, although after an anodic pretreatment the polypyrrole activity decreases. Therefore we can conclude that in these experimental conditions the polypyrrole modification with NiPcTs is efficient in general and that in principle, these electrodes can be used to carry out electrochemical reactions from an analytical point of view.

4.3. Effect of the polymerisation time on the PG voltammetry peak: estimation of the PPY/NiPcTs film thickness

As the polymer electrogeneration was carried out by chronoamperometry at controlled potential in the presence of the modifier, the amount of NiPcTs incorporated into the polymer matrix will depend upon the time of electrolysis. Therefore, in order to know this influence, different electrodes were prepared by varying the electropolymerisation time. We calculate the polymerisation charge by integrating the respective chronoamperometric curves I-t. Assuming that all the charge was used to form the polymeric film, it is possible to have an estimation of the polymer thickness. According to [4], we were considered that 0.1 μm = 24 mC cm^{-2}. Furthermore, taking into account the charge values involved in the electropolymerisation process, it is possible to calculate the number of NiPcTs moles incorporated into the polypyrrole matrix. By assuming that for each four pyrrole units one positive charge is created, and that phthalocyanine is tetravalent, the number of NiPcTs moles can be calculated by Faraday's equation, that is to say $N = Q_i/16 \times 96.500$, according to the expression:

$$16\,Py + NiPcTs^{-4} - 4e^- \rightarrow (Py_4)^{+4}NiPcTs^{-4}$$

The modified polymer electrodes, prepared with different electropolymerisation times, were washed with deionised water and immersed in a $4 \cdot 10^{-4}$ mol l^{-1} PG solution in Britton–Robinson buffer of pH 1.2. The values of polymerisation charge, moles of NiPcTs into the polymer, polymer thickness and PG peak current, are summarised in Table 1. From these data, it can be concluded that peak current increased as the electropolymerisation time increased up to 60 s, and then I_p decreased. This can be explained taking into account that the electron transport through the polymer slows down as the thickness of the polymer film becomes larger. An optimum electropolymerisation time of 60 s at +0.8 V was chosen for further experiments.

Table 1
Polymerisation charge, nanomoles of NiPcTs, polymer thickness and peak current for different modified polymer electrodes prepared with different electropolymerisation times

T_p (s)	Q_p (mC)	nmol NiPcTs	s (μm)	I_p (μA)
10	0.577	0.37	0.034	35.98
20	1.231	0.80	0.073	32.85

100	7.618	4.93	0.449	42.05

4.4. Electrochemical control of the polymer stability

Successive cyclic voltammograms of $1 \cdot 10^{-4}$ mol l^{-1} PG in a buffer solution of pH 1.05 recorded at 100 mV s^{-1} are shown in Fig. 5. As can be observed, the peak current decreases dramatically from the first to the second scan. Nevertheless, if a rest period of a few minutes with stirring is allowed (at a potential of 0.3 V), the first voltammogram is again obtained.

Another experiment consisted to record the PG oxidation current after having introduced a

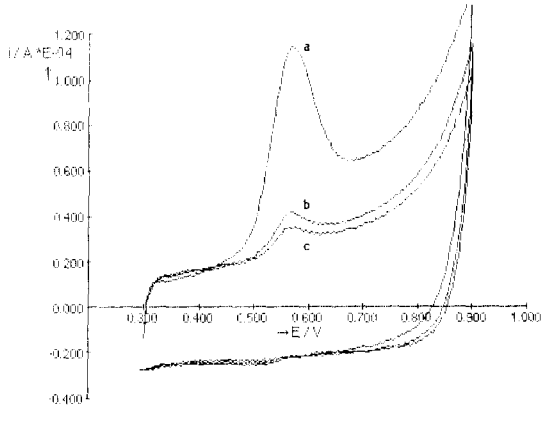

Fig. 5. Successive cyclic voltammograms of 10^{-4} mol l^{-1} PG obtained in a Britton–Robinson 0.1 mol l^{-1} solution (pH = 1.05; 5% methanol; v = 100 mV s^{-1}): (a) first voltammogram; (b) second voltammogoram|bdprime|; and (c) third voltammogram.

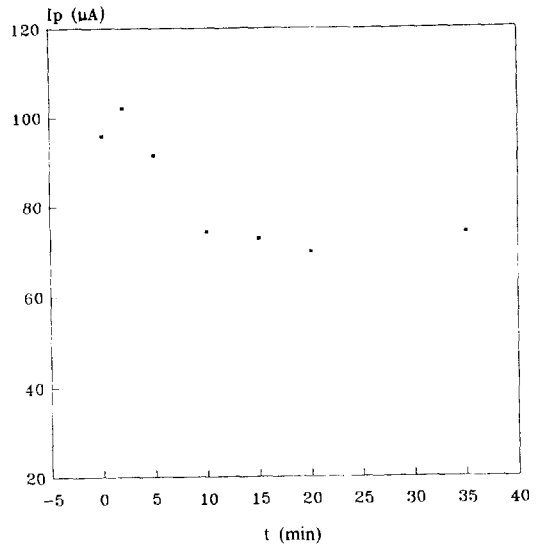

Fig. 6. Effect of working electrode permanency time into the analyte solution on PG peak current for cyclic voltammetry. PG $2.3 \cdot 10^{-4}$ mol l^{-1}; 0.5% methanol; 0.1 mol l^{-1} Britton–Robinson buffer; $v = 100$ mV s^{-1}.

freshly modified polymer electrode into the analyte solution for different times. By plotting the peak heights, I_p, (μA) c.s. time (min) the Fig. 6 was obtained. After an increase of PG anodic current from $t = 0$ to 5 min, an I_p exponential decrease with time up to $t = 10$ min was observed. Then, I_p remain approximately constant with time. For $t = 10$ min, the PG peak intensity is 21% lower than that registered on the first voltammogram ($t = 0$ min).

In order to check the reproducibility in the construction of the modified polypyrrole electrodes, ten Pt/PPy/NiPcTs were prepared under the same experimental conditions (60 s at 0.80 V). Two PG voltammograms were recorded: the first, immediately after the electrode was immersed in the analyte solution (time zero) and the second after immersing the electrodes for 3 min in the analyte solution (time three). The polymerisation charge was calculated by integrating the corresponding i-t curves, giving a Q mean value of 2.3 ± 0.2 mC. PG peak current mean values of 30.4 ± 0.60 and 36.9 ± 0.8 μA were obtained for time zero and time three, respectively. These results are good if we consider that reproducibility with this type of electrodes is not easy to achieve

since, during the electropolymerisation procedure, dimers, trimers, tetramers, etc, are formed. These forms consume polymerisation charge and are very difficult to control and quantify.

4.5. Effect of control solution composition containing PG

4.5.1. Influence of pH on voltammetric peak height and peak potential

In all cases the PG concentration was $2.3\ 10^{-4}$ mol l^{-1}, containing 0.5% of methanol. The potential scan rate was 100 mV s^{-1}.

The variation of E_p with pH shows a linear cathodic shift of 60 mV pH^{-1} units ($y = 0.62 + 0.06x$, $r^2 = 0.996$) indicating that an equal amount of protons and electrons are involved in the oxidation process [34].

The effect of pH on the PG peak height is displayed in Fig. 7. Initially, a decrease in I_p is observed up to pH 3 and then a levelling was produced. Finally, from pH 5 to peak height decreased and disappeared at pH 11. In order to obtain good sensitivity and to simplify the procedure, a pH of 1.05 was chosen for further studies.

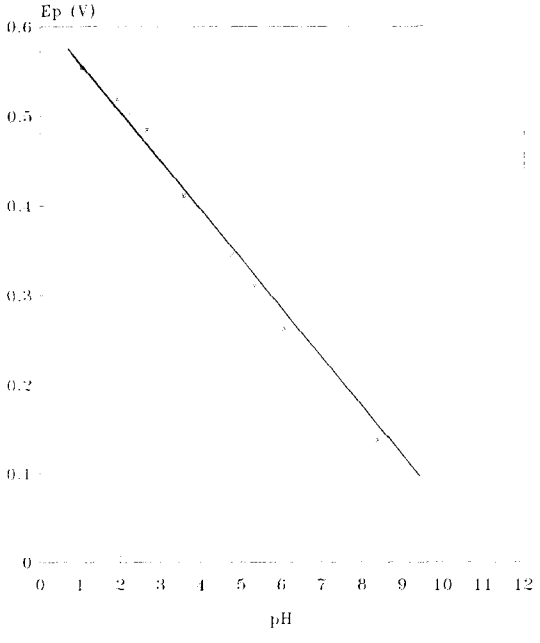

Fig. 7. Effect of pH on PG peak current for cyclic voltammetry at a nickel (II) phthalocyanine tetrasulfonate modified polypyrrole electrode (Pt/PPy/NiPcTs). PG $2.3 \cdot 10^{-4}$ mol l^{-1}; 0.5% methanol; 0.1 mol l^{-1} Britton–Robinson buffer; $v = 100$ mV s^{-1}.

4.5.2. Influence of the methanol/water ratio on the PG voltammetric peak

In order to study the influence of the presence of a non aqueous solvent, such as methanol, on the PG voltammetric peak obtained at Pt/PPy/NiPcTs electrodes, different electrodes were prepared under the experimental conditions mentioned above, and tested in $2.4\ 10^{-4}$ mol l^{-1} PG solutions prepared with different Britton–Robinson/methanol ratios. There is no significant pH change by adding methanol. We observed a gradual decrease of I_p with about 50% between 0.5 and 12% methanol. A solution with a 0.5% of methanol was selected as the optimum value.

4.5.3. Influence of scan rate

Cyclic voltammograms of $1.0 \cdot 10^{-4}$ mol l^{-1} PG solutions were recorded at different scan rates between 5 and 103 mV s^{-1}. We can deduce, as the scan rate was increased the peak current increased, as well as the background current and the peak potential. A clear shift of E_p was produced as expected for irreversible electrochemical reactions. On the other hand, I_p changed linearly with the square root of the scan rate, showing that the current is diffusion controlled. The PG oxidation can involve two electrons, as another similar substituted phenols [35]. We also can see that the current function, $I_p/Cv^{1/2}$, increases with potential scan rate. With these results a scan rate of 100 mV s^{-1} was chosen for further experiments.

4.6. Interferences

Different substances commonly present in commercial antioxidant mixtures, such as tert-butylhydroquinone (TBHQ), tert-butylhydroxyanisole (BHA), citric acid and ascorbic acid were tested by cyclic voltammetry at the NiPcTs modified electrode in order to check whether they interfere with the PG oxidation peak. Under the experi-

mental conditions used for the PG determination citric acid showed no oxidation peak in the potential range scanned (0–0.8 V), whereas BHA, TBHQ, and ascorbic acid gave rise to well-defined oxidation peaks at 566, 340 and 313 mV, respectively.

The closeness among the peak potentials for BHA with respect to that of PG (571 mV) gave rise to only one overall oxidation peak when voltammograms of mixtures of BHA and PG were registered. On the contrary, two well separated oxidation peaks were obtained for mixtures of PG with TBHQ or PG and ascorbic acid. In order to establish the degree of interference of each tested compound, voltammograms of solutions containing $1 \cdot 10^{-4}$ M PG and different concentrations of the interferent were registered. As expected, citric acid did not interfere even at 1/100 PG/citric acid ratio. Relative errors below 2.5% were obtained for a 1/1 PG/BHA ratio or higher, but for a 1/2 PG/BHA ratio the relative error was 22%. The presence of TBHQ affects the PG signal for a PG/TBHQ ratio of 1/10 or lower (a relative error of 4% was obtained for that ratio); this is because high TBHQ contents gave rise to a very high TBHQ peak whose descending part overlaps the PG peak yielding a flattened peak with decrease of its height. The interference of ascorbic acid is important for a PG/ascorbic acid ratio or lower (a relative error of 30% was obtained for a 1/55 ratio).

4.7. Influence of propylgallate concentration on its voltammetric signal

Using cyclic voltammetry under the optimised conditions, e.g. pH = 1.05, $v = 100$ mV s^{-1} and 0.5% methanol, linear relationships between peak intensity and concentration, summarised in Table 2, were obtained. The analytical characteristics of the method are included in this table. The detection and determination limits can be calculated according to the Miller and Miller criterium [36]. It can be observed that a detection limit of 1.53 mg l^{-1} of PG was reached, with better results than that obtained using a conventional Pt working electrode (linear range, $4–20 \cdot 10^{-4}$ mol l^{-1}; detection limit, 17 mg l^{-1}).

Table 2
Linear relationships detection limits (DL) and concentration limit (CL) obtained for propylgallate using cyclic voltammetry

Range (mol l^{-1}) $\times 10^4$	$r2$	DL	CL
4.0–44.0	0.998	$7.23 \cdot 10^{-6}$ mol l^{-1}	$2.05 \cdot 10^{-5}$ mol l^{-1}
2.0–4.0	0.997	(1.53 mg l^{-1})	(4.34 mg l^{-1})
0.2–2.0	0.998		

4.8. Application of the analytical method to the propylgallate determination in commercial food samples

Recovery studies of PG in commercial spiked potato flakes and cornflakes not containing this antioxidant were carried out by applying the procedure described under experimental. First, the commercial samples were tested in order to check the absence of PG. Thus, the described procedure was applied to a 1 g potato flake blank sample and to a 0.5 g cornflake blank sample. The cyclic voltammetry at the modified electrode of this potato flake sample solution showed one little peak (Fig. 8), which may correspond to the oxidation of the other compound present in the sample. Therefore, the intensity of the PG analytical response in the recovery studies must be measured

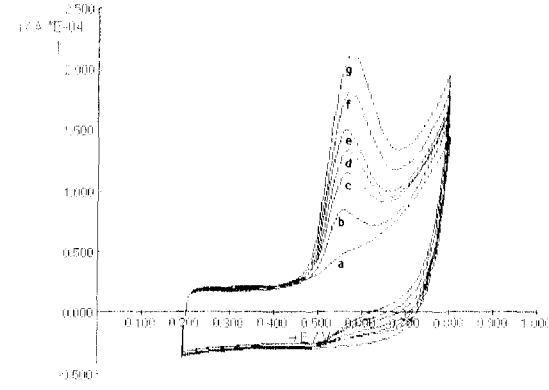

Fig. 8. Cyclic voltammograms at a nickel (II) phthalocyanine tetrasulfonate modified polypyrrole electrode (Pt/PPy/NiPcTs) for a commercial potato flake: (a) blank solution; (b)–(g) successive additions of 10 μl of a 0.5 mol l^{-1} PG standard solution.

against the blank background current. No signal was registered for the cornflakes blank sample.

Results obtained for three potato flake samples give a mean concentration in the analytical solution or $2.01 \pm 0.03 \cdot 10^{-3}$ mol l^{-1} PG, with a mean recovery of $100 \pm 1\%$. The experimental mean concentration obtained for three spiked cereal samples in the analytical solution was of $2.1 \pm 0.2 \cdot 10^{-3}$ mol l^{-1} PG, with a mean recovery of $103 \pm 9\%$. These results were for a significant level of 0.05 and demonstrate the validity of the proposed method for the determination of PG in samples of this kind.

5. Conclusions

The use of chronoamperometry at controlled potential is a rapid and efficient electrochemical procedure for the preparation of nickel (II) phthalocyanine tetrasulfonated modified polypyrrole electrodes. The species having electrocatalytic effect, NiPcTs, is incorporated as a counterion in the polymer film in order to maintain the electrical neutrality during the polymer formation by anodic oxidation of pyrrole. This modified electrode preparation procedure allows the control of the thickness film by varying the electropolymerisation time, t_p. This is of great importance to optimize the electrocatalytic reaction rate, because the higher the film thickness the slower the electron transfer, and consequently the analyte determination becomes more difficult. An optimum thickness of the polymer layer can be achieved. Voltammetry showed that the modified polymer electrode exerts an important electrocatalytic effect on the anodic oxidation of propylgallate, by comparing these voltammograms with those obtained by using a bare Pt electrode. When working with the modified polypyrrole electrode, Pt/PPy/NiPcTs, an E_p value 110 mV less positive than that at the Pt electrode was obtained, as well as an I_p value 2–3-fold higher. The modifier used is insoluble in the control solution employed, even after the electrode being immersed in this solution for 30 min and tends to stay in the film after cathodic or anodic treatment. A detection limit of 1.53 mg l^{-1} was found. The application of the proposed method to determine PG in spiked potato flake samples, using the standard addition method, gives a recovery of 100.3%, indicating that this electroanalytical method is suitable for the PG determination in this type of samples. The method was also applied to determine PG in spiked cereal samples (cornflakes) by using the same procedure. A mean recovery of 103% was obtained. Therefore, this method is also appropriate to analyse this type of sample, concerning the PG determination.

Abstract

Characteristics of cadmium ion-selective electrode made cadmium sulphide (CdS)-silver sulphide (Ag_2S) mixture were studied. CdS-Ag_2S mixtures were obtained by gas/solid-phase reaction between silver-cadmium mixed powder and hydrogen sulphide gas (dry method) and by ionic reaction between cadmium-silver mixed ions and sulphide ion (wet method). As a result, it was found that the CdS-Ag_2S mixture had to be made in the condition of excess existence of sulfur and had better regulate the excess sulfur quantity minimum, for the CdS-Ag_2S pressed membrane gave a good Nernstian response against the cadmium ion concentration change. As the best way, CdS-Ag_2S mixture was obtained by adding sulphide ion solution to 5 mol% cadmium ion and 95 mol% silver ion mixed solution while measuring silver sulphide (Ag_2S) electrode potential as an indicator electrode. According to the reaction was stopped when the potential variation from the initial potential in the sulphide ion solution reached at 87–116 mV which the sulphide ion concentration became 10^{-3}–10^{-4} of the initial concentration, the cadmium ion membrane pressed diameter of 8 mm and thickness of 2 mm showed a Nernstian response from 10^{-8} to 10^{-1} M of cadmium ion concentration. Furthermore, aiming to its application for industrial waste water, masking buffer for interfering metal ions such as lead ion (Pb^{2+}) and copper ion (Cu^{2+}), which were possibly coexisted and to adjust total ionic strength and pH of sample was developed. The present Cd^{2+} ion-selective electrode was applied to the determination of Cd^{2+} in the industrial waste water. The good regression line with correlation factor of 0.984 was obtained compared with the conventional atomic absorption spectroscopy. © 1997 Elsevier Science B.V.

1. Introduction

Potentiometric, ion-selective electrodes are available in the field of chemical analysis because lots of specific ions are able to be measured easily and monitored, though nowadays of the development of many analytical instruments such as an ion chromatograph, a flame spectrophotometer, an atomic absorption spectrophotometer (AA), an inductively coupled radio frequency plasma (ICP)

and so forth. In the case of measuring three divalent heavy metal ions such as Cd^{2+}, Cu^{2+} and Pb^{2+} in the industrial waste water, the ion-selective electrodes are very convenient because of their simplicity and selectivity. Though there have been some reports on the sensing materials of them, it has not become clear yet the relationship between the ion selective sensing materials and detection limit and high reproducibility, and also it is not to say sufficient discussions have been exhausted.

The books of Freiser [1] and Moody and Thomas [2] are very useful about the study of the divalent heavy metal ion selective membrane. Ross et al. [3,4] have reported the precipitate-based solid-state MS-Ag_2S mixture membrane by a stoichiometric reaction MS-Ag_2S mixture was made that mixed solution of $AgNO_3$ and $M(NO_3)_2$ with Na_2S. Also, Hirata et al. [5–7] have developed the ceramic solid-state MS-Ag_2S mixture membrane by baking the MS-Ag_2S mixed powder or its pressed membrane at 700°C. Up to now, some information concerning to the sensing membranes for the practical divalent heavy metal ion is as follows.

1. Mechanism of potential occurrence is based upon solubility equilibrium of MS compound. (M = Cd, Cu or Pb).
2. The sensing membrane had better be a solid state membrane consisted of MS-Ag_2S mixture. The ratio between MS and Ag_2S is not important to basic electrode characteristics.
3. Two methods have been reported. One is a coprecipitation method (wet method). Another is a baking method (dry method).
4. Whether electrode membrane is composed of homogeneous or heterogeneous is not important to basic electrode characteristics.

From information we have obtained to make the Cd^{2+} ion-selective electrode for the determination of Cd^{2+} ion of the industrial waste water, we found that CdS powder could not be moulded to a solid-state membrane by compression because of its fragility and CdS-Ag_2S mixture membrane moulded by commercialized CdS and Ag_2S compound had not shown Nernstian response mostly. However, it has not been clear that why CdS-Ag_2S mixture membrane can give Nernstian response till now. In the dry method, we found that CdS-Ag_2S mixture membrane could show the Nernstian response only under the next condition. (1) CdS-Ag_2S mixture was made by baking cadmium (Cd)-silver (Ag)-surpher (S) mixture at 500–650°C. (2) It was made by baking CdS-Ag_2S-S mixture or when it was made by baking these mixture in the hydrogen sulphide (H_2S) stream. In the wet method, we found that CdS-Ag_2S mixture membrane could show the Nernstian response when $Cd(NO_3)_2$-$AgNO_3$ mixed solution was added in Na_2S solution and the coprecipitation reaction had been ended in the condition of sulphide ion (S^{2-}) remained. In both methods, it seemed that the existence of sulphur was the key to get a good electrode performance. In comparison of the two methods, the wet method is better to control the ratio of each component and is more convenient to make easily and to obtain equal quality in the electrode characteristic.

The selectivity of the Cd^{2+} ion-selective electrode is affected by Cu^{2+}, Pb^{2+} and Fe^{3+} ions coexisted in industrial waste water. Also, it interfered by an oxidizer such as chlorine or hypochlorite ion. The detection limit and the calibration curve were slightly changed by pH of samples. In the basic solution, Cd^{2+} ion becomes cadmium hydroxide ($Cd(OH)_2$). In the acid solution, the detection limit becomes inferior owing to the increasing of solubility of CdS. All sample measurements should be performed in the best pH region. Therefore, the buffer solution for Cd^{2+} ion measurement such as Orion TISAB (total ionic strength adjustment buffer) [8] for the fluoride ion measurement which could mask the interfering substances was developed for the practical use. The present Cd^{2+} ion-selective electrode was applied to the determination of Cd^{2+} ion in the industrial waste water using the masking buffer mentioned above.
