The UV-visible spectrophotometry was demonstrated for studying the U(VI)-TBP complex dissolved in supercritical CO₂ under different conditions of pressure and temperature. The wavelength and intensity of absorption peaks are in good agreement with those for U(VI)-TBP complex dissolved in neat TBP at 25°C and atmospheric pressure, indicating that the chemical form of U(VI) species dissolved in CO₂ is UO₂(NO₃)₂(TBP)₂. The results also suggest the feasibility of using the spectrophotometric method for the determination of U(VI) concentration in the CO₂ phase, even in the presence of Pu(IV).

A solubility or phase behavior of an objective compound in the supercritical fluid medium should be properly examined in the experimental system containing the compound as a single component solute such as UO₂(NO₃)₂(TBP)₂ complex in the present case. This is because a presence of the other species such as H⁺-TBP and/or free TBP may affect the behavior of the solute of interest. However, from a practical viewpoint concerning the U(VI)-TBP extraction process using supercritical CO₂ medium, information from a more intricate system is required, e.g. the information on the solubility behavior of U(VI)-TBP complex in the mixture of UO₂(NO₃)₂(TBP)₂ + H(NO₃)(TBP) + free TBP and supercritical CO₂ as studied in the present work. In relation to this, it was not easy to synthesize UO₂(NO₃)₂(TBP)₂ complex as an isolated form.

Determination of nickel in human urine by ion chromatography with series bulk acoustic wave detection

Xiaorong Yang, Zhanchao Qiao, Wanzhi Wei, Shouzhuo Yao *

College of Chemistry and Chemical Engineering, Hunan University, Changsha, 410082, People's Republic of China

Received 7 July 1997; received in revised form 23 September 1997; accepted 24 September 1997

Abstract

By using ion chromatography with series bulk acoustic wave detection, a method for the determination of nickel at microgram per liter levels in urine has been developed. The highly sensitive response of series bulk acoustic wave (SBAW) detection has been combined with the selectivity of ion chromatography and hence sensitivity and precision have been improved. The detection and determination limits of the method for nickel are 0.4 and 2.0 ng ml⁻¹, respectively. For the IC analysis, the analytical column is a Shim-pack IC C1 column and the mobile phase is 4.5 mM tartaric acid solution. The method allows the determination of nickel in the presence of some ions commonly co-occurring with it. Urine samples from individuals with no occupational exposure to nickel were analysed successfully. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Ion chromatography; Series bulk acoustic wave; Nickel; Human urine

1. Introduction

Toxicological and physiological research on nickel have been a subject of growing interest over recent years. Nickel is immunotoxic and causes allergy and skin sensitization [1,2]. The concentration of nickel in biological materials in populations is known to be altered by acute myocardial infarction [3]. In particular, the carcinogenicity of this element has been extensively reviewed in the report by the International Committee on Nickel Carcinogenicity in Man [4,5] and the International Agency for Research on Cancer has concluded that nickel compounds are carcinogenic to

humans. Hence, the determination of nickel in biological materials in populations with and without occupational exposure is usually necessary.

As nickel occurs at very low levels in biological materials, a sensitive, selective and accurate method for its determination is desirable. Useful methods include electrothermal atomization spectrometry (ETAAS) [6,7], inductively coupled plasma mass spectrometry (ICP-MS) and voltametry [7,8]. These methods are powerful techniques for the determination of trace elements, but are not applicable to certain kinds of samples. For human urine and blood serum matrix effects are apparent for the ETAAS measurements. If the sample matrix contains large amounts of calcium, the determination of Ni by

Fig. 1. Schematic diagram of the SBAW detector. (a) TTL-IC oscillator; (b) piezoelectric quartz crystal; (c) detection cell; (d) mobile phase inlet; (e) mobile phase outlet; (f) conductivity electrode; (g) frequency counter; (h) F/V converter; (i) computer.

ICP-MS is troublesome [9–13]. In addition, the sensitivity of these methods is not always sufficient for direct determination in every conceivable sample. This paper reports a method for the determination of nickel at ultra-trace levels by ion chromatography with a series bulk acoustic wave (SBAW) detection system.

Originally, ion chromatography (IC) was developed as a chromatographic method for inorganic ions, with an ion-exchange resin as the stationary phase and using conductometric detection. At present, the scope of IC has been extended to include the determination of organic ions and other species. In addition to conductometric detection, many detection techniques have been used. In this work, an SBAW was used in the detection technique.

Bulk acoustic wave (BAW) sensing devices have been developed rapidly and utilized widely as chemical and biomedical microsensors [14–16]. The frequency of the BAW sensor in liquid is affected by properties of liquids such as density, viscosity, specific conductivity and permittivity [17–19].

A new type detection system for IC known as a SBAW has been developed [20]. It responds only to solution conductivity and permittivity and has been successfully applied as a BAW detector for IC monitoring. This device was designed and constructed in our laboratory [21,22] and its theory and application have been summarized [23,24]. Compared with conventional conductometric detection for IC, SBAW detection is advantageous in its high sensitivity, high resolving power and good reproducibility, as it can eliminate the interfering effect of double layer capacitance. In this work, an SBAW detector was used

to develop a procedure for the determination of nickel in human urine, when incorporated into a non-suppressed anion exchange chromatographic system.

2. Experimental

2.1. Reagents

All chemicals were of analytical reagent grade or better and were used as received. De-ionized water was used throughout. A stock standard solution of Ni (II), Fe (III), Co (II), Cu (II), Zn (II) and Ca (II) was prepared from the nitrate or sulphate salts and standardized gravimetrically. Working standard solutions were prepared by appropriate dilution as necessary. Standard solution was prepared daily. A 4.5 mM tartaric acid solution was used as the mobile phase. The mobile phase, standard and sample solutions were filtered through a 0.45 μm membrane (Millipore, USA)

2.2. Instrumentation

2.2.1. SBAW detector

A new SBAW detection system for IC was designed and constructed in our laboratory [14,15], a schematic diagram of which is shown in Fig. 1. The SBAW detector was composed of a quartz crystal oscillator connected in series and a conductivity detection cell. The oscillator was assembled by coupling a 9 MHz AT-cut quartz crystal to a TTL-IC oscillating circuit. The detection cell was made as follows. Two 1 mm platinum wires (pretreated with 6 M HNO_3 and then

with water and acetone), as conductivity electrodes, were inserted oppositely at the middle of the detection cell, with a distance of 0.5 mm between them. The body of the detector was made of two Plexiglass plates with a thickness of 5 mm, within which a cylindrical trough (2 mm diameter and 8 mm length) was used as the detection cell. The detector volume was about 25 μl . The cell constant 3.2 cm^{-1} was used. Two 0.5mm stainless steel tubes were connected at opposite ends of the detection cell separated by 7 mm and used as the mobile phase inlet and outlet. One of the platinum electrodes was connected to the quartz crystal which together with another platinum wire served as the feedback network of the IC-TTL oscillator. The frequency signal from the detector was sent either to the digital counter to give a direct frequency recording or to the F/V conversion circuit connected to the chromatography workstation to obtain voltage information. The base noise and hence sensitivity of the SBAW is influenced by temperature. When the SBAW detector temperature is equal to that of the column, the lowest noise and drift levels are achieved. Hence, the temperature of the SBAW detector was kept the same as that of the column, 37°C.

2.2.2. F/V converter

A universal frequency counter (Model SC-7201, Iwatsu, Japan) was used to investigate the performance of the BAW sensor with respect to frequency shift. As the frequency data must be transformed into a format which can be used by the chromatographic workstation, a frequency-to-voltage converter (made in our laboratory) was used to transform the frequency signal of the BAW detector to a CR-4A Chromatopac data processor (Shimadzu, Japan), which is used to record chromatograms in real time and integrate peak areas.

2.2.3. Chromatographic apparatus

Chromatographic separation was accomplished by means of a Shimadzu LP-6A liquid delivery pump, an SLC-6B system controller, an SIL-6B auto injector and a CTO-6AS column oven. The analytical column was a Shim-pack IC-C1 column (5.0 mm ID*15 cm, stainless), packed with a

surface functional group cation exchange resin on a polystyrene–divinylbenzene support with a particle size of 10 μm , incorporating a sulphonic acid base as a functional group. A Shim-pack IC-GC1 guard column (4.0 mm ID*10 mm) preceded the analytical column.

2.3. Chromatographic conditions

The mobile phase was 4.5 mM tartaric acid used at a flow rate of 1.2 ml min^{-1} and the injection volume was 100 μl . To obtain the optimum response of the SBAW detector and lowest noise level, the temperatures of both column and detector were set at 37°C.

2.4. Sample preparation

The human urine was acidified to 1% (v/v) with concentrated HNO_3 and stored frozen until analysed for nickel. The protein in human urine is removed by means of nitric acid and centrifugation. The supernatant was passed through a Sep-pak C18 cartridge to remove organic interference and then filtered through a 0.45 μm filter membrane. Following this, 100 μl of filtrate was applied to the IC column.

3. Results and discussion

3.1. Analytical conditions

3.1.1. Choice of the concentration of the mobile phase

The SBAW response vs conductivity change relationship is

$$\Delta f = k \Delta G$$

where Δf is frequency shift, ΔG is the conductivity change between the sample solution and the mobile phase, k is the constant depending on the construction of the SBAW detector and the conductivity of the mobile phase (G_0) [19,20]. Provided that all design parameters of the detector remain unchanged, as was the case in our work, the detector sensitivity is mainly affected by the conductivity of the mobile phase (G_0). It is well

known that the concentration of the mobile phase affects not only its conductivity but also the retention time and resolution of analytes. Hence, the proper choice of concentration of the mobile phase is very important. In order to achieve a sensitive response and good resolution with acceptable analytical time, various dilutions of the tartaric acid solution were evaluated. Fig. 2 shows the chromatogram of the mixture standard solution containing Ni(II) and the other ionic species tested, where 4.5 mM tartaric acid solution can clearly separate the Ni(II) peak from the other metal ions within a reasonable retention time. The concentration (in ppm) of the metal ions in the mixture standard solution are as follows: Fe(III), 1; Cu, 0.4; Zn, 0.6; Ni, 0.5; Co, 0.3; and Ca, 2. As can be seen in Fig. 3, the detector sensitivity increases with increasing concentration of the mobile phase until a maximum is reached and then decreases as the concentration of the mobile phase increases further. The maximum sensitivity is reached at 4.5 mM tartaric acid solution.

3.1.2. Effects of the detector temperature

As the SBAW detector responds to the solution conductivity and permittivity, which are affected by the temperature, the resonant and the oscillation frequency of the piezoelectric quartz crystal are influenced by temperature variation. Hence, the base line and the noise level of the SBAW vary with temperature change. In order to evaluate the behavior of the SBAW detector as a

Fig. 2. Chromatogram (obtained using IC-SBAW) of a mixture standard solution containing Ni(II) and the interfering ions tested.

Fig. 3. Effect of eluent concentration on detector response sensitivity.

function of temperature, experiments were carried out. According to Table 1, when the SBAW detector temperature is equal to that of the column, the lowest noise and drift levels are obtained. Therefore, the SBAW detector was maintained at the same temperature as the column, 37°C.

3.2. Analysis of real samples

The proposed IC-SBAW method was used to determine nickel levels in urine from individuals with no occupational exposures to nickel. Fig. 4 is a typical chromatogram of a real sample, where the peak for Ni was identified by the method of standard additions. Table 2 shows the results of the determination of Ni in human urine. According to the tentative reference value ($< 3 \text{ ng ml}^{-1}$) proposed by Templeton et al. [25], the individuals examined have no nickel-poisoning except for individual No. 2. For a person with no occupational exposures to nickel, nickel-poisoning is probably caused by handling metal objects such as jewellery and coins, dietary intake of nickel, or implantation of medical prostheses containing nickel.

Table 1
Effect of temperature on noise and drift of SBAW detector

T (°C)	25	30	33	35	37	40	45	50
Noise (Hz)	5	4	2	2	2	2	3	6
Drift (Hz h ⁻¹)	7	7	4	3	3	5	5	8

Fig. 4. Chromatogram (obtained using IC-SBAW) of urine from individuals having no occupational exposure to nickel.

3.3. Sensitivity, precision and accuracy

Under the optimized chromatographic and detector conditions, the detection and determination limits for nickel were 0.4 and 2.0 ng ml⁻¹, respectively. The precision of the IC-SBAW was tested using a standard solution of 5.0 ng ml⁻¹ analysed nine times on different days. The maximum relative standard deviation obtained was 3.6%.

In order to investigate the accuracy of the proposed method, the results obtained by IC-SBAW were compared to those from graphite-furnace atomic absorption spectrometry (GFAAS) [7], as shown in Table 2. The results obtained by the proposed method were in agreement with those obtained for the same sample types using GFAAS. Recovery experiments were also per-

Table 2
Determination of Ni in human urine using IC-SBAW and GFAAS

Sample No.	IC-SBAW (ng ml ⁻¹)	GFAAS(ng ml ⁻¹)
1	2.6 ± 0.1	2.3 ± 0.5
2	4.7 ± 0.1	5.1 ± 0.2
3	1.8 ± 0.3	1.7 ± 0.1
4	1.2 ± 0.4	1.1 ± 0.3
5	0.9 ± 0.3	1.3 ± 0.6
6	1.6 ± 0.2	1.2 ± 0.2

Values are expressed in mean ± SD (*n* = 5).

formed by spiking real urine samples with aliquots of Ni standard solutions. The nickel content was determined by the recommended procedure using standard additions and the results are shown in Table 3. Recoveries were found to be from 96 to 104%.

3.4. Comparison with BAW detector and conductometric IC detector

The proposed SBAW detector is based on its non-mass effect, i.e. conductivity change in the course of chromatographic separation. As there is no mass deposition on the detector surface, no intermittent removal of the deposited mass is required to restore the detector, as is the case with mass-effect-based conventional BAW detection techniques. Hence, the proposed detector can be used continuously.

Although the conductivity cell is among the most commonly used detectors in ion chromatography, the detection limit of this method is subject to background interference from the mobile phase, especially in single-column ion chromatography.

In a conductometric cell, double electric layer capacitance or Faradaic impedance can take place, causing the effective applied potential to change. This may affect sensitivity and accuracy in the determination of ions. To solve these problems, methods involving the use of alternating electrode potential and bipolar pulse conductance have been proposed, but the instrumentation is rather complicated. In the proposed SBAW detection technique, the interfering effect of the double layer capacitance on the detector response is eliminated and there was no use of the complicated alternating electrode potential technique or multiple electrodes method. Moreover, the SBAW detector has a long life-span and since the platinum electrode is chemically stable, the proposed detector can be used for at least two years.

The detection limit for Ni by ion chromatography with conductometric detection is more than 0.1 ppm [26], which is not adequate for determination of Ni in human urine. Using ion chromatography with SBAW detection, the detection and determination limits for Ni are 0.4 and 2.0 ng ml⁻¹, respectively.

Table 3
Recovery of Ni from spiked samples

Sample No.	Ni present (ng ml ⁻¹)	Ni spiked (ng ml ⁻¹)	Ni found (ng ml ⁻¹)	Recovery (%)
1	2.6	5.0	7.6	100
2	4.7	5.0	9.6	98
3	1.8	10.0	11.5	97
4	1.2	2.5	3.6	96
5	0.9	10.0	10.8	99
6	1.6	2.5	4.2	104

3.5. Comparison with graphite-furnace atomic absorption spectrometry

Current analytical methods for trace determination of nickel involve mainly the use of spectroscopic techniques, such as GFAAS. Although this technique is available in more laboratories, it has some serious drawbacks, including high equipment costs and matrix interference effects, as well as slow analysis, since only one element can be determined at a time. Cano Pavón and Vereda Alonso et al. [27] presented a method for the determination of nickel by GFAAS involving the prior extraction of the metal into methyl isobutyl ketone with 1,5-bis(di-2-pyridylmethylene) thio-carbonohydrazide. Although this method can determine Ni at ultra-trace (ng ml⁻¹) level, it is cumbersome, since it necessitates preconcentration.

In conclusion, the ion chromatographic method using the SBAW detector is advantageous in its rapidity, simplicity, sensitivity and accuracy. The high sensitivity, low equipment cost, simple construction and great potential for automation of the SBAW detector portend its development in the analysis of inorganic, organic and biological ions. The susceptibility of the proposed method to matrix effects is the subject of further study.

Spectrophotometric determination of lithium ion using a water-soluble octabromoporphyrin in aqueous solution

M. Tabata *, J. Nishimoto, T. Kusano

Department of Chemistry, Faculty of Science and Engineering, Saga University, 1 Honjo-machi, Saga 840, Japan

Received 8 July 1997; received in revised form 24 September 1997; accepted 25 September 1997

Abstract

A water-soluble porphyrin, (2,3,7,8,12,13,17,18-octabromo-5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin; $H_2obtpps^{4-}$) was synthesized and developed for the determination of lithium ion in aqueous solution. The octabromo groups lower the basicity of the porphyrin by their electron-withdrawing effect, and enable the porphyrin to react with the lithium ion in alkaline solution to form the lithium complex along with a shift of absorption maximum: λ_{max}/nm ($\log \epsilon/mol^{-1} dm^3 cm^{-1}$) of the lithium porphyrin are 490.5 nm (5.31) and 734 nm (4.36). Sodium and potassium ions did not react with the porphyrin. The equilibrium constant for the reaction $Li^+ + Hobtpps^{5-} \rightleftharpoons [Li(obtpps)]^{5-} + H^+$ was found to be $10^{-8.80}$ and the conditional formation constant of the $[Li(obtpps)]^{5-}$ at pH 13 is $10^{4.21}$. The above results were applied to the determination of lithium ion in aqueous solution. The interference from transition and heavy metal ions was masked by using *N,N'*-1,2-ethanediybis[*N*(carboxyl-methyl)glycinato]magnesium(II) ($[Mg(edta)]^{2-}$) solution. Absorbance at 490 nm was measured against a blank solution. A calibration graph was linear over the range of $0.007-0.7 \mu g cm^{-3}$ ($1 \times 10^{-6}-1 \times 10^{-4} mol dm^{-3}$) of lithium(I) with a correlation factor of 0.967. Lithium ion less than ppm level was determined spectrophotometrically in aqueous solution. The proposed method was applied to the determination of lithium in human serum and sea water samples. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Lithium ion has been used widely in science, medicine and technology in the treatment of manic depression and its use in the lithium battery [1]. In light of such applications, the methods for the determination and separation of the lithium

ion are receiving considerable attention. Many efforts have used synthetic multidentate ligands to form complexes with lithium ion. Since lithium ion is a hard acid, it prefers hard donor atoms [2]. Therefore, the stability constants of Li^+ complexes are expected to increase as ligand donor atoms change $S \ll N \ll O$. Crown ethers have been utilized for the determination and separation of lithium ion. Takagi et al. [3] first succeeded in synthesizing chromogenic crown ethers for alkali

* Corresponding author. Tel.: +81 952 288560; fax: +81 952 288548; e-mail: tabatam@cc.saga-u.ac.jp

metal ions in 1977 and extracted the colored complexes of the alkali metal ions into chloroform. Following from this, various monoaza-crown ethers [4,5] and cryptands [6] with chromophores bound to the ring nitrogen were synthesized, and spectral change upon the addition of alkali metal was observed. All these reagents, however, are insoluble in water and the measurement of lithium ion was limited to organic solvent system. Chromogenic ionophores soluble in homogeneous mixed aqueous solution containing DMSO or 2-(2-ethoxyethoxy)ethanol were synthesized [7–9] and applied to the determination of lithium ion in blood serum without solvent extraction [10].

The selectivity of alkali metal ion depends on the cavity size of crown ethers [11] and the chromogenic response upon metal complexation is enhanced when the chromogenic ligand has ionizable protons [4]. Porphyrins show high selectivity for metal ions due to rigid cavity size (400 pm in diameter) that accommodates medium-sized metal ions like nickel(II), copper(II) and zinc(II) [12,13]. Furthermore, porphyrins give high molar absorptivities (about $500\,000\text{ mol}^{-1}\text{ dm}^3\text{ cm}^{-1}$) at the

Soret band by metalation resulting in release of ionizable pyrrole protons [14]. We noticed that the ionic size of lithium ion (73 pm) is comparable with zinc(II) (74 pm) [15] that was selectively determined in a large excess of cadmium(II) and lead [16,17]. A weak point of porphyrins is that the ionization of protons occur at high pH > 14 [18]. In order to solve this problem, we synthesized a new water-soluble porphyrin with eight bromine atoms which decrease the basicity of the porphyrin and make it easy to release protons bound to the pyrrole nitrogen atom of porphyrin. We report here on a selective and sensitive colorimetric determination method for lithium ion in aqueous solution without using any organic solvents.

2. Experimental

2.1. Apparatus

Absorption spectra were recorded on a Shimadzu UV-2100 and a Jasco Ubest spectrophotometers. The pH values were determined with a radiometer Ion 85 analyzer with a combined electrode (GK2401C). A $1.000 \times 10^{-2}\text{ mol dm}^{-3}$ nitric acid solution containing 0.09 mol dm^{-3} sodium nitrate was employed as the standard hydrogen ion concentration ($-\log[\text{H}^+] = 2.000$). From the pH meter readings on various hydrogen ion concentrations, the pH meter and electrode system was calibrated in terms of $-\log[\text{H}^+]$ at an ionic strength of 0.1 mol dm^{-3} ($\text{HNO}_3 - \text{NaNO}_3$). All experiments were carried out at 25°C .

2.2. Synthesis of the porphyrin

2,3,7,8,12,13,17,18 - Octabromo - 5,10,15,20 - tetrakis(4-sulfonatophenyl)porphyrin ($\text{H}_2\text{obtpps}^{4-}$, Fig. 1) was synthesized by the bromination and sulfonation of 5,10,15,20-tetraphenylporphyrin (H_2tpp) as follows: H_2tpp (1g, 1.63 mmol) was treated with *N*-bromosuccinimide (NBS, 3 g, 16.8 mmol) instead of bromine as previously reported [19] in dibromomethane which was sufficiently dried by molecular sieve (4 \AA) before use. The

Fig. 1. 2,3,7,8,12,13,17,18-Octabromo-5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin ($\text{H}_2\text{obtpps}^{4-}$) and its Lithium porphyrin ($\text{Li}(\text{obtpps})^{5-}$).

crude product gave three bands on an activated alumina chromatography (300 mesh, Wako, Japan) using chloroform as eluent and the first band was collected. Yield was 53%. Absorption maximum-wave length and chemical shifts of ^1H NMR of the product, 2,3,7,8,12,13,17,18-octabromo-5,10,15,20-tetraphenylporphyrin (H_2obtpp , 1), were observed at 370, 469, 569, 626 and 743 nm in chloroform, and at 7.79 ppm (m, 12 H, for *m*- and *p*-H of phenyl) and 8.19 ppm (d, 8H, *o*-H of phenyl) in CDCl_3 vs. TMS, respectively. Compound 1 was sulfonated in concentrated sulfuric acid. The product was precipitated by the careful addition of small amounts of water and purified by a Sephadex column LH-20 which was soaked in a water-methanol (7:3) mixed solvent. Absorption maximum-wave length ($\log \epsilon/\text{mol}^{-1} \text{dm}^3 \text{cm}^{-1}$) and ^1H NMR data (δ/ppm) of the final product, H_6obtpps , were as follows: 376 (4.54), 478 (5.30), 657 (4.25) and 760 nm (4.07) in aqueous solution at pH 7.0; 8.62 (d, 8H, *o*-H of phenyl) and 8.09 (d, 8H, *m*-H of phenyl) in d_6 -dimethyl-sulfoxide.

2.3. Reagents

Sodium nitrate used for adjusting ionic strength was purified by solvent extraction using phenyldiazene-carbothionic acid 2-phenylhydrazide (dithizone) in carbon tetrachloride to remove transition and heavy metal ions like Cu(II), Zn(II), Fe(II) and Pb(II), and followed by recrystallization from hot water. Otherwise these metal ions form their metalloporphyrins in alkaline pH. Other metal nitrates were of analytical-reagent grade and were used without further purification. The buffer solutions were prepared by addition of nitric acid or sodium hydroxide to solutions of sodium acetate for pH 4–6, 2-morpholinoethanesulfonic acid (MES) for pH 6–7, 2-(4-(2-hydroxyethyl)-1-piperazinyl)-ethanesulfonic acid (HEPES) for pH 7–8.5 and sodium borate for pH 8.5–10 (Wako, Osaka, Japan). All solutions were prepared in water, treated with a Mill-Q SP TOC (Nippon Millipore, Japan).

Fig. 2. Change in absorption spectra of $\text{H}_2\text{obtpps}^{4-}$ at pH 4–6 (a) and 10–12 (b).

3. Results and Discussion

3.1. Acid-dissociation constants of $\text{H}_4\text{obtpps}^{2-}$

Absorption spectra of the porphyrin were measured at various pH values at ionic strength of 0.1 mol dm^{-3} (NaNO_3) and at 25°C . The absorption maximum-wave lengths were observed in three pH regions: 490 and 740 nm at pH lower than 2478 and 657 nm at pH 6–8.2 and 502 and 745 nm at pH higher than 11 (Fig. 2). The change in absorbance suggests three steps for the acid-dissociation equilibrium and their equilibrium constants as given in Eqs. (1)–(3)

where H_2P^{4-} denotes free-base form of the porphyrin which is the main chemical species at neutral pH. The acid-dissociation constants of the porphyrin were determined by using a nonlinear least-squares minimization program in two pH

ranges: one region, 1–8 and other pH 8–13. The octabromo groups lower the basicity of the porphyrin by their electron-withdrawing effect, and the deprotonation process of the free-base form, $\text{H}_2\text{obtpps}^{4-}$, producing Hobtpps^{5-} , occurred at pH 10.

3.2. Formation of lithium(I) porphyrin.

Lithium hydroxide reacted with $\text{H}_2\text{obtpps}^{4-}$ to shift the absorption spectrum towards a shorter wavelength. Sodium hydroxide and potassium hydroxide did not alter the absorption spectra (Fig. 3). The absorption maximum-wave length ($\log \epsilon/\text{mol}^{-1} \text{dm}^3 \text{cm}^{-1}$) of the lithium(I) porphyrin complex are 490.5 nm (5.31) and 734 nm (4.36). Non-brominated porphyrin like 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin did not give any spectral change even in $0.1 \text{ mol dm}^{-3} \text{LiOH}$. This behavior is unique to $\text{H}_2\text{obtpps}^{4-}$. The equilibrium constant of the lithium(I) porphyrin complex was determined as follows. Absorption spectra were measured at different concentrations of lithium ion (10^{-5} – $10^{-2} \text{ mol dm}^{-3}$) and sodium hydroxide (pH 11.7–12.3). If we assume that n molecules of lithium ions react with HP^{5-} to form lithium porphyrin with the release of m molecules of hydrogen ions, the equilibrium constant for the formation lithium porphyrin is given by Eqs. (4) and (5):

Fig. 3. Change in absorption spectra of $\text{H}_2\text{obtpps}^{4-}$ in pH 7.0 (a); $0.1 \text{ mol dm}^{-3} \text{LiOH}$ (b); $0.1 \text{ mol dm}^{-3} \text{NaOH}$ (c); and $0.1 \text{ mol dm}^{-3} \text{KOH}$ (d).

Fig. 4. Plot of $\log((\epsilon_1 - \epsilon)/(\epsilon - \epsilon_2))$ against $\log([Li^+]/\text{mol dm}^{-3})$ and $\log([OH^-]/\text{mol dm}^{-3})$ in order to determine the equilibrium constant of the lithium porphyrin complex and the number of lithium ions and protons in the lithium porphyrin.

$$K = \frac{[\text{Li}_n\text{H}_{1-m}\text{P}^{(5-n+m)-}][\text{H}^+]^m}{[\text{Li}^+]^n[\text{HP}^{5-}]} \quad (5)$$

The observed apparent molar absorptivity ($\epsilon = \text{absorbance}/C_{\text{H}_2\text{P}}$) at different concentrations of lithium and sodium hydroxide is correlated to the equilibrium constant as follows:

$$\begin{aligned} \log((\epsilon_1 - \epsilon)/(\epsilon - \epsilon_2)) \\ = -n\log[Li^+] - m\log[OH^-] + m\log K_w - \log K \end{aligned} \quad (6)$$

where ϵ_1 and ϵ_2 are the molar absorptivities of the lithium and nonmetalated porphyrins, respectively. The plots of the left-hand side of Eq. (6) against $\log[Li^+]$ and $\log([OH^-]/\text{mol dm}^{-3})$ give straight lines with a slope of one for both Li^+ and OH^- (Fig. 4). Thus, one lithium ion reacts with HP^{5-} to form $[\text{LiP}]^{5-}$ by releasing one hydrogen ion. The equilibrium constant of Eq. (5) was found to be $\log(K_{\text{LiP}}) = -8.80 \pm 0.02$ at 25°C and $I = 0.1 \text{ mol dm}^{-3}$ (NaNO_3).

Arnold et al. isolated lithium porphyrins and reported that two lithiums can interact with the porphyrin nitrogen in nonpolar solvents like THF and that one lithium can be bound to all four nitrogens in the porphyrin in polar solvents like alcohol [20,21]. Since water is a high polar solvent, the 1:1 $[\text{LiP}]^{5-}$ is formed for $\text{H}_2\text{obtpps}^{4-}$ in aqueous solution. In the lithium porphyrin, lithium is incorporated well in the porphyrin core like zinc(II) [22], due to the comparable ionic radius of lithium(I) (73 pm) to that of zinc(II) (74 pm) [15]. However, sodium and potassium ions do not form stable complexes with the porphyrin under the same experimental conditions because of the large ionic radii of sodium (113 pm) and potassium (151 pm) [15]. The octabromo groups decrease the basicity of the porphyrin so that the proton in the pyrrole group is released even at pH 10. This makes it easy for lithium ion to react with the porphyrin.

It is interesting to know how $[\text{LiP}]^{5-}$ is stable compared with lithium(I) crown-ether complexes. Although the equilibrium constant for the reaction $\text{Li}^+ + \text{P}^{6-} \rightleftharpoons [\text{LiP}]^{5-}$ could not be determined, the conditional formation constant defined by $K' = [\text{LiP}^{5-}][\text{Li}^+]^{-1}[\text{P}^{6-}]^{-1}$ was calculated as $10^{4.21}$ in 0.1 mol dm^{-3} NaOH from the formation constant (K) of $[\text{LiP}]^{5-}$ and acid-dissociation constant of $\text{H}_2\text{obtpps}^{4-}$ ($\text{p}K_{\text{a}3}$) values, where $[\text{P}^{6-}]$ denotes the total concentration of the porphyrin unbound to lithium(I). The equilibrium constant is much larger than the formation constant of Li with crown-ethers [11].

3.3. Determination of lithium

The above results were applied to the determination of lithium ion in aqueous solution. The general procedure is as follows. A 5-cm^3 water sample containing $0.014\text{--}1.4 \mu\text{g}$ of lithium(I) was placed in a 10-cm^3 calibrated flask. Then, 1 cm^3 of N,N' -1,2-ethanediybis[N (carboxylmethyl)—glycinato]magnesium ($[\text{Mg}(\text{edta})]^{2-}$) solution ($C_{\text{Mg}} = 1.1 \times 10^{-2} \text{ mol dm}^{-3}$; $C_{\text{H}4\text{edta}} = 1.0 \times 10^{-2} \text{ mol dm}^{-3}$), 1 cm^3 of $\text{H}_2\text{obtpps}^{4-}$ ($3.8 \times 10^{-5} \text{ mol dm}^{-3}$), and 0.5 cm^3 of 1 mol dm^{-3} NaOH were added to the flask. Distilled water was added to

the mark (10 cm^3) and absorbance was measured at 490 nm against a blank solution. A calibration graph was linear over the range of $1 \times 10^{-6}\text{--}1 \times 10^{-4} \text{ mol dm}^{-3}$ of lithium(I) with a correlation factor of 0.967. Lithium ion less than ppm level was determined spectrophotometrically in aqueous solution.

3.4. Effect of foreign ions on the determination of lithium

Since $\text{H}_2\text{obtpps}^{4-}$ forms stable complexes with transition and heavy metal ions like copper(II), zinc(II) and lead(II), these metal ions were masked by the addition of $[\text{Mg}(\text{edta})]^{2-}$ solution as a ligand buffer. Nakagawa and Tanaka have proposed the use of a ligand buffer solution for the polarographic determination of zinc(II) in the presence of cadmium(II) [23]. We determined the optimum conditions for the ligand buffer solution to mask transition and heavy metal ions in order to determine lithium in a sample solution. In order to mask metal M as completely as possible, most of M (zinc(II); copper(II) etc.) should be the form of $[\text{M}(\text{edta})]^{2-}$ and lithium should be a free ion. Magnesium(II) used as a component of the ligand buffer for masking metal M should satisfy the conditions: $K_{\text{M}(\text{edta})} > K_{\text{Mg}(\text{edta})} > K_{\text{Li}(\text{edta})}$. The formation constants (logarithmic values) of copper(II), zinc(II), magnesium(II) and lithium(I) are 18.70, 16.44, 8.83 and 2.79, respectively [24]. Thus, $[\text{Mg}(\text{edta})]^{2-}$ completely masks metal ions such as copper(II) and zinc(II). The results are listed in Table 1. Cations usually encountered in environmental samples are masked by $[\text{Mg}(\text{edta})]^{2-}$ and anions do not interfere with the determination of lithium(I). Even, chloride as high as $10^{-1} \text{ mol dm}^{-3}$ did not have any effect on the determination of lithium(I).

The high concentration of mercury(II) was not masked completely by $[\text{Mg}(\text{edta})]^{2-}$, therefore NaCN was used to mask mercury(II). Such high concentrations of mercury(II) are rare in environmental samples as such the addition of NaCN may not be required for the determination of lithium in environmental samples.

Table 1

The effect of foreign ions on the determination of Li⁺ using the present method

Ions	Concentration (mol dm ⁻³)	Recovery (%)	Ions	Concentration (mol dm ⁻³)	Recovery (%)
Al ³⁺	1.0 × 10 ⁻⁵	91	Na ⁺	1.0 × 10 ⁻¹	105
Fe ³⁺	1.0 × 10 ⁻⁵	102		1.0 × 10 ⁻²	101
Cd ²⁺	1.0 × 10 ⁻⁵	100		1.0 × 10 ⁻³	99
Zn ²⁺	1.0 × 10 ⁻⁵	92	F ⁻	1.0 × 10 ⁻⁵	97
Cu ²⁺	1.0 × 10 ⁻⁵	93	Cl ⁻	1.0 × 10 ⁻¹	96
Pb ²⁺	1.0 × 10 ⁻⁵	95		1.0 × 10 ⁻²	101
Mn ²⁺	1.0 × 10 ⁻⁵	94		1.0 × 10 ⁻³	97
Co ²⁺	1.0 × 10 ⁻⁵	98	Br ⁻	1.0 × 10 ⁻⁵	107
Ca ²⁺	1.0 × 10 ⁻⁵	95	SCN ⁻	1.0 × 10 ⁻⁵	99
Mg ²⁺	1.0 × 10 ⁻⁵	99	CO ₃ ²⁻	1.0 × 10 ⁻⁵	101
Hg ²⁺	1.0 × 10 ⁻⁵ a	105	SO ₄ ²⁻	1.0 × 10 ⁻⁵	107
	1.0 × 10 ⁻⁶	102	PO ₄ ³⁻	1.0 × 10 ⁻⁵	103
K ⁺	1.0 × 10 ⁻³	92			

^a NaCN (1.0 × 10⁻² mol dm⁻³) was added for masking mercury(II).

3.5. Application of the proposed method to real samples

The present method was applied to the determination of lithium ion(I) in human blood serum, sea water and hot spring water.

3.5.1. Human blood sample

Protein reacts with the porphyrin and reduces absorbance. Thus, protein in serum was removed using the following procedure. Human blood was centrifuged at 3000 rpm, and 1 cm³ of the upper serum was transferred slowly to a trichloroacetic acid solution (5 g and 50 cm³) under constant stirring. The sample was left for 10 min and was followed by centrifugation at 3000 rpm for 30 min—protein precipitated. Trichloroacetic acid in the supernatant was completely removed by extraction (repeated five times using diethyl ether). The aqueous phase was concentrated to ca. 1 cm³ of volume, and the sample was analyzed after dilution (100 times) using the method described above. Since serum contains millimolar quantities of Mg²⁺, H₄edta ([H₄edta] = 1.00 × 10⁻⁴ mol dm⁻³) in place of [Mg(edta)]²⁻ was added to mask other metal ions in serum. We checked the recovery of lithium ion by the addition of accurate amounts of standard lithium concentration in the order (1–10) × 10⁻⁵ mol dm⁻³. The results are shown in Fig. 5. The lithium concentration

was sufficiently recovered after removing protein. The recovery decreased if protein remained. Protein binds to the porphyrin and interferes with the formation of the lithium porphyrin.

3.5.2. Sea water and hot spring water

In the present method large amounts of sodium ions did not interfere with the determination of lithium ions, however, magnesium(II) ions more than 10⁻⁴ mol dm⁻³ interfered a little. Thus, an equivalent amount of H₄edta to the total quantity of magnesium ion in sea water was added to mask magnesium in the sea water sample. Lithium ions in the sea water sample was determined by the

Fig. 5. Recovery of lithium by the addition of accurate amounts of lithium to serum before (○) and after (●) removing protein and to pure water (Δ).

standard addition method using a calibration graph measured at the same ionic strength as sea water. The concentration of lithium was found to be $(1.99 \pm 0.04) \times 10^{-5} \text{ mol dm}^{-3}$. The concentration of lithium ion was deduced by flame photometry and the concentration was $(1.57 \pm 0.09) \times 10^{-5} \text{ mol dm}^{-3}$. The small difference observed in concentration of lithium using the two methods may be caused by the interference of sodium ions in the flame method. The concentration of lithium in hot-spring water was so small, less than $10^{-6} \text{ mol dm}^{-3}$ that its concentration could not be determined using the present method, but a recovery test using the hot-spring water was sufficient: zinc and iron in the hot-spring water were completely masked by $[\text{Mg}(\text{edta})]^{2-}$.

4. Conclusion

This work proposes the first example for the direct spectrophotometric determination of lithium, when present at less than 1 ppm in water using a water-soluble porphyrin. The method is sensitive, simple and selective, using a ligand buffer of $[\text{Mg}(\text{edta})]^{2-}$. It was used to determine lithium in serum and sea water. The method will be developed to a flow injection analysis.

Abstract

The electrochemical redox mechanism of I^- ion under different concentrations on gold electrodes was studied in detail using the EQCM technique (a combination of the QCM technique and cyclic voltammetry). The redox behavior of the I^- ion on a gold microelectrode when no supporting electrolyte was added was compared with a conventional gold microelectrode. Due to the small current and the very low solution iR drop of the microelectrode, the actual oxidation potential of I^- on the microelectrode was much more negative than that of the conventional electrode and its anodic peak was better defined. Therefore the gold microelectrode was employed for the determination of I^- . A linear range of 1.0×10^{-5} – 0.1 mol l^{-1} with a detection limit of $1.0 \times 10^{-6} \text{ mol l}^{-1}$ was obtained on the microelectrode in pure KI aqueous solution. Two samples were measured using this method and the results were in good agreement with those indicated or calculated. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Electrochemical quartz crystal microbalance; I^- ; Amperometric detection; Microelectrode

1. Introduction

Compared with the conventional electrode with a diameter in the order of 1 mm, microelectrodes offer several significant advantages in voltammetric experiments [1–3]. These include: (1) a steady-state response at appropriately low sweep rates; (2) the ability to determine moderately fast heterogeneous chemical reactions through steady-

state measurements; (3) the ability to decrease distortion from iR drop, which allows less polar solvents, lower electrolyte concentration, and faster sweep rates to be used; (4) rapid measurement of Faradaic processes due to a very small RC time constant; and (5) a favorable ratio of Faradaic current to charging current.

QCM is a new sensitive mass sensor which can respond to mass change in the order of 1 ng. The combination of the QCM technique and CV (cyclic voltammetry) is very useful to study a variety of electrochemical processes, such as ad-

sorption and deposition of metal ions, migration of ions in polymers modified on the electrode [4–9], etc.

The iodide ion, which is a clinically important, is generally determined using the ion selective electrode (ISE). The disadvantage of this method is that some coexisting anions such as Br^- , Cl^- and CN^- will interfere with the detection of I^- . The redox mechanism of iodide in iodide or iodide + iodine solutions has been studied extensively on the conventional electrode using a variety of electrochemical techniques such as voltammetry, chronoamperometry, RDE and RDDE techniques [10–13]. In this paper, we applied the QCM to investigate the redox mechanism of iodide in iodide solution on the gold electrode. The redox behavior of I^- on the gold micro-electrode was studied and compared with the conventional electrode. Because of the very small iR drop and the favorable signal to noise ratio, the gold microelectrode was selected for the measurement of I^- . A linear range of $0.1\text{--}1.0 \times 10^{-5} \text{ mol l}^{-1}$ with a detection limit of $1.0 \times 10^{-6} \text{ mol l}^{-1}$ was obtained. This electrode was also used for the measuring two samples, man-made sea water and table salt. Their results were in good agreement with those indicated or calculated.

2. Experimental

2.1. Apparatus and materials

The planar AT-cut quartz crystal, with diameter of 12 mm, fundamental frequency of 9 MHz, and two gold electrodes connected on both sides of the crystal with a diameter of 6 mm, was supplied by Beijing 707 Plant, People's Republic of China. An oscillator circuit was constructed from a transistor-transistor logic integrated circuit. The crystal frequency was monitored by a model GFC-8010G universal frequency counter (Good Mill Taiwan, People's Republic of China). The potential signal was generated by the model-366 biopotentiostat (EG&G, Princeton Applied Research, Princeton, USA). The curves of current \sim voltage, $I \sim E$, and frequency \sim voltage,

$f \sim E$, were recorded by a type-3086 xy recorder (Yokogawa Hukushin Electric, Japan). A model-485 autoranging picoammeter was used to amplify the current signal from the microelectrode. Gold microwires with a diameter of 30 μm were purchased from Goodfellow, UK. The gold disk microelectrode was home-made by sealing a gold wire in a pulled glass capillary or a small pipette. All solutions were prepared in deoxygenated double distilled water with analytical grade reagents. KI aqueous solution (0.1 mol l^{-1}) was prepared as stock solution. No supporting electrolyte was added to the KI solution.

2.2. Procedure

The working electrode used was either the gold electrode on the crystal ($d = 6 \text{ mm}$), or the conventional gold-disk electrode ($d = 4 \text{ mm}$), or else the gold-disk microelectrode ($d = 30 \mu\text{m}$). A potassium chloride saturated calomel electrode (SCE) was used as a reference electrode, and a platinum wire was used as a counter electrode ($d = 1 \text{ mm}$, $L = 0.5 \text{ cm}$). All the potential values were recorded against SCE. When the microelectrode was used as the working electrode, the electrochemical cell was set in a electrically shielded copper cage. In cyclic voltammetry, the potential was swept between -0.20 V and $+0.80 \text{ V}$. Before the experiment, all working electrodes were conditioned by potential cycling between -0.20 V and $+0.80 \text{ V}$ until steady voltammograms were obtained.

3. Results and discussion

3.1. Characterization of I^- by QCM

The QCM was composed of a piezoelectric crystal on which electrode pads were deposited; an oscillator circuit was appropriately employed to the system. For the stiff deposit on the crystal electrode, the changes of frequency as a function of mass changes can be expressed by the well known Sauerbrey equation [14].

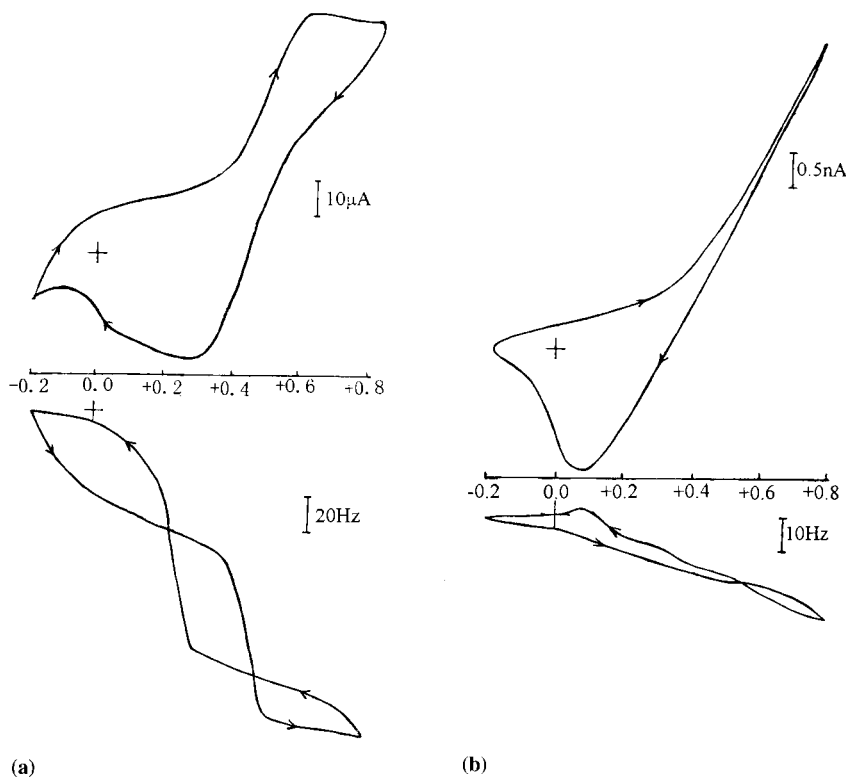

Fig. 1. EQCM characterization of I^- : (a), in 0.1 mol l^{-1} KI solution; (b), in $8.0 \times 10^{-5} \text{ mol l}^{-1}$ KI solution. The potential was swept between -0.2 V and $+0.80 \text{ V}$ at 100 mV s^{-1} .

$$\Delta f = -2\Delta m(f_0)^2/[nA(\mu\rho)^{1/2}] \quad (1)$$

When the properties of the solution remain the same, the frequency changes are also the function of mass changes and can also be described by the Sauerbrey equation. In cyclic voltammetry, the relationship of the frequency changes and the peak currents, i_p , is given by the following equation.

$$i_p = -nFvA(\mu\rho)^{1/2}[d(\Delta f)/dE]E_p/2f_0^2M_w \quad (2)$$

Here, Δf is the observed frequency changes; Δm , the mass changes at the electrode surface; f_0 , the fundamental frequency of the crystal; n , the order of the harmonic oscillator; A , the electrode area on the crystal; μ , the shear modulus of quartz; ρ , the density of quartz and v , the scan rate of electrode potential.

However, the above-mentioned equation, is valid only for adlayers of uniform thickness both

in vacuum and in solution while operating with the QCM. When crystals and electrode pads of a finite size are employed, the mass sensitivity across the surface of QCM is non-uniform. Fortunately, most of time, not all of the electrogenerated material would deposit on the electrode. Thus, from the frequency changes we can calculate the mass of the deposit by using Eq. (2). Combining the cyclic voltammogram, it is very easy to determine the electrode reaction mechanism of some redox systems.

In the EQCM experiment, the $I \sim t$ and $f \sim t$ curves were recorded simultaneously and shown in Fig. 1a and Fig. 1b, for 0.1 mol l^{-1} KI and $8.0 \times 10^{-5} \text{ mol l}^{-1}$ KI solutions, respectively, by using gold electrode on the crystal ($d = 6 \text{ mm}$). Both the $I \sim E$ curve and the $f \sim E$ curve depends on the concentration of the KI solution. In 0.1 mol l^{-1} KI solution, shown in Fig. 1a, an anodic peak at $+0.60 \text{ V}$ and a cathodic peak at $+0.25$

V was observed when the potential was cycled between -0.20 V and $+0.80$ V. The oxidative process was controlled by the diffusion rate. The frequency decreased when the potential was scanned from -0.20 V to $+0.80$ V, and increased when the scan was reversed. This indicated that I^- was oxidized to I_2 and deposited on the electrode. On the anodic curve of $f \sim E$, three sections were observed. When it becomes more negative than $+0.40$ V, the decrease of the frequency may be caused by the slow oxidation of I^- to the deposited I_2 or the direct absorption of I^- on the electrode. From $+0.40$ V to $+0.50$ V, the sharp fall of frequency was caused by the fast oxidation of I^- and the following deposit of I_2 . When it becomes more positive than $+0.50$ V, a frequency plateau was observed due to the depletion of the diffusion layer. The cathodic curve can also be divided into three parts. From $+0.80$ V to $+0.30$ V, the slow rise of the frequency may be caused by the reductive stripping of the deposited I_2 at a slow rate. Between $+0.30$ V and $+0.10$ V, the sharp increase of frequency was caused by the fast reduction of I_2 to I^- . When more negative than $+0.10$ V, a plateau was observed due to the complete reduction of I_2 . From the above results the redox process of I^- may be proposed as:

Sweeping anodically

Sweeping cathodically

In 8.0×10^{-5} mol l^{-1} KI solution, shown in Fig. 1b, no anodic peak was observed. Since the concentration of 8.0×10^{-5} mol l^{-1} was very low compared with the concentration of 0.1 mol l^{-1} and no supporting electrolyte was added, the resistance of the solution was larger, thus the iR drop of the solution was greater, hence the oxidative potential of the I^- ion was higher and no anodic peak was observed within the potential window (the anodic peak may be seen at a potential more positive than $+0.8$ V). Consequently, the frequency variation in 8.0×10^{-5} mol l^{-1} KI solution was smaller than that in 0.10 mol l^{-1} KI

solution due to its lower concentration. When the potential was swept anodically, the frequency fell gradually with the potential resulting from the deposit of I_2 . When the scan reversed, the frequency decreased smoothly with the scan, and finally reached a plateau. This can be explained— I_2 was continually deposited on the electrode at first, then it was reduced to I^- . When the deposited I_2 was completely reduced, the frequency came back to the original no further change was observed. Because the KI concentration was very low, the variation of frequency was smaller.

3.2. Effect of the electrode size on the redox behavior of I^-

A cyclic voltammogram of KI on a conventional gold electrode with a radius of 2 mm was shown in Fig. 2a. No anodic peak but a well defined cathodic peak was observed within the potential window on the cyclic voltammogram. In

Fig. 2. Cyclic voltammograms of 1.0 mmol l^{-1} KI solution on the conventional electrode ($d = 4$ mm) (a) and the microelectrode ($d = 30$ μ m) (b) at $\nu = 100$ $mV s^{-1}$. No supporting electrolyte was added.

Fig. 2b, however, an anodic plateau was observed. The anodic peak is at +0.50V, which is more negative than that of the conventional gold electrode, and the cathodic peak potential is +0.38 V. The ΔE_p value, 120 mV, was larger than that of the reversible redox system, indicating a quasi-reversible redox process for I^- on this electrode. The ratio of i_{pa} to i_{pc} was smaller than unity, indicating the absorption of I_2 on the electrode.

Since the area of the conventional electrode is larger than that of the counter electrode and the concentration of the KI solution was lower and no supporting electrolyte was added, the iR drop of the conventional electrode system was considerably larger resulting in a more positive oxidation peak potential and a large ΔE_p value. On the other hand, the area of the microelectrode is one percent of that of the counter electrode, the iR drop was very small, which brings about a well defined anodic plateau, a microelectrode character at steady-state diffusion. The well-defined cathodic peaks in the two cases were caused by the reductive stripping of the adsorbed I_2 on the electrodes. Therefore I^- was easily oxidized on the microelectrode and the oxidation peak was not distorted under low analyte concentration solution. The addition of the supporting electrolyte was unnecessary. Moreover, the charging current of the microelectrode was very small, hence the ratio of signal to noise improved.

3.3. Detection of I^- on the microelectrode

A gold microelectrode was selected for the determination of I^- , since I^- was easier to oxidize on the microelectrode and the addition of supporting electrolyte (which may bring about other interference since its concentration was usually high) was unnecessary. Fig. 3 shows that the anodic peak current, i_p , was linearly related to the concentration of I^- between 1.0×10^{-5} and 0.10 mol l^{-1} with a detection limit of $1.0 \times 10^{-6} \text{ mol l}^{-1}$. Because the range of the concentration was very wide, $\log(i_p)$ was plotted against $\log C$. The calibration curve can be expressed as $i(nA) = 3.16 \times 10^4 C (\text{mol l}^{-1})$.

Fig. 3. $\log(i_p) \sim \log C$ plot for the gold microelectrode in a series of KI solution without supporting electrolyte added. $v = 100 \text{ mV s}^{-1}$.

3.4. Interference

Negative ions such as Br^- , Cl^- did not interfere with the detection of I^- , because these ions can only be oxidized at potentials more positive than +0.80 V, which was 300 mV higher than the oxidation potential of I^- . Other ions such as CN^- , F^- , NO_3^- , SO_4^{2-} , PO_4^{3-} and K^+ , Na^+ , Ca^{2+} , Mg^{2+} , Fe^{3+} , Cu^{2+} , Zn^{2+} , Cd^{2+} did not interfere with the detection of I^- .

3.5. Effect of pH

When the pH value of the solution ranged from 1 to 7, the oxidative potential and current of I^- were not affected. Hence no buffer solution was used. The standard KI solutions used to obtain the $\log(i_p) \sim \log C$ plot were prepared with distilled water as shown in Fig. 3.

3.6. Measurement of I^- in samples

The man-made sea water was prepared by dissolving 6.0 g NaCl, 1.5 g $MgCl_2$, 0.5 g $CaCl_2$, 1.0 g $NaSO_4$, 0.8535 g KI and 0.0799 g KBr in 500 ml distilled water. The table salt was commercially obtained; its solution was prepared by dissolving

Table 1
Determination of samples by the microelectrode

Sample	Indicated amount	Measured value	Average value	Mean RSD %
Sea water (mg ml ⁻¹)	1.306	1.305	1.305	10.1
		1.300		
		1.310		
		1.302		
		1.308		
Table salt (mg ml ⁻¹)	2.452	2.450	2.457	12.8
		2.460		
		2.473		
		2.448		
		2.455		

1.0 g of this salt in 100 ml distilled water. Since the linear range for KI on the microelectrode was very wide, the two sample solutions were directly measured without further dilution. Results listed in Table 1 show that the measured values were in good agreement with the indicated values. The average anodic peak currents for sea water and table salt solution were 324.74 nA and 6.11 nA, respectively.

4. Conclusion

The method of combining QCM and CV together is a very useful technique both to study the redox process or to detect the content of I⁻. By using this technique, more information about the redox process from the $f \sim E$ and $i \sim E$ curves of I⁻ can be obtained. Compared with the conventional electrode, a better voltammogram could be observed using the gold microelectrode, and the oxidation-potential was relatively lower when the analyte concentration was low and no supporting electrolyte was added. The linear range of $1.0 \times 10^{-5} \sim 0.10 \text{ mol l}^{-1}$, was very wide. A detection limit of $1.0 \times 10^{-6} \text{ mol l}^{-1}$ was obtained. It is safe to say that the method is very useful, practical, and deserves more research.

Abstract

A pretreatment method based on borate complex formation is described for the selective and simultaneous quantitation of pharmacologically active catechins in human plasma and saliva. This method is based on the interaction of catechins with diphenylborate (as a complexing agent) and tetra-*n*-butylammonium (as a counter ion) in alkaline media to give the catechin–diphenylborate complex and ion-pair that are extractable to the organic phase. The complex extracted in an organic solvent is dissociated by shaking with an aqueous trifluoroacetic acid solution to back-extract free catechins to the aqueous phase, followed by high-performance liquid chromatography (HPLC) analysis with fluorometric and diode array detection. Under optimal conditions, all catechins originating from green tea extracts were selectively purified from plasma and saliva samples, and they were stabilized during the extraction procedures by forming the complex. The nano-scale quantitative analysis of eight catechins was achieved with high recovery and analytical reproducibility. The proposed method would be a useful tool for pharmacokinetic studies of catechins in plasma and saliva. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Catechins (3,3',4',5,7-pentahydroxyflavan and its derivatives) contained in tea leaves (*Camellia sinensis*) are known to possess various biological activities [1,2]. Among the known pharmacological effects, the practical applications of catechins are in the treatment of acute viral hepatitis [3] and in the prevention of dental caries [4]. The medi-

¹ Presented at the First Asia-Pacific International Symposium on Capillary Electrophoresis, and other Nano- and Microscale Analytical Techniques, held in Singapore, December 17–20, 1996.

nal effectiveness of catechins depends on their concentrations in blood after oral administration and on their concentrations in saliva after application to the oral cavity. Therefore, a quantitative method for catechins that are present or retained in body fluids has been needed for their pharmacokinetic studies.

Catechins in widely used tea extracts are composed of catechin (*trans*-2-[3,4-dihydroxyphenyl]-3,4-dihydro-1[2H]-benzopyran-3,5,7-triol: C), epicatechin (*cis*-catechin: EC), gallocatechin (*trans*-2-[3,4,5-trihydroxyphenyl]-3,4-dihydro-1[2H]-benzopyran-3,5,7-triol: GC), epigallocatechin (*cis*-gallocatechin: EGC), catechin-3-gallate (CG), epicatechin-3-gallate (ECG), gallocatechin-3-gallate (GCG) and epigallocatechin-3-gallate (EGCG) [5]. The prepurification selective for these eight catechins is essential to successful analysis of body fluids. Although several pretreatment methods were previously reported to purify catechins in biological samples [6–10], they are unsatisfactory in selectivity, sample-size and procedural simplicity.

Since borate specifically forms a complex with 1,2-diols [11], such borate complex formation has been used for the purification of catechol compounds [12–14]. Eight tea catechins possess the same 1,2-dihydroxyl structure. Hence, they are speculated to be selectively extracted from body fluid samples by forming the borate complex and ion-pair as shown in Fig. 1. The back-extracted catechins would be separately analyzed by high-performance liquid chromatography (HPLC).

To achieve a nano-scale analysis of catechins based on this speculative system, analytical conditions were optimized for their pretreatment using the borate complex extraction method. After treating human plasma and saliva under optimal conditions, all the purified catechins were subjected to HPLC analysis with fluorometric and diode array detection.

2. Experimental

2.1. Reagents

Standard C, EC, EGC, ECG and EGCG were supplied by Dr Munekazu Iinuma, Gifu Pharma-

ceutical University (Gifu, Japan). GC, CG and GCG were purchased from Funakoshi (Tokyo, Japan). Their stock solutions (1.0 mg ml^{-1} of each) were prepared by dissolving the standards in 0.01 N HCl, and then they were stored at 4°C . They were diluted as required with 0.01 N HCl before use. Pyrocatechol (PC) from Nacalai Tesque (Kyoto, Japan) and 4-methylcatechol (4-MC) from Tokyo Kasei (Tokyo, Japan) were used as an internal standard for plasma and saliva analysis, respectively. Diphenylborate–ethanolamine complex was obtained from Aldrich (Milwaukee, WI, USA). Catechin-containing green tea extract was supplied from Taiyo Kagaku (Yokkaichi, Japan). Tetra-*n*-alkylammonium bromides with different alkyl chains were of ion-pair chromatographic grade (Nacalai Tesque). Acetonitrile of HPLC grade (Kishida, Osaka, Japan) was used for the mobile phase preparation. All other reagents were of the highest analytical grade available. Water was redistilled by an all-glass apparatus after purifying by a Milli-Q water purification system (Nihon Millipore, Tokyo, Japan).

2.2. Pretreatment procedures and optimization of conditions

Extraction procedures were performed using polypropylene tubes with screw caps ($101 \times 14 \text{ mm}$; Sarstedt, Nümbrecht, Germany). All of the glassware used for quantitative analyses was silanized to avoid the adsorption of analytes onto the glass surfaces [15]. After adding $50 \mu\text{l}$ of a 4-MC solution in 0.01 N HCl (1.0 mg ml^{-1}), 0.5 ml of the sample solution was vortex-mixed for 1 min with 0.5 ml of 0.15% (w/v) diphenylborate in 2.0 M potassium phosphate buffer (pH 8.5) containing 5% (v/v) ethanol and 4.0 ml of 5 mM tetra-*n*-butylammonium bromide in *n*-octanol/*n*-hexane (20:80, v/v). The mixture was centrifuged at $1200 \times g$ for 3 min. The organic phase was vortex-mixed for 1 min with 0.25 ml of 7.5% (v/v) trifluoroacetic acid. After centrifugation at $1200 \times g$ for 3 min, the aqueous phase was subjected to HPLC separation.

Standard catechin solutions ($5.0 \mu\text{g ml}^{-1}$ of each) were treated by varying the diphenylborate concentration (0–0.2%, w/v), the phosphate

Fig. 1. Schematic analytical procedure using the extraction pretreatment based on diphenylborate complex and ion-pair formation.

Fig. 2. Effect of diphenylborate concentration on catechin extraction.

buffer pH (3.0–10.0), the type (alkyl chains of $(C_3H_7)_4^-$ to $(C_{10}H_{21})_4^-$) and concentration (0–10 mM) of tetra-*n*-alkylammonium bromide, the type of extraction solvent (*n*-alcohol: $C_5H_{11}-OH$ to $C_{10}H_{21}-OH$ and *n*-hydrocarbon: C_5H_{12} to $C_{10}H_{22}$), the solvent composition (*n*-alcohol in *n*-hydrocarbon: 5–40%, v/v), and the trifluoroacetic acid concentration (0.1–12.5%, v/v). The analytical conditions were optimized by comparing the relative peak areas obtained throughout all procedures (extractions and HPLC with diode array detection). The results were expressed as the means of duplicated experiments.

2.3. Stability of catechins

To 0.5 ml of a standard catechin solution (10.0 $\mu\text{g ml}^{-1}$ of each) was added 0.5 ml of 2.0 M potassium phosphate buffer (pH 2.0, 7.0, 8.5 or 10.0) or 2.0 M potassium phosphate buffer (pH 8.5) containing 0.15% (w/v) diphenylborate. The mixtures were allowed to stand for 2.5–30 min at room temperature. A 0.5 ml aliquot of each resulting solution was analyzed as described in Section 2.2. The relative stability of catechins under different conditions was evaluated by comparing the mean peak areas of duplicated experiments to the original peak areas (0.01 N HCl solution).

2.4. Sample preparation

2.4.1. Plasma

Heparinized blood plasma was collected from male subjects, all aged 44 years. To 150 μl of plasma samples was added 100 μl of 50 mM citrate buffer (pH 4.5) containing 0.02% (w/v) EDTA–2Na. The mixture was vortex-mixed with 100 μl of 5% (v/v) perchloric acid containing PC (5.5 $\mu\text{g ml}^{-1}$), and centrifuged at $20000 \times g$ for 10 min. To 300 μl of the supernatant were added 0.5 ml of 0.1% (w/v) diphenylborate in 5% (v/v) ethanol/2.0 M potassium phosphate buffer (pH 8.5) and 4.0 ml of 15 mM tetra-*n*-butylammonium bromide in *n*-octanol/*n*-hexane (20:80, v/v), and then treated as de-

scribed in Section 2.2. The back-extraction was performed with 0.2% (v/v) trifluoroacetic acid instead of 7.5% (v/v) trifluoroacetic acid.

2.4.2. Saliva

Unstimulated whole saliva was collected from male subjects, all aged 44 years, and then diluted 2–10 times with 0.01 N HCl. After adding 50 μl of a 4-MC solution in 0.01 N HCl (1.0 mg ml^{-1}), 0.5 ml of saliva diluent was treated as described in Section 2.2.

2.5. Liquid chromatography

2.5.1. Plasma sample

An LC-10AD liquid chromatograph (Shimadzu, Kyoto, Japan) controlled by an SCL-10A system controller (Shimadzu), a DGU-4A degasser (Shimadzu), a 7125 sample injector (injection volume of 100 μl ; Rheodyne, Cotati, CA, USA), a Shim-pack CLC-C8 (M) column (250 \times 4.6 mm, particle size 5 μm ; Shimadzu) placed in a CTO-6A column oven (Shimadzu), and an RF-550 spectrofluorometric detector (Shimadzu) connected to a C-R 6A Chromatopac data processor (Shimadzu) were used. Separation was performed by delivering the mobile phase, acetonitrile/trifluoroacetic acid/water (16.5:0.2:83.3, v/v/v), at a flow rate of 1.0 ml min^{-1} and at a column temperature of 50°C. C, EC and PC were detected at 282 nm for excitation and 314 nm for emission. C and EC were quantified based on the peak area ratios to PC by reference to the calibration graphs.

2.5.2. Saliva sample

An LC-9A liquid chromatograph (Shimadzu) connected to a KMT-30A auto sampler with an injection volume of 40 μl (Kyowa Seimitsu, Tokyo, Japan), a Shim-pack CLC-C8 (M) column (250 \times 4.6 mm, particle size 5 μm ; Shimadzu) placed in a thermo-controller (Kyowa Seimitsu), and an SPD-M10AVP diode array detector (Shimadzu) controlled by an FMV-5133D5 personal computer (Fujitsu, Tokyo, Japan) were used. The mobile phase, A: acetonitrile/trifluoroacetic acid/water (10:0.3:89.7, v/v/v), and B: acetonitrile/

Standard catechins ($5.0 \mu\text{g ml}^{-1}$ of each) were allowed to stand in phosphate buffer of different pH values (2.0, 7.0, 8.5 or 10.0) or phosphate buffer (pH 8.5) containing diphenylborate. They were analyzed after the indicated time. The values indicate the mean relative peak areas of duplicated experiments.

water (30:70, v/v), was delivered at a flow rate of 1.0 ml min^{-1} and at a column temperature of 50°C in a linear gradient elution mode. The gradient was prepared as follows: 100% A at 0 min to 25% A and 75% B at 17 min. The UV absorbances of the analytes were detected at 269, 274, 277 and 278 nm. All catechins were quantified based on the peak area ratios to 4-MC by reference to the calibration graphs.

3. Results and discussion

3.1. Optimal conditions

Various analytical conditions were optimized for the procedures schematically shown in Fig. 1. Among the borate compounds commercially available [13], diphenylborate was chosen as a complexing agent because it showed the highest

extractability for catechins. The peak areas of catechins varied with the diphenylborate concentrations as shown in Fig. 2. The peak areas of all the tested catechins increased with the addition of diphenylborate, indicating that their extraction is improved by the complex formation. The use of diphenylborate was especially effective on the extraction of GC, EGC, C and EC. Their extractability was significantly elevated by increasing the concentrations. In contrast, this effect was lesser on EGCG, GCG, ECG and CG, suggesting that their extraction is primarily based on relatively high lipophilicity. The concentrations of 0.1–0.15% (w/v), at which the peak areas of all the catechins became plateau, were used.

The complex formation between borate and catechol compounds proceeds in weakly alkaline media [12–14]. As shown in Fig. 3, catechins also formed the complex with diphenylborate depending on an increase of phosphate buffer pH, and

showed the largest and/or constant peak areas at pH 8.5. The peak areas tended to decrease above pH 9.0, indicating the possible decomposition of catechins.

C was recently reported to be stable in acidic media, but oxidatively decomposed above pH 5.0 [10]. Although catechins most efficiently formed the diphenylborate complex at pH 8.5, they had been presumed to be unstable under such alkaline conditions. When catechins were allowed to stand in phosphate buffer of different pH, their peak areas changed as shown in Table 1. After 30 min, catechins showed no change at pH 2.0. They were also relatively stable at pH 7.0. At pH 10.0, however, all catechins showed a reduction to 0–82% of their original concentrations. Catechins did decompose at pH 8.5 (the optimal extraction condition) and their concentrations decreased with time. Significant decomposition occurred especially in EGC, EGCG and GCG, which reduced to

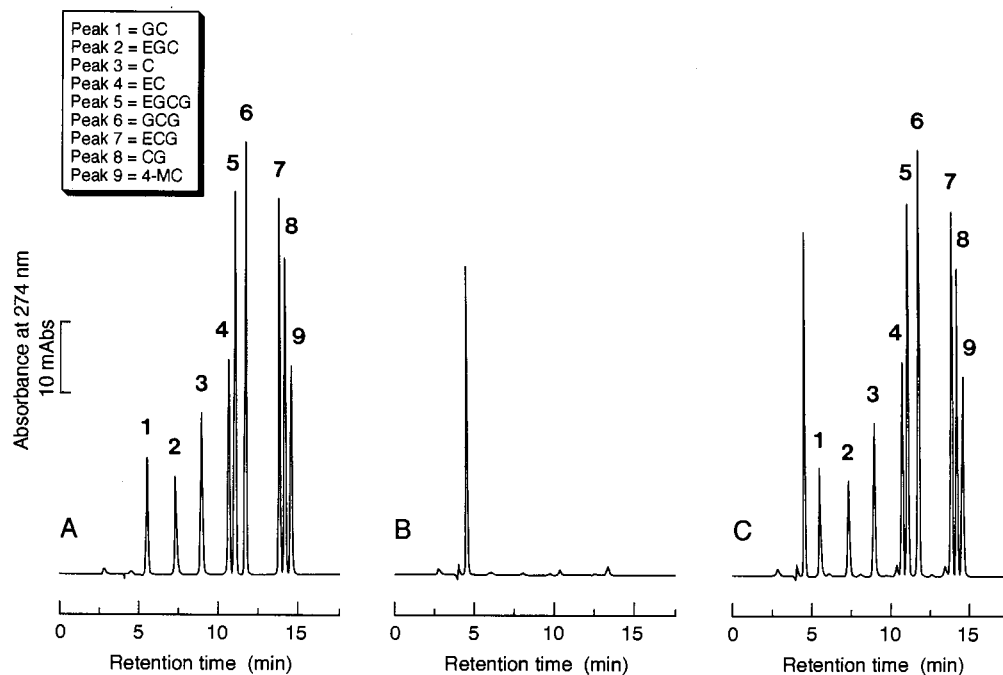

Fig. 6. Chromatograms obtained from standard and saliva samples. (A) Standard catechins ($5.0 \mu\text{g ml}^{-1}$ of each); (B) blank saliva; (C) saliva added with standard catechins ($5.0 \mu\text{g ml}^{-1}$ of each). UV detection: 274 nm.

52, 57 and 76%, respectively, after 10 min. In contrast, after mixing with diphenylborate, no or significantly less reduction was observed in all catechins even at pH 8.5. As the vortex-mixing time is only 1 min under such alkaline conditions, the decomposition of catechins is negligible at the step of complex formation and extraction. Although catecholamines, like catechins, are unstable at alkaline pH, they are stabilized by forming a complex with alumina [16]. Catechins in the diphenylborate complex form are similarly considered to be stable.

Since diphenylborate is negatively charged in alkaline media, it is speculated to form an anionic complex with catechins [12]. Therefore, ion-pair extraction using a cationic counter ion is favorable for increasing the extractability of the catechin-diphenylborate complex (Fig. 1). When using tetra-*n*-alkylammonium with different alkyl chains, $(\text{C}_3\text{H}_7)_4^-$ to $(\text{C}_{10}\text{H}_{21})_4^-$, tetra-*n*-butylammonium with $(\text{C}_4\text{H}_9)_4^-$ showed the highest extractability. The peak areas of catechins varied with tetra-*n*-butylammonium bromide concentrations, as shown in Fig. 4. The use of this counter-ion was so

effective that the extractability of all catechins was significantly enhanced by increasing the concentrations of tetra-*n*-butylammonium, although they were scarcely extracted without it. The peak areas of all catechins became constant over 5 mM. The reproducible extraction of C and EC from plasma samples required a concentration of 15 mM, suggesting the consumption of tetra-*n*-butylammonium by anionic compounds in plasma other than the catechin-diphenylborate complex.

The diphenylborate complex dissociates under acidic conditions to give free catechins back-extractable to the aqueous phase (Fig. 1). This dissociation easily occurs in a short time by shaking with an acidic aqueous solution [13]. GC, EGC, C and EC were back-extracted to the aqueous phase by vortex-mixing their diphenylborate complex with 0.2% (v/v) trifluoroacetic acid solution for 1 min. The efficient back-extraction for the other catechins needed a higher concentration of trifluoroacetic acid, 7.5% (v/v). These acidic back-extraction conditions are also advantageous for the stability of catechins.

3.2. HPLC analysis of plasma

Among catechins, C has been used for the treatment of acute viral hepatitis [3]. When the tea extract is orally administered, C and its isomer, EC, are expected to occur at ng ml^{-1} levels in blood [8,17]. The nanoscale separative analysis of C and EC was performed by HPLC with fluorometric detection. Fig. 5 shows the chromatographic results after the diphenylborate complex extraction pretreatment. Plasma C, EC and PC were simultaneously separated without interfering peaks, indicating that the present pretreatment is selective for catechins in plasma.

The quantitative evaluation is summarized in Table 2. Plasma samples spiked with standards were analyzed throughout all procedures. Plotting the peak area ratios of C and EC to PC against the known concentrations showed good linearity in the ng ml^{-1} concentration range for both C and EC. In replicate spiking experiments, the recovery and analytical reproducibility of C and EC were high enough for the quantitative analysis of plasma samples. The mean recovery ($n = 5$) of PC was 92.7%, which was determined by analyzing standard catechin and plasma samples added to 100 μl of the PC solution ($5.5 \mu\text{g ml}^{-1}$).

The present method is superior in selectivity for plasma C and EC to previous methods [8,9], in which plasma samples were purified by solid-phase or liquid-phase extraction, but the major unknown peaks appeared on chromatograms. Its plasma sample-size is only 150 μl volume, which is less than the 0.25–2 ml needed in other methods [6,8,10]. It is also effective for stabilization of C and EC during analysis, but in other methods [7–9,18] no attention was paid to their stability. The pretreatment procedure, consisting of simple two-step extractions, is applicable to multi-sample analysis.

The proposed method was applied to the analysis of plasma collected from human subjects after the oral administration of green tea extract (1.0 g) containing C and EC. Since the major fractions of flavanoids are conjugated in human blood [19], plasma was analyzed after enzymatic hydrolysis [9]. Neither C nor EC was detected in any plasma samples before administration. However, both C

and EC in plasma were found to increase in a time-dependent manner after their administration. The peak plasma levels of total (free plus conjugated) C and EC were reached 60–120 min after administration, which agrees with the report of Lee et al. [9].

3.3. HPLC analysis of saliva

The caries-preventive effects of catechins have been considered to be derived from their antibacterial activity against cariogenic bacteria [20] and inhibitory activity against plaque formation [21]. Since GC, EGC, EC, EGCG, GCG and ECG show such activities at $\mu\text{g ml}^{-1}$ levels [4,20,21], the nano- and microscale analysis of these catechins in saliva is needed to assess their retentivity in the oral cavity after mouth-rinsing with tea catechins. However, catechins other than C and EC did not possess fluorescent properties suitable for their simultaneous detection. Therefore, a diode array detector was employed to detect all of the eight catechins showing absorption maxima in the range 269–278 nm. Fig. 6 shows the chromatographic results after the diphenylborate complex extraction pretreatment. Eight catechins and 4-MC were simultaneously separated without major interfering peaks, indicating that the present pretreatment is selective for catechins in UV detection as well as in fluorometric detection.

The quantitative evaluation is summarized in Table 2. Calibration graphs prepared by plotting the peak area ratios of catechins to 4-MC were linear in the concentration range $\text{ng}–\mu\text{g ml}^{-1}$. The replicate spiking experiments showed high recovery and reproducibility applicable to the quantitative analysis for all salivary catechins of active concentrations. The mean recovery ($n = 5$) of 4-MC was 97.2%, which was determined by analyzing standard catechin and saliva samples added to 50 μl of the 4-MC solution (1.0 mg ml^{-1}).

Previous HPLC methods separately analyzed only some catechins, not all catechins [9,22,23]. The present method is the first to be successfully applied to the simultaneous analysis of all the eight catechins in saliva.

Saliva was analyzed after mouth-rinsing with an aqueous solution of green tea extract (5.0 mg ml⁻¹, 100 ml) for 2.5 min. The eight salivary catechins were found to show the µg ml⁻¹ concentrations 1–60 min after mouth-rinsing, although no catechins were detected in saliva before mouth-rinsing.

4. Conclusion

A pretreatment based on diphenylborate-complex formation and ion-pair extraction has been proven to be effective not only for the selective purification of catechins but also for their stabilization during analysis. The HPLC procedure combined with this pretreatment allows the nanoscale quantitative analysis of catechins in plasma and saliva. The proposed method is applicable to the pharmacokinetic study of pharmacologically active catechins in body fluids.

Received 19 February 1997; accepted 17 June 1997

Abstract

A simple but reproducible method has been explored for the preparation of polyacrylamide gradient gel-filled capillaries with low UV detection background. The principle is to fill a capillary by plugging it into a wide tube already filled with gradient gelling solutions including a section of buffer. Void-free capillaries can be prepared with a full success for gels below 13%T + 5%C (immobilised completely). For gels between 15%T and 25%T + 5%C, the preparation success rate is 80–95%, depending on the gel immobilisation methods. The resulting capillaries allow the use of any available wave-length for sensitive detection and in the separation of polylysines, a great improvement of their detection sensitivity has been achieved, up to 10^3 – 10^4 fold as compared to the common gel-filled capillaries. Unlabelled polysaccharides from the sacculi of *Escherichia coli* can hence directly be detected at 200 nm. These capillaries can continuously be used for more than 2 months in separating the biological polysaccharides at -200 V cm^{-1} and pH 7.8 while at pH 4.7, they can still be used for more than 400 injections (~ 1 month) of the polylysines at $+180$ V cm^{-1} . As expected by stacking effect, the gradient gels yield higher efficiency or running speed (1-fold) and even higher UV detection sensitivity (> 2 -fold) than the homogeneous gels. © 1998 Elsevier Science B.V. 1. Introduction

Capillary gradient gel electrophoresis (CGGE) is in theory an attracting model for the separation of closely-sized molecules or complicated samples

according to slab gradient gel electrophoresis [1–3], but the preparation of gradient gel-filled capillaries seems to be very difficult. Different from a wide slab chamber or column, capillaries have only microlitres of volume, their flowing rate is hardly controlled which varies part by part and from capillary to capillary. Consequently, gel gradients cannot precisely be located in the capillaries, resulting in irreproducible preparations (and separations). This is also different from pro-

ducing the homogeneous gel-filled capillaries used for capillary gel electrophoresis (CGE) [4].

To control the location of the gradients, we have suggested a step filling method (SFM) [5,6] which can be used for the preparation of not only homogeneous but also stepped and smooth gradient gel-filled tubes [5–8]. However, it needs 20 steps (1.5 cm per step) and 20 ml (1 ml per step) of monomer solutions to prepare a 30 cm smooth gradient gel. The capillary should hence be transferred from solution to solution for 19 times. This is somehow tedious and the transferring, if too slow, may introduce air bubbles in between the steps. By adjacently arranged wells, the transferring distance or time was reduced [6] but the problem has not yet been removed.

We have then tried to use paraffin membrane-separated wells so that a capillary can reach any well by breaking through the membranes. This is theoretically a method to eliminate the transferring problem but not ideal. It is labour-intensive to build up the 20 wells while the built wells can only be used for one time. An alternative way is to use a sort of liquid connected or continuous ‘wells’, that is, layering the gelling solutions inside a wide tube. This is thus a two-stepped filling (TsF) method: The first step is to prepare the gradient gelling solutions inside the tube, and the second step is to transfer the pre-gradient solutions from the tube into a capillary. Similar to SFM, TsF can also be used for producing both of the gradient and homogeneous gel-filled capillaries with low UV background.

In this paper, we will discuss the preparation of polyacrylamide gel-filled capillaries with smooth gradients and low UV detection background. The obtained capillaries are tested by both of negatively charged polysaccharides from the sacculi of *Escherichia coli* [9] and positively charged polylysines. Such samples are difficult to separate and have serious detection problem in CGE with common gel-filled capillaries [10–12] which yield no peak at 210 nm or shorter [5,8]. Different from the common tubes, the new capillaries, which allow the use of any available wave-length for sensitive UV detection, generate

a high detection sensitivity and fast separation of the tested samples. Their UV detection sensitivity is 10^3 – 10^4 fold higher than the common capillaries and at least 2-fold higher than the homogeneous gel-filled capillaries with also low detection background. A direct detection of unlabelled polysaccharides can thus be achieved at 200 nm. Their running speed is about 1-fold higher than the homogeneous gel-filled columns while their efficiency is similar to or better than the latter columns. The experiments also show that resulted capillaries are quite stable: They can be used for more than 400 injections (~ 1 month) of polylysines at pH 4.7, 25°C and +180V cm^{-1} and for more than 2 months at pH 7.8 and -200V cm^{-1} .

2. Experimental

2.1. Chemicals

Tris [tris(hydroxymethyl)aminomethane], EDTA, TEMED [*N,N,N',N'*-tetramethyl-ethylenediamine] and γ -MPS [γ -methacryloxypropyltrimethoxysilane] came from Sigma (St. Louis, MO). Acrylamide and BIS [*N,N'*-methylenebis(acrylamide)] were research reagent grade from Beijing Purchasing Station, Chinese Pharmacy (Beijing, PR China). Boric acid, APS [ammonium persulfate], phosphates, acetic acid, sodium acetate and other chemicals were all analytical reagent grade from Beijing Chemical Works (Beijing, PR China). Water used was triply distilled.

2.2. Sample

Poly(Lys)₃₈ and poly(Lys)₁₂₆ [poly-L-lysine hydrobromides, with polymerisation degree of 38 and 126 each, obtained from the viscosity measurements, Sigma products were dissolved in water at 0.05–100 mg ml^{-1} . The very diluted samples ($< 5 \text{ mg ml}^{-1}$) were prepared every morning to eliminate the hydrolysis problem. Poly(GlcNAc-Mur) is a mixture of $\alpha(1 \rightarrow 4)$ linked regular interpolymers of *N*-acetylglucosamine-2

(GlcNAc) and muramic acid (Mur). It was prepared by enzymatic digestion of the murein peptidoglycan from the sacculi of *E. coli* KN126 (detailed preparation see [9]) and desalted by dialysing against water for 3×4 h at 4°C , with Spectra/Por membrane (MWCO 1000, from Carl Roth GmbH., Karlsruhe, Germany). The desalted sample is blown to dry with nitrogen gas and stored at -20°C . Before use, it was dissolved in water at a total concentration of 1 mg ml^{-1} .

2.3. Preparation of capillaries

The main point is to fill a capillary and a tunnel with sufficiently short steps (≤ 1.5 cm) of gelling solutions. The stepwise distributions will spontaneously change to smooth gradients [6]. The detection background is reduced just by replacing the gels at the detection part of the capillary with UV-transparent buffers [5,6]. To stabilise the capillaries, the gels are immobilised by forming chemical bonds along the entire tubing wall. This is realised by coating the capillaries just before filling. The suggested filling method is TsF.

2.3.1. Coating

A fast coating procedure modified from those of our previous works [5–8] is as follows: A new capillary (J&W) is filled with a solution of 0.5% γ -MPS and 0.5% acetic acid in dichloromethane. After 30 min of reaction at room temperature, it is washed with acetonitrile and water for 2 min each and then filled with a gelling solution of 1.5%T + 5%C², allowed to react at $50\text{--}70^\circ\text{C}$ for 30 min. This capillary is washed with water for 2 min and dried by inrush of air for 1 min.

2.3.2. Filling

Step 1: Into the mixing well (Fig. 1A-3), a volume (V_0) of buffer (pH 7.8–8.4) containing TEMED and APS is filled and a $V_{F(0)}$ volume of

it is allowed to flow into the tunnel till the mark 1T . The left buffer is then mixed with a volume [$V_{A(1)}$] of a concentrated gelling solution. Following the buffer, the mixed solution is filled into the tunnel till the buffer reaches the mark 2T . The left gelling solution is then diluted with the buffer and filled into the tunnel step by step until the buffer reaches the mark $^{\text{end}}T$ which is at the position including the mechanically untouchable volume (V_{un}) in between the valve and the well so that the final solution can flow into the tunnel. About 10 steps (1 cm per step) is required to fill a capillary with 20 steps of gelling solutions. The theoretical

V_{un} , untouchable volume; S , cross sectional area; $P_1, P_2, \dots, P_{\text{end}}$, capillary plugging positions marked at 0.3–0.5 cm from $^{\text{end}}T$ and 2–2.5 cm from P_1 and then at every 0.5 cm; $^1T, ^2T, \dots, ^{\text{end}}T$, position symbols for filling the tunnel marked at every 1 cm except for $^{\text{end}}T$ which includes $V_{\text{un}}/S \approx 1$ cm; $F_1, F_2, \dots, F_{\text{out}}$, capillary filling symbols marked at 12–13 cm from the tip and then at every 1.5 cm.

² By gelling solution is meant the monomer solution added with TEMED and APS. The concentration of a gelling solution is given by $x\%T + y\%C$ where x is the grams of acrylamide and BIS in 100 ml solution and y the grams of BIS per 100 g monomers.

concentrations in the middle part of step i (C_i) and at the boundary ($C_{(i+1)/i}$) are

$$C_{(i+1)/i} = (C_{i+1} + C_i)/2$$

$$C_{i+1} = \frac{C_i[V_i - V_{F(i)}] + V_{A(i+1)}C_{A(i+1)}}{V_i - V_{F(i)} + V_{A(i+1)}}$$

$$i = 0, 1, 2, 3, \dots$$

$$V_i = V_0 - V_{un} + \sum_1^i V_{A(i)} - \sum_0^{i-1} V_{F(i)} \quad (1)$$

where $V_{A(i)}$ is the newly added volume of the solution at step i and $C_{A(i)}$ its concentration ($= 0$ except for $i = 1$), $V_{F(i)}$ is the volume filled into the tunnel at step i . C_i has thus a value sequence of $C_0 (= 0) < C_1 > C_2 > C_3 > \dots > C_{end}$. By this equation we can see that non-linear gradients will be resulted if $V_{A(i)}$ is kept constant. To produce linear gradient [$(C_{i+1} - C_i) = \text{constant}$], $V_{A(i)}$ should be changed at different steps which can be calculated by re-writing the Eq. (1) as follows:

$$V_{A(i+1)} = \frac{C_{i+1} - C_i}{C_{A(i+1)} - C_{i+1}} (V_i - V_{F(i)}) \quad (2)$$

In the case of continuous dilution and filling, the concentration of the mixed gelling solution at time t [$C(t)$] is given by

$$C(t) = C_{A(1)} V_{A(1)} \left\{ V_0 - V_{un} + \int [v_A(t) - v_F(t)] dt \right\} \quad (3)$$

where $v_A(t)$ is the volume flow rate of the solution for dilution at time t and $v_F(t)$ that of the mixed gelling solution flowing into the tunnel. $C(t)$ can be transformed to the concentration distribution along the tunnel [$C(L)$] through $L = \int v_F(t) dt / S$, where S is the cross sectional area of the tunnel.

Step 2: The coated capillary is marked at the required filling positions and mounted in a glass rod amplifying device (Fig. 1B). It (F_1 end) is then horizontally inserted in the tunnel at the position P_1 (Fig. 1A). As soon as the buffer flows, by surface tension, to mark F_1 , the capillary is further plugged in and stopped at P_2 until the buffer reaches F_2 . Repeatedly, the capillary

will pass through all the marked positions till it meets the P_{end} . When the buffer inside the capillary moves to F_{out} , the capillary is quickly pulled out and both its ends are plugged into a sealed glass vial (Beckman, 358807), followed by injection of about 4 ml of ice-cooled water into the vial to form a slight pressure and to cool the pressurised ends [5]. The capillary is hung (Fig. 1C) for at least 5 h to accomplish the polymerisation.

After polymerisation, the capillary is pulled out and a detection window is created at 2 cm away from the gel-buffer boundary (at the F_{out} end) by manually removing the capillary overcoating with a scalpel. The capillary is then mounted in Beckman P/ACE system and equilibrated with a running buffer at -200 V cm^{-1} and 35°C for > 30 min. The equilibrated capillary is stored at room temperature for 2–3 days with both its ends dipped into the running buffer. This storage increases the stability and separation efficiency of the gels. The reasons are not clear but we suggest that this is due to the over-bending or over coiling of the capillaries inside the cartridges. The gels should thus be re-shaped which is not easy and may take a long time.

All the gel-filled capillaries are described by $X \mu\text{m ID} \times L_g(x_1 \rightarrow x_2\%T + 5\%C) + 2/L$ cm where X is their inner diameter, L_g is the gel length located at 2 cm before the detection window and L is the total tube length; $x_1 \rightarrow x_2\%T + 5\%C$ shows the gradient range and migration direction.

2.4. Electrophoresis

All separation was performed at 25°C using the Beckman P/ACE system (model 2050) controlled by a computer with the System Gold software. The electric field strength is $+180 \text{ V cm}^{-1}$ for the separation of poly(Lys) $_i$ ($i = 38/126$) and -200 V cm^{-1} for the separation of poly(GlcNAc-Mur). Poly(Lys) $_i$ is introduced into the gel end at $+5 \text{ kV}$ for seconds and poly(GlcNAc-Mur) at -5 kV cm^{-1} for 15 s. The separated bands were detected at 200 nm and 1 s rise-time while the peak data acquired at 1 Hz.

3. Results and Discussion

3.1. Control of polymerisation speed and direction

It is needed to prevent the gelling solutions from polymerisation before filling is finished. A glass tube is not suitable for preparing the pre-gradient gelling solutions because the polymerisation sometimes starts just in the half way of filling. By lowering the amount of TEMED and/or APS is a way to decrease the speed but not preferred: For gels below 10%T, the polymerisation may not happen at all or the resulted gels may be unstable if TEMED and APS are < 0.02%. Another way is to cool the gelling solutions in an ice-bath. This method may also results in unstable or irreproducible capillaries.

Interestingly, the polymerisation can effectively be inhibited by preparing the gelling solutions in teflon or polystyrene plastic tubes and can be recovered by transferring the solutions into the glass vials. Although the mechanism is not clear (it seems that some plastics prevent the radicals from passing to acrylamide), a polystyrene filling device is used to control the polymerisation speed. This transparent plastic allows an easy observation of the solution flow.

The formation of voids in polyacrylamide gels due to their volumetric losses during polymerisation is a common but serious problem, this problem will become even more serious in the preparation of concentrated gels and when the gels are immobilised along the entire capillary wall [7]. The voids can be eliminated by programmed initiation of the polymerisation so that the volumetric losses in the polymerised parts of can be compensated for by attracting the not-yet-polymerised solutions. A successful way reported to introduce APS and TEMED into a monomer solution-filled capillary by isotachopheresis [10]. It is also theoretically possible to control the polymerisation direction by sequentially warming or cooling the filled capillaries. We suggest here a fast way, that is, using gradient TEMED and/or APS. This is impossible with a normal sucking or pressing filling method but TsF allows a regulation of TEMED and APS concentrations at each mixing step.

Gradient gels themselves will form in a direction from high to low concentrations at a given amount of APS and TEMED. This can be enhanced by adding more TEMED or APS to the concentrated solutions and can be reversed if we change the gradient direction of APS or TEMED. This control, associated with cooling and pressurising the tube end, was shown to be effective and fast. The pressure assists the solution flowing to the polymerised part and the cooling prevent the tubing ends from polymerisation before other parts.

As a result, void-free capillaries can be prepared with a full success for gels below 13% + 5%C, independent of the gel immobilisation methods and buffers used for the preparation of the gelling solutions, both of which have shown to influence on the formation of voids [7]. The preparation success rate will be reduced but still higher than 80% for the gels above 15%T but < 25%T (higher gels were not tried). The rate can be improved up to 95% if the gels are not immobilised but stabilised by stoppers [5,6]

3.2. Reproducibility

A lot of factors which influence the reproducibility of a homogeneous gel-filled capillary will also affect the quality of the gradient gel-filled capillaries. However, the most special one for the gradients gels is their locations as mentioned at the beginning.

Using TsF, the gradient gels can quite easily be located at the required positions in any size of capillaries (< 25 μm ID), with a deviation < 3%. By passing a monomer solution-filled capillary (without over-coating) through a UV-detector (model 166 from Beckman) at 2 mm s⁻¹ [6], an absorption curve parallel to the gradients or concentrations can be measured at 285 nm. The gradient location deviation (GLD) at different parts of the capillary can thus be defined and calculated by

$$\text{GLD (\%)} = 100 [A(L)_{\text{grad}} - A_{\text{homo}}]/A_{\text{homo}} \quad (4)$$

where $A(L)_{\text{grad}}$ is the absorbency of the gradient gel-filled capillary at position L and A_{homo}

that of an identically sized capillary filled with only one monomer solution at the expected concentration. The measurements were performed with five capillaries at five positions per capillary. The overall GLD was 2.53%

The location deviation mainly depends on the tunnel size, the capillary plugging process and the following of the solution flow inside the capillaries. The tunnel should be wide enough for plugging a capillary without seriously disturbing the pre-gradient solutions but it should also be sufficiently narrow to keep the solutions stable. According to our experience, a $\phi 2\text{--}3$ mm tunnel is suitable for plugging a $375\ \mu\text{m}$ OD capillary. If a wider tunnel is used, the solutions can also be maintained by raising the tunnel outlet up. The capillary should gently be plugged into the tunnel along its one side. To correctly follow the solution flow, the observation field of the capillary is suggested to be amplified. This can easily be achieved with a glass rod (Fig. 1B).

3.3. Stability

The capillaries prepared by TsF have been shown to be stable. In the separation of polylysines, they can normally be used for about 400 injections (ca 45 min per run, including the reconditioning time to be discussed below) even at pH 4.7. The total running time is then 300 h (~ 1 month). By checking 10 capillaries, we found that there was a capillary which was used for only 1 week (ca. 100 injections) but there was also a capillary used for 1.5 months (ca. 800 injections). Most of the capillaries were injected for 400–500 times, with quite an acceptable reproducibility (Fig. 2). At pH 7.7–8.4, the capillaries can be used for more than 2 months as demonstrated in the separation of poly(GlcNAc-Mur). This is due to the great reduction of the gel hydrolysis.

Importantly, to run the capillaries for a longer time it is needed to recondition them every 5–10 separations, at an electric field countering that for separation. The reconditioning may take as long a time as the 5–10 runs but can be reduced to < 1 h if the applied electric field strength is increased to $\pm 400\ \text{V cm}^{-1}$ or higher.

Fig. 2. Reproducible CGGE of poly(Lys)₃₈ at $0.05\ \text{mg ml}^{-1}$. Capillary: $75\ \mu\text{m ID} \times 30\ \text{cm}$ ($5 \rightarrow 10.1\%T + 5\%C$) + $2/38.8\ \text{cm}$; buffer: $20\ \text{mmol l}^{-1}\ \text{NaH}_2\text{PO}_4$ in $10\ \text{mmol l}^{-1}$ sodium acetate/acetic acid at pH 4.71; injection: $+5\ \text{kV}$ for 1 s.

3.4. Detection sensitivity and separation efficiency

Detection is another serious problem in using the CGE and CGGE as well. Nevertheless, it can at least partially be overcome with the low background capillaries: They allow the use of any available UV wave-length for sensitive detection. As a result, the poly(Lys)₃₈ can be detected at 200 nm at a concentration as low as $0.05\ \text{mg ml}^{-1}$, requiring only 1 s of injection (Fig. 2). In the case of common gel-filled capillaries, the most sensitive detection wave-length is 220 nm and the sample should be injected for > 10 s at a concentration of $50\text{--}100\ \text{mg ml}^{-1}$ [7,10]. The detection sensitivity is thus improved by the new capillaries for at least $50 \times 10 / 0.05 \times 1 = 10^4$ -fold. This may be an extreme case. For more complicated samples such as poly(Lys)₁₂₆, a suitable concentration is $0.5\ \text{mg ml}^{-1}$ (see Fig. 3). The sensitivity improved is thus 10^3 -fold. With such a sensitivity, direct detection of unlabelled poly(GlcNAc-Mur) can be achieved as shown in Fig. 4. This polysaccharides has no reducing end and we have not yet found out an acceptable labelling method.

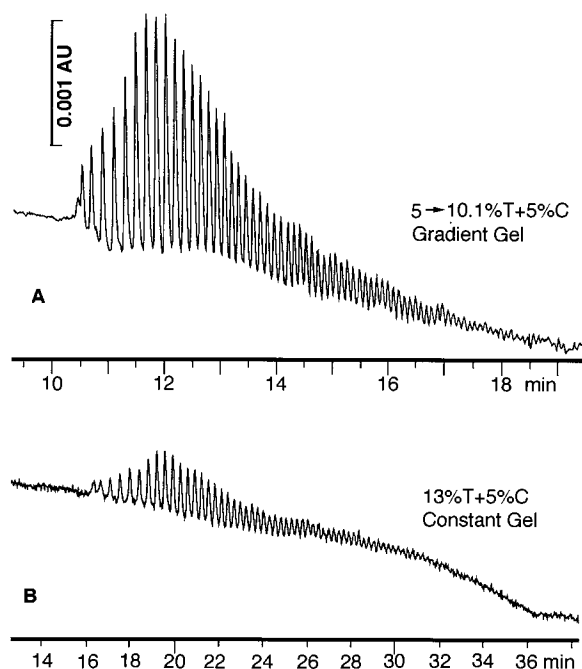

Fig. 3. Comparison of CGGE (A) with CGE (B) using 0.5 mg ml^{-1} poly(Lys)₁₂₆ as a testing sample. Capillary: $50 \text{ }\mu\text{m ID} \times 30 \text{ cm}$ (gels) + $2/38.8 \text{ cm}$; buffer: $20 \text{ mmol l}^{-1} \text{ NaH}_2\text{PO}_4$ in 10 mmol l^{-1} sodium acetate/acetic acid at pH 4.71; injection: + 5 kV for 2 s.

Fig. 3 shows that gradient gel-filled capillaries yield higher detection sensitivity (> 2 -fold) than homogeneous ones although their background is reduced using the same way. There might be different reasons responsible for this phenomenon but the stacking effect generated by the gradient gels is clearly the most important one. We can predict that this effect will increase not only the detection sensitivity but also the separation effi-

Fig. 4. CGGE of polysaccharides from the sacculi of *E. coli*. Capillary: $75 \text{ }\mu\text{m ID} \times 28 \text{ cm}$ (gradient gel) + $2/36.8 \text{ cm}$; buffer: 100 mol l^{-1} Tris and 250 mol l^{-1} boric acid.

ciency. In other words, if the efficiency is maintained, CGGE should be faster than CGE. This can also be seen from Fig. 3: About 1-fold improvement of the running speed can be achieved by CGGE without reducing the solution. More interestingly, the very complicated biological polysaccharides can be finely be separated at a fairly low concentration of gradient gels (Fig. 4) It should be noted that, to obtain a fine separation of these substances by CGGE, the running conditions should be optimised which will be discussed elsewhere.

4. Conclusion

TsF is an easy method for the preparation of gradient gel-filled capillaries, requiring fairly small volume of gelling solutions ($< 3 \text{ ml}$) and without the capillary transferring problem. It can in principle be used for filling any size of capillaries with different materials, including polyacrylamide gradient and non-gradient gels, non-polyacrylamide gels and non-gels (such as buffer, radicals, or additives). Automatic operation of TsF is also possible, which is being in exploration.

CGGE with low back ground gradient gel-filled capillaries is surely superior to CGE with both of the common and low background capillaries in some separations but further investigations are required to make a conclusion. Increasing the detection sensitivity of CGE and CGGE by lowering the background of the capillaries is a simple and reliable method but the detected base-lines may drift positively or negatively, depending on wave-length, buffers and samples which has already been discussed in our previous work [5].

Received 19 February 1997; received in revised form 16 July 1997; accepted 17 July 1997

Abstract

A new kind of sieving matrix is presented in this paper to allow satisfactory separation of DNA fragments in a relatively low viscous solution. When a certain amount of mannitol was added to cellulose solution not concentrated enough to separate PGEM-3Zf(+) /HaeIII standards well, a polymer solution with low viscosity but with very good separation effects was obtained. The separation result of this sieving buffer was comparable with those using highly concentrated cellulose solutions. The sieving ability of solutions with different cellulose concentrations and different amounts of mannitol has been investigated. It was proved that 0.5% was the minimum hydroxypropylmethylcellulose (HPMC) concentration that could be used to separate DNA fragments satisfactorily. HPMC solutions with a concentration of less than 0.5% could not separate the standard DNA fragments even in the presence of mannitol. It was found that 6% was the optimized mannitol concentration because either more or less mannitol will lead a decrease of resolution. The principle of the positive influence of mannitol has also been discussed. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Capillary electrophoresis (CE) has thrown a new light on the separation of biomolecules such as protein, peptides and nucleic acids since it

came into being more than a decade ago. High performance, high resolution, automation and versatility of CE seem to be the main advantages over traditional slab electrophoresis, which is labor intensive and time consuming. It has found widespread application in the analysis and separation of DNA fragments, which is very important in forensic sciences, clinical diagnosis, biological researches, etc. [1–6]. Polymerase chain reaction (PCR) is a very strong tool which can amplify specific genes or gene fragments conveniently and efficiently. PCR coupled with CE plays a more

¹ Presented at the First Asia-Pacific International Symposium on Capillary Electrophoresis, and other Nano- and Microscale Analytical Techniques, held in Singapore, December 17–20, 1996.

and more important role in DNA HPA (heteroduplex polymorphism analysis) [7], DNA STR (short tandem repeats) [8], DNA VNTR (variable number of tandem repeats) [9], DNA RFLP (restriction fragment length polymorphism) [10] and DNA SSCP (single strand conformation polymorphism) [11–13] analysis.

The mobility of DNA fragments is independent of length because the charge to mass ratio of DNA fragments with different lengths is almost the same. Introducing a sieving mechanism into CE seems very useful because it is impossible to separate DNA fragments using capillary free zone electrophoresis. Two kinds of sieving media are employed in capillary electrophoresis: gels and entangled polymer solutions. They are called capillary gel electrophoresis (CGE) and entangled solution capillary electrophoresis (ESCE), respectively. It is difficult to prepare a gel-filled capillary because it is very sensitive to bubble forming. Gel capillaries have a very limited lifetime since the gel is easily destroyed by high current densities and Joule heating. Great care must be taken while preparing or using gel capillaries [14]. The reproducibility of CGE is not satisfactory and is not suitable for routine use. Researchers prefer to use entangled polymer solutions as sieving media because they can be replaced after each run and therefore are much easier to operate [15,16].

The viscosity of entangled polymer solutions are always very high in order to obtain satisfactory separation of DNA fragments in PCR-based CE studies. Those DNA fragments are always no more than several hundred base pairs (bp) in length; hence, they are not able to be separated in dilute polymer solutions. It is difficult to pump those high viscous solutions into or out of the capillary. Cheng and coworkers [17] have found that glycerol can enhance the separation of DNA fragments in cellulose derivative solutions. Another additive is presented in this paper that can enhance the separation of DNA fragments significantly. When mannitol was used as additive to the HPMC solution, a less viscous polymer solution was obtained. The sieving effect was very good.

2. Experimental

2.1. Apparatus

All the ESCE experiments were performed with the Bio-Focus 3000™ capillary electrophoresis system (Bio-Rad Company, Hercules, CA, USA). This capillary electrophoresis system was equipped with a UV high-speed scanning detector. The data were collected and analyzed with a CE3000 software at 260 nm. The capillaries (30 cm × 50 μm ID with the effective length of 25.5 cm) used in this study were internally coated with polyacrylamide using our coating process.

2.2. Chemicals

HPMC (viscosity of 2% aqueous solution is 4000 cp. at 25°C) and γ -methacryloxypropyltrimethoxysilane (MAPS) were purchased from Sigma (St. Louis, MO, USA). Acrylamide, ammonium persulfate and *N,N,N',N'*-tetramethylethylene diamine (TEMED) were obtained from Bio-Rad Labs (Hercules, CA, USA). Tris(hydroxymethyl) aminomethane, mannitol, boric acid and EDTANa₂ (sodium ethylene diamine tetracetate) were obtained domestically. DNA standard sample PGEM-3Zf(+)/HaeIII was purchased from the Sino-American Biotechnology Company (Shanghai, People's Republic of China). The sample was diluted with the storage buffer (10 mM Tris-HCl, 10 mM NaCl, 1 mM EDTA, pH = 7.5) and kept at -20°C until use. The concentration of the sample was about 20 μg ml⁻¹.

2.3. Coating of the capillary inner wall

The uncoated capillary was purchased from Yongnian Optical Factory (Yongnian, Heibei, China). The capillaries were first washed with 1 N NaOH for 2 h and then rinsed with water for a few minutes. Secondly, the capillaries were rinsed with 1 N HCl for another 2 h followed by water rinsing for 10 min. The capillaries thus treated were then washed with methanol for 10 min. After that, the capillaries were filled with MAPS and methanol mixture, then the two ends of the capil-

larities were sealed with gel and incubated at room temperature for several hours. The capillaries were washed with methanol and water for several minutes, respectively, and then were ready for coating. Pump the reaction reagent (5% acrylamide, 0.6% TEMED and 3% ammonium persulfate) into the capillaries and keep for 2 h at room temperature. Then the reaction reagent was washed out with water and the capillaries were dried with nitrogen gas. The capillaries thus treated can be used for at least 100 runs without any decrease in efficiency.

2.4. Preparation of the polymer solutions

The carrier electrolyte used in this study was TBE (100 mM Tris–borate, 2 mM EDTA, pH = 8.3) buffer that was frequently used by other researchers. HPMC solutions at concentrations of 0, 0.2, 0.3, 0.4, 0.5, 0.8, 1.0 and 1.2% (w/v) were prepared using the above buffer. Add the HPMC powder slowly into the container with TBE buffer while stirring and then keep the container at 4°C overnight until all the powder was solved. Mannitol at concentrations of 2, 4, 6 and 8% (w/v) was added to the above HPMC solutions (except the 1.2% HPMC solution). All the solutions were prepared using double-distilled water and then filtered with 0.45 µm nylon membrane. Buffers thus prepared were kept at 4°C for storage.

2.5. Entangled solution capillary electrophoresis

The capillary was rinsed with water for 2 min first and then with sieving buffer for another 2 min. Before injection, the inlet end of the capillary was dipped two times in a water container in order to clean the outside wall. This washing process can prevent the sample from contamination by the viscous buffer solution. The sample was injected at 10 kV for 15 s. The running voltage was 4 kV from negative to positive. While running, the capillary was kept at 30°C by liquid cooling and the sample vials were also kept at 30°C by a computerized device.

3. Results and discussion

HPMC at concentrations of 0, 0.2, 0.3, 0.4, 0.5, 0.8, 1.0 and 1.2% was used as sieving buffer to separate PGEM-3Zf(+)/HaeIII standards first. HPMC solutions with different amounts of mannitol were then used to separate the same sample in order to investigate the influence of mannitol on the separation. From the results, a significant enhancement of separation was observed when adding mannitol to HPMC solutions of any investigated concentration, but there was no good separation of all those fragments when the HPMC concentration was below 0.5% (data not shown). This indicates that 0.5% is the minimum HPMC concentration that can form a network in the solution, i.e., the threshold concentration. The electropherograms using 0.5% HPMC containing 0, 2, 4, 6 and 8% mannitol were presented here (Fig. 1). It can be seen from Fig. 1 that the smaller fragments were gradually separated while the concentration of mannitol was increased. The separation of larger fragments was also enhanced. Fig. 1(d) and (e) showed that all the fragments are resolved (11 and 18 bp fragments are undetectable because the concentration of these fragments was not high enough). As for solutions with concentration higher than 0.5%, the mannitol amount added to the buffer in order to obtain complete separation became smaller. For 0.8 and 1.0% HPMC solutions, only 2% mannitol was needed, and for HPMC solutions with concentration greater than 1.2%, it was not necessary to add mannitol to the buffer.

Although HPMC solutions at concentrations of 1.2% or more can resolve the separation satisfactorily without the presence of mannitol, this is difficult to achieve because of the high viscosity. High pressure or a long time must be needed to pump the sieving buffer into or out of the capillary. Adding mannitol to HPMC solution makes it possible to separate DNA fragments using a lower concentration of HPMC solution. The viscosity data of the solutions are not available in this paper but can be evaluated through the fluidity of those buffers. The viscosity of two kinds of buffers (0.5% HPMC + 6% mannitol and 1.2% HPMC without mannitol) was evaluated by an

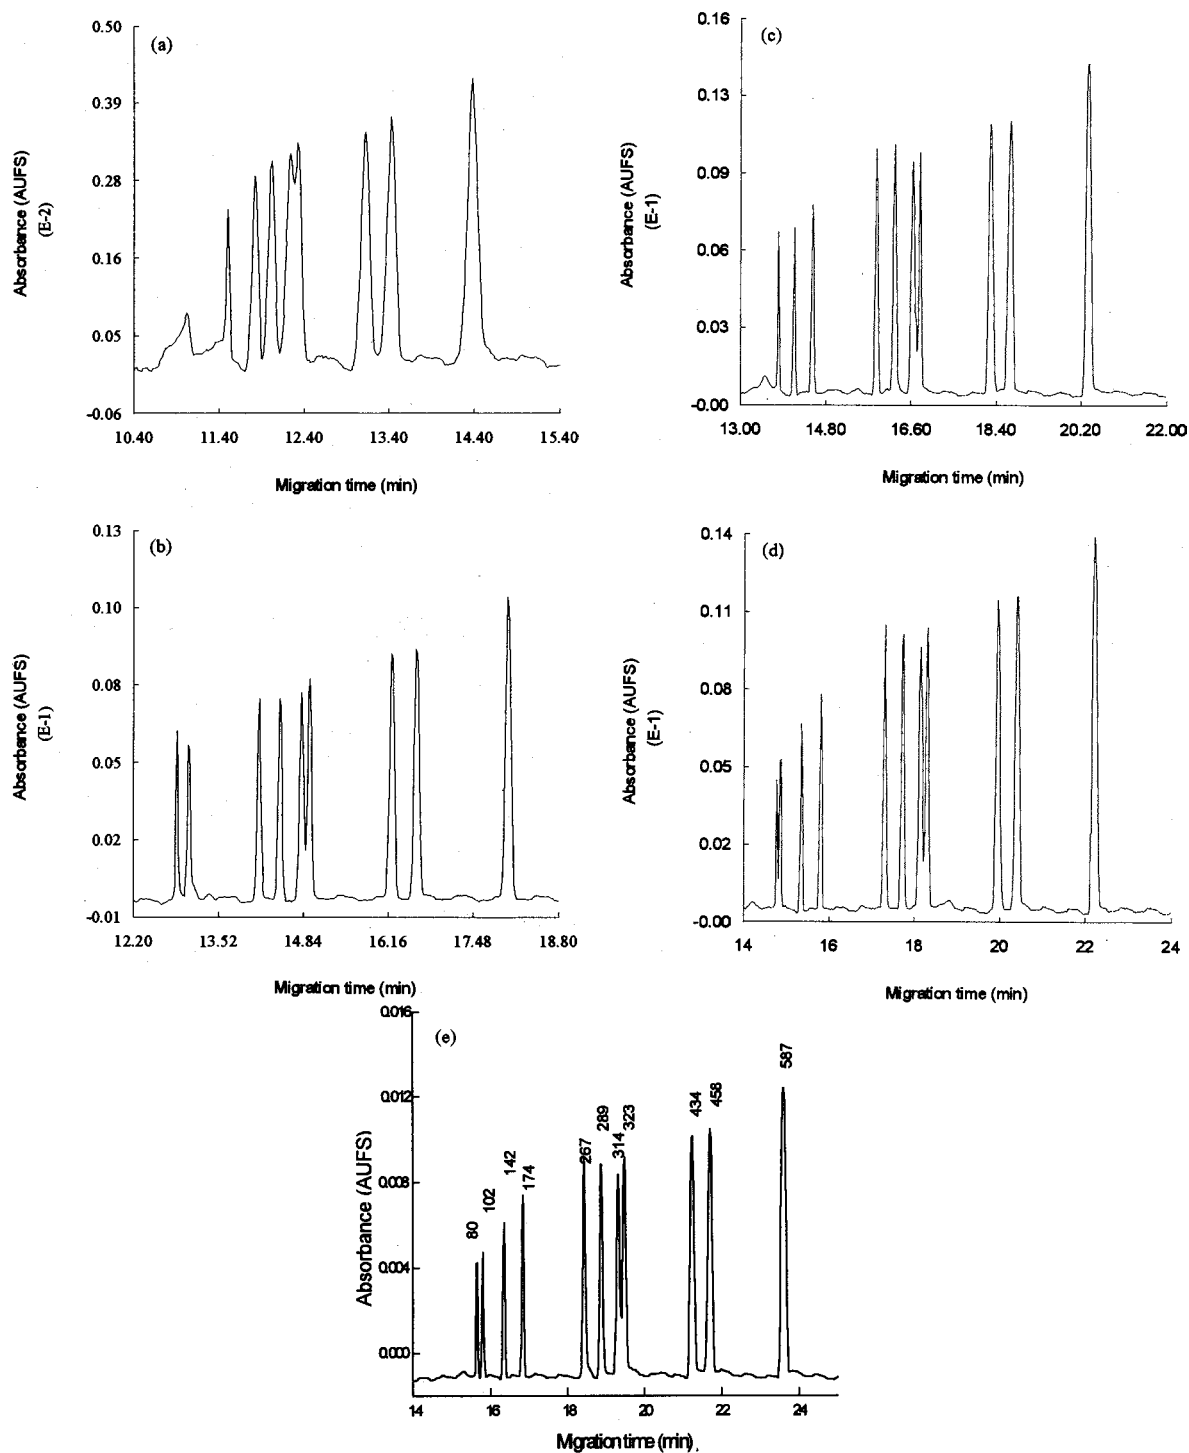

Fig. 1. Electropherograms of PGEM-3Zf(+)/HaeIII standard fragments in 0.5% HPMC sieving buffer at different mannitol concentrations: (a) 0% mannitol, (b) 2% mannitol, (c) 4% mannitol, (d) 6% mannitol, and (e) 8% mannitol. Injection: 10 kV \times 15 s; running at 4 kV from negative to positive. Other conditions are as listed in Section 2.

indirect method. It took only 4 s for the first buffer to fill a 30 cm × 50 μm ID capillary under a pressure of 3.1 MPa. For the latter buffer, the time is 10 s. It is obvious that the viscosity of the solutions decreases with decreasing HPMC concentration. Although adding mannitol to these buffers raises the viscosity slightly, they are still much easier to work with than those buffers with a high HPMC concentration.

The resolution of the 314/323 fragment pair was calculated using a traditional chromatographic equation (Eq. (1)). Where t_2 and t_1 are the migration time of the two fragments, and $W_{1,0.5}$ and $W_{2,0.5}$ are the halfwidth of the two peaks:

$$R = \frac{1.18(t_2 - t_1)}{W_{1,0.5} + W_{2,0.5}} \quad (1)$$

Fig. 2 demonstrates the change of resolution according to cellulose concentration and mannitol concentration. It may be noticed that the resolution increased when the concentration of HPMC changes from 0.2 to 1.0%, as may be expected. The pore size of the network decreases and then influences the resolution. The resolution also goes upward when the mannitol concentration changes from 0 to 6% and then decreases when the mannitol concentration is 8%.

Fig. 2. Plot of resolution of 314/323 bp fragments vs. HPMC concentration (%) at different mannitol concentrations (%).

Fig. 3. Plot of migration time (min) of the 587 bp fragment vs. HPMC concentration (%) at different mannitol concentrations (%).

The mobility of the DNA fragments decreases when adding mannitol to the HPMC solution since the migration time becomes longer. The greater the concentration of mannitol, the longer the migration time. The plot of the migration time versus mannitol concentration is almost linear, which means that the mobility of the DNA fragment is inversely proportional to the mannitol concentration. This phenomenon indicates that mannitol interacts with HPMC and the pore size becomes smaller and, as a result, the obstruction becomes larger. From the plot of migration time versus HPMC concentration (Fig. 3), we can say that the migration time increases with increasing HPMC concentration. This is also due to the decrease of the pore size of the network with increasing HPMC concentration.

The migration time versus DNA fragment length in 0.5% HPMC + 2, 4, 6 and 8% mannitol gave perfect linear relationships. The linear coefficients were more than 0.9991. This phenomenon indicates that we can use a (CE-based) calibrating method to calculate the length of a DNA fragment such as PCR products more precisely than using the traditional slab gel electrophoresis method.

Fig. 4 is the Ferguson plot that illustrates the sieving effect of HPMC solutions with 6% mannitol additive. All the curves of the four selected fragments are similar in shape. This result implies that under certain sieving matrix conditions, the sieving mechanism is the same for these fragments. This is the reason why the mobility of the DNA fragments are proportional to the fragment length. It may also be noticed that the curves are non-linear. This result does not match with what Schwartz and coworkers observed [18]. In the same work, they also found that there would still be certain separation of DNA fragments in CZE without any sieving media, which also did not match with our result. It was found in our experiments that when the HPMC concentration reaches zero, there was no separation of the DNA fragments.

The influence of mannitol on the separation of the DNA fragments may be due to the specific structure of this substance. The structure of mannitol is special because the hydroxyl groups are on the opposite side of the chain (Fig. 5). It is well known that boric acid can complex with carbohydrates to form tetraborate structure as shown in Eq. (2). This may also happen between mannitol, HPMC and boric acid. The tetrabo-

Fig. 4. Ferguson plot of 267, 323, 434 and 587 bp fragments in HPMC buffer with the existence of 6% mannitol.

Fig. 5. Structure of mannitol.

rate structure can form a bridge between HPMC chains and then influence the dynamic sieving network in the entangled solution. Fig. 6 illustrates the linkage of HPMC chains through mannitol and tetraborate. Mannitol's influence on the separation is superior to that of glycerol because glycerol has fewer hydroxyl groups and cannot form the bridge chain.

The formation of tetraborate can be proved by the increasing of the running current when adding mannitol to the HPMC solution. The plot of running current versus mannitol concentration is shown in Fig. 7. This current increase results from the formation of the tetraborate structure. When the tetraborate structure is formed, a hydrogen ion is released, increasing the ionic strength of the buffer. When the mannitol concentration is above 6%, the current remains constant, which implies that the formation of tetraborate has reached equilibrium and that there are no more free polyhydroxy groups on the HPMC chains.

Fig. 6. Illustration of the entanglement of HPMC molecules and the tetraborate bridge through mannitol and HPMC chains.

This kind of linkage decreases or shapes the dynamic pore size of the polymer solution and results in the enhancement of the separation. When there is an overdose of mannitol, the resolution will be reduced because the saturation of mannitol prolongs the migration time, broadens the peak and then affects the resolution of 314/323. The electropherograms also show that the resolution of 80/102 is enhanced when the mannitol concentration is changed from 4 to 8%. No

resolution of these two smallest fragments is observed when the mannitol concentration is less than 4%.

4. Conclusion

Mannitol can interact with HPMC in the presence of boric acid to form a dynamic flexible network in the sieving matrix. A less concentrated HPMC solution is then able to be used as a sieving buffer to separate smaller DNA fragments. Because its viscosity is much lower than that of the more concentrated sieving matrix, it is much easier to operate. After examining a series of sieving buffers with different amounts of HPMC and mannitol, it can be concluded that 0.5% HPMC with 6% mannitol can give the optimum results. This kind of sieving matrix can be used to analyze PCR products conveniently and precisely. PCR CE may prove to be a potential method in clinical diagnosis, forensic analysis and molecular biology research.

Abstract

As part of a comprehensive screening program on the separation of chiral drugs by capillary zone electrophoresis, we have investigated the enantio-separation of 54 drug racemates with β -cyclodextrin as a chiral solvating agent (CSA), thus complementing previous studies on 34 drug racemates. Fourteen out of the 54 analytes investigated have been separated into the enantiomers, yielding an overall success rate of 24.4% for 86 drug racemates investigated in total. © 1998 Elsevier Science B.V. Keywords: Capillary electrophoresis; Chiral drugs; β -Cyclodextrin; Enantiomer separation

1. Introduction

Stimulated by the extensive development of enantio-specific analytical methods in the recent decades, the world market of single enantiomer drugs has grown to a multi-billion dollar business [1], paralleled by enantio-pure pesticides, flavors and fragrances [2]. For the approval of new chiral drugs, enantio-specific analyses are now demanded in all industrial countries [3].

Capillary electrophoresis (CE) bears the advantage of enantiomer determination directly from compound mixtures in aqueous solution [4,5]. According to our database Chirbase/CE (available from the authors on request), capillary zone electrophoresis (CZE) [6] and micellar electrokinetic chromatography (MEKC) [7,8] are most commonly used for enantiomer separation by CE, contributing to 72 and 20%, respectively, of articles published in this field. Other modes add to approximately 10% of all original research articles, including reports on several modes in the same document.

Apparently, Chirbase/CE provides a solid basis for further studies on structure–enantio-selectivity relationships. However, in view of the lack of

consistent data for marketed drugs in the literature, a dedicated ‘German–Chinese Chiral Drug Screening Program’ [9] was started. Meanwhile, a huge amount of reliable data has been collected under constant experimental conditions for a large set of analytes and chiral solvating agents (CSAs) [10–13]. In this article, we report on hitherto unpublished results with β -cyclodextrin (β -CD) as the CSA, applied to CZE of 54 enantiomeric pairs of drugs.

2. Experimental

All experiments were carried out on a Bio-Focus 3000 automatic capillary electrophoresis system (Bio-Rad Laboratories, Hercules, CA, USA), equipped with a variable wavelength detector operated at 200 or 210 nm. Operating parameters were as follows: injection, 15 kV for 3 s; analysis, 15 kV + \rightarrow -; capillary temperature, 25°C. Fused silica capillaries (0.05 mm ID, 0.375 mm OD) were obtained from Yongnian Optical Conductive Fiber Plant (Yongnian, Province Hebei, People’s Republic of China). In the laboratory these were coated with polyacrylamide on the inner surface.

The plain run buffer contained 100 mmol l⁻¹ sodium dihydrogenphosphate and was adjusted to pH 2.5. β -Cyclodextrin was added to the plain buffer in concentrations of 15 mmol l⁻¹. The analytes were dissolved in the run buffer to give a sample concentration of 0.1 mg ml⁻¹.

β -Cyclodextrin was kindly donated by Wacker Chemie (Munich, Germany). The drug samples

were donated by a large number of German and international manufacturers. Internal purity standards of the manufacturers apply to all drug samples. All other chemicals were analytical grade.

3. Results and discussion

In order to facilitate later investigations on structure–enantio-selectivity relationships, attention was focussed on entries with one stereogenic center, mounting to a collection of 123 drug racemates. Two prerequisites, a solubility of 0.1 mg ml⁻¹ (0.2–0.6 mmol l⁻¹) in aqueous phosphate buffer at pH 2.5, and migration towards the cathode, were met by a subset of 86 drugs thereof. The results for 52 enantiomeric pairs presented in this article complement a previous report [12] on the screening of 34 drugs with β -CD as the CSA.

A report on the analytes separated is listed in Table 1, in alphabetic order. Based on the observation that the electro-osmotic flow (EOF) could be neglected, the ratio t_{m2}/t_{m1} of the migration times of the second and first eluted enantiomer, respectively, was taken for a measure of the degree of enantio-discrimination [12]. This definition bears the advantage over the peak resolution of being independent of most experimental parameters, such as solvent viscosity, capillary length, the electric field strength, etc.

Because of the limited solubility of β -CD in the run buffer, the concentration had to be kept at 15 mmol l⁻¹. A total of 12 (23%) drug racemates out of 52 analytes investigated could be resolved in

Fig. 1. Two representative electropherograms of drug enantiomers with 15 mmol l^{-1} β -CD; for other conditions see Section 2. Left panel, dimetindene with one stereogenic center; right panel, mefloquine with two stereogenic centers. The second peak pair may be caused by the minor diastereomer.

this straightforward approach. In addition, two drugs (isothipendyl and naftidrofuryl) could now be separated that had not been resolved previously [12], presumably because of insufficient peak resolution. The migration separation factor of isothipendyl and naftidrofuryl in our study is, however, still at the limit of the method, with migration separation factors of only 1.010 each.

Two representative examples for the many electropherograms obtained are shown in Fig. 1. A satisfactory migration separation factor, $\alpha_m > 1.015$, was attained for 10 analytes. For the less well separated enantiomeric pairs and even for some not yet resolved examples, there is still a chance of achieving sufficiently high separation factors by adjusting the operation variables, especially CSA concentration and pH [14,15].

Many of the drug racemates separated into enantiomers in this study have been separated by

CE quite often, some also with β -CD (bromphenamine, clenbuterol, doxylamine, homatropine, isoprenaline, oxomemazine, terbutaline, tioconazole), although under different conditions (concentrations, modifiers, pH), others with different CSAs (dimetindene, isothipendyl, mefloquine, pholedrine); whereas, to the best of our knowledge, the enantiomer separation of naftidrofuryl and reproterol by capillary electrophoresis was not yet published.

The new results, including the failure of separation in several cases (as documented in Table 2), constitute a valuable complement to the increasing amount of data accumulated in our extended screening study. These data are of interest in their own right; moreover, systematic insight into the underlying molecular recognition phenomena may also prove valuable in other fields. A dedicated publication on this topic is in due preparation.

Separation of polycyclic aromatic hydrocarbons by micellar electrokinetic chromatography with aqueous short-chain alcohol solvent¹

Xiaoyun Fu *, Jiande Lu, Yaozu Chen

Analytical and Testing Center, Zhejiang University, Hangzhou 310027, People's Republic of China

Received 19 February 1997; received in revised form 20 October 1997; accepted 20 October 1997

Abstract

Micellar electrokinetic capillary chromatography (MEKC) with aqueous organic solvent has been developed to separate polycyclic aromatic hydrocarbons (PAHs). Methanol, ethanol or propanol as an organic modifier was added to sodium dodecyl sulfate (SDS) micellar solution in order to increase the solubility of very hydrophobic solutes in mobile phase. Both methanol and ethanol can be used as co-solvents for the separation of PAHs. Use of ethanol resulted in a shorter analysis time than use of methanol. The separations of some PAHs were unsatisfactory using propanol although the analysis time was much shorter than with ethanol. The influence of ethanol content, SDS concentration and temperature on the separations was studied. Benzene and nine polycyclic aromatic hydrocarbons were successfully separated using 50 mM SDS–20 mM phosphate–5 mM borate, containing 40% (v/v) ethanol at 35°C. The relative standard deviation (R.S.D.) of t_R ranged from 0.5 to 1.5% for six repeat injections. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Micellar electrokinetic capillary chromatography; Polycyclic aromatic hydrocarbons; Separation of aromatic compounds

1. Introduction

Micellar electrokinetic chromatography (MEKC) combined capillary electrophoresis with chromatography has been proven to be a very

useful separation method for the determination of neutral compounds [1,2]. The separation mechanism is based on the difference in the partition between the electro-osmotically pumped aqueous phase (mobile phase) and the ionic micellar phase (pseudostationary phase). Naturally, this technique has been introduced for the separation of PAHs. However, it is difficult to separate highly hydrophobic PAHs by conventional MEKC because their partition coefficients are so high that they tend to co-elute with the micelles [3].

¹ Presented at the First Asia-Pacific International Symposium on Capillary Electrophoresis, and other Nano- and Microscale Analytical Techniques, held in Singapore, December 17–20, 1996.

Walbroehl and Jorgenson [4] first reported the separation of limited PAHs by EKC and proposed a solvophobic interaction mechanism for the separation of aromatic compounds. Later, Terabe et al. [5] reported that PAHs could be separated by cyclodextrin-modified MEKC. Cole et al. [6] separated PAHs by MEKC with bile salt in the presence of organic modifier. In addition, a monomolecular pseudostationary-phase MEKC [7] was demonstrated to separate PAHs. Hydrophobic interaction electrokinetic chromatography [8] and an organic modifier MEKC [9,10] were also found to improve the resolution of hydrophobic solutes.

Sodium dodecyl sulfate (SDS)-MEKC with organic co-solvent is a convenient and effective method for the separation of hydrophobic compounds. The addition of organic solvent decreases the relative affinity between the hydrophobic solute and micellar phase, and increases the solubility of hydrophobic solute in mobile phase. However, it has been reported that this method is not appropriate for the separation of PAHs [5,6] because a high concentration of organic solvents is required and the micelles may not be stable in the presence of a high amount of organic solvents [11]. In this work, we studied the influence of the properties and content of short-chain alcohol, SDS concentration and temperature on the separation of PAHs by MEKC.

2. Experimental

Many of the experiments were performed with laboratory-constructed apparatus, consisting of a high-voltage d.c. power supply and a fixed wavelength UV detector of Shimadzu IP-2A Isotachophoresis instrument (Kyoto, Japan). Other experiments were performed with a Waters Quanta 4000 CE system (Milford, MA, USA). The UV detector was operated at 254 nm. Electrokinetic chromatograms were recorded with a Shimadzu Chromatopac C-RIB data processor (Kyoto, Japan). A fused-silica capillary of 0.05 mm ID was used without any special wall treatment. Sample solutions were injected into the end of the capillary by the siphoning method. The

siphoning height was 9.8 cm and the injection time was 15 or 20 s. The separation temperature was controlled by circulating air.

All reagents were of analytical-reagent grade. SDS, sodium tetraborate ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$), potassium dihydrogen phosphate (KH_2PO_4), methanol, ethanol, 1-propanol, benzene, naphthalene, and 2-methyl naphthalene were purchased from Shanghai Chemicals (Shanghai, People's Republic of China). Other PAHs were obtained from Sigma Chemicals (St. Louis, MO, USA).

Samples were dissolved in ethanol or micellar solution with 40% (v/v) ethanol. The concentration of each component in the samples ranged from 50 to 500 mg l^{-1} . The micellar solutions were filtered through a membrane filter of 0.45 μm and degassed by ultrasonic cleaner before being used. The capillary was rinsed with the operating micellar solution for 3 min before and between runs, and with the 70% (v/v) ethanol-water for 15 min before and after the experiment.

3. Results and discussion

3.1. Influence of short-chain alcohol co-solvent on the separation of PAHs

PAHs are highly hydrophobic compounds and have a great affinity for the micellar phase. Consequently, using only micellar aqueous solution, it is impossible to separate PAHs by MEKC. We have chosen short-chain alcohols as organic co-solvent because of their low viscosity, relatively high dielectric constant and low influence on the stability of SDS micelles. To study the influence of different short-chain alcohol co-solvent on the separation of PAHs, the experiments were carried out with a micellar solution of 40 mM SDS–20 mM KH_2PO_4 –5 mM $\text{Na}_2\text{B}_4\text{O}_7$, containing the different contents of methanol, ethanol and propanol, respectively. As expected, the addition of alcohol caused two different effects on retention time of the solute (t_R). The presence of alcohols decreased electro-osmotic flow, resulting in longer t_R . The results showed that the elution time of the electro-osmotic flow marker (t_0) in-

Fig. 1. Influence of short-chain alcohol co-solvent on the separation of PAHs. 1. benzene; 2. naphthalene; 3. 2-methyl naphthalene; 4. acenaphthene; 5. phenanthrene; 6. anthracene; 7. fluoranthene; 8. pyrene; 9. chrysene; 10. perylene. Micellar solution: 40 mM SDS–20 mM KH_2PO_4 –5 mM $\text{Na}_2\text{B}_4\text{O}_7$, containing (a) 50% (v/v) methanol, (b) 40% ethanol, (c) 30% propanol. Capillary: 0.05 mm i.d. \times 450 mm (400 mm to detector). Voltage: (a) 16 kV, (b) 16 kV, (c) 11 kV. Temperature: 35°C.

creased with the molecular weight of alcohol and/or alcohol content because the ratio of dielectric constant to viscosity decreased. The addition of alcohol, on the other hand, increased the solubility of PAHs in mobile phase and lowered t_R . Hence, the different alcohols had different optimum contents. Fig. 1 showed the separation of benzene and nine PAHs using methanol, ethanol and propanol as organic co-solvent under the given conditions. Good separations of PAHs were obtained in the presence of 50% methanol or 40% ethanol as organic co-solvent. The presence of methanol produced better separation of PAHs, but longer analysis time and higher content were needed compared to ethanol. Using propanol, which has stronger hydrophobicity than ethanol and methanol, as an organic co-solvent resulted in a shorter analysis time, but the resolution for some PAHs was unsatisfactory. Although different alcohols showed various improvements in resolution, no elution order change was observed. The higher the hydrophobicity of the solute, the higher the t_R value.

Fig. 2. Influence of ethanol content on t_R . Voltage, 18 kV, other conditions as in Fig. 1(b), except for ethanol content.

Fig. 3. Dependence of t_R on SDS concentration. Voltage, 18 kV, other conditions as in Fig. 1(b), except for SDS concentration.

3.2. Influence of alcohol content on separation

We studied the influence of ethanol content on the separation of PAHs. It was found that the addition of a small amount of ethanol co-solvent did not improve the separation sufficiently. Ethanol content in the range 30–50% (v/v) was investigated. Fig. 2 illustrates the influence of ethanol content on t_R . As the ethanol content increased, t_R of PAHs decreased and then increased because both the partition coefficient and the electro-osmotic flow were reduced. The change in the partition coefficient was predominant when ethanol content was less than 40%. It was also observed that the separation efficiency increased significantly with increasing ethanol content from 30 to 45%, but decreased when the ethanol content was 50%. Furthermore, when

ethanol content reached 60%, poor separation of PAHs was obtained. A similar result was observed with 40% propanol. The reason may be mainly that such a high alcohol content leads to micelle breaking.

3.3. Influence of SDS concentration on the separation

In order to optimize the separation, we studied the influence of SDS at concentrations from 20 to 70 mM. As in conventional MEKC, both t_R and resolution increased with increasing SDS concentration. Fig. 3 illustrates the dependence of the t_R on SDS concentration. When 70 mM SDS was used, the retention times of chrysene and perylene were longer than 60 min. It can be seen that the

Fig. 4. Influence of temperature on t_R . Micellar solution: 40 mM SDS–10 mM $\text{Na}_2\text{B}_4\text{O}_7$, 40% ethanol. Voltage: 28 kV. Capillary: 0.05 mm i.d. \times 465 mm (390 mm to detector), other conditions as in Fig. 1.

baseline separation of benzene and nine PAHs was achieved when SDS concentration increased to 50 mM.

3.4. Influence of temperature on the separation

Temperature is another important factor which affects separation and retention time. Fig. 4 demonstrates the influence of temperature on t_R . The temperature was raised from 25 to 35°C, the t_R of pyrene decreased from 84.4 to 12.9 min. These results may be attributed to the increase of electro-osmotic flow and the decrease of the partition coefficient. The separation efficiency, in terms of the number of theoretical plates (N), raised slightly with increasing temperature, but decreased when the temperature was higher than 35°C. It may be explained in terms of micelle–monomer exchange. The rate of micelle–monomer exchange was increased by increasing the temperature. It may reduce the loss in efficiency due to micelle polydispersity [11], but a higher temperature may lead to an increase in molecular dispersion.

3.5. Separation of PAHs

Fig. 5 showed that benzene and nine PAHs were separated successfully using 50 mM SDS–10 mM $\text{Na}_2\text{B}_4\text{O}_7$, containing 40% ethanol. The separation efficiency was about 10^5

Fig. 5. Separation of benzene and nine PAHs. Micellar solution: 50 mM SDS–10 mM $\text{Na}_2\text{B}_4\text{O}_7$, 40% ethanol. Voltage: 18 kV, other conditions as in Fig. 1.

theoretical plates per meter. To demonstrate the stability of micellar in mobile phase, the reproducibility of t_R was investigated under the conditions given in Fig. 4 (35°C). The relative standard deviation (R.S.D.) of t_R ranged from 0.5 to 1.5% for six repeat injections. This indicated that the micelles were still present under the given conditions. The separation mechanism may be mainly based on solute–micelle interaction.

In conclusion, PAHs were successfully separated by MEKC with short-chain alcohol co-solvent. The MEKC condition can be optimized by changing the alcohol content, SDS concentration and separation temperature.

Short communication

Determination of plasma heparin by micellar electrokinetic capillary chromatography¹

Xiao-Mian Zhou *, Jian-Wu Liu, Meng-En Zhang, Shun-jin Chen

Department of Medical Laboratory, NanFang Hospital, Guangzhou 510515, People's Republic of China

Received 19 February 1997; received in revised form 14 August 1997; accepted 18 August 1997

Abstract

The micellar electrokinetic capillary chromatography (MECC) method is reported for the separation of heparin, and for the possibility of direct determination of free heparin in plasma. The conditions for MECC were: pH 8.5, 25 mM sodium dodecyl sulfate (SDS), 25 mM borate buffer, with a 30 cm × 50 μm ID fused-silica capillary. The sample was detected with a UV-detector at 270 nm with heparin as external standard. The recovery rate was 95.6–98.7%. This method was linear in the range 80–7000 U l⁻¹. The within-run and between-run relative standard deviations were lower than 3.1 and 4.5%, respectively. It is suggested that this MECC method may be used to determine blood samples containing high levels of heparin. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Heparin; High-performance capillary electrophoresis; Plasma

1. Introduction

Blood coagulation tests are used mostly to monitor plasma heparin levels in clinical therapy: tests such as the thrombin time (TT), activated partial thrombokinase time (APTT), etc., which measure anticoagulation activity of heparin in blood. However, these methods cannot quantitate the concentration of plasma heparin. Several tech-

niques have been investigated for the analysis of heparin preparations. Gradient polyacrylamide gel electrophoresis (PAGE) [1] and strong anion exchange high-performance liquid chromatography (HPLC) [2] have been the methods of choice for the qualitative and quantitative analysis of heparin preparations. Recently, a number of workers who carried out investigations [3–5] reported that high-performance capillary electrophoresis (HPCE) was a sensitive, high-resolution method for the determination of the heparin fragment. However, the samples described above in the papers were non-biological samples. Mao et al. [6] reported that free heparin

* Corresponding author.

¹ Presented at the First Asia-Pacific International Symposium on Capillary Electrophoresis, and other Nano- and Microscale Analytical Techniques, held in Singapore, December 17–20, 1996.

in plasma was separated and its concentration was successfully determined by HPLC. HPLC is, however, a time-consuming, labor-intensive and high-cost method.

This paper describes and compares different methods for determining plasma heparin. The MECC method is simple, rapid, highly sensitive, especially suitable for determining a high dosage of heparin, and not affected by fibrin decomposing product (FDP) and other factors.

2. Material and methods

2.1. Instrument

The instrument used in this work is the automated BioFocus 3000 capillary electrophoresis system (Bio-Rad, USA) with a diode array UV detector, an automatic injector, and a fluid cooled cartridge. The capillary cassette used was filled with a 50 μm ID fused-silica column, 30 cm in length (to detector). Injection of the sample was by pressure for 8 s. All electrophoresis was carried out at 20°C, with an applied voltage of 20 kV and UV detection at 270 nm. The electrophoresis buffer was boric acid (25 mmol l^{-1}), sodium dodecyl sulfate (SDS) (25 mmol l^{-1}), adjusted to pH 8.5 with 1 N sodium hydroxide. Sodium heparin solution (250000 u l^{-1}) was purchased from Shangshia Biochemistry Pharmaceutical Factory. The anticoagulation activity of sodium heparin was calibrated with the standard solution of sodium heparin (355000 u l^{-1} , US Pharmacopeia). The sodium heparin accorded with the unit marked by the factory.

2.2. Methods

Object of study: 10 extraneous circulation patients (360–500 units sodium heparin per kg body weight), 15 dialysis patients (10 patients, 65 u kg^{-1} ; five patients, 10.5 u kg^{-1}).

Preparation of samples: after 30 min of intravenous injection, 2 ml blood was collected. Plasma was isolated by centrifugation at 3000 \times

g for 10 min. A total of 200 μl plasma was deproteinized by mixing with 300 μl acetonitrile for 2 min and then centrifuging for 5 min at 3000 \times g. Heparin plasma may be stored at -20°C for 1 week, but cannot be subjected repeatedly to a freeze/thaw cycle.

Stock standard solution: stock standard solution was prepared by diluting 250000 u l^{-1} sodium heparin 50-fold with redistilled water.

Working standard solutions: the stock standard solution was diluted to concentration levels that bracketed the concentration level of interest, prior to analysis.

Electrophoresis: the supernatants from the acetonitrile deproteinization were introduced into the capillary by pressure injection. After each sample, the capillary was washed with water (1 min); 1 N NaOH (1 min); and fresh buffer by pressure injection. The capillary was washed daily with NaOH, 1 N (2 min); water (1 min); and finally, electrophoresis buffer.

3. Results

Sodium heparin has maximum absorbance at 270 nm. Fig. 1 illustrates the peak of sodium heparin, which is single, intact, symmetrical, with good separation, its migration time being 2.58 ± 0.02 min.

The working standard solution was diluted to 0.08, 0.1, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0 and 7.0 u ml^{-1} . The peak area and the amount of heparin were linear in the range 80–7000 u l^{-1} with the detection limit of 25 u l^{-1} ($y = 131253.1x - 13895.6$, $r = 0.998$). A known amount of heparin was added to 1 ml plasma of a normal person in the manner described above, and the peak area and the standard peak area were measured. Recovery rates of 95.6–98.7% were obtained. With regard to the reproducibility of different concentrations of heparin, the within-run R.S.D. and between-run R.S.D. were 1.5–3.0 and 2.0–4.4%, respectively.

For comparison, the results of the improved TT [7] and HPCE were similar ($P > 0.05$) (see Table 1).

Fig. 1. (A) Electrophoretograms of blank plasma. (B) Electrophoretograms of heparin plasma: (a) sodium heparin; (b) protein peak. Conditions: pH 8.5; 25 mmol l^{-1} SDS; 25 mmol l^{-1} borate buffer.

4. Discussion

Our experimental results show good separation of heparin by HPCE. The peak is single, intact and symmetrical. The peak area and the concentration of plasma heparin are strongly linear. HPCE may quantitate free heparin in plasma. During deproteinization, deproteinization with acetonitrile was greater than with methanol, ethanol, trichloroacetic acid, or methanol combined with acetone. Acetonitrile deproteinization allows a larger sample volume to be introduced into the capillary and increases the plate number and peak height [8], thereby increasing the sensitivity of the material determined.

When heparin was injected into the blood circulation, its anticoagulation activity depended on the amount of heparin in blood. Our results

show that free heparin in plasma is basically in direct proportion to the dose of heparin. The concentration of free heparin measured by HPCE was similar to the activity of plasma heparin determined by the improved TT. Hence, the concentration of plasma heparin determined by HPCE may stand for the activity of heparin anticoagulation.

It is essential to monitor high doses of heparin in plasma in clinical therapy. The HPCE method may determine higher doses of heparin: the results of three patients were measured at 5958, 6270 and 5876 u l^{-1} , respectively. However, the clotting tests were difficult to use to measure them and their reproducibility was very poor. When the concentrations of FDP of two patients were 75 and 96 mg l^{-1} , the concentrations of free heparin by HPCE were 152 and 276 u l^{-1} , respectively. However, it is very difficult to measure the levels of heparin by the improved TT method. HPCE has the advantage that it is not affected by the level of fibrinogen, FDP and antithrombin-III, and the operation is simple to perform.

Table 1
Comparison of the results from the two methods

Group	n	Conc. of plasma heparin (u l^{-1} , $\bar{x} \pm s$)	
		TT	HPCE
Extraneous circulation	10	5100 ± 510	5230 ± 490
Blood dialysis			
Dose of 65 u kg^{-1}	10	290 ± 100	300 ± 110
Dose of 10.5 u kg^{-1}	5	100 ± 20	110 ± 30

5. Conclusion

The HPCE method may be used to quantitate plasma heparin and is especially suitable for measuring high doses of heparin in clinical therapy. Its operation is simple, rapid, and highly sensitive.

Review

Application of ternary and multicomponent complexes to spectrophotometric and spectrofluorimetric analysis of inorganics

T. Prasada Rao *, M.L.P. Reddy, A. Ramalingom Pillai

Received 11 March 1997; received in revised form 6 August 1997; accepted 7 August 1997

Abstract

The application of ternary and multicomponent complexes in spectrophotometric and spectrofluorimetric determination of trace elements is reviewed. Newer types of colour systems employing mixed ligand, surfactant sensitized, ion-association, flotation, derivative and FIA systems are described. Separate sections are devoted to advances in both spectrophotometric and spectrofluorimetric determination of individual elements. Future trends in spectrophotometric and spectrofluorimetric analysis are discussed. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Spectrophotometric; Spectrofluorimetric; Complexes

1. Introduction

Atomic absorption and inductively coupled plasma emission and mass spectrometry, rapidly developed during the past two decades, have

Abbreviations: A, aqueous; BPR, Bromopyrogallol red; CPB, cetylpyridinium bromide; CPCI, Cetylpyridinium chloride; CTAB Cetyltrimethyl ammonium bromide; CTACI, Cetyltrimethyl ammonium chloride; DMG, Dimethylglyoxime; EDTA, Ethylenediamine tetra acetic acid; Erio T, Eriochrome Black T; E, Extraction; NTA, Nitrilotriacetic acid; 1,10-Phen, 1,10-Phenanthroline; PAR, 4,2-pyridylazo Resorcinol; Q, Quenching; TTA, Thenoyltrifluoroacetone; TEA, Triethanolamine; TOPO, Trioctylphosphine oxide.

diminished the role of spectrophotometry as the routine analytical technique in many laboratories. The low detection limits and enhanced selectivity of atomic spectrometric techniques together with the use of sequential multi-element determination capabilities makes these techniques better suited than spectrophotometry and spectrofluorimetry. However, the latter two techniques continue to be widely popular in view of their speed, simplicity, precision, accuracy and common availability of the instrumentation. This has resulted in extensive literature being published over the years [1–16].

Ternary complexes, wherein central ion reacts with two different ligands, have aroused considerable interest in the past two decades. West [17]

has classified ternary complexes into two major categories: coordination unsaturated type and ion-association type. The coordination unsaturated ternary complex results when a binary complex ('binary' here refers to a complex containing one type of central ion and another type of ligand, regardless of their stoichiometric ratio) has free coordination positions available on the central ion, allowing further reaction with a different ligand. Alternatively, if the binary complex is charged, the ion-association with an ion of opposite charge (usually dye stuff) may occur. In addition, multicomponent complexes (metal ion with more than two reagents) are used for spectrophotometric and spectrofluorimetric determination of inorganics. The modes of formation of all three types of complexes together with improvements in selectivity and sensitivity which accompany their formation, have been extensively discussed in a series of reviews [18–26]. Since the publications relating to the use of ternary and multicomponent complexes are rapidly increasing in frequency in the chemical literature of spectrophotometry and spectrofluorimetry and also possible simultaneous analysis based on multiwavelength and derivative measurements and being the most widely used detection technique in flow injection analysis (FIA), it is appropriate to present, in this review, a detailed evaluation of various procedures reported since 1980 on this subject.

2. Advances in colour systems

Most spectrophotometric and spectrofluorimetric determination of inorganic species are based on the formation of coloured compounds or complexes by their reaction with unidentate or chelating ligands. These methods are usually not sufficiently sensitive, excepting for those involving charge transfer transition, as the sensitivity, in general, is controlled by the extent of π -conjugation present in the ligand. Selectivity, most often, is achieved either by the proper choice of a reagent or by the use of masking agents. The sensitivity and selectivity can be improved through the synthesis of organic ligands possess-

ing extensively delocalized π -electron system along with appropriately placed ligating sites. However, apart from the synthesis being an arduous task, the reactivity of such ligands towards metal ions is restricted by the steric factors.

In recent years, this problem of designing model ligands for improving sensitivity and selectivity have been circumvented by reacting the metal ion with two different ligands, instead of one, to form a ternary complex [17]. The increase in sensitivity observed in these systems is due to the complex organic envelope around the central metal ion. The improvement in selectivity can be explained as due to the decreased probability of similar interaction with other metal ion. Even if other metal ions should react in a similar manner, they can effectively be masked, for now the system can tolerate more masking agents due to the increased stability of the complex.

3. Spectrophotometry

Ternary and multicomponent systems in spectrophotometry can be classified into:

1. Mixed ligand systems
2. Surfactant sensitized systems
3. Flotation-spectrophotometric methods
4. Ion-association systems

In addition, ternary and multicomponent systems are used in signal processing (derivative) and sample processing (FIA) analytical techniques in spectrophotometry and these are also included in the present review.

3.1. Mixed ligand systems

The mixed ligand systems makes use of coloured complexes, charged or neutral, consisting of metal ion and two different ligands. One of these ligands is anionic and the other can be anionic or neutral. Thus in $[\text{Fe}(\text{OH})(\text{EDTA})]^{2-}$ both the ligands are anionic while in $\text{Ni}(\text{HDz})_2(\text{Py})_2$ both an anionic and a neutral ligand are involved. Table 1 surveys ternary and multicomponent mixed ligand complexes with various metal ions for the determination of the latter.

3.2. Surfactant sensitized systems

The surfactant sensitized systems are based on the ability of certain surfactants to sensitize the binary complexes of the metal ion with chromogenic ligands. The ligands, most often, are metallochromic indicators and for sensitization, cationic surfactants are used. Sensitization can result either due to the replacement of acidic protons of the ligated dye molecule by surfactant cations as is the case in Pb-bromopyrogallol red-CTAB/CPB colour systems [318] or by adsorption of the metal-reagent complex on the micelles of the cationic surfactant as with Th-phenylfluorone-CPB [377] system. The applications of surfactant sensitized systems in spectrophotometric analysis are summarized in Tables 2–4.

3.3. Flotation-spectrophotometric methods

Basic non-chelating dyes enjoy high popularity in spectrophotometric analysis due to a high molecular extinction coefficient ($\approx 1 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). They are able to form extractable ion-pairs with monovalent or bivalent anionic complexes of metals leading to a variety of sensitive methods. Polyvalent anionic metal complexes also react with basic dyes but the reaction products cannot be extracted by slightly polar solvents. Instead, the compounds formed accumulate during shaking on the phase boundary or on the wall of the separating funnel. The precipitate can be separated off and dissolved in a polar solvent, producing an intensely coloured solution that forms the basis of a flotation-spectrophotometric method of determination. Flotation-spectrophotometric methods developed so far since 1980 are listed in Table 5.

3.4. Ion-association systems

Ion-association systems, in a more general way, could be said to result from the interaction of charged binary complexes with oppositely charged ions. When a neutral ligand, e.g. a nitrogenous base, is used, the primary complex produced is cation, possessing the same charge as that of metal. Such complexes were made to associate

with anionic dyes like eosin, rose bengal etc. to form ion-associates that are extractable into organic solvents. When charged ligands, e.g. halides, thiocyanate or carboxylic acids, are used, the primary complex produced is anionic which can be associated with onium compounds like tetraphenylarsonium and phosphonium chlorides or cationic dyes. Onium compounds are used when the primary complex is chromophoric in nature. Thus the thiocyanato complexes of Fe(III), Co(II) and W(VI) have been extracted with tetraphenyl salts and the extracts, when subjected to spectrophotometry, were shown to provide improved sensitivity over the methods that simply involve the extraction of the primary complex. When the primary complex formed is anionic and colourless, they can be made to ion-associate with oppositely charged dye molecules. The particular advantage of such colour systems containing dye molecules over the onium salts is the increased sensitivity arising from the high molar absorptivity of the dyes which usually lie in the range 6.0×10^4 to $1.25 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$. The selectivity is also improved due to the inability of most other ions to react with two ligands to form an ion-association complex of the same nature as the desired ion. Tables 6 and 7 lists various ternary and multicomponent ion-association complexes utilized for the trace determination of inorganics.

3.5. Derivative systems

Derivative systems have enjoyed extensive activity during the last 10 years due to the incorporation of electronic differentiators in most of the commercial spectrophotometers. These, together with associated software, are able to compute derivatives up to n th order of the spectrum. Today, this technique has proved to be very useful, providing both qualitative and quantitative information derived from mathematical processing of UV and VIS spectra. Derivative spectrophotometry leads to an increase in selectivity and in some cases, sensitivity of determination due to elimination of errors resulting from overlapping bands. It permits measurements in turbid media (even in the UV range) thus eliminating the need for centrifugation and allowing in situ measurements us-

ing fibre optics. It has proved particularly useful in eliminating matrix interferences. The derivative spectrophotometric methods utilizing ternary and multicomponent complexes in inorganic analysis are summarized in Table 8.

3.6. FIA systems

During the past decade FIA has rapidly grown in popularity. This is because of its simplicity, versatility, precision, high sampling rate, low sample consumption, low cost and ease of automation. This technique involves the injection of the sample into a stream of chromogenic reagent and ligand which transports it to the detector. The analysis requires a small amount of sample (10–300 μl) which, together with a light path of 10 mm usually used, is responsible for relatively high sensitivity. Virtually each colour reaction in a homogenous medium, provided it is sufficiently fast, can be adapted to flow injection processing resulting in a flow injection spectrophotometric method. Table 9 shows several FIA procedures, reported so far, for inorganics which make use of ternary and multicomponent complexes.

4. Spectrofluorimetry

A summary of fluorometric methods based on ternary complex formation until 1975 is given in a review article by Haddad [20]. A summary of spectrofluorimetric luminescence methods described so far since 1976 for inorganics is given in Table 10.

4.1. Ternary complexes with anionic binary complexes

Ternary complexes formed by ion-association of an anionic complex with a basic dye cation comprise the vast majority of ternary complexes used in spectrofluorimetry as in the case of spectrophotometry. The fluorescent dyes of the xanthene series (i.e. rhodamine dyes) serve as the cationic counter-ion in the ternary complex. Ion-association ternary complexes formed from these dyes may be classified into two groups—those contain-

ing an anionic binary complex formed between a metal and electronegative ligand and those formed from an anionic chelate binary complex.

4.2. Ternary complexes with cationic binary complexes

The availability of fluorescent anionic dyes of the fluorescein series has led to the possibility of fluorescent ion-association ternary complexes wherein the binary complex is cationic. Fluorescein dyes (often referred to as phthalein dyes) are very closely related in structure to the xanthene (Rhodamine) dye series.

4.3. Coordination unsaturated ternary complexes

Coordination unsaturated complexes do not suffer from the lack of selectivity often experienced with the ion-association type. This is generally attributed to a reduction in the likelihood of unwanted side reactions, because of the increased complexity in conditions required for two ligands to react. Fluorescent ternary complexes of rare earth ions are typified by the reaction of europium and samarium with TTA and 1,10-phenanthroline [764] and TTA-dibenzo-18-crown-6 [779] wherein terbium acts as an activator.

4.4. Advances in spectrophotometric and spectrofluorimetric methods for individual elements

4.4.1. Group I (H, Li, Na, K, Rb, Cs, Fr, Cu, Ag, Au)

Until the last decade, lithium, sodium, potassium, rubidium and cesium had not generally been determined spectrophotometrically or spectrofluorimetrically. A rapid development in synthetic chemistry, however, brought a dramatic increase in the number of spectrophotometric methods developed for these elements.

Selective ion-association procedures were developed for sodium using crown ether and triphenyl methane dyes [607–609]. A mixed ligand procedure was developed for the determination of potassium [60] in rocks, soil and plants by using benz-15-crown-5 and dipicrylamine. Selective extraction spectrophotometric methods were devel-

oped based on ion-association complex formation using crown ethers [595,597] and cryptand [596] in the presence of triphenylmethane dyes.

Of the various mixed ligand procedures developed for copper, the method based on the SCN^- and 2,3 or 4 picoline [46] is selective and applicable over a wide pH range 3–8. A number of reasonably sensitive spectrophotometric procedures were developed using surfactant sensitized systems [209–226]. Of these, the procedure based on chromal blue G and CTA Cl [219] is highly sensitive as it is useful to determine as low as 0.1–16 ppb of copper. The ion-association procedures developed for copper utilize both cationic and anionic dyes [559–568]. Amongst these, the procedure based on thiocyanate and Rhodamine B [564] is useful in determining traces of copper in steel and alloys. Ion-association procedure using 1,10-phenanthroline and 4,5-dibromofluorescein [758] forms the basis for sensitive spectrofluorimetric determination of copper.

Mixed ligand complex based on 2[3,4-phenylazophenyl]triazeno]phenol and TEA [28] is highly sensitive ($\epsilon = 1.28 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) for the determination of traces of silver by spectrophotometry. Of the various surfactant sensitized systems developed for silver [131–138] cadion 2B and sodium dodecyl sulphate [132] is highly sensitive ($\epsilon = 1.23 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). Flotation spectrophotometric method based on I^- , SnCl_2 and CI basic green [456] is more sensitive than SCN^- and Rhodamine 6G [455] for the determination of silver. The determination of silver based on thiocyanate and Rhodamine B [494] is more sensitive than other similar ion-association procedures [493–504]. As low as 2–15 ppb of silver can be determined spectrofluorimetrically by the use of benzothiacrown ether and eosine [739]. This procedure is more sensitive than the two other similar spectrofluorimetric procedures [737,738].

The surfactant sensitized procedures developed for gold [164–166] are not at all selective and sensitive. The halide and thiocyanate complexes form ion-associates with basic dyes, which were proposed for sensitive determination of gold either after extraction [510–519] or flotation [457–459]. As low as 6 ppb of gold can be determined by spectrofluorimetry using chloride and acridine yellow [742]. Other spectrofluorimetric procedures

[741,743,747] developed for gold are only reasonably sensitive.

4.4.2. Group II (Be, Mg, Ca, Sr, Ba, Ra, Zn, Cd, Hg)

Of the seven surfactant sensitized systems evaluated for spectrophotometric determination of beryllium [167–173], the use of 4,5-dibromophenylfluorone, CTAB and polysorbate 60 is the best as it gives highest sensitivity ($\epsilon = 1.7 \times 10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$) and is applied to the determination in Be–Cu alloys and minerals.

Of the two surfactant sensitized systems developed for magnesium [286,287] sensitization of Mg-4,5-dibromophenylfluorone complex with CTAB [287] is more sensitive ($\epsilon = 13.8 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been successfully used for its determination in minerals. An extractive spectrometric method was developed for the determination of traces of magnesium based on the formation of ternary ion-association complex with 5,7-diiodoquinolin-8-ol and Rhodamine S [598]. The sensitization of chromeazurol S-1,10-phenanthroline [184] and Ca-xylene orange [185] complexes by CTAB formed the basis for reasonably sensitive spectrophotometric procedures for the determination of calcium. The latter system was also used in flow injection mode [724]. Up to 12 μM of strontium could be determined by extractive spectrophotometric determination using cryptand 222 and erythrosine B [680].

A mixed ligand system, based on phenylfluorone and diphenyl guanidine [128], was developed for the determination of traces of zinc in clays and silicates. Of the various surfactant sensitized systems developed for zinc [435–440], chromeazurol B-quinoline-CTAB system [436] is more sensitive ($\epsilon = 1.13 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). However, none of the procedures are applicable for the determination of zinc in real samples. Formation of binary complexes with 1,10-phenanthroline or thiocyanate and subsequent association with anionic or cationic dyes respectively formed the basis for trace determination of zinc [705–710]. Of these, the procedure based on thiocyanate and Rhodamine 6G [707] is an aqueous procedure and has been used for its determination in soils. Among the four systems described for spectrofluorimetric determination of zinc [827–830], the procedure

based on the use of ferron-CTAB is applicable for its determination in alloys.

A highly sensitive mixed ligand system based on the use of crystal violet and bromopyrogall red [39] was developed for the determination of traces of cadmium in high purity zinc. Three other procedures [37–40] in this category involve extraction and have not been applied to real samples. Sixteen ion-association procedures [534–549] were described for the trace determination of cadmium and most of these utilise iodide for the formation of binary anionic complex and associate with different oppositely charged cationic dyes. A few of them [536,538,543] are successfully applied for the determination of traces of cadmium in high purity zinc materials. Amongst the spectrofluorimetric procedures developed for cadmium [749–755], the method based on the quenching of fluorescence of I^- -Rhodamine S [752] is more sensitive and is useful in the determination of as low as 4–20 ppb.

Though two mixed ligand systems are mentioned in the literature for mercury [57,58] the details of the former are not available and the sensitivity of the latter is very low ($\epsilon = 2.3 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) and involves extraction. Of the three flotation spectrophotometric procedures developed for mercury [460–462], the method based on the use of ternary system iodide and Brilliant green [462] is more sensitive ($\epsilon = 5.96 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and is applicable to its determination in paper industry effluents. Of the 12 ion-association systems developed for mercury [581–592], the formation of anionic mercury-halide complex and association with oppositely charged cationic dyes are more popular. A third order derivative spectrophotometric procedure was developed for mercury [714] based on the formation of ternary ion-associate $Hg-I^-$ -pyronine G. This procedure has been applied to the determination of traces of mercury in industrial effluents. Three spectrofluorimetric procedures were developed during this period for the determination of mercury [782–784]. Amongst these, the procedure based on extraction of ternary ion associate formed with cryptand 221 and eosine [782] is most sensitive and is applied to coal and fly ash samples.

4.4.3. Group III (B, Al, Ga, In, Tl, Sc, Y, lanthanides, actinides)

A rapid development in the methods based on the formation of ion-associates with anionic boron complexes were observed [520–526]. The extraction of boron with 3,5-di-*t*-butylcatechol and ethyl violet [522] is most sensitive ($\epsilon = 1.05 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to sea water samples. Similarly, an extractive spectrofluorimetric method was developed for the determination of as low as 8–120 ppb of boron in plants [745].

Mixed ligand system based on 5-bromosalicylfluorone and 5,7-dibromo-8-hydroxyquinoline [31] is more sensitive ($\epsilon = 6.2 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) than that with bromopyrogallol red and diphenyl guanidine [30] ($\epsilon = 3.1 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$). The latter procedure involves extraction with butanol. Of the 15 aqueous spectrophotometric methods developed for aluminium [139–163] based on surfactant sensitized systems, the reaction based on the sensitization of Al chromeazulur S complex by CPB and OP [145] is more sensitive ($\epsilon = 1.35 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and is applicable for the determination of 0.04–0.4 ppm of aluminium. The Al-chromeazurol S-CPCl system has been carried out in FIA mode also [724]. The only mixed ligand system described for gallium [56] is based on the formation with PAR and diphenylguanidine. Among the surfactant sensitized systems developed for gallium [240–258] the reaction based on *o*-chlorophenyl fluorone and CPB is more sensitive ($\epsilon = 1.7 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied for its determination in ores [243]. A number of metal triphenylmethane dye complexes sensitized by cationic surfactants formed the basis for sensitive determination of indium [272–277]. Of these, the procedure based on 9-(2-chlorophenyl)2,6,7-trihydroxyxanthene-3-one-CTAB [275] is most sensitive ($\epsilon = 1.92 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to Sn foil and lead mining samples. Two surfactant sensitized systems [403,404] were developed for the sensitive determination of thallium based on the sensitization of Tl-gallein and Tl-bromopyrogallol red complexes by cationic surfactants. The anionic binary complex formed with halide and association with oppositely charged cationic dyes [692–

696] formed the basis for sensitive spectrophotometric determination of thallium. Of these, the ion-associate formed with chloride and pyronine G is most sensitive ($\epsilon = 1.2 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and found application to thallium in Cd sponge and rocks.

Barring one each of mixed ligand [102] and ion-association system [669], the most frequently developed spectrophotometric procedures for scandium are based on the formation of surfactant sensitized systems [345–356]. Of these, the sensitization of Sc-chromeazurol S complex with zephiramine [350] is most sensitive ($\epsilon = 1.64 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). A multicomponent surfactant sensitized system based on Y-chromeazurol S, 1,10-phenanthroline and dimethyldodecylamino acetic acid [434] formed the basis for sensitive determination of yttrium ($\epsilon = 1.4 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$).

Two mixed ligand systems are described for the trace determination of lanthanum with antipyrine A and diphenylguanidine [61] and lutetium with pyrogallol red or bromopyrogallol red and 1,10-phenanthroline [62]. The ternary complexes with methylthymol blue-CPCl [285] and Hexaazo-18-crown-6-erythrosine A [569] formed the basis for the sensitive determination of lutetium and europium, respectively. However, the above ternary systems developed for a particular lanthanide are not selective as other lanthanides react in a similar way. The development of derivative techniques has increased the potential of many of the old methods by allowing the poor selectivity of sensitive reagents to be circumvented. The resolution of complex absorption spectra of ternary complexes of rare earth ion by using derivative mode allowed the determination of single or a few target elements in a mixture. Thus, a few derivative procedures were developed for the determination of neodymium [717,718], samarium [723] and mixtures of neodymium and erbium [717], praseodymium, neodymium, holmium and erbium [720] and praseodymium and holmium [721] in other rare earth oxides. Sensitive and selective spectrofluorimetric procedures were developed over the last five years for the determination of europium [761–779] and samarium [809–816]. Of these, few procedures find application for the determination of europium in other rare earth oxides [764,766,773,774,779].

4.4.4. Group 4 (C, Si, Ge, Sn, Pb, Ti, Zr, Hf)

The methods developed for silicate invariably use molybdate to form binary complex and subsequently associated with malachite green [486] or chromopyrazol II [487] methods. Similar ion-association complexes were used both in flotation spectrophotometric determination [673–675] or in FIA mode [734,735]. Ten surfactant sensitized procedures were developed for the trace determination of germanium [259–268]. Of these, the sensitization of Ge-*p*-chlorophenylfluorone by Tween-60 is more sensitive ($\epsilon = 1.8 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) [261]. Germanium is also determined by formation of two ternary ion-association complexes based on molybdate-butyl Rhodamine B [578] and mandelic acid-malachite green [579]. The former one is an aqueous procedure and has been applied to trace determination of germanium in Cu–Cd slag.

Surfactant sensitized systems are mostly investigated for the determination of trace amounts of tin, with as many as 15 procedures [357–371] are described during the last two decades. The sensitization of Sn-bromopyrogallol red complex with CPB is more sensitive ($\epsilon = 3.72 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been used for its determination in $\text{Pb}(\text{NO}_3)_2$. The association of binary complex of tin formed with 3-nitroalizarin, iodide and thiocyanate and with oppositely charged Brilliant green [677], 5,7-dichlorooxine [678] and crystal violet [679], formed the basis for sensitive determination of tin. The sensitization of Sn-2-chlorophenylfluorone complex with CTAB [817] formed the basis for spectrofluorimetric determination of 20–120 ppb of tin. The extraction of lead with bismuthiol II in presence of 1,10-phenanthroline allows the determination of 0.3–30 ppm of lead [86]. The sensitization of lead-salicylfluorone complex with CPCl [316] is more sensitive ($\epsilon = 9 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) compared to other surfactant sensitized procedures developed for lead [315–320]. Lead-crown ether or cryptand binary complexes and their association with oppositely charged anionic dyes [626–630] resulted in development of sensitive spectrophotometric procedures. Only Pb-cryptand 2,2,2-eosine [762] procedure has been successfully applied for the determination of traces of lead in highly purity metals and alloys. Similarly, ion association com-

plexes formed with eosine in the presence of 18-crown-6 or cryptand 2,2,2 are used for sensitive determination of lead by spectrofluorimetry. Of the few mixed ligand system investigated for titanium [105–110], none of them are sensitive enough to find application in trace analysis. On the other hand, of the various surfactant sensitized systems [383–402] almost all of them, excepting one, are aqueous determinations and are reasonably sensitive. The first two of these procedures finds application to steels and rocks [383] and rocks and alloys [384]. As in the case of titanium, surfactant sensitized systems are most often investigated [443–454] for the sensitive determination of zirconium. Of these, the sensitization of Zr-*p*-acetylchlorophosphonazo complex with sodium dodecyl benzene sulphonate [448] is most sensitive ($\epsilon = 6.03 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and allows the determination of as low as 0–0.12 ppm of zirconium. An ion association complex formed with fluoride and alizarin and subsequent extraction into MIBK formed the basis for the determination of 0–20 μg of zirconium in alloys [711].

4.4.5. Group V (*N, P, As, Sb, Bi, V, Nb, Ta*)

The flotation of ternary complex of phosphate with molybdate and malachite green [473] using butyl acetate formed the sensitive determination of phosphate and has been applied to Fe, Co, Ni and Zn samples. Similarly, formation of ion association complexes of phosphate in the presence of molybdate with various cationic dyes [621–625] formed the basis for development of sensitive spectrophotometric procedures. A third order derivative spectrophotometric procedure was developed for phosphate which is also based on the formation of ternary ion-association complex with molybdate and Rhodamine 6G [719]. Similar ion-association complexes formed by arsenic in the presence of molybdate and different cationic dyes [505–509] are the basis for its sensitive determination. Similar procedures using ethyl rhodamin B [505] and Rhodamine B, PVA [507] as counter cations have been applied to the determination of arsenic in steel and chemical reagents and flue dust and plants, respectively.

Three surfactant sensitized procedures [342–344] were developed for the determination of

traces of antimony. Of these, sensitization of Sb-4,5-dibromophenyl fluorone complex by CTAB [342] is most sensitive ($\epsilon = 3.96 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to copper alloys. Ion-association systems are the most often studied for the determination of antimony [661–668]. None of these procedures have been applied to real samples. The mixed ligand systems described for bismuth [32–36] are not sensitive, in spite of using extraction in two cases [33,34]. Among the surfactant sensitized systems described for bismuth [179–183] the sensitization of Bi-*m*-fluorophenylfluorone complex with CTAB is more sensitive ($\epsilon = 1.83 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) [179] and none of these are applied to real samples. The formation of binary anionic complex with iodide and subsequent association with cationic dyes resulted in the development of a few sensitive spectrophotometric procedures for the determination of bismuth [527–533]. Two fluorescence quenching procedures have been described for the determination of 0.02–0.4 ppm of bismuth in rocks and minerals [746] and cast iron [747].

Of the various mixed ligand systems described for vanadium [113–123], the one based on thiocyanate and diphenylguanidine [123] is most sensitive ($\epsilon = 1.7 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) while the other procedures are very low sensitive. Among the 11 surfactant sensitized systems described for vanadium [413–423], the V-3,4,5,6-tetrachlorogallein-CPCl [423] is most sensitive ($\epsilon = 7.0 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). Highly sensitive flotation-spectrophotometric procedures were developed for vanadium [491,492]. These are based on the formation of floatable ion-associates with 3,5-dinitrocatechol-Rhodamine B and 3,5-dinitrosalicylic acid-Rhodamine B using hexane and cyclohexane, respectively. Both these procedures have been applied to real samples. The extraction of vanadium as its ion-association complex with 3,5-dinitrocatechol and Brilliant green [702] into CCl_4 formed the basis for its sensitive determination ($\epsilon = 1.7 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). FIA-spectrophotometric procedure was described for vanadium based on sensitization of caraminic acid by CTAB [731]. An extractive spectrofluorimetric procedure was developed for vanadium based on the ternary complex PAR and safranin T [825]. Nine mixed

ligand systems are described for niobium [73–81] and none of them are sensitive enough to be mentioned here. Of the two surfactant sensitized systems described for niobium [308,309], the one based on Nb-4,5-dibromophenylfluorone-CTAB [309] was more sensitive ($\epsilon = 2.1 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). Aqueous spectrofluorimetric procedures [791,792] were developed based on sensitization of Nb-morin [791] and Nb-4,5-dibromophenylfluorone complexes [792] by cationic surfactants. Among the surfactant sensitized systems developed for tantalum [372–375], the one based on sensitization of Ta-2,7-dihydroxyfluoresein complex by CPB [372] has been applied to minerals and rocks. Ion-association systems are the most popular for the determination of tantalum and as many as six procedures [681–686] were described. Of these two procedures based on molybdate-butyl Rhodamine B [683] and fluoride-Brilliant green [686] have been applied to the determination of tantalum in rocks and ores respectively.

4.4.6. Group VI (O, S, Se, Te, Po, Cr, Mo, W)

Of the three ion-association procedures reported for selenium [670–672], indirect determination by formation of ICl_2^- which associate with Rhodamine 6G [670] procedure is good and finds application in bark and copper ore. Two flotation spectrophotometric procedures were developed based on papaverine-butyl Rhodamine B [489] and iodide-Nile blue A [490] and the former is applicable to copper. Ion-association systems based on halide or thiocyanate complexes of tellurium in association with suitable cationic dyes [687–690] formed the basis for its sensitive determination and all these procedures were applied to real samples.

Surfactant sensitized systems [197–208] are the most often studied for the trace determination of chromium. The sensitization of Cr-*o*-hydroxyquinol phthalein complex by CTAB [205] is most sensitive ($\epsilon = 1.64 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and finds application in ferrosilicon and steel samples. The formation of iodocomplex with chromium and subsequent ion-association with crystal violet [757] formed the basis for the determination of ppb amounts by an extractive spectrofluorimetry. Of the few mixed ligand systems described for

molybdenum [65–72], the one based on the use of bromopyrogallol red and ethyl violet [66] is more sensitive ($\epsilon = 1.7 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). Among the various surfactant sensitized systems [293–307], the sensitization of Mo-*o*-nitrophenylphenylfluorone complex with CTAB and OP [297] is more sensitive ($\epsilon = 1.53 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has not been applied to real samples. The flotation of molybdenum thiocyanate-catechol violet complex with toluene formed the basis for flotation spectrophotometric determination of molybdenum [465]. Of the eight ion-association procedures described for molybdenum [599–606], the procedure based on thiocyanate and Rhodamine B [600] allows the determination of as low as 12–220 ppb of molybdenum and has been applied to Fe–Ni–Mo thin films. A third order derivative spectrophotometric procedure was developed for the simultaneous determination of Mo and Ti [715]. Mo and V have been determined in FIA mode by sensitization of their caraminic acid complexes by CTAB [731]. A multicomponent system based on Mo–SCN–Rhodamine B and sodium dodecyl benzene sulphonate [789] formed the basis for the determination of as low as 0.1 ppm of Mo by spectrofluorimetry. As low as 2–80 ppb of molybdenum could be determined spectrofluorimetrically based on the sensitization of Mo-*o*-chlorophenylfluorone complex by CTAB [790]. Of the four mixed ligand systems described for tungsten [124–127] none of them are sensitive enough to mention here. Surfactant sensitized systems [424–432] are the most often investigated for tungsten. The multicomponent system, W-salicylfluorone-polysorbate-CTAB [427] offers high sensitivity though not applicable to real samples. Ion-association with crystal violet [703] and ethyl Rhodamine B [704] with anionic thiocyanate complexes of tungsten results in its sensitive determination. A fluorescence quenching procedure was developed for tungsten [826] based on the sensitization of salicylfluorone with CTAB.

4.4.7. Group VII (F, Cl, Br, I, At, Mn, Tc, Re)

Ternary complexes of manganese based on 1,10-phenanthroline-TTA [63] and 1,10-phenanthroline-dithizone [64] were described for its determination but these are not sensitive with ϵ values of 3.6×10^4 and $4.6 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$.

Of the five surfactant sensitized systems described for manganese [288–292], the sensitization of Mn-*o*-nitrophenylfluorone complex with CTAB and OP is most sensitive ($\epsilon = 1.53 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$). Mixed ligand systems described for rhenium utilize thiocyanate as one of the ligand [96–98] and none of them are sensitive enough to mention here. An FIA procedure is developed for the determination of rhenium based on the formation of ternary ion-association complex viz. Re-dicyclohexano-18-crown-6-Brilliant green [733].

4.4.8. Group VIII (Fe, Co, Ni, Ru, Rh, Pd, Os, Ir, Pt)

A large number of methods are developed for iron based on the mixed ligand formation [48–55]. None of these procedures, excepting the one based on the use of erio T, mesotetra(4-sulphophenyl)porphyrin [50] are sensitive. Of the 12 surfactant sensitized procedures described for iron [228–239], the sensitization of Fe-alizarin yellow complex by CTAB provides highest molar absorptivity ($\epsilon = 9.3 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$). The formation of cationic or anionic binary complexes with 1,10-phenanthroline [570,571] or thiocyanate [572–574] and subsequent association with oppositely charged reagents formed the basis for sensitive determination of iron. Of these the formation of ternary ion-association complex with thiocyanate and crystal violet [574] is most sensitive ($\epsilon = 1.1 \times 10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to the determination of traces of iron in alloys and pure salts. A second order derivative spectrophotometric procedure was developed for iron [713] based on the extraction of ternary ion-associate formed with iron in presence of 1,10-phenanthroline and perchlorate. One FIA procedure is described for iron by using chromeazourol S and HD MAA, but the details are not available. Of the six surfactant sensitized systems described for cobalt, the reaction based on sensitization of Co-4,5-dibromophenylfluorone complex with CPB [192] is more sensitive ($\epsilon = 1.27 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to ore samples. As in the case of iron, the formation of charged binary complexes with 1,10-phenanthroline [552,554,555] and thiocyanate [553,556–558] and association with oppositely

charged triphenyl methane or xanthene dyes formed the basis for the sensitive determination of cobalt. The procedure based on formation of ternary complex with thiocyanate and Brilliant green [556] is most sensitive ($\epsilon = 1.47 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to rock samples. The mixed ligand systems described for nickel [82–84] are not that sensitive to mention here. The sensitization of nickel-chromeazourol S complex [310] by CTAB is the most sensitive ($\epsilon = 1.48 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) of the various other similar systems described during this period [311–314].

Flotation spectrophotometric procedures are most often investigated for noble metals during this period [463,464,467–472,474–476,478–485]. These reactions are highly sensitive and have been applied to various real samples. The highest sensitive reactions are SnCl₂-Rhodamine B (for Ir) [463], SnCl₂-Rhodamine B (for Os) [471], SnCl₂-Rhodamine 6G (for Rh) [480] and Cl⁻-Rhodamine 6G (for Ru) [482]. In addition, four ion-association systems are described for the determination of osmium [617–620]. Of these, the sensitivity obtainable by ternary complex Os-SnCl₂-Brilliant green is more sensitive ($5.6 \times 10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$) than flotation spectrophotometric procedures. This procedure has been applied to the determination of traces of osmium in pure nickel. Of the three ion-association systems described for ruthenium [658–660] during this period, the formation of ternary complex with SnCl₂-crystal violet allows the determination of as low as 8 ppb [659] and is most sensitive ($\epsilon = 1.1 \times 10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$). A first order derivative spectrophotometric procedure was developed for the determination of as low as 7 ppb of ruthenium [722] using ternary mixed ligand system 2,4,6-tri(2-pyridyl)1,3,5-triazine and picrate. Two aqueous spectrofluorimetric procedures were developed for ruthenium [801,802] based on the ternary complexes formed with oxine-CTAB and 1,10-phenanthroline-sodium dodecylsulphate. Surfactant sensitized systems are the most often investigated for palladium [321–334]. Of these, the sensitization of Pd-salicylfluorone complex with CTAB is most sensitive ($\epsilon = 1.17 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to catalyst

samples. The formation of anionic binary complex with halide or thiocyanate with palladium and subsequent association with cationic dyes formed the basis for its determination [635–640]. The reaction based on iodide and pyronine G is most sensitive ($\epsilon = 9.5 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to steels and alloy samples. A FIA procedure is described for palladium [731] based on the sensitization of Pd-orange G complex by CPB. An extraction-fluorimetric procedure was developed for the determination of ≤ 2 ppm of palladium after formation of ternary ion-association complex with bromide and acridine orange [798]. Of the three surfactant sensitized systems described for platinum [336–338], the reaction based on Pt-4,5-dibromophenylfluorone-CTAB [337] is most sensitive ($\epsilon = 8.3 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$). As many as 12 ion-association complexes are utilized for the determination of traces of platinum [641–652]. Among these, the procedure based on formation of ion-association complex with SnBr_2 -malchite green [652] is most sensitive ($\epsilon = 1.67 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) and has been applied to catalyst samples. Extractive spectrofluorimetric procedures were developed for the determination of traces of platinum based on the formation of ternary ion-association complexes with chloride-Rhodamine 6G [799] and chloride-rose bengal [800]. The former procedure allows the determination of as low as 15 ppb of platinum. Three sensitive and aqueous spectrophotometric procedures were described during this period for the determination of traces of rhodium [655–657]. Of these, the ion-association complex formed with SnCl_2 -crystal violet [657] is more sensitive ($\epsilon = 1.0 \times 10^6 \text{ l mol}^{-1} \text{ cm}^{-1}$) and allows the determination of 0–0.2 ppm of rhodium. A similar ion-association system Ir– SnCl_2 -malachite green was described for the sensitive determination of iridium ($\epsilon = 1.45 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$) [594].

5. Future trends

Despite being regarded by many analysts as obsolete, spectrophotometry still enjoys great popularity, which seems to be increasing in some fields. Advances in the synthesis of new organic

reagents will occur, but whether they will be able to bring about a breakthrough in analytical spectrophotometry or spectrofluorimetry is rather doubtful. Examination of various mixed ligand ternary and multicomponent systems, developed over the last two decades, indicates there is little scope in the future as they are unlikely to surpass in sensitivity over ion-association and surfactant sensitized systems. The use of multicomponent systems in surfactant sensitized procedures are finding increasing attention over the last five years. This trend is likely to continue in improving the sensitivity and selectivity of surfactant sensitized procedures. Flotation spectrophotometric procedures developed over the last decade are mainly for noble metals. In the coming years, one could see the development of flotation spectrophotometric procedures for the transition elements and *p*-block elements in view of their superior sensitivity. There is a shift in ion-association procedures over the last 15 years in the development of rapid, reliable, selective and sensitive aqueous procedures in place of extractive spectrophotometric procedures. This trend will continue with an emphasis on the application of developed procedures to real samples and in analysis of reference materials. Derivative and FIA spectrophotometric procedures are the novel and emerging areas where we will see many developments in the future. However, growing interest in automatic sample processing can place spectrophotometry as a detection technique due to the relatively low cost of the equipment and above all, its far easier and cheaper maintenance. The drawback of poor selectivity is frequently overcome by powerful signal processing techniques. These all make spectrophotometry a competitive technique, if not in ultra trace, at least in trace analysis.

Prior to 1980s, spectrofluorimetric procedures developed for inorganics utilize extraction and in most cases with xanthene dyes as one of the ligands in ternary and multicomponent complexes. In the last two decades also, this trend continued. During the last five years there is a trend towards the development of aqueous spectrofluorimetric procedures based on the quenching of the fluorescence of the dye. This trend is likely to increase in the future. A mention has to

be made here in the development of novel spectrofluorimetric procedures for europium and samarium wherein another rare earth ion acts as an activator. The development of such novel spectrofluorimetric systems may find increasing attention from various researchers throughout the world in view of its ramifications in the development of procedures for the determination of individual lanthanides in high purity rare earth oxides [834].

Review

Fluorimetric analysis of pesticides: Methods, recent developments and applications

Atanasse Coly¹, Jean-Jacques Aaron*

Received 27 December 1996; received in revised form 27 October 1997; accepted 4 November 1997

Abstract

The fluorimetric analysis of pesticides is reviewed with emphasis on the description of direct and indirect fluorimetric methods, including chemical derivatization, fluorogenic labelling, and photochemically-induced fluorescence. The use of fluorescence detection in TLC, HPLC and FIA as well as applications to environmental samples are discussed in detail. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Pesticides; Fluorimetry; Analysis

1. Introduction

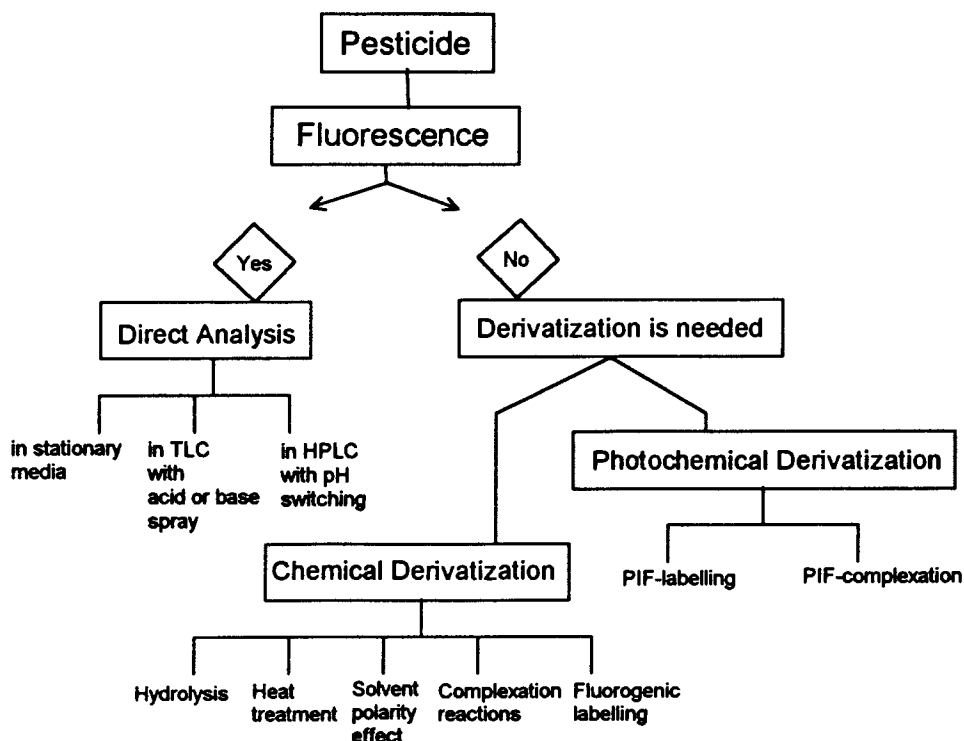

Confined to inorganic or organic compounds until the second world war, the list of pesticides—antiparasitic products for agricultural purposes—has rapidly grown in the last thirty years, because of the development of synthetic organic chemistry and the urgent need for intensive agriculture. At present, the number of different pesticides used widely for plant protection has exceeded several hundred [1–4]. Therefore, the input of agrochemical pollutants in the environment has increased

proportionally and has required the use of more sensitive and selective analytical methods in order to monitor the pesticide residue levels and to control the bioaccumulation process.

Important progress has occurred in the development and applications of various analytical tools including separation methods such as gas chromatography (GC) and high performance liquid chromatography (HPLC) and detection techniques such as electrochemistry, spectrophotometry and spectrofluorimetry. These techniques have allowed the identification and determination (at low concentration levels) of pesticide residues in a number of food and environmental samples [1,2,4–7]. Although several classes of pesticides (e.g. carbamates, phenylureas and some organo-

phosphorus insecticides) are rapidly degraded, by various biological, chemical or photochemical processes in soil, ground water and/or surface water [4,6,8], others (e.g. organochlorinated insecticides), are not biodegradable, and have been forbidden in many countries after evidence has been found of their toxicity and bioaccumulation in the environment and biosphere.

Currently, GC remains the main analytical method used for pesticide residue analysis because of its excellent separation and detection potential, especially when combined with MS [1,2]. However, it has some drawbacks such as the need for pre-treatment procedures in the case of weakly volatile and/or thermally labile pesticides (e.g. carbamates, phenylureas and sulfonylureas). The second most utilized method is HPLC, with UV-visible absorption detectors; it remains the technique of choice for screening work.

The use of fluorescence techniques for organic pesticide residue analysis has been limited by the fact that, relatively few of these compounds are

strongly fluorescent. However, many compounds possess the necessary degree of aromaticity and may be converted to fluorescent species using a variety of methods. Hence, two distinct cases (Scheme 1) have to be considered. (i) If the pesticide under study is fluorescent, then it can be determined directly by fluorimetry; (ii) if the pesticide is non or weakly fluorescent, it can be converted into a fluorescent compound using various physicochemical means, including chemical and/or photochemical reactions.

Generally speaking, literature results [9–19] show that fluorimetric detection is much more selective and sensitive than most other detection systems. Some laboratories involved in HPLC analysis of pesticide residues have chosen fluorimetry with post-column chemical and/or photochemical reactor rather than the classical UV-visible absorption for detection purposes [13,17,19].

Derivatization is an important aspect of pesticide analysis in fluorimetry as well as in GC and

other methods, since many pesticides have one or more functional groups and can be converted into more stable derivatives to successfully ensure environmental analysis. This increase in the use of derivatization is demonstrated by the number of papers, especially reviews [9–13] and books [15–18] published on the subject. In the present review, only the most important publications describing significant advances in the fluorescence methodology, instrumentation and applications to environmental analysis of pesticides are reported. The main advantages as well as the drawbacks of each method are outlined or discussed. Other aspects of the fluorimetric technique concerning bioanalysis (i.e. fluoroimmunoassays) will not be considered.

The scope of this review covers the available literature of the last twenty years up to the middle of 1996. It is intended to assist workers involved in the areas of trace spectrofluorimetric analysis of pesticides in environmental matrices and to provide readers with a critical summary of primary papers concerning the application of fluorescence to pesticide analysis. Recent instrumentation including sophisticated electronics and precise optical systems makes fluorescence a powerful method for pesticides residues determination because of its high sensitivity and selectivity.

The summary of the review is outlined in Scheme 1.

2. Fluorimetric methods

The original work on the fluorescence of pesticides has been carried out in stationary solutions, (i.e. batch procedure) by Hornstein [20] and has been limited to naturally-fluorescent pesticides such as guthion, pomsan, warfarin and piperonyl butoxide. The aim of this early fluorimetric assay was to investigate the possibility of quantifying low levels of pesticide residues. The promising results of this first attempt has led to the development of a number of direct fluorimetric methods and derivatization techniques allowing the transformation of non fluorescent pesticides into fluorescent derivatives.

2.1. Direct fluorimetric methods

The direct methods are based on the fluorescence detection of analyte and are mainly applied to those pesticides exhibiting an intrinsic fluorescence strong enough to be analytically useful. Therefore, the fluorescence properties of anticoagulant rodenticides including indanediones [21–23] and coumarins [21–31], carbamates insecticides such as aminocarb [32], bendiocarb [23,33], benomyl [29,34], carbaryl [33,35–38] and carbofuran [37,38], and some organophosphorus insecticides, including coumaphos [33] and pirimiphos-methyl [21], and other classes of pesticides [33] have been investigated. For example, Krause [33] has selected seventy-five pesticides, metabolites and a number of industrial chemicals for HPLC studies based on their known fluorescence or on chemical structures indicating possible fluorescence. The main analytical results obtained using these methods are shown in Table 1.

Direct fluorimetry has also been applied to herbicides [39–41], and fungicides [42–45]. In most cases, the fluorimetric detection of pesticides has been performed on solid support by thin layer chromatography (TLC) [34,46], in combination with dynamic systems including HPLC [22,24–33,35–39,42–44,47–50], flow injection analysis (FIA) [23,45], and by using specific techniques such as synchronous and/or derivative spectra in batch procedures [40,41].

2.1.1. Fluorimetric detection on solid support, (TLC)

At present, this type of pesticide analysis is not frequently used. Among the various existing solid substrates, silica gel plates [34,46] are the most utilized. TLC is inexpensive and rapid, but lacks sensitivity and selectivity.

Recent ameliorations in support quality, involving layers prepared from particles with narrow size distributions and mean diameters between 5 and 15 μm [51]—associated to modern quantitative, instrumental high performance TLC (HPTLC) [52] has improved the analytical performance of the method. For example, the limits of detection, (LOD) of four different aromatic pesticides in several environmental water matrices

were in the range 0.04–0.15 ng ml⁻¹ according to the molecular structure of the pesticides [34].

2.1.2. Fluorimetric detection in combination with HPLC

Fluorimetric detection has been closely bound to the important development of HPLC instrumentation since it is generally more sensitive than the classical UV absorption detection. In addition, fluorescence detectors are very selective, eliminating matrix interference. However, it must be mentioned that several research groups have recently used HPLC with diode array UV and MS detection for extensive and successful analytical studies of many classes of pesticides and their mixtures in real samples [53–64]. HPLC is particularly useful because of the effectiveness of the various separative columns. Several types of HPLC systems have been reported for the fluorimetric determination of pesticides. As an example, the following LOD values are compared for the same series of rodenticides: (i) 2–20 ng ml⁻¹ for normal phase HPLC [22,26], (ii) 2–20 ng ml⁻¹ for reversed-phase HPLC [22,25,26,29,33], (iii) 2–10 ng ml⁻¹ for ionic column HPLC [22]. Finally, in other HPLC applications, fluorimetric detectors are connected in series with UV or electrochemical detectors [39,42,50].

2.1.3. Fluorimetric detection in stationary media

Although relatively time-consuming, this fluorimetric method has gained widespread acceptance because of enhanced selectivity brought about by the use of first and/or second derivative spectra in conjunction with a specific technique such as synchronous spectrofluorimetry [40,41]. The sensitivity and selectivity of this approach has been demonstrated by Garcia-Sanchez and co-workers [65–68]. The simplification of the spectral profile and the band-narrowing effect coupled with the derivative technique (very useful for the reduction of band overlapping) makes both identification of weak bands and magnification of the overall fluorescence signal feasible. For instance, a LOD value of 1 ng ml⁻¹ was achieved using the first derivative approach in the determination of the plant growth regulator naphthylacetic acid [40], recoveries from spiked apple samples ranged from 97 to 99%.

The potential of variable angle synchronous spectrometry (VASS) for the resolution of fluorescent mixtures was assessed in the case of the cyclodextrin-enhanced fluorescence determination of ternary mixtures of aminocarb, carbendazim and coumatetralyl [69]. The method was compared with the rank annihilation method (RAM). Fluorescence spectral distribution exhibits a great overlap that precludes the direct determination of this type of mixture. VASS shows better analytical

performance (recovery: 99–104%) than RAM (recovery: 84–130%) due to better resolution of mixtures of overlapping fluorescent compounds.

The use of organized media viz. cyclodextrins [70], micelles [71] and liposomic vesicles [72] for resolution of mixtures of analytes [69], enhancement of fluorescence detection [73] and reduction of interferences from impurities [74] has continued to grow rapidly. However, the application of such media in analytical spectrofluorimetry generally involves other organic aromatic compounds rather than pesticides [69,73,75].

In conclusion, the fluorimetric detection in stationary media or in combination with TLC or HPLC techniques proves to be highly sensitive and selective. LODs are in the low ng or ng ml⁻¹ range but these values must be used cautiously because they depend on enrichment during sample pretreatment (Table 1). Unfortunately, the number of pesticides presenting an intrinsic fluorescence is rather limited. For this reason, several derivatization reactions have been proposed.

2.2. Fluorimetric pretreatment methods

Chemical derivatization is generally used for non or weakly fluorescent compounds in order to convert them into fluorescent species following pretreatment. The type of chemical derivatization reaction applied to the analyte depends essentially on the pesticide class [9,11,13,76–79]. The principle of the method—which is designed to improve the quantum fluorescence yield—generates a fluorophore by means of a reagent, a thermal treatment or solvent polarity effect. The choice of reagent or treatment utilized dictates the type and mechanism of the derivatization reaction scheme. Hydrolysis, heat treatment, solvent polarity effect, complexation reactions and fluorogenic labelling are the most widely applied derivatization methods in pesticide fluorimetric analysis.

2.2.1. Hydrolysis

Hydrolysis is the most simple pretreatment method for pesticide residue analysis. It is accomplished in a strongly alkaline aqueous medium (NaOH) and at a high temperature (50–100°C). It

leads to the formation of fluorescent anions. The method has been successfully applied to the determination of carbamates such as carbaryl [34,80,81], benomyl [34] and organophosphorus insecticides such as guthion [82] and quinalphos [83] with LODs in the low nanogram range.

For instance, a LOD of 6 ng per spot has been found for carbaryl hydrolyzed in α -naphthol on a TLC plate by spraying with 1 M NaOH, and using scanning fluorimetry [80].

Moreover, for many pesticides, the sensitivity of the method was improved after heat treatment of the hydrolysis products.

2.2.2. Heat treatment

In this procedure, the pesticide sample is put on a chromatoplate, thermally decomposed during a specific time at a given temperature (75–225°C) and fluorimetrically monitored in situ. Although the mechanism of fluorescence thermal production is not completely established, it probably occurs through decomposition or rearrangement of the original molecule into a more stable and/or more conjugated species; a number of fluorescent products have been obtained. In fact, the only necessary criterion for the thermal production of fluorescence is a certain degree of aromaticity within the structure of the compound under investigation.

The TLC technique has been employed for determining non fluorescent organophosphorus insecticides [84] and other pesticides exhibiting native fluorescence [84,85]. Significant changes in excitation and emission spectra occur for the naturally-fluorescent compounds as well as an increase or decrease in their fluorescence signal upon heating (Table 2). The effect of a variety of external reagents such as acids, bases [85] and inorganic salts [86] on a number of pesticides heated on silica gel thin layers was also investigated. The spray of alkali reagents was found to be more efficient as fluorescence intensifiers than that of acid reagents. Background fluorescence, which affects many fluorogenic spraying techniques is absent here, ensuring more reproducible results. The LODs are in the low nanogram range (Table 2).

Table 2
Effect of heat treatment on the TLC fluorescence analytical properties of several aromatic pesticides

Pesticide	Optimum heating conditions	Maximum wavelength (nm)	LOD (ng)	Reference

2.2.3. Solvent polarity effect

A series of flavone derivatives (II–VI, Scheme 2) were proposed as fluorogenic reagents to spray upon polar pesticides deposited on cellulose [87] and silica gel [88] thin layers. A number of flavonol (II) derivatives (unsubstituted in the five position) almost non fluorescent in non polar media, exhibited a dramatic fluorescence enhancement in a polar environment [87].

Mallet and Frei [87,88] exploited such polarity effects to detect a large variety of pesticides separated by TLC. The developed chromatoplates were sprayed with flavone compounds, resulting in a fluorescent spot appearing at the location of the pesticide on a weakly-fluorescent or non fluorescent background. It was theorized that the pesticide increased the medium polarity locally, producing a fluorescence enhancement of the flavone in the spot area. Although not selective, the technique was applied to carbamates, organophosphorus insecticides *s*-triazine herbicides, organochlorine pesticides, chlorophenoxy-acid herbicides, and phenylurea insecticides, with LODs between 10 and 100 ng [87,88].

Among the flavones derivatives under study, robinetin produced the best result and was preferred over fisetin and flavonol because of its low background fluorescence [88].

(II) flavonol: (3- hydroxyflavone)

(III) fisetin: (3, 3', 4' 7- tetrahydroxyflavone)

(IV) robinetin: (3, 3', 4', 5', 7- pentahydroxyflavone)

(V) morin: (2', 3, 4', 5, 7- pentahydroxyflavone)

(VI) quercetin: (3, 3', 4', 5, 7- pentahydroxyflavone)

Scheme 2.

2.2.4. Complexation reactions

Complexation reactions have been widely used for pesticide residue determination in the environment. Two approaches have been developed for this purpose, including (i) a direct complexation method which leads to the formation of a strongly fluorescent pesticide–ligand complex [79,89–93]; and (ii) an indirect approach, based on a ligand-exchange reaction [94].

Organotin compounds have been frequently employed in agriculture as fungicides and insecticides. Flavonol(II), morin(V) and quercetin(VI) can form fluorescent complexes with both inorganic and organic tin compounds [79,89,90]. The morin–organotin complexes are the most convenient, because they form rapidly at room temperature and lead to a very sensitive assay. They are also stable for long periods in organic solvents [89], (*n*-hexane, ethylacetate) but are poorly soluble in aqueous media [90]. Morin is especially sensitive to dialkyltin compounds. In a stationary medium, LODs are 10^{-9} M for dialkyltins, 10^{-7} M for monoalkyltins, 5×10^{-7} M for trialkyltins, and 10^{-7} M for triphenyltins [79]. The recoveries of the same organotins compounds in spiked human urine and various rat organs at 1–100 nmol levels range from 91.0 to 99.7%, depending on the organotin species. A simultaneous determination of dialkyltin compounds and their possible metabolites was conducted using HPLC on a cyanopropyl-bonded column after post-column morin derivatization. LODs between 0.1 and 1 ng and recoveries of 91–99% were found for dialkyltin compounds added to animal tissues at the 5 nmol level. Langseth [90,91] has described a method requiring only a single HPLC pump by incorporating the ligand in the mobile phase. This approach is based on an eluent containing morin or another complexing agent; it appears to have considerable potential for determining different organotins compounds at low picogram levels. Furthermore, the use of an epifluorescence microscope as an imaging detector [92] and micellar solutions [93] permits the improvement of detection limits for ultratrace measurements and to increase the solubility of organotin–morin complexes in aqueous media.

Fig. 1. Ligand exchange reaction scheme between non fluorescent metal/calcein and pesticide/metal complexes

Metal chelates have also been utilized for the fluorimetric analysis of pesticides. A complexation technique named ligand-exchange reaction has been applied by Bidleman et al. [94] to the TLC analysis of 16 organophosphorus pesticides. In this method, based on the fluorescence of a metal chelate, calcein [94]—two steps take place successively: (i) formation of a complex between a fluorescent ligand and a metal (M); and (ii) introduction of the pesticide which induces the release of the fluorescent ligand and then recomplexes with the free metal, (Fig. 1). The amount of added pesticide is proportional to the free calcein concentration, measured by its fluorescence signal.

Calibration curves are linear over a 10–15 fold range, according to the insecticide and calcein-metal spray used. LODs are 10–50 ng for phosphorodithioate and 50–100 ng for phosphorothioate pesticides. Relative standard deviations are less than 15%. The mean recovery of cygon from spiked samples of local lake water is $102 \pm 8\%$. The reaction between palladium and pesticides does not readily occur in solution but only in the adsorbed state.

Although the spray techniques are rapid and simple, they are not selective, and are therefore rather susceptible to interference. An alternative method is fluorogenic labelling, which involves fixing a fluorophore to the analyte, it can be determined fluorimetrically, using TLC or HPLC rather than batch procedures.

2.2.5. Fluorogenic labelling

This pretreatment method is the most widely used for pesticide analysis, probably because of its high sensitivity, which depends on the type of fluorogenic labelling reagent [9,13]. Fluorogenic labelling involves fixing a fluorophore molecule to a non fluorescent analyte; in this process, only a hydrogen atom or a single atom of the analyte is substituted by the fluorophore moiety. Lawrence and Frei [95,96] determined pesticides using fluorogenic labelling with dansyl chloride (dans-Cl). At present, four types of labelling reagents, including dans-Cl, NBD chloride (NBD-Cl), fluorescamine and orthophthalaldehyde with 2-mercaptoethanol (OPA/2-ME) or with 3-mercaptopropionic acid (OPA/3-MP) are used in pesticide residue analysis [9–11,97]. They react easily with alkylamines, arylamines, thiols and phenols, which are widely found among the pesticide reaction products. For instance, carbamates are hydrolyzed into amines and phenols [96,98], urea herbicides lead to aniline derivatives [99,100], many organophosphorus insecticides yield thiols and phenols upon hydrolysis [101], and the *s*-triazine herbicides are hydrolyzed into alkylamines [102]. For numerous pesticides, the labelling reaction mechanism is usually a two-step process which is simple, rapid, and selective, the first step is pesticide alkaline hydrolysis, the second step, fluorogenic labelling of the hydrolysis products. Dans-Cl and NBD-Cl are generally used as pre-column derivatization reagents, while fluorescamine and OPA/2-ME are more suitable for

Fig. 2. Reaction scheme for dans–Cl labelling of *N*-methylcarbamate insecticides, ([95,96]). (1) Hydrolysis of the carbamate into phenol and methylamine: performed in 1 M sodium carbonate solution for 10–30 min at 45°C. (2) and (3) labelling of the hydrolysis products: the coupling reaction proceeds faster than the carbamate or the reagent hydrolysis, and it was generally carried out in a water-miscible solvent (acetone, dioxane, acetonitrile) for 20 min at 45°C. (4) Complete hydrolysis of dans–Cl by carbonate into sulfonic acid. Then, the dans–Cl derivative is extracted from the alkaline aqueous solution with non-polar solvents (hexane, benzene, cyclohexane), while sulfonic acid remains in the aqueous phase. The organic phase is then dried and used for analysis. Such a reagent would obviously not be suitable for post-column derivatization, since the reagent is highly fluorescent itself and the reaction kinetic is too slow.

post-column derivatization. Several examples of labelling reaction mechanisms are given, for several classes of pesticides, in the following paragraphs

2.2.5.1. Labelling with dansyl chloride. Dans–Cl readily reacts with primary and secondary amines, at slightly higher pH, with phenols, some thiols and to a lesser extent, with aliphatic alcohols. The derivative products are more fluorescent than dans–Cl [95,96,103–105].

The procedure employed by Lawrence and Frei [95,96], i.e. the hydrolysis of carbamate into phenol and methylamine, is followed by the reaction

of dans–Cl with both hydrolysis products. (Fig. 2) Generally, the phenol derivative is chosen for quantitation since it is characteristic for each carbamate [96]. The technique has been applied to the detection of carbamates in water and soil samples [103] without additional clean-up procedures. LODs are in the low nanogram range (Table 3).

Solvents also have a significant effect on both the dansylation reaction and the extraction process [105]. The fluorescence characteristics of dansyl–phenol derivatives vary significantly with the dielectric constant of the solvent. Apolar solvents such as hexane, cyclohexane and benzene generally increase the fluorescence intensity and shift

the emission wavelength towards the blue, whereas polar hydrosoluble solvents reduce the fluorescence intensity and produce a red-shift of the emission maxima. The dansylation reaction of most carbamates does not occur in non hydrosoluble solvents such as chloroform and methyl isobutyl ketone (MIBK). In contrast, a two-phase solvent system is preferred for organophosphorus pesticides while the phenylureas hydrolysis products have to be extracted before the coupling reaction. A concentration excess of dans–Cl (10 times) over carbamate is required, and complete hydrolysis of the remaining dans–Cl into sulfonic acid is necessary to avoid high blank signals.

Fig. 3 shows an example of the labelling mechanism with linuron, a phenylurea herbicide [99].

After alkaline hydrolysis of the herbicide the released aniline derivative is extracted with hexane from the hydrolysis mixture, spotted on a TLC plate, and reacts in situ with a 10-fold excess of dans–Cl. A 300 ng linear dynamic range, a 1-ng detection limit and reproducibility (3–5%) are obtained (Table 3).

Dans–Cl labelled organophosphorus insecticides such as fenthion, ruelene, fenchlorphos and parathion, yield phenols upon hydrolysis and are detected in the low nanogram range [101]. After alkaline hydrolysis the coupling reaction is carried out in a two-phase system, at the interface—water:MIBK, the resulting dansyl–phenol is extracted with benzene and analyzed by quantitative in situ TLC and HPLC. (Table 3)

Scheme 3.

Dans-Cl labelling has also been applied to *s*-triazine herbicides (atrazine, simazine, propazine) [102]. Hydrolysis (Scheme 3) is carried out in an acidic medium, the resulting mixture is then made alkaline: the released alkylamines are coupled with dans-Cl (Fig. 2).

2.2.5.2. Labelling with NBD chloride. NBD-Cl only reacts with primary and secondary aliphatic amines under weakly basic conditions to form highly fluorescent derivatives. It is more selective than dans-Cl since it does not form fluorescent derivatives with phenols, thiols, alcohols or anilines. Unlike dans-Cl, the NBD-Cl hydrolysis product is non fluorescent and does not interfere in quantitative analysis. In addition, the NBD-Cl fluorescence excitation ($\lambda_{\text{ex}} \approx 470\text{--}480$ nm) and emission ($\lambda_{\text{em}} \approx 530\text{--}550$ nm) maximum wavelengths are located in the visible region of the spectrum, where there is no interference from naturally fluorescent compounds that may be present as co-extractives. Therefore, a quantitative labelling method based on NBD-Cl has been developed for the determination of *N*-methyl and *N,N*-dimethylcarbamate pesticides in aqueous solutions [106] (Fig. 4). The reaction rates, as well as fluorescence and TLC properties were investigated to optimize the technique, subnanogram quantities of pesticides were detected.

The advantage of NBD-Cl labelling method is its selectivity, since only one fluorescent derivative is produced with most carbamates, which eliminates possible interference. Its disadvantages include its inability to distinguish between carbamates of different classes.

2.2.5.3. Labelling with fluorescamine. Fluorescamine, a powerful fluorogenic reagent, was synthesized by Weigle et al. [107]. It reacts directly with primary aliphatic amines in aqueous medium (pH 8–10) at room temperature in less than a second, yielding a highly fluorescent derivative. Fluorescamine itself is non fluorescent and excess reagent is hydrolyzed in a few seconds, producing non fluorescent products [108]. The large rate of the reaction and its good selectivity makes it suitable for post-column HPLC detection of primary amines, (Scheme 4). In addition to its affinity for aliphatic amines, fluorescamine can react with primary aromatic amines in aqueous media [109].

Fluorescamine has been widely used as a labelling compound for the determination of amine-generating pesticides [9,110–112]. The reaction mechanism is similar to dans-Cl labelling of amines and has been carried out on amines obtained either by hydrolysis of carbamates [110,111], or by reduction of some nitrosubstituted pesticides such as fenitrothion, and parathion methyl [112], LODs are in the ng ml^{-1} range (Table 4).

2.2.5.4. Labelling with orthophthalaldehyde/2-mercaptoethanol (OPA/2-ME). Initially OPA was applied to the HPLC analysis of seven *N*-methylcarbamate insecticides [97]. OPA selectively reacts with primary aliphatic amines. The reaction mechanism involves two steps: the alkaline hydrolysis of carbamate into methylamine and alcohol, and the derivatization of the released methylamine with OPA in the presence of 2-mercaptoethanol (2-ME) [97,113–135] or 3-mercapto-propionic acid (3-MP) [129,136] to form a highly

Fig. 4. Reaction scheme of the labelling of *N*-methylcarbamate insecticides with NBD-Cl, ([106]). (1) Hydrolysis of the insecticide in aqueous buffer phase. (2) Labelling of methylamine in an organic methyl isobutyl ketone (MIBK) phase. Due to the low solubility of NBD-Cl in water, the labelling reaction with methylamine was carried out at a water:MIBK interface. The coupling reaction is faster in polar solvents such as alcohols and ketones. Performed at 80°C, using a 1% NBD-Cl in MIBK solution, the reaction completed in about 30 min. NBD-Cl is not suitable for post-column derivatization because the reaction kinetics is too low.

fluorescent isoindole derivative identified by NMR and mass spectrometry [137] (Fig. 5). Most studies employing OPA and 2-ME or 3-MP are based on post-column HPLC derivatization, since the reagents can be easily introduced in the reaction system by successive pumps (Fig. 6).

HPLC post-column reaction derivatization parameters have been optimized by Krause [138,139] and Engelhardt et al. [140]. The OPA/2-ME HPLC method which has been recognized by the US Environmental Protection Agency (EPA) [141] is widely used as a multiresidue method for *N*-methylcarbamate and carbamoyloxime insecticides determination in food [119,120,139] as well as in a variety of media including water [115–117,123,127,131,134,135,142], soils [115,132,135], and plant tissues [114,118,121,122,124,126,132,133,140]. De Kok et al. [124] extended the method

to other *N*-methylcarbamates, and developed a simple clean-up method which is applicable to various types of crop samples.

Nondek et al. [142,143] significantly improved the OPA/2-ME method, by hydrolyzing carbamates at 100–120°C, in a catalytic solid-phase reactor packed with a strong anion exchanger resin, (e.g. Aminex A-28, a tetralkylammonium anion exchanger). This approach eliminates one of the post-column reagent delivery pumps avoiding possible mixing problems and flow pulsations. Moreover, it suppresses band broadening due to dilution of the analyte in the mobile phase, thus improving the sensitivity and selectivity of the method. In these conditions, as little as 0.1 ng aldicarb and 0.3 ng methomyl can be detected [143]. Jansen et al. [144] miniaturized the catalytic solid-phase reactor using 1-mm i.d. narrow-bore HPLC columns, and obtained LODs in low

Scheme 4.

nanogram range. Furthermore, De Kok et al. [130] applied solid-phase catalysis to the determination of 22 *N*-methylcarbamates and their major metabolites in crop samples. Magnesium oxide was substituted as anion exchanger resin, which minimized band broadening.

Another useful simplification—the hydrolysis and derivatization steps were combined by means of a single reagent, (OPA/2-ME in 0.01 M KOH) delivered by a single post-column pump [129]. This feature eliminates the need for both an alkali post-column pump and solid-phase or photolytic reactors. LODs were about 0.1 ng for 11 *N*-methylcarbamates. This single-step technique has also been applied to the analysis of oxamyl in potatoes [145] and oxamyl and methomyl in crops and water samples (LOD: 1 ng) [146]. This single-step post-column derivatization method is more convenient than the two-step conventional technique since sensitivity is increased, the hardware and cost are reduced and the daily procedure is simplified.

Among all the derivatization methods, OPA/2-ME labelling remains the most sensitive and practical for the analysis of pesticides yielding primary amines under hydrolysis or photodegradation. *N*-methylcarbamate and carbamoyloxime insecti-

cides, and to a lesser extent, herbicides [147], plant growth regulators [148], and phenylureas [113,139,144] have been determined using this technique. Generally the LODs range from the low ng ml⁻¹ to upper pg ml⁻¹ according to the compound (Table 3).

2.2.5.5. Labelling with other reagents. Other pesticide labelling reagents [76,78] exist, but have not as yet gained widespread acceptance. For example, Suzuki et al. [76] used 9-anthryldiazomethane, as a labelling reagent to detect about 500 pg of chlorophenoxyacid herbicides in ground water. A rapid determination of glufosinate was also performed in environmental water samples using 9-fluorenylmethoxycarbonyl, with pre-column derivatization at 0.25 ng ml⁻¹ in less than 15 min [78].

2.2.5.6. Advantages and drawbacks of fluorogenic labelling. Generally speaking, fluorogenic labelling constitutes a sensitive analytical procedure which as yet presents poor selectivity. As compared with other derivatization methods (hydrolysis, heat treatment etc.), fluorogenic labelling offers a number of advantages, simplified optimization procedures, dual or multiresidue methods, wide range

Fig. 5. Reaction scheme of OPA/2-ME labelling of a monomethyl carbamate insecticide. ([132]). (1) Hydrolysis. (2) Labelling of the liberated methylamine to (1-hydroxy-ethylthio)-2-methylisindole,

of labels and accessible experimental variables with ideal sensitivity. However, limitations exist due to problems associated with the simultaneous detection of individual components in mixtures, the development of HPLC has significantly improved the selectivity of the labelling method relative to the originally-used TLC [95,96], and other time-consuming procedures in stationary solutions [105].

The labelling reagents should be sufficiently stable and the derivatization reaction must be fairly rapid to provide a short residence time in the post-column reactor.

3. Photochemically-induced fluorimetric (PIF) methods

The concept of photochemically-induced fluorimetry (PIF) is based on the conversion of non fluorescent analytes into strongly fluorescent photoproduct. PIF is more recent than chemical derivatization and has been much less applied to pesticide quantitative analysis. Several chapters in various books have been devoted to PIF methods [16–18]. In addition to its simplicity, these methods present several advantages, but also have

some drawbacks, relative to derivatization methods.

The main advantages are as follows: (i) the use of photons for analyte conversion instead of a chemical reagent means it does not require a mixing system, and therefore, the analyte must not be diluted; (ii) since most photochemical reactions take place via free radicals, the reactions rates are generally fast, resulting in short conversion times; (iii) the use of room temperatures constitutes an advantage of a photoinitiated in situ analyte conversion, relative to thermally-initiated derivatization; (iv) the technique is very easy to implement, requires inexpensive equipment and is suitable for various experimental conditions such as stationary liquid solutions [149–151], dynamic systems, including flow injection analysis (FIA) [23,152,153], HPLC [154–160] and TLC[161].

Obviously, PIF provides a selective fluorogenic transformation of non fluorescent compounds since it does not require the usual separation of fluorescent photoproduct from other photoproducts in the reaction medium. This simplicity is brought about by the fact that the photochemical conversion of pesticides in solution occurs either by the direct photolysis mechanism in which the

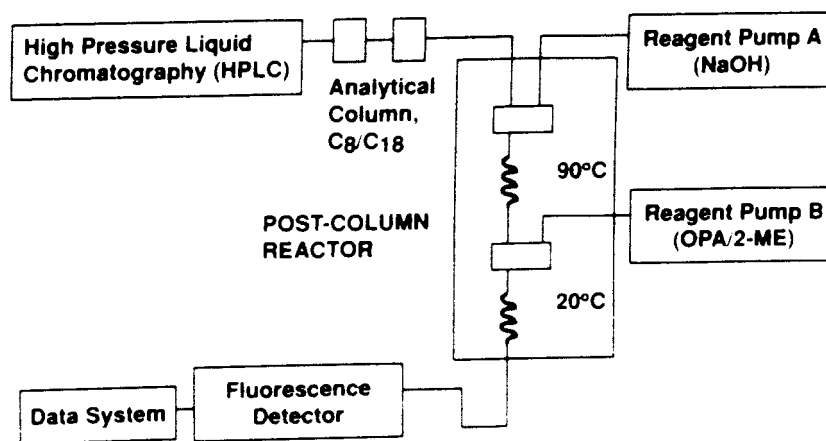

Fig. 6. Schematic diagram of carbamates post-column HPLC derivatization, using OPA/2-ME, ([132], with permission).

compound directly absorbs the incident radiation, or by an indirect photolysis process in which an additional compound acts as a photosensitizer and transfers absorbed energy or generates an active oxidizing species.

From an analytical point of view, another advantage is that it is not really necessary to identify the structure of the fluorescent compound(s) formed after UV irradiation, provided that reproducible PIF signals are obtained. However, photoproducts identification could be helpful and is recommended not only for academic relevance, but to ensure the applicability of PIF to the quality control of different types of samples, especially in environmental studies. In some cases, PIF simultaneous determination of a mixture can be performed without a prior separation step, using different optimum UV irradiation time (t_{opt}) values—characteristic of each compound—[149,162] or by applying specific techniques, such as derivative PIF spectra, and/or partial least square (PLS) multivariate method [163].

PIF has some drawbacks, such as the formation of non fluorescent photoproducts; secondary thermal reactions and/or photoreactions leading to non stable and difficult to identify photoproducts, particularly those responsible for fluorescence emission [18].

Generally, PIF conversion methods have proven to be efficient fluorophore-generating systems for stationary media [149–151] as well as

flowing devices such as HPLC post-column photoreaction [152,154–158] or FIA [23,152,153] method. Several parameters affecting the analyte conversion reactions have been investigated. It was found that two parameters affect the sensitivity of the method, namely the UV irradiation time [149,162] and the type of solvent used [149,152,156,162]. In fact, t_{opt} and PIF intensity values vary considerably with solvent polarity and its protic or aprotic character. For example, pesticides such as fenvalerate, deltamethrin and diflubenzuron have a good affinity for protic solvents (i.e. high PIF intensity with short t_{opt}), while for fenitrothion and chlorpyrifos, polar aprotic solvents are a better choice [149,162]. Therefore, for analytical purposes, the solvent selected should be one giving the shortest t_{opt} and the largest PIF signal. When these ideal conditions are not matched by any solvent, the solvent having the shortest t_{opt} is generally chosen even if PIF intensity is not the strongest [162].

3.1. Photochemical reactivity and photodegradation pathways

The photochemistry and photodegradation pathways of several classes of pesticides have been investigated by a number of workers [164–181].

The photochemical degradation of herbicides is well documented. Plimmer [164] has summarized the photochemical loss of chlorine mechanism

from halogenated aromatic herbicides. Crosby [165] has reviewed in detail the effect of UV irradiation time on nitrophenol and chlorophenol derivative herbicides. The photolytic dehalogenation is a well known and an important degradation pathway for chlorophenoxyacid herbicides, and the main photoproducts are identified as lower chlorinated phenols, dihydroxylated products, phenols and polymers [166–168]. Hence, the occurrence of a photolytic dechlorination mechanism explains the relatively high fluorescence efficiency generally observed for chlorophenoxyacid and chlorophenol pesticide photoproducts [150,153,154].

The study of the photodegradation pathway of phenylurea herbicides indicates that one of the photoproducts is dimethylamine [169,170]. This observation led Luchtefeld [155] to believe that the photolysis of phenylureas herbicides may also produce methylamine which could then react with OPA/2-ME.

The photodegradation mechanism of pyrethroid insecticides has been widely investigated. Ruzo et al. [171–174] have elucidated the photodecomposition steps of several pyrethroid insecticides including deltamethrin [172], while Mikami et al. [175] found that fenvalerate photodegradation rates and pathways depended on environmental conditions (soils, water, ...).

The photolytic degradation of organophosphorus insecticides [176–180], carbamates [21,180] and chlorotriazines [180] have also been studied. Sometimes, in the presence of a sensitizer, several compounds, otherwise inert may undergo photodegradation reactions. For instance, Ross and Crosby [181] have shown that the addition of acetone as a sensitizer increased the disappearance of ethylenethiourea under natural and artificial light. Furthermore, it has been demonstrated that photolysis reactions can improve the indirect fluorescence detection of several aromatic or non aromatic compounds [16–18].

3.2. PIF related mechanisms

Since the application of PIF to pesticide determination is relatively new, very few and fragmentary studies have been devoted to describing the

photoinduced mechanisms of formation of fluorescent photoproduct(s) [149,152,154]. No systematic identification of the exact nature of fluorescent (or non fluorescent) photoproduct(s) formed during the photolysis reactions has been reported. Some authors [149,152] have suggested that the photodegradation pathways of aromatic pesticides probably involve some changes in the aromatic moiety of the molecules under study. However, the identification of a number of photoproducts during the photolysis of fenitrothion [177], fenvalerate [175] and deltamethrin [171,172] in various experimental conditions demonstrates the great complexity of photolysis mechanisms.

In the case of the photolysis of four aromatic pesticides, including deltamethrin, diflubenzuron, fenitrothion and fenvalerate, Coly and Aaron [149] have proposed the existence of two distinct types of mechanisms based on different curves of PIF intensity vs. irradiation time. Further investigations have allowed the same authors [162] to identify the nature of the fluorescent photoproducts obtained during the photolysis reaction of three of these pesticides, (fenitrothion, fenvalerate and deltamethrin) (Fig. 7).

3.3. PIF application to pesticides analysis

Comparing the analytical performances of the PIF method with other fluorogenic derivatization techniques, several workers have highlighted the main advantages of this technique, including simplicity, shorter analysis time, enhanced sensitivity and selectivity. The following results have been reported for pesticide PIF analysis.

Werkhoven-Goewie et al. [154] were probably the first to apply PIF to the liquid chromatographic analysis of chlorophenol pesticides in effluent water samples and biological fluids. The fluorescence signals of photolysed chlorophenols were linearly related to the amounts of analyte over 2–3 orders of magnitude. The LODs were in the low nanogram range and recoveries from spiked river water samples were $100 \pm 4\%$.

Since the chemical hydrolysis of urea compounds was generally inefficient [139], Luchtefeld [155] modified this step to produce a larger amount of methylamine which can react with

Fig. 7. Reaction scheme for the photolysis of fenitrothion (acetonitrile + 1% DMSO), fenvalerate (acetonitrile), and deltamethrin (methanol) into fluorescent derivatives, (Coly and Aaron, (unpublished)).

OPA/2-ME after photolytic degradation of 14 phenylurea herbicides. Linear dynamic ranges between 2 and 48 ng, with correlation coefficients larger than 0.99 were found. Herbicides with *N,N*-dimethyl group give a greater response than those with an *N*-methyl, *N*-methoxy moiety. The selectivity of the PIF method was compared with that of UV absorption detection in the case of herbicides extracted from carrots. This PIF labelling technique has the advantage of eliminating the need for the alkali reagent post-column pump shown in Fig. 6.

The applicability of the amine-generating photolysis reaction of pesticides OPA/2-ME derivatization was extended by Moye et al. [152,156–158] to a broad range of different

classes of nitrogenous pesticides including carbamates, carbamoyloximes, carbamothioic acids, dithiocarbamates, organophosphorus, sulfonyleureas, thiadiazolureas, thioureas, bipyridiniums, triazines, dinitrophenols, amides, acetamides and amines. Among the various compounds, carbamoyloximes produced the highest yield of methylamine [157]. PIF detection was used with [152,155–159] and without OPA/2-ME [152,156,157].

A post-column photolysis fluorescence detector, combining HPLC and PIF allowed these researchers to determine several classes of pesticides such as phenylcarbamates, phenylamides and phenylurea herbicides [157]. Linear calibration curves were obtained over two orders of magni-

tude, while LODs were in the low nanogram range. The same authors applied HPLC post-column photolysis and fluorogenic labelling with OPA/2-ME to the analysis of five pesticides including aldicarb sulfoxide, aldicarb, propoxur, thiram and neburon, in three fortified ground water samples, at 10–50 ng ml⁻¹ level, (Table 4). Using the same HPLC or FIA apparatus, Patel et al. [152,158] measured the PIF signal of several nitrogenous pesticides. Several solvent systems were evaluated as typical reversed-phase mobile phase, and the use of surfactants as photosensitizing agent was found to increase the PIF response of most pesticides. The LODs [152] ranged between 5 and 50 ng ml⁻¹, (Table 4). This laboratory-made post-column PIF detector gave satisfactory results with and without OPA/2-ME. Another interesting feature is that many pesticides that gave a good PIF response did not give any signal when the alkaline hydrolysis OPA/2-ME detection system was used [113]. However, aromatic carbamates were found to be rather slowly photolysed [21,180], thus leading to a low yield of methylamine photoproducts. Therefore, in the case of the latter compounds as well as non aromatic pesticides (i.e. aldicarb, aldicarb sulfone, methomyl...), the use of a sensitizing agent such as acetone [152,158] is recommended to enhance the photoconversion ratio.

PIF application with a normal-phase HPLC, on a cyanopropyl-bonded silica stainless steel column coupled on-line with post-column photoconversion and morin (V) complexation has been described by Stab et al. [160] for the determination of low nanogram amounts of triorganotin pesticides in surface water, sediments and soils. An advantage of this PIF complexation technique was the very short reaction times (Table 4). Another useful PIF approach based on complexation with morin and combined with TLC was also applied by Brown et al. [161] to screen phenyltin fungicides in potato extracts down to 0.01 ppm.

PIF detection coupled with FIA has been also reported by Aaron et al. [23,153] for the determination of several types of aromatic pesticides. The interest in this system for improving the sampling rate has been clearly demonstrated. Indeed, as many as 60 samples can be analysed per hour,

with satisfactory recoveries (88–109%) and LOD values ranging from lower nanogram to upper picogram levels (Table 4).

PIF has been used in stationary media, allowing fluorescent photoproducts to be obtained from four naturally non fluorescent aromatic insecticides viz., fenitrothion, fenvalerate, deltamethrin and diflubenzuron [149]. The PIF properties of these insecticides were investigated in various solvents. The LODs range from 0.7 to 33 ng ml⁻¹ according to the compound, with relative standard deviations of about 2.5%. The use of aqueous anionic micellar media improves the sensitivity of PIF in some cases [151]; i.e. the LODs of pyrethroid insecticides are 2.2–2.5 times lower in sodium dodecyl sulfate (SDS) micelles than in the common organic solvents. Eremin et al. [150] used the same procedure to determine several widely-used chlorophenoxyacid herbicides in spiked river water samples. The photolysis time is about 15 min. LODs vary from 36 to 179 ng ml⁻¹.

We can conclude that the usefulness of PIF for quantifying several classes of pesticides with good sensitivity and selectivity has been demonstrated. The combination of the PIF technique with dynamic systems (TLC, HPLC, FIA) is currently making progress and future developments of this method are expected.

4. Photosensitized fluorimetric (PSF) methods

When the analyte is weakly or non fluorescent and its irradiation also leads to weakly or non fluorescent photoproducts, it becomes necessary to photosensitize the photoreaction. In this case, anaerobic photoreduction reactions of sensitizers such as aromatic ketones by hydrogen atom-donating (HAD) compounds like aliphatic alcohols, aldehydes, saccharides, glycosides, amines and steroides are generally used [182–185]. The aromatic ketones employed as sensitizing reagent are quinone [182,183] and anthraquinone derivatives [19,184,185]. The mechanism of photosensitizing process is known to occur via the sensitizer triplet state [19]. An asset of the photosensitized fluorimetric (PSF) method is that it can be applied either to

the detection of HAD compounds [19,184] or to that of quinones themselves [182,183].

However, the use of this method in pesticide residue analysis has been very limited until now. Traore and Aaron [184] have sensitized the fluorescence of four naturally non fluorescent dinitroaniline herbicides, using anthraquinone. The PSF signal was found to be proportional to the herbicide concentration. The LODs ranged from 0.3 to 4 $\mu\text{g ml}^{-1}$, and the optimal irradiation times were short (<5 min), resulting in a decrease in analysis time. PSF can be considered a rapid and precise method for the analysis of dinitroaniline herbicides.

5. Conclusions and future trends

Obviously, pesticide residues from crops and environmental samples can be handled and analysed using a number of techniques. Pesticide analysis requires selective as well as sensitive detectors. At present, an important trend is to directly monitor the analytes by GC and/or HPLC with UV (including diode array) plus MS detection, since these tools generally yield the type of information required by the environmental and health legislations.

Due to its great sensitivity, fluorescence detection is very useful in pesticide analysis, but because of its selectivity, it cannot be the recommended method for pesticides screening or early-warning procedures. Nevertheless fluorescence detection is an important aid in environmental analysis, especially when monitoring specific analytes and, occasionally, a class of compounds such as carbamates and chlorophenoxy acids. Moreover, derivatized fluorescence and photochemically-induced fluorescence (PIF) are adaptable to various experimental conditions such as TLC, stationary liquid solutions, and flow systems, including HPLC and FIA. As a result of its procedural simplicity PIF seems to be more convenient and rapid than fluorogenic derivatization, for pesticides analysis. In addition, the inability of direct or indirect fluorimetric methods for determination of pesticides containing neither chromophores nor fluorophores should be overcome

in some specific cases by using photosensitized fluorimetry.

Other developments, including the use of organized media, (cyclodextrins, micelles, liposomic vesicles), special spectral techniques (synchronous, derivative spectra, variable angle scanning spectra,...), and statistical treatments of the spectral data such as partial least squares regression (PLS), should help fluorescence and photochemically-induced fluorescence to become valuable complementary approaches for environmental analysis of pesticides.

No doubt, because of these recent technological advances and their inherent sensitivity, selectivity, and versatility, fluorescence methods will continue in the future to find numerous applications in environmental complex matrices and to be widely employed for trace analysis in pesticide research.

Received 2 January 1997; received in revised form 24 July 1997; accepted 29 July 1997

Abstract

A flow-injection method for the simultaneous determination of iron and zinc in the human hair with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) using a pH gradient technique has been developed. The linear range for the determination of iron is 0.1 ~ 1.8 $\mu\text{g ml}^{-1}$ and for zinc is 0.2 ~ 5.0 $\mu\text{g ml}^{-1}$. About 20 ~ 30 samples can be determined in 1 h. The proposed method is simple, rapid and accurate. It has been applied to the simultaneous determination of trace amounts of iron and zinc in the human hair with satisfactory results. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Iron; Zinc; Simultaneous determination; Flow injection

1. Introduction

Flow injection analysis (FIA) is a simple, rapid, precise, highly reproducible technique which has advantages of exhausting little reagent and can be easily automated. It has recently, developed very quickly. Owing to the need for simultaneous fast monitor and control of multicomponents in clinical, environmental, industrial in-line analyses and other fields, much attention has been paid to simultaneous determination of multicomponents by FIA [1–8]. A pH gradient technique, constructed from a flow-injection system, is that ac-

ording to the different pH value of the reaction of chromogenic reagent with different metallic ions, simultaneous determination of multicomponents is realized by making different metallic ions encolor at the same time in pH gradient between sample plug and carrier. By this method, D. Betteridge et al. reported simultaneous determination of lead and vanadium [9]; nickel and copper [10]. S. Baban, reported simultaneous determination of bismuth, thorium and copper [11] and R. Liu et al. of copper and zinc [7]. But simultaneous determination of iron and zinc has not been reported.

This paper proposes a pH gradient technique in the FIA system for simultaneous determination of iron and zinc by using 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) as a chromogenic reagent with satisfactory results.

¹ Project supported by the Natural Sciences Foundation of Liaoning Province, China.

5-Br-PADAP is an analytical reagent with a high degree of sensitivity [12], it reacts with iron at pH 3 ~ 8 and with zinc at pH 5 ~ 8, the absorption maximum wavelength of the two complexes are the same and the determination conditions were identical. When iron and zinc were determined by using the pH gradient technique, a large volume of pH 3.0 sample solution was injected into the pH 7.5 carrier stream. A constant pH gradient might be formed between the sample plug and the carrier in a flowing process of the sample solution with the carrier. Because the pH value at the center of the sample band was 3.0, only the iron complex could be formed, while the pH value at the two ends of the sample band was 7.5 because the dispersion of the carrier and the two complexes of iron and zinc could be produced simultaneously. Thus, from the absorbance signals at the center and at the two ends of the sample band, iron and zinc were quantified, respectively and simultaneous determination of them was realized.

2. Experimental

2.1. Reagents

Analytical-reagent grade chemicals and deionized water were used throughout.

2.1.1. An iron (III) stock solution

An iron (III) stock solution (1.000 mg ml^{-1}) was prepared by dissolving 1.0000 g of pure iron (99.99%) in 15 ml of 8 M nitric acid and diluted to volume in a 1000-ml calibrated flask with water. Working solutions were prepared by suitable dilution of the stock solution with masking agent solution.

2.1.2. A zinc stock solution

A zinc stock solution (1.000 mg ml^{-1}) was prepared by dissolving 1.0000 g of pure zinc (99.99%) in 15 ml of 6 M hydrochloric acid and diluted to volume in a 1000-ml calibrated flask with water. Working solutions were prepared by suitable dilution of the stock solution with masking agent solution.

2.1.3. Mixed chromogenic reagent solution

80 ml of $5 \times 10^{-4} \text{ M}$ 5-Br-PADAP ethanol solution and 120 ml of 1% emulsifier OP solution were mixed and the pH value of the solution was adjusted to 3.0.

2.1.4. Carrier

A total of 6.8 g of potassium dihydrogen phosphate and 1.6 g of sodium hydroxide were dissolved in 900 ml of water. The pH of the solution was adjusted to 7.5 and the solution diluted to 1000 ml.

2.1.5. Masking agent

Ten g of thiourea and 2.0 g of ascorbic acid were dissolved in 1000 ml of water and the pH value of the solution was adjusted to 3.0.

2.2. Apparatus

The flow-injection manifold used is shown in Fig. 1. The peristaltic pump and injection valve were supplied by Shenyang Zhaofa Analytical Instruments Research Institute. A Model 722 spectrophotometer (Shanghai Third Analytical Instruments Factory) with a flow cell was used as the detector. Absorbance signals were recorded with a Model WXT-204 Table-type equilibrium automatic recorder (Shanghai Dahua Instruments Factory). A Model pHS-3 pH meter (Shanghai Second Analytical Instruments Factory) was used to measure the pH values of the solutions.

Fig. 2. Absorption spectra of iron and zinc complexes. 1. iron-5-Br-PADAP; 2. zinc-5-Br-PADAP.

2.3. Procedure

The flow injection system is shown in Fig. 1. Teflon pipes with an interior diameter of 0.7 mm were used as reaction tubes and linking tubes. The pH of the sample solutions was adjusted to 3.0 with the masking agent and the main parameters of the adjusted apparatus were: pump rate, 4.2 ml min⁻¹; the volume of the sample cycle of taking sample valve, 1000 μ l; the interval of taking sample, every 80 s; injecting time, every 60 s. Then the sample solutions were injected into the carrier stream and the absorbance was measured in the flow cell at 560 nm. The transient signal was recorded as a peak, the height of which was proportional to the iron and zinc concentration in the sample. The first and third peaks correspond to the sum of iron and zinc present, and the second to iron only.

3. Results and discussion

3.1. Measurement wavelength

In the presence of nonionic surfactant OP, 5-Br-PADAP reacts with iron and zinc to form red

soluble complexes. The absorption spectra of complexes are shown in Fig. 2. The absorption maximum of two complexes was located at 560 nm. Therefore, a wavelength of 560 nm was chosen for the determination.

3.2. Effect of reaction acidity

The effect of acidity on the absorbance of the complexes was studied. The results obtained are shown in Fig. 3. 5-Br-PADAP reacts with iron at pH 3 ~ 8 and with zinc at pH 5 ~ 8. Based on this characteristic, when a large volume of pH 3.0 sample solution was injected into pH 7.5 carrier, the transient signal shown in Fig. 4 could be obtained according to the principle of pH gradient. Only iron complex could be formed because the pH value was 3.0 at the center of sample plug, so the absorbance signal of the zinc complex went back to the basic line and only the absorbance signal of the iron complex appeared at the center of the mixed signals. But at the two ends of the mixed signals the absorbance was the sum of iron and zinc complexes because the pH value was 7.5 as a result of the dispersion and buffering of the carrier.

Fig. 3. Effect of pH on the absorbance. 1. iron complex; 2. zinc complex.

3.3. Effect of concentration of reagents

The experiment results showed that both complexes had a higher and more suitable absorbance in the reagent solution containing $1.75 \times 10^{-4} \sim 2.75 \times 10^{-4} \text{ mol l}^{-1}$ of 5-Br-PADAP and 0.4 ~ 0.8% of emulsifier OP. So the optimum concentrations of 5-Br-PADAP and OP were selected as $2.0 \times 10^{-4} \text{ mol l}^{-1}$ and 0.6% in the experiment, respectively.

In this system, thiourea was added to prevent the interference of copper. Ascorbic acid was added to reduce Fe^{3+} to Fe^{2+} and to increase the sensitivity of the iron determination. Neither of them affected the measurement in the masking reagent solution which contained < 1% thiourea and < 0.25% ascorbic acid. So the concentrations of the ascorbic acid and thiourea in the masking reagent solution were chosen as 0.2 and 1%, respectively.

3.4. Effect of flow rate of carrier and reagent solution

Under the conditions where both carrier rate and reagent solutions rate were the same, there was no effect on the absorbance for zinc over the range $2.0 \sim 5.4 \text{ ml min}^{-1}$, while the sensitivity to iron decreased with the increasing of the flow rate, but the change was minimal between 4.0 and 5.4

ml min^{-1} . Therefore, the flow rate of carrier and chromogenic reagent solution was selected as 4.2 ml min^{-1} for this experiment.

3.5. Selection of the reaction coil length

The effect of the reaction coil length was investigated in the range 100–250 cm. The experiment results showed that when the reaction coil length was changed from 180 to 250 cm, using a 0.7 mm interior diameter for the reaction coils, there was a maximum and agreeable sensitivity for both iron and zinc. Hence a coil length of 200 cm was chosen as optimal.

3.6. Sample injection volume

The sample injection volume is a key to realizing simultaneous determination of both iron and zinc. In order to ensure that the second peak corresponds only to iron, a pH gradient must be formed in the sample plug and the carrier. The influence of the sample injection volume on the determination was studied by injecting zinc solution into the carrier. The results indicated that two separate peaks corresponding to zinc could be observed when the sample injection volume was larger than 0.8 ml. Therefore, 1.0 ml of sample injection volume was employed in the experiment.

Fig. 4. Typical recording of absorbance. 1. iron only; 2. zinc only; 3. the mixture.

3.7. Calibration graph

Under the condition described, a mixed standard solution of iron and zinc was measured. The calibration graph was linear in the range $0.1 \sim 1.8 \mu\text{g ml}^{-1}$ for iron with the regression equation $A = 0.5277C - 0.0082$ ($r = 0.9994$), and $0.24 \sim 4.4 \mu\text{g ml}^{-1}$ for zinc with the regression equation $A = 0.2272C - 0.0048$ ($r = 0.9998$). Where A is the absorbance, C is the content of iron or zinc in $\mu\text{g ml}^{-1}$ and r is the correlation coefficient.

3.8. Effect of diverse ions

The effect of interference from diverse ions was investigated in a 25 ml solution containing $15 \mu\text{g}$ of iron and $50 \mu\text{g}$ of zinc. There was no interference from $1500 \mu\text{g}$ of Mg^{2+} , $1000 \mu\text{g}$ of Ca^{2+} , $300 \mu\text{g}$ of Mo(VI) , $150 \mu\text{g}$ of W(VI) , $100 \mu\text{g}$ of Mn^{2+} , Cr(VI) , Cu^{2+} , $50 \mu\text{g}$ of Sr^{2+} , $30 \mu\text{g}$ of Pb^{2+} , Ba^{2+} , Bi^{3+} , $20 \mu\text{g}$ of Cd^{2+} , $15 \mu\text{g}$ of Al^{3+} , $10 \mu\text{g}$ of Ni^{2+} , Co^{2+} , $5 \mu\text{g}$ of Ti(IV) . The above results showed that there was no effect on the determination of iron and zinc in the presence of diverse ions below the physiological content in human hair.

4. Determination of mixed standard solutions

Mixed standard solutions of different mass ratios of zinc and iron between 1:2 and 9:1 were measured. Recovery of both zinc and iron for

these solutions is given in Table 1. A recovery of between 95–101% for zinc and iron can be obtained.

5. Determination of iron and zinc in human hair

A 2.0 g sample of rinsed, dried hair was placed in a 100-ml flask, 15 ml of nitric acid and nitrate were added at low temperature. After the solution turned clear, 5 ml of perchloric acid was added. The temperature of the solution was raised until white fumes of perchloric acid were produced and the solution color changed from yellow to colorless. The solution was then evaporated to nearly dry. After it was cooled, 40 ml of water was added and the solution was then heated to dissolve the salt. The pH value was adjusted to 3.0. The solution was then transferred into a 50-ml calibrated flask and diluted to the mark with water. A portion of the sample solution was

pipetted into a 25-ml calibrated flask and diluted to the mark with masking agent solution. The operation was carried out by the proposed method and the results are shown in Table 2.

6. Conclusions

This paper proposes a new method for simultaneous determination of iron and zinc with a single detector by a pH gradient technique in a flow injection system. The results obtained by the pro-

posed method, when applied to the hair, were in agreement with those obtained by atomic absorption spectrophotometry. The proposed method is a rapid, simple, precise, highly sensitive and highly selective technique.

Abstract

Imazethapyr is the herbicide developed for use in leguminous crops. In this study, flow-injection liposome immunoanalysis (FILIA) has been shown to be capable of measuring imazethapyr in a buffered solution with a detection limit of 0.1 ppb through the optimization process. Protein A coated glass beads covalently conjugated with antibody were contained in a glass column, and this column was used as an immunoreactor. Liposomes which encapsulated a fluorescent dye, sulforhodamine B (SRB) or carboxyfluorescein (CF), generated the analytical signal. By loading larger volumes of sample onto the column, it was shown that the detection limit could be lowered. Liposomes containing carboxyfluorescein gave more sensitive response and a lower detection limit than those with sulforhodamine B. Also, improved response was obtained by using a smaller flow cell in the fluorescence detector due to the reduced dilution effect. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Imazethapyr [5-ethyl-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)nicotinic acid] belongs to the imidazolinone class of herbicides and is the active ingredient of PURSUIT^{®1} herbicide. The structure of imazethapyr is shown in Fig. 1. Imazethapyr is currently approved for soybean

[*Glycine max* (L.) Merr] and all edible legumes [1]. The herbicidal activity is from inhibiting acetoxy acid synthase, the feedback enzyme in the biosynthesis of branched chain amino acids [2,3]. Mammals, birds, and fish do not have this enzyme and are known to be unaffected by imazethapyr. In general, tolerant species can convert imazethapyr to a more polar and less phytotoxic metabolite by hydroxylation of the ethyl substituent on the pyridine ring [4,5]. This hydroxylated metabolite has herbicidal activity, although it is less active than the imazethapyr. However, in soybean, imazethapyr is metabolized to nontoxic form by the conjugation of the hydroxylated metabolite to glucose.

The conventional analytical techniques for monitoring agrochemicals are time-consuming and expensive. The demand for a rapid and inexpensive analytical method has increased. As an alternative or complement to classical analytical methods, immunoassays have gained the attention of many researchers. Recently, many papers are published which are about the application of immunochemical methods for environmental analysis. Hammock and Gee reported that more research has been done in the last few years than in the preceding two decades [6]. Immunoassays exploit the specificity and selectivity of antibody–antigen reactions. These factors, as well as the reduced need for sample preparation and short analysis times, make immunoassays a good choice to replace the traditional analytical methods.

A liposome is a uni- or multilamellar vesicle containing an aqueous cavity which can be used for the encapsulation of drugs, genetic material or markers depending on its intended application. Liposomes can be used in immunoassays by preparing them to have appropriate antibodies or antigens on their surface [7]. To achieve this, antigen- or antibody-conjugated phospholipids are used as a component of lipid mixture for the preparation of liposomes. Alternatively, this conjugation step can be done after the liposomes are prepared. The advantage of liposomes in immunoassay is that the amplification of response can be obtained immediately upon lysis, because they have many marker molecules in their aqueous interiors. The incubation step for color production is not necessary, unlike the enzyme linked immunosorbent assay (ELISA).

Flow-injection analysis (FIA) has been developed during the last twenty years into a well established laboratory technique [8,9]. The scope of applications of FIA covers clinical, food, pharmaceutical and environmental fields [10,11]. Flow-injection systems can be easily automated and adapted to a wide variety of analysis formats.

Liposomes have been used in solid-phase assays [12] and an ELISA-type immunoassay [13]. The flow-injection immunoanalysis system has also been demonstrated to function well with liposomes as the detectable label [14–17]. In these papers, immunoreactor columns were prepared by

conjugating antibody to some functional groups on the matrix or injecting the same amount of antibody into the column for each analysis. The disadvantages of those methods are the loss of antibody activity as a result of randomly oriented conjugation and the reduced reproducibility by introducing one more variable step. To overcome these problems, glass beads coated with protein A were covalently bound to the non-antigen binding Fc region of antibody and used for the immunoreactor packing material in this study. In this research, we describe flow-injection liposome immunoanalysis (FILIA) for the measurement of imazethapyr and the optimization process for improving the detection limit and sensitivity in the FILIA.

2. Methods

2.1. Materials

Imazethapyr, monoclonal antibody to imazethapyr and dipalmitoyl phosphatidyl ethanolamine-analyte (DPPE-analyte) were supplied by American Cyanamid (Princeton, NJ). Sulforhodamine B (SRB) was purchased from Eastman (Rochester, NY), and 5-(and-6)-carboxyfluorescein (CF) was obtained from Molecular Probes (Eugene, OR). Dipalmitoyl phosphatidyl choline (DPPC) and dipalmitoyl phosphatidyl glycerol (DPPG) were purchased from Avanti Polar Lipids (Alabaster, AL). Polycarbonate syringe filters of 3, 0.4 and 0.2 μm pore sizes were purchased from Poretics (Livermore, CA). Dimethylpimelimidate (DMP) was obtained from Pierce (Rockford, IL). Protein A immobilized on porous silica glass was from Bioprocess-

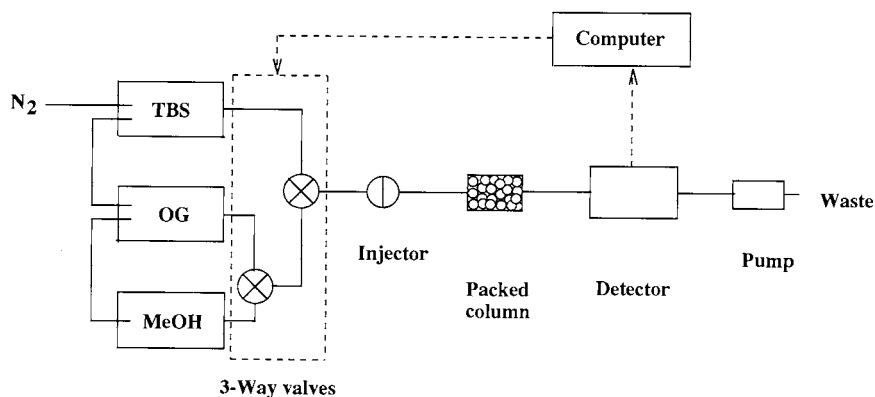

Fig. 2. Flow injection liposome immunoanalysis system. TBS, Tris-buffered saline with 0.01% sodium azide, pH 7.0; OG, 30 mM *n*-octyl- β -D-glucopyranoside in TBS; MeOH, 40% methanol solution.

ing (Princeton, NJ), and all other chemicals from Sigma (St. Louis, MO).

2.2. Apparatus

Fig. 2 shows a diagram of the FILIA system. A 20- μ l, 500- μ l or 1-ml sample loop (Rainin, Emeryville, CA) was used in the injector (Rheodyne Model 7725, Rainin, Emeryville, CA). Two three-way 12-V solenoid pinch valves (Biochem Valve, East Hanover, NJ) directed the flow of reagent into the FILIA system and were computer-controlled through a valve controller (Solenoid Interface, Rainin). All connecting PEEK tubing (0.02 in. i.d.) and standard fingertight fittings were purchased from Upchurch (Oak Harbor, WA). A peristaltic pump (Rainin) at the outlet of the system was used to maintain a flow rate of 1.3 ml min⁻¹ of TBS (Tris buffered saline) in conjunction with 41 kPa (6 psi) head pressure on each of the mobile-phase bottles. A HPLC pump used for achieving a constant flow rate was from Varian (Walnut Creek, CA). A MacIntegrator I data analysis package, used for valve operation, data collection and integration, was purchased from Rainin. The fluorescence detectors used were a Model FD-300 with a 24- μ l flow cell obtained from GTI/Spectrovision (Concord, MA) and a Model FL-1 with a 3.5- μ l flow cell from Rainin.

2.3. Preparation of immunoreactor column

Anti-imazethapyr monoclonal antibody was covalently linked to protein A glass beads according to the method described by Wong et al. [6]. Two batches were prepared by using different amounts of anti-imazethapyr antibody. One batch had a binding capacity of 6.6 μ g ml⁻¹ for imazethapyr and the other had 0.15 μ g ml⁻¹. The beads were packed in a glass column (6 \times 50 mm, Omnifit, New York, NY) and held in place with two polyethylene frits. An adjustable column endpiece was used to make a bed length of 1 mm. For the determination of non-specific binding, protein A coated beads which were covalently bound to rabbit anti-mouse IgG were prepared by the same method used for the production of beads conjugated with antibody to imazethapyr, a modification of Brew [18] and Schneider [19] methods. The beads were mixed with the desired amount of antibody in 1 M glycine/0.15 M NaCl (pH 8.6) buffer and incubated overnight. After washing with glycine buffer and 0.2 M triethanolamine (TEA, pH 8.2), cross-linking was done by resuspending the beads in 20 volumes of 25 mM DMP in 0.2 M TEA for 45 min. The beads were washed with 0.1 M ethanolamine (pH 8.0) and incubated overnight. After rinsing with TEA, the beads were stored in TBS buffer (pH 7.0) at 4°C.

2.4. Production of liposomes

Liposomes were prepared by the reverse-phase evaporation method [20–22] from a mixture of DPPC, cholesterol, DPPG, and DPPE-analyte in a molar ratio of 5:5:0.5:0.02. This mixture was dissolved in a solvent system containing chloroform, isopropyl ether and methanol (6:6:1, v/v). The dye solution of 150 mM sulforhodamine B, or 150 and 200 mM carboxyfluorescein, was added with swirling. This mixture was sonicated for 5 min under a low flow of nitrogen. The organic phase was removed under vacuum on a rotary evaporator at 45°C. An additional aliquot of the dye solution was added, and the liposomes were then extruded through three polycarbonate filters of decreasing pore sizes of 3, 0.4 and 0.2 μm . To remove any unencapsulated dye the liposomes were gel filtered on a 1.5×25 cm Sephadex G-50-150 column and finally dialyzed overnight against TBS at 4°C.

2.5. Flow-injection liposome immunoanalysis (FILIA)

The imazethapyr sample in TBS was introduced onto the immunoreactor column by manual injection. This was followed by injection of the liposomes. These two steps were done in the flow of the TBS carrier solution. After all unbound liposomes were eluted, a detergent solution (30 mM *n*-octyl- β -D-glucopyranoside in TBS) was passed through the column. The detergent caused rupture of the bound liposomes, and the fluorescence of the released dye was generated and measured. Finally, 40% methanol solution was passed through the column to regenerate the antibody binding sites by dissociating bound analyte, and the column is then reconditioned for the next analysis by returning the mobile phase to TBS. All solutions were degassed under vacuum before use each day, because introduction of the methanol solution created a large temperature differential and caused bubbles to form.

3. Results and discussion

3.1. FILIA assay

A typical trace for an analytical run is shown in Fig. 3. Peak B shows the inverse response to the amount of imazethapyr in the sample. The sample containing imazethapyr is first introduced onto the immunoreactor column. A 30 μl aliquot containing ca. 10^{10} tagged liposomes are next injected and bind to the unoccupied antibody binding sites in the column. Peak A represents the signal from unbound liposomes and traces of free dye passing through the fluorescence detector. Peak B is the analytical signal produced by the lysis of bound liposomes and consequent release of the fluorescent marker. Response is measured as the area of peak B. For samples containing a high concentration of imazethapyr, most of the antibody sites are occupied by imazethapyr, resulting in few remaining antibody sites available to liposomes. As a result, few liposomes can bind in the column and thus give a small peak upon lysis. Conversely, when a low concentration of imazethapyr is injected, a large number of liposomes bind to the unoccupied antibody binding sites thereby producing a large peak.

3.2. Displacement of the dose–response curve by loading larger sample volumes

The antibody in the column binds to imazethapyr contained in the flow of TBS buffer solution. In principle, until all antibody binding

Fig. 3. Typical FILIA run. One analysis can be performed in 15 min.

Fig. 4. Dose–response curves for imazethapyr with 20- μ l (○), 500- μ l (◆) and 1-ml (△) sample loops in the injector. Liposome encapsulating 150 mM SRB and the fluorescence detector with a 24- μ l flow cell were used. The column capacity for imazethapyr was 6.6 μ g ml⁻¹. Each point represents the mean of three measurements with error bars representing ± 1 SD.

sites are saturated with imazethapyr, they can continue to bind imazethapyr from the sample passing through the immunoreactor column. Therefore, even though a low concentration of imazethapyr sample is injected, the total amount of imazethapyr bound to the antibody can be increased by loading a larger amount of sample. To demonstrate this concept, 20-, 500- and 1000- μ l sample loops were used in the injector for increasing the sample volume. In this system, liposomes encapsulating 150 mM SRB were used with the Model FD-300 fluorescence detector from GTI/Spectrovision. The antibody used in this experiment had a very high affinity to imazethapyr and did not show any significant dissociation during the sample loading. Fig. 4 shows the comparison of three response curves obtained using the three different loop sizes. The fluorescence data were recorded as arbitrary units using MacIntegrator software and transformed as in Eq. (1), where F is the fluorescence at a given concentration of imazethapyr, F_0 is the fluorescence at zero imazethapyr, and F_∞ is the fluorescence in the presence of excess imazethapyr.

$$\%B/B_0 = (F - F_\infty / F_0 - F_\infty) \times 100 \quad (1)$$

$\%B/B_0$ represents the percentage of liposomes bound to the immunoreactor column. As the size of the loop, that is, the volume of sample increases, the dose–response curve is shifted toward lower concentration. That means the system with a larger sample loop has a lower detection limit than the one with a smaller loop. In Fig. 4, the dose–response curve from the 1-ml sample shows the most sensitive response for lower concentrations of imazethapyr than two others. However, introducing a larger volume of sample into the system takes a longer period of time. As a result, a compromise must be made between the detection limit and the analysis time.

3.3. Comparison of responses by two fluorescent dyes, SRB and CF

Liposomes containing 150 mM CF were prepared and compared to those containing 150 mM SRB. Fig. 5 shows two dose–response curves produced by the same amount of the two different types of liposomes using the same sample loop of 500- μ l. CF liposomes gave ca. 3.5 times larger response than the SRB liposomes. The free fluorescent dyes showed the same results, CF giving ca. 3.5-fold more sensitive response. This

Fig. 5. Dose response curves with 500- μ l sample loop when SRB (○) and CF (◆) liposomes were used. The concentration of two fluorescent dyes for preparation of liposomes was 150 mM. The fluorescence detector with a 24- μ l flow cell was used and the column capacity for imazethapyr was 6.6 μ g ml⁻¹.

Fig. 6. Comparison of responses by liposomes containing 150 mM (◆) and 200 mM CF (○). A 500- μ l sample loop was used and the column capacity for imazethapyr was 6.6 μ g ml⁻¹.

difference results from the spectral response of the photomultiplier tube (PMT) in the fluorescence detector. A PMT is a device that generates a current when photons of light strike it and has different wavelength sensitivities. The PMT used in the GTI/Spectrovision fluorescence detector has ca. 3.5 times higher sensitivity at the emission wavelength (520 nm) of CF than at that (583.5 nm) of SRB according to the specifications of the PMT manufacturer (Hamamatsu, Shizuoka-ken, Japan). Therefore, the sensitivity variance of the PMT corresponds to the response difference shown by the liposomes containing SRB and CF. As a result, in this system, imazethapyr can be detected with higher sensitivity using the liposomes encapsulating CF.

The comparison of responses by liposomes containing two different concentrations of CF is given in Fig. 6. The liposomes containing 200 mM CF produce ca. 1.4 times higher response than those with 150 mM CF. In principle, liposomes encapsulating 200 mM CF are expected to have ca. 1.3-fold more dye molecules in the aqueous cavity than the ones with 150 mM CF. This response increase shows a good correlation with the concentration differences between the liposomes.

3.4. Effect of the column capacity on the response

The glass beads, which had a binding capacity of 0.15 μ g ml⁻¹ for imazethapyr, were packed in the glass column and used to investigate the effect of the column capacity on the sensitivity (Fig. 7). For the above study, the glass beads having a binding capacity of 6.6 μ g ml⁻¹ were used. In comparison with the higher capacity beads, the response from the lower capacity column is very small. The high capacity column has many antibody binding sites, and a large amount of imazethapyr is needed for saturation of the antibody binding sites. Therefore, the dynamic dose-response range is shown only over quite high concentrations of imazethapyr. To overcome this limitation and improve the detection limit, the column binding capacity was reduced. However, this results in a decrease in the number of liposomes that can bind to the antibody of the column and, as a result, the detector response was too small to quantify the amount of imazethapyr in the sample. From this result, it was decided that a significant improvement of the detection limit was not attainable by a simple optimization process but could be achieved only by an instrumental change to increase the sensitivity.

Fig. 7. Comparison of two columns having the binding capacities of 0.15 (○) and 6.6 (◆) μ g ml⁻¹ for imazethapyr. A 500- μ l sample loop, liposomes encapsulating 200 mM CF and the fluorescence detector with a 24- μ l flow cell were used.

Fig. 8. Comparison of two sizes of flow cells. (○) was obtained from the fluorescence detector with a 24- μl flow cell and (◆) was from the one with a 3.5- μl flow cell. A 1-ml sample loop and the column with 0.15 $\mu\text{g ml}^{-1}$ binding capacity for imazethapyr were used. Each point represents the mean of three measurements with error bars representing ± 1 SD.

3.5. Influence of the flow cell size on the response

A model FL-1 fluorescence detector from Rainin was used instead of the GTI/Spectrovision fluorescence detector. A pulsed xenon lamp was used as an excitation source in both fluorescence detectors. The main difference between the two fluorescence detectors was the size (volume) of the flow cell. The flow cell is a quartz tube which allows for the transmission of the excitation and emission radiation. The fluorescence detector from Rainin has a 3.5 μl flow cell volume and that from GTI/Spectrovision has a 24 μl . Fig. 8 shows two dose–response curves obtained with the two different sizes of flow cells when the beads of 0.15 $\mu\text{g ml}^{-1}$ binding capacity were used. The total response increases over five times with the 3.5- μl flow cell. However, for the fluorescence detector having the 3.5- μl flow cell, the liposome solution was diluted ten-fold because, if the same amount of liposomes was injected, the detector response was off scale. For the determination of the actual response increase, free CF dye was injected into both detectors, and the concentration of the free dye required to produce the same peak area was obtained and compared. From this study, it was

determined that the response with the fluorescence detector having the 3.5- μl flow cell is ca. 50 times more sensitive than that with the 24- μl flow cell. While a part of this increased sensitivity results from the reduction of the flow cell volume giving rise to the decreased dilution of the dye, this difference in the sensitivity may also be caused by other instrumental differences.

3.6. Non-specific binding study

In Fig. 8, the dose–response curve from the 3.5- μl flow cell appears to show that 0.1 ppb of imazethapyr can be easily detected. However, the shape of the curve is not the typical sigmoidal form obtained in an immunoassay, instead showing two leveling-off regions in the low concentration range of imazethapyr. In this case, it was found that non-specific binding (F_{∞}) accounted for about 60% of the total response, and this high non-specific binding may cause the unusual shape of the curve. The graph showed only specific binding portion ($F_0 - F_{\infty}$). In the above study with the beads of 6.6 $\mu\text{g ml}^{-1}$ binding capacity, less than 30% of the total response was from non-specific binding. The uncoated glass sites are thought to bind to liposomes and give the non-specific binding response. Also, while not directly observed, liposomes captured in the pores of the glass beads could give the non-specific binding response. Fig. 9 shows the results obtained when the beads conjugated with different amounts of rabbit anti-mouse IgG were used in the column. For rabbit polyclonal antibody, a typical capacity of 37 mg ml^{-1} of glass beads was given in the manufacturer's instructions (Bioprocessing). This amount of antibody was used for conjugation with protein A beads, and these beads were designated as 100% saturation. By the reference to this amount, the other bead loadings were prepared. The binding of liposomes obtained from the beads without antibody was considered as 100% non-specific binding. At the level of 100% saturation with IgG, 25% of the total non-specific binding remains, and this results from the binding to the frits and tubing. This indicates that, when the high capacity beads were used, about 30% of non-specific binding is mainly from the binding to

the frits and tubing. From the beads 50% saturated with rabbit anti-mouse IgG, the non-specific binding decreased considerably, and this may result from the inhibition by antibody of the liposome access to the pores and uncoated sites of the glass beads.

Total amount of antibody molecules (specific and non-specific) attached to the beads was larger for the smaller capacity beads. For the high capacity beads, 5 mg anti-imazethapyr antibody was used per ml of the glass beads. In the case of the low capacity beads, after binding 1 mg anti-imazethapyr antibody per ml of the glass beads, the beads were incubated with 5 mg of mouse IgG to block the unoccupied protein A sites giving rise to total 6 mg of antibody binding. Therefore, the total amount of antibody on the column has only an indirect relationship with the degree of non-specific binding, suggesting that imazethapyr bound to the antibody binding sites makes the nearby uncoated glass sites and pores inaccessible to liposomes by steric hindrance and/or ionic interactions. In case of the low capacity beads, 5 mg of mouse IgG used for blocking was not enough to saturate the protein A binding sites, and many glass sites and pores were still accessible to liposomes. In the beads having a larger amount of anti-imazethapyr antibody, even

Fig. 9. Non-specific binding related to the antibody amount on the column. 37 mg ml^{-1} of rabbit anti-mouse IgG was used for preparation of 100% saturated beads, and by the reference to this amount, the other beads were prepared. The binding of liposomes obtained from the beads without antibody was regarded as 100% non-specific binding.

though total antibody amount was smaller, the quantity of imazethapyr bound to the antibody binding sites is high when a high concentration imazethapyr is injected. As a result, liposomes cannot easily access the uncoated glass sites and pores giving the low degree of non-specific binding.

3.7. Achieving a constant flow rate

In this FILIA system, a constant flow rate could not be maintained within and between days because it was difficult to regulate gas pressure precisely. It was observed that the flow rate changed slowly as the amount of solution in the bottles decreased. To achieve a constant flow rate, the peristaltic pump at the outlet of the system was replaced with a HPLC pump. Because the HPLC pump has quite a large holdup volume, it was not appropriate to connect it into the front part of this system which needed the switching of three solutions within a short time period. The HPLC pump was not sufficient by itself for drawing solutions due to the amount of resistance between the pump and the mobile-phase bottles which still needed the application of head pressure. However, the flow rate was no longer influenced by the pressure applied to the solution bottles. Another concern was that without enough back pressure, the pump would not work properly. This problem was solved by connecting an old HPLC column at the outlet of the pump.

4. Conclusions

FILIA was successfully used for the detection of imazethapyr herbicide. The detection limit could be lowered by loading larger volume of sample. Also, the sensitivity increased by using liposomes encapsulating CF instead of SRB. The dose–response study with a smaller flow cell and a low capacity column suggests that FILIA can be used for imazethapyr quantitation over a broader linear range, if the non-specific binding is reduced. For future study, a capillary column will be derivatized with protein A conjugated to the inside of the capillary wall. Due to the reduction of

the surface area-to-volume ratio and the elimination of the frits, the non-specific binding should be significantly lowered. Also, a constant flow rate achieved by using a HPLC pump will improve the reproducibility of response.

Rate study of reduction of 2-heptanone with samarium iodide by gas chromatography

M.-R.S. Fuh *, T.-Y. Lin, S.-C. Chang

Department of Chemistry, PO Box 86–72, Soochow University, Taipei, Taiwan, ROC

Received 21 July 1997; accepted 15 September 1997

Abstract

This article describes a newly developed method of gas chromatography (GC) for the rate study of the reduction of organic compounds by samarium iodide. Solvent extraction was used to reduce the interference of GC analysis by inorganic species. Adequate recoveries ranged from 88.3 to 94.5 % and good linearity ranging from 0.1 to 2.1 mM was determined. An internal standard, decane, was used to enhance the precision of this test. The coefficient variations of intra-day and inter-day ranged from 0.22 to 3.00%. The stability of the reacted sample was also assessed. In addition, the reaction rates of the reduction of 2-heptanone by samarium iodide in the presence of hexamethylphosphoramide were examined. The results presented herein demonstrate the utility of this method in kinetic studies. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: 2-heptanone; Samarium iodide; Gas chromatography

1. Introduction

The samarium iodide (SmI_2) reduction of organic compounds has been one of the most interesting research topics in recent decades, since Girard et al. And others reported its reactivity towards various functional groups [1–4]. Although some mechanisms were proposed for these reductions, reaction rates were seldom studied [3,4]. Hasegawa and Curran measured the first bimolecular rate constants for the SmI_2 reduction of a primary alkyl radical by using a competitive hexenyl radical clock [5]. Sturino and Fallis ob-

tained the rate constants of competitive ‘radical clock’ type cyclization of hydrazones and alkenes by SmI_2 [6]. However, the above rates only reflected the reactivity of the radicals formed. The measurement of the rate for the first electron transfer step by SmI_2 to organic substrate remains an unsolved problem. We therefore present a method for further understanding the speed of this step. Owing to the characteristic absorption of SmI_2 solution, we attempted to trace SmI_2 concentration by UV/Vis spectroscopy [7–10]. Unfortunately, the results were extremely complicated and the experiments were difficult to control. This may be attributed to air sensitivity of SmI_2 and different absorption coefficients of various forms of the complexes.

Another approach for investigation of the reaction is to monitor the reduced reactants. Since these reactants are small organic molecules, gas chromatography (GC) can be used to monitor the amount of reactant in the mixture during the reaction. In this paper, we describe a newly developed GC method to determine the reduction of 2-heptanone by SmI_2 . In this analysis, inorganic species were removed from the reaction mixture by HCl solution to minimize their effect on GC analysis. 2-Heptanone was extracted to hexane and then determined by GC. An internal standard, decane, was used to minimize experimental variation. External standards were used to quantitatively measure 2-heptanone. The linearity, detection limit and precision associated with this are also discussed. Furthermore, this method is applied to investigate the reduction of 2-heptanone by SmI_2 in the presence of hexamethylphosphoramide, which is an efficient catalyst.

2. Experimental

2.1. Chemicals

Samarium iodide, decane, 2-heptanone and hexamethyl phosphoramidate (HMPA) were purchased from Aldrich (Milwaukee, WI, USA). Hydrochloric acid and iodine were purchased from Nacalai Tesque (Kyoto, Japan) and Wako Pure Chemical Industries (Osaka, Japan). Hexane was purchased from Tedia (Fairfield, OH, USA). The chemicals were used as received, without further purification. Tetrahydrofuran (THF) was obtained from Labscan (Dublin, Ireland). THF was freshly distilled before use and immediately transferred to a glove box. GC system A Shimadzu 14B GC with a flame ionization detector (FID) and a 14AO autosampler (Shimadzu Scientific Instruments, Tokyo, Japan) were used for analysis. A split/splitless injector was used for analysis. A Scientific Information Service Corporation (SISC; Taipei, Taiwan) chromatography data system and a personal computer were used for data acquisition and processing. Separation was carried out in a DB-1 column (15 m., 0.53 mm i.d., 1 mm film thickness; Supelco, Bellefonte, PA, USA).

The instrument settings for GC–FID were as follows: injector temperature, 250°C; FID temperature, 250°C; oven temperature, 50°C initially, increased to 95°C at 10°C min⁻¹, then to 240°C at 40°C min⁻¹ and finally held for 3 min at 240°C. The injector split ratio was set at 30/1. The injection volume for GC analysis was 6 µl.

2.2. Standard solutions

A solution of hexane with added decane (1.46 mM) was prepared and used to develop 2-heptanone standards (2.06, 1.03, 0.52, 0.25 and 0.10 mM). These standards were used to establish the calibration curve for quantitative analysis.

2.3. Reaction sample preparation

The concentration of SmI_2 was determined by I_2 titration prior to reaction. 0 µl of 2-heptanone (0.25 M) in hexane was injected into a 5.0 ml of SmI_2 solution and thoroughly mixed. Subsequently, at each time interval, 0.50 ml of reaction mixture was transferred into 0.50 ml of hexane containing decane and I_2 . This procedure ensured that unreactive Sm(II) is quenched by I_2 . This I_2 quenching solution was freshly prepared with equal concentrations of SmI_2 . After the mixture was removed from the glove box, 0.50 ml of 0.12 M HCl solution was added to each quenched solution and mixed for 3 min using a Virtex mixer. This procedure extracts most inorganic species into the aqueous phase and minimizes their effect on GC analysis. The solution was left at room temperature (1–2 min.) until organic and aqueous layers were well separated. Finally, the clear organic layer was injected into the GC apparatus for analysis.

3. Results and discussion

Fig. 1 depicts typical GC chromatograms of standard and reaction extract. Adequate separation was achieved in approximately 10 min. The retention time of 2-heptanone was 3.5 min. To minimize experimental variation and volume change due to the mixing of tetrahydrofuran and

Fig. 1. Typical chromatograms of: (A) standard solution; (B) samarium(II)/THF solution after quenching with I_2 ; and (C) reacted sample. Peak 1, 2-heptanone, peak 2, decane.

hexane, decane was added as an internal standard and eluted at 5.7 min. As reported elsewhere, 2-heptanol was the reaction product in the presence of a proton source [1]. Therefore, we also examined the separation of 2-heptanol (eluted at 4.1 min) to ensure that there is no proton source in the reaction mixture which may create other reaction routes. Additional unidentified peaks appeared in the reac-

tion extract; however, these did not interfere with 2-heptanone or decane.

The calibration curve was constructed by plotting the ratio of the peak area of 2-heptanone to that of decane versus the concentration of 2-heptanone. The linearity was good, being from 2.1 to 0.1 mM ($r_2 = 0.9998$). The detection limit was about 0.001 mM based on a signal-to-noise ratio of 3.

Table 1
Intra-day and inter-day precision study

Added amount (mM)	Intra-day ^a			Inter-day ^b		
	Mean (mM)	SD	CV	Mean (mM)	SD	CV

^a The mean and SD represent three measurements of each amount.

^b The inter-day reproducibility was determined from five different runs over a 2 week period.

The precision of this test method was evaluated by replicate analysis of 2-heptanone spiked n-hexane solution. The intra-day precision revealed a coefficient of variation (CV) of 0.22–1.11 %. The inter-day variation was similarly evaluated for five days. The inter-day CV ranged from 0.24 to 3.00%. Details of the precision study are summarized in Table 1.

The extraction efficiency of 2-heptanone by hexane was investigated and the results are summarized in Table 2. In this study, SmI₂/THF solution was first oxidized by air. A different amount of 2-heptanone was added to Sm(III)/THF solution, while hexane and HCl solution was added subsequently, as described in Section 2. The extracted 2-heptanone was evaluated by GC.

In order to match the sample matrix of the reaction mixture, SmI₂/THF solution was quenched with I₂/decane/hexane and 0.12 M HCl solution, as described in Section 2.3. Some 2-heptanone was added to the mixture and mixed by a Virtex mixer. The clear organic layer was injected into the GC apparatus for analysis. Recoveries ranged from 90.7 to 101.4%, as determined through the concentration range examined herein.

Fig. 2 summarizes the stability of the sample. The extracted samples were stored at room temperature (about 26°C). Samples were withdrawn from solutions daily and analyzed by GC to examine their stability under storage. The first day sample served as a control. The difference between the results of each of subsequent measure-

Fig. 2. Stability of 2-heptanone (●, 0.8 mM; ■, 0.5 mM; ▲, 0.2 mM) in reacted mixture versus time, which stored at room temperature. Values are represented as percentile changes of control (mean \pm SEM; $n = 3$).

ments and the control was examined by a one-tail student t -test. Statistical significance was taken as $P < 0.05$. The response significantly decreased after storage at room temperature over the period of study. Therefore, all collected samples were measured immediately after preparation.

This newly developed method was used to examine the reduction rate of 2-heptanone with

Fig. 3. Unreacted 2-heptanone in the mixture.

SmI₂. According to these results, 2-heptanone was reduced by this powerful reagent surprisingly slowly. In a reaction mixture of 0.12 M SmI₂ and 1.5 mM 2-heptanone, only 28% of the ketone reacted 16 days. However, in the presence of 0.11M HMPA, the reaction under the same conditions was nearly complete in 1 h, as shown in Fig. 3. The initial rate constant can be estimated as 0.062 M⁻¹ min⁻¹ if both reactants were assumed to be first order.

4. Summary

This paper presents a simple, accurate and sensitive GC method for the rate studying the rate of reduction of 2-heptanone with SmI₂. A simple sample preparation procedure was utilized to remove inorganic species in the organic phase and increase the sensitivity of the GC analysis. Good linearity ($r_2 = 0.999$) in the range of 0.1 to 2.1 mM was determined. In addition, the precision of this method is also very good. This method was used to assess the reduction rate of 2-heptanone by Sm(II). The reaction rate was significantly affected by HMPA.

This method can be easily applied to examine the reduction rate of other organic compounds with Sm(II). Currently, we have applied this newly developed method to investigate the reduction of other carbonyl group compounds with Sm(II).

Received 14 May 1997; received in revised form 12 September 1997; accepted 15 September 1997

Abstract

In this study a special sequential extraction method is proposed to discriminate between arsenic adsorbed and co-precipitated in precipitates arising mainly from iron hydroxides or bound in low solubility mineral phases. Synthetic iron hydroxide precipitates were prepared to investigate the influence of the amount of arsenate, of the manganese additionally added and of the valence state of arsenic on the remobilisation of arsenic. After preparing the precipitates with arsenate no arsenic could be detected in the supernatant solution. About 82% (w/w) of the arsenate is adsorbed to the precipitate and the remaining part can be dissolved by shaking with an oxalate buffer. A significant difference between the amount of arsenic added and the amount analysed in the two steps was not found. Consequently, compounds with a low solubility, such as scorodite, were not formed in the synthesized precipitates. The valence of the arsenic and addition of manganese influence significantly the uptake of arsenic by iron hydroxides. Natural precipitate samples from a percolate water of tin mill tailings were investigated using this method. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Arsenic; Speciation; Sequential extraction

1. Introduction

Mining activities have both local and regional impacts on terrestrial and aquatic ecosystems. Mines produce large quantities of waste-rock and mill tailings which require disposal [1]. Tin ore has been mined in the Erzgebirge in the east of Germany for a long time. Near the city of Altenberg a settling pond for the tailings was constructed by isolating a segment of the Biela River valley by two dams. The pond covers an area of about 0.53 million m². Presently, about 30 l s⁻¹

of seepage water percolates through the main dam. This effluent water contains arsenic in concentrations up to 1 mg l⁻¹ [2]. Precipitates are formed under oxidizing conditions in the effluent water and consist mainly of iron hydroxides. These contain arsenic in concentrations up to 8% w/w.

The well known sequential extraction methods after Tessier et al. [3] or Förstner [4] were designed to deal with M²⁺ metal ions. However, the behavior of arsenic is very different. The use of the method after Förstner for the precipitate samples from Biela River valley leads to the expected result, that the arsenic is bound to the amorphous iron hydroxide. However, to understand the im-

mobilisation or possible remobilisation processes of arsenic it is important to know, how the arsenic is incorporated into the precipitate. To discriminate between arsenic adsorbed or co-precipitated to iron hydroxides and bound in minerals like scorodite, a two step sequential extraction method was applied in this study.

Pierce and Moore [5] investigated the adsorption of arsenite and arsenate on amorphous iron hydroxide. They found that at pH values higher than 10, no adsorption takes place. Therefore, 1 mol l⁻¹ NaOH is used for the desorption of the arsenate. Such a solution would be able to solve also organic substances (e.g. humic acids) [6,7]. However, the concentrations of organic material in the precipitates described are very low. In this case a determination of the arsenic adsorbed to the iron hydroxide surface should be possible.

Amorphous and poorly crystallized iron hydroxides, as well as manganese hydroxides are the main components in the precipitate and can be dissolved in an oxalate buffer (pH = 3) [7,8] or with a hydroxylamine solution [9,10]. The arsenates which are bound to these compounds can be determined after the dilution of the hydroxides. The low solubility compounds, such as iron arsenate (solubility product = 5.7×10^{-21} [11]) or other heavy metal arsenates, remain in the residue.

Synthesized precipitates from iron, manganese and arsenate were prepared with different amounts of arsenic to test this sequential extraction scheme. Precipitate samples from the seepage water of the tailings pond in the Biela River valley were investigated for comparison.

2. Experimental

2.1. Reagents

Deionized water (Millipore) was used throughout. All reagents were of analytical reagent grade or higher purity. Fe(II) stock solution containing 0.5 g Fe/10 ml was prepared by dissolving (NH₄)₂Fe(SO₄)₂·6 H₂O (Merck). As(V) and Mn(II) as nitrates were taken from standard solutions (Merck, 1000 mg l⁻¹).

The As(III) stock solution containing 1 mg As l⁻¹ was prepared by dissolving NaAsO₂ (Merck). The oxalate buffer was prepared by dissolving ammonium oxalate and oxalic acid (0.2 mol l⁻¹ ammonium oxalate, 0.2 mol l⁻¹ oxalic acid).

2.2. Analysis

Iron, manganese, and arsenic concentrations in the solutions were determined using ICP-AES (Spectroflame, SPECTRO A.I.) with pneumatic nebulization (cross flow).

The total content of these elements in the solid samples from the Biela River valley was determined with wavelength-dispersive X-ray fluorescence spectrometry (WDXRF, SRS 3000, Siemens) using pellets prepared in stearine wax (4 + 1 g).

2.3. Synthetic precipitates

In a first experiment different amounts of As(V) (0.5–5.0 mg) were mixed with 10 ml of the Fe(II) stock solution (0.5 g). The mixture was diluted with water up to a total volume of 30 ml. The pH of this mixture was adjusted with a NaOH solution to a value of 6.8 to form the iron hydroxide precipitates. This pH-value was measured in the effluent water in the sampling area. To accelerate the oxidation process oxygen was bubbled into the suspension for about 5 min until the precipitate had changed its colour into reddish-brown. After 18 h the precipitate was separated from the solution by centrifugation and the supernatant liquid was decanted. The concentrations of iron and arsenic were determined in this solution by ICP-AES to calculate the amounts of the elements precipitated. Additionally, some precipitates were prepared using As(III) instead of As(V) and a few precipitates containing manganese in different amounts. These precipitates were prepared in the same way. Three replicates of each precipitate were done.

2.4. Natural samples

The precipitate samples were collected from different site locations in the Biela River valley as

surface samples. Three samples were taken near the dam and one about 50 m downstream. The slurry was filled in 1000 ml polyethylene bottles and stored at 4°C. For the extraction wet material was used and the dry weight was calculated by weighing a different part of the sample after drying at 40°C. Each sample was analysed in three replicates.

2.5. Sequential extraction

An amount of 20 ml 1 mol l⁻¹ NaOH was added to the synthesized precipitates or to the natural samples to solubilize the adsorbed arsenate. After shaking for 1 h the suspension and the liquid phase were separated by centrifugation (step I).

Two different solutions were tested to extract arsenic bound to the iron hydroxide precipitate. An extraction with a 0.04 mol l⁻¹ NH₂OH·HCl solution in 25%(v/v) CH₃COOH (heating at 96°C, [12]) was chosen first. This method was inappropriate for our purpose, because only a small amount of the synthetic iron hydroxide precipitate was dissolved. Next a method based on an oxalate buffer (pH = 3) [9] was investigated. The synthesized precipitate was totally dissolved in this way. The volume of 20 ml of the oxalate buffer was added to the residue of step I and the mixture was shaken over night and the liquid phase was separated by centrifugation (step II).

The amount of arsenic bound in sparingly soluble compounds (e.g. heavy metal arsenates) can be calculated from the difference of the total amount determined by WDXRF and the sum of step I and step II.

3. Results and discussion

3.1. Synthetic precipitates

In a first experiment synthetic precipitates were prepared with varying amounts of As(V) (0.5–5.0 mg) to study the influence of the concentration of the arsenic on its binding to the iron hydroxide precipitate. The different amounts of arsenic were added to 10 ml Fe(II) stock solution and the

mixture was filled with deionized water up to a volume of 30 ml. The precipitate was formed in the described way and leached sequentially with the NaOH solution and the oxalate buffer.

The discussion of all results is done with the mass of the elements to avoid confusion originating from the dilutions in the different steps of extraction.

After preparing the precipitates no arsenic was detectable in the supernatant liquid, which means that the precipitation of the arsenic was complete. As shown in Fig. 1 the average recovery for arsenic added was 95% in the two steps of leaching. Most of the arsenic was found in the NaOH leaching solution. About 82% (w/w) of the arsenic was leached in this step of the procedure. The same pattern was observed in the oxalate buffer solution with approximately 13% (w/w). There was no significant difference between the arsenic added and found, which suggest that no significant quantity of arsenic is bound up in sparingly soluble forms.

In Fig. 2 the behaviour of iron in this experiment is shown. Surprisingly, about 94% (w/w) of the iron remains in solution.

The iron concentrations in the water (soluble) was for all arsenic concentrations the same with a standard deviation smaller than 2%. Obviously the amount of iron precipitated was not affected by the arsenate concentrations. As expected, no iron was determined after the extraction with 1 mol l⁻¹ NaOH. This means that the arsenic

Fig. 1. Correlation plot of the arsenic amount added and found in the different extraction steps (step I, NaOH solution; step II, oxalate buffer).

Fig. 2. Iron amounts analysed in the different fractions.

which is determined after this extraction step is extracted from the precipitate without dissolving.

The extraction scheme seems to be suitable to discriminate between the arsenic species described above.

In a further step the influence of an additional redox species was investigated using synthetic precipitates. Different amounts of manganese (Mn^{2+}) were added to the mixture of Fe^{2+} (0.5 g) and AsO_4^{3-} (2 mg As) in a total volume of 30 ml. During the procedure of preparing the precipitates, described above, Mn^{2+} is also oxidised forming MnO_2 . The various amounts of manganese (2, 4, and 6 mg) showed no influence on the amount of iron precipitated (Fig. 3). This is in agreement with the results found, when varying the As(V) concentrations.

However, the addition of manganese leads to significant changes in the binding of arsenic (Fig. 4). As shown, even small additional amounts of

Fig. 3. Behaviour of iron depending on the amount of manganese added.

Fig. 4. Arsenate binding as a function of the amount of manganese added.

manganese (2 mg) have the effect of more arsenate being bound to the precipitate. The amount of manganese is obviously not important in this range of concentrations. Less than 3% of the manganese amount added was detected in the precipitate (step II). Most of the manganese remain in the solution. The small amounts of manganese detected in the precipitate seems to change the structure of the precipitate with the result of binding more arsenic. The precipitation of arsenic was incomplete if only manganese (6 mg Mn(II)) without any iron was used.

The influence of the valence of arsenic on its binding was studied in an additional experiment with synthetic iron hydroxide precipitates. Again 2 mg As (III) were added to 0.5 g iron corresponding to a total volume of 30 ml. Additionally manganese (2 mg) was added to a few samples before preparing the precipitate. Using As(III) instead of As(V), an identical behavior of iron and manganese was found, but the valence of arsenic has a significant influence on its binding as illustrated in Fig. 5.

As shown above, the addition of manganese leads to changes in the binding form of arsenic if As(V) was used. When As(III) instead of As(V) was added, again more arsenic is bound to the iron hydroxides (more than 1 mg As). However, the difference between the results with and without manganese was not significant ($t = 2.89$, $t(0.95;3) = 3.18$) in this experiment with As(III). A small amount of arsenic (about 0.1 mg) was still in solution after the precipitation, according to a concentration of about 3 mg l^{-1} . The con-

Fig. 5. Influence of the valence of arsenic on its binding.

centrations of arsenic measured in the effluent water were about 1.5 mg l^{-1} [2]. The slow oxidation process of As(III) to As(V) may be the reason for such high concentration in these water samples.

Additional oxidizable substances in the system are able to change the structure of the precipitate. In both cases, if Mn(II) or As(III) was used, the amount of arsenic bound to the precipitate increased.

3.2. Natural samples

Three different precipitate samples (sample 1–3) taken near the dam of the tailings and one additional taken about 50 m downstream (sample 4) were extracted sequentially with 1 mol l^{-1} NaOH and the oxalate buffer. The total contents of the analytes were determined by XRF for comparison. The results of the elements arsenic and iron are summarized in Tables 1 and 2.

More than 80% (w/w) of the total arsenic of the original samples can be removed by an extraction with NaOH. This means that a remobilisation of this part is easily possible without dissolving the

iron precipitate. The arsenic amounts analysed in the solution of step II (oxalate buffer) were always lower than 4% (w/w) of the total content. This fraction is much smaller in the natural samples than in the synthesized precipitates (> 13%). The highest total arsenic concentration was measured in the sample taken 50 m downstream. In this sample the amount analysed in step I is similar to the total contents.

This results prove the absence of any redistribution or re-adsorption processes discussed often for sequential extraction methods ([13–15]). This phenomenon can be excluded in the case of this simple two step method for iron hydroxide precipitates.

A calculation of the difference between the total contents and the sum of step I and II is not possible in all cases. The standard deviation in the different steps is too high considering the error propagation [16] to find a significant value for this difference. A significant difference was determined only for the samples 1 and 2. There was no difference between the results of the sequential extraction and the total content of the sample taken 50 m downstream. Consequently arsenic compounds existing in these samples taken near the dam, which have a low solubility in the used extraction solutions. A transport of particles from the tailings should be discussed to explain the presence of these compounds only in these samples.

From the samples near the dam (sample 1–3) only about 50% (w/w) or less of the total iron can be dissolved by the oxalate buffer, whereas almost all iron was detected in this extraction solution of the sample taken 50 m downstream. In this sample the iron is obviously bound in amorphous or poorly crystallized iron hydroxides. The absence

of crystallized iron compounds, which should be formed as a consequence of aging of the amorphous iron hydroxide precipitates, confirm with the findings of Paige et al. [17]. They have found that iron hydroxide precipitates containing more than 3 mol% (As/(As + Fe)) do not crystallize even at a temperature of 60°C and a pH of 12. The concentration of arsenic in the sample taken 50 m downstream is about 18 mol%.

In the area near the dam, where the other samples have been taken, the precipitate contains other iron compounds in different quantities. This confirms the hypotheses of a particle transport of hardly soluble minerals containing iron as well as arsenic. These particles settle a few meters after the seepage water source.

4. Conclusions

The synthesized precipitates prepared under controlled conditions and the sample taken 50 m downstream which obviously contains mainly amorphous or poorly crystallized iron hydroxides lead to similar results of the arsenic binding. The only difference was found in the extraction step II, where arsenic bound to the iron hydroxides is dissolved with the oxalate buffer. Only 1.6% of the total arsenic content in the natural sample 4 was detected in the extraction solution of step II. Values up to 40% of the total arsenic of the synthetic precipitates were detected in step II, if additional manganese or As(III) instead of As(V) was added. Values in this range were expected, because the concentrations of As(III) are remarkable high. Obviously the simple combination of two or three components is not able to describe

this complex process of precipitation satisfactorily. Nevertheless, it was a useful tool for checking the extraction method and for understanding the influence of the different components on the system. The developed procedure will be used for further investigations, which are aimed to immobilize the arsenic by modification of the precipitate.

A potentiometric study of protonation and complex formation of xylenol orange with alkaline earth and aluminum ions

M.B. Gholivand *, F. Bamdad, J. Ghasemi

Department of Chemistry, Razi University, Kermanshah, Iran

Received 1 July 1997; received in revised form 26 August 1997; accepted 23 September 1997

Abstract

Xylenol orange (XO) is one of the complexometric indicators, that can bind to metal cations at both their amino and acidic groups. In this study the protonation constants and distribution diagrams of XO were studied pH-metrically, and the corresponding six protonation constants were calculated. The complex formation between XO (L) and alkaline earth ions (M) was investigated and the formation constants of the resulting complexes ML, MHL, M₂L and M₂HL were determined. The stabilities of both ML and M₂L complexes were found to vary in the order Mg²⁺ > Ca²⁺ > Sr²⁺ > Ba²⁺. Studying the complex formation between Al³⁺ ion (M) and XO (L), it was observed that four complexed species with stoichiometries ML, ML₂, MHL and MH₂L could be formed in solution. It was also found that the Al L₂ complex can act as a chelating agent for further complexation with two cations other than Al³⁺ ion (i.e. Ba, L, Al, L, Ba, Mg, L, Al, L, Mg, and Mg, L, Al, L, Ba). The formation constants of the resulting mixed complexes were determined and their distribution diagrams were investigated. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Xylenol orange; Complexation of alkaline earth aluminum ions; Mixed complexes

1. Introduction

Xylenol orange (I) is an excellent complexometric indicator and potentiometric reagent for determination of many metal ions [1–15].

* Corresponding author.

Xylenol orange [3,3'-bis-*N,N*, di(carboxy methyl)-aminomethyl-*o*-cresol sulphonphthalein]. Due to the existence of more than one chelating system and the various acidic and basic properties of the XO molecule which can form various complexes, the investigation of such a system can be difficult. Therefore the differences in the composition of the XO-metal ion complexes and their stabilities [1–15] are due to this and the methods employed. To solve this problem the program developed by Martell and his coworkers [16] for potentiometric titration has been used. By using this method not only can the composition and stability of XO-metal ion complexes be solved but

the study of mixed complexes using iterative methods and the FORTRAN program Best [16] is possible.

In this paper the composition and the protonation constants of XO and the stability constants of its complexes with alkaline earth, aluminum ions and mixed metals have been investigated.

2. Experimental section

2.1. Potentiometry

The apparatus consisted of a custom-designed, thermostated 80-ml capacity all-glass vessel. It was fitted with a cover having a 50-mm 'O' ring seal, through which was inserted a combined

glass electrode, a delivery tube for a Metrohm piston buret, and inlets and outlets for prepurified nitrogen. Each experiment was preceded by standardization of the pH meter, which was calibrated to display $-\log[\text{H}^+]$ using dilute standard HCl and KOH solutions. The system was maintained

at an ionic strength of $\mu = 0.10$ M with KNO₃ as a supporting electrolyte.

In general, an experimental run involves collecting equilibrium data points throughout the entire pH range, between 2.0 and 11.0 as a function of millimoles standard KOH, added using the piston buret through a fine capillary tip immersed in the solution. In titration, after each addition, the required time was allowed to reach chemical equilibrium. The concentration of the reactants in the experimental solution were in the order 10^{-3} M for each component. The hydrogen concentration was measured using a Metrohm model 686 titro-processor connected to a confident 286 PC for data transfer and computation.

The potentiometric equilibrium measurements of the ligand solution in the absence and presence of metal ions was calculated using the program Best [16]. The protonation and formation constants of all species were obtained through the least-squares refinement of its $\text{p}[\text{H}^+]$ profiles. Throughout this investigation the function minimized was the weighted average of the sums of squares of deviations between calculated and observed $\text{p}[\text{H}^+]$ value (σ_{fit}).

2.2. Electronic spectra

The electronic spectra were produced on a Beckman 34 spectrophotometer and the absorbance measurements were carried out on a Metrohm 662 probe-type photometer.

Fig. 2. The structure of alkaline earth-XO complexes

Fig. 3. Distribution of major species as a function of $-\log[H^+]$ for 1:1 and 2:1 molar ratio of XO to Mg^{2+} and Ba^{2+} ions, (a) (Mg^{2+}); (b) (Ba^{2+}).

2.3. Reagents

Xylenol orange and metal salts (nitrate) were of reagent grade (Merck) and were used without any

further purification. KOH solution (titrisol) was prepared and eluted from an anion exchange column to remove carbonate, and standardized with potassium hydrogen phthalate (KHP).

Fig. 3. (Continued)

3. Results and discussion

3.1. Protonation constants

The protonation constants of xylenol orange

(XO) were calculated from the potentiometric titration of free ligand using the program Best. XO can be represented by the symbolic formula H_6L showing the presence of six ionizable hydrogens. In the absence of metal ions, depending on

Fig. 4. Visible absorption spectra for titration of XO (5.0×10^{-5} M) with Al^{3+} ion; $\text{CaAl}^{3+} = 1(0.0)$, $2(1.0 \times 10^{-5})$, $3(2.0 \times 10^{-5})$, $4(2.5 \times 10^{-5})$, $5(3.0 \times 10^{-5})$, $6(4.0 \times 10^{-5})$, $7(5.0 \times 10^{-5})$, $8(6.0 \times 10^{-5})$, $9(7 \times 10^{-5}$ M).

the pH there are several possible forms that XO can adopt. In addition XO can acquire up to three positive charges. The resulting protonation constant values are listed in Table 1. The small differences between our values and previously reported values are in part due to the more accurate nature of the present computational technique compared with graphical or approximate methods used by earlier workers.

It can be seen from the distribution curves of XO (Fig. 1) and Table 1, the two last constants are too low and, after dissolution, XO immediately loses these protons. Therefore at pH 2, H_8L and H_9L make no contribution to the distribution curve, the concentration of H_7L is so low that it can be ignored. The other six species are distributed (in considerable concentrations) from pH 2.0 to pH 12.0.

According to previous reports [17], the first two protonation constants are due to protonated nitrogen atoms, the remaining constants are due to one-OH group and three carboxylic acid groups of the iminodiacetate arms of XO. These three

latter protonation steps have no effect on the color change of XO, the color of the solution is yellow and has an absorption maximum at 435

nm. At a pH of 6.5 another maximum appears at 580 nm, becoming prominent at pH 7.0 and being the only one at pH > 8, the color then changes to red.

3.2. Alkaline earth complexes

Alkaline earth cations react with XO at a pH above 6 in aqueous solutions. The program Best

Fig. 6. The structure of Aluminum–XO with mole ratio 1:2.

allowed us to calculate the formation constants reported in Table 2. All cations used form four species, namely ML^{4-} , MHL^{3-} , M_2L^{2-} , and M_2HL^- . Fig. 2 shows the possible structures of alkaline earth–XO complexes [18]. The metal ion may bind with one of the phenol groups and with two carboxyl groups of the iminodiacetate arm at the same side as sulphonphthalein. As a result of this combination, a proton of MHL from the nitrogen atom of the iminodiacetate arm of the XO dissociates to form the ML complex.

The M_2HL complex is a result of the second metal ion binding with the vacant coordination sites located at the other side of the XO molecule—with an arrangement similar to the first coordinated metal. A proton of M_2HL can dissociate to form the M_2L complex.

The distribution curves for various dissociated forms of the ligand and its alkaline earth complexes are shown in Fig. 3. These curves show the complication of the complexation reactions. For all alkaline earth–XO systems used, the ML and M_2L complexes can be formed in an alkaline pH range. It is obvious from distribution curves that the contributions of MHL and M_2HL complexes are smaller than ML and M_2L types. With the exception of the XO– Ba^{2+} system, all distribu-

tion curves have relatively similar features. Barium ion having the smallest stability constant in the series, shows complex formation with XO at higher pH values than any other metal ion used, and thus a fair amount of the free ligand species HL and L exist in the barium distribution curve which are negligible in other cation systems.

Table 2 shows a decrease in the stability of the XO–alkaline earth complexes for M_2L and ML, in the order $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$. The same stability order has been previously reported [18]. This sequence shows that the interaction between XO and alkaline earth cations increases with increasing charge density of the metal ion. However, it should be noted that the stability constants result from a balance between the binding energy and the solvation energies of all charged species involved in complexation reactions.

3.3. Aluminum and mixed metal complexes

The three charges on the small aluminum cation causes the cation to react strongly with XO forming two major complexes, with metal to ligand stoichiometries of 1:1 and 1:2 (i.e. ML and ML_2) [19]. From the absorption curve (Fig. 4) it is apparent that two complexes can be formed. The existence of 1:1 and 1:2 (metal to ligand) complex has been proven using the molar-ratio and continuous variation methods, measuring the absorbance at 550 nm (Fig. 4) at a pH 5. The aluminum ion is capable of forming protonated complexes, as well as normal 1:1 (ML) complexes. Two protonated forms of the ML complex were found in this study and their formation constant, were calculated using the program Best (Table 3). A comparison of the normal stability constants (K_{mL}) and their protonation constants reveal a concerted two-proton reaction, going from Al_2L to AlH_2L . Such behavior seems to involve a change in the coordination geometry and/or coordination number of the complexes involved. According to the corresponding distribution diagram (Fig. 5) these protonated species ($AlHL^{2-}$ and AlH_2L^-) are formed at low pH ranges.

In the ML_2 system, however, the protonated complexes (MHL_2 , MH_2L_2 etc.) were not found

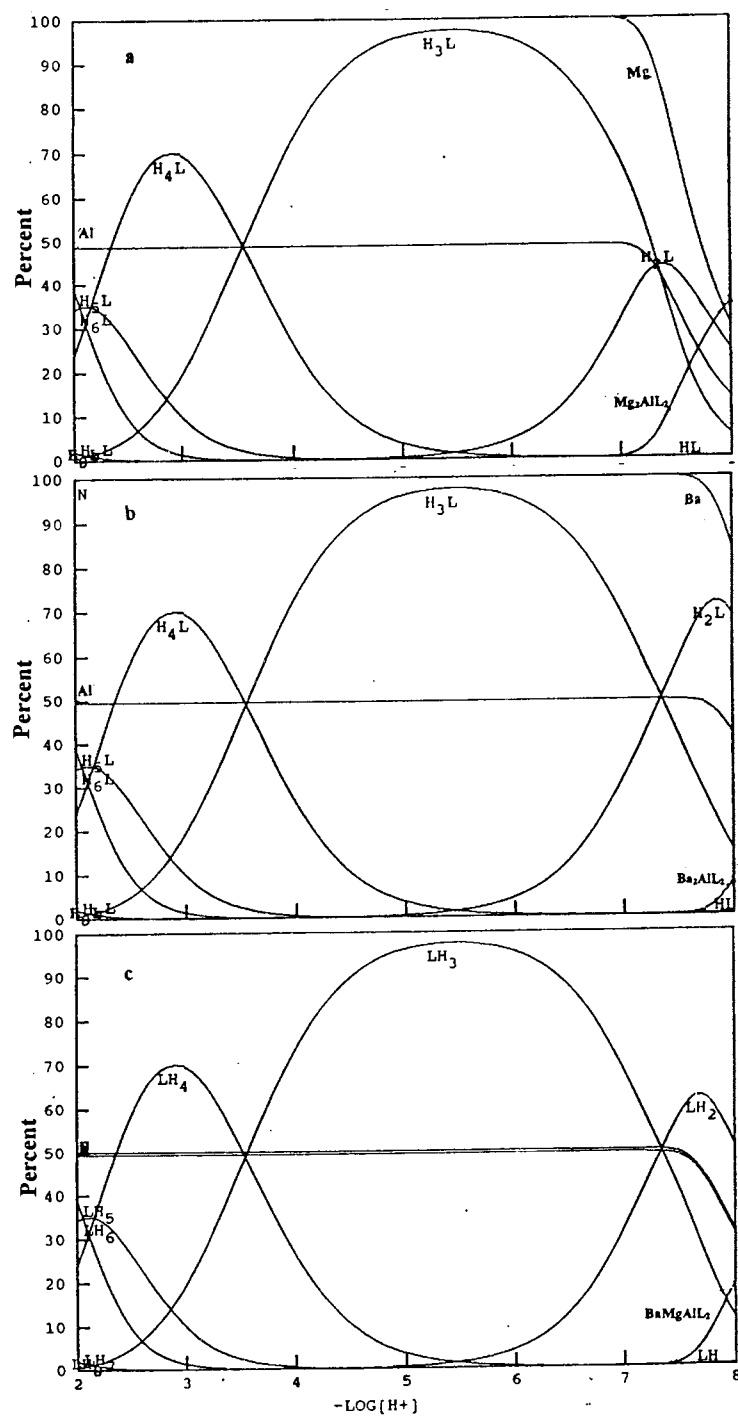

Fig. 7. Distribution of major species as a function $-\log[H^+]$ for 2:1:2 mole ratio of alkaline earth-Aluminum-XO, (a) $(Mg_2Al(L_2)_2)$, (b) $(Ba_2Al(L_2)_2)$, (c) $(BaMgAl(L_2)_2)$, (L = XO).

by the program, the deprotonated complex has the unique form of the $Al^{3+}-XO$ complex, in the corresponding distribution curve (Fig. 5). According to the literature [20], XO forms complexes at each of the iminodiacetate arms independently, hence in the ML_2 complex a metal cation can be coordinated by the other arms of two XO molecules (Fig. 6).

Further complexation of the ML_2 complex with other cations such as Ba^{2+} and Mg^{2+} indicates that the free sites of the resulting ML_2 complex can act as a chelating agent for mixed metal complexation. Using this property the Ba, L, Al, L, Ba, Mg, L, Al, L, Mg and Mg, L, Al, L, Ba mixed metal complexes were studied. The existence of these complexes was proven using the program Best. They are the major species that can be found in the $2M^{2+}:Al:2XO$ mixture in aqueous solution. The search for other species as well as protonated complexes ($2M^{2+}:Al:H_n:2XO$) gave results that did not correlate well with experimental data. From Table 3 it can be clearly observed that the formation constant of the $MgBa(XO)_2Al$ complex falls between the calculated values for the two complexes $Mg_2(XO)_2Al$ and $Ba_2(XO)_2Al$. The distribution curve for mixed metal complexes (Fig. 7) shows, that the $Mg:XO:Al:XO:Ba$ complex is formed between the pH range of formation of $Mg_2(XO)_2Al$ and $Ba_2(XO)_2Al$.

New cesium ion-selective electrodes based on anilino-(1,3-dioxo-2-indanylidene) acetonitrile derivatives

Mohamed B. Saleh *

Chemistry Department, Faculty of Science, Minia University, Minia, Egypt

Received 27 May 1997; received in revised form 1 September 1997; accepted 23 September 1997

Abstract

Cesium ion-selective PVC membrane electrodes based on anilino-(1,3-dioxo-2-indanylidene) acetonitrile derivatives as a novel class of neutral ionophores were examined. The ionophores were *p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile, *p*-methylanilino-(1,3-dioxo-2-indanylidene) acetonitrile and *p*-*N,N*-dimethylanilino-(1,3-dioxo-2-indanylidene) acetonitrile. The anilino-(1,3-dioxo-2-indanylidene) acetonitrile proved to work well with cesium, the corresponding electrodes display a response to this ion. The most favourable ionophore was *p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile, especially when the secondary ion exchanger potassium tetrakis (4-chlorophenyl) borate was incorporated in 2-nitrophenyl octyl ether for ion-selective electrode membrane construction. The response function was linear within the concentration range 10^{-1} – 2.5×10^{-5} mol l⁻¹ and the slope was 52 mV decade⁻¹. The detection limit remained at 6.3×10^{-6} mol l⁻¹. The selectivity and response time of the electrode was studied and it was found that the electrode exhibited good selectivity for cesium over alkali, alkaline earth and some transition metal ions. The electrode response was stable over a wide pH range. The lifetime of the electrode was about 1 month. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Anilino-(1,3-dioxo-2-indanylidene) acetonitrile; Cesium ion-selective electrodes; Potentiometry

Crown ethers have been used as neutral ionophores in Cs⁺ ion-selective electrodes (ISE_S). Those based on 15-crown-5 functionality have produced excellent Nernstian response slopes, detection limits (DL_S), and short response times of less than 1 min. However, the selectivities for interferents was relatively high [1]. The bis(benzo-18-crown-6) derivatives seem to produce the best Cs⁺ electrodes [2], since the *cis*-form is capable of forming sandwich-type Cs⁺

complexes. The electrode developed by Attiyat et al. [3] which incorporates a dibenzo dioxatetraazacylotetradecin-carbonitrile exhibited a twenty-five-fold selectivity over Rb⁺ and K⁺ respectively. A dibenzo-24-crown-8 has been proposed as a promising Cs⁺ PVC-based ISE [4]. The plasticizing agent was dibutyl phthalate (DBP) as opposed to the more frequently employed 2-nitrophenyl octyl ether (2-NPOE). Moreover, the influence of membrane components such as secondary ion exchangers [5], plasticizers [6] and polymer base [7] on electrode

* Tel.: +20 86 323011; fax: +20 86 342601.

performance has been examined in the literature. Recently, Michael et al. [8] constructed cesium-selective electrodes based on crowned benzoquinones with 2-NPOE, and incorporating the secondary ion exchanger potassium tetrakis(4-chlorophenyl) borate (KTCIPB). The selectivity coefficients of the cesium electrode based on the best ionophore 2,3-benzoquinol[15]crown-5 to Rb^+ , K^+ and Na^+ ($\log K_{\text{Cs,M}}^{\text{Pot}}$) were -0.47 , -0.99 and -2.38 , respectively. There was interference from Ag^+ ($\log K_{\text{Cs,Hg}}^{\text{Pot}} = 0.94$) and Hg^{2+} ($\log K_{\text{Cs,Hg}}^{\text{Pot}} = 2.12$). In this work, anilino-(1,3-dioxo-2-indanylidene) acetonitrile derivatives are examined as a novel class of neutral ionophores in cesium-selective PVC membrane electrodes.

1. Experimental

1.1. Materials

The neutral ionophores [anilino-(1,3-dioxo-2-indanylidene) acetonitrile derivatives] used in this work (Fig. 1) were synthesized as previously described [9,10].

The plasticizer dioctyl adipate (DOA), diethyl phthalate (DEP), dibutyl adipate (DBA), tris(2-ethylhexyl) phosphate (TEHP) and dibutyl phthalate (DBP) were obtained from Aldrich (Milwaukee, WI) and 2-nitrophenyl octyl ether (2-NPOE) from Fluka (Buchs, Switzerland).

The lipophilic salts (as membrane additives) used were obtained as follows: sodium tetraphenylborate (NaTPB) from BDH (Poole, UK), sodium tetrakis (4-fluorophenyl) borate (NaTFPB) from Aldrich and KTCIPB from Fluka. High molecular mass poly(vinyl chloride) (PVC) was obtained from Fluka and tetrahydrofuran (THF) from Aldrich. All solutions were prepared from salts of reagent grade using doubly-distilled water.

1.2. Electrode preparation

The membrane components outlined in Table 1 were mixed and dissolved in THF overnight. The resulting homogeneous mixture was poured into a glass ring [11] with an inner diameter of 30 mm

Fig. 1. Ionophores employed in this work: I, *p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile; II, *p*-methylanilino(1,3-dioxo-2-indanylidene) acetonitrile; III, *p*-*N,N*-dimethylanilino-(1,3-dioxo-2-indanylidene) acetonitrile.

resting on a smooth glass plate and the THF was evaporated at room temperature. Transparent PVC membranes were obtained with an average thickness of 0.2 mm. A 1 mm (approximately) diameter piece was cut out from the PVC membrane and attached to a PVC tube by means of PVC-THF solution (250 mg of PVC powder in 5 ml of THF). The PVC tube with the membrane was then connected to an Ag-AgCl wire electrode. After filling with a solution of $10^{-3} \text{ mol l}^{-1}$ CsCl as internal solution, the electrode was conditioned for 24 h by soaking in $10^{-3} \text{ mol l}^{-1}$ CsCl solution.

Table 1
Membrane components used in ISE membrane construction

Component	Amount (% m m ⁻¹)	Mass (mg)
Ionophore	0.99	1.8
Lipophilic salt	0.27	0.5
Plasticizer	65.83	120
PVC	32.91	60
THF	—	2 ml

Fig. 2. Effect of plasticizers on the responses of cesium ion-selective electrodes based on ionophore I.

1.3. Measurements of electrode potentials

All potential measurements were made with a Fisher Scientific Computer-Aided pH-meter (Model 450). The sample solutions were stirred and thermostated at $25 \pm 1^\circ\text{C}$. The electrochemical system was as follows: Ag–AgCl/internal solution ($10^{-3} \text{ mol l}^{-1} \text{ CsCl}$)/PVC membrane/sample solution/saturated KCl/AgCl–Ag. The external reference electrode was a double-junction Ag–AgCl (Cole-Parmer 7425 N). Standard CsCl solutions for calibration was obtained by the gradual dilution of $0.1 \text{ mol l}^{-1} \text{ CsCl}$ solution. Response times were determined as follows: after the potential of one cesium solution becomes constant, similar measurements were carried out in another

solution, of 100-fold concentration. Potentiometric selectivity coefficients were determined by the separate solutions method [12] using aqueous 0.1 mol l^{-1} solutions of metal chlorides in accordance with the equation

$$\log K_{\text{Cs},\text{M}}^{\text{Pot}} = \frac{E_{\text{M}} - E_{\text{Cs}^+}}{S} + \left(1 - \frac{Z_{\text{Cs}}}{Z_{\text{M}}}\right) \log[\text{M}] \quad (1)$$

where $K_{\text{Cs},\text{M}}^{\text{Pot}}$ is the selectivity coefficient, E_{Cs^+} is the potential measured in $0.1 \text{ mol l}^{-1} \text{ CsCl}$ solution, E_{M} is the potential measured in 0.1 mol l^{-1} solution of the chloride of the interfering cation, Z_{Cs}^+ and Z_{M} are the charges of cesium and the interfering ions, respectively, and S is the slope of the response function. For monovalent interferent ions, Eq. (1) simplifies to

Table 2

$$\log K_{Cs,M}^{Pot} = \frac{E_M - E_{Cs^+}}{S} \quad (2)$$

The influence of pH on the electrode response was examined by adjusting the pH of the measured solution with 1 mol l⁻¹ sodium hydroxide and hydrochloric acid. Electrode lifetimes were also examined by monitoring the slope of Cs⁺ calibrations periodically.

2. Results and discussion

The effect of plasticizers DOA, DEP, DBA, TEHP, DBP and 2-NPOE on cesium-selective PVC membrane electrodes based on ionophore I were studied. The electrode properties are shown

in Fig. 2 and summarized in Table 2. They demonstrate that the electrode based on ionophore I with 2-NPOE as plasticizer gives a good response to the cesium ion with a slope of 52 mV decade⁻¹ and a detection limit of 6.3 × 10⁻⁶ mol l⁻¹. With other plasticizers, the performance of the electrode was inferior to that containing 2-NPOE. Table 2 reveals that the selectivity coefficients of the 2-NPOE systems are generally much smaller than those of other systems. The variation in observed electrode response and selectivity using different plasticizers may be attributed to different carrier mechanisms [13]. Moreover, polar plasticizer 2-NPOE leads to the lowering of the membrane resistance as compared with apolar plasticizers DOA, DEP, DBA,

Table 3

Effect of anionic membrane components on selectivities of cesium ion-selective electrode based on ionophore I

Fig. 4. Potential responses of cesium ion-selective electrodes based on ionophores I–III.

TEHP and DBP. 2-NPOE was presented as the best plasticizer for the proposed PVC membrane electrode systems.

The dependence of the electrode response and selectivity coefficient of the cesium-selective PVC membrane electrode on the anionic membrane components is shown in Fig. 3 and presented in Table 3. The results indicate that the membrane containing ionophore I with 2-NPOE, in the ab-

sence of anionic sites in the membrane phase (membrane component a, Fig. 3) gives a response to cesium ion with a sub-Nernstian slope of $24 \text{ mV decade}^{-1}$ and a detection limit of $4.0 \times 10^{-5} \text{ mol l}^{-1}$. The response of this electrode, however, is linear in the range 10^{-1} – $10^{-4} \text{ mol l}^{-1}$ and the electrode selectivity for Cs^+ over Li^+ , Na^+ , K^+ , Rb^+ and Mg^{2+} is fairly high (Table 3). Several neutral ionophores are known that do not induce

Table 4
Effect of anionic additives (TCIPB) on selectivities of cesium ion-selective electrodes

Anionic additives	$\log K_{Cs,M}^{Pot}$					
	H ⁺	Li ⁺	Na ⁺	K ⁺	Rb ⁺	NH ₄ ⁺
(a) 0.5 mg TCIPB+2-NPOE+PVC	-2.19	-2.87	-2.40	-0.98	-0.53	-1.42
(b) 1.5 mg TCIPB+2-NPOE+PVC	-2.18	-2.90	-2.39	-1.00	0.54	-1.45
(c) 3.0 mg TCIPB+2-NPOE+PVC	-2.20	-2.92	-2.42	-1.01	-0.56	-1.46

any selectivity in membranes, in the absence of additional anionic sites [5,14]. The selectivity data of the membrane without anionic site additives is possibly due to interfacial kinetic limitations in the transfer of ions from the sample solution to the membrane phase and vice versa. Lipophilic anionic components can efficiently catalyze this cation transfer [15].

Incorporation of TPB or TFPB as a lipophilic anion with ionophore I (membrane components (b) and (c), Fig. 3) in the membrane phase improves the detection limits (2.2×10^{-5} and 1.8×10^{-5} mol l⁻¹, respectively), increases the slope of the electrode response (36 and 46 mV decade⁻¹,

respectively) and increases the membrane selectivity (Table 3). It is obvious from Fig. 3 that the incorporation of a highly lipophilic anion, TCIPB, with ionophore I (membrane component (d)) in the membrane phase leads to a decrease in the detection limit (6.3×10^{-6} mol l⁻¹), increase in the calibration slope (52 mV decade⁻¹) and an increase in membrane selectivity compared with TPB or TFPB. This occurs because its water solubility is lower than that of TPB and TFPB [16], and as such decreases membrane resistance and increases the permselectivity of the membrane for cations.

The potential response of the PVC cesium-selective electrode based on ionophore I (Fig. 1) using of 2-NPOE as plasticizer, and incorporating the secondary ion exchanger KTCIPB is shown in Fig. 4. The electrode seems to exhibit a linear response to cesium ions within the concentration range 10^{-1} – 2.5×10^{-5} mol l⁻¹ CsCl with a slope of 52 mV decade⁻¹ and a detection limit of 6.3×10^{-6} mol l⁻¹. For ionophores II and III, as shown in Fig. 4, linear responses in the concentration range 10^{-1} – 6.3×10^{-5} and 10^{-1} – 4.0×10^{-5} mol l⁻¹, respectively were also observed, they showed slopes of 48 and 51 mV decade⁻¹ and detection limits of 2.0×10^{-5} and 1.3×10^{-5} mol l⁻¹, respectively. The alkali metal ion calibration plot of the electrode based on ionophore I, i.e., *p*-methoxyanilium-(1,3-dioxo-2-indanylidene) acetonitrile, is given in Fig. 5. The corresponding plots for this electrode for other metal ions indicate high Cs⁺ selectivity over divalent ions. All cations produced responses with slopes and detection limits values lower than the Cs⁺ response. The cation response order for metal ions is Cs⁺ > Rb⁺ > K⁺ > NH₄⁺ > H⁺ > Na⁺ > Li⁺. This series is similar to the 2-NPOE plasticized PVC

Fig. 6. Effect of sample anion on responses of cesium ion-selective electrodes based on ionophore I.

electrodes incorporating the KTC1PB secondary ion exchanger (see Table 4), where the logarithm of selectivity coefficient is inversely proportional to the free energy of hydration.

The cation response order for alkaline earth ions was $\text{Mg}^{2+} > \text{Ba}^{2+} > \text{Ca}^{2+} > \text{Sr}^{2+}$. The response for Mg^{2+} was $12 \text{ mV decade}^{-1}$, whereas responses for other divalent cations was consider-

ably less. The transition metal ion responses were very poor with the response order being $\text{Zn}^{2+} > \text{Pb}^{2+} > \text{Cu}^{2+} > \text{Co}^{2+} \sim \text{Ni}^{2+} > \text{Mn}^{2+}$. Both Mn^{2+} , Co^{2+} and Ni^{2+} produced no response (zero slope) across the calibration concentration range. The slope was obtained for Ag^+ ($44 \text{ mV decade}^{-1}$) in the concentration range 10^{-3} – $10^{-2} \text{ mol l}^{-1}$ followed by a sharp drop in potential at

Fig. 7. Effect of internal solution concentration on the responses of cesium ion-selective electrodes based on ionophore I: (a) 10^{-1} ; (b) 10^{-2} ; (c) 10^{-3} ; (d) 10^{-4} and (e) $10^{-5} \text{ mol l}^{-1}$.

Fig. 8. Dependence of electrode response on pH.

$10^{-1} \text{ mol l}^{-1}$. The Ag^+ calibration plot has a higher detection limit ($4.0 \times 10^{-4} \text{ mol l}^{-1}$) than the Cs^+ calibration ($6.3 \times 10^{-6} \text{ mol l}^{-1}$).

The selectivity coefficients ($\log K_{\text{Cs},\text{M}}^{\text{Pot}}$) for a wide range of metal ions determined by the separate solutions method at 0.1 mol l^{-1} are presented in Table 5. The results in Table 5 reveal that the electrode based on ionophore I (*p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile shows a high selectivity for cesium ions over other metal ions compared with ionophores II, III. The incorporation of the *p*-methyl group instead of *p*-methoxy for electrode II leads to a

decrease in selectivity of cesium over metal cations studied. Electrode III incorporating the *p*-*N*-*N*-dimethyl group on anilino-(1,3-dioxo-2-indanylidene) acetonitrile is significantly different from the other electrodes (I and II) with an increase in the selectivity coefficients, H^+ ($\log K_{\text{C},\text{H}}^{\text{Pot}} = +0.17$), Cu^{2+} ($\log K_{\text{Cs},\text{Cu}}^{\text{Pot}} = -2.82$) and Zn^{2+} ($\log K_{\text{Cs},\text{Zn}}^{\text{Pot}} = -1.39$). This is accompanied by an increase in the response to H^+ , Cu^{2+} and Zn^{2+} ions and is attributed to the presence of the nitrogen atom of tert-amine capable of accepting protons and coordination to Cu^{2+} and Zn^{2+} ions on the anilino group.

The results in Fig. 4 and Table 5 indicate that the changes in the structures of ionophores I–III affect the detection limit, the slope of the electrode response and selectivity. These in turn are expected to affect the formation constants and distribution coefficients of cesium complexes. Introduction of an electron donor substituent to the ionophore molecule [$-\text{OCH}_3$ (ionophore I) instead of $-\text{CH}_3$ (ionophore II)] increases the electron density in the anilino group, which in turn is reflected in the high stability of the complex formed. On the other hand, the presence of the nitrogen atom of tert-amine in the ionophore III which is capable of accepting protons, decreases the electron density on the anilino group com-

Table 6

45	1.8×10^{-5}	40

Table 7
Comparison studies of cesium ion-selective electrodes based on ionophore I (in the present electrode) and previously described ionophores

Ionophore	Response time (s)	Linearity (mol l ⁻¹)	Detection limit (mol l ⁻¹)	Slope (mV decade ⁻¹)	log $K_{Cs,M}^{Pot}$				
					Li ⁺	Na ⁺	K ⁺	Rb ⁺	NH ₄ ⁺
15-Crown-5 phosphotungstic acid precipitate (I1)	<60	0.1–10 ⁻⁴	1.0 × 10 ⁻⁵	60	-0.89	-0.46	-0.31	-0.46	—
2,3-Benzo-quinone [15]	<3	0.1–10 ⁻⁴	5.0 × 10 ⁻⁵	51.9	-3.00	-2.38	-0.99	-0.47	-1.40
<i>p</i> -Methoxy-anilino(1,3-dioxo-2-indanylidene) acetonitrile (tonophore)	= 60	0.1–2.5 × 10 ⁻⁵	6.3 × 10 ⁻⁶	52	-3.33	-2.72	-1.22	-0.70	-1.59

pared with $-\text{OCH}_3$ group in ionophore I. In brief, the membrane response and selectivity can be arranged in terms of ionophore molecular structure in the order $\text{I} > \text{III} > \text{II}$. Thus, the electrode of ionophore I [*p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile] has the best response and cesium selectivity, which might be due to the favourable structure of ionophore I which forms a stable complex with the cesium ion.

The effect of the sample anion on the responses of cesium ion-selective electrodes based on ionophore I has been studied and no significant change was observed using various anions such as Cl^- , NO_3^- and SO_4^{2-} (Fig. 6). The potential response of the electrode was found to be linear over the concentration range 10^{-1} – 2.5×10^{-5} mol l^{-1} for CsCl , 10^{-1} – 8×10^{-5} mol l^{-1} for CsNO_3 and 10^{-1} – 1.0×10^{-5} mol l^{-1} for Cs_2SO_4 with a slope of 52–53 mV decade $^{-1}$. According to IUPAC recommendations [17], the practical detection limits, taken as the concentration corresponding to the point of intersection of the two extrapolated lines, are 6.3×10^{-6} , 6.0×10^{-6} and 5.6×10^{-6} mol l^{-1} for chloride, nitrate and sulfate, respectively.

The concentration of the internal solution affects both the transmembrane electric potential and the stability of the cell potential [18]. The effect of the internal solution concentration on the responses of cesium ion-selective electrodes based on ionophore I has also been studied (Fig. 7) and it can be seen that 10^{-3} mol l^{-1} CsCl appears to be the optimum concentration of the internal solution to obtain the best response function. The response time and reproducibility were measured to elucidate the practical properties of cesium-selective electrode. By the 'dip to read' measurements, a response time of within 1 min was obtained with this electrode system. To evaluate the reproducibility of the potential response of the electrode, alternating measurements were performed in 10^{-4} and 10^{-3} mol l^{-1} CsCl . The potential difference in these two solutions was found to be reproducible to 52 ± 0.3 mV ($s, n = 3$) for an upward change in concentration and 52 ± 0.4 mV ($s, n = 3$) for the reverse change. A 1 min period was needed to achieve stable and reproducible potential readings. The potential response curves retrace themselves

without any appreciable hysteresis on increasing and decreasing the concentration of cesium ion.

Measurements of pH dependence of the electrode response was made using the electrode of ionophore I (Fig. 8). In the pH range 2–11, the slope of the potential response seems to indicate no significant change, but at $\text{pH} < 2.0$ and $\text{pH} > 11.0$ the slope decreased. This is perhaps due to a change in the activity coefficients superimposed.

The experimental results in Table 6 show that the lifetime of the present electrode was about 30 days. During this time, the detection limit of the electrode slightly increased from 6.3×10^{-6} to 7.9×10^{-6} mol l^{-1} and the slope of the electrode response decreased from 52 to 48 mV decade $^{-1}$. After this time, the electrochemical behaviour of the electrode gradually deteriorated. This is attributed to the decrease in quantity of plasticizer and ionophore resulting in their migration from a PVC membrane into a PVC tube [19].

The electrode with ionophore I compares well with previously described electrodes (Table 7). The proposed cesium electrode based on ionophore I exhibits much better linearity (10^{-1} – 2.5×10^{-5} mol l^{-1}), detection limit (6.3×10^{-6} mol l^{-1}) and potentiometric selectivity for cesium over metal ions (e.g. Li^+ , Na^+ , K^+ , Rb^+ and NH_4^+) when compared with previously described electrodes. On the basis of these results, the superiority of ionophore I over other reported reagents for cesium is attributed to the high stability of its complex with cesium ion.

3. Conclusion

Anilino-(1,3-dioxo-2-indanylidene) acetonitrile as a new class of neutral ionophores induces useful selectivities for Cs^+ . A cesium-selective PVC membrane electrode based on ionophore I [*p*-methoxyanilino-(1,3-dioxo-2-indanylidene) acetonitrile] exhibits good selectivity compared with ionophores II and III (ionophores under investigation) and previously described electrodes. The present electrode can be used over a wide pH range (2–11). It also has good detection limit (6.3×10^{-6} mol l^{-1}), reproducibility and a short response time (≈ 1 min).

Chemometrical optimization FIA of perphenazine assay

Salah M. Sultan *, Anthony D. Walmsley

School of Chemistry, Cottingham Road, The University of Hull, Hull HU6 7RX, UK

Received 1 August 1997; received in revised form 22 September 1997; accepted 23 September 1997

Abstract

A flow injection method for the assay of perphenazine using cerium(IV) as oxidant in a sulphuric acid media was adopted. Different chemometric techniques, considered the main objective of this work, were utilised to optimise sensitivity and sample throughput as a function of five experimental variables. The optimum conditions obtained by the super modified simplex method were, 0.170 M sulphuric acid, 2.13 mM cerium(IV), 2.56 ml min⁻¹ flow rate, 52 cm coil length, and 136 µl sample loop size. A central composite design was successfully employed, characterising the relation between these variables and the response surface, and hence validating the optimum conditions obtained by the simplex method. Regression analysis of the data from the experimental design, demonstrated that a second order polynomial model is an adequate description of the surface over the factor limits studied. Further analysis of the response surface revealed the presence of a broad maximum around the simplex method optimum. A linear calibration curve in the range 50–500 ppm together with a sampling frequency of at least 120 s h⁻¹ and a relative standard deviation of less than 0.8% were obtained for the determination of perphenazine in its pure analytical grade. Results of the perphenazine assay in pharmaceutical preparations indicates that the method does not suffer interference from excipients rendering the method suitable for the assay of perphenazine in drug formulations. © 1998 Elsevier Science B.V. 1. Introduction

Chemometrics has been shown to be successful for the optimization of chemical reactions in flow injection procedures [1–7] and also proven to be

an efficient technique when four or more interacting variables are involved. Experimental design can be a powerful tool when used as part of the optimisation. Ruggedness testing and modelling of chemical analysis procedures usually employed to understand the relationship between experimental factors and their corresponding responses, as well as a need to determine the optimum operating conditions at which small changes of these factors can be tolerated. Screening designs, such as a two level factorial or fractional design

nation of perphenazine. In addition to the optimisation study, an attempt to model the response surface and so correlate the effect of the experimental factors and the kinetics of the reaction to the response function will be described. Cerium(IV) was used as an oxidant in a sulphuric acid media. The coloured product of the oxidised form of perphenazine is followed spectrophotometrically at 525 nm using the FIA technique.

2. Experimental

2.1. Reagents

Cerium(IV) stock solution (0.01 M) was prepared by dissolving 16.0 g of cerium(IV) sulphate dihydrate (Merk, UK) in 250 ml of 0.05 M sulphuric acid. This solution has been used after 24 h.

Stock sulphuric acid solutions were prepared by diluting Analar grade concentrated acid.

The pure perphenazine solution (1000 ppm) was prepared by dissolving 0.1 g of the pure analytical reagent grade compound (May and Baker products, supplied by Rhone-Poulenc, batch No.D11) in 100 ml of 0.01 M sulphuric acid.

2.2. Apparatus

An Alitea, USA/FIA Lab (Medina, WA) apparatus described in a previous communication [15] was used for FI measurements. The apparatus consists of a peristaltic pump, injector, reactor module and a spectronic Mini 20 Spectrophotometer

connected to a single-channel strip-chart recorder (Cole-Parmer, Chicago, IL).

Fig. 1 shows the double-line FI manifold used. The carrier was pumped through a poly(vinyl chloride) (PVC) pump tubing 1.3 mm i.d. The sample injector was a Rheodyne (Cotati, CA) Model 5041 four-way PTFE rotary valve with a 136 μl injection loop. The reactor coil was 52 cm PTFE tubing 0.5 mm i.d. A Unovic (Plainsville, NY) ultramicro flow cell of 20 μl and path-length 1.0 mm was used.

2.3. Procedure

The drug sample (136 μl) was injected into 0.170 M H₂SO₄, which acts as a carrier solution. The carrier solution together with the injected drug zone, was then mixed with 2.13×10^{-3} M cerium(IV) solution and propelled through a reaction coil of 52 cm length to the spectrophotometer detector. The absorbance of the resulting solution was monitored at 525 nm with the chart recorder operated at a speed of 0.5 cm min^{−1}.

2.4. Experimental design

The super modified simplex procedure [6,7] was initially utilised for the optimization of five parameters; sulphuric acid concentration, cerium(IV) concentration, flow rate, coil length, and sample loop size. The criteria on which the performance of the analytical system can be evaluated, so that an optimum set of operating conditions can be obtained, was selected to include sample throughput and sensitivity, in one expression:

Fig. 2. Response function progress of the simplex.

$$R = \frac{A_{\text{exp}}}{A_{\text{base}} \cdot t_b} \times 100 \quad (1)$$

where R is the response function, A_{exp} is the peak absorbance at the peak maximum for a given set of conditions, A_{base} is the peak absorbance for the reference set of conditions, and t_b is the peak width at baseline. The response function is related to sensitivity by the term $A_{\text{exp}}/A_{\text{base}}$ and sample throughput by t_b . The range of experimental variables investigated are given in Table 1.

The response surface was then mapped and explored using a rotatable five factor central composite design [10,11], the centre of which was located on the simplex optimum. The central composite design, introduced by Box and Wilson [16], consists of a 2^k factorial or fractional facto-

rial design augmented by 2^k axial points and a number of centre points (N_0). The five factor central composite design is composed of 42 experiments plus six centre experiments, so that a total of 48 experiments were performed. The coded levels of the variables together with their real experimental values are given in Table 2. The centre point represents the set of optimum conditions obtained by the simplex, save the coil length which was changed from 52 cm to 75 cm in order to simultaneously cover a broad region of factor space, within the factor limit, and to maintain the desired properties of the experimental design [10,11]. The sigma plot software package was used to generate the full design in two blocks and to randomise the time order of the experiments within each block. All experiments were performed on the same day.

Fig. 3. Surface plot of the response vs. sulphuric acid and cerium(IV), all other factors are kept constant at their zero levels.

3. Results and discussion

Before undertaking any optimization study, it is important to delineate clearly the boundaries of the selected system and to define the performance criterion or response function. In this study, five factors namely, sulphuric acid concentration, cerium(IV) concentration, flow rate, coil length and sample loop size were investigated. The lower and upper levels of these five factors are shown in Table 1 which are limited by the physical distances of the apparatus or those beyond where no response was observed.

One way of treating multiple competing objectives is to select a criterion as primary and the remaining criteria as secondary. The primary criterion is then used as an optimization performance measure, while the secondary criteria are assigned acceptable minimum or maximum values and treated as system constraints [4,5,17]. The performance criterion or the response function was formulated (Eq. (1)) in a single expression as

a compromise between sensitivity and the time of analysis. The super modified simplex program was employed to obtain optimum operating conditions. The progress of simplex is given in Fig. 2 showing a gradual improvement in the response function and clear levelling towards maximisation. The simplex results given in Fig. 2 were obtained by injecting 200 ppm drug standard solution. A total of 29 experiments were needed to decide on optimum conditions. The optimum conditions were obtained by calculating the average of the four sets of conditions that give rise to the top four responses. The maximum response functions obtained are more or less similar and range between 39.8 and 40.8. The set of conditions that generated these maximum responses vary within a very narrow range. Therefore, the optimum operating condition obtained by the simplex technique for the determination of perphenazine are 0.170 M sulphuric acid, 2.13×10^{-3} , cerium(IV) concentration flow rate of 2.56 ml min^{-1} , coil length of 52 cm and sample loop size of 136 μl .

3.1. Response surface modelling

Response surface methodology (RSM) was used to assemble the model in order to describe the way in which the variables are related and the way in which they influence the response function. The form of the relationship between response function and experimental variables is initially assumed to be unknown. Therefore, the data obtained from the set of conditions employed by the central composite design were fit to the following parametric equation (full second order polynomial)

$$R = \beta_0 + \sum_{i=1}^5 \beta_i X_i + \sum_{i=1}^5 \beta_{ii} X_i^2 + \sum_{i < j} \beta_{ij} X_i X_j \quad (2)$$

where R is the response (given by Eq. (1)), β_0 is the intercept, X_i s are the five main variables, β_i is the linear parameter, β_{ii} is the quadratic parameter, β_{ij} represents the interaction parameters. Table 3 gives the estimates of 21 parameters, contained in Eq. (2), obtained by the matrix least squares [11,18].

The adjusted correlation coefficient of regression (R^2) was found to be 0.956. The significance of regression was tested by the F -ratio of the mean square due to the factors divided by the mean of squares due to the total error, and was found to be highly significant. Analysis of the residuals from the regression model and the lack of a fit test [11,18], revealed that the second order polynomial model, tentatively assumed, would be an adequate description of the surface over the region studied.

3.2. Response surface plots

Response surfaces for all two factor interactions were produced using the second order polynomial model. All plots were generated to describe two factors at a time by holding the other factors constant at the zero level. Only a few plots are illustrated here, i.e. factors with considerable interaction.

Fig. 3 shows the response surface as a function of sulphuric acid and cerium(IV) concentration,

Fig. 4. Surface plot of the response vs. cerium(IV) and flow rate, all other factors are kept constant at their zero levels.

other factors are at their zero levels. Both factors exhibit significant main effects as well as highly significant interaction effects (Table 3). It is evident from Fig. 3 that a broad optimum is obtained at the middle levels of both factors. Moving away from the optimum to high acid concentration and low cerium(IV) concentration, a sharp decrease in the response is observed. Response surface plots demonstrating the effect of varying cerium(IV) concentration versus flow rate, loop size versus cerium(IV) concentration, and coil length versus loop size are shown in Figs. 4, 5 and 6, respectively.

4. Analytical application

The optimum operating conditions obtained by the simplex procedure and those obtained from the stationary point of the experimental design are shown in Table 1. Series of standard perphenazine

solutions were run using the set of conditions obtained by the super modified simplex optimization procedure, and the stationary point conditions one at a time. Peak absorbance versus concentration was found to be linear between 50 and 500 ppm for both methods, an almost two-fold improvement in the linear range as compared with the previous study [14]. The calibration equations obtained for the simplex optimized method and the experimental design stationary point are as follows:

$$A = -0.02812 + 1.916 \times 10^{-3}C, \quad R^2 = 0.998$$

$$A = -0.034 + 2.233 \times 10^{-3}C, \quad R^2 = 0.997$$

Where A is the peak absorbance and C is the concentration of perphenazine in ppm. The relative standard deviation was found to be 0.74 and 0.77%, when the simplex and experimental design method set of conditions were performed, using five repeated determinations of 200 ppm drug,

Fig. 5. Surface plot of the response vs. loop size and cerium(IV), all other factors are kept constant at their zero levels.

respectively. A standard deviation of less than 0.10 was obtained from the slopes and less than 1.1 at y -intercepts. Three calibration standards were present per calibration relation. The stationary point of the experimental design was found to be characterised by a higher sampling frequency, 190 S h^{-1} as compared with the simplex depicted method of only 120 S h^{-1} .

The tolerance of the two sets of optimum operating conditions to excipients which could be present in a typical pharmaceutical preparation containing perphenazine, was investigated. Synthetic solutions of 200 ppm perphenazine in the presence of 2000 ppm interfering compounds, such as starch, glucose, lactose and maltose, have been analysed using the two optimum conditions. The percent recovery, standard deviation (SD) and the student t -test values are given in Table 4. The student t -test values reveal that a similar degree of accuracy is obtained by the two set of conditions. Foreign compounds expected to be present in drug formulations show minimum or no interference in both cases.

5. Conclusion

This work outlines the important application of a systematic optimization of many variables for such a complicated system in order to obtain a rapid, sensitive and reproducible quantitative FIA procedure. The super modified simple method successfully attained optimum conditions which were further confirmed by experimental design techniques. Response surface modelling helped in understanding the effect of each factor on the response and enabled a good correlation to the kinetics of the chemical reaction to be achieved.

The chemometrics applied in this work is not new, but its application in analytical chemistry is seldom represented. The growing interest of the industrial sectors to acquire data and information rapidly with minimal measurement during the manufacturing process, would suggest that simplex optimization is best suited for the final refinement stage of a method, especially if the method provides a simple and well characterized response

Fig. 6. Surface plot of the response vs. coil length and loop size, all other factors are kept constant at their zero levels.

like FIA. The results generated and presented in tables and figures demonstration this reduction of data thus indicating the novelty of the outcome.

Table 4

It is postulated that simplex optimization will be used more frequently when it becomes easier to use. Once a given algorithm proves successful then the next step leading to common acceptance is a user friendly computer programme. Maybe future applications need to focus less on insignificant comparisons of similar algorithms in favour of providing a uniform algorithm or software package. The results presented in this manuscript indicate that ruggedness testing is the more logical application of simplex optimization because this application makes use of the response surface around optimum parameter values.

Abstract

The combination of a chiral-selective separation mode with polarimetric detection was investigated in terms of its ability to quantitate enantiomeric mixtures of the dansylated derivatives of phenylalanine, threonine, and valine under conditions of poor chromatographic resolution. Using the difference between two Gaussian functions to model the bimodal response obtained using polarimetric detection and incomplete chiral resolution, correlation coefficients as high as 0.999 were obtained when actual enantiomeric fractions were plotted against observed enantiomeric fractions calculated from the fitting procedure. The methodology was evaluated at different levels of chromatographic resolution, and as a function of the sign and magnitude of the specific rotation of the model compounds. Limits of quantitation calculated at different levels of enantiomeric excess demonstrate the potential of the method to quantitate enantiomeric mixtures even under conditions of poor chromatographic resolution. Minimum measurable quantities (MMQ) at, or below the 1.0% enantiomeric excess (ee) level were obtained for the three amino acid derivatives tested under various conditions of chromatographic resolution when the polarimetric data were fit to the bimodal response model. Even under the lowest resolution conditions tested, the MMQ was determined to be at the 5% ee level. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Chromatographic resolution; Enantiomeric mixtures; Polarimetric detection

1. Introduction

The quantitation of mixtures in chromatographic analysis frequently utilizes either peak height or peak area as the basic analytical descriptor. For baseline-resolved peaks, the measurement

of these parameters is easy, straightforward, and accurate. However, the distortion caused by excessive overlap of peaks has presented problems with respect to precision due to uncertainties in the determination of baselines and peak boundaries [1,2].

In response to problems which arise in situations involving overlapping peaks in chiral separations, the use of peak height and area in the

* Corresponding author. Tel.: +1 501 5754601; fax: +1 501 5754049; e-mail: dbobbitt@comp.uark.edu

determination of enantiomeric excess in a mixture was investigated in a recent study [3]. Using conventional enantiomeric separation methods, a laser-based polarimetric detection system was interfaced with a chiral-selective separation mode (CSS/PD) for the precise quantitation of enantiomeric mixtures even under conditions of poor chromatographic resolution. Quantitation was achieved using this combined technique as a consequence of the unique bimodal response function of the polarimetric detector when presented with a mixture of enantiomers in the detection cell. The bimodal response results from the fact that enantiomers rotate the plane of polarized light in opposite directions. With peak height and peak area as the analytical descriptors, the experimentally obtained bimodal response function provided a well-defined crossing point that served as a reference in the determination of these parameters [3].

The goal of this study was to extend the analytical capabilities of the CSS/PD method for the quantitation of enantiomeric mixtures. The development of an appropriate response function was proposed as a way to offset the problems of baseline stability and integration limits on the determination of peak areas. The bimodal response obtained from the polarimetric detection scheme is well-characterized by the difference between two Gaussian functions. By fitting the data to this model, the entire data set can be used which allows the relative concentration of the two enantiomers in a mixture to be determined with excellent measurement precision. The analytical capabilities of this analysis procedure will be compared to both peak height and area for three model compounds at various levels of enantiomeric resolution.

2. Theoretical analysis

Various approaches have been developed in order to characterize chromatographic peak profiles and provide a clearer understanding of the physical and chemical processes occurring in the chromatographic column. Under conditions where random processes shape the analyte distri-

bution in a column, peak shapes can be adequately described by a Gaussian function [4–6], which is represented by:

$$h(t) = [A/\sqrt{(2\pi\sigma^2)}] \exp[-(t-m)^2/2\sigma^2] \quad (1)$$

In Eq. (1), $h(t)$ is the height or amplitude at time, t ; s is the standard deviation of the distribution; m is the peak position along the time axis; and A is the peak area of the function.

Theoretically, the ideal shape of this function is approached when an analyte undergoes a sufficiently large number of random sorption and desorption processes in a column [7]. Representing the frequency distribution of the analyte migrating through the system, a chromatographic peak can functionally be taken as a time distribution of the chromatographic height, $h(t)$ at any retention time, t . At the center of the distribution lies the 'average' position that is used to characterize a particular analyte. It has been shown that a Gaussian function can accurately describe the concentration profile of an eluting substance [8,9].

A pair of enantiomers have the unique property that they rotate plane polarized light to the same extent, but in opposite directions. A distribution consisting of two incompletely resolved enantiomers will produce a bimodal response with polarimetric detection and this response can be characterized as the difference between two Gaussian functions, as given in Eq. (2) below

$$h(t) = [A_1/\sqrt{(2\pi\sigma_1^2)}] \exp[-(t_1-m_1)^2/2\sigma_1^2] - [A_2/(\sqrt{2\pi\sigma_2^2})] \exp[-(t_2-m_2)^2/2\sigma_2^2] \quad (2)$$

where $h(t)$ is the height or amplitude at time, t ; s is the standard deviation of the peak; m is the peak position along the time axis; and A is the peak area.

By fitting the polarimetric response obtained for an incompletely resolved enantiomeric pair to this difference function, the entire response is used for quantitation of each enantiomer thereby enhancing the precision of the methodology.

In this study, the application of Eq. (2) to polarimetric data obtained at different levels of chromatographic resolution and specific rotation will be evaluated in order to more fully characterize and apply the CSS/PD technique.

3. Experimental

3.1. Reagents

The dansylated amino acids (Dns-D- and L-phenylalanine, Dns-L-threonine and Dns-L-valine), as well as the underivatized forms (D-threonine and D-valine) were obtained from Sigma (St. Louis, MO). Dns-D- and L-phenylalanine were available in the free acid form while Dns-L-threonine and Dns-L-valine were purchased as cyclohexylammonium salts. The derivatizing agent, 5-[dimethyl-amino]naphthalene-1-sulfonyl chloride (DnsCl) and the HPLC solvents acetonitrile and methanol were also obtained from Sigma.

3.2. Derivatization of amino acids

The derivatization of the amino acid samples was carried out as described previously [3,10]. DnsCl was dissolved in acetonitrile (1.5 mg ml^{-1}) while the amino acid (0.75 mg ml^{-1}) was dissolved in 40 mM lithium carbonate buffer adjusted to pH 9.5 with HCl. A 1-ml volume of the DnsCl solution was rapidly added to 2 ml of the amino acid solution, the mixture was shaken for 2 min and then allowed to stand overnight at room temperature (22–23°C). Termination of the reaction was accomplished by adding 100 μl of a 2% ethylamine hydrochloride solution. Containers were wrapped with aluminum foil to exclude light.

For polarimetric detection, the quantity of the derivatizing agent as well as the amino acid, was increased to 0.0500 and 0.0250 g, respectively. DnsCl was dissolved in 20.0 ml of acetonitrile while the amino acid was dissolved in 10.0 ml of 40 mM lithium carbonate buffer adjusted to pH 9.5. The mixture was heated to about 55°C for 1 h and the reaction was terminated, as before, using the 2% ethylamine hydrochloride solution. Solvents were evaporated at the same temperature under a vacuum.

3.3. Determination of specific rotation

Samples of commercially available, dansylated amino acids (DNS-L- and D-phenylalanine, DNS-

L-threonine and DNS-L-valine) were dissolved in a 70/30 (v/v) acetonitrile/ NH_4NO_3 solvent mixture at a level of 0.100 g/10.00 ml. Specific rotations were obtained using a conventional polarimetric system at a measurement wavelength of 488.0 nm. The specific rotation of each compound was calculated from α , the actual rotation measured, c , the concentration of the solute in g ml^{-1} of solution, and l , the pathlength, in decimeters.

3.4. UV and polarimetric detection

The UV detector (Shimadzu, Kyoto, Japan, model LC-6), was equipped with a solvent delivery module, a UV-VIS spectrophotometric detector and a CR 601 integrator. The laser-based polarimetric detection system has been described in detail previously [11,12]. Briefly, the source was an argon ion laser (Lexel, Palo Alto, CA, model 85) mounted on a 4×6 ft optical breadboard. The source light passed through a pair of Glan-Thompson polarizing prisms, (Karl Lambrecht, Chicago, IL, model MGT-E8). The source light was modulated using an in-house constructed Faraday cell driven by a signal generator (Wavetek, model 190). The modulation and detection cells had volumes of 1.1 ml and 29 μl , and pathlengths of 0.85 and 0.38 dm, respectively. The polarized laser light passing through the analyzer was detected with a photomultiplier tube (PMT), (Hamamatsu, Middlesex, NJ, model 928) powered by a high-voltage supply, (Bertran Associates, Hicksville, NY, model 215). The signal from the PMT was demodulated, amplified and digitized using a lock-in amplifier, (Stanford Research Systems, Palo Alto, CA, model SR 510). The digitized data were transferred to a PC Computer over an IEEE interface, (National Instruments, Austin, TX, model PC-2A) for storage and analysis. The Faraday coil used as an internal standard was made from a 10 cm \times 0.125 o.d. piece of stainless-steel tubing wrapped with 8000 turns of a 30 A WG magnet wire (Bendon, Geneva, IL). A DC current of 0.266 A produced a rotation of 3.85×10^{-40} at 488 nm, as calculated from the results of Ingersoll and Liebenberg [13].

3.5. Chromatographic analysis

The 25 cm × 4.6 mm i.d. Cyclobond column was purchased from Astec, (Whippany, NJ). The stationary phase for this column is a chiral β -cyclodextrin chemically bound to a spherical gel support through a non-nitrogen-containing spacer arm.

Enantiomeric mixtures of D and L dansylated amino acids were prepared using different D to L ratios: 1/0, 0/1/, 1/1/, 1/2/, 2/1, 1/3, 3/1, 1/4, 4/1. In these mixtures, the total amount (L + D) of amino acid dissolved in the methanol solvent was prepared such that the amount of material injected with the polarimetric detection system was 15 μ g for phenylalanine, 40 μ g for threonine and 60 μ g for valine using a 20 μ l injection loop. With UV detection, the concentration of all three samples was set at 1.50 mg/250.0 ml. All separations were achieved at a flow rate of 1.00 ml min⁻¹ using a degassed solvent system consisting of combinations of acetonitrile and NH₄NO₃. Since near baseline separation for DNS-D- and L-phenylalanine was obtained with a solvent system of 80/20 acetonitrile/NH₄NO₃, other solvent systems were prepared, for example, 70/30, 50/50 and 40/60, to decrease resolution. For the 40/60 solvent, the [NH₄NO₃] was 0.10 M. Chromatographic analyses were performed using the different D:L ratios and a combination of four eluent systems. Concentrations for the derivatized samples (Dns-D-threonine and Dns-D-valine) were determined using known concentrations of the corresponding Dns-L-amino acid and UV absorption spectroscopy. Resolution values for the dansylated enantiomers of phenylalanine, valine and threonine as a function of eluent composition are given in Table 1.

A minimum of three determinations for each enantiomeric mixture were obtained for all three amino acids using four solvent systems and different L/D mixtures.

3.6. Analysis of bimodal response function

The bimodal response function was simulated using the difference of two Gaussian functions, as given in Eq. (2). This simulated bimodal response

model was then fit to the polarimetric response data for various enantiomeric mixtures using standard techniques. Correlation coefficients were obtained using actual and calculated enantiomer concentrations after taking the ratio of areas for the L and D enantiomers and translating these area ratios into concentration ratios.

4. Results and discussion

In order to adequately evaluate the use of a bimodal response model for polarimetric detection under conditions of low enantioselective resolution, both the magnitude of the specific rotation and the extent of separation must be varied. Dansylation of the three amino acid test compounds produced a range of specific rotations (phe, -131; val, 65.3; and thr, -18.7; units °(g ml⁻¹)⁻¹ dm⁻¹). This range of chirality provides a good test of the methodology and the model compounds also encompass a sign change in their respective specific rotations. In order to create a range of chromatographic resolutions, various eluent compositions were evaluated and the corresponding resolutions are given in Table 1. As is evident for these eluent compositions, experimentally determined resolutions varied from approximately 1.0–0.3. Even under the highest

resolutions tested, conventional approaches to enantioselective analysis would not be able to provide accurate and precise compositional information on an enantiomeric mixture. Thus this range of chromatographic resolutions provides a rigorous test of the proposed methodology.

In Fig. 1, a simulated response for a single enantiomer is compared to the experimentally determined profile obtained using polarimetric detection. The simulated response was calculated using the first segment of Eq. (2). It is clear that the CSS/PD system provides a well characterized response which can be modeled precisely by a Gaussian function. In Fig. 2, both parts of Eq. (2) were used to simulate the bimodal response expected for two enantiomers which are incompletely resolved. As is evident, the simulated and experimental profiles agree well. In order to prepare the simulated response, only the distance between the maximum and minimum of the bimodal response and the width of the profile were used. Therefore, with Eq. (2) as the model, polarimetric data obtained for incompletely resolved enantiomeric mixtures can be used to obtain quantitative information on each enantiomer separately. It should be emphasized that this approach does not require baseline separation, although the obtainable resolution would be expected to effect the quality of the measurement.

Table 2 summarizes the correlation coefficients obtained when experimentally determined enantiomeric fractions were plotted against actual enantiomeric fractions for DNS-phenylalanine, DNS-threonine and DNS-valine. The experimentally determined values were obtained by fitting the bimodal response function given in Eq. (2) to the polarimetric data. Several points are evident in these results. First, for most eluents tested, excellent correlation is noted between the experimentally determined and actual values. Even under conditions of incomplete chromatographic resolution, the quantitative capability of the CSS/PD methodology is very good. For this range of chromatographic resolutions, a non-selective detector would not produce a response which could be used to differentiate the various enantiomeric fractions. It also is clear that the quality of the determination is affected, to some extent by the

chromatographic resolution. However, valuable quantitative information can still be obtained with the CSS/PD system under conditions which would be problematic or impossible for a non-chiral-se-

lective detector. This approach could have merit, for example in synthetic development studies where changes in the enantiomeric fraction of the product mix is monitored as a function of experimental conditions in order to optimize the yield of

a desired product. In such situations, chiral columns are easily degraded by the conditions since the composition of the injected sample can vary greatly and, due to the uncontrolled nature of the sample, irreversible absorption of material to the column could degrade the chiral resolution. Even under such conditions, the CSS/PD approach could provide useful information. Finally, it should be noted that the quality of the data does not appear to be affected by the magnitude or sign of the specific rotation of the enantiomeric pair over the range of linearity for the polarimetric detection system.

The data in Table 2 serves to establish that a relationship exists between the CSS/PD response and the amount of each enantiomer in a mixture. Of more importance is the ability of the methodology to provide accurate and precise quantitative information on each enantiomer under conditions of poor enantioselective resolution. For such an evaluation, the limit of quantitation, in terms of enantiomeric excess can provide information about the quantitative capability of the methodology as a function of the relative amounts of the two enantiomers. The enantiomeric excess (ee) is defined as the difference between the amount of the two enantiomers in a mixture divided by their total. For example, 0% ee is equivalent to a

racemic mixture that contains equal amounts of the two enantiomers, 60% ee contains 80% L and 20% D while –40% ee, in the interest of this study, contains 30% L and 70% D. In this study, the limit of quantitation (LOQ) constitutes the confidence interval (2σ) for the quantitation of one enantiomer in an enantiomeric mixture at a particular level of enantiomeric excess, as determined by the calibration function and the standard error of the slope of this function. The LOQ may vary over the range of enantiomeric excess and as a function of chromatographic resolution and elution order.

Tables 3–5 show the LOQs obtained for dansylated phenylalanine, threonine, and valine at three different values of enantiomeric excess. At 0% ee, the range varied from 49.3–50.8, 49.0–51.0, to 48.8–51.3, for phenylalanine, threonine, and valine, respectively, using the 80/20 solvent system. Values obtained using the 70/30 and 50/50 or 60/40 solvent systems are comparable with these numbers, although, the LOQ range obtained for the 40/60 solvent system was larger. These numbers suggest that low levels of each enantiomer can be detected in the presence of the other. For example, the LOQs for Dns-L-phenylalanine using the 80/20 and 40/60 eluent systems were 29.6–30.5 and 28.4–31.8 at the –40% ee level, suggesting that the minimum measurable change in

enantiomeric excess that can be detected with this approach is less than 1% ee for Dns-L-phenylalanine at a resolution of 1.0, and approximately 3% ee at a resolution of 0.3. It is important to note that at these resolution values, traditional approaches would not be able to provide useful quantitative information. The bimodal response model also is superior to simple peak height or area analysis. In a previous study [3] in which peak area was used for quantitation of

partially separated enantiomers, corresponding minimum measurable changes at these resolution values were 2 and 6%, respectively. Over the range of enantiomeric excess and resolutions evaluated, the minimum measurable change varied from 1 to 2% ee at low enantiomeric excess, to 2–3% ee at 0% enantiomeric excess, to 3–6% ee at high enantiomeric excess. Similar results were obtained for the three test compounds with differing sign and magnitudes of specific rotation.

As described earlier, one important application of the CSS/PD technique may be as an aid in the development and optimization of an enantio-selective synthetic strategy for a new target compound, for example, a therapeutic pharmaceutical. In such applications, a large number of synthetic variables may be evaluated in an attempt to control the enantiomeric composition of the final product. In these situations, rapid feedback is necessary with respect to the composition of the reaction mixture and the CSS/PD methodology may be able to provide this information without the need for extensive chromatographic development work.

The success of this methodology is limited by the sensitivity of the polarimetric detection system, the quality of the separation and the innate optical activity of the enantiomeric pair. Recently, a commercially available, laser source polarimeter has been introduced based upon the same operational principles as the experimental instrument used for this work, and which has demonstrated similar performance specifications [15]. Thus the method is not limited by available polarimetric instrumentation. Although polarimeters do not provide a response for racemic mixtures, a situation which will occur under conditions of extremely low enantio-selective resolution, as long as a modest degree of resolution has been achieved ($R_s \sim 0.3$), the method may be used to provide a reasonable estimate of the enantiomeric composition of the sample.

5. Summary and conclusions

This study combined a chiral selective separation mode with polarimetric detection for the

analysis of enantiomeric mixtures at low enantioselective resolution. A bimodal response function was developed using the difference between two symmetrical Gaussian functions, and found to fit the polarimetric response well. Excellent quantitative results were obtained for assessing enantiomeric excess and the bimodal response model was found to provide equivalent results over a range of specific rotations and enantioselective resolutions. At the lowest resolutions tested, conventional approaches would not be able to provide any useful quantitative information on an enantiomeric mixture.

In many circumstances, symmetrical peak profiles may not be obtained for one, or both of the eluting enantiomers. In such situations, the symmetrical Gaussian peak model may not be appropriate. Recent work has demonstrated that an exponentially modified Gaussian function (EMG) can be used as a valid model of a tailed analyte distribution [14]. Thus, in such situations, modification of the methodology described herein by the use of the EMG in place of a symmetrical Gaussian function may allow similar results to be obtained even on tailed analyte distributions.

Methods for determination of hexachlorobenzene and pentachlorophenol in soil samples

Luciana Polese *, Maria Lúcia Ribeiro

Departamento de Química Orgânica, Instituto de Química, UNESP 14800-900, CP 355, Araraquara, SP, Brazil

Received 08 July 1997; received in revised form 29 September 1997

Abstract

The efficiency of methods for the determination of hexachlorobenzene (HCB) and pentachlorophenol (PCP) in soil samples was evaluated. An on-line method was applied for HCB determination. Soil samples were transferred to chromatographic columns prepacked with alumina. The HCB elution was processed with n-hexane. The PCP was extracted from soil samples with n-hexane–acetone in an ultrasonic bath. After re-extraction with K_2CO_3 solution PCP was acetylated with acetic anhydride. The pentachlorophenyl acetate derivative was then extracted with n-hexane. The HCB and PCP derivative were analyzed by gas chromatography with electron capture detection (GC-ECD). Mean recoveries obtained from soil samples fortified at levels of 0.5; 4 and 20 $ng\ g^{-1}$, ranged from 91 to 100% for HCB, and for PCP, at levels of 10; 40 and 200 $ng\ g^{-1}$, ranged from 88 to 101%. These results demonstrated the efficiency of the proposed methods. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Hexachlorobenzene; Pentachlorophenol; Soil; GC-ECD

1. Introduction

As a result of agricultural practices and industrial waste disposal, the environment is being continually polluted by pesticides and industrial chemicals. The behaviour of these polluting compounds in the environment is determined by the physicochemical properties of the compounds and their relationship to processes such as adsorption, leaching, vaporization, and degradation.

Hexachlorobenzene (HCB), a fungicide and by-product resulting from the manufacture of many chlorinated hydrocarbons [1], and pen-

tachlorophenol (PCP), an insecticide, fungicide and herbicide [2], were dumped by a chemical company near a populated area in the town of São Vicente, in the State of São Paulo, Brazil. Whereas governmental norms have been established for controlling water pollution by pesticides, none exist concerning soil pollution [3], it is therefore important to develop suitable, accurate, and sensitive methods to determine the extent of soil contamination.

Many methods for the determination of contaminants which include HCB and PCP in soils and sediments have been described in the literature [4–12]. Seidel et al. [4] made a comparison of simultaneous steam distillation-solvent extraction

* Corresponding author. Fax.: + 55 162 227932.

(SDE) with two preconcentration techniques (Soxhlet extraction-SE and supercritical fluid extraction-SFE) for the determination of organochlorine pesticides (OCPs) and HCB in soil and oleagineous matrices. A new SDE apparatus was developed and the extraction efficiency for OCPs proved to be better for SDE than for SE or SFE.

Several studies have described the optimization of SFE for the extraction of OCPs, HCB, and polychlorinated biphenyls from soils [5–7]. Although SFE has been shown to be a viable alternative to conventional extraction techniques, it presents certain limitations such as the high cost of equipment, the influence of soil-water content in the recovery of pesticides, and the low recovery of polar substances [3].

The application of the SFE technique for determination of polar compounds such as PCP and other chlorophenols in soil samples was demonstrated by Lee et al. [8]. Phenols were extracted from soil and acetylated *in situ* with supercritical carbon dioxide in the presence of triethylamine and acetic anhydride. This procedure increases the extractability of polar compounds since acetyl derivatives are in general less polar.

Phenol derivatization prior to gas chromatography (GC) analysis is not a new technique. However, the advantages of different procedures for derivatizing such as sensitivity, and improved gas chromatographic performance are still being discussed and continue to be recommended [8,9,11,13,14].

Despite differences in the chemical properties between HCB and PCP, analytical methods for simultaneous determination of these compounds in soil and sediments have been developed [9,12]. Kolb et al. [9] proposed a method for the analysis of a wide variety of compounds. After extraction at different pH values, first high molecular matrix compounds were separated by gel permeation chromatography and fractionation of the samples into five groups of substances was performed by column chromatography; phenols were derivatized by pentafluorobenzoylchloride. Recoveries of most of the compounds were higher than 80%. Lopez-Avila et al. [12] used a commercially available system (Soxtec) for extracting organic com-

pounds from soils and sediments. Average recoveries of 62.7% were obtained for PCP and ranged from 52.5 to 85.6% for HCB.

The aim of this study is to evaluate the applicability of two methodologies for determination of HCB and PCP in soil samples.

The determination of HCB was made by means of an on-line method combining extraction and cleanup in a single step. Soil samples were transferred to chromatographic columns and HCB was quantitatively eluted with n-hexane. The PCP was extracted from soil samples with a solvent mixture followed by a K_2CO_3 solution. The addition of acetic anhydride led to the formation of pentachlorophenyl acetate which was then extracted with n-hexane. The HCB and PCP derivative were analyzed by gas chromatography with electron capture detection (GC-ECD).

2. Experimental

2.1. Apparatus

A Varian 3300 gas liquid chromatograph equipped with 200 cm \times 2 mm i.d. glass column packed with 1.5% OV 17/1.95% QF 1 on 100–120 mesh Chromosorb WHP, a constant current ^{63}Ni electron capture detector (ECD) and a Varian 4290 integrator were used. The operating conditions were as follows: injector temperature, 230°C; column temperature, 180°C; detector temperature, 300°C; nitrogen flow rate, 30 ml min⁻¹; ECD range, 10; ECD attenuation, 4; and chart speed, 0.5 cm min⁻¹.

2.2. Reagents

n-Hexane (Mallinckrodt) and acetone (Merck) were of pesticide grade. Acetic anhydride (Merck), anhydrous potassium carbonate (Grupo Química) and sulphuric acid (Merck) were of analytical grade. Anhydrous sodium sulphate (pesticide grade, Merck) was heated at 130°C for 24 h. Alumina 90 neutral (70–230 mesh, Merck) was deactivated according to the procedure described by Ribeiro et al. [15]. Reference standards of HCB and PCP were obtained from the Envi-

ronmental Protection Agency (Triangle Park, NC). Standard solutions were made up in n-hexane and stored at -18°C .

2.3. Sample preparation and fortification

Soil samples were air-dried, homogenized, ground, sieved (48–150 mesh) and stored in stoppered glass flasks at -18°C . Fortified soil samples were prepared by adding 1.0 ml of each standard solution to 5.0g of soil. The standard solution was added to the sample drop by drop while verifying that the solution covered the soil particles completely. After fortification the samples were homogenized with the use of a glass rod and kept at room temperature for 1 h to allow evaporation of the solvent.

2.4. Analytical procedures

2.4.1. Hexachlorobenzene

A glass chromatographic column (350 \times 10 mm i.d.) was prepared by adding, in this order: a small plug of glass wool, n-hexane up to 30 mm, and 2.0 g of 4.6% deactivated alumina as a slurry. The column was tapped gently and 5.0 g of the soil sample was transferred to the column. The elution was processed with 60 ml of n-hexane at 2 ml min^{-1} . The eluate was collected in a 100 ml round-bottom flask and concentrated to 3 ml using a rotary evaporator. The final extract was reconstituted to an adequate volume with n-hexane.

2.4.2. Pentachlorophenol

An analytical sample of 5.0 g was adjusted to a $\text{pH} < 1$ with approximately 1 ml of H_2SO_4 (1:1) and extracted twice with 20 ml of n-hexane–acetone (1:1) in an ultrasonic bath (Branson) for 20 min. Following each extraction, the soil was allowed to settle and the supernatant was transferred to a separatory funnel. The organic layer was extracted three times with 20 ml of potassium carbonate solution (5%), and after the last extraction the organic layer was discarded. To combined aqueous extracts 1.0 ml of acetic anhydride and 20 ml of n-hexane were added. The separatory funnel was stirred slowly until the evolution

of CO_2 subsided, and then stirred vigorously for 2 min. The acetylation extraction process was repeated twice. The combined organic layers were dried through anhydrous sodium sulphate, concentrated, and diluted as described above

2.5. Gas chromatographic analysis

Suitable aliquots of soil extracts and standard solutions were injected into a gas chromatograph. The percentages of recoveries were calculated by comparing the average chromatographic peak areas of the standard, fortified samples and unfortified samples. Standard solutions of PCP were extracted with potassium carbonate solution and acetylated as described previously.

3. Results and discussion

The efficiency of the proposed methods was evaluated by means of recovery studies with soil samples fortified at three different levels. The physicochemical properties of the soil samples are presented in Table 1. The fortification levels and recovery values of HCB and PCP are shown in Table 2.

3.1. HCB procedure

The development of the HCB procedure was based on an on-line method previously developed in our laboratory [16] for determination of

Table 1

^a Eight analyses.

organochlorine pesticides in soil. Preliminary analyses were performed by using n-hexane–dichloromethane (7:3) for HCB elution from the column. Low recovery data (44 and 65%) were obtained when the elute was concentrated to dryness. Then, n-hexane was tested for elution of HCB in place of n-hexane–dichloromethane (7:3); this substitution is of interest due to the carcinogenic properties of dichloromethane and the need to remove dichloromethane before GC-ECD analysis [17]. The concentration step was performed as described in the experimental section and the recovery values ranged from 85 to 110% for soil samples fortified at 0.5; 4 and 20 ng g⁻¹. Different solvent systems such as toluene and n-hexane–dichloromethane were tested for the elution of PCP from the column. Recovery results were very low in all cases and demonstrated that this method was not adequate for PCP determination.

3.2. PCP procedure

The establishment of the experimental conditions followed a described methodology [18] developed for the analysis of chlorophenols in sediments. In this method, after acidification, sediment samples were Soxhlet extracted with a mixture of acetone-hexane for 20 h. Phenols in the organic extract were extracted with KHCO₃ solution, and then acetylated with acetic anhydride. After extraction with petroleum ether, the acetates were cleaned on a silica gel chromatographic column.

In the present study, after acidification, PCP was extracted from soil in an ultrasonic bath. In the first step, n-hexane and n-hexane–acetone were tested for their efficiency to extract PCP. Low percentages of recovery (64 and 65%) were obtained with n-hexane, however by using the mixture of n-hexane–acetone (1:1) better recoveries were obtained (80 and 83%). The extraction and acetylation of PCP were achieved by using a K₂CO₃ solution and acetic anhydride. n-hexane was used for extraction of the PCP derivative. Recovery data from samples fortified at 10; 40 and 200 ng g⁻¹, ranged from 80 to 110%. These values are in good agreement with the results reported by Lee et al. [18] but the procedure presented in this study has certain advantages such as time saving and reduction of solvents required for extraction; also, no further cleanup steps were necessary.

Capillary columns instead of packed columns have been widely used in residue determination. However the isothermal GC analysis on a packed column provided satisfactory separation of PCP from other compounds that could interfere in the analysis. In addition, gas chromatograms obtained for HCB determination were free of interfering compounds. The detection limits for HCB and PCP, determined by the described procedure [19], were 0.2 and 5 ng g⁻¹, respectively. The reproducibility of these methods was demonstrated by standard deviation values that ranged from 3.2 to 9.3%. Although the proposed methods do not allow for the simultaneous determination of HCB and PCP, they are efficient, selective, and

can be employed in monitoring studies to estimate the contamination of soil by HCB and PCP.

In order to evaluate the dispersion and retention of HCB and PCP in soil, the methods were applied using soil samples from the Samaritá, a district in the city of São Vicente, São Paulo. The samples were taken at different depths and sampling points, pre-selected by pedological criteria. The concentrations of HCB and PCP are given in Table 3. The fungicides HCB and PCP were detected in 100 and 11% of the analyzed samples, respectively. When the concentrations of HCB and PCP were compared, HCB had the highest levels of contamination of all the soil samples. The concentrations of HCB ranged from 0.2 to 81300 ng g⁻¹. These data show the applicability of the proposed method to a wide range of concentrations.

The HCB concentrations found in the deeper soil layers indicated a vertical dispersion of HCB.

In this study, the distance from the dumping site appears to be one of the main factors in

determining the levels of HCB and PCP in soil samples. The highest levels of HCB (29298 and 81300 ng g⁻¹) and PCP (21 and 135 ng g⁻¹) were obtained from soil samples collected at about 10 m from the dumping site. It was observed that concentrations of these compounds decreased depending on the distance from the dumping site.

A comparison was not made of the proposed methods with other extraction techniques as the methods did not require specific optimizations for naturally contaminated samples and in addition the statistical analyses of recovery values confirmed the precision and accuracy of these methods.

Radiometric determination of trace amounts of zinc using liquid scintillation counting

D. Sandhya, M.S. Subramanian *

Department of Chemistry, Indian Institute of Technology, Madras, Chennai-600 036; Madras, India

Received 7 July 1997; received in revised form 30 September 1997

Abstract

A sensitive and selective radiometric method of substoichiometric isotope dilution analysis for the determination of trace amounts of zinc is described. The activity of ^{65}Zn used as a tracer in this method was measured by liquid scintillation counting and its counting efficiency was found to be $76 \pm 2.7\%$. The method is based on the extraction of the ion-association complex of zinc from thiocyanate medium at pH 7.9 using substoichiometric amount of Aliquat-336 in toluene. The method is sensitive to 20 ng of Zn(II) in an aqueous phase volume of up to 15 ml and its reliability was tested by applying it to a certified reference material—magnesium alloy and pharmaceutical samples. © 1998 Elsevier Science B.V. Keywords: Zinc determination; Liquid scintillation counting; Substoichiometric isotope dilution analysis; Aliquat-336

1. Introduction

Traditionally, liquid scintillation counters have been used primarily to measure the radioactivity of soft β^- emitters. It is now being used to measure the activity of a wide range of radioactive emissions like α , γ and also electron-capture decay. Advances in LSC has led to its use in environmental monitoring of a number of radionuclides [1].

The use of LSC as an analytical tool was described by Gibson and Lally [2]. Recent methods have been reported detailing the routine trace analysis of elements like indium [3], thallium [4]

and selenium [5] using liquid scintillation counting (LSC). These methods provide very low detection limits which were attained by the high counting efficiency and low background activity of LSC. Our aim here is to develop a sensitive analytical method for zinc using LSC which has not been considered in any of the standard methods.

The main drawback with zinc is the lack of selectivity with organic reagents used for its detection and determination [6]. However, substoichiometric extractions can improve the selectivity for zinc in the sense that at least those metal ions which possess lower extractions constants than that of zinc will not interfere in its estimation [7]. Nevertheless, a few reagents [8–10] have been used as substoichiometric reagents in the isotope dilution analysis of zinc—either poor sensitivity

* Corresponding author. Tel.: +91 44 2351365; fax: +91 44 2350509; e-mail: mss@chandra.iitm.ernet.in

or selectivity or the poor stability of the substoichiometric reagent used imposes a limitation on these methods.

Numerous methods have been reported detailing the extraction of zinc as its $\text{Zn}(\text{NCS})_4^{2-}$ anion with brilliant green [11], 2-hexylpyridine, [12], rhodamine-6G [13], tributyl phosphate [14], etc. as counter cations for either the spectrophotometric determination of zinc or for separation by solvent extraction. In any case these counter cations were added in excess. We found that Aliquat-336 (tri-caprylmethylammonium chloride) was a very effective extractant in the extraction of this anionic complex. This reagent is very stable and works very well under substoichiometric conditions. In the present study a ^{65}Zn radioisotope was used as the tracer and its activity was measured using LSC. The counting efficiency of ^{65}Zn that decays by electron-capture was found to be $76 \pm 2.7\%$. The developed method is very sensitive and selective, down to 20 ng of zinc from a final volume of 15 ml could be determined.

2. Experimental

2.1. Apparatus

A Packard Tri-Carb 1500 Liquid Scintillation Analyser was used to measure the activity of ^{65}Zn .

2.2. Optimum window settings

In a liquid scintillation counter, the entire energy dissipated by a radioactive particle is converted from analog pulse to a digital value by a high speed analog to digital converter (ADC) which is the address of a memory slot of a spectralyzer spectrum analyzer. This spectralyzer spectrum analyzer consists of many storage slots or channels covering an energy range from 0 keV to 2000 keV and the optimum window settings are made from 0 keV to E_{max} of the radionuclide to obtain maximum counting efficiency and at the same time to exclude all unwanted radiation falling outside the region of interest [15]. The activity measurements of ^{65}Zn were made using a window-width of 0–1115 keV so that both the

electron capture decay of ^{65}Zn as well as the γ transitions of its daughter, ^{65}Cu will be counted.

2.3. Reagents

Analytical-reagent grade chemicals were used throughout. A ^{65}Zn tracer of specific activity 14×10^{11} dpm g^{-1} was procured from the Board of Radiation and Isotope Technology (BRIT), Mumbai, India.

A bulk solution of 1000 $\mu\text{g ml}^{-1}$ of standard Zn(II) solution was first prepared by dissolving 0.4398 g of pure $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ in doubly distilled water and diluting to 100 ml. Suitable aliquots of this solution were diluted to obtain the working standards.

Radioactive Zn(II) solution, 10 $\mu\text{g ml}^{-1}$ (1.5×10^{-4} M) was prepared by mixing a 10 ml volume of 100 $\mu\text{g ml}^{-1}$ of Zn(II) solution with approximately 51×10^6 dpm of ^{65}Zn tracer and diluting to 100 ml with doubly distilled water.

A stock solution of 8.5×10^{-3} M Aliquat-336 solution was prepared by dissolving 0.1886 g of it (Merck; 442 g mol^{-1}) in 50 ml toluene. From this a working solution of 3.06×10^{-5} M was prepared by appropriate dilution with toluene. A 5 ml volume of this solution was used for each extraction.

A Packard Scint-A XF scintillator solution was used for activity measurements.

2.4. Calibration

To a 1 ml volume of 10 $\mu\text{g ml}^{-1}$ (1.5×10^{-4}) solution of radioactive Zn(II), in a separatory funnel, 2 ml of borax buffer, pH 7.9 and 1 ml of a 25% solution of NH_4SCN was added. After dilution to 10 ml the resulting anionic tetrakis(isothiocyanato) zincate (II) complex was extracted with 5 ml of 3.06×10^{-5} M Aliquat-336 in toluene. A blank experiment was performed under identical conditions without the use of Aliquat-336 to eliminate the activity caused by the extraction of zinc in any other form. The activity in each case was determined by mixing 2 ml of organic extract with 10 ml of cocktail and measuring the activity using a window-width of 0–1115 keV. The blank-corrected activity (a_s) was

then calculated. Another set of experiments was performed as above by adding varying amounts of inactive Zn(II), taken in a series of separatory funnels to 10 μg of radioactive Zn(II). The solution thus gets isotopically diluted. The blank-corrected activities (a) were similarly determined. A plot of a_s/a versus the concentration of inactive Zn(II) served in calibration (see Fig. 1). It was found to be linear in the range 0–3 μg of zinc. The regression equation obtained was $Y = 0.076 X + 0.9998$.

To determine zinc in various samples, suitable aliquots of the diluted sample digest were analyzed using the procedure described above and was repeated to obtain the 'a' value. Using the a_s/a value, the amount of zinc present in these samples was obtained from the calibration plot.

3. Results and discussion

3.1. Quenching studies:

The method of internal standardisation was employed to determine the presence of any kind

Fig. 1. Calibration plot ratio of activities versus amounts of inactive zinc(II).

of quenching, when using LSC to measure the activity of ^{65}Zn .

To about 10 ml of the scintillation cocktail, ^{65}Zn radioisotope of known activity was added and its count rate was measured. The counting efficiency 'E' was calculated using the formula, $E = \text{counts per minute (cpm)} / \text{disintegrations per minute (dpm)} \times 100$. It was found to be $76 \pm 2.7\%$. Inactive Zn(II) (10 μg) was extracted at pH 7.9 from thiocyanate medium using 5 ml of 3.06 ± 10^{-5} M solution of Aliquat-336 in toluene. Toluene extract (2 ml) was added to the above cocktail and ^{65}Zn mixture, the count rate was again measured to determine the counting efficiency. It was found that there was no decrease in the counting efficiency, indicating the absence of quenching due to inactive zinc solution, thiocyanate and chemicals used in the extraction.

3.2. Effect of variable

The optimum pH for maximum extraction of the complex was determined by extracting 10 μg ml^{-1} of radioactive Zn(II) from excess thiocyanate medium at different pH conditions. Maximum extraction was achieved in the pH range 7.7–8.1. Hence a borate buffer of pH 7.9 was used in all subsequent experiments. An equilibration time of 3 min was sufficient for maximum extraction and an aqueous phase volume of up to 15 ml was tolerated using this method.

The effect of various solvents on extraction showed toluene to be the most suited one with maximum blank-corrected activity even though blank activities were negligible with all other solvents. The results are summarized in Table 1. The use of halogenated or oxygenated hydrocarbons was avoided as they would cause chemical quenching effects on the LSC measurements.

Extractions carried out under optimum conditions with varying concentrations of NH_4SCN maintaining an aqueous volume of 10 ml, showed that for maximum activity, the addition of at least 1 ml of 15% solution was required, beyond which the activity remained constant. However, a 1 ml volume of 25% solution of NH_4SCN was added in all extractions.

Table 1
Choice of solvent for the extraction of zinc(II) with aliquat-336 from thiocyanate medium

Solvent	Sample activity (cpm)	Blank activity (cpm)	Blank-corrected activity (cpm)
Toluene	108 419	98	108 321
Xylene	98 035	24	98 011
Benzene	63 047	19	63 028
<i>n</i> -Pentane	6028	10	6018
Cyclohexane	33 633	12	33 621

3.3. Verification of reproducibility of substoichiometric extraction

This is an important parameter and is verified using this method. It ensures that under substoichiometric conditions, extractions are reproducible.

In this experiment varying concentrations of radioactive Zn(II) ranging from 1 to 16 μg (1.51×10^{-5} – 2.4×10^{-4} mM) were extracted from a solution containing 1 ml of 25% NH_4SCN at pH 7.9 using 5 ml of 3.06×10^{-5} M Aliquat-336 in toluene. The activity of the extract (2 ml) was measured after mixing with 10 ml of cocktail. A blank extraction was performed in the absence of Aliquat-336 and the activity of 2 ml of the extract after mixing with 10 ml cocktail was again measured. The blank-corrected activity in each case was determined. A plot of blank-corrected activity versus the concentration of radioactive ^{65}Zn is shown in Fig. 2. As can be seen, the activity reaches a saturation point corresponding to 7.1×10^{-5} mM concentration of Zn(II) indicating a 1:2 stoichiometric ratio of zinc to Aliquat-336. Beyond this concentration of zinc the amount of Aliquat-336 used in the extraction studies becomes substoichiometric and it can be seen that in the substoichiometric region (beyond 7.1×10^{-5} mM concentration of zinc) extractions are reproducible with the activity remaining fairly constant with further increase in zinc concentration.

3.4. Precision and detection limit

The relative standard deviation at the 2 μg level of zinc (ten determinations) was found to be 2.16%. The detection limit was calculated on the basis of its definition $C_B + 3\sigma_B$ (where $C_B =$

blank activity and $\sigma_B =$ standard deviation of the blank activity) [16] was found to be 16 ng from an aqueous phase volume of 15 ml, i.e. (2.1×10^{-8} M).

3.5. Effect of interfering ions

An investigation was carried out to determine the effect of a number of cations and anions on 2 μg of Zn(II). Ions that are capable of forming complexes with thiocyanate were examined as well as a number of other ions. A 1 mg amount of each ion was added prior to the addition of other reagents and determinations were carried out as previously outlined. The ions examined and their interference effects are summarized in Table 2.

Fig. 2. Verification of reproducibility of substoichiometric extraction.

Table 2
Interference studies

Ion added, (1 mg level)	Remarks
Ba ²⁺ , Sr ²⁺ , Mg ²⁺ , Ni ²⁺ , Cd ²⁺ , Bi ³⁺ , Cu ²⁺ , Tl ⁺ , Sb ³⁺ , WO ₄ ²⁻ , tartrate, S ₂ O ₃ ²⁻ , citrate, PO ₄ ³⁻ , C ₂ O ₄ ²⁻ , SO ₃ ²⁻ , Br ⁻ , Cl ⁻ , I ⁻ , Cr ₂ O ₇ ²⁻ , AsO ₄ ³⁻ , VO ₃ ⁻ , Pb ²⁺ (500 µg) ^a	No interference
Co ²⁺ , Hg ²⁺ , Sn ²⁺ , Fe ³⁺ , Al ³⁺ , Mn ²⁺ , F ⁻	Interfered by decreasing the counts

^a Corresponds to tolerance limit.

The interfering effects of Hg²⁺ (1 mg) and up to 500 µg of Co²⁺ could be overcome by masking with 1 ml of 4% sodium thiosulphate solution. Fe³⁺, Al³⁺ (1 ml) and up to 500 µg of Mn²⁺ were removed using 2 ml of 4% solution of sulphosalicylic acid. The interference of Sn²⁺ (1 mg) could be removed by complexing it with 1 ml of 4% tartrate solution.

3.6. Application studies

The city waste incineration ash sample was decomposed using H₂SO₄-KMnO₄-H₂O₂ mixture [17]. The Fourts-B tablets (Fourts India, Chennai, India) was carefully boiled with dilute HNO₃ and the magnesium alloy sample with 1:1 HCl. The Boro-plus ointment sample (Himani, Calcutta, In-

dia) was decomposed using HNO₃-H₂SO₄-HClO₄ [18]. The digest in each instance was filtered, if necessary, and diluted to known volumes. Suitable aliquots were taken and analyzed for zinc as described earlier in Section 2.4. Known amounts of zinc were then added to the samples before decomposition and the above procedure was repeated to check the recovery of zinc.

Simultaneously the method of internal standardisation was repeated with aliquots of all the sample solutions taken for analysis (as mentioned in Section 3.1) to verify the presence or absence of quenching arising from matrix constituents of these samples. However it was found that the counting efficiencies remained the same which was confirmed by the absence of any kind of quenching.

Table 3
Application studies

Sample	Zinc present (µg)	Zinc added (µg)	Zinc found by the proposed method ^a (µg)	Recovery
City waste incineration ash (CRM ^c 176) 0.02 g 500 ml ⁻¹	516	---	511 ± 3.2	-
		250	764 ± 3.8	101.2
Fourts-B tablet 0.02 g 250 ml ⁻¹	494 ^b	---	496 ± 1	---
		125	620 ± 0.9	99.2
		250	747 ± 1.9	100.4

		125	615 ± 3.9	98.4
		250	741 ± 2.1	99.6
Boro-plus ointment 0.03 g 250 ml ⁻¹	435 ^b	---	438 ± 4.6	---
		250	685 ± 2.7	98.8

^a Average of three determinations.

^b Determined by inductively coupled plasma-atomic emission spectrometry (ICP-AES).

^c CRM = certified reference material.

The results obtained in the case of Fourts-B tablet and Boro-plus ointment samples were compared with those obtained by inductively coupled plasma-atomic emission spectrometry (ICP-AES) to assess the reliability of the method since the certified values were not available. A 213.856 nm zinc emission line was used for the analysis of zinc which is relatively free from spectral interference. The results of the application studies are shown in Table 3 which indicates a close agreement between the proposed method and that of ICP-AES or the certified values.

4. Conclusion

The proposed method has demonstrated the feasibility of using LSC for the routine analysis of zinc by measuring the electron-capture decay activity of ^{65}Zn with fairly good efficiency. The advantage of carrying out solvent extraction prior to LSC measurements is the minimization of quenching due to the elimination of extraneous matrix constituents, as demonstrated in this method. Also elaborate sample preparation is not required. The method is simple and reliable and can be used to determine as low as 16 ng of Zn(II) from an aqueous phase volume of up to 15 ml. The method has been successfully applied to the determination of zinc in pharmaceutical preparations, magnesium alloy and a certified reference material. The sensitivity of the method can be further improved by the use of a radioisotope of higher specific activity.

Separation study of cadmium through an emulsion liquid membrane using triisooctylamine as mobile carrier

Quan-Min Li *, Qi Liu, Qing-Fen Zhang, Xian-Jun Wei, Jin-Zhi Guo

Department of Chemistry, Henan Normal University, Xinxiang 453002, People's Republic of China

Received 14 March 1997; received in revised form 15 September 1997; accepted 1 October 1997

Abstract

A study of the transport of Cd^{2+} ions through a triisooctylamine (TIOA)—sorbitan monooleate (Span 80)—dimethylbenzene liquid membrane has been performed with varying concentrations of HCl, KI, TIOA, Span 80 and NaOH in the feed, membrane and stripping solutions. Maximum transport was observed with 0.025 M HCl, 0.01 M KI, 0.02 M TIOA, 3% (w/v) Span 80 and 0.05 M NaOH. With this system cadmium could be completely separated with Cu^{2+} , Zn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Mn^{2+} , Cr^{3+} and Al^{3+} . The transport mechanism of this metal ions through the membrane has been discussed. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Ions; Transport; Mechanism

1. Introduction

As a new method, the emulsion liquid membrane (ELM) has been studied for the preconcentration and separation of metal ions [1–3], because of its advantage of high efficiency and low expense. Tri-*n*-octylamine (TOA) has been studied as an ELM mobile carrier to separate metal ions [4,5], but triisooctylamine (TIOA) has not been applied for the separation of cadmium from coexistence ions. As an important extractant, TIOA can be combined with CdI_4^{2-} ions after its protonation [3].

In this paper, an ELM with TIOA as mobile carrier is studied for the transport of cadmium. Various parameters influencing the transport of cadmium across the membrane have been optimized to separate cadmium from Cu^{2+} , Zn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Mn^{2+} , Cr^{3+} and Al^{3+} , and the transport mechanism of this metal ions through the membrane has been discussed.

2. Experimental

2.1. Reagents

A standard (1 mg ml^{-1}) solution of cadmium was prepared from metal cadmium (99.99%) dis-

* Corresponding author.

solved in nitric acid and distilled, deionized water. TIOA (analytical grade) was obtained from Aldrich. Sorbitan monooleate (Span 80; chemical grade) was obtained from Shanghai Dazhong Medical Company (Shanghai, People's Republic of China). A 0.10 M solution of TIOA and a 3% (w/v) solution of Span 80 in dimethylbenzene were used in this work.

2.2. Apparatus

The following instruments were used: a motor-driven emulsifier (range 0–6000 rpm); motor-driven stirrers (range 0–600 rpm); and a model 722 spectrophotometer (Shanghai Analytical Instrument Factory, People's Republic of China).

2.3. Procedure

2.3.1. Preparation of ELM

A 20 ml portion of solution TIOA and Span 80 in dimethylbenzene are emulsified at a stripping speed of 2000 rpm. Stripping solution was added at a rate of 20 ml min⁻¹ until the volume ratio of organic membrane solution to stripping solution was 1:1. The solution was then stirred continuously for 15 min to obtain a stable white ELM.

2.3.2. Transport of metal ions

To small beakers containing 10 ml metal ion feed solutions was added 2 ml of ELM and the contents stirred at 200 rpm for a given transfer time; the phases were allowed to separate, clear feed solution was pipetted into a 25 ml volumetric flask and analyzed for the amount of cation remaining.

2.3.3. Determination of cadmium [6]

Three millilitres of 5 × 10⁻⁴ M 4-(2-pyridylazo) resorcinol (PAR) alcohol solution was added to 5 ml of 0.1 M Na₂B₄O₇·10H₂O buffer solution (pH = 9.2) in a 25 ml volumetric flask containing cadmium ions, after diluting to the mark the absorbance was read at 495 nm against the reagent blank.

In separation experiment, the concentration of cadmium as well as other cations was determined by inductively-coupled plasma atomic emission spectrometry (ICP-AES).

3. Results and discussion

3.1. The effect of hydrochloric acid concentration in the feed

The relationship between the concentration of hydrochloric acid in the feed solution and extraction of cadmium is shown in Fig. 1. An acid concentration of 0.025 M was found to be best for transport of Cd²⁺ through ELM. In Fig. 1, it also is found that the transport of cadmium is completed in 5 min, this is because extraction and back-extraction occur simultaneously, and the degree of dispersion of the ELM in the feed solution is high [7]. In the presence of HCl and KI in the feed solution, the transport process of cadmium through an ELM is illustrated by the following equations:

1. TIOA (shown as R₃N) in the membrane phase reacts with hydrochloric acid in the feed phase.

2. In the feed, CdI₄²⁻ exchanges with Cl⁻ of R₃NH⁺Cl⁻ in the membrane phase.

3. NaOH in the stripping solution reacts with (R₃NH)₂CdI₄²⁻ to strip cadmium into the stripping solution.

Fig. 1. Effect of HCl conc. in the feed on the percent extraction of Cd²⁺ membrane phase: 0.02 M TIOA + 3% (w/v) Span 80 + dimethylbenzene; stripping phase: 0.05 M NaOH; feed phase: 50 μg ml⁻¹ Cd²⁺ + 0.01 M KI + HCl (M): 1–0.01–0.10, 2–0.005, 3–1.0.

Fig. 2. (a) Co-transport of CdI_4^{2-} with H^+ . (b) Counter-transport of CdI_4^{2-} with Cl^- co-transport or counter-transport of CdI_4^{2-} with protonated triisooctylamine as carrier.

The expected mechanism of cadmium transport in the present case is shown in Fig. 2a. Cd^{2+} and H^+ were transported from the feed solution to the stripping solution where H^+ was neutralized by NaOH . The transport of H^+ along a concentration gradient supplied the energy for the transport of cadmium against a concentration gradient. It was discovered that the decrease of H^+ concentration in the feed solution was more considerable than that of cadmium. This was due to the formation of $\text{R}_3\text{NH}^+\text{Cl}^-$ -type species and their transport into the stripping phase. When the concentration of HCl was < 0.005 M, transport of cadmium

abruptly decreases with time. This is because less H^+ is available to protonate R_3N , and precipitation of Cd^{2+} as $\text{Cd}(\text{OH})_2$ blocks the membrane. These can be proved by finding white $\text{Cd}(\text{OH})_2$ precipitation in the stripping solution after demulsification. When the concentration of $\text{H}^+ > 0.1$ M, the extraction of cadmium decreased too, this is because a great amount of H^+ transport into the stripping where OH^- is neutralized immediately, then the original transport direction of cadmium is changed (the cadmium transport from the stripping to the feed) [8]. This process is shown in Fig. 2b.

3.2. The effect of the concentration of surfactant

Span 80 is better than other surfactant when used in ELM [2]. Both the stability of the emission and the viscosity of the liquid membrane were altered by the proportion of surfactant in the organic phase. An increase in the concentration of Span 80 increased the stability of the emulsion, however as follows from Table 1, the extraction of cadmium decrease. When the concentration of Span 80 was $< 2\%$ by weight in the organic phase, the ELM was easy to break with transfer time. A concentration of 3% (w/v) in the organic phase resulted in good extraction and stability.

3.3. The effect of the concentration of TIOA

The effect of the concentration of TIOA (mobile carrier) in the organic phase on the extraction of cadmium is shown in Fig. 3. The optimum concentration range of carrier was 0.02–0.03 M. When the concentration of TIOA was 0.01 M, less H^+ entered the stripping, Cd^{2+} precipitated as $\text{Cd}(\text{OH})_2$ and clogged the membrane, the extraction of Cd^{2+} decreased. When the concentration of TIOA was > 0.05 M, H^+ transported into the stripping and neutralized OH^- immediately, then the cadmium transported inversely from the stripping to the feed [8] (see Fig. 2b). In the experiment 0.02 M concentration of TIOA was selected for a rapid and complete transport of cadmium.

Table 1
The effect of concentration of surfactant

Conc. of Span 80 [(w/v)]	1	2	3	4	5
Percent extraction	93.3	94.7	99.0	96.5	96.8

Membrane phase: 0.02 M TIOA+Span 80; feed phase: 0.025 M HCl+50 $\mu\text{g ml}^{-1}$ Cd(II)+0.01 M KI. Stripping phase: 0.05 M NaOH; transfer time: 10 min.

3.4. The effect of the concentration of NaOH in the stripping solution

The NaOH in the stripping phase functioned as a back-extracting solution. When the composition of emulsion was fixed, the maximum extraction was obtained in different stripping solution at 0.01–0.05 M NaOH. It has been observed that above a concentration of 0.2 M NaOH, the transport decreased markedly (see Fig. 4). This may be because more H^+ transported the stripping, formed more water, made the membrane swell and break. When the concentration of NaOH increased to 1.0 M, CdI_4^{2-} precipitated $\text{Cd}(\text{OH})_2$ and the membrane was clogged as soon as the transport began. In the experiment, 0.05 M NaOH was selected.

When the concentrations of NaOH were 0.025 and 0.5 M, by changing the transfer time (from 0.5 to 2.5 min) measured the natural logarithm of the ratio of initial concentration (C_0) to give time

concentration (C) of cadmium the kinetic curve can be obtained (see Fig. 5). In $C_0/C - t$ curve line is a good straight line, they are (1) $\ln C_0/C = 1.479 \times 10^{-2}t + 0.6386$, $r = 0.9908$; (2) $\ln C_0/C = 1.285 \times 10^{-2}t + 0.2556$, $r = 0.9985$, respectively. This shows that transport of cadmium is near kinetic pseudo-first-order reaction. The transfer rate constant of Cd^{2+} was 0.0148 and 0.0128 s^{-1} , which are similar. This shows that the transfer rate of Cd^{2+} was controlled only by $(\text{R}_3\text{NH})_2\text{CdI}_4$ concentration on the feed-side interface. Its kinetic equation is illustrated by the following equation

$$-d[\text{Cd}(\text{II})] = k[(\text{R}_3\text{NH})_2\text{CdI}_4] dt$$

3.5. The effect of other reagents in the feed solution

With a suitable acid concentration of the feed solution, the concentration of KI in the feed was

Fig. 3. Effect of TIOA conc. in the membrane phase on the percent extraction of Cd^{2+} feed phase: 50 $\mu\text{g ml}^{-1}$ Cd^{2+} + 0.01 M KI + 0.025 M HCl; stripping phase: 0.05 M NaOH; membrane phase: 3% (w/v) Span 80 + TIOA (M): 1–0.02 ~ 0.03, 2–0.01, 3–0.05.

Fig. 4. Effect of concentration of NaOH on the percent extraction of Cd^{2+} membrane phase: 0.02 M TIOA + 3% (w/v) Span 80 + dimethylbenzene; feed phase: 50 $\mu\text{g ml}^{-1}$ Cd^{2+} + 0.025 M HCl + 0.01 M KI; stripping phase: NaOH (M): 1–0.01–0.05, 2–0.10, 3–0.20.

Fig. 5. Kinetic curve line of transport of Cd²⁺ membrane phase: 0.02 M TIOA + 3% (w/v) Span 80 + dimethylbenzene; feed phase: 50 µg ml⁻¹ Cd²⁺ + 0.025 M HCl + 0.01 M KI; stripping phase: NaOH (M): 1–0.025, 2–0.05.

> 0.01 M, the extraction efficiency of cadmium was always > 98%. If KI was replaced by KBr or KSCN in turn, the extraction of cadmium decreased greatly, it is because the logarithm of their cumulative stability constants ($\log \beta_4$) of CdI₄²⁻, CdBr₄²⁻ and Cd(SCN)₄²⁻ are respectively 5.35, 2.93 and 2.91 [9], the $\log \beta_4$ of CdI₄²⁻ is the highest. If KCl, KNO₃, K₂SO₄ or KClO₄ were added to above systems in turn, the results were shown in Fig. 6, ClO₄⁻ is the biggest anion and so its association with TIOA resulted in the most significant decrease in the transport of cadmium (see curve 4 in Fig. 6). The smallest anion Cl⁻ did not interfere the transport of cadmium (see curve 1 in Fig. 6).

3.6. Separation of cadmium from other metal ions

Under suitable conditions, transport of Cu²⁺, Zn²⁺, Fe²⁺, Co²⁺, Ni²⁺, Mn²⁺, Cr³⁺ and Al³⁺ were studied. Results for the competitive transport of cadmium and other common cations in mixed solution are shown in Table 2. (Note that the data of Table 2 comes from ICP-AES measurements. All other data are from colorimetric measurements.) Selectivity of separation of cadmium was excellent and the transport of Cu²⁺, Zn²⁺, Fe²⁺, Co²⁺, Ni²⁺, Mn²⁺, Cr³⁺ and Al³⁺ was found to be negligible.

Fig. 6. Effect of different salts in the feed solution on the percent extraction of Cd²⁺ membrane phase: 0.02 M TIOA + 3% (w/v) Span 80 + dimethylbenzene; stripping phase: 0.05 M NaOH; feed phase: 50 µg ml⁻¹ Cd²⁺ + 0.05 M HCl + salt: 1–0.01 M KI + KCl, 2–0.01 M KI + K₂SO₄, 3–0.01 M KI + KNO₃, 4–0.01 M KI + HClO₄, 5–0.01 M Br, 6–0.01 M KSCN; transfer time: 10 min.

The TIOA-Span 80-dimethylbenzene liquid membrane is feasible to separate cadmium from other common cations, specifically from Zn²⁺, because the character of Zn²⁺ is significant.

4. Conclusion

In this paper, transport of cadmium through a TIOA-Span 80-dimethylbenzene ELM was studied. The mechanism of transport of cadmium was discussed and is presented in Fig. 2a, b. The optimum conditions of transport have been found to be 0.01 M KI and 0.025 M HCl in the feed

Table 2

The percent extraction of Cd²⁺ in a mixed solution

Initial amount of each co-ions (Fe ²⁺ , Zn ²⁺ , Co ²⁺ , Ni ²⁺ , Al ³⁺ , Mn ²⁺ , Cr ³⁺)	The percent extraction of Cd ²⁺
10 µg ml ⁻¹	99.3
50 µg ml ⁻¹	97.6
100 µg ml ⁻¹	95.8

Initial amount of Cd²⁺: 50 µg ml⁻¹; membrane phase: 0.02 M TIOA + 3% (w/v) Span 80 + dimethylbenzene; feed phase: 0.05 M HCl + 0.025 M KI; stripping phase: 0.05 M NaOH; transfer time: 10 min.

solution, 0.02 M TIOA and 3% (w/v) Span 80 in the liquid membrane, and 0.05 M NaOH in the stripping solution. It is concluded that this method can be applied for the selective separation of cadmium from a mixed solution of Cu^{2+} , Zn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Mn^{2+} , Cr^{3+} and Al^{3+} or as a preconcentrating step of measuring cadmium. Small amount of carriers are involved and the extraction efficiency is high.

Abstract

A very simple spectrophotometric method is described for resolving ternary mixtures of the food colorants Tartrazine, Sunset Yellow and Ponceau 4R by using the first derivative of the ratio spectra with measurements at zero-crossing wavelengths. Calibration graphs are linear up to 20 mg l^{-1} of Tartrazine (E-102), 40 mg l^{-1} of Sunset Yellow (E-110) and 32 mg l^{-1} of Ponceau 4R (E-124). Standard deviations of 0.9, 0.8 and 2.4% were obtained for nine standards of 8 mg l^{-1} of Tartrazine, 8 mg l^{-1} of Sunset Yellow and 8 mg l^{-1} of Ponceau 4R, respectively. This method was satisfactorily used for determining synthetic mixtures of these colorants in different ratios (from 1:1:1 to 1:5:5 or even higher) with recoveries in 94–105% range and it was successfully applied over three commercial products containing the three dyes and it did not require any separation step. The results were compared with those obtained by HPLC and very similar values were found by both methods. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Derivative spectrophotometry; Tartrazine; Sunset Yellow; Ponceau 4R

1. Introduction

Food colorants may often be considered simply cosmetic in nature, but their role in the food industry is actually very significant. Colour is the first sensory quality by which foods are judged and food quality and flavour are closely associated with colour. Consumers are conditioned to expect foods of certain colours and to reject any

deviation from their expectations. The psychological basis for the need of food colours is well established [1].

Colorants also play a significant role in enhancing the aesthetical appeal of food. They are very important ingredients in many convenience food such as confectionery products, gelatin desserts, snacks and beverages, since many of these would be colorless and would thus appear undesirable without the inclusion of dyes.

The term colour additive can be applied to any dye, pigment or other substance made (artificial

* Corresponding author. Tel.: +34 26295339; fax: +34 26295318; e-mail: jjberzas-cr@qata-cr.uclm.es

colorant) or obtained from a vegetable, animal, mineral or another natural source, that are capable of colouring food, drugs or cosmetics [2].

Tartrazine (T), Sunset Yellow (S) and Ponceau 4R (P), subjects of this work, are three synthetic dyes available as yellow, orange and red powders, respectively, that can be present in common food (drinks, yoghurts, ice cream, sweets, etc...). The content of these dyes must be controlled because its presence and/or contact with some kinds of drugs (aspirin, benzoic acid and other analgesics) in the human body can induce allergic and asthmatic illness in sensitive people. Development of regulations for using food colorants was reviewed by Haveland-Smith [3].

Tartrazine (E-102)

Ponceau 4R(E-124)

Taking into account the chromogenic characteristics of the three compounds, spectrophotometric methods can be used for their quantitative analysis. However, the absorption spectra of T, S and P are very much overlapping and direct measurement of the absorbance is not suitable for resolving ternary mixtures of these dyes without a separation step. Derivative spectrophotometry, particularly with digital processing [4] is an analytical technique of great utility to resolve binary mixtures with overlapping spectra.

Recently, spectrophotometric methods have been developed by us in order to resolve binary mixtures of dyes [5–8]. These methods were successfully applied to several commercial foods.

On the other hand, chromatographic methods have been used for colorant analysis in food and they are recommended when mixtures contain many different colorants [9–11], but ternary mixtures can be easily resolved by means of a spectrophotometric method [12,13], which is based on the simultaneous use of ‘zero-crossing’ and ‘ratio spectra derivative’ methods.

Adsorptive stripping voltammetry has been also applied by the authors in order to quantify sepa-

Sunset Yellow (E-110)

rately two dyes (Tartrazine and Sunset Yellow) of this ternary mixture in different commercial products [14,15].

The aim of this work is to propose a simple method for resolving ternary mixtures of Tartrazine, Sunset Yellow and Ponceau 4R dyes in commercial products without prior separation. In the same way, this method yields accurate and reproducible results in three different commercial products.

2. Experimental

2.1. Apparatus

A Beckman Instruments DU-70 spectrophotometer connected to an IBM PS/2 fitted with Beckman Data Leader Software [16] was used for all measurements and treatment of data.

Fig. 1. Absorption spectra of 20.0 mg l^{-1} of Tartrazine (T), 24.0 mg l^{-1} of Sunset Yellow (S), 28.0 mg l^{-1} of Ponceau 4R (P) and their mixture (T + S + P).

The HPLC equipment used was: a SHIMADZU model LC-10A with a diode-array detector model SPD-M10A, equipped with a double pump system, that permitted us to work in the gradient mode and, as stationary phase, a chromatographic column Apex C_{18} (25 cm of length \times 3.9 mm i.d. and 5 μm as particle diameter).

2.2. Solutions

All solvents and reagents were of analytical reagent-grade unless otherwise indicated. Tartrazine (T) was supplied by Sigma Products (Sigma number T0388); Sunset Yellow (S) was obtained from Sancolor S.A. enterprise and Ponceau 4R (P) was provided by ALDRICH (number 19973-7). T, S and P stock aqueous solutions with a concentration of 200 mg l^{-1} were prepared. Acetic acid/sodium acetate (0.1 M and pH = 4.8) was used as buffer solution.

In order to achieve all chromatographic assays, the following solutions were also used: an $\text{NaH}_2\text{PO}_4/\text{Na}_2\text{HPO}_4$ buffer (0.1 M and pH = 7.1) and methanol (HPLC quality).

2.3. Procedure

2.3.1. Spectrophotometric procedure

The general procedure for 'derivative ratio spectrum-zero crossing' method was the following: samples were prepared in 25 ml calibrated flasks containing $2\text{--}20 \text{ mg l}^{-1}$ of T, $4\text{--}40 \text{ mg l}^{-1}$ of S and $4\text{--}32 \text{ mg l}^{-1}$ of P or their ternary mixtures, 5 ml of buffer solution and diluted with water to the mark. The absorption spectra of the samples thus prepared were recorded and stored in the computer.

The determination of two of the dyes in a ternary mixture can be done by the use of a

Fig. 2. Ratio spectra derivative of 24.0 mg l^{-1} of S and 28.0 mg l^{-1} of P when the divisor is a spectrum of 8.8 mg l^{-1} of T.

standard spectrum of the third colorant of this mixture as divisor. The ratio spectra is obtained by dividing the amplitudes of the absorption spectrum of the ternary mixture by a standard spectrum of one of the components; the first derivative of this ratio spectra is achieved and the measurements have to be done in the previously selected zero-crossing wavelengths of the other two dyes.

The determinations carried out by this method are the following:

(a) When a spectrum of T (whose concentration is 8.8 mg l^{-1}) is used as divisor, S is determined at 526.0 nm (${}^1\text{DD}_{526.0}$) (zero-crossing point for ratio spectra derivative of P) and P can be determined by measuring at 514.0 nm (${}^1\text{DD}_{514.0}$) (zero-crossing point for ratio spectra derivative of S), using a $\Delta\lambda = 8 \text{ nm}$ and a smoothing function of 23 experimental points in order to reach their first derivative spectra.

(b) When a standard spectrum of 16 mg l^{-1} of S is used as divisor, T is determined by measuring at 445.0 nm (${}^1\text{DD}_{445.0}$) (zero-crossing for ratio spectra derivative of P) and also a calibration graph was used to measure P at 514.0 nm (${}^1\text{DD}_{514}$) (zero-crossing point for ratio spectra derivative of T); $\Delta\lambda = 6 \text{ nm}$ and a smoothing of 16 experimental points were applied to obtain first derivative spectra.

(c) When a spectrum of P of 8 mg l^{-1} is used as divisor, a calibration graph for T determination is established at 444.0 and 430.0 nm (${}^1\text{DD}_{444.0}$ and ${}^1\text{DD}_{430.0}$) (zero-crossing points for ratio spectra derivative of S). On the other hand, similar graphs were used in order to measure S at 526.0 nm (${}^1\text{DD}_{526.0}$) (zero-crossing point for ratio spectra derivative of T). In order to reach these first derivative spectra, a $\Delta\lambda = 14 \text{ nm}$ and a smoothing of 15 experimental points were applied.

Table 1

C_T = mg l⁻¹ of T; C_S = mg l⁻¹ of S; C_P = mg l⁻¹ of P.

^a C_L = 3S_B/m, where C_L = detection limit; S_B = standard deviation of blank; and m = slope of calibration.

The proposed method was applied to determine T, S and P in three commercial products:

Gelatin, flavour pineapple: with sugar, gelatin, acidulant (E-334, E-331), flavorings, authorized artificial dyes (E-102, E-110 and E-124) and ascorbic acid. From the enterprise Royal Brands, S.A. (Spain).

Gelatin, flavour tropical: with sugar, gelatin, acidulant (E-334, E-331), flavorings, authorized artificial dyes (E-102, E-110 and E-124) and ascorbic acid. From the enterprise Royal Brands, S.A. (Spain).

Creamy dessert, flavour vanilla: with sugar, modified starch, preservatives (E-450, E-401 and E-339), acidulant (E-263), salt, flavorings and authorized artificial dyes (E-102, E-110 and E-124). From the enterprise Royal Brands, S.A. (Spain).

The ingredients are in all products in decreasing order of concentration.

The preparation of the samples was very similar in the three cases:

- For the determination of the three dyes in the first product, 50 g (exactly known) were dissolved in 250 ml of hot water. From this stock solution aliquots of different volumes were

taken in order to apply standard additions method for each dye.

- In the second product, the procedure was almost the same, dissolving a mass of 12 g of commercial product in 250 ml of hot water.
- With regard to the third product, the stock solution was obtained by dissolving 30 g in 250 ml of hot water in strong stirring conditions; a centrifugation step was also necessary to remove the starch from the sample; after that, different aliquots were taken in order to achieve standard additions of each dye over the clarified solution.

2.3.2. Chromatographic procedure

The determination of contents of T, S and P in the three commercial products was also verified by HPLC using a diode-array detector with measurements at 430, 483 and 507 nm (wavelengths where the absorbance was maximal for each dye) and using the stationary phase already mentioned in Section 2.1; as mobile phase, we have employed a mixture of methanol and 0.1 M NaH₂PO₄/Na₂HPO₄ buffer solution (pH = 7.1), with the following gradient of concentrations:

Fig. 3. Ratio spectra derivative of 20.0 mg l^{-1} of T and 4.0 mg l^{-1} of P when the divisor is a spectrum of 16.0 mg l^{-1} of S.

Time (minutes)	Concentrations
0.0–2.0	20–35% Methanol in linear gradient
2.0–12.0	35% Methanol constant
12.0–17.0	35–20% Methanol in linear gradient

The flow rate was 1.0 ml min^{-1} ; under these conditions the retention times were 4.1 min for T, 8.6 min for P and 9.6 min for S.

3. Results and discussion

3.1. Method development

The influence of pH on the absorption spectra of T, S and P was studied. In order to establish suitable pH values for this study, a range of values were examined between pH 1.5 and 12. The following results were obtained. The spectra of T showed a maximum at 430.0 nm between 1.0 and 9.0 pH values, whereas for higher pH values this maximum decreases; S shows a maximum at 483.0 nm, which is stable between 1.0 and 10 pH values, decreasing for higher values; with regard to P, its

Fig. 4. Ratio spectra derivative of 12.8 mg l^{-1} of T and 40.0 mg l^{-1} of S when the divisor is a spectrum of 8 mg l^{-1} of P.

absorbance spectrum shows a maximum at 507.0 nm, whose absorbance remains constant between 1 and 9 pH units, decreasing from this last value. We have chosen a pH value of 4.8 as optimum. Under these conditions diluted aqueous solutions of T, S and P were stable for 7 days at least.

In Fig. 1 the zero order spectra of T, S and P in the 350–600 nm wavelength range are shown. It can be seen that the absorption spectra of the three dyes are strongly overlapped and as a result, only P could be determined from direct measurements of absorbance in a very small zone around 570 nm. In order to resolve this ternary mixture we have applied the proposed method, based on the simultaneous use of the first derivative of ratio spectra and zero-crossing measurements.

3.2. Derivative ratio spectrum zero-crossing method

According to the proposed method, we can determine two dyes by means of the third colorant which is used as divisor. The ratio spectrum is obtained by dividing the amplitudes of the absorption spectrum of the mixture by a standard spectrum of one of the three components and obtaining the first derivative of this ratio spectrum, where the other two dyes can be determined by measuring at their respective zero-crossing points, that has been previously established by means of a similar study for each dye of the ternary mixture.

^a Spectrum used as divisor.

In order to obtain the best recoveries for the three dyes, it is necessary to study and to optimize the following parameters: concentration of the standard spectrum used as divisor, $\Delta\lambda$ to obtain the first derivative, smoothing function and zero-crossing wavelengths.

3.2.1. Selection of optimal instrumental conditions

3.2.1.1. Determination of S and P in the presence of T. The above mentioned variables were studied and the following values were chosen as optima: a standard spectrum of T of 8.8 mg l⁻¹, an $\Delta\lambda$ of 8 nm for the first derivative ratio spectra and a smoothing function of 23 experimental points. In these conditions, the first derivative ratio spectra of S/T and P/T are shown in Fig. 2. We can see that the S content can be measured at 526 nm (zero-crossing point for ratio spectra derivative of P), whereas P is determined at 514 nm (zero-crossing point for ratio spectra derivative of S) and in a very small zone around 570 nm. Calibration graphs were obtained at the previously selected wavelengths up to 40 mg l⁻¹ of S and 32 mg l⁻¹ of P (Table 1).

3.2.1.2. Determination of T and P in the presence of S. Once studied the usual variables we have established as optimal values: a standard spectrum of S of 16 mg l⁻¹, an $\Delta\lambda$ of 6 nm for the ratio spectra derivative and a smoothing function of 16 experimental points. In these conditions, the first derivative ratio spectra for T/S and P/S ob-

tained are shown in Fig. 3. It can be seen that T content can be determined at 445 nm (zero-crossing point for ratio spectra derivative of P) and, in the same way, P content is measured at 514 nm (zero-crossing point for ratio spectra derivative of T). Two calibration graphs were obtained at the previously selected wavelengths giving straight lines up to 20 mg l⁻¹ of T and 32 mg l⁻¹ of P (Table 1).

3.2.1.3. Determination of T and S in the presence of P. The determination of these two dyes was realized using the same method. The optimal values established were: a standard spectrum of 8 mg/l of P as divisor, an $\Delta\lambda$ of 14 nm for the first derivative ratio spectra and a smoothing function of 15 experimental points. Fig. 4 shows the first derivative ratio spectra of T/P and S/P in these conditions. As can be observed in this figure, the determination of T can be made at 444 nm (zero-crossing point for ratio spectra derivative of S), whereas the S content can be measured at 526 nm (zero-crossing point for ratio spectra derivative of T). Calibration graphs were obtained at the previously selected wavelengths up to 20 mg l⁻¹ for T and 40 mg l⁻¹ for S.

4. Statistical data

In Table 1, the most characteristic data obtained from the different calibrations, from the repeatability of the reagent-blank and from nine

Table 3
Contents of T, S and P in commercial products^a

Product	Derivative spectrophotometry			HPLC		
	T	S	P	T	S	P
Gelatin flavour pineapple	1.9×10^{-3} (-6.2%)	1.1×10^{-3} (2.6%)	2.5×10^{-4} (2.3%)	2.0×10^{-3}	1.1×10^{-3}	1.2×10^{-4}
Gelatin flavour tropical	4.4×10^{-2} (-2.5%)	7.5×10^{-3} (11.1%)	2.6×10^{-3} (8.7%)	4.2×10^{-2}	8.0×10^{-3}	2.5×10^{-3}
Creamy dessert of vanilla	2.3×10^{-2} (0.0%)	1.5×10^{-3} (7.4%)	1.5×10^{-3} (-11.6%)	2.2×10^{-2}	1.3×10^{-3}	1.2×10^{-3}

() Percentages of deviation between the slopes of calibration graphs and that obtained for each dye in the three products by standard additions procedure.

^a Contents expressed as percentage mass/mass.

standards of 8 mg l^{-1} of T, nine standards of 8 mg l^{-1} of S and nine standards of 8 mg l^{-1} of P, respectively have been summarized. Standard deviations of 0.9, 0.8 and 2.4% were recorded for each dye.

On the other hand, we can see in this table that very good regression coefficients are reached in all cases for the tested concentration ranges; with regard to detection limits, similar values are obtained for each dye when different dyes are used as divisor as it is shown in Table 1, obtaining the best detection limit for S determination.

5. Applications

The method under study was tested to determine of T, S and P in artificial mixtures (Table 2). The recoveries obtained in most cases were in the range 94–105% except for those ones in which the dye to be determined was present in very small concentrations with regard to the other two dyes (ratio 1:5:5 or even lower). Nevertheless, taking into account the results shown in Table 2, we advise the use of a standard spectrum of P as divisor for S determination, the use of a standard spectrum of T as divisor for P determination, and the use of S as divisor for determining T in all ratios shown in this table.

Lastly, the proposed method was applied to determine T, S and P in the commercial products described in Section 2.3.

The percentages of the dyes in the three commercial products were calculated by direct measurement and standard addition method (in order to check the presence of matrix effects) using selected wavelengths. We do not advise the use of direct measurements because of the low levels of dyes in the three commercial applications, the reason being, it would be necessary to work with high volumes of stock commercial solutions that would involve matrix effects and consistently it could produce erroneous results.

When the standard addition procedure was applied for each dye in the three commercial products, slopes very similar to those of the calibration graphs were obtained, as it can be deduced from the percentages of deviation between the slopes of the calibration and standard addition method for each dye in the three applications (Table 3). In this table the contents obtained by standard additions are also shown for each dye in the three products, given as percentage mass/mass.

Under the conditions already described in Section 2.3 for the HPLC study, the calibration graphs established for each dye at wavelength corresponding to its maximum are given in Table 4.

Chromatographic results are also summarized in Table 3. They are in agreement with values provided by the derivative ratio spectrum-zero crossing method, except for the determination of Ponceau 4R dye in the product 'Gelatin dessert of pineapple'. In this case spectrophotometric and

Table 4

T	430	0.2–12.0	4.1	Area (μ V s) = 74.32 + 6382.9 C_T	0.9999
S	483	0.8–16.0	8.6	Area (μ V s) = 285.1 + 5897.0 C_S	0.9999
P	507	0.8–16.0	9.6	Area (μ V s) = 289.2 + 5452.0 C_P	1.0000

^a C_T , C_S and C_P are concentrations of Tartrazine, Sunset Yellow and Ponceau 4R given as mg l⁻¹.

chromatographic values differ because of interference from matrix gelatin in the spectrophotometric determination of very low levels of Ponceau 4R in this product. For this reason, the chromatographic method seems to be appropriate in this case since it provides separation of dyes from matrix interferences.

6. Conclusions

Satisfactory results are reached when the derivative ratio spectrum-zero crossing method was applied over this ternary mixture. In order to resolve synthetic mixtures and taking into account the recoveries shown in Table 2, we advise the use of a standard spectrum of P as divisor for S determination, and a standard spectrum of T as divisor for P determination, as well as the suitable use of S and P as divisors for determining T for all ratios showed in Table 2, except for those in which the dye to quantify was in the ratio 1:5:5 or lower.

We also recommend the proposed spectrophotometric method due to the simplicity of determination, inexpensive instrumentation and the satisfactory results obtained in the analysis of complex matrix such as gelatins and creamy dessert.

Abstract

Selectivity properties are established for three new electrodes prepared by incorporating three pentacoordinate organotin(IV) complexes, mono(2,4-pentanedionato-*o,o'*) tri(phenylmethyl)tin (DMTBS), mono(benzoylacetonato-*o,o'*) tri(phenylmethyl)tin (MPTBS) and mono(dibenzoylmethanato-*o,o'*) tri(phenylmethyl)tin (DPTBS) into plasticized PVC membranes. These electrodes exhibit linear response to salicylate and an anti-Hofmeister selectivity pattern with high specificity for salicylate over many common anions. The results show that the potentiometric response characteristics are related to the structure of organic ligands. The detection limit and the slope of the electrodes based on these pentacoordinate organotin complexes exhibit a tendency to decrease as the substituent in organic ligands changes from a methyl group to a phenyl group. Electrodes prepared with DMTBS have the best detection limit and the highest degree of selectivity and sensitivity for salicylate. The response mechanism is also investigated by use of a.c. impedance and i.r. spectroscopic techniques. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Pentacoordinate organotin complex; Neutral carrier; Salicylate-selective PVC membrane electrode

1. Introduction

Recently, electrodes using a plasticized PVC membrane incorporating derivatives of vitamin B₁₂, Co(III), Sn(IV), Mo(IV) and Mn(III) porphyrin complexes and electropolymerized Co(II) porphyrin derivative films demonstrated potentiometric anion selectivity sequences which deviated from the Hofmeister pattern [1–5]. These deviations resulted from the direct interactions between the central metal and the analyte ions. Thus, this

unusual anion selectivity behaviour was based on the properties of the central metal and the chemical environment around the central metal. Since the 1960s, hundreds of thousands of organometallic compounds have been synthesized and some of them have been applied in many fields. Some new anion-selective electrodes based on organometallic species, such as metallocenes, alkyl-substituted derivatives of Hg(II), Sb(III) and Sn(IV), have been reported [6–13]. Although these electrodes exhibited an unusual response to respective anions (e.g. chloride, nitrate, dibasic phosphate and salicylate), the research on new carriers for improve-

^a Calculated values are given in parentheses.

ment the potentiometric response characteristics of these electrodes was of considerable interest in order to be applied for the analysis in actual samples. Because of the stereospecific configurations of organometallic compounds, they are expected to be used as components in anion-selective electrodes and accelerate the development of novel anion ionophores.

Salicylate and its analogues, including acetyl-salicylate (aspirin), are available to the public in a wide variety of formulations. The most widely used analytical method for the detection of salicylate is based on the Trinder reaction in which sample salicylate reacts with ferric ions to form a colored complex in acid solution [14]. Since similar complexes can be formed under the same experimental conditions, this method always lacks adequate selectivity over many common anions. Polymeric membrane electrodes based on quaternary ammonium salts of salicylate suffered from the same problem [15,16]. Electrodes prepared by incorporating Mn(III) and Sn(IV) porphyrin complexes into PVC membranes exhibited high selectivity towards salicylate, but it is necessary to improve some potentiometric response characteristics such as linear range, detection limit and detection sensitivity, etc. [17]. In the present work, we report on the anion-selective properties of pentacoordinate organotin complexes (DMTBS, MPTBS and DPTBS). The results indicate that electrodes based on DMTBS offer a wide linear response range, high selectivity and high sensitivity to salicylate. The novel electrodes have been used for the detection of salicylate in human urine with satisfactory results.

2. Experimental

2.1. Reagents and materials

All chemicals used were of analytical-reagent grade. Twice-distilled water was used throughout all experiments. Tribenzyltin chloride was prepared by the method described previously [18]. The melting point was found to be 141–142°C, the same as the reported value in the reference. Pentacoordinate organotin complexes were synthesized by the reaction of tribenzyltin chloride with 2,4-pentanedione, benzoylacetone and dibenzoylmethane according to published procedures [19,20]. They were characterized by elemental analysis and i.r. spectra (see Table 1) and will be reported elsewhere.

2.2. Apparatus

The PVC membrane electrodes were fabricated from various carriers and assembled according to Thomas and co-workers [21,22]. The membrane compositions were 2.5 wt.% ionophores (DMTBS, MPTBS or DPTBS), 66.5 wt.% membrane solvent (*o*-nitrophenyl octyl ether) and 31 wt.% PVC. Before use, the electrodes were conditioned in 0.1 mol · l⁻¹ sodium salicylate aqueous solution for 24 h. Potentiometric and pH measurements were made with a model PHS-3E digital ion analyzer (Jiangshu instruments). The cells for millivolt measurements were of the following type:

Hg – Hg₂Cl₂/KCl(satd.)/sample solution/
membrane/0.01 mol · l⁻¹ KCl/AgCl – Ag

The a.c. impedance of the electrode membrane was recorded with a PAR M386-2 System (EG&G Princeton Applied Research) in $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ buffer at pH 5.0. The frequency region used was from 10^5 to 10^{-2} Hz (25°C). For the infrared measurements and the spectra manipulations, a Fourier infrared spectrophotometer, model AQS-20 (Analect instruments, USA) was used.

3. Results and discussion

3.1. Response characteristics of the electrodes

The structures of pentacoordinate organotin complexes are shown in Fig. 1, and potentiometric response characteristics of the electrodes containing different carriers are shown in Fig. 2. The electrodes incorporating DMTBS show a specific response to salicylate ranging from 1.0×10^{-1} to 1.0×10^{-4} mol \cdot l $^{-1}$ in a $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ buffered solution adjusted to pH 5.0 with a detection limit of 3.4×10^{-5} mol \cdot l $^{-1}$ and a slope of 96.0 mV per decade. The d.c. resistance of the DMTBS membrane is 645.5 ± 0.3 k Ω ($n = 6$). The response time ($t_{90\%}$) is less than 1 min in the linear response range which implies the reversible anion exchange is rapid, these novel prepared electrodes do not display any hysteresis effects. The standard deviation of the DMTBS-based electrode potential readings over a period of 12 h in 0.001 mol l $^{-1}$ sodium salicylate buffered with $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ to pH 5.0 is 0.8 mV ($n = 72$). The potential readings for the same electrode dipped

alternatively into stirred solutions of 1.0×10^{-3} and 1.0×10^{-4} mol \cdot l $^{-1}$ sodium salicylate show a standard deviation of 1.3 mV over 4 h ($n = 12$). Detectable loss of performance characteristics has not been found after these electrodes have been used for 5 months, which implies that this type of organotin complex is stable in the presence of water. The electrodes based on MPTBS and DPTBS exhibit similar potentiometric response characteristics, but their slopes decrease to 80.6 and 69.0 mV per decade, respectively, while the

detection limits change to 2.0×10^{-4} and $3.2 \times 10^{-4} \text{ mol} \cdot \text{l}^{-1}$ respectively. It is obvious that the potentiometric response characteristics have a close relationship with the chemical environment around the central metal.

3.2. Selectivity

Possible interferences from a number of mono-valent anions were studied. Anion selectivity coefficients, $\log K_{ij}^{\text{pot}}$ were determined by the separate solution method according to IUPAC recommendations and were obtained with the respective $0.1 \text{ mol} \cdot \text{l}^{-1}$ anion solutions of sodium salts [23]. The single-ion activities were calculated by the extended Debye–Hückel equation. The results shown in Table 2 indicate that the new electrodes based on mono(2,4-pentanedionato-*o,o'*) tri(phenylmethyl)tin (DMTBS) demonstrate excellent selectivity towards salicylate anion and exhibit a selectivity sequence of anions in the following order: salicylate > benzoate \cong perchlorate > thiocyanate > iodide > nitrite > nitrate > acetate > bromide > chloride > citrate. The most striking feature of these data is the apparent relationship between the selectivity and the substituent in the ligands. As the substituent changes from the methyl group to the phenyl group, the selectivity for salicylate deteriorates.

3.3. Effect of pH on response characteristics of the electrodes

The effect of pH on the response of the potential readings of the DMTBS-based electrode was examined by recording the emf of a cell which contained sodium salicylate solutions ranging from 1.0×10^{-6} to $1.0 \times 10^{-1} \text{ mol} \cdot \text{l}^{-1}$ in a buffered solution ($\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$) adjusted to the respective pH values. The results show that the linear range, the detection limit and the detection sensitivity deteriorate to some extent as the pH increases. The results in Fig. 3 indicate that the change in pH has less effect on the electrode potential within the pH range of 2–7 (average slope of $14.5 \text{ mV} (\text{pH unit})^{-1}$), but the slope of the descending part of the curve within the pH range of 7–11 is nearly Nernstian (average slope of $48.1 \text{ mV} (\text{pH unit})^{-1}$) pointing out a hydroxyl ion exchange at the membrane surface. In accordance with previous research, the deterioration of potentiometric response characteristics at higher pH values was due to an increasing level of interference from hydroxyl [24].

3.4. Mechanism of salicylate response

Some lipophilic organometallic compounds were reported as unusual anion ionophores, and exhibited specific anion-selective behaviour which was different from the so-called Hofmeister sequence. Their anion selectivities were mainly governed by the specific interactions between organometals and anions, rather than the lipophilicity of anions or simple opposite charge interactions with anions. That the electrodes based on pentacoordinate organotin complexes exhibited high potentiometric selectivity for salicylate, must be related to the strong interactions between the central Sn(IV) atom in organotin complexes and salicylate anions. In order to investigate the interactions between the carriers and salicylate in membrane phase, infrared spectra of a DMTBS membrane, which had been conditioned in $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ buffer for 24 h was carried out with a PVC membrane as the background (see curve 2 in Fig. 4). Certain relative features of the bands at 1743.6, 1574 and 504

Fig. 4. Comparison of infrared spectra (2) of a DMTBS membrane with that (1) of the same membrane which has been dipped into $0.1 \text{ mol} \cdot \text{l}^{-1}$ salicylate for 24 h using a blank PVC membrane as background.

cm^{-1} are due to the vibrations of C=O, C=C and Sn–O bonds, respectively. The $\nu\text{C}=\text{O}$ stretch (1743.6 cm^{-1}) in DMTBS membrane corresponding to the free ligand (acetylaceton) indicates that the strength of chelation is relatively weak in solution and the coordinate carbonyl group in this kind of complex may be replaced by solvent molecule reversely. This agrees with the results in pentacoordinate triphenyltin complexes obtained by Gopinathan et al. [19]. Obvious changes are observed in infrared spectra after the same membrane has been dipped into $0.1 \text{ mol} \cdot \text{l}^{-1}$ salicylate for 24 h (see curve 1 in Fig. 4). A strong broad band appearing at $3117\text{--}3508 \text{ cm}^{-1}$ shows that the phenolic hydroxyl of salicylate can form an adduct with the carbonyl of the ligands by hydrogen bonding. The band at 1743.6 cm^{-1} shows a considerable red shift at about 1702

Fig. 5. Impedance plot of a DMTBS membrane with *o*-nitrophenyl octyl ether as plastizer immersed in $1.0 \times 10^{-4} \text{ mol} \cdot \text{l}^{-1}$ salicylate buffered with $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ to pH 5.0.

Fig. 6. The suggested mechanism of the unusual potentiometric response characteristics and high selectivity of the electrodes based on pentacoordinate organotin compounds for salicylate.

cm^{-1} , this red shift may be caused by the formation of a hydrogen bond between the phenolic hydroxyl of salicylate and the carbonyl of the carrier. Bands at 1574 and 550.3 cm^{-1} rise to higher frequencies, 1635.7 and 560.6 cm^{-1} , re-

spectively, which indicates coordinate exchange takes place between the central Sn(IV) atom and the carboxyl of salicylate in the membrane phase.

Fig. 5 shows the a.c. impedance of a DMTBS membrane with *o*-nitrophenyl octyl ether as plas-

ticizer immersed in $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ buffer at pH 5.0 for 4 h. A well-resolved semicircle at high frequencies and Warburg impedance at low frequency intervals are observed. As the concentration of salicylate increases, the bulk resistance decreases as follows: $2.00 \times 10^6 \Omega$ in $10^{-4} \text{ mol} \cdot \text{l}^{-1}$ salicylate, $1.65 \times 10^6 \Omega$ in $10^{-3} \text{ mol} \cdot \text{l}^{-1}$ and $1.50 \times 10^6 \Omega$ in $10^{-2} \text{ mol} \cdot \text{l}^{-1}$ salicylate. The results obtained indicate that the transfer process of salicylate across the PVC membrane is controlled by the diffusion process [25].

The suggested mechanism of salicylate response and selectivity is shown in Fig. 6. Coordination-unsaturated tin complexes can form adducts with the solvent molecule [26]. A similar process takes place in pentacoordinate organotin complexes used in this paper. The Sn(IV) atom in this kind of compound is a typical Lewis acid and seems to exhibit an unusual coordinate behaviour with anions [27]. The high potentiometric selectivity for salicylate (see Table 2) must be related to the unique interactions with salicylate [28]. The most striking feature of these data is the apparent relationship between the potentiometric response characteristics of these new electrodes and the substituent in the ligands. As the substituent changes from the methyl group to the phenyl group, the selectivity for salicylate deteriorates, accompanied by a lowering of the slope and a narrowing of linear range. The results have led us to hypothesize that a suitable electron density of the central Sn(IV) atom was important for the unique interaction between the carriers and salicylate. As the amount of phenyl groups increases, the electron-withdrawing power of the ligands increases, with the enhancement of hyperconjugation which decreases the electron density of the

central Sn(IV) atom. The low electron density could weaken the coordinate exchange interactions between salicylate and the central metal which resulted in the deterioration of the potentiometric response characteristics and selectivity for salicylate. Under the conditions of our experiments (pH 5), part of the salicylate in the sample solutions forms salicylic acid with hydrogen ions. Both salicylate and salicylic acid could transfer across the PVC membrane by diffusion simultaneously, and form adducts with the carrier molecule. Only the reversible transfer of salicylate anions is a potential-developing process, while the reversible transfer of salicylic acid does not contribute to the membrane potential. We presume that salicylate and salicylic acid transfer across the membrane phase at the same rate, the average charge of total salicylate (including salicylate and salicylic acid) which takes part in the transfer process from the sample solutions to the membrane phase corresponds to half of the negative charge. The super-Nernstian response to salicylate may be due to the transfer of salicylate with half of the negative charge.

3.5. Analytical application

The DMTBS-based electrode was shown to be useful in the potentiometric determination of salicylate in human urine samples, which can be easily prepared by 10-fold dilution of urine with $\text{KH}_2\text{PO}_4\text{--Na}_2\text{HPO}_4$ buffer adjusted to pH 5.0. The results (shown in Table 3) showed a standard deviation of 0.053(%), indicating that the DMTBS-based electrode can be applied for the determination of salicylate in actual samples with satisfactory results as compared with the conventional method.

Acid–base equilibria of diazepam and prazepam in montmorillonite suspensions

A.E.M. Ismail Mohamed *

Department of Pharmaceutical Analytical Chemistry, University of Assiut, Assiut, Egypt

Received 24 February 1997; received in revised form 22 September 1997; accepted 2 October 1997

Abstract

The distribution of ionic species of diazepam and prazepam in aqueous and aqueous montmorillonite clay suspensions at several pH conditions (pH 1–12) was monitored spectrophotometrically. Measurements were performed at 284 and 365 nm for diazepam and 285 and 361 nm for prazepam. The interaction between the negative clay surface and protonated species of the drugs studied relative to the unchanged species is responsible for the apparent displacement of pK_a values from 3.3 and 2.7 to 4.4 and 3.9 for diazepam and prazepam respectively. Changes in the partial molar free energy of the ionic species of both drugs (ΔG_i) as a result of interactions with montmorillonite suspensions was -1.47 and -1.72 for diazepam and prazepam respectively. The effect of an additional ionic solute i.e. sodium chloride was also studied. The recovered amounts of both drugs from five different concentrations of veegum at pH 2, 5 and 10 indicates the effect of drug–clay interactions in drug analysis. © 1998 Elsevier Science B.V. Keywords: Diazepam; Prazepam; Acid–base equilibria in montmorillonite suspensions; Drug–clay interactions

1. Introduction

Diazepam (Valium) and prazepam (prazene) are important drugs, widely used in the treatment of several anxiety states, sometimes as anticonvulsants, for premedication in anesthesiology and in spastic disorders [1,2]. Silicate clays were widely used in the manufacture of dosage forms of many drugs [3]. They have also been suggested as vehicles for controlled release formulations [4,5].

The effect of the clay surface on acid–base equilibria of weak bases in aqueous clay suspensions was investigated for some drugs [6–8]. Previous investigations have shown that, protonation was enhanced as a result of base–clay interactions and consequently the rate of hydrolysis.

Knowledge of the degree of equilibrium displacement and the fractions of studied drugs bound in the presence of clay suspensions may be of great value in the analysis of such drugs.

The effect of montmorillonite on the acid–base equilibria of diazepam and prazepam and the determination of quantities recovered from five different veegum concentrations at three pH levels was investigated in this study.

Fig. 1. UV-absorption spectra for prazepam ($10 \mu\text{g ml}^{-1}$) in aqueous solutions at different pH values.

2. Experimental

2.1. Apparatus

Measurements were performed with,

1. Uvidec-320 spectrophotometer (Jasco, Tokyo, Japan).
2. Unicam-SP 1750 spectrophotometer (Pye-Unicam, Cambridge, UK).
3. pH-Meter, Model 3305 (Jenway, UK).

2.2. Materials and reagents

Diazepam (Hoffmann-La-Roche AG, 7889 Grenzach-Wyhlen, Germany), and prazepam (Gödecke AG, Freiburg, Germany) were used as working standards without further treatment. All chemicals and solvents used throughout this work were of analytical grade.

1. Montmorillonite suspension: (Veegum HV as a source of montmorillonite used: R.T. Vanderilt, New York, USA): Veegum HV was finely pulverized and passed through $63 \mu\text{m}$ sieve to remove any extraneous matter and then weighed and diluted with distilled water to obtain 1% w/v veegum suspension.
2. Standard drug solution: Into a 100 ml volumetric flask, 100 mg of the studied drug (accurately weighed) was dissolved in about 80 ml ethanol and then completed to the mark with the same solvent. The standard drug solution was kept refrigerated in a light protected flask.
3. Buffer solutions (pH 1–12); were prepared in freshly boiled and cooled water [9].
4. Sodium chloride solution: 1 N solution in distilled water.

Fig. 2. UV-absorption spectra for prazepam ($20 \mu\text{g ml}^{-1}$) in aqueous veegum suspensions at different pH^b values.

2.3. General procedure

The standard drug solution (2 ml) was transferred to a 100 ml volumetric flask containing about 25 ml buffer solution at the desired pH, the volume was completed to about 95 ml with water. The veegum suspension (2 ml) was added to the flask prior to dilution to 100 ml with water to minimize the change in pH while mixing the drug with clay. The exact pH^b (the bulk pH of the suspension) of the stirred suspension was measured after the pH^b had stabilized. About 50 ml of the solution was then separated from the solid by centrifugation. Absorbance of the clear supernatant was measured at 284 and 365 nm for diazepam and at 285 and 361 nm for prazepam against a blank treated similarly using 2 ml of ethanol instead of the drug solution.

2.4. Effect of presence of sodium chloride

The standard drug solution (2 ml) was transferred to a 100 ml volumetric flask containing about 25 ml buffer solution at the desired pH, followed by 10 ml of sodium chloride solution, then completed as in Section 2.3 starting from “then the volume was completed...”.

3. Results and discussion

The absorption spectra of prazepam (as a representative example), in aqueous solutions and montmorillonite suspensions at different pH levels are illustrated in Figs. 1 and 2. These figures show that veegum suspensions significantly affect the absorption profiles and intensities of the drugs at certain pH values.

Fig. 3. pK_a values of diazepam in aqueous solutions (1), aqueous veegum suspensions (2), and aqueous veegum suspensions containing 0.1 N NaCl (3).

The acid–base equilibria of both drugs were markedly influenced by the presence of montmorillonite suspensions. In aqueous solutions, pK_a values of diazepam and prazepam were 3.3 and 2.7 respectively which agree well with the reported values [10,11]. However, in the presence of veegum, pK_{eff} were 4.4 and 3.9 (Figs. 3 and 4 and Table 1). The interaction of protonated species of diazepam and prazepam with the negative clay surface was responsible for these shifts.

ΔG_i ($i = \text{BH}^+, \text{B}$) is the change in partial molar Gibbs free energy for the constituent i , accompanying the addition of clay to the system at constant temperature, pressure and composition. ΔG_{B} and ΔG_{BH^+} could be related to the equilibrium constants by Eq. (1),

$$\Delta G_{\text{BH}^+} - \Delta G_{\text{B}} = RT \ln K_{\text{eff}}/K \quad (1)$$

For any individual species (i) in a reaction mixture, the free energy is described by Eq. (2),

$$G_i = G_i^* + RT \ln a_i \quad (2)$$

where G_i represents the free energy of formation of the substance, at activity a_i , from its elements in their standard state; G_i^* is the standard free energy of formation [7,12,13]. Because the system is heterogenous, external electric fields are present (due to the charged clay). As a consequence, ΔG_i may be identified using electrochemical potential, and the activity a_i is regarded as the total activity as described by Low [13]. This activity is not to be confused with the that commonly applied to homogenous systems (i.e. solutions for which the activity is defined in terms of the chemical potential and relates to field-free systems). Consequently, the values K_{eff}/K or $pK_{\text{eff}}-pK$ serve as reliable parameters indicating the degree of equilibrium displacement due to the BH^+ –clay and B–clay interactions.

If the system is sufficiently diluted with respect to clay and all other solutes, ΔG_{BH^+} and ΔG_{B} values can be calculated individually from Eqs. (7) and (8) [6,7]. As $C_i \rightarrow 0$ K_{eff} and ΔG_i values approach a definite value that reflects an intrinsic

Fig. 4. pK_a values of prazepam in aqueous solutions (1), aqueous veegum suspensions (2), and aqueous veegum suspensions containing 0.1 N NaCl (3).

interaction of species i with the clay surface, independent of C_p .

As seen in Table 1, ΔG_{BH^+} values were -1.47 and -1.72 Kcal mol $^{-1}$ for diazepam and prazepam respectively, indicating a greater stabilization of the protonated species than the free bases ($\Delta G_B = -0.04$ and -0.06 for diazepam and prazepam respectively).

The interaction of protonated drugs with veegum was affected by other ionic species in the system. As seen in Figs. 3 and 4 and Table 1, the

shift in the pK_{eff} values were reduced in the presence of 0.1 N sodium chloride solutions. It is hypothesized that sodium ions compete with BH^+ for the negative sites on the clay surface, or equivalently, that sodium ions screen the negatively charged clay surface, thereby reducing the apparent negative charge of the clay surface. Sodium chloride may also affect the interaction by altering the dispersion state of the clay, so that negative sites are less accessible to BH^+ species. Thus, the values for pK_{eff} calculated approached

Table 1
Effect of veegum on the acid–base equilibria of diazepam and prazepam

Sample (Kcal mol $^{-1}$)	Diazepam			Prazepam		
	pK_{eff}	ΔG_B (Kcal mol $^{-1}$)	ΔG_{BH^+} (Kcal mol $^{-1}$)	pK_{eff}	ΔG_B (Kcal mol $^{-1}$)	ΔG_{BH^+} (Kcal mol $^{-1}$)
Aqueous solution	3.3	—	—	2.7	—	—
Aqueous veegum suspensions	4.4	-0.04	-1.47	3.9	-0.06	-1.72
Aqueous veegum suspensions containing 0.1 N NaCl	3.5	-0.05	-0.16	2.8	-0.07	-0.27

Fig. 5. Effect of pH^b on the fractions of diazepam (1) and prazepam (2) bound to the clay surface.

normal pK_a values (3.5 and 2.8 for diazepam and prazepam respectively) and ΔG_{BH^+} values approached zero (-0.052 and -0.066 for diazepam and prazepam respectively).

The fraction bound curves in Fig. 5 indicate that, the fraction of the drug bound to the clay surface increased with pH^b until a maximum was observed at pH^b 3.3 for diazepam and 2.6 for prazepam. At lower pH^b values, protons apparently compete with BH^+ for the negative clay sites. The fraction of drug bound to montmorillonite decreased rapidly in all conditions because pH^b conditions allowed the unionized form of the

drug to appear in the system. The ΔG_{B} values which range from -0.035 to -0.062 for both drugs indicates little interaction with the clay surface.

The recovered quantities of diazepam and prazepam from five different veegum concentrations at three pH levels (pH 2, 5 and 10) were listed in Table 2. It is clear from the table that, the drug concentration in solution is greatly affected in acid medium, while in alkaline medium, there is no significant effect due to the presence of the drug in its unionized form. The magnitude of the fraction bound as well as the shift in the pK_a

Table 2

^a Average of five measurements.

value of drug at a given pH range due to the interaction with the clay surface may explain the failure of some analytical procedures to determine the exact quantities of drugs due to the presence of certain additives such as silicates.

The distribution of ionized and nonionized species of prazepam as representative example, in aqueous solutions and aqueous montmorillonite suspensions, based on the respective values of pK_a and pK_{eff} found in this study as shown in Fig. 6. The changes in the acid–base equilibria of both drugs due to the stabilizing effect of the montmorillonite clay surface favored the protonated forms to be present over a wider pH range than expected with acid–base equilibria in solutions and consequently may lead to an accelerated hydrolysis rate.

In contrast, stability might be increased due to the drug–clay interaction as a result of increasing the activation energy for the hydrolysis reaction. The net effect on the hydrolysis rate will vary for each system, depending on the relative magnitude of each factor.

Fig. 6. Distribution of the ionized and unionized species of prazepam. (---), aqueous solutions; (—), veegum suspensions.

4. Conclusion

The acid–base equilibria of diazepam and prazepam could be significantly affected by interaction with the clay surface. Clays may be found as vehicles in many dosage forms. Therefore, understanding their effect on the acid–base equilibria of the drug under investigation should provide the information needed to select the proper analysis method and pH at which the determination must be carried out. K_{eff} and ΔG_i are useful values for following the drug–clay interactions.

Appendix A. Determination of the effective equilibrium constant (pK_{eff})

UV-spectrophotometric determinations were performed at the previously given maxima to determine $C_{\text{B}}/C_{\text{BH}^+}$ as required for determination of K and K_{eff} by Eqs. (3) and (4).

$$K = \alpha\text{H}^+ \frac{\alpha\text{B}}{\alpha\text{BH}^+} \quad (3)$$

Where a_i is the activity of the species i ($i = \text{B}, \text{BH}^+, \text{H}^+$). In very dilute solutions (clay free) $C_{\text{B}}/C_{\text{BH}^+} = \alpha\text{B}/\alpha\text{BH}^+$ (in our case 7×10^{-5} and 6×10^{-5} M solutions of diazepam and prazepam were used respectively).

$$K_{\text{eff}} = \alpha\text{H}^+ \frac{C_{\text{B}}}{C_{\text{BH}^+}} \quad (4)$$

Where, C_i ($i = \text{B}, \text{BH}^+$) is the average suspension concentration of the species i .

Molar absorptivity (ϵ) of the drugs studied, is related to $C_{\text{B}}/C_{\text{BH}^+}$ by Eq. (5),

$$\frac{C_{\text{B}}}{C_{\text{BH}^+}} = \frac{\epsilon - \epsilon_{\text{BH}^+}}{\epsilon_{\text{B}} - \epsilon} \quad (5)$$

The symbols ϵ_{B} and ϵ_{BH^+} represent the molar absorptivities when all of the studied drug is present as B and BH^+ respectively, while ϵ represents the observed molar absorptivity at a given pH^{b} value.

For graphical representation, the theoretical lines for the drugs studied was calculated from Eq. (6)

$$\text{p}K_{\text{eff}} = \text{pH}^{\text{b}} + \log\left(\frac{\epsilon_{\text{B}} - \epsilon}{\epsilon - \epsilon_{\text{BH}^+}}\right) \quad (6)$$

to fit experimental points.

Appendix B. Determination of ΔG_i

If the system is sufficiently dilute with respect to clay and other solutes, ΔG_{BH^+} and ΔG_{B} values are given by Eqs. (7) and (8),

$$\Delta \overline{G}_{\text{BH}^+} = RT \ln(1-f) \left(\frac{K_{\text{eff}} + \alpha\text{H}^+}{K + \alpha\text{H}^+} \right) \quad (7)$$

$$\Delta \overline{G}_{\text{B}} = RT \ln(1-f) \left(\frac{K}{K_{\text{eff}}} \right) \left(\frac{K_{\text{eff}} + \alpha\text{H}^+}{K + \alpha\text{H}^+} \right) \quad (8)$$

where f is the fraction of base initially added to the system that is bound to clay. The fraction bound (f) was calculated from, $f = (A_i - A_s)/A_i$; where A_i represents the absorbance of a solution only containing the protonated species (BH^+), having a concentration equal to the initial concentration (C_o), while A_s represents the absorbance of the sample supernatant of initial concentration (C_o) measured against a blank treated similarly.

Abstract

A flow-injection analytical method for the determination of hydrochlorothiazide is presented. The method is based on the chemiluminescence reaction of hydrochlorothiazide with cerium(IV) in sulphuric acid, sensitized by the fluorescent dye rhodamine 6G. The proposed procedure allows quantitation of hydrochlorothiazide in the concentration range of 0.33–130 $\mu\text{mol l}^{-1}$ with a detection limit of 0.15 $\mu\text{mol l}^{-1}$, an RSD of 2.4% at 10 $\mu\text{mol l}^{-1}$ and a sample measurement frequency of 200 h^{-1} . The method was successfully applied to the determination of hydrochlorothiazide in pharmaceutical preparations containing, amongst others, lactose, maize starch, calcium phosphate, magnesium stearate, potassium chloride and E 110 (disodium-6-hydroxy-5-(4-sulphonatophenylazo) naphthalene-2-sulphonate) as the concomitant species. Apart from the single formulation, hydrochlorothiazide was also determined in tablets combined with the antihypertensive lisinopril. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Chemiluminescence; Hydrochlorothiazide; Cerium (IV); Rhodamine 6G; Flow-injection analysis; Pharmaceutical analysis

1. Introduction

Hydrochlorothiazide (6-chloro-3,4-dihydro-2H-1,2,4-benzothiadiazine-7-sulphonamide-1,1-dioxide) is a powerful thiazide diuretic. It has been used as such and in combination with other drugs,

e.g. amiloride [1], captopril [2], lisinopril [3] and fosinopril [4] for the treatment of hypertension and related disorders.

Hydrochlorothiazide is classically determined using electrochemical [5,6] or spectrophotometric [4,7] methods, the latter being recommended by the British Pharmacopoeia [8]. As hydrochlorothiazide is sometimes combined with other drugs in tablet formulations, liquid chromatographic procedures with UV detection have been suggested

* Corresponding author. Tel.: + 32 92 648097; fax: + 32 92 648196; e-mail: willy.baeyens@rug.ac.be

for its determination [9–11]. Multicomponent analyses based on derivative or multiwavelength spectrophotometry have been considered as simple and selective methods, the analysis of hydrochlorothiazide in a mixture with amiloride in tablet formulation being an excellent example [1]. The accuracy of this technique, however, mostly depends on the knowledge of all components present that contribute to the mixture absorbance [1,4]; a complicated mathematical calculation might also be needed. Therefore the method for the analysis of hydrochlorothiazide still requires improvement.

Analytical procedures applying chemiluminescence (CL) measurements in flow-injection (FI) set-ups combine the advantages of instrument simplicity (no monochromator required) and rapidity in signal detection (normally 0.1–10 s) and have been extensively used for the analysis of pharmaceutical compounds [12,13]. An early electrochemiluminescent study of hydralazine briefly mentioned the reaction of hydrochlorothiazide with $\text{Ru}(\text{bpy})_3^{3+}$ [14]. This system was further investigated by Holeman and Danielson in 1993 [15]. The main disadvantages of this proposed system for the determination of hydrochlorothiazide is the complicated instrumental set-up used for the electro-generation of CL, and the serious interference by organic amines which react with $\text{Ru}(\text{bpy})_3^{3+}$. Also, compounds combined with hydrochlorothiazide in tablet formulations such as amiloride and lisinopril may cause significant interferences in the hydrochlorothiazide determination.

The CL reaction of cerium(IV)-ions with drugs containing a thiol-group, sensitized by fluorescent dyes has been proposed by the present group for the analysis of captopril, penicillamine and tiopronin [16–18]. One of the advantages of the system is a certain degree of selectivity for S-containing compounds. When coupled with FI analysis (FIA), the method proves to be cheap, rapid, simple, and reproducible, which is essential in drug quality control studies.

The primary aim of the present work was to develop a simple and selective CL-based FIA method, applying the CL reaction of cerium(IV), sensitized by fluorescent dyes, for the routine de-

termination of hydrochlorothiazide in pharmaceutical preparations, in single form or combined with other drugs such as amiloride and lisinopril.

2. Experimental

2.1. Chemicals and Reagents

All chemicals were of analytical grade unless specified otherwise. Hydrochlorothiazide was obtained from Sigma (St. Louis, MO, USA), lisinopril and amiloride were purchased from Merck (Brussels, Belgium), cerium(IV) sulphate, rhodamine B and rhodamine 6G from UCB (Leuven, Belgium). All solutions were prepared with de-ionized water. An aqueous stock standard solution of hydrochlorothiazide ($130 \mu\text{mol l}^{-1}$) was freshly prepared in 20% (v/v) methanol. The cerium(IV) solution (10 mmol l^{-1}) was prepared by dissolving the ceric salt ($\text{Ce}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$) in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$; the 0.1 mmol l^{-1} rhodamine 6G solution was similarly prepared by dissolving rhodamine 6G in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ medium.

2.2. Apparatus

The FI system consists of a Gilson peristaltic pump (Minipuls 2 from Gilson, Villier-le-Bel, France; two channels, variable speed), provided with PTFE tubing. An HPLC isocratic pump (SP8770, Spectraphysics, CA) and an injector (VALCO, home-made loop $100 \mu\text{l}$) was installed as shown in Fig. 1. CL emission was measured using a CL detector (Chemlab, The Netherlands). CL data were handled by an IBM-compatible computer employing the luminometer software (Bio-orbit, Turku, Finland) for graphical viewing of the measured values and for calculation.

2.3. Procedure

2.3.1. Procedure for calibration

Working standard solutions containing hydrochlorothiazide in the range of $0.33\text{--}130 \mu\text{mol l}^{-1}$ were prepared by diluting a concentrated fresh standard solution of hydrochlorothiazide

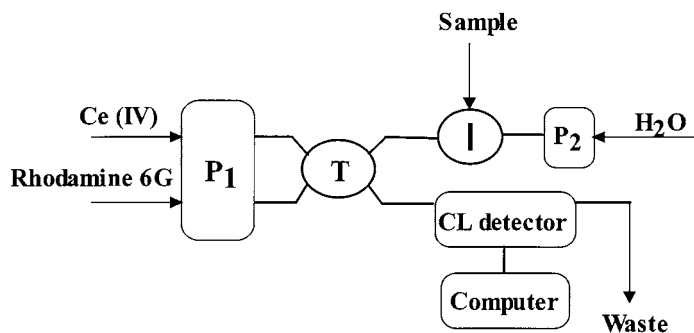

Fig. 1. FI manifold for hydrochlorothiazide determination: Ce(IV), 10 mmol l^{-1} in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$; Rhodamine 6G, 0.1 mmol l^{-1} in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$; P1, peristaltic pump; P2, HPLC pump; T, mixing cross; I, injector ($50 \mu\text{l}$).

($130 \mu\text{mol ml}^{-1}$) with 20% (v/v) methanol solution. The CL signal was measured by injecting $100 \mu\text{l}$ of the working standard solution into the carrier stream, which then joined the reagent streams (10 mmol l^{-1} Ce(IV) and 0.1 mmol l^{-1} rhodamine 6G in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ solutions). Peak heights of the CL light emission versus hydrochlorothiazide concentration were used for the calibration.

2.3.2. Procedure for tablets

Two types of tablets containing 12.5 and 50.0 mg of hydrochlorothiazide, single and in combination with lisinopril, respectively, were analyzed using the proposed method. Ten tablets were weighed so as to obtain the mean tablet weight.

An accurately weighed portion of the homogenized powder corresponding with 10 mg of hydrochlorothiazide was treated with HPLC-grade methanol up to 50 ml in the ultrasonic generator for 1 h. Then 2.5 ml of the solution was diluted with 20% (v/v) of methanol to 50.0 ml for the CL-FIA, providing a theoretical hydrochlorothiazide concentration of $10 \mu\text{g ml}^{-1}$.

3. Results and Discussion

The effects of Ce(IV), sulphuric acid, methanol, rhodamine concentrations and the reagent flow-

Fig. 2. Effect of Ce(IV)-concentration on the hydrochlorothiazide CL emission. Ce(IV) solutions prepared by dissolving $\text{Ce}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$ in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$; rhodamine 6G-concentration, 0.10 mmol l^{-1} in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$; hydrochlorothiazide-concentration, $10 \mu\text{mol l}^{-1}$ in 20% (v/v) aqueous methanol.

Fig. 3. Effect of methanol concentration on the CL emission of hydrochlorothiazide. Ce(IV)-concentration, 10.0 mmol l^{-1} ; rhodamine 6G concentration, 0.10 mmol l^{-1} , both in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$.

rates on the CL emission were investigated, together with the effects of sample injection volume and some micellar reagents.

3.1.1. Effect of Ce(IV) concentration

The concentration effect of Ce(IV) upon the CL behaviour of hydrochlorothiazide was examined over the range $0.5\text{--}20 \text{ mmol l}^{-1}$ in $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$. The results are shown in Fig. 2. Maximum emission intensity was observed at Ce(IV)-concentrations of $10\text{--}15 \text{ mmol l}^{-1}$. Lower concentrations of oxidant cause decreased CL emission. Higher concentrations produce self-absorption of the emitted radiation by the deep yellow colour from the Ce(IV) solution. Therefore, a concentration of 10 mmol l^{-1} of the ceric salt was used for further work.

3.1.2. Effect of H_2SO_4 concentration

Since acidic Ce (IV) reacts with hydrochlorothiazide yielding measurable CL emission, the effect of acid added to the Ce(IV) and rhodamine 6G solutions was examined. The highest CL signal was observed in the concentration range $0.1\text{--}0.2 \text{ mol l}^{-1}$ of H_2SO_4 . Higher and lower concentrations of the acid produced a decrease of CL. Hence, $0.1 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ solution was chosen to

prepare and dilute the Ce(IV) and rhodamine 6G solutions.

3.1.3. Effect of methanol concentration

As hydrochlorothiazide is practically water-insoluble, methanol was used to dissolve the compound from the samples. It is known that organic solvents in general influence CL behaviour, hence the effect of methanol was examined. As shown in Fig. 3, an increase in CL intensity was observed when the methanol concentration was increased up to 20% (v/v). Methanol concentrations higher than 20% (v/v) caused a decrease in CL intensities, as illustrated with hydrochlorothiazide concentrations ranging from $0.0013 \text{ mmol l}^{-1}$ to $0.013 \text{ mmol l}^{-1}$. Therefore 20% (v/v) methanol was selected as the optimum concentration for the present work. It should be stated that the 20% (v/v) methanol concentration used will also be of benefit in the separation of this diuretic drug using HPLC. In this respect the effect of acetonitrile was also tested, but caused a strong suppression of the hydrochlorothiazide CL emission.

3.1.4. Effect of rhodamine concentration

A few fluorescing compounds were tested as energy transfer-reagents in the CL reaction of

Ce(IV) with thiol-containing drugs [16,17]. The rhodamine series and quinine produced a remarkable increase of CL efficiency. These fluorophores were therefore examined in this study. As shown in Table 1, both rhodamine dyes as sensitizers increase the CL efficiency 25 to 40-fold. The effects of the concentration of rhodamine 6G and rhodamine B were further examined. The results in Fig. 4 show that 0.1 and 0.5 mmol l⁻¹ of rhodamine 6G and rhodamine B, respectively, provide maximum CL intensities. Higher concentrations cause self-absorption of the emission by the sensitizers and therefore lower CL intensity. As rhodamine 6G produces higher emission yields than rhodamine B, this dye was used in further experiments.

Table 1
Effect of different fluorophores on the CL emission from Ce(IV)-hydrochlorothiazide

Fluorescer	Optimized Concentration (mmol l ⁻¹)	Relative CL
None	—	1.0
Eosine	0.2	1.3
Lucigenin	0.1	3.3
Quinine	1.0	10.0
Riboflavine	0.1	13.0
Rhodamine B	0.5	25.4
Rhodamine 6G	0.1	40.5

Fig. 4. Effect of rhodamine 6G and rhodamine B on the CL emission of hydrochlorothiazide. Ce(IV)-concentration, 10.0 mmol l⁻¹; hydrochlorothiazide-concentration, 10 μmol l⁻¹ in 20% (v/v) methanol (Rh 6G, rhodamine 6G; Rh B, rhodamine B).

Table 2
Effect of some organized solutions on CL emission

Surfactant, cyclodextrin	Relative CL intensity ^a
Triton X-100	25
β-Cyclodextrin	86
Cetyltrimethylammoniumbromide	90
Tetrabutylammoniumbromide	99
None	100
Sodium dodecyl sulphate	105
Heptanal sodium bisulfite	110
Brij 35	135

^aConcentration: 10 mmol l⁻¹.

3.1.5. Effect of reagents flow-rate

The flow-rate of the reagent solutions was optimized in order to obtain satisfactory CL emission. The highest intensity was achieved at 1.0 ml min⁻¹ for both Ce(IV) and rhodamine 6G reagents. Decreasing the flow-rate from 1.0 to 0.7 ml min⁻¹, significantly spared the consumption of reagents with only a slight loss of CL intensity. Further study was therefore carried out using a flow-rate of 0.7 ml min⁻¹ for each reagent. In spite of the effect of the sample carrier stream on CL emission, the carrier stream flow-rate of 1 ml min⁻¹ was installed so as to easily couple the system with an HPLC set-up. Increasing sample carrier stream flow-rates may be applied to increase the CL emission intensity and thus improve detection limits.

3.1.6. Effect of sample injection volume

It is well-known that the sample injection volume in a FI set-up affects the signal intensity. An increase in sample volume normally leads to an increase in the emitted CL signal. The present study shows that a change in loop size from 50–200 μl can improve the CL intensity by a factor of 2, further increase in sample volume from 200–500 μl increases the CL intensity much slower. Therefore, 200 μl was considered the optimum sample injection volume in the FI system. The final purpose of this work is to couple the CL detector to an HPLC separation set-up, hence a sample volume of 50 μl was used throughout. Obviously, the injection volume, when applied to

Table 3
Recovery of 10 $\mu\text{mol l}^{-1}$ of hydrochlorothiazide applying various additives used as excipients

Additive	Concentration ratio additive/hydrochlorothiazide (w/w)	Recovery (%) ($n = 4$)
CaHPO ₄	100	100.0
KCL	100	98.5
Lactose	100	105.7
Magnesium stearate	100	100.0
Mannitol	100	101.0

Maize starch, pregelatinized	100	103.0
E110	10	102.0

HPLC set-ups should be appropriately reduced so as to prevent overload and subsequent peak deformation.

3.1.7. Effect of some micellar solutions

The effect of some organized systems, including two neutral surfactants (Brij 35, Triton X-100), two cationic surfactants (tetrabutylammonium-bromide and cetyltrimethylammoniumbromide), and two anionic surfactants (heptanal sodium bisulfite (1-hydroxy-1-heptanesulphonic acid monosodium salt) and sodium dodecyl sulphate) and β -cyclodextrin upon the cited CL reaction was similarly investigated. As can be seen from Table 2, apart from Brij 35 most of these systems could not enhance CL emission; on the contrary, substantial signal decreases were noticed. About

35% of increase in CL intensity was observed by the Brij 35 surfactant. As the increase is not significant for determination, the micellar solutions were not used for further FI work.

3.2. Determination of hydrochlorothiazide

Under optimum conditions described above, the hydrochlorothiazide calibration graph was linear in the range 0.33–130 $\mu\text{mol l}^{-1}$ and the regression line was $I = 1.8155C + 6.4564$, $r = 0.9993$ ($n = 10$), where I is the relative peak intensity and C the concentration of hydrochlorothiazide. The relative standard deviation (RSD) for 10 $\mu\text{mol l}^{-1}$ hydrochlorothiazide was 2.4% ($n = 10$). The detection limit, defined as three times the standard deviation for the reagent blank signal is 0.15 $\mu\text{mol l}^{-1}$ hydrochlorothiazide.

Table 4
Determination of hydrochlorothiazide with amiloride and lisinopril in synthetic mixtures using the proposed method

Amount added ($\mu\text{g ml}^{-1}$)		Amount found ($\mu\text{g ml}^{-1}$)		Recovery (%)

^a Data obtained by the determination of 10 independent samples (including sample preparation and measurements).

The mechanism of the CL reaction using Ce(IV) and the energy transfer to rhodamine dyes has been discussed [16]. The possible reactions are as following:

where, HCT, hydrochlorothiazide; Rho 6G, rhodamine 6G; $h\nu$, chemiluminescence emission; Red, reduced form; Ox, oxidized form.

3.3. Interference studies

The influence of commonly used excipients and additives in pharmaceutical dosage forms of hydrochlorothiazide was investigated in the determination of 10 $\mu\text{mol l}^{-1}$ hydrochlorothiazide. No interference was observed using the proposed method in the presence of lactose, mannitol, CaHPO_4 , magnesium stearate, KCl, maize starch and pregelatinized maize starch even when present in 100-fold excess. E110 (disodium-6-hydroxy-5-(4-sulphonatophenylazo) naphthalene-2-sulphonate) decreases the CL emission at a 100-fold higher concentration (1 mmol l^{-1}) than hydrochlorothiazide due to the deep orange colour of this dye, which results in the absorption of CL emission produced by the reaction of Ce(IV) with the analyte in the acidic medium. However, once the concentration of E110 is decreased to 0.1 mmol l^{-1} (1:10 ratio), no significant influence on

CL intensity is noticed. The results are shown in Table 3.

3.4. Application

In order to determine hydrochlorothiazide content in a mixture with lisinopril in tablet formulation, the interference of lisinopril with the hydrochlorothiazide CL reaction was examined. A 30-fold higher concentration of lisinopril did not cause significant interference in the determination of hydrochlorothiazide. Compared with only a 2-fold higher concentration of lisinopril in the pharmaceutical tablet, the proposed method was reliable for the analysis of hydrochlorothiazide in the mixture preparation. Similar experiments were carried out so as to investigate the feasibility of analysing preparations containing hydrochlorothiazide mixed with amiloride. The results listed in Table 4 show that, apart from two cases, no significant interference from amiloride was observed in the ratios listed, which offers the possibility of determining hydrochlorothiazide in the mixture preparation with amiloride. The cited interference of amiloride concentration in two cases was not relevant because the concentration of amiloride in tablet formulations is generally about 10-fold lower than hydrochlorothiazide. However, it should be noted that the antihypertensive thiol captopril has a significant effect on the determination of hydrochlorothiazide due to the CL reaction between captopril with Ce(IV) in the given CL system. A HPLC separation of captopril with

hydrochlorothiazide will be considered in future work.

The proposed method was successfully applied to the determination of hydrochlorothiazide alone and in a mixture formula containing 12.5 mg of hydrochlorothiazide and 20 mg of lisinopril (tablet formulation). The results of some synthetic mixtures are shown in Table 5. As can be seen, an acceptable correlation was found between the label values and the results obtained using the proposed method. In order to evaluate the validity of this method for hydrochlorothiazide determination in pharmaceuticals, recovery studies were carried out on samples where known amounts of hydrochlorothiazide were added. The recoveries for the different concentration levels varied from about 96–107%, as shown in Table 5. The reliability of the proposed method was also evaluated using an official method [8]. No significant differences were observed between the results obtained by the official method and the proposed method (Table 5). The method shows promise for routine control analysis of pharmaceutical preparations containing hydrochlorothiazide, or mixed with lisinopril. In view of the unpredictable effects on CL emission by decomposition products of the active principle, column liquid chromatographic analysis based on the proposed technique will be further evaluated.

Acknowledgements

The company Chemlab Instruments (The Netherlands) is greatly acknowledged for the use of their CL-based detector.

Received 6 June 1997; received in revised form 24 September 1997; accepted 2 October 1997

Abstract

A completely automated method to determine the most common parameters in cured meat products is proposed. The approach to full automation is based on the coupling of a robotic station for development of preliminary operations (namely weighing of the sample, grinding, leaching, filtration and transport to the aspiration zone) and a continuous unsegmented manifold for derivatisation and spectrophotometric monitoring of the reaction coloured products. This assembly works in an unattended fashion thus eliminating the bottleneck produced by the determination of these parameters in routine laboratories. The good agreement between results obtained by the proposed method and those from conventional methods for target analytes confirms its excellent performance and usefulness. © 1998 Elsevier Science B.V. Keywords: Robotic; Chloride–nitrite–nitrate; Meat; Continuous flow

1. Introduction

Curing is one of the most widely used technologies in meat manufacturing. The different curing modes (namely dry curing, wet curing, injection curing [1]) are based on the same principle, addition of a mixture of sodium chloride, either nitrite or nitrite plus nitrate salts to the fresh product. Even though the use of these curing agents involve some minor disadvantages, the advantages are so overwhelming [2] that no alternatives are

available at present. In the case of nitrite and nitrate, some of the most remarkable beneficial aspects of the curing process [3] are as follows; appearance of a red colour due to a reaction between muscular hemoglobin and the nitric oxide generated in nitrite reduction; reaction of nitrite and different compounds such as sugars, alcohols, amines, etc. to yield products which contribute to the typical aroma of meat cured products; antioxidant effect on lipid rancidity; antimicrobial activity, which hinders the growth of pathogenic microorganisms, such as *C. Botulinum*. The negative effects of curing anions only appear in products with excess amounts of

* Corresponding author. Tel.: +34 57 218615; fax: +34 57 218606; e-mail: qallucam@uco.es

these agents [4]. Some of the well-known undesirable effects are; the oxidant action of nitrite on the hemoglobin–Fe(II) complex, which can produce poisonous symptoms; formation of *N*-nitrosocompounds in the presence of both nitrosamine formers and acid pH; and the toxic action of nitrate, not per se but due to reduction to nitrite. For these reasons, the routine analysis of nitrite and nitrate is common practice in the meat industries in order to keep their levels within a range which ensures the development of the beneficial effects without the toxic aspects. The presence of sodium chloride in the curing process is advantageous, its protective effect hinders or makes it difficult for germ development by decreasing water activity; its conserving action by potentiating the effects of other preservative agents and inhibiting fungi and yeast proliferation, it also increases flavour. High salt concentration in cured products results in consumer rejection.

We have developed a fully automated method based on the coupling of a robotic station for sample weighing and pretreatment and a continuous flow system for derivatisation and detection in order to help big meat industries in the development of routine determinations of these three more commonly determined parameters.

2. Experimental section

2.1. Instruments and apparatus

The flow injection (FI) manifold was built using a Gilson Minipuls-HP3 peristaltic pump, a Rheodyne 5041 injection valve (adapted for use as switching valve), reduction columns of copperised cadmium of different lengths (1.8 mm i.d.) and a Pye Unicam SP6-500 spectrophotometer furnished with a Hellma 178. 12QS flow-cell and connected to the AD (Analog-Digital) converter of the PEC via its analog output for data acquisition, processing and delivery of the results via a computer program designed in our laboratory, which permits the use of so-called electronic dilution FIA technique [5–7]. All tubing used to construct the hydrodynamic system was of PTFE of 0.5 mm i.d.

The robotic station consisted of a Zymate II Plus robot (Zymark, Hopkinton), a System V controller, and the following peripherals.

2.1.1. Master laboratory station (MLS)

The proposed method uses two MLSs (MLS1 and MLS2), which consist of three syringes each, intended to dispense liquids in conjunction with the dilute and dissolve unit. Only two of the syringes of MLS1 were used, one of them was connected to a water bath and the other to a filter. Both were also connected to a dispenser; one of the syringe-dispenser assembly was used to dispense water; the other one to dispense filtered solution.

2.1.2. Small-size object all-purpose (SSOAP), big-size object all-purpose (BSOAP) and solid dispenser (SD) hands

The SSOAP hand allows the robot to seize centrifuge tubes and objects of similar size. The BSOAP hand allows the robot to seize 250 ml fleakers and objects of similar size. The SD hand (designed by the authors) allows the robot to manipulate solid samples. This hand is installed on the SSOAP hand forming 180° with its fingers and consists of a pair of tweezers which have a basket at their ends (see details in Fig. 1A).

2.1.3. Power and event controller (PEC)

The PEC module acts as an interface between the controller, peripherals and robot.

2.1.4. System V controller

This module sends orders to the rest of the units, including the robot and controls additional units such as a peristaltic pump, a photometer, switching valves, etc. The RS232 outputs of these units allow them to be operated by the System V via the PEC.

2.1.5. Balance

The balance plate for tube weighing was modified as shown in Fig. 1A (closer to the top of the balance), thus allowing the fleaker to be manoeuvred to and from the balance by the robot.

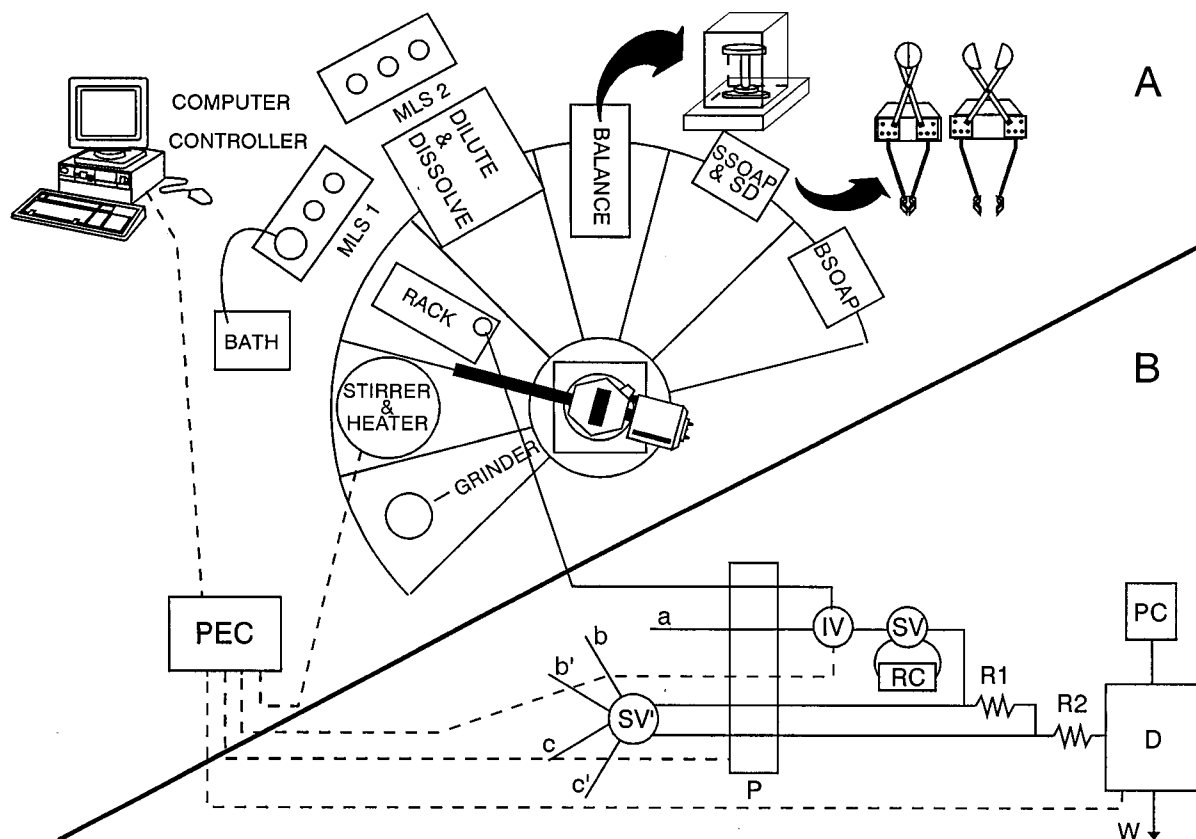

Fig. 1. Robotic station (A) coupled to a FI manifold (B) for the determination of nitrate, nitrite and chloride in cured meat products. MLS, master laboratory station; SSOAP, small-size object all-purpose hand; BSOAP, big-size object all-purpose hand; SD, solid dispenser hand; PEC, power and event controller; IV, injection valve; SV, selecting valve; RC, redox column; R, reactor; PC, personal computer; D, detector; W, waste; A, carrier solution; b, and c, reagents.

The following units in the flow manifold are also controlled by the robotic station: The peristaltic pump, the HPLC injector (only its valve is employed for automatic injection of the sample into the FI system), the injection valves used as switching valves and the photometer. The controller also makes absorbance readings at short intervals and stores that which is followed by a lower value; that is the maximum absorbance.

In addition, an Agimatic-N stirrer, a coffee grinder and a Technicon stainless steel filter were used. The System V controller was interfaced to a Netset 286/400 personal computer.

2.2. Reagents and solutions

2.2.1. Sample pretreatment

A 5% di-sodium tetraborate decahydrate aqueous solution and Carrez reagents (a 15% potassium ferrocyanide aqueous solution and a 30% zinc acetate aqueous solution) are used.

2.2.2. Derivatisation

Manual method [8]. Determination of chloride, a 0.1 N AgNO_3 and a 10% K_2CrO_4 aqueous solution. Determination of nitrate and nitrite, 37 g l^{-1} CdSO_4 aqueous solution, 5% NH_4OH aqueous solution and Zambelli reagent

(52 ml of 1.18 g ml^{-1} HCl aqueous solution in a 100 ml volumetric flask is made to volume with distilled water). This solution is transferred to a 200 ml volumetric flask. Sulphanilic acid (1 g) and 1.5 g of phenol are added in this order while heating to 100°C . The solution is cooled down and made to volume with a saturated NH_4Cl aqueous solution. FI method. Determination of nitrate and nitrite, a $0.001 \text{ M HAcO} + 1 \text{ g l}^{-1} \text{ Na}_2\text{EDTA}$ solution is used as carrier. Sulphonylamide solution, a volume of 10 ml of HCl containing 0.95 g of sulphonylamide diluted to 250 ml with distilled water. *N*-1-naphthylethylenediamine solution, 0.36 g of *N*-1-naphthylethylene-diamine and 2.9 g of sodium chloride is made to volume with distilled water in a 250 ml volumetric flask. Copperisant solution, a $0.1 \text{ M Na}_2\text{EDTA} + 0.1\% \text{ CuSO}_4$ solution. Determination of chloride, 0.86 ml of concentrated HNO_3 added to an aqueous solution containing 0.086 g of potassium thiocyanate and 0.169 g of $\text{HgCl}_2 \cdot 2\text{H}_2\text{O}$ and then 12.650 g of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ are added. The mixture is made to volume with distilled water in a 250 ml volumetric flask.

2.2.3. Preparation of the copperised minicolumns

FI method. A representative amount (ca. 10 g) of cadium granules are rinsed with a 1 N HCl solution and then with distilled water. The metal is placed in a precipitate vessel where 50 ml of a 0.1% CuSO_4 solution is added and then stirred until the blue colour of the solution disappears and then rinsed for 10 min with distilled water in order to remove all the semi-colloidal copper formed. The granules of the treated metal are packed in a cylindrical glass column which is coupled to the FI manifold.

Manual method. The column is packed with a bed of glass wool and then 20–25 cm of cadmium powder. The packed column is successively rinsed with a 0.1 N HCl solution, distilled water and a 5% NH_4OH solution.

All reagents were supplied by Merck.

2.3. Manual sample pretreatment and determination

2.3.1. Sample pretreatment

The meat sample is ground and homogenised. A representative amount (ca. 10 g) of the sample is

weighed (within 1 mg precision) and introduced into a 250 ml Erlenmeyer flask where 5 ml of 5% di-sodium tetraborate decahydrate solution and about 150 ml of distilled water at 60°C is added. The resultant suspension is maintained warm and stirred for 30 min, after which, it is transferred to a 200 ml volumetric flask and 2 ml of each Carrez reagent is added. The suspension is stirred, let cool down and made to volume. Then, it is filtered and the filtrate transferred to a 250 ml Erlenmeyer flask.

2.3.2. Determination of nitrite

Between 5 and 10 ml of filtrate is taken and introduced into a 25 ml volumetric flask. Distilled water ca. 20 ml and 1 ml of Zambelli reagent are added and the solution stirred, then stood at room temperature for 10 min. After this, 1 ml of an ammonia concentrated solution is added and made to volume with distilled water. It is let cool down for a further 10 min and the absorbance of the solution is then measured at 436 nm.

2.3.3. Determination of nitrate

The filtrate (20 ml) is transferred to a 25 ml Erlenmeyer flask. NH_4OH (5 ml) of a 5% solution is added and the mixture is heated until it starts to softly boil it is then passed through the cadmium column. The eluate is collected in a 100 ml volumetric flask. The column is rinsed for 3 min with hot water and the liquid is added to a volumetric flask which is then made up to volume. The nitrite obtained after this treatment is determined in solution by the method previously described.

2.3.4. Determination of chloride

The filtrate (10 ml), ca. 100 ml of distilled water and some drops of a 10% K_2CrO_4 solution are added to a 250 ml Erlenmeyer flask. This solution is titrated with 0.1 N AgNO_3 solution until a red colour appears.

2.4. Proposed procedure

2.4.1. Sample pretreatment

The robot gets the BSOAP hand, catches a 250 ml fleaker and tares it. The sample is ground using a coffee grinder connected to an AC output (AC2) of the PEC. After this, the robot takes the SSOAP

hand, adds the sample into the fleaker until the sample weight is between 10 and 12 g. The controller collects the weight-datum, and the robot takes the fleaker out from the balance, sets it under the dilute and dissolve dispenser, adds 5 ml of 5% sodium tetraborate solution inside the fleaker and then places it on the stirrer. It takes the distilled water dispenser, sets it over the fleaker and adds 150 ml of distilled water which is aspirated from a reservoir in a thermostated bath at 60°C. The controller drives the AC output (AC1) of the PEC, the stirrer is turned on and the sample stirred for 30 min maintaining the temperature at 60°C. The robot carries the fleaker from the stirrer and 2 ml of each Carrez reagent is added and then returns it to the stirrer for 20 s. Now, the robot catches the fleaker, places it in the rack and, once the solution is cooled down adds distilled water until the weight is 200 g, homogenises the solution by stirring, takes the filter, introduces it into the solution and acts on the MLS2 syringe, connected to the filter. The syringe is filled with filtered solution and emptied into a clean fleaker. This operation is repeated twice in order to rinse the filter from stuck particles. The filtered solution is aspirated to the continuous manifold.

The hydrodynamic system (FI configuration) for the determination of nitrite and nitrate is shown in Fig. 1B. Valve SV lets the sample merge directly with the reagents for nitrite determination (filling position). In the inject position the sample passes through the reduction column before mixing with the reagents. The original nitrite, and nitrite resulting from the reduction of nitrate are thus determined. The concentration of nitrate is calculated by the difference.

The continuous manifold for the determination of nitrate is also used for chloride determination. Sulphonylamide and *N*-1-naphthylethylenediamine solutions are exchanged by distilled water and chloride reagent solution, respectively. The carrier is distilled water in all instances.

2.4.2. Calibration

This is accomplished by running a calibration curve with seven standards every week. Three standards are inserted every day in order to correct the slope, if necessary.

2.4.3. Overall procedure

Once the filtrate has been acquired by the robot, it is aspirated by means of the aspiration probe connected to the injection valve of the flow injection manifold with the aid of the peristaltic pump. First, the nitrite is determined, then the nitrate, in both cases by interpolation of the peak absorbance of the sample in the corresponding calibration line stored in the computer, and finally the chloride is determined using electronic dilution for collection and data treatment.

2.4.4. Computer program for electronic dilution

Two main reasons make the use of a computer program necessary for chloride determination. (1) The wide determination range of this analyte (between 3 and 18% w/w) which makes mandatory signal measurement at times longer than the residence time without significant errors. (2) Management of the huge numbers of data obtained in routine analysis of a large series of samples (up to 400 sample day⁻¹).

Fig. 2 shows the flow-chart of the designed program. Signal–time data is collected by the computer at preset intervals from the maximum of the peak. This data is stored either for individual samples or batch samples. In the former case the computer works like a recorder. In the latter case the time at which the absorbance is measured is selected when the data from all the samples have been acquired. Depending on the concentration of the target sample, the time selected can correspond to the maximum or a longer time in the tail of the diagram where the absorbance is lower due to a higher dispersion. Once the time is selected, the computer provides the absorbance signal, which is imported to a LOTUS chart from which the calibration line corresponding to the selected time is run and the absorbance of the sample interpolated.

3. Results and discussion

3.1. Chemical systems

The determination of nitrite is based on the Griess reaction, adopting Shin's modification [9]

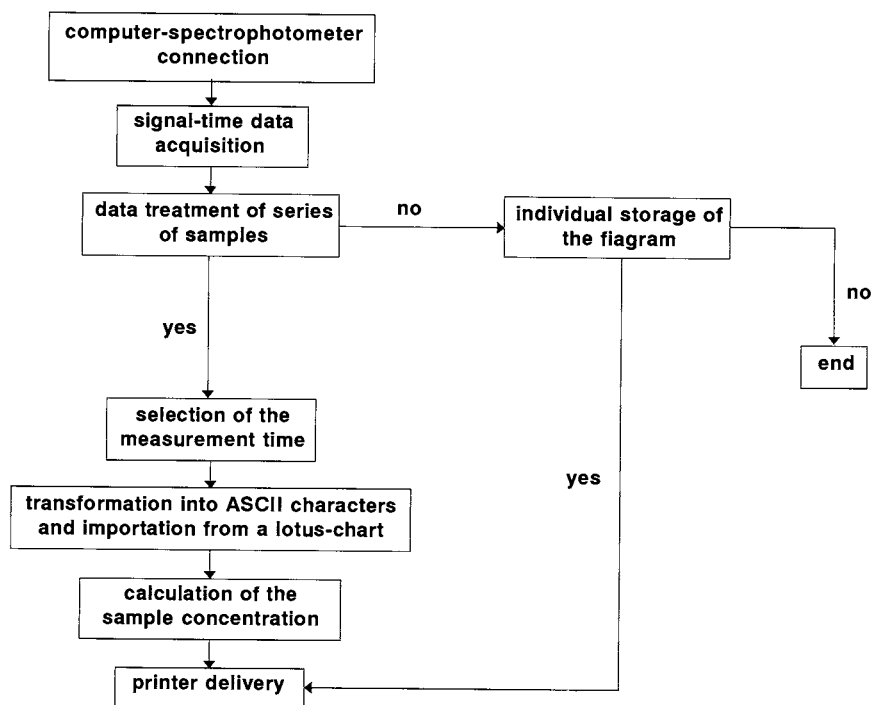

Fig. 2. Flow-chart of the computer program for electronic dilution.

in order to avoid the manipulation of carcinogenic reagents. The determination of nitrate is based on the same derivatisation reaction after reduction to nitrite. The determination of chloride is based on displacement of thiocyanate in the mercury–thiocyanate complex. Then, the displaced thiocyanate forms a red complex with ferric ion, which is monitored at 480 nm. As the overall process consists of two parts (discontinuous or robotic and continuous or FI), the optimisation of each was accomplished separately.

3.2. Discontinuous or robotic stage: sample pretreatment

A computer program was developed to control the different unitary operations (UOs) carried out by the robotic station. The performance of both the program and the different UOs was then checked.

In order to obtain a ground sample suitable for handling by the robot (not sticky mass but di-

vided in small particles) the grinding time must be short (about 10 s is sufficient).

The solutions were made to weight (as described in Section 2.4) rather than to volume as the robot was a sensorless device.

3.3. Determination step

Detailed methods for the determination of nitrite, nitrate and chloride by flow techniques are abundant in the literature. The ruggedness of the method for chloride is guaranteed because of its routine use since 1960 in segmented-flow analysers, and since 1975 in FI. As the aim of this research was focused on overall automation rather than the development of new determination methods, some variables such as reagent concentration, diameter of the tubing system, length of reactors and geometry of the reduction column were not optimised and the values developed by our research team in previous studies [10–12] were used (see Table 1).

Table 1
Optimum values of variables for the determination of NO_2^- , NO_3^- and Cl^-

Parameter	Optimum value
Injection volume ($\text{NO}_2^-/\text{NO}_3^-$) (μl)	100
Injection volume (Cl^-) (μl)	10
Flow-rate (ml min^{-1})	1.1
R1 length (cm)	15
R2 length (cm)	200
Column length (cm)	8.5
Column diameter (mm)	3

3.4. Features of the methods

3.4.1. Nitrite and nitrate determination

This method requires running three calibration lines. One for nitrate and two for nitrite (with and without passage of the sample through the reduction minicolumn). A series of solutions were prepared from solutions of both anions within a wide range of concentrations and subjected to sample pretreatment to minimise matrix effects. The data treatment gives the values shown in Table 2(A). Linear ranges between $0.1\text{--}15\text{ mg l}^{-1}$ for nitrite and between $0.5\text{ and }30\text{ mg l}^{-1}$ for nitrate were obtained. These ranges are appropriate for the determination of these anions in meat. The RSD obtained for 11 samples of 5 mg l^{-1} injected in

triplicate was lower than 1.5% in all instances. The sampling frequency was 30 h^{-1} .

3.4.2. Chloride determination

The characteristics of this system makes it necessary to run only one calibration line. The so called electronic dilution was used in order to adapt the method to the usual wide range of concentrations of this anion in meat (between 3 and 18% (w/w)). The data was acquired and processed using a computer program designed in our laboratory (see flow-chart in Fig. 2). Standards were prepared in a wide range of concentrations. The features of the calibration lines obtained at different times from the maximum of the transient signal are listed in Table 2(B).

3.5. Applications of the method to meat samples

The proposed method was validated by applying it to 10 samples of fresh and cured meat from Navidul. The content of the samples was also determined using the manual method. In both cases the concentrations are referred to the filtrated solution. The excellent agreement between both approaches is shown in Table 3, where the precision of the proposed method for each sample, expressed as SD, and that of the manual method, expressed as a reproducibility study during a

^a The 1-month reproducibility ($n = 7$) was as follows: RSD (NO_2^-) = 5.5%; RSD (NO_3^-) = 3.5%; RSD (Cl^-) = 0.5% for 1.4 mg l⁻¹, 3.1 mg l⁻¹ and 3.55 g l⁻¹, respectively.

month, demonstrated that the automatic method is more precise than its manual counterpart.

4. Conclusions

A completely automated method for the determination of nitrite, nitrate and chloride in cured meat based on the coupling of discontinuous (robotic)/continuous (flow injection) automated alternatives is proposed.

The assembly works in an unattended fashion thus eliminating human intervention with results in a subsequent decrease in the overload created in routine laboratories.

The method also allows a reduction in analysis time, as the conventional method involves a number of steps which are deleted in the automated counterpart. This shortening in the time required for the overall process is mainly due to the faster development of the derivatisation/monitoring step, which takes place in non-equilibrium conditions characteristic of FI methods. A decrease in the time required for this step from 20 to 3 min was achieved.

The time required for the development of the robotic preliminary operations is similar to that required by the conventional method, the most significant advantage of its implementation being

the elimination of human intervention which makes a 24 h working-day feasible.

Abstract

The reaction of 3,8,13,18-tetramethyl-21H,23H-porphine-2,7,12,17-tetrapropionic acid or coproporphyrin-I (CPI) with mercury(II) was studied spectrophotometrically, and kinetic and equilibrium constants were determined; the influence of temperature on the reaction rate was also studied. It was verified that mercury(II) accelerates the incorporation reaction of cobalt(II) into CPI; the kinetics and mechanism of this reaction at high alkaline pH were studied. Sensitive kinetic methods for the determination of mercury(II) at ppb levels have been established; the apparent molar absorptivity and Sandell's sensitivity for the recommended procedure, at 368 nm, and 400 s after the start of the reaction, were: 4.23×10^5 ($1 \text{ mol}^{-1} \text{ cm}^{-1}$) and 0.474 (ng cm^{-2}) (for $A = 0.001$). © 1998 Elsevier Science B.V. Keywords: Mercury(II); Cobalt(II); Spectrophotometry; Coproporphyrin-I

1. Introduction

In recent years many articles and reviews have been published on the mechanisms and kinetics of metal-ion incorporation reactions into the porphyrin nucleus [1–5]. The rate of metallo-porphyrin formation is generally much slower than that of complex formation with other open-chain ligands [6] and, in order to study these reactions, different organic catalysts such as pyridine and

imidazole have been proposed [7–9]; these reactions can also be accelerated using several metal-ions with high atomic radii, such as mercury(II), cadmium(II) and lead(II) [10–14]. In fact the coordination reactions of these metal-ions are very fast and cause the deformation of porphyrin ring helping the attack from the back side of other metal-ions with smaller ionic radii. This property has been suitably used for the catalytic determination of low concentrations of different metals [12,14,15].

In this paper we detail a study on the reaction mechanism of 3,8,13,18-tetramethyl-21H,23H-

* Corresponding author. Tel.: +39 737 40369; fax: +39 737 40370.

porphine-2,7,12,17-tetrapropionic acid or coproporphyrin-I (CPI) with mercury(II), the aim being to determine the equilibrium and kinetic constants of the reaction. The catalytic effect of mercury(II) on the formation of $\text{Co}^{\text{II}}(\text{CPI})$ complex, highlighting the presence of the reactive intermediate $\text{Hg}^{\text{II}}(\text{CPI})$, was also studied and a reaction mechanism was suggested. On the basis of these results a kinetic method for the spectrophotometric determination of sub-microgram amounts of mercury(II), founded on the catalytic effect of mercury(II) on the $\text{Co}^{\text{II}}(\text{CPI})$ complex formation, was developed. The optimum conditions for the determination of mercury(II) was discussed.

2. Experimental

2.1. Reagents

All reagents were of analytical-reagent grade and used without further purification. All the solutions were prepared using ultrapure water treated by a Milli-Q-Plus 185.

2.1.1. CPI solution

Stock solution containing $4.40 \times 10^{-5} \text{ mol l}^{-1}$ was prepared by dissolving 16.0 mg of CPI–dihydrochloride in 500 ml of 4.8 mmol l^{-1} sodium hydroxide solution.

2.1.2. Standard mercury(II) and cobalt(II) solutions

Stock aqueous solutions containing ca. 5 or 0.05 mmol of HgCl_2 and ca. 4 mmol $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ per litre, and sufficient nitric acid to prevent precipitation, were prepared; these solutions were standardized by ICP.

2.2. Apparatus

Absorption spectra were recorded on a Hewlett–Packard 8452A diode array spectrophotometer with a 1 cm quartz cell connected to Lauda K2R thermostat. The pH values were determined using a Metrohm 655 pH meter with a combined electrode (Inlab 413). The stock metal solutions were standardized by an Inductively Coupled Plasma (ICP) Jobin Yvon JY 24R.

2.3. Recommended procedure for catalytic determination of mercury(II)

The reactions were started by mixing (with magnetic stirring) 2 ml of an alkaline CPI solution ($\text{NaOH } 0.5 \text{ mol l}^{-1}$) with 20 μl of a solution containing cobalt(II) and up to 75 μl of mercury(II) solutions. The rates of the $\text{Co}^{\text{II}}(\text{CPI})$ complex formation was monitored spectrophotometrically by recording the disappearance of free CPI at 368 nm (λ_{max} of CPI) or the increase of $\text{Co}^{\text{II}}(\text{CPI})$ at 412 nm (λ_{max} of $\text{Co}^{\text{II}}(\text{CPI})$), as a function of mercury(II) concentrations, at fixed times. The absorbances were measured in a 10-mm thermostated cell at 20°C and at ionic strength of 0.5 mol l^{-1} , against blank.

3. Results and discussion

3.1. Determination of the stability constant of $\text{Hg}^{\text{II}}(\text{CPI})$ complex

Aqueous solutions of CPI at high alkaline pH, ionic strength of 0.5 mol l^{-1} and temperature of 20°C, was pale pink and presented absorption maxima at 368 nm (Soret band; $\epsilon = (1.015 \pm 0.006) \times 10^5$), 500, 538, 558 nm, and a shoulder of about 606 nm. Adding excess mercury(II), the colour of the solution changed to yellow and the resulting spectrum showed absorption maxima at 348, 414 nm (Soret band; $\epsilon_{348} = (3.392 \pm 0.032) \times 10^4$, $\epsilon_{414} = (5.707 \pm 0.033) \times 10^4$), 538 and 558 nm. The spectra of CPI and $\text{Hg}^{\text{II}}(\text{CPI})$ complex are shown in Fig. 1.

The stoichiometry of the of $\text{Hg}^{\text{II}}(\text{CPI})$ formation reaction, has been determined, applying two different experiments, the Job method in which the sum of metal ion and ligand concentrations ($C_{\text{Hg}} + C_{\text{CPI}}$) were 8.796×10^{-6} or $4.398 \times 10^{-6} \text{ mol l}^{-1}$; the results suggest the formation of a 1:1 complex (Fig. 2).

It was previously reported that mercury(II) does not fit well into the porphyrin core and is displaced over its plane forming 1:1, 2:1 and 3:2 species (mercury(II)/porphyrins), that changed at alkaline pH into a 1:1 complex [4]. For this reason the equilibrium between mercury(II) and CPI, in

Fig. 1. Absorbance spectra of 8.796×10^{-6} M CPI (a) and 8.796×10^{-6} M $\text{Hg}^{\text{II}}(\text{CPI})$ (b), at 0.5 mol l^{-1} ionic strength ($T = 20^\circ\text{C}$).

0.5 mol l^{-1} NaOH can be represented by the equation

and the equilibrium constant,

$$K = [\text{Hg}^{\text{II}}(\text{CPI})][\text{Hg}(\text{II})]^{-1}[\text{CPI}]^{-1}$$

where $[\text{Hg}(\text{II})]$ and $[\text{CPI}]$ denote the equilibrium concentrations of Hg(II) and CPI respectively. Mercury(II) is known to form numerous hydroxo complexes as a function of pH and concentration [16], in the studied equilibrium, at alkaline pH, it was mainly in the form of $\text{Hg}(\text{OH})_2(\text{aq.})$, $\text{Hg}^{\text{II}}(\text{CPI})$ must be considered as mercury(II) hydroxo–CPI complex; consequently, the corresponding equilibrium constant known as the ‘conditional’ constant. The presence of chloro-complexes in this alkaline medium can be excluded [17]. In order to calculate the stability constant, this reaction was studied at mercury(II)

concentrations of 2.199×10^{-6} – 1.992×10^{-3} mol l^{-1} and CPI concentrations of 2.199×10^{-6} – 1.759×10^{-5} mol l^{-1} . When $C_{\text{Hg}} = C_{\text{CPI}}$ and $[\text{Hg}(\text{II})] = [\text{CPI}]$, the stability constant K can be calculated from the intercept of the straight line obtained by plotting $\log[\text{Hg}^{\text{II}}(\text{CPI})]$ versus $2 \cdot \log[\text{CPI}]$, where $[\text{Hg}^{\text{II}}(\text{CPI})] = (A_1 - A_2)/(\epsilon_{\text{CPI}} - \epsilon_{\text{HgCPI}})$ and $[\text{CPI}] = C_{\text{CPI}} - [\text{Hg}^{\text{II}}(\text{CPI})]$, where A_1 and A_2 denote the absorbance in the absence and presence of mercury(II), ϵ_{CPI} and ϵ_{HgCPI} the absorbivities of CPI and complex, respectively, at $\lambda = 368 \text{ nm}$ (corresponding to CPI absorbance maximum). The value of K was $(2.64 \pm 0.01) \times 10^3 \text{ l mol}^{-1}$.

When $C_{\text{Hg}} \gg C_{\text{CPI}}$,

$$[\text{Hg}^{\text{II}}(\text{CPI})] = \frac{A_1 - \epsilon_{\text{CPI}}C_{\text{CPI}}}{(\epsilon_{\text{HgCPI}} - \epsilon_{\text{CPI}})}$$

and

Fig. 2. Job's diagram for the reaction between CPI and Hg(II) at 0.5 mol l^{-1} ionic strength ($T = 20^\circ\text{C}$). $C_{\text{Hg}} + C_{\text{CPI}} = 8.796 \times 10^{-6} \text{ mol l}^{-1}$, $\lambda = 414 \text{ nm}$ (a) and 368 nm (b).

$$[\text{CPI}] = \frac{(\varepsilon_{\text{HgCPI}}C_{\text{CPI}} - A_l)}{(\varepsilon_{\text{HgCPI}} - \varepsilon_{\text{CPI}})},$$

where A_l is the absorbance measured at 414 nm (corresponding to $\text{Hg}^{\text{II}}(\text{CPI})$ absorption maximum); the value of K obtained by plotting $\log[\text{Hg}^{\text{II}}(\text{CPI})]$ versus $\log[\text{CPI}]$, was $(2.56 \pm 0.01) \times 10^3 \text{ l mol}^{-1}$, is in good agreement with previous results.

3.2. Reaction rate for the formation of $\text{Hg}^{\text{II}}(\text{CPI})$ complex

The reaction of CPI with mercury(II) studied at six different 1:1 ratios at concentrations of $2.199 - 8.796 \times 10^{-6} \text{ mol l}^{-1}$, at alkaline solutions and temperature of 20°C , was completed within 100 s . The results obtained are shown in Fig. 3 where the values of $[\text{Hg}^{\text{II}}(\text{CPI})]$ against time are reported, the reaction rate increases with the concentration of the reaction product as a typical autocatalytic reaction [18]. In this case, the kinetic equation for the reaction is given by:

$$-d[\text{CPI}]/dt = k_3 [\text{CPI}][\text{Hg}^{\text{II}}][\text{Hg}^{\text{II}}(\text{CPI})]$$

where k_3 represents the 'conditional' rate constant. Since we have carried out measurements at $C_{\text{Hg}} = C_{\text{CPI}}$, the kinetic equation has been changed

$$-d[\text{CPI}]/dt = k_3 [\text{CPI}]^2[\text{Hg}^{\text{II}}(\text{CPI})],$$

integration between t_1 and t gives,

$$-K_3 t = \frac{1}{C_{\text{CPI}}^2} \ln \frac{C_{\text{CPI}} - [\text{CPI}]_{t_1}}{C_{\text{CPI}} - [\text{CPI}]_t} \cdot \frac{[\text{CPI}]_t}{[\text{CPI}]_{t_1}} + \frac{1}{C_{\text{CPI}}^2} \left(\frac{C_{\text{CPI}}}{[\text{CPI}]_{t_1}} - \frac{C_{\text{CPI}}}{[\text{CPI}]_t} \right).$$

Plotting the right term of the equation versus time, for different 1:1 concentration ratios of metal and ligand, we obtained good straight lines, the slopes of which represent the values of the rate constant k_3 , confirming presence of an autocatalytic reaction. The average value of k_3 , from the mean of six experiments, at 20°C , was $(2.463 \pm 0.051) \times 10^9 \text{ l}^2 \text{ mol}^{-2} \text{ s}^{-1}$ and the constant for the reverse reaction, got from $k_{-3} = k_3/K$, was $9.329 \times 10^{-5} \text{ l mol}^{-1} \text{ s}^{-1}$.

$10^6 [\text{Hg}^{\text{II}}(\text{CPI})] / \text{mol l}^{-1}$

Fig. 3. Change of $[\text{Hg}^{\text{II}}(\text{CPI})]$ against time for different $\text{CPI} = \text{Hg}(\text{II})$ concentrations: (a) 2.20×10^{-6} ; (b) 3.08×10^{-6} ; (c) 4.40×10^{-6} ; (d) 6.60×10^{-6} ; (e) 7.50×10^{-6} ; (f) $8.80 \times 10^{-6} \text{ mol l}^{-1}$. Ionic strength, 0.5 mol l^{-1} ($T = 20^\circ\text{C}$).

Measurements performed at temperatures of 5–35°C have shown an increase in the reaction rate (about 0.2 times per degree). Plots of $\ln k_3$ against $1/T$ at different wavelengths, enables the activation energy E_a to be determined according to the well-known relationship, $\ln k_3 = \ln A - (E_a/RT)$. The mean value for a series of five measurements was $E_a = (4.234 \pm 0.026) \times 10^4 \text{ J mol}^{-1}$.

3.3. Catalytic effect of mercury(II) on the formation of $\text{Co}^{\text{II}}(\text{CPI})$ complex

The rate of $\text{Co}^{\text{II}}\text{CPI}$ complex formation was very low [9] but could be accelerated in the presence of mercury(II). The reaction of CPI ($2.099 \times 10^{-6} \text{ mol l}^{-1}$) with cobalt(II) ($3.914 \times 10^{-5} \text{ mol l}^{-1}$) was studied in the presence of mercury(II) concentrations from 4.750×10^{-7} to 1.782×10^{-6}

mol l^{-1} in $\text{NaOH } 0.5 \text{ mol l}^{-1}$. The rate of CPI complex formation with cobalt(II) was monitored spectrophotometrically every 3 s at 20°C, by measuring the change in absorbance at 412 and 368 nm for the $\text{Co}^{\text{II}}(\text{CPI})$ complex and CPI respectively. Fig. 4 shows this change in absorbance against time, in which biphasic kinetic behaviour can be observed. The first-step reaction was completed in a few seconds, and was related to the formation of the $\text{Hg}^{\text{II}}(\text{CPI})$ complex with third order kinetics, as described above; the second-step corresponded to $\text{Hg}^{\text{II}}(\text{CPI})$ disappearance, and to the simultaneous formation of $\text{Co}^{\text{II}}(\text{CPI})$ by the exchange reaction,

with a second order kinetic according to the equation:

Fig. 4. Typical kinetic runs showing the two-step reaction of CPI with Co(II) in the presence of Hg(II). [CPI] = 4.31×10^{-6} mol l^{-1} , [Co(II)] = 4.02×10^{-5} mol l^{-1} , [Hg(II)] = 4.89×10^{-5} mol l^{-1} , ionic strength, 0.5 mol l^{-1} ($T = 20^\circ C$). (a) First step: $CPI + Hg(II) \rightarrow Hg^{II}(CPI)$; (b) second step: $Hg^{II}(CPI) + Co(II) \rightarrow Co^{II}(CPI) + Hg(II)$.

$$\begin{aligned} -\frac{d[Co^{II}(CPI)]}{dt} &= -\frac{d[Hg^{II}(CPI)]}{dt} \\ &= k_2[Co(II)][Hg^{II}(CPI)] \end{aligned}$$

The rate constant k_2 was determined from the slope of the straight line obtained from the plot

$$\frac{1}{(C_{Co} - C_{HgCPI})} \ln \frac{[Co(II)]}{[Hg^{II}(CPI)]} \text{ vs. } t,$$

where,

$$[Co(II)] = C_{Co} - \frac{A_t - A_\infty}{\epsilon_{CPI} - \epsilon_{CoCPI}}$$

and

$$[Hg^{II}(CPI)] = \frac{A_t - A_\infty}{\epsilon_{CPI} - \epsilon_{CoCPI}}$$

C_{Co} and [Co(II)] denote the total and the equilibrium concentrations of Co(II) and ϵ_{CoCPI} the

molar absorptivity of the $Co^{II}(CPI)$ complex. The value of k_2 at $20^\circ C$, obtained from a mean of four measurements, was $(2.25 \pm 0.04) \times 10^7$ $l \text{ mol}^{-1} \text{ s}^{-1}$.

3.4. Catalytic determination of mercury(II)

3.4.1. Calibration graphs

In an alkaline medium the rate constant of $Co^{II}(CPI)$ formation depends only on the mercury(II) concentration, therefore this metal-ion can be determined by means of its catalytic effect. The reaction of CPI (4.198×10^{-6} mol l^{-1}) with cobalt(II) (3.914×10^{-5} mol l^{-1}) was studied in the presence of mercury(II) concentrations from 0 to 1.785×10^{-6} mol l^{-1} . The increase of absorbance at 412 nm (ΔA_{412}) or its decrease at 368 nm (ΔA_{368}) measured at two fixed times (300 and 400 s) depends on the concentration of mer-

cury(II), the plots of these (ΔA) values against [Hg(II)] gave good straight lines. Apparent molar absorptivities ($l \text{ mol}^{-1} \text{ cm}^{-1}$) and Sandell's sensitivities (ng cm^{-2}) of the calibration graphs at 412 nm were 2.54×10^5 , 0.789 (after 300 s), 3.67×10^5 and 0.546 (after 400 s), while at 368 nm, 3.24×10^5 and 0.619 (after 300 s), 4.23×10^5 and 0.474 (after 400 s). The equations for the straight lines, obtained according to the procedure described were,

- after 300 s Hg(II) (ng ml^{-1}) = 619 (ΔA_{368}) = 789 (ΔA_{412})
- after 400 s Hg(II) (ng ml^{-1}) = 474 (ΔA_{368}) = 546 (ΔA_{412})

The suggested kinetic method allowed the determination of small amounts of mercury(II) with a detection limit of $3.5 \times 10^{-9} \text{ mol l}^{-1}$. The present method obtained detection limit similar to that described by Tabata and Tanaka [12] where similar results were obtained but with a ten fold pre-concentration of the sample by distillation.

3.4.2. Effect of foreign ions

Synthetic solutions containing mercury(II) (7.140×10^{-7} and $1.070 \times 10^{-6} \text{ mol l}^{-1}$), cobalt(II) ($3.914 \times 10^{-5} \text{ mol l}^{-1}$), and various amounts of foreign ions were prepared. The effects of foreign ions according to the procedure described, were examined. The tolerance limits of foreign ions are summarized in Table 1. Pd(II) and Fe(II) interfere with the determination, but the interference of Pd(II) can be re-

Table 1
Tolerance limits of foreign ions for the determination of mercury(II) ($7.140 \times 10^{-7} \text{ mol l}^{-1}$) at 20°C

Tolerance limit ($\text{mol}^{-1} \text{ l}$)	Ion
4.0×10^{-3}	Ca(II), Mg(II), Sr(II), Ba(II)
1.0×10^{-4}	Fe(III)
1.0×10^{-6}	Mn(II), Cu(II), Ni(II)
5.0×10^{-7}	Cd(II), Pb(II), Zn(II)
1.0×10^{-2}	F ⁻ , NO ₃ ⁻ , I ⁻ , Br ⁻ .
5.0×10^{-2}	Cl ⁻
4.0×10^{-4}	SO ₄ ²⁻

moved by adding 0.01 mol l^{-1} potassium iodide, while Fe(II) can be initially oxidated to Fe(III). The results obtained using the proposed kinetics has given values with a standard deviation lower than 2%.

4. Conclusions

The kinetic study of equilibrium between mercury(II) and CPI at alkaline pH, has emphasized the formation of 1:1 complex (Hg^{II}(CPI)) with a constant of $K = (2.64 \pm 0.01) \times 10^3 \text{ l mol}^{-1}$. The study of the mechanism has shown that this reaction is autocatalytic with kinetics of a third order with respect to Hg^{II}(CPI), CPI and mercury(II) concentrations.

Mercury(II) significantly accelerates the rate of the reaction of cobalt(II) with CPI to give Co^{II}(CPI); to highlight this increase with respect to the uncatalyzed reaction, we have contrasted this result with that obtained by other authors [9], although in different conditions, the rate can become about 10^7 times faster. In the study of this reaction biphasic kinetics was observed: in the first-step Hg^{II}(CPI) was formed, while in the second-step Hg^{II}(CPI) reacted with cobalt(II), (a metal substitution reaction) to give Co^{II}(CPI) and mercury(II). In the first-step the formation of Hg^{II}(CPI) was favoured, for the higher reaction rate with respect to Co^{II}(CPI); mercury(II) does not fit well in CPI and was displaced over the porphyrin plane, deforming CPI in the second-step, promoted the incorporation of cobalt(II). As was observed, deformation of the porphyrin plane is the most important factor governing the reaction mechanism [4].

The absorbance of the Co^{II}(CPI) complex at 412 nm (λ_{max}) depends only on the mercury(II) concentration allowing the determination of mercury(II) by means of its catalytic effect. Trace amounts of mercury(II) at concentration as low as $10^{-9} \text{ mol l}^{-1}$ on the basis of a clearly defined chemical reaction can be determined with high sensitivity. Recovery tests for mercury(II) in synthetic solutions in the presence of

various cations and anions was 98–102%. The present method permitted quick determination of mercury(II) at ppb levels without manipulation of the samples: only 400 s for each measurement on the calibration graph are necessary.

The best experimental conditions can be easily set, knowing the rate and equilibrium constants.

Cyclic voltammetry determination of epinephrine with a carbon fiber ultramicroelectrode

P. Hernández, I. Sánchez, F. Patón, L. Hernández *

Departamento de Química Analítica, Universidad Autónoma de Madrid, 28049 Madrid, Spain

Received 22 July 1997; received in revised form 1 October 1997; accepted 2 October 1997

Abstract

A carbon fiber ultramicroelectrode was used for the electroanalytical determination of epinephrine in biological fluids (urine) by cyclic voltammetry. The ultramicroelectrode was subjected to an electrochemical pretreatment in order to improve the epinephrine adsorption on the electrode surface. With this preconcentration step, detection limits of 7.8 ng ml^{-1} and determination limits of 27.6 ng ml^{-1} can be reached. The method was contrasted with native fluorescence determination—similar results were obtained. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Epinephrine; Adrenaline; Carbon fiber ultramicroelectrode

1. Introduction

Epinephrine or adrenaline is a hormone in the catecholamine family which is secreted by the suprarenal gland along with norepinephrine. It was first isolated in 1901 by Takamine and Aldrich, and was synthesized in 1904 by Stolz and Dalkin [1].

Catecholamines stimulate the nervous system. One of its more important functions is the increase in strength and frequency of cardiac contraction in the heart.

Epinephrine is synthesized naturally in the body from L-tyrosine by the action of different enzymes. Almost 50% of the secreted hormone appears in urine as free and conjugated, 3% as

vanilmandelic acid, (VAM), the most abundant metabolite in urine [2]. Only small amounts of free epinephrine is excreted.

All methods for determining catecholamines in urine require careful purification of the sample due to the many related amines and catecholes in urine. The oldest methods for epinephrine analysis are based on the native fluorescence of original amines. The trihidroxiindol method requires prior separation in a weak cationic resin for subsequent determination by fluorescence. Another method involves condensation with ethylenediamine after absorption in alumina.

Current methods focus on the use of high performance liquid chromatography (HPLC) with fluorimetric or electrochemical detection [3] and capillary electrophoresis [4].

As with other catecholamines, epinephrine has electroactive groups, the oxidation process to

Fig. 1. Photograph of the working ultramicroelectrode after being polished with the alumina suspension (a). The surface of the carbon fibre which constitutes the working ultramicroelectrode can be appreciated in photograph (b).

quinone has been widely studied from an electrochemical point of view [5]. Wightman et al. used ultramicroelectrodes to detect a second oxidation wave for adrenaline, a secondary amine, at high scan rates [6]. In this work we used an adsorption process for adrenaline on a carbon fiber ultramicroelectrode previously activated to reduce the detection limit of epinephrine.

2. Experimental

2.1. Equipment and reagents

The carbon fiber ultramicroelectrode was constructed using a 10 μm diameter carbon fiber (Textron) as the working electrode.

Electrochemical measurements were taken with an EG&G Princeton Applied Research Corporation (PARC) model 263 potentiostat with an Ag/AgCl 3 M reference electrode and a platinum counter-electrode. The potentiostat is equipped with an EG&G PARC model 181 current pre-amplifier and a faraday box. The data obtained was stored in a personal computer.

Solutions of epinephrine, norepinephrine and ephedrine (Aldrich) were prepared from the solid product dissolved in perchloric acid 0.1 M. Separation of biological fluids was accomplished using an ion exchange column with 'Amberlite C-G 50' resin and alumina.

The pH of the epinephrine solutions was changed using buffer solutions ranging from pH

2–12 on the basis of phosphoric, acetic and boric acid, using KOH to adjust the pH. All reagents used were Reagent Analysis Quality and the water was deionised using MilliRO-MilliQ (Water System) equipment.

2.2. Working ultramicroelectrode construction.

The working ultramicroelectrode was constructed from 10 μm diameter carbon fiber, which was fed into a 0.5 mm i.d. polypropylene tube. This tube was carefully sealed using a mild heat source in order to slowly melt the end of the tube where the fibre had entered so as to completely wrap it with polypropylene. The electrode was perfectly sealed [7]. At the other end of the tube, we fed a copper wire and mercury droplets to make electrical contact between the carbon fiber and the copper wire. This end was then closed using a fast-dry glue.

Finally the carbon fiber had to protrude from the polypropylene. To achieve this, we included an electrode polishing stage: P-1200 (PRESI) sandpaper was first used to reach the carbon fibre, then smoother paper (P-4000) and finally an alumina suspension (1 μm particle size) on a felt pad was used to produce a flat, easily reproducible disk surface (Fig. 1).

2.3. Activation and regeneration of the working electrode

The working ultramicroelectrode performance was checked against a 50 mM solution of potas-

The working ultramicroelectrode performance was checked against a 50 mM solution of potassium hexacyanoferrate(III) in a H_2SO_4 0.1 M medium. A cyclic voltammogram was recorded at 50 mV s^{-1} scan rate, obtaining a sigmoidal wave as corresponds to an ultramicroelectrode (Fig. 2). The current intensity of the steady-state may be used to calculate the radius of the electrode's active surface, as with an ultramicroelectrode we find that,

$$i_{\text{lim}} = 4nFDC^*r$$

[8]where i_{lim} is the limiting current (A), n is the number of electrons involved in the reaction, F is the Faraday constant, D is the diffusion coefficient of the electroactive substance ($7.2 \cdot 10^{-6} \text{ cm}^2 \text{ s}^{-1}$) [10], C^* is the concentration of the electroactive substance within the solution (mol cm^{-3}) and r is the electrode radius (cm). The limiting current we measured was 50 nA, and the active electrode surface was $3.6 \text{ } \mu\text{m}$.

In order to obtain a reproducible response in solutions of epinephrine, the electrode should be subjected to an activation process prior to use. This activation step was performed once after assembly, using cyclical scans from 0.0 to 1.500 V at 200 mV s^{-1} in a $\text{H}_3\text{PO}_4/\text{H}_2\text{PO}_4^-$ 0.04 M buffer at pH 3. This procedure produced a constant residual current indicative of the electrode activation. This activation process was only necessary once after polishing the electrode.

Fig. 2. Cyclic voltammogram of potassium hexacyanoferrate(III) 50 mM in a 0.1 M H_2SO_4 medium. $v = 50 \text{ mV s}^{-1}$.

Fig. 3. Cyclic voltammograms recorded for a $2.0 \text{ } \mu\text{g ml}^{-1}$ epinephrine solution in a $0.04 \text{ M H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$ buffer at pH 8; $v = 100 \text{ mV s}^{-1}$; $T_{\text{ac}} = 100 \text{ s}$: (a) before the activation step; (b) after the activation step.

We found in epinephrine, an adsorption process (of the molecule) that occurs on the electrode surface, facilitated by our activation step of the ultramicroelectrode (Fig. 3). We also found that the electrode cleaning treatment is not necessary after each measurement, since the product of epinephrine oxidation is not retained on the electrode surface, thus maintaining the active surface constant.

3. Results and discussion

Initially, the effect of the medium's pH on the electrochemical signal was analysed. The pH of the epinephrine solutions was changed using buffer solutions ranging from pH 2–12. The buffer solution concentrations were 0.04 M, and the measurements were made with a variable accumulation potential in accordance with the solution pH, at 60 s accumulation time, 100 mV s^{-1} scan rate and $2.0 \text{ } \mu\text{g ml}^{-1}$ concentration of epinephrine.

Fig. 4 shows the voltammograms recorded for pH below 9. The epinephrine had no oxidation wave in experimental conditions above pH 9. This is not the observed behaviour for other catecholamines [5]. This behaviour is due to the deprotonation of epinephrine ($\text{p}K_{\text{a}}$ around 8) this prevents its adsorption to the electrode surface, and removes the oxidation wave [10,11].

Fig. 4. Cyclic voltammograms recorded for a $2.0 \mu\text{g ml}^{-1}$ concentration solution of epinephrine with an accumulation time of 60 s and scan rate 100 mV s^{-1} at different pH levels.

There was also a shift in the peak potential when the pH was changed. The potential shifted to lower values as the pH increased according to the equation:

$$E_p(\text{V}) = 0.60 - 0.06 \text{ pH} \quad r = 0.999$$

the intervention of H^+ in the electrochemical reaction correlates with the mechanism proposed by other authors for the oxidation of catecholamines (Fig. 5).

The best relationship between peak current and its resolution is found at a buffer concentration of 0.04 M and pH 8, we took this as the optimum pH and used it in the subsequent experiments.

After selecting the working pH, the accumulation potential was analysed. A solution of epinephrine ($2 \mu\text{g ml}^{-1}$) was used in a phosphate medium at pH 8, varying the accumulation potential (-0.1 – 0.0 V), with a 60 s accumulation time, and 100 mV s^{-1} scan rate. Because we did not find any significant variation in the peak intensity, we chose an accumulation potential of -0.050 V , since the wave is well defined and the electrode is

Fig. 5. Oxidation mechanism for epinephrine.

Fig. 6. Isotherm of adsorption for different concentrations of epinephrine. Peak current (i_p) is in pA, T_{ac} is in seconds and C is in $\mu\text{g ml}^{-1}$.

not subjected to drastic conditions that might alter its performance, especially for values below -0.1 V .

The study of the variation of accumulation time enabled us to ascertain the level of epinephrine adsorption on the electrode surface. To accomplish this, we varied the accumulation time between 0 and 600 s for different concentrations of epinephrine in the measurement cell, in all cases without shaking, i.e. the hormone only reached the electrode by electrostatic attraction or chemical attraction. Measurements were carried out in a phosphate buffer at pH 8, applying an accumulation potential of -0.05 V and a scan rate of 100 mV s^{-1} . Fig. 6 shows the isotherms of epinephrine adsorption. For long accumulation times, an equilibration between substance concentration on the surface of the electrode and epinephrine concentration of the solution was reached. This occurs at shorter times when the epinephrine concentration is increased. In light of

these results, we chose 100 s as the accumulation time for subsequent analyses. Because epinephrine concentrations found in biological fluids are lower than those analysed, an accumulation time must be chosen that varies according to the sample—without considering any time as optimum the isotherms follow a similar pattern.

We then analysed the effect of scan rate on the electroanalytical signal. For this purpose we used optimum conditions from previous studies and varied the scan rate between 10 and 250 mV s^{-1} . The accumulation time was 100 s.

The voltammograms recorded (Fig. 7) revealed that the peak intensity increases, the peak potential shifted towards more anodic values with increasing scan rate. While the intensity increases with scan rate, there is also an increase in the width at half height and the peak definition worsened. The peak intensity reaches a maximum at 250 mV s^{-1} , a compromise must be reached between peak intensity and width at half height, 100 mV s^{-1} was chosen as the optimum scan rate.

When i_p is plotted against $v^{1/2}$, and E_p against $\log v$, we obtain a linear relationships that fits the following equations:

$$i_p \text{ (pA)} = -43.9 + 33.5v^{1/2} \quad r = 0.998$$

$$E_p \text{ (V)} = 0.037 + 0.064 \log v \quad r = 0.991$$

Fig. 7. Cyclic voltammograms recorded at different scan rates from -0.05 to $+0.70$ V. A $2 \mu\text{g ml}^{-1}$ epinephrine solution was used at pH 8, 0.04 M phosphate buffer: (a) 250 mV s^{-1} ; (b) 200 mV s^{-1} ; (c) 150 mV s^{-1} ; (d) 125 mV s^{-1} ; (e) 100 mV s^{-1} ; (f) 75 mV s^{-1} ; (g) 25 mV s^{-1} ; (h) 10 mV s^{-1} . $T_{ac} = 100$ s and $E_{ac} = -0.05$ V.

indicating that the electrochemical process is irreversible, a similar behaviour observed in the conventional sized electrode [9].

We also analysed the effect of buffer concentration on electrochemical measurement. To determine this we employed previously established conditions and changed the concentration of the phosphate buffer at pH 8 from 1 to 0.02 M. We found that the peak intensity falls exponentially as the concentration of the buffer increases. The maximum intensity is thus obtained for a 0.02 M concentration of the buffer electrolyte.

With a view to the future applicability of this method, and taking into consideration the range of epinephrine concentrations in urine, we opted to use two regression lines for calibration, one for high and the other for low concentrations, using 100 and 600 s accumulation time respectively.

At an accumulation time of 100 s, there were two linear sections in the regression line, which fit the following equations:

For concentrations below $4.0 \mu\text{g ml}^{-1}$,

$$i_p \text{ (pA)} = 54.1 + 102.3 C \text{ (}\mu\text{g ml}^{-1}\text{)} \quad r = 0.997$$

For concentrations above a $4 \mu\text{g ml}^{-1}$,

$$i_p \text{ (pA)} = 267.6 + 40.9 C \text{ (}\mu\text{g ml}^{-1}\text{)} \quad r = 0.998$$

Using 600 s as the accumulation time, concentrations in the order of 10 ng ml^{-1} can be measured. Plotting the values of peak intensity against concentration (Fig. 8), we find, as in the previous case, two linear sections in the regression line which fit the following equations:

For concentrations below 100 ng ml^{-1} ,

$$i_p \text{ (pA)} = 0.72 + 1.06 C \text{ (ng ml}^{-1}\text{)} \quad r = 0.998$$

For concentrations above 100 ng ml^{-1} ,

$$i_p \text{ (pA)} = 42.02 + 0.65 C \text{ (ng ml}^{-1}\text{)} \quad r = 0.994$$

The analytical characteristics of this method were established, taking into consideration the measurements made under optimum conditions. The statistical treatment of the data obtained indicates that the procedure has a standard error that ranges between 6.7 and 14.3%, and a standard deviation ranging between 2.6 and 27.6% ($n = 10$) for epinephrine concentrations $10\text{--}150 \text{ ng ml}^{-1}$, with an accumulation time of 600 s.

Fig. 8. Regression line according to the epinephrine concentration in the medium for an accumulation time of 600 s at an accumulation potential of -0.05 V and a scan rate of 100 mV s^{-1} . Scan limits are -0.05 and $+0.75$ V in pH 8, 0.02 M phosphate buffer.

At the same time, a value was found for the typical standard deviation of the background current (3 pA). Hence, the detection limit, considered to be three times the typical deviation of the background current, is 7.8 ng ml^{-1} , and the determination limit, considered to be ten times the value of the typical deviation of the background current, is 27.6 ng ml^{-1} with an accumulation time of 600 s [12].

In the analysis of potential interferences that might change the signal of our compound, we chose two principal compounds with similar characteristics, norepinephrine and ephedrine. The interference of these substances was analysed under the same measurement conditions as those used to study the effects of epinephrine concentration.

The presence of norepinephrine in the medium produces an increase in ip , a similar percentage to epinephrine concentration, although the presence of norephedrine can be detected under these measurement conditions, the norephedrine wave reduction is detected as it is a quasi-reversible system, presenting the reduction wave at 100 mV. The presence of ephedrine does not cause significant interference, until additions exceed 300% of the

adrenaline concentration. Because of the interference produced by these compounds, it is necessary to perform a separation pretreatment for epinephrine before analytical measurement.

4. Application

4.1. Determination in urine

Pre-treatment is a specific, standardized method for determining epinephrine in biological fluids [3]. Urine (5 ml) is mixed with a pH 7 phosphate buffer. The solution is passed through an Amberlite CG-50 ion exchange column. The catecholamines retained in the resin are eluted with an ammonium sulphate solution (2 M) and mixed with alumina powder for 10 min. The mixture is centrifuged and the solution is discarded. Catecholamines are extracted from the alumina with phosphoric acid (0.3 M).

The extract is raised to pH 8 with 2 M NaOH, a final volume of 3 ml is obtained using the appropriate buffer solution i.e. 0.02 M $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$.

This solution is fed into the measurement cell, the voltammogram (Fig. 9) is recorded under conditions used for calibration, using 600 s accumulation time. In order to quantify the epinephrine

Fig. 9. Cyclic voltammograms corresponding to standard additions applied to the urine extract. Accumulation potential was -0.05 V; $T_{ac} = 600$ s, $v = 100$ mV s^{-1} in pH 8, 0.02 M phosphate buffer: (a) sample; (b) 132 ng ml^{-1} ; (c) 198 ng ml^{-1} ; (d) 333 ng ml^{-1} ; (e) 533 ng ml^{-1} ; (f) 600 ng ml^{-1} ; (g) 666 ng ml^{-1} .

concentration we used the standard addition method.

A regression line is obtained which fits the equation:

$$ip \text{ (pA)} = 8.08 + 219.44 C \text{ (ng ml}^{-1}\text{)}$$

$$r = 0.997$$

by extrapolation we detected a concentration of 18.8 ng ml⁻¹ for the sample in the measured extract. Taking into consideration the fact that the recovery index for the whole process is 40%, we find that the epinephrine concentration in the initial sample is 47.11 ng ml⁻¹, a range considered normal for the excretion of human fluids in a state of repose [2].

4.2. Determination by native fluorescence

After analysing the extract electrochemically, the above method was contrasted using the native fluorescence determination of epinephrine [3]. This determination was carried out at an excitation wave length of 200 nm and emission in the range of 300–600 nm. The urine extract and successive additions of epinephrine of known concentration were recorded in the range of 10–50 ng ml⁻¹, obtaining a regression line which fits the equation,

$$I_{em} = 16.7 + 0.84 C \text{ (ng ml}^{-1}\text{)} \quad r = 0.999$$

and a concentration of 19.1 ng ml⁻¹ at 420 nm, similar to the result obtained using the ultramicroelectrode.

Abstract

The C₆₀- γ -cyclodextrin and Nafion chemically modified electrode exhibits two redox waves by cyclic voltammetry. Such an electrode will effect reduction and oxidation of cytochrome *c* and be capable of mediating the electron transfer to cytochrome *c*. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Electrocatalysis; Cytochrome *c*; C₆₀- γ -cyclodextrin; Nafion; Chemically modified electrode

1. Introduction

The electrochemical behavior of C₆₀ films has been widely investigated in non-aqueous solution since the large-scale method for successful laboratory synthesis of the fullerenes became available [1–8]. It indicates that reduction can form insoluble films with incorporated cations or lead to dissolution. The electrochemical behavior of C₆₀ films in an aqueous solution is also reported [9,10], showing that both the reduction and the oxidation are completely irreversible. In order to study the interaction between C₆₀ and biomacromolecules, water-soluble derivatives of C₆₀-C₆₀- γ -cyclodextrin inclusion complexes were synthesized according to the paper described [11–13]. Their electrochemical behavior has been studied in an

aqueous solution and the electrochemical behavior and electrocatalysis of hemoglobin by a thin coating of C₆₀- γ -cyclodextrin (C₆₀- γ -CD) and Nafion, deposited by evaporation on a glassy carbon electrode in an aqueous solution, have been investigated [14].

This paper is concerned with the electrocatalysis of cytochrome *c* at a C₆₀- γ -CD and Nafion chemically modified electrode. It was found that C₆₀- γ -CD is capable of mediating the electron transfer to cytochrome *c*.

2. Experimental

2.1. Reagents

C₆₀ was prepared in our laboratory. Its purity was 99.9%, as determined by mass spectrometry. The γ -cyclodextrin was bought from Tokyo Kasei

* Corresponding author. Fax: +86 10 62751708; e-mail: lmwx@chemms.chem.pku.edu.cn

and the 5% Nafion (Dupont) was from Aldrich and was diluted to 1% with ethanol before use. Horse heart cytochrome *c* (Type III) was obtained from BDH Chemicals, Poole. The water-soluble C_{60} - γ -CD inclusion complexes were prepared according to the literature [11–13]. Other reagents used were of analytical grade. Water was triply distilled from an all-quartz still and experiments were carried out at room temperature ($25 \pm 2^\circ\text{C}$).

2.2. Electrochemical measurements

The electrochemical cell consisted of a single-compartment glass cell with an Au counter electrode and a saturated calomel reference electrode located near the working electrode. The solutions were routinely deaerated by purging with high purity nitrogen. Cyclic voltammetric experiments were performed with a Princeton applied research (PAR) Model 273 potentiostat/galvanostat. The UV-Vis spectra were recorded using a Shimadzu Model UV-3100 spectrophotometer.

2.3. Electrodes and preparation

The working electrode was glassy carbon (GC) ($d = 4$ mm). Before use in electrochemical experiments and also before the start of modification procedures, the surface of the GC electrode was polished on fine emery paper and chamois leather containing Al_2O_3 slurry and then rinsed thoroughly with water in an ultrasound bath. Chemically modified electrodes (CME) were prepared by evaporation of a few microliters of C_{60} - γ -CD (1:2) in an aqueous solution on the electrode surface with an infrared lamp and then by casting a Nafion protection film. The experiments showed that there was an optimal CME response for the C_{60} - γ -CD reaction with $10 \mu\text{l}$ $2.0 \times 10^{-5} \text{ mol l}^{-1}$ C_{60} - γ -CD (1:2) dripped on the surface of the GC electrode. As C_{60} - γ -CD is soluble in water, to avoid a desorptial C_{60} - γ -CD layer, a thin film of Nafion was used to coat the C_{60} - γ -CD layer on the GC electrode surface. Experimental results demonstrate that the optimum electrode performance for the C_{60} - γ -CD reaction is obtained when C_{60} - γ -CD layer is coated with $4 \mu\text{l}$ 1% Nafion.

3. Results and discussion

3.1. Electrochemistry of CME

In Fig. 1, the curve a shows the cyclic voltammogram of C_{60} - γ -CD (1:2)/Nafion CME in a 0.10 mol l^{-1} KCl (pH = 6.4) medium. The curve exhibits two redox peaks P_1 and P_1' , with $E_{P_1} = -0.60 \text{ V}$ and $E_{P_1'} = -0.56 \text{ V}$. Furthermore, the corresponding peak currents were a linear function of the scan rates. Based on the experimental results and the papers reported [14–16], the electroreduction of the C_{60} - γ -CD (1:2)/Nafion CME is a reversible, surface-confined one-electron-transfer process. Possibly due to the effect of the heterogeneous kinetic factor and other factors (such as IR drop, ionic strength, solvent effect etc.), the peak potential difference between the redox peaks is not 0 V.

In order to examine the stability of the CME, it was exposed to air for 24 h, after which the currents remained unchanged. Furthermore, scanning more than 100 complete CV cycles at a scan rate of 500 mV s^{-1} between -0.20 and -0.80 V produced no significant decrease in cathodic and

Fig. 1. C_{60} - γ -CD (1:2) electrocatalysis cyclic voltammograms for: (a) 0.10 mol l^{-1} KCl; (b) 0.10 mol l^{-1} KCl + $3.3 \times 10^{-5} \text{ mol l}^{-1}$ cytochrome *c*; initial potential, $E_i = -200.0 \text{ mV}$; scan rate, 200 mV s^{-1} .

Fig. 2. Cyclic voltammograms for $3.3 \times 10^{-5} \text{ mol l}^{-1}$ cytochrome *c*, 0.10 mol l^{-1} KCl; initial potential, $E_i = -200.0 \text{ mV}$; scan rate, 100 mV s^{-1} . (a) bare GC electrode; (b) γ -CD/Nafion CME.

anodic peak currents, indicating that CME in the neutral form has good stability.

3.2. Electrocatalysis of cytochrome *c* at the CME

The experiments show that cytochrome *c* demonstrates no evident electrochemical response at a bare GC electrode and a γ -CD/Nafion CME between -0.20 and -0.80 V in a 0.10 mol l^{-1} KCl medium (Fig. 2). This implies that the electron-transfer rate of cytochrome *c* at two kinds of electrodes is very slow in the absence of C_{60} - γ -CD.

Cyclic voltammograms obtained with C_{60} - γ -CD (1:2)/Nafion CME and run in 0.10 mol l^{-1} KCl both with and without added cytochrome *c* are shown in Fig. 1. The voltammograms obtained upon addition of cytochrome *c* showed an increase in both the C_{60} - γ -CD (1:2) reduction current and oxidation current, but with little change in the peak potentials. This behavior persisted even at a scan rate as fast as 3 V s^{-1} . C_{60} - γ -CD (1:1)/Nafion CME was tested in the same way and it was found that there is an increase in both the C_{60} - γ -CD (1:1) reduction and oxidation currents in 0.10 mol l^{-1} KCl containing cytochrome *c*, but that this effect is weaker than that of C_{60} - γ -CD (1:2)/Nafion CME. This indicates that C_{60} - γ -CD is capable of mediating the electron-transfer rate of cytochrome *c*. However, the formal potential of

the C_{60} - γ -CD system may not be close to that of cytochrome *c* according to papers described [17,18].

Hinnen and Niki [17] have studied the roles of surface modifies (4-pyridyl derivatives) in the electron-transfer reaction of cytochrome *c* at a gold electrode surface. They concluded that the formal potential of the adsorbed cytochrome *c* is about 440 mV more negative than the potential of native cytochrome *c*. Wrighton and his co-workers [18] reported the preparation of nearly reversible electrode for cytochrome *c*. They pointed out that in principle, it should be possible to effect a redox reaction when the E^0 's of the surface mediator and biological system are unfavorable.

In order to examine whether cytochrome *c* has penetrated into the Nafion film, Nafion coating was prepared by transferring $40 \mu\text{l}$ of 1% solution onto a quartz microscopic slide and allowing the solution to evaporate. Following this, the quartz microscopic slide was soaked in 0.10 mol l^{-1} KCl containing $5.0 \times 10^{-5} \text{ mol l}^{-1}$ cytochrome *c* for 1 h and the surface was rinsed thoroughly with water after removal from the solution. The spectrum of cytochrome *c* in Nafion is shown in Fig. 3. Penetration of cytochrome *c* into the Nafion film is indicated by the appearance of the Soret band of porphyrin in the spectrum.

Andrieux and Saveant have discussed some cases of the following system by redox polymer film CME [19]:

where *A* and *B* are oxidized and reduced forms of the substrate, respectively and $K = k_1/k_2$ is the equilibrium constant.

Based on above theory, Dong et al. proposed a reversible catalytic reaction mechanism in the research of dye CMEs promoting redox of protein [20]:

where *M* is the mediator, *P* the redox protein, *O* and *R* correspond to oxidation and reduction, respectively and *k* is the rate constant of the catalytic reaction.

Fig. 3. UV-Vis spectra: (a) no cytochrome *c*; (b) incorporating cytochrome *c*.

Fig. 4 shows that the ratio of the catalytic cathodic peak current I_{k_1} to the reversible cathodic peak current I_{p_1} of C_{60} - γ -CD (1:2)/Nafion CME at different scan rates in 0.10 mol l^{-1} KCl containing $1.2 \times 10^{-5} \text{ mol l}^{-1}$ cytochrome *c*. It indicates that I_{k_1}/I_{p_1} first increases and then decreases slowly, finally approaching a constant as the scan rate increases.

According to the experimental results and the literature [14–20], electrocatalytic reaction mecha-

nism of cytochrome *c* at C_{60} - γ -CD/Nafion CMEs can be expressed as follows:

In conclusion, this work presents the first reported observation for reversible electrocatalytic activity of cytochrome *c* at C_{60} - γ -CD/Nafion CMEs in aqueous solution.

Fig. 4. The effect of scan rate on i_{k_1}/i_{p_1} . 0.10 mol l^{-1} KCl; $1.2 \times 10^{-5} \text{ mol l}^{-1}$ cytochrome *c*; initial potential, $E_i = -200.0 \text{ mV}$.

Laboratoire de Chimie Analytique, Sciences de l'Eau et de l'Environnement, Faculté des Sciences, 123 avenue Albert-Thomas, 87060 Limoges, France

Received 3 June 1997; received in revised form 3 October 1997; accepted 6 October 1997

Abstract

The complex formation constants of two phosphonic acids, HEDP and ATMP, with three trivalent metallic cations, Al(III), Cr(III) and Fe(III), have been determined by acid–base titration at 25°C and constant ionic strength (0.1 mol l⁻¹, KNO₃), using Martell and Motekaitis' computer programs. Species distribution curves showed that all three cations are in complex form in the pH range of fresh waters (5–9). The study of different cation/ligand ratios proved that both ligands mainly form anionic soluble complexes for systems having an excess of ligand—as protonated and unprotonated forms and especially ternary complexes with HEDP. For higher metal concentrations (excess of cation), weakly soluble species of HEDP and ATMP were formed with Al(III) and Cr(III). Two insoluble complexes with ATMP have been identified by SEM/EDAX as AlH₃X_(s) and Cr₂X_(s). Regarding Fe(III) species, Fe(OH)_{3(s)} precipitate seems to predominate in solution. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Complexation; Phosphonic acids; Speciation; Trivalent cations

1. Introduction

Due to a growing increase in public environmental concern, the use of sodium tripolyphosphate has been banned in domestic detergents. In recent years phosphonate derivatives have been used in washing powder formulations. However, some concerns still exist about their behaviour when released in lakes or rivers, as they can complex with toxic elements previously immobilized in sediments. We have studied two com-

monly used phosphonic acids, 1-hydroxyethane-1,1'-diphosphonic acid (HEDP) and aminotris(methylenephosphonic acid) (ATMP) (Scheme 1), whose acid/base and complexation behaviours with divalent cations have recently been characterized [1].

After domestic use, these phosphonic acids are released along with the rest of the domestic waste waters. In municipal waste treatment plants, a phosphorus elimination step can reduce phosphonate levels by 80% [2]. This step is however costly and is not always included in the treatment process. Phosphonates can enter aquatic ecosystems, and later flow through water potabilization plants

* Corresponding author. Fax.: +33 555 457459; e-mail: jcbollinger@unilim.fr

where a common process—coagulation/flocculation with ferric or aluminium hydroxides occurs. These complexing agents (including HEDP and ATMP) have recently been shown to retard hydration of cement slurries [3], possibly by preventing the formation of gelatinous Fe(III) hydroxide during the hydration of a calcium/aluminium/iron(III) cement as a result of iron chelation. It is therefore important to study the possible interactions of HEDP and ATMP with Fe(III) and Al(III).

The toxicity of Al(III) in drinking water is now well documented [4], and its contribution to Alzheimer's disease has been detailed [5]. Although Cr(III) is an essential oligoelement for animal life, its oxidation to toxic Cr(VI) can lead to ecological problems [6]. Both Al(III) and Cr(III) salts are commonly used in the tannery industry [7].

Trivalent cation complexation with multidentate ligands bearing phosphonate groups has previously been reported, but very few papers deal with HEDP and ATMP and frequently these studies only give qualitative results [8–13].

In this study we present the metal complex formation constants of HEDP and ATMP with three trivalent cations (Al(III), Cr(III) and Fe(III)), determined using protometric titration. Some insoluble compounds have been characterized using a SEM/EDAX technique and their solubility has been estimated by flameless AA. The potential impact of these complexes on natural systems is discussed using speciation diagrams.

2. Materials and methods

2.1. Chemicals

All chemicals were analytical grade reagents (Fluka or Prolabo) dissolved in ultra-pure water produced by the Millipore Milli-Q Plus system (resistivity of 18.2 M Ω cm and T.O.C. lower than 10 ppb). Solutions of metal cations were prepared from nitrate salts and standardized by acid–base titration in the presence of ligand. Phosphonic acid concentration was also determined by pH-metric titration.

2.2. Acid–base titrations

All experiments were carried out in a constant temperature cell at $25 \pm 0.5^\circ\text{C}$, at constant ionic strength $I = 0.1 \text{ mol l}^{-1}$ (KNO₃) under a purified nitrogen stream. In these conditions, the water ion concentration product is $\text{p}K_w = 13.78$ [14].

The pH-metric titrations were performed with a Metrohm 716 DMS automatic titrator using the dynamic equivalent point titration (DET) mode. The correct response of the combined glass electrode (Ag/AgCl, KCl 3 mol l⁻¹, Metrohm 6.0233.100) was verified with standard buffer solutions at pH 4, 7 and 10 and especially with a calibration in H₃O⁺ concentrations using strong acid–strong base titration as suggested by Irving et al. [15]. Experimental and calculated pH values are therefore equal to $-\log[\text{H}_3\text{O}^+]$.

The sodium hydroxide solution was prepared from pure grade (Prolabo) anhydrous solid dissolved in boiled and degassed ultra-pure water in order to prevent carbonate interference. This solution was standardized by hydrochloric acid titration. The extent of NaOH carbonation was measured using the Gran method [16,17]. It never exceeded 0.5% but was taken into account for the determination of protonation constants.

Solutions having metal ion/ligand molar ratios of 1/1, 1/2 and 1/5 were analysed. The ligand concentration was always 0.002 mol l⁻¹. For each ratio, three different titrations were repeated in triplicate, thus giving at least nine experimental data sets per ratio to be computed.

2.3. SEM/EDAX

Insoluble complex stoichiometry was characterized from atomic percentages produced by the scanning electron microscope.

The apparatus was either a Philips microscope (XL30 model), associated with a spectrometric X-ray detector (EDAX 9100/60) or a JEOL microscope (JSM 820 model) with a KEVEX system. The detection limit was 1% of analysed volume.

Precipitates were isolated according to the following procedure: Insoluble complexes were prepared from solutions at three cation/ligand molar

ratios: 1/1, 1/2 and 2/1. These were filtered on a cellulose nitrate Whatman membrane (pore diameter 0.2 μm) and recovered solids were dried for 48 h in a 96°C oven.

2.4. Flameless atomic absorption spectrometry

We determined the solubility of the studied precipitates using a SpectrAA-800, Graphite Furnace Spectrometer GTA 100 (Varian). A known precipitate amount was placed in a solution containing KNO_3 0.1 mol l^{-1} and stirred at a constant temperature ($25 \pm 2^\circ\text{C}$) sheltered from light. The solution was sampled regularly and the pH measured each time, until equilibrium was reached. Samples were acidified, filtered (on the cellulose nitrate membrane) and analysed.

2.5. Computer programs

Protonation and metal complex formation constants were calculated from pH-metric titration data using PKAS and BEST computer programs [18].

These computer programs use experimental data (concentration, volume, pH_{exp}). The known or estimated values of the overall stability constants are used to calculate pH_{calc} and minimize the sum of weighted squares of pH residuals ($\text{pH}_{\text{exp}} - \text{pH}_{\text{calc}}$). Constants are calculated according to an iterative method until minimisation is no longer possible. The overall and stepwise stability constants are defined as:

$$\beta_{ijk} = [\text{M}_i\text{H}_j\text{L}_k]/[\text{M}]^i[\text{H}]^j[\text{L}]^k \text{ and}$$

$$K_{ijk} = [\text{M}_i\text{H}_j\text{L}_k]/[\text{M}_i\text{H}_{j-1}\text{L}_k][\text{H}]$$

or

$$\beta_{ijk} = [\text{M}_i(\text{OH})_j\text{L}_k][\text{H}]^j/[\text{M}]^i[\text{L}]^k \text{ and}$$

$$K_{ijk} = [\text{M}_i(\text{OH})_j\text{L}_k][\text{H}]/[\text{M}_i(\text{OH})_{j-1}\text{L}_k]$$

where L is the HEDP or ATMP ligand (Y^{4-} or X^{6-} respectively), charges are omitted for simplification.

Calculated overall stability constants were averaged from a large number of experiments, good agreement exists between theoretical and experimental pH-metric curves, confirming their reliabil-

ity. The standard deviation ($\sigma_{(n-1)}$) was determined from all stability constants calculated for each titration. Stepwise stability constants were calculated from the overall constants determined for each individual experiment, not from averaged overall constants. This explains the gap sometimes observed between the errors in $\log K$ and in $\log \beta$.

A calculation method recently described [1] was used and validated (by two different workers) by the IUPAC procedure [19] with the glycine/nickel(II) system.

The SPE computer program developed by Martell and Motekaitis [18] was also used to draw speciation diagrams from calculated stability constants.

All protometric titration data were computed in the pH range 2–10 for the determination of metal complex formation constants. Protonation constants were determined in a pH range of 2–12 [1]. For more clarity, only complex metal forms were represented on species distribution curves in the pH range of fresh waters, i.e. 5–9.

3. Results and discussion

3.1. Protonation constants of ligands

The values for stepwise protonation constants determined here are identical to those previously reported [1] using the same experimental procedure i.e. calculated at 25°C with an ionic strength of 0.1 mol l^{-1} (KNO_3), using the PKAS computer program (Table 1). The protonation constant relative to the acidity of the HEDP hydroxide group was not considered [1,13].

3.2. Complexing properties of HEDP (H_4Y)

The pH-metric titration curves for free ligand and ligand in the presence of metallic cations at 1/2 cation/ligand molar ratio are shown in Fig. 1. It can be assumed that the phosphonate anion Y^{4-} forms relatively stable complexes with the three cations in the entire pH range studied and its complexing behaviour towards Al(III) and Fe(III) is similar. Up to pH 7, HEDP complexes

1-Hydroxyethane-1,1'-Diphosphonic Acid

HEDP H₄Y

Nitrilotris(Methylenephosphonic Acid)

ATMP H₆XScheme 1. Representation of HEDP (H₄Y) and ATMP (H₆X)

with Al(III) and Fe(III) are more stable than those of Cr(III). At pH > 7, there is an inversion of complex stability. The use of fresh metallic solutions in the presence of excess ligand allowed a good reproductibility of experiments at 25°C, with a stable electrode response.

These acid–base titration data were computed with BEST for the determination of metal complex formation constants. Several authors have shown the importance of taking into account both soluble and insoluble hydroxide complexes of trivalent metal ions because they can influence complexation reactions by their easy formation in solution [20–23]. In the presence of organic ligands with stronger affinity, such species could be inhibited. MY(OH)_x^{1-x} ternary complexes must also be considered. They can result from the hydrolysis of species like MY⁻ or be formed from M(OH)_x^{3-x} in the basic pH range as shown for divalent cations in the same system [1] and for Al(III) with other phosphonate ligands [24,25].

The calculation procedure previously described for the determination of metal-complex equi-

librium constants [1] was used with iterations only with Y⁴⁻ complexes formed, while the protonation constants and metal hydrolysis constants were fixed. These last values (Table 2) were taken from reported data [26–28] and recalculated for our experimental conditions using the Davies equation. Hydrolysis constants recalculated using the semiempirical equation of Daniele et al. [29] for Fe(III), and relations given by Baes and Mesmer [28] for Al(III) and Cr(III) agree with ours, with differences not exceeding 0.1 in log β.

Values of metal complex formation constants for each system at the 1/2 cation/ligand ratio (Table 3) clearly show that there are no significant differences between stability constants of Al(III), Cr(III) and Fe(III) complexes. The highest stabil-

ity of MY^- complexes corresponds to the lowest stability of the corresponding protonated MHY^0 species. This stability inversion was also observed by Gaizer et al. [24] and could be due to a strong electron transfer from ligand to metal, which would decrease the basicity of uncoordinated donor oxygen atoms. The same tendency is also observed for the MH_2Y^+ species of Cr and Al systems (the calculation of formation constants for FeH_2Y^+ and $\text{AlH}_3\text{Y}^{2+}$ species was not possible because of their low concentration in solution). Moreover, the gap between MY^- and MHY^0 successive constants, and also for MY_2^{5-} and MHY_2^{4-} in the case of Cr, is quite vast. This is probably due to the interference caused by the HEDP hydroxyl group in the cation complexation, as has been previously suggested with other di- and tri-valent cations [9,30].

In all three systems, the formation of mono and/or binuclear hydroxophosphonate complexes indicates the easy hydrolysis of these metal ions.

Standard deviations on stability constants are quite high. Such gaps are however in no way reflective of data treatment, regarding the high stability of complexes.

Comparison of our constant values with those in the literature was difficult as the latter were very scarce and experimental procedures for constant determination were often either not identical to ours or not specified. Nevertheless, for the Cr/HEDP system, our values for MHY^0 and MH_2Y^+ conditional constants ($\log K_1^* = 13.9$; $\log K_2^* = 11.0$) are close to those of Yamashita et al. [12] ($\log K_1^* = 14.6$; $\log K_2^* = 10.4$ where $K_j^* = [\text{M}(\text{H}_j\text{Y})]/[\text{M}][\text{H}_j\text{Y}]$). For Al and Fe/HEDP systems, the overall constant values of Kabachnik et al. [9] and Vasil'ev et al. [13] differ somewhat for several complexed species.

Speciation diagrams were drawn from the metal complex formation and protonation constant values for a 1/2 cation/ligand molar ratio for the pH range 5–9 of fresh waters (Fig. 2). This confirms that even at the acidic end of this pH range, each metal ion is present as a complex. Unlike ternary complexes, free metal cations and hydroxide species are negligible in solution, over the pH range (2–10) that was studied. Species such as M(OH)_4^- are present only at $\text{pH} \geq 12$. No polynuclear hydroxide species was observed in the pH range studied. Below pH 7, interfering protonated and unprotonated complexes have the highest constant values for Al(III) and Fe(III); for $\text{pH} \geq 7$ the predominant species are Al(OH)Y^{2-} and Fe(OH)Y^{2-} with stability constant values lower than those of CrY_2^{5-} .

Acid–base titration data for Al and Cr/HEDP systems with a 1/1 ratio could not be computed by BEST. Interference might occur from insoluble species slowly formed and dissolved during titration. Unfortunately, BEST cannot calculate formation constants when insoluble complexes predominate in solution because it does not take into account solubility products.

When the metal concentration increased (solution containing an excess of cation), insoluble hydroxide complexes such as $\text{Fe(OH)}_{3(s)}$ were formed at $\text{pH} \geq 8$ for the Fe/HEDP 1/1 system, but this was not observed for the other two systems. Tchoubar and Bottero [23] studied the hydrolysis and condensation behaviour of Al and Fe oxy-hydroxides $\text{M}_x\text{O}_y(\text{OH})_z^{(3x-2y-z)}$. They observed the formation of polynuclear hydroxide

$$\beta_{ijk} = \frac{[M_i (OH)_j L_k]}{[M]^i [L]^k} \quad K_{ijk} = \frac{[M_i (OH)_j L_k] [H]}{[M_i (OH)_{j-1} L_k]}$$

metallic species at $\text{pH} \geq 4$. In the presence of organic ligands, they reported the formation of heterogeneous aggregates where metals were coordinated by two or three ligands rather than hydroxide ions. Moreover, Spiccia et al. [31,32] and Avena et al. [22] noted the predominance of insoluble mono- and poly-nuclear Cr(III) species in fresh and aged solutions, respectively.

This suggests that such species interfere in solutions containing high concentrations of metal, and that the titration time and age of solutions can lead to the evolution of species. No attempt was made to identify them.

3.3. Complexing properties of ATMP (H_6X)

No titration data could be obtained for the Al/ATMP system due to immediate precipitation of an insoluble complex. This precipitate was therefore characterized by the SEM/EDAX technique at the three different cation/ligand molar ratios: 1/1, 1/2 and 2/1. From the phosphorus/aluminium P/Al = 3.1 ± 0.2 atomic ratio, we can create the simplified formula AlH_3X (without any indication of water molecules). NaOH titration showed the solubilization of this species at $\text{pH} \geq 7$. The titration of the 1/5 ratio solution also led to the formation of an insoluble complex.

Nikitina et al. [10] studied this complexation between ATMP and Al(III) using IR spectroscopy. Employing high metal concentrations (0.1 mol l^{-1}), they observed the formation of both sparingly ($Al_3H_3X_2$ and Al_2X) and readily soluble ($AlHX^{2-}$ and AlX^{3-}) compounds, but gave no stability constants. We can assume that other complexes interfere when metal concentrations are lower, particularly the AlH_3X insoluble species. The kinetic study of precipitate solubilization showed that equilibrium was reached after 33 days and at a pH of 3.67 ± 0.03 . The solubility of the AlH_3X complex, determined by AA, is $s = (4.8 \pm 0.5) \times 10^{-6} \text{ mol l}^{-1}$. The apparent solubility product is directly dependent on the pH value; with $K_s = [Al^{3+}][X^{6-}][H^+]^3 = s^2[H^+]^3$, we calculated $\text{p}K_s = 21.6 \pm 0.1$.

pH -titration curves for the Cr/ATMP and Fe/ATMP systems at 1/2 ratio are presented in Fig. 3. For $\text{pH} < 7.5$, ATMP complexing behaviour towards Cr(III) and Fe(III) is similar and for $\text{pH} \geq 7.5$, Cr(III) is the most complexed. As has been observed in the Al/ATMP system, the formation of insoluble complexes perturbed the Cr/ATMP study for the 1/2 and 1/1 ratios. During titration, the solution became cloudy in the pH range 4–9 and this induced irregularities on the curve. Morozova et al. [11] studied the complexation properties of ATMP with transition metals

and Cr(III). They also observed the formation of a precipitate during titration with a 1/1 ratio. The precipitate in solutions with cation/ligand ratios of 1/1, 1/2 and 2/1 was the same. It was isolated and identified by SEM/EDAX from the P/Cr = 1.6 ± 0.1 atomic ratio as Cr_2X (without indicating the number of water molecules). Unlike the Al/ATMP system, the solubility of Cr_2X species could not be determined because the results in five replicates were not reproducible.

Acid–base titration data for the 1/5 ratio could be analysed using BEST.

Calculated overall and stepwise metal complex formation constants for the Cr/ATMP 1/5 and Fe/ATMP 1/2 systems (Table 4) are very similar. The large decrease in stability of MHX^{2-} species might be caused by the broken bond between the metal and the ATMP amino group. The first protonation of these complexes should, therefore, occur on the nitrogen atom and the following ones on oxygen phosphonate groups as in the case of the free ligand. This phenomenon was described by Bollinger and Roundhill [33] for Fe(III) complexes with aminodiphosphonic acids, and by Nikitina et al. [10] and Sawada et al. [34,35] for various trivalent cation complexes with ATMP. A crystallographic study by Rajendram and Hoggard [36] showed that the coordination of monoprotonated aminophosphonates with Cr(III) occurred on the oxygen atom of phosphonate groups as it probably did for our MHX^{2-} species.

Fig. 3. Titration curves of free ATMP and metal ion/ATMP complex at a 1/2 M/L molar ratio by NaOH (0.1 mol l^{-1}). $[\text{ATMP}] = 0.002 \text{ mol l}^{-1}$, $I = 0.1 \text{ mol l}^{-1}$ (KNO_3), $t = 25^\circ\text{C}$ (a) free ATMP; (b) Fe(III)/ATMP; (c) Cr(III)/ATMP.

$$\beta_{ijk} = [\text{M}_i\text{H}_j\text{L}_k]/[\text{M}]^i[\text{H}]^j[\text{L}]^k \quad K_{ijk} = [\text{M}_i\text{H}_j\text{L}_k]/[\text{M}_i\text{H}_{j-1}\text{L}_k][\text{H}]$$

Literature concerning Cr/ATMP complexes gives only qualitative data. No complex formation constant values could be found. Nevertheless, constant values determined here seem to be reliable as a small standard deviation value was obtained between calculated and experimental pH-metric curves (0.03 pH unit).

The study of the Fe/ATMP system was somewhat difficult because of the formation of $\text{Fe}(\text{OH})_{3(s)}$ during titration. Indeed, the speciation diagram shows that $\text{Fe}(\text{OH})_{3(s)}$ becomes the major species at $\text{pH} \geq 5.2$. Titration data were only exploited at $\text{pH} \leq 6.5$ because above this, Fe(III) is totally complexed with hydroxide ligand as $\text{Fe}(\text{OH})_{3(s)}$. Vuceta and Morgan [37] showed that the degree of $\text{Fe}(\text{OH})_{3(s)}$ precipitation was only slightly influenced by complexing agents. Although our calculated and experimental data are very similar (without taking into account the solubility quotient Q_s value (see Table 2) for the $\text{Fe}(\text{OH})_3$ precipitate), stability constants for this system have to be used with caution. Other reported constant values [8] differ from ours. Moreover, at lower metal and ligand concentrations, the present author obtained a colloidal precipitate, which slowly dissolved above pH 5. It would therefore be necessary to precisely characterize the interfering species in this solution in order to verify our results.

Our calculated constants are in agreement with the complexing behaviour of ATMP towards

Fig. 4. Distribution curves of Fe(III) and Cr(III)/ATMP (X^{6-}) complexed species, as percentage of total metal vs. pH.

these two metallic cations as it appears on the species distribution curves (Fig. 4). Below pH 7, the interfering complexed species are FeH_2X^- , $FeHX^{2-}$ and FeX^{3-} and CrH_3X^0 , CrH_2X^- , $CrHX^{2-}$ and CrX^{3-} with similar overall constant values. Above pH 7, the major species is the $Fe(OH)_{3(s)}$ precipitate for the Fe/ATMP system, and the ATMP ligand is in its free form. The gap observed between the pH-metric curves for the free ligand and the ligand in the presence of Fe(III) (Fig. 3) corresponds to the decrease in the hydroxide ion concentration in solution due to the formation of $Fe(OH)_{3(s)}$ species. Concerning the

Cr/ATMP system, the CrX^{3-} and CrX_2^{9-} species predominate at basic pH values.

Quantities of hydroxide species, ternary complexes and free metals were negligible for the Cr/ATMP 1/5 solution, as was the Cr_2X^0 soluble species (which precipitates at higher metal concentrations). Ternary complexes and free metals did not appear in the Fe/ATMP 1/2 solution.

4. Conclusion

HEDP and ATMP form strong complexes with the three trivalent cations Al(III), Cr(III) and

Fe(III) studied. These phosphonates could therefore have a major impact on metal speciation in fresh waters or in waste water treatment plants.

With an excess of ligand, there is a predominance of anionic complexed species in the pH range of non acidic natural waters, and therefore little chance that such species can be adsorbed electrostatically onto natural solids. With metal and phosphonate concentrations close to those encountered in natural waters, these metallic complexes would potentially persist in the liquid phase and could increase water contamination.

With an excess of metallic cation, weakly soluble complexes of HEDP seem to form (even though they were not in evidence here), insoluble complexed metals appear in the presence of ATMP as $\text{AlH}_3\text{X}_{(s)}$ and $\text{Cr}_2\text{X}_{(s)}$. Concerning Fe(III), $\text{Fe}(\text{OH})_{3(s)}$ precipitate predominates and its formation is independent of phosphonate concentration. A recent study on the behaviour of phosphonates during wastewater treatment [2] has shown that their elimination rate can reach 80%. This would be due to their adsorption onto or co-precipitation with sludge containing high levels of precipitated iron or aluminium oxides. These phosphonates would not therefore perturb the coagulation/flocculation step when metals are at quite high concentrations.

The presence of insoluble species makes computation of data difficult because only formation constants relative to soluble complexes can be calculated. At present, no computer program amongst those commonly used for analysing the data from acid–base titration can take into account solubility products. This is due to the lack of chemical equilibrium during precipitation.

Our experimental methods did not provide precise information on the coordination and structure of metallic complexes. A study of these complexes using ^{31}P NMR is in progress. Other species that exist in fresh waters, such as carbonates, calcium and magnesium ions, which could interfere in the complexation phenomena between phosphonates and metal ions will also be studied.

Complexation of trivalent cations (Al(III), Cr(III), Fe(III)) with two phosphonic acids in the pH range of fresh waters

Stella Lacour, Véronique Deluchat, Jean-Claude Bollinger *, Bernard Serpaud

Laboratoire de Chimie Analytique, Sciences de l'Eau et de l'Environnement, Faculté des Sciences, 123 avenue Albert-Thomas, 87060 Limoges, France

Received 3 June 1997; received in revised form 3 October 1997; accepted 6 October 1997

Abstract

The complex formation constants of two phosphonic acids, HEDP and ATMP, with three trivalent metallic cations, Al(III), Cr(III) and Fe(III), have been determined by acid–base titration at 25°C and constant ionic strength (0.1 mol l⁻¹, KNO₃), using Martell and Motekaitis' computer programs. Species distribution curves showed that all three cations are in complex form in the pH range of fresh waters (5–9). The study of different cation/ligand ratios proved that both ligands mainly form anionic soluble complexes for systems having an excess of ligand—as protonated and unprotonated forms and especially ternary complexes with HEDP. For higher metal concentrations (excess of cation), weakly soluble species of HEDP and ATMP were formed with Al(III) and Cr(III). Two insoluble complexes with ATMP have been identified by SEM/EDAX as AlH₃X_(s) and Cr₂X_(s). Regarding Fe(III) species, Fe(OH)_{3(s)} precipitate seems to predominate in solution. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Complexation; Phosphonic acids; Speciation; Trivalent cations

1. Introduction

Due to a growing increase in public environmental concern, the use of sodium tripolyphosphate has been banned in domestic detergents. In recent years phosphonate derivatives have been used in washing powder formulations. However, some concerns still exist about their behaviour when released in lakes or rivers, as they can complex with toxic elements previously immobilized in sediments. We have studied two com-

monly used phosphonic acids, 1-hydroxyethane-1,1'-diphosphonic acid (HEDP) and aminotris(methylenephosphonic acid) (ATMP) (Scheme 1), whose acid/base and complexation behaviours with divalent cations have recently been characterized [1].

After domestic use, these phosphonic acids are released along with the rest of the domestic waste waters. In municipal waste treatment plants, a phosphorus elimination step can reduce phosphonate levels by 80% [2]. This step is however costly and is not always included in the treatment process. Phosphonates can enter aquatic ecosystems, and later flow through water potabilization plants

Flow injection spectrophotometric determination of trace amounts of selenium

M.F. Mousavi *, A.R. Ghiasvand, A.R. Jahanshahi

Department of Chemistry, Tarbiat Modarres University, P.O. Box 14155-4838, Tehran, Iran

Received 11 December 1996; received in revised form 8 October 1997; accepted 10 October 1997

Abstract

A simple, rapid and sensitive flow injection spectrophotometric method for determination of selenium ($0.005\text{--}1.5\ \mu\text{g ml}^{-1}$) is described. The method is based on the catalytic effect of Se(IV) on the reduction reaction of thionine (TN) with sulphide ion, monitored spectrophotometrically at 598 nm. The detection limit is $5\ \text{ng ml}^{-1}$ the relative standard deviation for eight replicate measurements is 1.1% for $1\ \mu\text{g ml}^{-1}$ of selenium. The sampling rate is 25–30 samples h^{-1} . The procedure was applied successfully to the determination of selenium in real samples. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

There is a rather narrow range of concentration levels for several essential elements such as Se in most organisms. Low concentrations result in different abnormalities because of pertinent specific biochemical changes. High concentrations result in toxicity [1].

Selenium is used in photocells, metal rectifiers, in colouring glass a red or reddish tint and in the production of flame-proof insulated electric wires [2]. Selenium compounds are also used in lubricating oils as oxidation inhibitors, in the improvement of the detergent properties of lubricating oils, and in shampoo (small amounts) as a dan-

druff inhibitor. Adding selenium to certain stainless steels is believed to improve their machining properties [3].

There is an increasing demand for sensitive determination methods for selenium in different samples. Many extraction-spectrophotometric [4,5], catalytic-spectrophotometric [6,7], fluorimetric [8], neutron activation [9,10], ICP-AE [11], voltammetric [12], chromatographic [13], hydride generation [14], ICP-MS [15], X-ray fluorescence spectrometric [16], electrothermal [17], and flow injection analysis [18,19] methods that have been developed for determination of selenium. Some of these methods give good selectivity and sensitivity, but require very expensive reagents and are time consuming and complicated procedures.

This paper describes a simple, sensitive and rapid method for the determination of Se(IV)

based on its catalytic effect on the reduction reaction of thionine (TN) with sulphide ion.

2. Experimental

2.1. Reagents

All chemicals used were of the highest purity available and used without any further purification. Doubly distilled water was used throughout.

Sulphide stock standard solution ($1000 \mu\text{g ml}^{-1}$) was prepared by dissolving 0.7500 g of $\text{Na}_2\text{S}\cdot x\text{H}_2\text{O}$ ($7 < x < 9$, Merck) in water and diluting to 100 ml in a calibrated volumetric flask. This solution was prepared daily and standardized iodometrically [20]. Working solutions were prepared by appropriate dilution of the stock solution with water.

Selenium stock solution ($1000 \mu\text{g ml}^{-1}$) was prepared by dissolving 0.1405 g of SeO_2 (Merck) in water and diluting to 100 ml in a volumetric flask. The solution was standardized iodometrically [20].

A $200 \mu\text{g ml}^{-1}$ stock solution of TN was prepared by dissolving an appropriate amount of dyestuff (Merck) in water this was kept refrigerated.

2.2. Apparatus

The flow injection configuration that was employed is outlined in Fig. 1. Silicon tubing of 0.5 and

1 mm i.d. was used for the manifold and mixing coil, tees were made of glass. A twelve-channel peristaltic pump (PLG, Desaga) was used for propelling the solutions. Samples were injected using a rotating Rheodyne valve (VALCO-C8W) with a sample loop of 110 μl . A double beam UV-Vis spectrophotometer (Shimadzu, 2100) with a thermostated flow cell was used to record the absorbance of TN at 598 nm. Except for the sulphide solution, all other reagents were placed in a 37°C thermostated water bath.

The sulphide solution was kept at 0°C, to ensure solution stability during the course of the reaction.

The reaction coil was placed in a 37°C water bath. The flow cell was also maintained at 37°C by circulation of the thermostated water. A thermostated bath (Shimadzu, TB-85) and a water bath (GFL-D 3600) were used. Measurement of pH was made using a Metrohm (691) pH-meter.

2.3. Recommended procedure

A $54 \mu\text{g ml}^{-1}$ TN solution (containing 20% citrate-phosphate buffer [21], pH 7.2) and a $90 \mu\text{g ml}^{-1}$ sulphide solution were each pumped at a flow rate of 0.56 ml min^{-1} . An 110 μl sample volume containing selenium ($0.005\text{--}1.5 \mu\text{g ml}^{-1}$) was injected into the carrier which was also pumped at a flow rate of 0.56 ml min^{-1} . The absorbance of the mixture was measured and recorded at 598 nm.

Fig. 2. Absorbance spectra of thionine ($18 \mu\text{g ml}^{-1}$) in the presence of sodium sulphide ($30 \mu\text{g ml}^{-1}$) at pH 7.2, time intervals 70 s, $T = 37^\circ\text{C}$, (a) in the absence of Se(IV), (b) in the presence of $0.33 \mu\text{g ml}^{-1}$ of Se(IV).

Under optimum conditions the peak height was proportional to selenium concentration.

3. Results and discussion

3.1. Batchwise studies

The reaction for the reduction of TN is as follows [22]:

This reaction proceeds slowly without a catalyst (see Fig. 2). However, trace amounts of Se(IV) catalyzes the reaction so that it proceeds much faster (Fig. 2 curve b). The accelerating effect of Se(IV) has been explained [23] by the formation of $[\text{S}\dots\text{Se}]^{2-}$, after the initial reduction of Se(IV) to its elemental state [24]. This compound can reduce the dye molecule faster than the sulphide ion and then reform Se(IV). The reaction can be

monitored spectrophotometrically, because the reduced TN (leucothionine) is colorless.

3.2. Effect of chemical reaction variables

3.2.1. Effect of pH

The effect of pH on peak height was studied in the range of 2.2–10.3 using a mixture of citrate and phosphate buffers, and NaOH. The reaction exhibits its largest peak height at about pH 7.2. This was used as the optimum pH for further studies.

3.2.2. Effects of dye and sulphide concentrations

The influence of thionine and sulphide concentrations on peak height was investigated (Fig. 3). The concentrations of thionine and sulphide were adjusted in the range 15–72 and 30–126 $\mu\text{g ml}^{-1}$ respectively. An increase in peak height was observed when the concentration of dye was varied from 15–54 $\mu\text{g ml}^{-1}$, at higher dye concentration a slight change in response was observed. Sulphide concentrations higher than 90 $\mu\text{g ml}^{-1}$ causes a decrease in the response peak. A concentration of 54 and 90 $\mu\text{g ml}^{-1}$ was selected for dye and sulfide respectively.

Fig. 3. Effects of thionine and sulphide on peak height. Conditions, Se(IV), 1 $\mu\text{g ml}^{-1}$; pH, 7.2; T, 25°C; sample loop volume, 110 μl ; reaction coil length, 1.5 m; flow rate, 0.56 ml min^{-1} ; thionine, 30 $\mu\text{g ml}^{-1}$ for sulphide curve; sulphide, 90 $\mu\text{g ml}^{-1}$, for thionine curve.

Fig. 4. Effects of the reaction coil length and flow rate on the peak height. Conditions: Se(IV), 1 $\mu\text{g ml}^{-1}$; pH, 7.2; T, 25°C; sample loop volume, 110 μl ; thionine, 54 $\mu\text{g ml}^{-1}$; sulphide, 90 $\mu\text{g ml}^{-1}$; flow rate 0.56 ml min^{-1} , for curve (a); reaction coil length, 5 m for curve (b).

3.2.3. Effect of temperature and ionic strength

The effect of temperature on peak height was studied. A continuous increase in the response peak was observed when the temperature was varied from 20–39°C. A temperature of 37°C was selected for further studies.

The effect of ionic strength on the response was studied using NaNO_3 . Up to a value of about 0.6 M of NaNO_3 , change in ionic strength had no considerable effect on peak height. A further increase in ionic strength caused a slight increase in peak height.

3.3. Effect of flow injection variables

In the application of any flow injection method, the change in absorbance depends on the residence time of the sample zone in the system i.e. on the flow rate and the reaction coil length. The effect of the flow rate on the peak height was studied over a range 0.1–0.9 ml min^{-1} in each stream (Fig. 4, curve a). Lower flow rates produced higher peaks, but flow rates lower than 0.56 ml min^{-1} resulted in peak broadening leading to lower sample output. High flow rates (higher than

0.8 ml min⁻¹) had two drastic effects, decreasing sensitivity by decreasing peak height and second, the driving force of each peristaltic pump roller was seen as noise (small peak) on the baseline. The latter effect decreases reproducibility and makes the detection limit of the system worse, hence a flow rate of 0.56 ml min⁻¹ was selected.

Reaction coil lengths of 1–9 m were tested (Fig. 4, curve b). The peaks became higher as the length of coil increased from 1 to 7 m, but a further increase did not result in any significant change in sensitivity lengths of exceeding 5 m caused peak broadening, a reaction coil length of 5 m was chosen.

To obtain the best overall response the effect of sample volume was also investigated in the range 20–200 µl (Fig. 5). The peak height increased up to a sample volume of 110 µl and then remained more or less constant. A sample volume of 110 µl was chosen.

3.4. Calibration curve, reproducibility and detection limit

Under optimum conditions described above, a selenium concentration range of 0.005–1.5 µg ml⁻¹ produced a quite linear calibration curve ($r = 0.9992$, $n = 14$).

Fig. 5. Effect of sample volume on peak height. Conditions, Se(IV), 1 µg ml⁻¹; pH, 7.2; T, 25°C; thionine, 54 µg ml⁻¹; sulphide, 90 µg ml⁻¹; reaction coil length, 5 m; flow rate 0.56 ml min⁻¹.

Table 1

Tolerance limits of diverse ions on the determination of 1 µg ml⁻¹ selenium at optimum conditions

Ion	Tolerated ratio of foreign ion to Se(IV)
K ⁺ , Na ⁺ , NO ₃ ⁻ , Cl ⁻	0.1M
HPO ₄ ²⁻ , CH ₃ COO ⁻ , I ⁻	2000 ^a
Ca(II), CO ₃ ⁻	500
Ag(I), Pb(II), Cu(II), Hg(II), Fe(III)	200 ^b
Zn(II), HCO ₃ ⁻ , tartarate	200
SO ₃ ²⁻	150 ^c
Cr(III), Br ⁻ , H ₂ PO ₄ ⁻ , OCN ⁻ , N ₃ ⁻ , B ₄ O ₇ ²⁻	100
Mg(II), NH ₄ ⁺ , SO ₃ ²⁻ , BrO ₃ ⁻	40
Ni(II), IO ₃ ⁻	10
Mn(II), Cd(II), Co(II), S ₄ O ₆ ²⁻	5

^a Above of which was not tested.

^b After removal with cation exchange resin.

^c After masking with formaldehyde (2×10^{-5} M).

Using a signal to noise ratio of three, as a limiting requirement, the experimental detection limit was found to be 0.005 µg ml⁻¹.

For eight replicate measurements of standard selenium solution (1 µg ml⁻¹), the relative standard deviation was 1.1%. The sampling rate was 25–30 samples h⁻¹.

3.5. Effect of foreign ions

The effects of various cations and anions on the determination of 1 µg ml⁻¹ of Se(IV) was studied. The results are summarized in Table 1. The tolerance limit was taken as the concentration of added ion causing less than 3% relative error.

Almost all anions (with respect of SO₃²⁻) and many cations used have no effect on the determination of selenium. However, as expected the presence of cations which can form insoluble precipitates with the sulphide ion cause interference.

3.5.1. Removal of interfering ions

Cations such as Ag(I), Pb(II), Cu(II), Hg(II), Fe(III), interfere with the determination of the Se(IV) ion. These cations can be removed using a cation exchanger resin (Aldrich, strongly acidic form) [25]. A series of 10 ml solutions containing 7.5 µg of Se(IV) plus 1500 µg of the desired cation

Table 2
Determination of selenium in Kjeldahl tablets

Sample taken (ml)	Se ($\mu\text{g ml}^{-1}$)		Recovery (%)
	Contained	Found	
0.5	0.100	0.976	97.6
1.0	0.200	0.207	103.5
1.5	0.300	0.295	98.3
2.0	0.400	0.418	104.5
2.0	0.400	0.410	102.5

were prepared. Each solution (10 ml) was passed through a 20 cm column containing the cation exchanger resin. The column was washed with distilled deionized water (four times, with 10 ml of water) and the eluent was transferred to a 50 ml volumetric flask. The solution was diluted to the mark with distilled deionized water and the amount of Se(IV) was determined using the recommended procedure.

Among the anions studied, the presence of sulphite ion causes serious interference. The interfering effect of this anion was removed using formaldehyde [25].

3.6. Application

To evaluate the analytical applicability of this method, it was applied to the determination of selenium in Kjeldahl tablets and a health-care product (a shampoo for the treatment of dandruff) respectively. One tablet (1.1151 g) containing 0.05 g of selenium was dissolved in an appropriate volume of 4 M HCl solution and was then boiled for 15 min. This stage converts Se(VI)

completely to Se(IV) [26]. The solution was neutralized by the addition of 2 M NaOH solution and diluted with water to 100 ml in a volumetric flask. This solution (2 ml) was diluted to 100 ml with water. During the final stage different volumes of the resulting solution were transferred to a 50 ml volumetric flask and was determined using the recommended procedure after diluting to volume with water. The results are given in Table 2.

A shampoo sample dissolution was carried out using the procedure described by Afkhami et al. [27]. Approximately 1 g of the sample was weighted into a 100 ml Kjeldahl flask. Concentrated sulphuric acid (1 ml) was added and the mixture was heated to fuming for 15 min. The solution was allowed to cool and 5 ml of 30% w/v hydrogen peroxide was added. The mixture was boiled vigorously to eliminate excess hydrogen peroxide, the flask was then allowed to cool. The mixture was diluted to 1.0 l with doubly distilled water. A 1 ml volume of this solution was taken for the determination of selenium(IV) as in the recommended procedure. The results are given in Table 3.

4. Conclusion

The method adopted was significant with respect to the development of a simple, precise and rapid flow injection method for the analysis of selenium in real samples. The high sensitivity, selectivity, broad dynamic range of selenium determination and mild pH conditions required are just some of the advantages of this method. The

Orthogonal array design (OAD) for the optimization of mercury extraction from soils by dilute acid with microwave heating

Wei Gu, Chao Yan Zhou, Ming Keong Wong *, Leong Ming Gan

Department of Chemistry, National University of Singapore, Lower Kent Ridge Road, Singapore 119260, Singapore

Received 8 July 1997; received in revised form 9 October 1997; accepted 10 October 1997

Abstract

The use of dilute acid for mercury extraction from geological samples with microwave assisted heating was investigated. An orthogonal array design $OA_{16}(4^1 \times 2^{12})$ was applied to select the optimum conditions. The effects of the concentration of HNO_3 , the additions of HCl and H_2SO_4 , the extraction time and their interactions were evaluated by the mixed-level orthogonal array design (OAD). The results indicated that the addition of small amount of HCl would improve significantly the extraction of mercury from soil matrices. From the study, it is seen that the mercury in the soil matrices could be extracted completely by 14% (v/v) HNO_3 with small quantity of HCl . The effects of the pressure within the digestion vessel and the sample mass were studied under the optimum conditions derived from the OAD. The extraction methods with optimum conditions were evaluated by determining mercury in NIST SRM 1645 River Sediment, NIES CRM No. 2 Pond Sediment and NRCC BCSS-1 Marine Sediment. Recoveries of 78–109% were achieved. Good mean recoveries of 95–98% were also obtained from real soil samples spiked with different species of mercury. © 1998 Elsevier Science B.V. Keywords: Dilute acid; Mercury; Microwave digestion; Soil; Orthogonal array design

1. Introduction

Mercury is a toxic element sparsely distributed in the lithosphere. Its concentration has been estimated to be 0.08–0.4 mg kg^{-1} in igneous and sediment or soil samples [1]. Industrial and other human activities have resulted in increased localized concentration of Hg. Since soils and sediments are the principal sinks of most of these

localized discharges [2], they are good indicators of the extent of environmental contamination [3].

The most widely used procedure for the determination of Hg in geological samples is digestion by mineral acids and then the Hg in solution is measured by cold vapor atomic absorption spectrometry (CVAAS). The technique of CVAAS is highly sensitive for mercury with a method detection limit of 0.2 $\mu g l^{-1}$ and has gained generalized acceptance for routine mercury analysis. However, there are a variety of methods for the chem-

* Corresponding author.

ical pretreatment of the sample. The wet ashing method is recommended for the mercury determination by CVAAS methods. For most wet digestion with open vessel, different mixtures of acids and chemicals are used to increase the oxidizing power and the boiling temperature of the digestion medium [3–6]. Generally, several hours are needed for completely extracting the mercury from sample matrices for most of these methods.

In the past few years, closed vessel microwave dissolution procedures have been developed to reduce sample preparation/pretreatment times from hours to minutes and to prevent the loss of the volatile analytes [7–10]. Pressure dissolution procedures have been recommended for the determination of mercury in different types of samples using different acid mixtures [11,12]. Most of these methods also use the concentrated acid mixtures with strong oxidizing nature, such as nitric-sulfuric acid mixtures [11] and concentrated nitric hydrochloric acid mixtures [10,12]. In the closed vessel digestion, the oxidizing power of the acids is increased with increasing digestion temperature and the loss of the volatile component is limited.

The optimum conditions of extraction were evaluated by a chemometric method—orthogonal array design (OAD). In OAD [20], orthogonal arrays are used to assign factors to a series of experiment combination, the results of which can then be analyzed by analysis of variance (ANOVA) and other common mathematical methods. The main effects of the variables and interaction effects between variables can be extracted separately. This statistical method can be used to optimize experimental conditions and reduce the number of experiments [8,18,21]. This method was introduced into the area of analytical chemistry in 1989 by Oles and Yankovich [22], who used OAD to optimize operation conditions of gas chromatographic analysis. Since then, OAD was applied in gas chromatography [23], liquid chromatography [24] and microwave digestion of biological samples [25].

It was reported that the poor recoveries of Hg were obtained when nitric acid alone was used to extract mercury in soil samples [13]. However,

dilute nitric acid has been successfully used to extract mercury from traditional Chinese medicines with heating [17]. In this work, the OAD was used to investigate the mercury extraction from soil samples by dilute acid in a closed vessel digestion system. The effectiveness of the various extraction methods was compared using the National Institute for Environmental Studies (NIES) Certified Reference Materials (CEM) No. 2 Pond Sediment. Other standard reference materials were also used to verify the selected extraction conditions.

2. Experimental

2.1. Instrumental

A flow injection analysis system (Perkin-Elmer FIAS-200) interfaced to an atomic absorption spectrometer (Perkin-Elmer Model 4100ZL) was used. This system consists of two peristaltic pumps, Tygon pump tubing, 1.0 mm-i.d. Teflon manifold tubing, a gas-liquid separator and a quartz T-cell with resistive furnace heating. Pump action, injection time, quartz cell temperature and all data processing were controlled through Perkin-Elmer FIAS200 software on a personal computer. Specific instrumental parameters for mercury analysis in this system are given in Table 1.

Soil samples were digested in the MDS-2000 Microwave Sample Preparation System with 630

Table 1

Cell temperature	150°C
Sample Loop	500 µl

W power (CEM, Matthews, NC). An internal pressure and temperature control system allowed for programming to control pressure from 0 to 1380 kPa (200 psi) and temperature up to 200°C in five separate stages. The system can digest 12 samples using low pressure screw-top polytetrafluoroethylene (PTFE) digestion vessels.

2.2. Reagents

Deionized distilled water was used in all final washings and in the dilution of all chemicals. Analytical grade concentrated nitric acid (65% w/v), sulfuric acid (98% w/v) and hydrochloric acid (37% w/v) (Merck, Germany) were used throughout the study. Mercury standards were prepared by appropriately diluting a 1000 mg/l mercury nitrate aqueous standard solution (BDH, UK). Sodium tetrahydroborate (NaBH_4) (Fluke, Buchs, Switzerland) reducing agent (0.25% w/v) in 0.05% (w/v) sodium hydroxide (ARISTA grade, BDH, UK) was prepared fresh daily by dissolving the appropriate mass of NaBH_4 and NaOH in deionized distilled water. The solution was then filtered with 0.45 μm Millipore filter. Oxidative stabilizing agent was prepared fresh by dissolving 5 g of analytical-grade potassium permanganate (AJAX, Australia) in 100 ml deionized distilled water.

2.3. Procedure

2.3.1. Drying of sample

Separate real world soil samples obtained from the campus (Singapore) and standard references were dried in the oven at 110°C for 4 h to obtain mass loss data. Undried samples were analyzed to avoid the effects of mercury loss. The results for the undried samples were multiplied by the mean undried to dried sample mass ratio obtained from the separate drying experiment. All reported values are based on the dried sample.

2.3.2. Preparation of sample spiking

HgO/HgS/HgAc of 0.05 g were weighed and mixed well with 100 g soil. The mixtures were finely ground in an agate mortar. Then 0.10 g mixtures were further mixed with another 100 g

soil. The finely ground final mixtures were kept in a desiccator.

2.3.3. Microwave digestion procedure

In the optimization procedure, the digestion parameters of 14 ml 2–20% (v/v) HNO_3 , 1 ml conc. HCl, 1 ml conc. H_2SO_4 and extraction time were changed according to the arrangement of orthogonal array design (Table 2). The digestion was carried out under pressure setting 1035 kPa (150 psi). The optimized parameters were then used for the analysis of 'application' samples.

Approximately 0.25 g samples and blanks were digested using the different parameter settings. After the digestion, the vessels were cooled in the air until the pressure in the vessels was reduced to below 345 kPa (50 psi). The vessels were opened and the digest was filtered and then diluted with deionized distilled water to 50.0 ml in a volumetric flask.

2.4. Analysis

Ten millilitres of digested solution (and blanks) were transferred to test tubes (used for auto sampler AS-90) and 0.2 ml of 5% (w/v) potassium permanganate solution was added as an oxidative stabilizing agent before analysis. The mixtures were introduced to the FIA system by AS-90 auto sampler. A continuously flowing HCl acid carrier stream transported the sample from the valve to the mixing manifold, where it was merged with NaBH_4 reductant. The reaction mixture was then purged with argon gas stream and transported to the gas–liquid separator, where the cold vapor mercury was swept to the absorption cell, and the peak area signal was measured. Mercury concentration in the sample solution was determined by direct comparison to a calibration curve prepared using solutions from 0.5 to 20 $\mu\text{g l}^{-1}$ that were matched in acid and stabilizer concentration with that of the sample.

2.5. Assignment of experiments

In the closed vessel microwave assisted extraction system, the extraction is carried out under high pressure and high temperature. The extrac-

tion efficiency is increased dramatically with rising temperature and pressure. The relation between pressure and temperature in the extraction vessel is affected by the sample matrix, the composition and the concentration of acid mixture used. When using volatile acid such as HNO_3 for extraction, the pressure control is critical. When the extraction is carried out with less volatile acids such as H_2SO_4 or $HClO_4$ [15], the temperature control is important. From the literature and our experience, the following six variables were chosen for evaluation in this study. They are: the concentration of HNO_3 (variable i); the addition of H_2SO_4 (variable ii); the addition of HCl (variable iii); the extraction time (variable iv); the mass of sample (variable v); and the pressure setting (variable vi). The first four variables were optimized by a mixed-level OAD. The mass of sample and the pressure setting were studied separately. In the mixed-level OAD, the concentration of HNO_3 (variable I) was evaluated in four-level, the additions of H_2SO_4 (variable ii) and HCl (variable iii) and the extraction time were evaluated in two-level. Since there were one four-

level and three two-level variables to be evaluated, the $OA_{16}(4^1 \times 2^{12})$ matrix was used to assign the variables considered. After a randomization process, the variable assignment and level setting in the mixed-level orthogonal array design were listed in Table 2. The randomization process for the level setting was to reduce the error from personal inclination on level assignment. In this paper, the interactions among the variables $A \times B$, $A \times C$, $A \times D$, $B \times C$, and $C \times D$ were considered. The interaction A and B ($A \times B$) was obtained by the sum of $(A \times B)_1$, $(A \times B)_2$ and $(A \times B)_3$. The other interactions $A \times C$ and $A \times D$ were similarly obtained.

The variable assignment, the level setting and experimental arrangement in the mixed-level orthogonal array design are shown in Table 3. A total of 16 experiments are listed in the column of trial. The numbers 1, 2, 3 and 4 under the various column number in the table represent the level setting in the experiment. The K_m ($m = 1-4$) values in the last four rows are the sum of response (R) with variable m . K_m is used to estimate the effect of the variable.

^c $P = 0.05$ (95% confidence level) $F_{(1,6)} = 5.99$.

^d $P = 0.25$ (75% confidence level) $F_{(3,6)} = 1.78$.

For evaluating the effects of the variables at different levels from 16 experimental trials, the concentration of mercury in the NIES CRM No. 2 Pond Sediment was used as response function. The mercury was analyzed by CVAAS. The output response (*R*) in our work is defined as:

$R = \text{accuracy of mercury analysis (\%)} = \frac{\text{mercury content from experiment}}{\text{certified value given by CRM No. 2}} \times 100\%$

The optimization was performed under the pressure setting at 1035 kPa (150 psi) and the sample mass at about 0.25 g. The effects of the pressure setting and the mass of sample were then studied separately.

3. Results and discussion

After implementing the 16 experimental trials

which were designed according to the $OA_{16}(4^1 \times 2^{12})$ matrix, the corresponding results of output response for each experimental trial were calculated and listed in Table 3. The analysis of variance (ANOVA) technique was used and the results of ANOVA and *F*-test are shown in Table 4. From Table 4, it is seen that factor *D* (addition of HCl) is statistically the most significant at $P < 0.01$, whereas no statistical differences are observed for any other variable or interaction considered at $P < 0.01$. The percent contribution was over 50%. The factor *A* (concentration of HNO_3), factor *B* (extraction time) and factor *C* (addition of H_2SO_4) are statistically significant at $P < 0.05$. The percent contributions of the interactions of *A* × *B* and *A* × *D* are quite low and contribute < 5%, thus they can be pooled as error. The effect of interaction of *A* × *C* was also discussed. The effects of pressure setting and sample mass were studied later after the other variables had been optimized.

Fig. 1. Effect of the concentration of nitric acid on mean of response (R) for extraction.

3.1. Effect of the concentration of HNO_3

The effect of the concentration of HNO_3 as factor A was evaluated at four different levels in the $\text{OA}_{16}(4^1 \times 2^{12})$ matrix. The ANOVA results indicated that the concentration of HNO_3 significantly influenced the mercury extraction since the F -test result is significant at $P < 0.05$, but its effect was less than that of other factors evaluated. Fig. 1 shows the relationship between the concentration of HNO_3 and the mean responses (R) which are the mean values of K_m ($m = 1-4$). From Fig. 1, the best level is 20% (v/v) HNO_3 , but the increase in mercury recovery was very small from 79.6 to 81.4% when the concentration of HNO_3 was increased from 14 to 20%. From the four-by-two table of the interaction between the HNO_3 concentration (factor A) and the addition of HCl (factor D) (Table 5), it is seen that the mercury recoveries increased substantially from 75.6 to 89.1% as the HNO_3 concentration was increased from 2 to 14% with the addition of HCl . Table 5 was obtained from the mean values of R containing different level settings of variables A

and D in 16 trials. When the concentration of HNO_3 in the extract solutions with HCl was further increased from 14 to 20%, no significant difference (89.1–90.8%) was observed from the mercury recoveries. Thus the 14% (v/v) HNO_3 was used in the subsequent study.

3.2. Effect of addition of HCl

The addition of other acids such as HCl and H_2SO_4 along with HNO_3 was to improve the oxidizing ability and enhance the partition coefficient of mercury between vapor and solution [13,15]. Most of these added acids in the digestion mixtures were no longer decisive factors when closed-vessel microwave digestion was used, since the selected parameter settings could produce similar effects. However, the addition of HCl in the extraction or digestion mixtures is still critical, since it would result in better recovery of mercury from soil samples.

Most of the mercury in soil or sediment samples exists in the form of HgO , HgS and organic mercury. Both organic mercury and HgO are soluble in acid [14,15,17]. However, HgS is only very slightly soluble in acid which is the main reason for the reduced recovery of mercury in the commonly used wet digestion and microwave digestion methods. HgS is often present in geological materials such as rock, soils and sediments [14,16]. When HgS is placed in dilute HNO_3 , the following equilibrium exists:

Since HgS is only slightly soluble in dilute HNO_3 , the concentration of Hg^{2+} is very low. When HCl is added to the solution, the stable $[\text{HgCl}_4]^{2-}$ complex formed will shift the equi-

Table 5

Mean response (R) for four-by-two table of the interaction between the concentration of HNO_3 (variable A) and the addition of HCl (variable D)

	Concentration of HNO_3			
	2% (level 1)	8% (level 4)	14% (level 2)	20% (level 3)
Addition of HCl				
0 ml (level 1)	65.2	68.3	70.2	72.0
1 ml (level 2)	75.6	83.6	89.1	90.8

Fig. 2. Temperature change with the addition of 1 ml different acids in 14% (v/v) HNO_3 .

librium to the right and hence more HgS will be dissolved. Thus the addition of HCl would improve the extraction of Hg from soil samples. From the results of ANOVA, the addition of HCl was statistically significant at $P < 0.01$ and the percent contribution is 58%. As shown in Table 5, good recoveries ($\sim 90\%$) were obtained when 1 ml of HCl was added to 14 ml of extract solutions of either 14 or 20% (v/v) HNO_3 . The addition of 1 ml of HCl in the extraction solution thus was used in the subsequent study.

3.3. Effect of addition of H_2SO_4

In the closed vessel microwave digestion of soil samples with acid mixtures containing H_2SO_4 , the temperature setting was considered first, because the temperature increased quickly during initial digestion time and reached easily to vessel tolerance [15]. In the soil sample digestion with acid mixtures with high ratio of H_2SO_4 , the temperature control is preferred and the single pressure control can not be used to control the digestion. The acid mixtures with low ratio content of H_2SO_4 could be used in microwave digestion with pressure control. In this study, only 1 ml of H_2SO_4 was added in the acid mixture, and acid mixtures with and without H_2SO_4 were evaluated. The addition of H_2SO_4 was found to be significant at $P < 0.05$ but the percent contribution in SS

(Table 4) is only 9.9. It means that the addition of 1 ml of H_2SO_4 had improved the extraction of mercury from the soil sample but was not the main factor to be considered. To study the effect of the addition of H_2SO_4 in our present study, the temperature was recorded during the closed-vessel microwave digestion process and is shown in Fig. 2. It is seen that the addition of the H_2SO_4 had increased the digestion temperature $\sim 7^\circ$ during most of the digestion period. High temperature would increase the oxidizing power of the acid which would improve the mercury extraction efficiency. Comparing the results of digestion medium with and without H_2SO_4 in the four-by-two Table 6 which is similarly obtained as that of Table 5, the addition of 1 ml H_2SO_4 in HNO_3 (2–14%) had improved the mercury extraction efficiency from 75.5 to 81.8%. However, when 20% HNO_3 were used to extract mercury from the soil samples, no advantage could be obtained by adding 1 ml H_2SO_4 .

3.4. Effect of extraction time

With the assistance of microwave oven, the extraction time can be reduced from several hours even a day to within an hour. In this work, the extraction time was evaluated at two levels of 15 and 30 min, respectively. From the results of ANOVA, the effect of the extraction time was

Table 6

Mean response (R) for four-by-two table of the interaction between the concentration of HNO_3 (variable A) and the addition of H_2SO_4 (variable C)

Addition of H_2SO_4	Concentration of HNO_3			
	2% (level 1)	8% (level 4)	14% (level 2)	20% (level 3)
0 ml (level 2)	65.3	70.3	77.5	81.2
1 ml (level 1)	75.5	81.6	81.8	81.6

statistically significant at $P < 0.05$. From our earlier work [8,18], it is known that extraction time is an important factor to be considered. Fig. 3 shows the effect of extraction time on the mercury recoveries. The results indicate that increasing the extraction time from 15 to 30 min had improved the extraction efficiency from 85 to $100 \pm 2\%$. Considering the different matrix of soils, extraction time of 30 min was subsequently used in the study.

3.5. The interaction effect

The interactions among the variables A , B , C and D were considered. The interaction $A \times B$ was obtained by the sum of $(A \times B)_1$, $(A \times B)_2$, $(A \times B)_3$, and similarly for $A \times C$ and $A \times D$. The interaction $C \times D$ is in the same column of $(A \times B)_1$, $B \times D$ in the same column of $(A \times C)_1$ and $B \times C$ in the same column of $(A \times D)_1$. It is difficult to separate the effects from different interactions in the same column. Since the SS of $B \times D$ and $(A \times C)_1$ and $B \times C$ and $(A \times D)_1$ are 2.030 and 6.125 (Table 4), the effects of $B \times D$ and $B \times C$ can be ignored in the study. The effects of $B \times D$ and $B \times C$ were merged in $A \times C$ and $A \times D$, respectively. The SS of $(A \times B)_1$ and $C \times D$ is 20.475 (Table 4). Even if all the SS came from $C \times D$, the percent contribution from $C \times D$ would still be $< 1.2\%$. Thus the effect of $C \times D$ was not considered in later study. The sum of the SS from $(A \times C)_1$, $(A \times C)_2$ and $(A \times C)_3$ is 78.890. Hence, the interaction $A \times C$ is considered separately. The effects of $A \times B$ and $A \times D$ are not significant, they were pooled as error. The interaction $A \times C$ was evaluated in Table 6 and its effect was discussed in the section in the effect of addition of H_2SO_4 .

3.6. Effect of pressure

The extraction of mercury from soil samples by microwave oven depends on the quantities of acids used, the extraction time, the sample mass and the parameter settings of the microwave oven. The concentration of HNO_3 , the addition of HCl and H_2SO_4 and the extraction time were evaluated using the $\text{OA}_{16}(4^1 \times 2^{12})$ orthogonal array design. During the study, the pressure setting was fixed at 1035 kPa (150 psi) for the 16 runs. After optimizing the other conditions (acid mixture, 14% HNO_3 (v/v) + 1 ml HCl ; the sample mass, 0.3 g; the digestion time, 30 min), the effect of pressure setting was studied. The results are listed in Table 7. Good recoveries were obtained at pressures higher than 828 kPa (120 psi). Considering the complex nature of soils and sediments, the pressure setting of 1035 kPa (150 psi) was selected.

3.7. Effect of sample mass

Sample mass is also an important factor for the extraction of mercury from soil sample, especially for the dilute acid extraction. For the closed-vessel digestion or extraction of trace metals from soil samples, the sample mass is dependent on the vessel volume, the quantity of the acid mixture and the concentrations of the acids [15]. Most of the sample sizes used in the microwave digestion were < 0.50 g [15,19]. Under the selected conditions, samples ranging from 0.15 to 0.55 g of the NIES CRM No. 2 Pond Sediment were tested. Results are listed in Table 8. When the sample mass was over 0.35 g, the recoveries of the mercury were reduced significantly. It indicates that the selected acid mixture cannot extract mercury completely from soil sample matrices under the

Fig. 3. Effect of the extraction time on mercury recovery using 14 ml 14% (v/v) HNO_3 + 1 ml HCl.

recommended conditions. Although good recovery of mercury was obtained at the sample mass of 0.3 g, considering the complex and varied nature of soil samples, a sample size of 0.25 g was recommended for dilute acid extraction.

3.8. Application to samples

From our previous discussion, the use of 14% (v/v) HNO_3 combined with the addition of 1 ml concentrated HCl was recommended for the extraction of mercury from 0.25 g soil samples using closed vessel microwave digestion. The digestion was carried out under the pressure setting at 1035 kPa (150 psi) and 30 min for the extraction time. To further verify this extraction method, three standards of NIST SRM 1645 River Sediment,

NIES No. 2 Pond Sediment and NRCC BCSS-1 Marine Sediment and one real world soil sample spiked with different mercury compounds were tested. The analytical results are listed in Table 9. Good recoveries were obtained for standard samples and the real world soil sample spiked with different mercury species. Thus the proposed method is suitable for different sample matrices. There was no loss of either organic and inorganic mercury during extraction.

4. Conclusion

In conclusion, with the use of microwave-assisted closed vessel extraction system, mercury

^a After subtracting the amount of Hg originally present in soil.

could be extracted from 0.25 g soil samples using 14% (v/v) HNO_3 within 30 min. The addition of a small amount of HCl in the dilute nitric acid improved the extraction efficiency significantly by forming the stable $[\text{HgCl}_4]^{2-}$. This recommended method had been successfully applied to the analysis of different soil samples.

Stability studies and purification procedure for nitrite solutions in view of the preparation of isotopic reference materials¹

Jean-Claude Wolff *, Ulf Örnemark ², Philip D.P. Taylor, Paul De Bièvre

Institute for Reference Materials and Measurements (IRMM), European Commission-JRC, B-2440 Geel, Belgium

Received 15 July 1997; received in revised form 9 October 1997; accepted 10 October 1997

Abstract

The lack of reference materials, accurately certified for nitrite, is a problem in view of the importance of this species for environmental and medical reasons. This work outlines a plan for the preparation of nitrite isotopic reference materials (IRMs) in the form of high purity solutions, certified for their nitrite–nitrogen isotopic composition and nitrite concentration. To achieve the desired accuracy (expanded uncertainty U with a coverage factor $k = 2$ of $\leq 2\%$), primary methods of measurement such as isotope dilution mass spectrometry (IDMS), gravimetry, and titrimetry must be used. The main difficulty is the stability of nitrite. Other problems expected in the preparation and certification of nitrite IRMs are described. Results from long term stability studies (up to 1.5 years) and a procedure for the purification of the candidate nitrite IRMs are presented. The purpose is to use these IRMs for high accuracy method calibrations and as anchor points for SI-traceable nitrite concentrations. Reference values linked to the SI system are useful to demonstrate the degree of international comparability of nitrite measurements in intercomparison programmes such as the IRMM—International Measurement Evaluation Programme (IMEP). © 1998 Elsevier Science B.V. 1. Introduction

Among nitrogen species occurring in waters, nitrite represents a relatively unstable and toxic

intermediate in the nitrification and denitrification processes of the nitrogen cycle. Nitrite may indicate incomplete oxidation and bring to light recent water pollution. The sources of nitrite for humans are mainly consumption of contaminated drinking water, cured meat and fish. However, 75% of nitrite entering the stomach originates from nitrate reduced in saliva. The toxicity of nitrite is far more severe from contaminated water than from food, as ascorbic acid (vitamin C) may react competitively with nitrite and thus protect the organism. Nitrite may cause methemoglobinemia, i.e. the reduction of the oxygen-carrying

Autoclaving	Seawater	27 months	[12]

capacities of blood, especially in infants and concern exists about the role nitrite may play in carcinogenesis [1].

Due to its toxicity, the nitrite concentration of drinking water has been regulated by the European Community Directive 80/778/EEC, which states the maximum admissible concentration i.e. 0.1 mg l⁻¹ [2]. Thus intercomparison of results is needed in order to provide legal and political authorities with values they can base decisions on. With the search for comparability and traceability of results, an IMEP-round (International Measurement Evaluation Programme) has been requested by the Austrian government services (K. Schwaiger, personal communication). In such an IMEP-round the anchor points are SI-traceable reference values, which rely on primary methods of measurement (as defined by the Comité Consultatif pour la Quantité de Matière [3], mostly isotope dilution mass spectrometry (IDMS) [4]. In order to carry out IDMS measurements, isotopic reference materials (IRMs), certified for isotopic composition and concentration (spikes) with an expanded uncertainty U of $\leq 2\%$, are needed. The concept of uncertainty is used to describe the reliability of the measurements and the terminology introduced by ISO is employed [5].

A prerequisite for establishing a spike IRM, which should have a shelf-life of at least 2–5 years, is stability and purity. Nitrite is known to be quite unstable, especially in natural water, due to chemical and biological processes. After a few weeks in oxic water it transforms readily into nitrate [6]. To avoid deterioration of nitrite, water samples and calibration solutions are often treated with biocidal or bioinhibitory agents, such as mercury salts or chloroform [7–10]. Filtration [7,11], cold storage [6–8] and autoclaving [12] are also used (Table 1). Besides the importance and diversity of biological life, factors such as the chemical composition of water, the influence of light, the storage temperature as well as the material and history of storage containers may have a considerable impact on the preservation method adopted. The candidate nitrite IRMs are prepared from ‘pure’ chemicals and sub-boiling distilled water so that instability caused by biological activity becomes a minor problem. Aminot and K erouel [13] found that unpreserved nitrite calibration solutions were stable for several months, but recommend a storage period of 1–2 months. In this work the influence of bottle material, pH and biocidal agents (chloroform and phenyl mercury chloride) on the stability of nitrite solutions was investigated in order to find conditions that guarantee the stability of the candidate IRMs.

A preliminary analysis of two commercially available ^{15}N -enriched sodium nitrite materials (Medgenix Diagnostics GmbH, Ratingen, Germany and Euriso-top, Groupe CEA Saclay, Gif-sur-Yvette, France), revealed that these contained approximately 8.8 and 1.3% mass fractions of nitrate respectively [14]. For the NLM-1535-Q ^{15}N -enriched potassium nitrite salt (CIL, Woburn, MA), the manufacturer stated a nitrate content of 5–10% mass fraction. The thermal ionisation mass spectrometric measurement procedure for nitrite is identical to that for nitrate, as nitrite is measured via nitron–nitrate and negative ionisation of nitrogen dioxide after oxidation to nitrate [14–17]. Hence a chemical clean-up procedure for the removal of interfering nitrate was investigated.

2. Experimental

2.1. Chemicals, reagents and solutions

Analytical grade chemicals from Merck (Darmstadt, Germany) and water, purified in a MilliQ system (MilliQ-water), were used unless otherwise stated. Nitrite solutions with $c(\text{NO}_2^-) = 1 \mu\text{g ml}^{-1}$ were prepared from NaNO_2 . Solutions were acidified using $1 \text{ mol l}^{-1} \text{H}_2\text{SO}_4$, or rendered alkaline using $1 \text{ mol l}^{-1} \text{NaOH}$. Chloroform (0.02 ml l^{-1}) or phenyl mercury chloride (0.01 ml l^{-1} of a 1% solution) were added to some of the nitrite solutions.

The nitrite solutions were stored in daylight and room temperature ($20\text{--}25^\circ\text{C}$) either in FEP (fluorinated ethylene propylene from Nalgene®, Nalge, Rochester, NY) or in PE (polyethylene from Kartell, Italy) bottles. Table 2 gives an overview of the nitrite solutions investigated during the stability studies.

For column experiments, 0.050, 0.50 and $1.00 \text{ mol l}^{-1} \text{HCl}$ were prepared by dilution of stock acid and standardised against sodium hydroxide.

2.2. Spectrophotometry

Nitrite was measured spectrophotometrically ($\lambda_{\text{max}} = 543.9 \text{ nm}$) using Aquaquant® nitrite test (Merck), which is based on the classical Griess

reaction [18]. To 2 ml of nitrite solution, approximately 20 mg Aquaquant® reaction powder was added. The solution was shaken for 30 s and allowed to stand for 10 min. The measurements were made in 1 cm plastic cells using a Cecil CE 1010 spectrophotometer (Cecil Instruments, Cambridge, UK).

2.3. Ion chromatography

Ion chromatography was used to monitor possible formation of nitrate in the stored solutions and to check the separation of nitrite and nitrate on anion exchange resins. The ion chromatography system consisted of an isocratic HPLC pump, fitted with a titanium analytical pump head (Knauer, Berlin, Germany), an Ion-Pac AG12A guard column, an Ion-Pac AS12A separator column, an anion self-regenerating suppressor ASRS-1 and a CD20 conductivity detector with DS3-1 detection stabiliser cell (Dionex, Sunnyvale, CA). Chromatograms were recorded on a Shimadzu Chromatopac C-R6A integrator (Kyoto, Japan). The injection valve (Knauer) as well as all tubings and connections were made of inert polyether ether ketone (PEEK). The injection volume was $20 \mu\text{l}$ and the flow rate of the eluent ($\text{Na}_2\text{CO}_3 \text{ } 2.7 \text{ mmol l}^{-1}/\text{NaHCO}_3 \text{ } 0.3 \text{ mmol l}^{-1}$) was 1.5 ml min^{-1} . The background conductivity was typically $14.1 \mu\text{S}$, and the backpressure 14.5 MPa . Samples were injected using disposable 2 ml plastic syringes (B. Braun Melsungen AG, Germany). The injection loop was flushed with at least 1 ml of solution, thus avoiding cross-contamination.

Table 2
Summary of the experimental conditions for the nitrite solutions investigated

Solution	Chemicals added	pH	Bottle material
1A	None	6	FEP
2A	H_2SO_4	3	FEP
6A	NaOH	9	FEP
B	None	6	PE
C	CHCl_3	6	PE
D	NaOH , CHCl_3	10.5	PE
E	$\text{C}_6\text{H}_5\text{HgCl}$	6	PE
F	NaOH	12	PE

2.4. Low pressure anion exchange chromatography for the separation of nitrite and nitrate

The AG 1X8 anion exchange resin, 100–200 mesh, chloride form (Bio-Rad, Nazareth, Belgium), was used. The capacity is approximately 2.6 eqv kg^{-1} (dry weight) or 1.2 eqv l^{-1} . Fines were removed by decantation and the resin was washed with 1 mol l^{-1} NaOH, MilliQ-water, 1 mol l^{-1} HCl and finally, MilliQ-water in which the resin was stored until further use. Columns, 1.5–2 ml (0.75–1 g dry weight) bed volume, were prepared by packing the resin under a small piece of quartz wool in 10 ml Poly-Prep plastic tubes (Bio-Rad). Conditioning was achieved by passing 10 ml of 1 mol l^{-1} HCl followed by MilliQ-water through the column.

Initial column experiments were aimed at optimising analytical separation and verifying chromatographic predictions. Nitrite and nitrate (100–500 μg) from neutral solutions were put on the column. Elution (flow rate $1\text{--}1.2 \text{ ml min}^{-1}$) was performed with HCl of various concentrations and fractions of 5 or 10 ml were collected. The fractions were pre-treated using Ag-OnGuard cartridges (Dionex) to remove chloride prior to injection on the ion chromatograph. The contributions of metal impurities from the Ag-OnGuard column were checked by flushing with water and analysing the effluent using a VG Plasma Quad2+ (VG Elemental, Winsford, UK) inductively coupled plasma mass spectrometer (ICP-MS). The influence of dissolved oxygen on nitrite solutions was investigated. Solutions, $5 \mu\text{g ml}^{-1}$ in nitrite, prepared from deaerated or normal HCl, were monitored for the $\text{NO}_3^-/\text{NO}_2^-$ ratio at regular intervals during a 6 h period. Finally, the influence of pH on the fraction containing nitrite was studied. Eluted nitrite was collected in NaOH to render the solution alkaline. By using an acid–base indicator (chlorophenol red), the pH can easily be adjusted to conditions required for the Ag-OnGuard column and ion chromatographic analysis.

3. Results and discussion

3.1. Stability

As it was intended to measure relative changes in the nitrite concentration of solutions, it was estimated that the precision provided by the rapid, cost-effective Aquaquant® nitrite test would be sufficient to indicate which storage conditions should pertain. The (combined) uncertainty depicted in the figures was chosen arbitrarily and is deliberately large, i.e. 5%, in order to take into account all possible non-controlled sources of uncertainty, and does not represent the relative standard uncertainty of the measurements, which were typically about 1%.

3.1.1. Influence of pH

Fig. 1 shows that the NaOH-preserved solution (6A) was stable for almost 1.5 years at a concentration level of 1 mg l^{-1} . The ion chromatographic analysis of this solution did not show any appearance of nitrate whereas in the neutral solution (1A), nitrate was detected after 200 days. Alkaline preservation avoids the use of toxic mercury and prevents the liberation of nitrous acid as well as the disproportionation reaction which nitrite undergoes in acidic medium (HNO_2 ; $\text{p}K_a = 3.14$) according to Eq. (1).

Solution F stored in PE bottles (pH = 12.5) remained stable for almost 1 year, the decrease in NO_2^- concentration after 1.5 years can still be considered to be within the uncertainty of measurement. The same is held for solution D which had a pH of about 10.5. Acid preservation (2A) must be precluded.

3.1.2. Influence of the bottle material

Bottle material apparently plays an important role in the stability of NO_2^- (Fig. 2). The neutral solution stored in the PE bottle showed a clear

Fig. 1. Influence of pH on the stability of NO_2^- solutions stored in FEP bottles.

decrease in NO_2^- concentration, whereas the latter remained constant in the FEP bottle. The decrease observed at pH 6 could be linked to the manufacturing process (use of catalysts) of the two plastics investigated. Leaching of Zn from PE could lead to the reduction of NO_2^- to NH_4^+ . At higher pH (D and F, Fig. 3) the decrease in nitrite concentration was slower. Storage in PE bottles even at higher pH did not appear as satisfactory as using FEP bottles (Fig. 1). Adsorption of NO_2^- on the walls of the PE bottle, or the higher porosity of PE to NO_x and/or CO_2 compared with that of FEP, could explain the difference in stability observed. The nitrate concentration, increased to a large extent than if only due to the transformation of nitrite into nitrate. This fact supports the hypothesis that nitrate increase is due to the adsorption of NO_x which diffuses from the air through the PE into solutions. The NO_x adsorption by the solution was favoured in neutral or acidic medium.

3.1.3. Influence of biocidal agents

The unpreserved solution B as well as the mercury-preserved solution E showed a slight decrease in NO_2^- concentration after approximately 50 days of storage (Fig. 3). Chloroform is a poor method of preservation as shown by the results for solution C where nitrite concentration decreased drastically after 100 days of storage.

Chloroform is commonly used together with NaOH to stabilise nitrite calibration solutions prior to spectrophotometric measurements [19,20]. From the present work, it seems that stability depends mainly on NaOH (solution D, Fig. 3).

Addition of HgCl_2 and/or storage at 4°C are the methods chiefly used for short term preservation of water samples (< 1 month, c.f. Table 1). The former method proved unsuitable for the preservation of our nitrite solution (E), as we observed formation of nitrate in the order of 5%. The present work confirms results reported by Kremling and Wenck [21] and Aminot and Kérrouel [13], who showed that mercury had a rather adverse effect on the preservation of nitrite. After 20–30 days of preservation, mercury induced the disappearance of nitrite. It is thought [13] that Hg(II) oxidises NO_2^- to NO_3^- . Due to the presence of dissolved oxygen, the Hg(I) formed is re-oxidised to Hg(II) , thus enabling nitrite oxidation to proceed.

3.2. Purification of the candidate nitrite IRM

Several possibilities were envisaged for the removal of interfering nitrate. These were based either on the reduction of nitrate to nitrite or on the separation of both species using anion exchange chromatography.

Fig. 2. The influence of bottle material (PE and FEP) on the stability of NO_2^- solutions at pH 6.

3.2.1. Reduction of nitrate to nitrite

Nitrate could be reduced to nitrite since both the nitrite concentration and the nitrogen isotope amount ratio in nitrite species, are measured after purification and storage in adequate vials. The reduction could employ a Cd-column [22] or Zn [23] as used for spectrophotometric measurements of nitrate via nitrite (Griess reaction) in a great number of flow injection systems. However, the reaction is often not quantitative, sometimes proceeds to lower oxidation states (i.e. NH_4^+) and introduces Cd^{2+} or Zn^{2+} to the solution. Photolytic reduction [24,25], is a very clean way of removing nitrate, as no additional chemicals are brought into contact with the candidate IRM. This approach was abandoned since equilibrium between both species was always established in the system investigated in our laboratory [26].

3.2.2. Separation of nitrite and nitrate

With the development of ion chromatography, nitrate–nitrite trace determinations are now done on a routine basis using a variety of instrumentation and column materials [6,27–30]. The number of practical procedures, used in analytical or preparatory applications with classical ion exchange chromatography is limited [31]. The procedure should allow microgram to milligram amounts of nitrite to be quantitatively separated from nitrate in a reasonable time and from the

simplest possible matrix. For both reasons, the procedure described by Gürtler and Holzapfel [32] is less suitable. The authors used the hydroxide form of the strongly basic anion exchanger Wofatit and separated nitrite from nitrate using litre volumes of $1 \text{ mol l}^{-1} \text{ NaCl}$ – $0.1 \text{ mol l}^{-1} \text{ NaOH}$ or $0.5 \text{ mol l}^{-1} \text{ Na}_2\text{SO}_4$ – $0.1 \text{ mol l}^{-1} \text{ NaOH}$. Gilbert and Dobbs [33] demonstrated a fast and efficient separation on Dowex 2 but used $1.25 \text{ mol l}^{-1} \text{ NaCl}$.

Recovery of nitrite seems to be quantitative or near quantitative in most ion exchange applications [34–36]. A high recovery is desirable in this work, especially for the enriched materials due to their price and availability. Both nitrate and nitrite are adsorbed from neutral or weakly acid solutions on anion exchange resins in various forms and efficient separation is achieved from all cations [31]. The difference in resin selectivity is approximately a factor of three for these ions [37] but poor column efficiency can hinder fast separations. Previous attempts in our laboratory, using sodium sulphate proved unsatisfactory for this reason. We decided to exploit the possibility of using acid conditions to separate nitrite as nitrous acid. In an analytical application aimed at direct accurate quantification, this approach would (due to the stability of nitrite) be less attractive. However, in preparatory work there are some advantages. Minor losses on the column are not

Fig. 3. Influence of biocidal agents (CHCl_3 and $\text{C}_6\text{H}_5\text{HgCl}$) and NaOH on the stability of NO_2^- solutions stored in PE bottles.

important as long as the integrity of the purified (eluted) solution, on which the assay is later done, can be maintained. Short contact times also lowers the levels of impurities released from the resin. Chemical manipulations after separation should be limited to additional purification and those which assure stabilisation. Davenport and Johnson [38] demonstrated the potential of acid separation conditions using 0.010 mol l^{-1} perchloric acid on Amberlite IRA-900 at 0.2 ml min^{-1} .

Eqs. (2) and (3) were derived to predict the behaviour and the retention volume V_R of nitrite and/or nitrate on the preparatory ion exchange column [39].

$$V_R(\text{NO}_x^-) = V_m + w \cdot \frac{E_{\text{Cl}^-}^{\text{NO}_x^-} \cdot [\text{Cl}^-]_R}{[\text{Cl}^-]_{\text{aq}}} \quad (2)$$

$$V_R(\text{NO}_2^-) = V_m + w \cdot \frac{E_{\text{Cl}^-}^{\text{NO}_2^-} \cdot [\text{Cl}^-]_R}{[\text{Cl}^-]_{\text{aq}} + \beta \cdot [\text{H}^+]_{\text{aq}} \cdot [\text{Cl}^-]_{\text{aq}}} \quad (3)$$

$[\text{Cl}^-]_{\text{aq}}$ is the counter ion concentration in the eluent (mol l^{-1}), E is the selectivity coefficient, w is the dry mass of resin (kg) and V_m is the column dead volume (l). $[\text{Cl}^-]_R$ is approximately equal to the resin capacity for analytical applications. Eq. (2) is used in the absence of side reactions. However, while nitrate corresponds to a strong acid, nitrite also exists in the nitrous acid form ($\text{p}K_a(\text{HNO}_2) = 3.14$). This is considered in Eq. (3)

where β is the protonation constant for nitrite ($\log \beta = \text{p}K_a$) and $[\text{H}^+]_{\text{aq}}$ reflects the acidity (mol l^{-1}) in the aqueous phase. E -values for nitrite (1.2) and nitrate (3.8) relative to chloride on this resin type, were taken from [37]. By insertion of this data into Eqs. (2) and (3) and varying the concentration of chloride (derived from NaCl or HCl), Fig. 4 was obtained. Examining this figure reveals that both anions ought to be readily pre-concentrated on the column from solutions having $[\text{Cl}^-] < 10^{-4} \text{ mol l}^{-1}$ and that ‘separation’ could be significantly improved using 0.010 mol l^{-1} HCl compared with 0.010 mol l^{-1} NaCl .

Fig. 4. Predicted retention volumes (ml) for nitrite and nitrate on Bio-Rad AG1X8 as function of chloride concentration. The curves are derived from Eqs. (2) and (3) and the following column data: $\log \beta = 3.14$; $V_m = 0.001 \text{ l}$; $w = 0.001 \text{ kg}$; $E_{\text{Cl}^-}^{\text{NO}_2^-} = 1.2$; $E_{\text{Cl}^-}^{\text{NO}_3^-} = 3.8$; resin capacity = 2.6 eqv kg^{-1} .

Experimental results agreed well with the predicted results. A flow rate of 1 ml min^{-1} could be maintained during the separation. Using $0.010\text{--}0.050 \text{ mol l}^{-1}$ HCl, nitrite can be quantitatively collected in a fraction of $\leq 25 \text{ ml}$ with no trace of nitrate. Conversion of nitrite during the preparation of the solution or on the ion exchange column is not critical. However, as soon as the solution leaves the resin, conditions must be such that sample integrity is preserved. The time elapsed between collecting the fractions and ion chromatographic analysis, i.e. a few hours, was enough to result in a solution with the same, or higher levels of nitrate than initially present in the spike material. A possible explanation is that the resin contributes compound(s) which catalyse the oxidation of nitrite. Removal of dissolved oxygen had no influence on the conversion rate, as could have been anticipated from Eq. (1).

Collecting the effluent in NaOH so as to obtain a neutral solution provides the basis for the subsequent removal of chloride using the Ag-OnGuard column. Once excess chloride has been removed, the solution is further stabilised by increasing the pH to about 10. No nitrate could be detected in solutions treated this way whereas non-stabilised solutions showed approximately 19% conversion after 4 h. The acid–base indicator provides a simple means of adjusting the pH of the solution. However, in subsequent removal of chloride some of the indicator passes the silver column—this is why a potentiometric measurement of pH should be considered in the final procedure. The capacity of the silver cartridge is $1.8\text{--}2.0 \text{ meqv}$. The cartridges work well for solutions $0.01\text{--}0.05 \text{ mol l}^{-1}$ in chloride where usually $1\text{--}2 \text{ }\mu\text{g ml}^{-1}$ remains in the effluent. This is sufficient to evaluate the neighbouring nitrite peak using the ion chromatographic procedure. Low $\mu\text{g kg}^{-1}$ levels of B, Ca, Zn, Ni, Pb, Al, Ca, Fe, Cr, Mo, Zr, Sn and Hg were noted in effluents from cartridges when rinsed with MilliQ-water. The levels of Ag were $10\text{--}30 \text{ }\mu\text{g l}^{-1}$. No attempts have been made so far to prepare ‘our own’ Ag-column. Possible difficulties are associated with flow restrictions and efficient trapping of the precipitate. This would probably require a pressurised system. The drawback of the commercial cartridge is its lim-

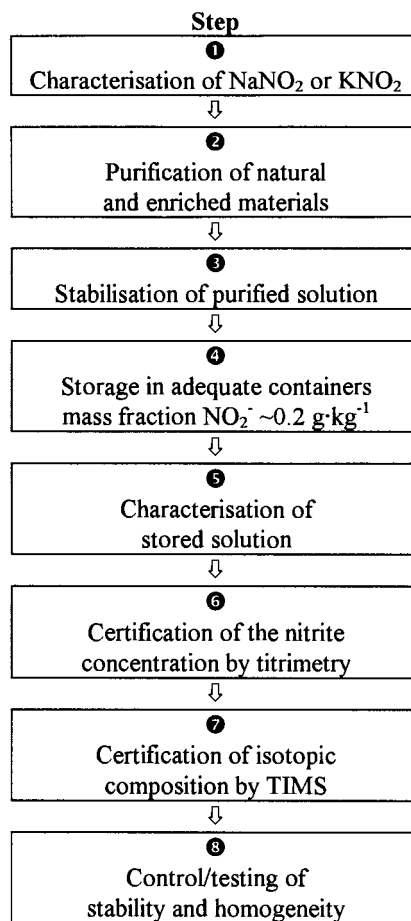

Fig. 5. Flowchart outlining the procedure for the preparation of nitrite IRMs.

ited capacity, it also becomes impractical if filtration is carried out manually.

3.3. Outline of the certification procedure

Fig. 5 indicates the procedure requirements for preparing a nitrite IRM. Characterisation, purification and stabilisation have been discussed in previous paragraphs. The alkaline medium creates an additional problem i.e. the storage container to be used. Storage in quartz ampoules seems unlikely, as silicon, released by the alkaline etching of the surface will decrease the pH of the solution with time. The use of plastic containers on the other hand raises the question of water loss due to

evaporation and also the question of diffusion and permeation of gases like CO_2 and NO_x , which could potentially affect the integrity of the candidate nitrite IRM. Data from the National Institute of Standards and Technology (NIST) shows that annual losses of 0.1% are about the best that can be obtained from 60 ml plastic containers inside a foil lined bag (J.R. Moody, personal communication). Evaporative losses of this magnitude could be tolerated since the combined uncertainty of the certified nitrite amount content will be in the order of 1%. Storage in small FEP bottles inside a foil lined bag are preferred.

The nitrite mass fraction (200 mg kg^{-1}) has been chosen to allow spiking of natural waters, resulting in blends having ‘easy-to-measure’ isotope amount ratios, and containing an amount of nitrite permitting chemical treatment of the sample, especially the ‘indirect’ isolation of nitrite via precipitation (Fig. 6). The stored candidate IRM

can be characterised for impurities using ion chromatography and ICP-MS. The purification procedure effectively removes interfering nitrate, reduces the chloride content but adds traces of silver. The NaOH used for stabilisation, introduces chloride, nitrite and traces of alkali and alkaline earth elements.

The certification of nitrite–nitrogen isotopic composition is carried out using negative thermal ionisation mass spectrometry (NTI-MS) based on the procedure described by Wolff et al. [16] to establish a nitrate isotopic reference material. Fig. 6 outlines the major steps for nitrite NTI-MS measurement. Adopting this procedure, a certified isotope amount ratio $n(^{14}\text{NO}_2^-)/n(^{15}\text{NO}_2^-)$ can be established with a combined uncertainty u_c of about 2% for both ^{15}N -enriched and natural nitrite solutions.

The nitrite concentration of candidate IRM has to be measured using a primary method of measurement. This assay can be done by titrimetry to a combined uncertainty of 1% using tetravalent manganese or permanganate [40,41]. Reverse IDMS cannot be used, as no primary nitrite RM exists.

3.4. Future work and use of nitrite reference materials

The present materials will be certified employing primary methods of measurement. An uncertainty budget, accounting for all known sources of uncertainty during the preparation will be created [15,16]. Both these conditions are prerequisites for obtaining SI-traceable values which can then be used as anchor points for comparability in a measurement evaluation programme such as IMEP [4] and for calibration of other instrumental methods. This is important as commercial nitrite calibration solutions have proven (from our experience) to be somewhat unreliable. These solutions are often made up in deionised water having a pH of about 6, which inherently leads to solution instability and serious potential errors. Providing the IRMs in small volumes, in containers for single use, is preferred rather than the larger bottles commercially available.

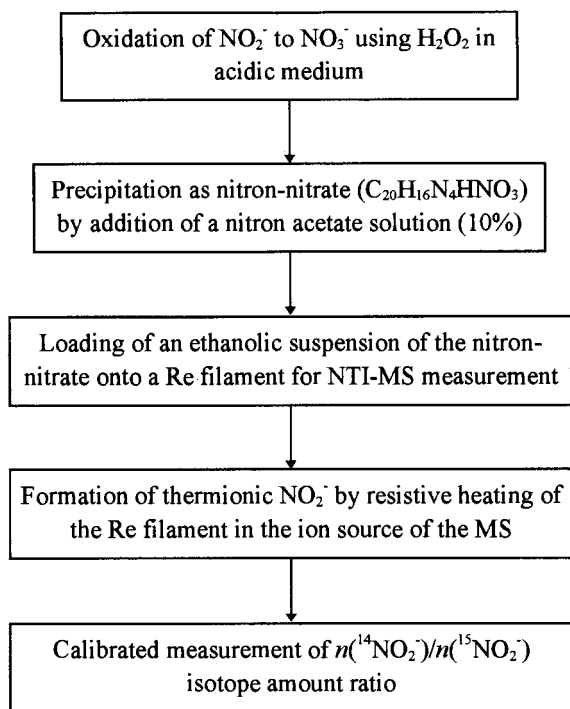

Fig. 6. NTI-MS procedure for the measurement of the isotopic composition of nitrite.

Acknowledgements

The authors wish to thank the Luxembourg 'Ministère de l'Éducation Nationale et de la Formation Professionnelle, Recherche Scientifique et Recherche Appliquée' for financial support given to JCW, and the European Commission for the research grant awarded to UÖ, which enabled this work to be carried out under the 4th Framework Programme of the European Union. They are also grateful to Hedin Joensen (Technical University of Lyngby, Denmark) for his contribution to some stages of the work.

Abstract

A new calixarene hydroxamic acid, 25,26,27,28-tetrahydroxy-5,11,17,23-tetrakis (*N-p*-chlorophenyl) calix[4]arene hydroxamic acid (CPCHA) is synthesized and used for the extraction and graphite furnace atomic absorption determination of zirconium(IV). The extract is also determined spectrophotometrically as CPCHA–SCN complex having maximum absorbance at 447 nm with molar absorptivity $9.4 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$. The Beer's law obeys in the range of 1.0–9.5 ppm of zirconium. The graphite atomic absorption (GFAAS) increases the sensitivity by about 50 folds. The method is applied to the trace determination of zirconium(IV) in standard samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Liquid–liquid extraction; Graphite furnace atomic absorption spectrometric (GFAAS); Spectrophotometric determination; Zirconium(IV); Calixarene hydroxamic acid

1. Introduction

The literature continues to be enriched by many different methods for the determination of zirconium at various levels. Several organic reagents, in particular, the metallochromic indicators like arsenazo-III [1–5], xylenol orange [6–8], pyrocatechol violet [9], alizarin red S [10–12], phenyl fluorone [13,14], bromopyrogallol red [15], morin [16–18] etc. have been used for spectrophotometric determination of zirconium, however, hafnium

interferes seriously. Zirconium has a good chemical stability, high melting and hence, its method of determination by atomic absorption spectrometry is not very sensitive and zirconium cannot be determined at less than 8 ppm [19]. However, this can be overcome by preconcentration by liquid–liquid extraction technique. The combination of liquid–liquid extraction and GFAAS is rather effective and versatile hybrid technique for trace analysis [20]. The primary reason for the wide use of extraction in combination with GFAAS is the improvement in sensitivity arising partly from increased element concentration and also because nebulization of organic solvents can produce a more finely dispersed aerosol [21].

Fig. 1. 25,26,27,28-tetrahydroxy-5,11,17,23-tetrakis(*N-p*-chlorophenyl calix[4]arene hydroxamic acid (CPCHA).

Calixarenes are baskets that can serve as vehicles of transport for chemical baggage such as metal ions and molecules [22–25]. They are amenable to chemical modifications [26] and their derivatives with donor groups containing soft bases (N or S) have proved to be effective receptors that can selectively bind a range of transition metals [27–31]. The hydroxamic acids, are bidentate ligands and have remarkable versatility for the organic and inorganic analysis [32–37]. They have achieved tremendous importance as analytical reagents for the separation and determination of large number of metal ions [38–42].

In the present investigation, the reagent 25,26,27,28-tetrahydroxy-5,11,17,23-tetrakis(*N-p*-chlorophenyl calix[4]arene hydroxamic acid (CPCHA), Fig. 1, have been synthesized [43] and used for the liquid–liquid extraction, pyrolytic graphite furnace AAS which increases the sensitivity 50 times, and simultaneous spectrophotometric determination of zirconium(IV). The zirconium(IV) is extracted as Zr(IV)-calixarene hydroxa-

mate–thiocyanate complex into ethyl acetate and determined spectrophotometrically.

2. Experimental section

2.1. Apparatus

A Hitachi (Tokyo, Japan) 3210 UV-Visible spectrophotometer with matched quartz-cells was used for spectral measurements. AAS measurements were made on Perkin Elmer Model 420 with pyrolytically coated HGA-76 graphite furnace. A zirconium wavelength 360.1 nm with a spectral width of 0.2 nm, lamp current 15 mA.

2.2. Reagents

All the chemicals were of analytical reagent grades of E. Merck (Bombay, India). Glass distilled and deionized water was used throughout. A 0.2% solution of the ligand CPCHA was prepared

in ethyl acetate. Zirconium(IV) stock solution was prepared by dissolving 0.089 g zirconyl chloride hydrate in minimum volume of dilute hydrochloric acid and diluting up to 500 cm^3 with double distilled water. Its final concentration $9.9 \times 10^{-4} \text{ M}$ was determined spectrophotometrically [44]. It was further diluted as and when required. A 20% solution of KSCN was prepared in double distilled water.

2.3. Calix[4]arene hydroxamic acids

Calix[4]arene was synthesized by the acid catalyzed reaction of *p*-hydroxy benzoic acid with benzaldehyde. Further the calix(4)arene acid chlo-

a 200 cm³ Pyrex beaker and digested on a sand bath for 1 h to dryness. The residue was redissolved in 10–15 cm³ of concentrated hydrochloric acid along with 0.5 g ammonium persulphate and centrifuged at 3000 rpm. The solution is finally diluted to 100 cm³ with distilled water.

2.5. Soil samples

1–2 g sample of dried solid was digested with 50 cm³ of concentrated hydrochloric acid and 10 cm³ of concentrated nitric acid for 1 h on sand-bath, then the solution was evaporated to dryness. The residue was boiled with 10 cm³ 5 M hydrochloric acid, filtered and diluted to 100 cm³ with distilled water.

2.6. Extraction procedure

An aliquot of zirconium(IV) solution (25–237.5 ppm) was transferred into a 60-cm³ separatory funnel. The molarity of the aqueous phase was adjusted to 4 M with concentrated hydrochloric acid. 10 cm³ of 0.2% CPCHA solution in ethyl acetate was added. The mixture was shaken for 5 min and the organic phase was separated. To ensure the complete recovery of zirconium, the extraction was repeated with 5 cm³ of CPCHA

solution and the combined organic phase was dried over 1 g of anhydrous sodium sulphate and transferred into 25 cm³ calibrated flask. The sodium sulphate was washed with 2 \times 2 cm³ ethyl acetate. The extracts and washings were diluted up to the mark with ethyl acetate and the extract was injected into furnace for GFAAS measurements. For spectrophotometric determination the ethyl acetate extract was shaken with 10 cm³ of KSCN the organic layer was separated and determined spectrometrically at 447 nm against blank.

3. Results and discussion

3.1. Absorption spectra, adherence to Beer's law and sensitivity

The determination of zirconium by the GFAAS has a sensitivity 15 ng/0.005 absorbance, detection limit 0.1 μ g cm³ zirconium using 100 μ l volume, precision 1–2% CV. Reproducibility of sensitivity is very good. About 100 determinations could typically be performed without significant drops in sensitivity. Since the automatization signal is generated slowly, a larger time constant can be used with recorder tracing to improve noise levels without loss of sensitivity. The extraction of zirco-

nium(IV) was carried with the various calixarene hydroxamic acids (Table 1). It is observed that the *N-p*-chlorophenyl-calixarene hydroxamic acid (CPCCHA) has the highest sensitivity compared to others and hence the extraction of zirconium was studied in detail. The absorption spectrum of zirconium(IV) -CPCCHA-SCN complex recorded against a reagent blank has maximum absorbance between 440–450 nm. At 447 nm, the absorbance was reproducible and hence all measurements were made at this wavelength. The molar absorptivity of the complex at 447 nm is 9.4×10^3 l mol⁻¹ cm⁻¹. The system obeys Beer's law in the range 1.0–9.5 ppm. The regression analysis represents Conc. = $4.76 \times$ Absorbance - 0.05 ($r = 0.999$).

3.2. Choice of extracting solvents

Chloroform, carbon tetrachloride, benzene, toluene, ethyl acetate, isoamyl acetate and nitrobenzene were tested as extracting solvents of zirconium(IV) -CPCCHA-SCN system. Of these, ethyl acetate was found to be most suitable (Table 2). No extraction occurs in chloroform and carbon tetrachloride, however, the extraction is incomplete in isoamyl acetate and nitrobenzene.

3.3. Effect of acidity and time of equilibration

The percentage extraction and formation of

chelate is influenced by the molarity of solution. The extraction % is obtained as $\%E = 100D/D + [V_{aq} \setminus V_{org}]$ where V_{aq} and V_{org} are the volume of the aqueous and organic phases and distribution coefficient, $D =$ Concentration of zirconium in organic phase/(total zirconium taken-zirconium in organic phase). The extraction of zirconium complex from 2.5 to 4.5 M HCl is rapid and selective. The data given in (Table 3) shows that the extraction at lower and higher molarity is incomplete. It was observed that 5 min. for equilibration is sufficient for quantitative extraction of zirconium.

3.4. Effect of CPCCHA concentration

The effect of CPCCHA was studied by extracting zirconium with different amounts of CPCCHA, keeping the concentration of thiocyanate fixed. It has been observed (Table 4) that 10 cm³ of 0.2% solution of CPCCHA is adequate for the complete extraction of zirconium. Lower concentration of CPCCHA reduces the percentage extraction, while an excess of reagent can be used without any difficulty.

3.5. Effect of thiocyanate concentration

The influence of thiocyanate was studied by extracting zirconium with different amounts of thiocyanate, keeping the concentration of ligand

Fig. 2. (A) General structure of the complexes of zirconium with calix[4]arene hydroxamic acid (CPCHA). (B) Complexes of zirconium with calix[4]arene hydroxamine acid (CPCHA) (top view).

CPCHA fixed. It was observed that 10 cm³ of 20% KSCN solution is adequate for obtaining maximum absorbance of extracted complex (Table 5).

3.6. Stoichiometry of the complex

The composition of zirconium(IV) -CPCHA-SCN complex extracted into ethyl acetate has been studied by slope ratio method [44,45]. i.e. by plotting a graph of logarithm of distribution coefficient of the metal ($\log D_M$) against the negative logarithm of ligand concentration ($-\log$ ligand). Two sets of extractions were carried out.

One, by taking fixed amount of zirconium and thiocyanate solution and varying amounts of CPCHA. The second, by varying concentration of thiocyanate keeping zirconium and CPCHA concentrations fixed. The graph of $\log D_M$ against $-\log(\text{CPCHA})$ and $\log D_M$ against $\log \text{SCN}^-$ gives a straight line of slope 0.90 and 0.98, respectively. Hence the expected stoichiometry of extracted species is Zr(IV):CPCHA:SCN⁻: (1:1:1). The possible reactions are as

The CPCHA consists of four groups of hydroxamic acid (4L) hence, forms a (1:1) complexes with Zr(IV) (Fig. 2) which are extracted with ethyl acetate. On addition of SCN[–] it gives (1:1:1) complexes of [Zr(IV):CPCHA:SCN].

3.7. Effect of foreign ions

In order to examine the utility of this method in

the presence of other commonly associated ions, a systematic study of their interferences was carried out. Moderate amounts (20–40 mg) of many commonly occurring metal ions with zirconium were tolerated and did not interfere in the determination of zirconium (Table 6). Interference was determined by measuring the absorbance of the extracted organic phase and also by making the measurements by GFAAS from both extract as

^a Average of ten determinations.

well as aqueous phase. The tolerance limit was set as the amount of foreign ions causing a change of ± 0.02 absorbance or 2% error in the recovery of zirconium. Moderate amounts of various metal ions, commonly associated with zirconium were tolerated and also most anions. The interference of molybdenum and titanium, vanadium and uranium were eliminated either by masking or stripping them with 0.3 M tartarate and 0.25 M sodium oxalate, respectively. Zirconium, is separated and determined in presence of large amount of hafnium by it with 20% solution of hydrogen peroxide, as described by Cheng [46,47].

The determination of zirconium in standard samples is given in (Table 7).

Received 7 July 1997; received in revised form 13 October 1997; accepted 14 October 1997

Abstract

Low capacity adsorbents, based on iminodiacetic acid and a crosslinked agarose, Novarose™, have been synthesised for the enrichment of metal ions. Test ions Cu^{2+} with high, and Cd^{2+} with a moderate affinity for the sorbent were selected. The study includes the effect of specific capacity and matrix composition on the rate of uptake and recovery of these ions. Using a column packed with 0.25 ml of a sorbent and a sample volume of 100 ml, Cu^{2+} is quantitatively accumulated from all of the matrices studied even at a capacity of $6 \mu\text{mol ml}^{-1}$ of adsorbent and a flow rate as high as 100 ml min^{-1} . The enrichment of Cd^{2+} is affected by the matrix and for quantitative recovery the flow rate and capacity must be properly adjusted. In the presence of 0.01 M Ca^{2+} , a specific capacity of $45 \mu\text{mol ml}^{-1}$ is needed for quantitative retention and a flow rate of 100 ml min^{-1} , whereas a capacity of $10 \mu\text{mol ml}^{-1}$ suffices at 10 ml min^{-1} . The advantage of low specific capacity on the removal of matrix elements has been demonstrated. A method based on the determination of conditional stability constants of the metal sorbent complex is suggested for predicting the sorbent capacity needed to acquire quantitative recovery and optimal matrix elimination. © 1998 Elsevier Science B.V. Keywords: Iminodiacetate adsorbent; Low capacity; Preconcentration; Matrix elimination

1. Introduction

Sorbents are used in trace metal determinations for different purposes such as preconcentration of analyte [1–3], elimination of major cations or anions from the matrix [4,5], and speciation [6,7].

The capacity of sorbents range from $\mu\text{mol ml}^{-1}$ of bed volume in low capacity sorbents to mmol ml^{-1} in high capacity sorbents [8]. The efficiency

of a sorbent in the removal of analytes from the matrix ions is determined by its selectivity towards the ions of interest and its total capacity. Since most sorbents are non-selective, major cations will often saturate the sorbent. Complexing sorbents are often charged at the pH of accumulation and non-complexing ions may therefore be taken up by ion exchange. On elution of the preconcentration column, these ions will accompany the analytes to the detector and may cause interference. In such cases, loosely held disturbing ions can be pre-eluted by a more ‘innocent’ ion

* Corresponding author. E-mail: Barbro.Noresson@kemi.uu.se

such as the ammonium ion, but it requires an additional step in the procedure and some analytes may be lost during the washing.

The concentration of the co-eluted ions may become quite high at column capacities normally used. For a column of total capacity 250 μmol eluted into 0.5 ml, the concentration of a major ion could reach 0.5 M and interfere with the measurements of some elements by, for instance, ICP-AES. Such interferences could be even more problematic in ICP-MS or GFAAS since with these techniques matrix modification is often more important than preconcentration [4,5,9]. A sorbent column of low capacity, which collects less matrix ions, would be preferable. The equilibrium constant of the sorption reaction and its kinetics will determine the extent of analyte uptake from the percolating test solution. Therefore, quantitative accumulation of analyte will be facilitated by the high specific capacity of the sorbent. Hence, arguments can be raised both in favour of large and low capacity sorbents in trace element preconcentration.

No systematic study, to our knowledge, has been made on the effect of the specific capacity of a sorbent and its performance in trace element preconcentration. The reason might be practical difficulties in controlling the capacity by synthesis or unfavourable kinetics, which requires high capacities for quantitative uptake. In a recent paper [10], the kinetics and equilibrium properties of a fast iminodiacetate chelating ion exchanger was reported. This sorbent can conveniently be prepared with different specific capacities which makes it suitable for investigation of capacity effects. As test ions Cu^{2+} with a high, and Cd^{2+} with a moderate affinity for the sorbent were selected. In particular, the influence of specific capacity, flow rate and buffer concentration on the accumulation process were elucidated.

2. Experimental

2.1. Chemicals

A highly crosslinked agarose called Novarose™ Act^{High}-100/40 (Inovata AB, Stockholm, Sweden)

was used as the support material for the adsorbent. Test solutions were made by dilution of AAS standards (Referensmaterial AB, Sweden). Other solutions were prepared from analytical grade chemicals and Milli-Q filtered deionized water.

2.2. Apparatus and analysis

The determination of the metal ion binding capacity of the adsorbent was carried out with the TraceCon computer controlled flow analysis equipment (Knapp Logistics, Graz, Austria), and for the preconcentration measurements the same flow system was used as previously reported [10].

Glass columns of 6.5 mm i.d. and of variable length (Omnifit) held the adsorbent. Endpieces were made of PTFE and porous polyethylene frits kept the adsorbent in place.

Determination of metal ion concentrations were performed by FAAS (PerkinElmer 2380) for the capacity measurements or by ICP-AES (Spectroflame, Spectro, Kleve, Germany). The manufacturers recommendations for instrumental settings were followed in both cases.

2.3. Synthesis and capacity determination

The low capacity adsorbents were synthesised according to the method described by Inovata AB [11], with minor modifications. To 5 ml of suction dry Novarose™ (about 5 g) in a 20 ml PE (polyethylene)-bottle the appropriate amount (fig. 1) of a 10% iminodiacetate solution in 0.1 M NaOH, pH 13, and 5 ml of 0.5 M Na_2CO_3 were added. The bottle was agitated on a shaker for 17 h. The adsorbent was then transferred onto a Millipore glass filter holding a membrane filter (HA, 0.45 μm) and washed with 50 ml portions of 1 M NaOH, 0.1 M HCl and Milli-Q water. The adsorbent was next returned to the PE-bottle and deactivated by adding 15 ml of 1 M NaOH. After shaking for 24 h, the adsorbent was washed with Milli-Q water and then stored in 20% ethanol.

The capacity was determined using a previously described procedure [12], packing a known volume of the adsorbent in a column and saturating

it with Cu^{2+} . After washing with 0.1 M acetate buffer, pH 5.5, the copper was eluted with 1 M HCl and determined by FAAS. The specific capacity was calculated as the quotient between the number of μmol of copper found and the bed volume. The adsorbents are named by their functional group imino diacetic acid, IDA, followed by their capacity in $\mu\text{mol ml}^{-1}$. For example, IDA45 refers to the IDA-Novarose adsorbent with a capacity of $45 \mu\text{mol ml}^{-1}$.

2.4. Adsorption rate and equilibrium concentrations

The measurements of the adsorption rate and equilibrium concentrations were performed in batch mode as described earlier [10] with some minor changes. A test solution of 100 ml of $3 \mu\text{M}$ Cd^{2+} , and/or Cu^{2+} , buffered to pH 5.5 by acetate–acetic acid, was added to a beaker. The solution was continuously sampled through a filter into the ICP-AES instrument by a peristaltic pump at 2 ml min^{-1} . When the signal stabilised, 0.5 ml of IDA-Novarose was quickly added to the stirred solution. The adsorption of the metals was followed by recording the emission signal every other second for at least 10 min. Equilibrium concentrations were also determined in the off-line mode by sampling after 2 and 24 h. The concentrations were found by ICP-AES calibrated against matched standards.

2.5. Enrichment

The FIA-ICP-AES system and the procedures used in the enrichment studies were essentially the same as reported earlier [10]. The preconditioning of the column was performed by either 0.005 or 0.1 M acetic acid–acetate buffer, depending on the buffer concentration of the sample. The enrichment flow rates were between 10 and 100 ml min^{-1} . The column was usually washed with 4 ml of 0.1 M acetate buffer before elution and eluted with 1 ml of 2 M hydrochloric acid. In the recovery measurements the eluates were collected in an off-line mode and determined by ICP-AES against matched standards.

3. Results and discussion

3.1. The sorbent

The preparation of the sorbents followed the recommendations of the manufacturer of Novarose™ (the crosslinked, bromohydrine activated agarose), as described in Section 2. Thus for a fixed reaction time, the concentration of iminodiacetate in the reaction mixture can be used as the sole parameter to control the specific capacity. Fig. 1 shows the capacities obtained as a function of the amount of IDA added per ml of Novarose™, for the capacity range $0\text{--}45 \mu\text{mol ml}^{-1}$. Sorbents with capacities up to about $150 \mu\text{mol ml}^{-1}$ can be prepared in a reproducible way. The sorbent was kept and handled in the zwitterion form, $\text{R-NH}^+(\text{CH}_2\text{COO}^-)(\text{CH}_2\text{COOH})$. The intrinsic acidity constants were determined in a previous study, $\text{p}K_{\text{li}} \cong 3.0$ and $\text{p}K_{\text{zi}} = 8.7$ [10]. At pH 5.5, the sorbent is present almost solely in the monoprotonated form.

A low capacity adsorbent must be more thoroughly packed than a high capacity adsorbent, since in a loosely packed column, channels may form resulting in analyte losses. For a high capacity adsorbent ($> 20 \mu\text{mol ml}^{-1}$) the number of active groups in such channels is sufficient for quantitative uptake and few packing problems were encountered.

Fig. 1. The capacity obtained in the synthesis of IDA-Novarose as a function of the amount of imino diacetic acid (IDA) added per ml of Novarose™. The regression line levels at higher capacities and a practical upper limit is set at about $150 \mu\text{mol ml}^{-1}$.

3.2. Influence of the specific capacity on retention

One way of discussing the influence of specific capacity on the uptake of small amounts of a metal ion at low concentration is to apply the basic chromatographic relationship

$$V_R = V_M(1 + k') \cong V_M k' \quad (1)$$

to the enrichment process in the sorbent column. As usual V_R is the retention volume, V_M the volume of the mobile phase and k' the capacity factor. Initially sorbed metal ions are thus regarded as being eluted by subsequent portions of the sample under equilibrium conditions and V_R becomes an estimate of the sample volume which can be processed before a break-through occurs. The rapid uptake shown by IDA-Novarose and its high dynamic capacity in relation to the static capacity, even at high flow rates [10], indicates that the assumption of equilibrium conditions is a reasonable approximation. However, with increasing flow rates and decreasing capacity, kinetic and other effects can be expected to increase the dispersion of the analyte in the column substantially. The ability of the model to predict the permissible enrichment volume will decrease correspondingly.

The exchange reaction between the metal ion, M^{2+} , and the sorbent in zwitterion form, $R-H_2$, is

with

$$\beta = \frac{[H^+]^2 [\overline{R-M}]}{[M^{2+}] [\overline{R-H_2}]} \quad (2)$$

Bars indicate the species in the resin phase, CAP signifies specific capacity, expressed in $\mu\text{mol ml}^{-1}$. For divalent ions, CAP would be equal to the concentration of IDA-groups. Under normal conditions an enrichment is made from a solution with constant electrolyte background and at constant pH. Consequently, the free metal ion concentration in the mobile phase, $[M^{2+}]$, will be a constant fraction, α_1 , of the corresponding total metal ion concentration, $[M^{2+}]_t$, in equilibrium with the sorbent. Furthermore, the resulting $[\overline{R-M}]$

is generally much smaller than CAP (not more than 1%) so that the total concentration of IDA-groups will be

$$\begin{aligned} [\overline{R-H_2}]_t &= [\overline{R-H_2}] + [\overline{R-H^-}] + [\overline{R-M}] \\ &\cong [\overline{R-H_2}] + [\overline{R-H^-}] \end{aligned} \quad (3)$$

thus $[\overline{R-H_2}]$ constitutes a constant fraction, α_2 , of $[\overline{R-H_2}]_t$. This fraction is determined by the acidity constant of $R-H_2$ and pH. Eq. (2) can now be rewritten

$$\beta = \frac{[H^+]^2 [\overline{R-M}]}{\alpha_1 \alpha_2 [M^{2+}]_t [\overline{R-H_2}]_t} = \frac{[H^+]^2}{\alpha_1 \alpha_2} \beta' \quad (4)$$

and the conditional constant, β' , is

$$\beta' = \frac{[\overline{R-M}]}{[M^{2+}]_t [\overline{R-H_2}]_t} \cong \frac{[\overline{R-M}]}{[M^{2+}]_t \text{CAP}} \quad (5)$$

The expression k' can then be written as,

$$k' = \frac{V_s [\overline{R-M}]}{V_M [M^{2+}]_t} = \frac{V_s}{V_M} \beta' \cdot \text{CAP} \quad (6)$$

The volume of the stationary phase, V_s , equals the bed volume since concentrations in this phase are expressed with reference to unit bed volume. Eqs. (1) and (6) gives

$$V_R = \beta' V_s \cdot \text{CAP} \quad (7)$$

If the volume which can be enriched is assumed to be roughly equal to V_R , this volume would be proportional to the total capacity, $V_s \cdot \text{CAP}$, of the column under equilibrium conditions according to Eq. (7).

Column capacity can be diminished if the sample volume for enrichment, V_0 , is less than V_R . The ratio between the analyte and interferent concentrations will increase and use of a low capacity sorbent is advantageous. When V_R approaches V_0 , no improvement in the above ratio can be achieved by lowering the specific capacity. A low CAP value must be compensated for by a longer column in order to reach the total capacity needed.

Table 1 presents recoveries from enrichments of Cu^{2+} and Cd^{2+} on 0.25 ml columns of IDA-Novarose of different capacities. Two flow rates, 10 and 100 ml min^{-1} , were used corresponding to

Table 1

Recovery of Cu^{2+} and Cd^{2+} from enrichment of 100 ml of 10 ppb Cu^{2+} and Cd^{2+} in 0.1 M ammonium acetate–acetic acid buffer, pH 5.5, at different specific capacities and flow rates

Sorbent	Recovery (%)			
	Cu		Cd	
	Flow rate (ml min^{-1})			
	10	100	10	100
IDA45	100	100	99	98
IDA20	96	99	100	94
IDA15	98	99	99	83
IDA10	99	98	93	67
IDA6	98	98	67	42

Column, 6.5 (i.d.) \times 9 mm; $n = 3$, RSD = 2–3%.

the residence times of about 0.8 and 0.08 s, respectively. The loading of a column did not exceed 1% of the total capacity. The recovery in all experiments with Cu^{2+} was close to quantitative. With this metal, which has a high affinity for the iminodiacetate group [10], it could be possible to diminish the amount of unwanted ions by decreasing the capacity of the column even further. Use of a sorbent with a low CAP is required for this ion. The Cd^{2+} ion has a much smaller β -value than Cu^{2+} and the sorbent incompletely accumulates the ion from 0.1 M acetate buffer below a CAP of about $20 \mu\text{mol ml}^{-1}$. Hence the lower limit for quantitative collection has been reached and further reduction in the amount of accumulated matrix ions by lowering the capacity is not possible at the prevalent level of β' . When an increase in the total capacity is needed for quantitative enrichment it can be achieved by increasing the column length or the specific capacity. Experiments with column lengths of 5 and 9 mm, and flow rates between 10 and 100 ml min^{-1} indicates no marked difference between the options except for the increased back pressure when the column length was extended.

3.3. Enrichment in batch

The previous discussion was based on an equilibrium model. The results presented in Table 1

and other column enrichments at different flow rates indicate that the kinetic aspects of the enrichment process must also be considered. For instance, the recovery of Cd^{2+} in 0.1 M acetate buffer, pH 5.5, decreased steadily from 97 to 64% on a 6.5 mm i.d. \times 5 mm IDA15 column when the flow rate was gradually increased from 10 to 100 ml min^{-1} . Measurements of the rate of metal accumulation by the sorbent was carried out in batch mode and the removal of test ions from 100 ml of solution by 0.5 ml of sorbent was followed at pH 5.5. Three series of experiments were run with different electrolyte backgrounds, viz. 0.1 M ammonium acetate–acetic acid buffer, 0.005 M acetate buffer + 0.095 M ammonium nitrate and 0.005 M acetate buffer only. The use of a 0.1 M NH_4^+ medium was based on the assumption that the addition of ammonium ions to a water sample would effectively diminish the uptake of Ca^{2+} , which was found to interfere with the determination of some metal ions [10].

Fig. 2 shows the results obtained in 0.1 M acetate buffer. The kinetic curves for Cu^{2+} were similar and no systematic trend with CAP was observed. The small differences most likely reflect the difficulties in establishing a reproducible addition of sorbent and stirring of the test solution. These problems affect the curve shapes particularly at the start of an experiment before the sorbent has been homogeneously distributed. The Cu^{2+} concentration drops below the detection limit ($\approx 2 \text{ ppb}$) in about 3–4 min and the decline follows a first order reaction with a half-time of about 10 s.

The results for Cd^{2+} show that sorption reaches a steady state after about 5 min. The steady state concentrations follow the expected order and only with IDA45 does the concentration reach the detection limit ($\approx 2 \text{ ppb}$). Assuming that the steady state concentrations are equilibrium concentrations, the conditional constant β' (Eq. (5)) can be calculated. The values obtained ranged between 1.1 and $0.4 \times 10^5 \text{ M}^{-1}$ with a steady decrease in the numerical value with CAP. A similar trend was observed in previous determinations of β and reasons for this trend were suggested [10]. The equilibrium constant of

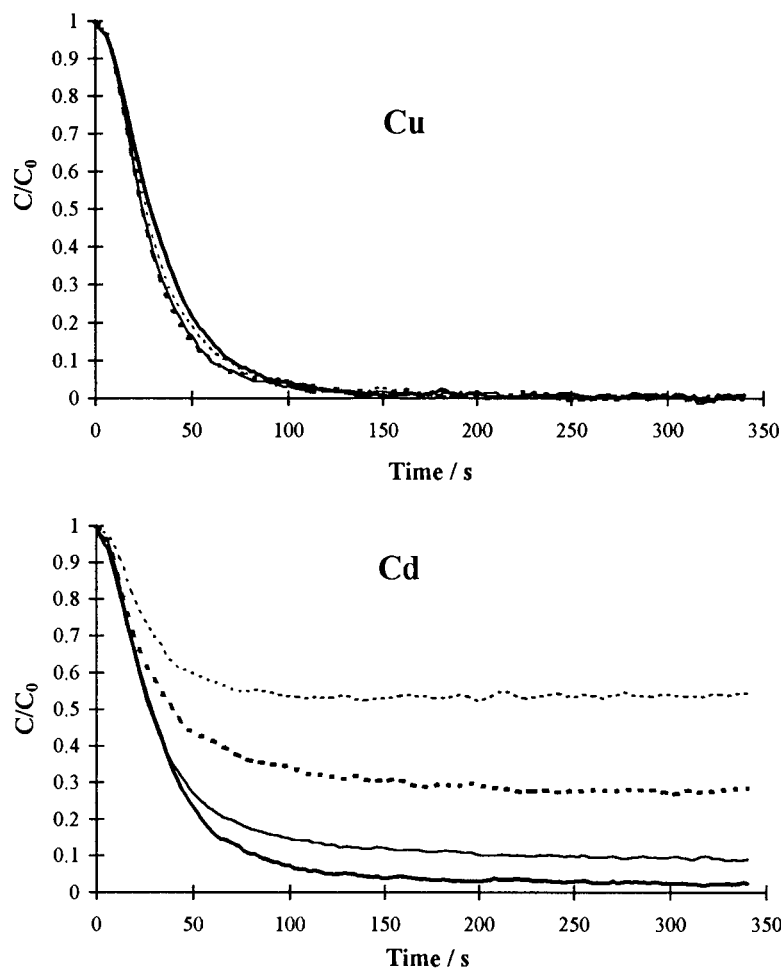

Fig. 2. Adsorption profiles of Cu^{2+} and Cd^{2+} on IDA-Novarose adsorbents of different specific capacity. Start solution, 100 ml of $3 \mu\text{M}$ Cd^{2+} and Cu^{2+} . Sorbent, 0.5 ml. Background electrolyte, 0.1 M ammonium acetate–acetic acid buffer, pH 5.5. (---, IDA6; — — —, IDA10; —, IDA20 and —, IDA45).

the sorption reaction is known from determination with high capacity IDA-Novarose. $\log \beta = -2.85$ was obtained at $I = 0.1 \text{ M}$ and the first apparent acidity constant of R-H_2 at this ionic strength should be close to $\text{p}K_{a1} = 3.0$ [10]. Using the presented equilibrium constants and Eq. (4), the predicted value of β' is $1.6 \times 10^5 \text{ M}^{-1}$, in agreement with the present results.

Since the acetate ion is known to complex with Cd^{2+} and thereby render the sorption more difficult, a second series was run at an acetate buffer concentration of 0.005 M. The NH_4^+ concentration was still kept at 0.1 M by the addition

of ammonium nitrate. The diminished acetate concentration led to lower equilibrium concentrations of Cd^{2+} . The calculated β' values ranged between 2.3 and $0.8 \times 10^5 \text{ M}^{-1}$ and the same trend with CAP was present as before. The quotient between the two sets of stability constants was 2.5 ± 0.4 from which the formation constant of the cadmium acetate complex is estimated at 15 M^{-1} . The value reported in 0.1 M NaClO_4 is 40 M^{-1} [13].

Using the β' values from the batch experiments, the retention volumes in the column experiments (Table 1) can be estimated from Eq. (7). The V_R

Fig. 3. Adsorption profiles of Cd^{2+} on IDA-Novarose adsorbents of different specific capacity. Start solution, 100 ml of $3 \mu\text{M}$ Cd^{2+} . Sorbent, 0.5 ml. Background electrolyte, 0.005 M ammonium acetate–acetic acid buffer. (---, IDA6; - - -, IDA10; — — —, IDA20 and —, IDA45)

values obtained for IDA20, IDA10 and IDA6 are 550, 135, and 50 ml, respectively. With IDA20 quantitative uptake is indicated and also found at a low flow rate. At a high flow rate, some loss occurs and the residence time, about 0.1 s, is apparently too short for equilibrium to be established. With IDA10 the retention volume is only slightly larger than the sample volume so that some loss can be expected also at a low flow rate. Low recoveries are anticipated and also found for IDA6 since the retention volume is smaller than the sample volume.

The result for the sorption from 0.005 M acetate buffer is shown in Fig. 3. A striking decrease is observed in equilibrium concentrations when the ionic strength of the buffer is lowered (cf Fig. 2). The half-times are independent of CAP and close to 10 s. Hence, no significant difference in the sorption rates between Cu^{2+} and Cd^{2+} was found.

Equilibrium data from the three matrices studied are summarised in Table 2.

3.4. Influence of the matrix on recovery

Table 3 shows the influence of buffer concentration on the recovery of Cd^{2+} by IDA6 and IDA10 at flow rates between 10 and 80 ml min^{-1} .

As predicted, the larger retention volume in a 0.005 M buffer, results in improved recoveries and almost quantitative recovery (96%) was achieved even for the lowest capacity tested (IDA6) at 80 ml min^{-1} .

An attempt to clarify the reason for the much improved performance at low ionic strength might begin at Eqs. (1) and (2). It is well known that an increase in the ionic strength increases the apparent acidity constant of R-H_2 [14]. Membrane (Donnan) equilibria are responsible for this effect. A decrease in the ionic strength at constant pH leads to an increase in the activity of R-H_2 . This

in turn leads to an increase in the ratio $\overline{[R - M]}/[M^{2+}]$ resulting in improved accumulation of M²⁺. In order to quantify the effect, the somewhat simplified approach by Pesavento et al. [14] was applied to calculate the activity of R–H₂. The result is shown in Fig. 4 which depicts the relative activity change as a function of ammonium ion concentration. The range of a pronounced Donnan effect increases with CAP since electrolyte invasion, which eventually suppresses the differences in potential between the two phases, starts at increasingly higher electrolyte concentrations. Even though calculations point out the benefits of keeping the electrolyte content of the sample low, the observed effect of a decrease in ionic strength is considerably larger than predicted.

An alternative approach would be to consider the effect of a diminished NH₄⁺ concentration in terms of an ion exchange equilibrium

The equilibrium constant of the exchange would be a ‘true’ constant since an equal number of charges is passed in both directions across the phase boundary. At pH 5.5 the sorbent is almost completely in the RH⁻NH₄⁺ form and the ratio $\overline{[R - M]}/[M^{2+}]$ is predicted to be inversely proportional to [NH₄⁺]. This model seems to overestimate the effect but again emphasises the advantages of keeping electrolyte additions to a minimum.

Since the electrolyte concentration is of such importance, the uptake of the analytes will be influenced by major matrix ions occurring in the sample. For instance, concentrations of alkali and alkaline earth metal ions have to be considered for samples of natural waters. To estimate the influence of such a matrix the adsorption of Cd²⁺ and Cu²⁺ at different concentrations of Ca²⁺ was measured. Table 4 presents equilibrium concentrations of Cd²⁺ in 0.005 M acetate buffer containing 0, 0.001 M and 0.01 M CaCl₂. The equilibrium concentrations in the 0.01 M Ca²⁺ solution are similar to those in 0.1 M acetate buffer. The recoveries of Cd²⁺ at 0.01 M Ca²⁺ and different flow rates by an IDA10 column were 98, 92, 86 and 78% at 10, 30, 60 and 80 ml min⁻¹, respectively. These figures are similar to those obtained in 0.1 M acetate buffer and presented in Table 3. Thus, at flow rates greater than 10 ml min⁻¹, a natural water matrix could affect the recovery of Cd²⁺ when an IDA-Novarose of lower capacity than 45 μmol ml⁻¹ is used. However, in comparison with other adsorbents, which are used at flow rates generally less than 10 ml min⁻¹, a low capacity IDA-Novarose could have the advantage of yielding smaller concentrations of the matrix ions in the enriched sample.

For Cu²⁺ no influence on recovery by the matrices studied was observed, probably due to the high affinity of this ion for the IDA-Novarose sorbent. Quantitative recovery was always obtained.

3.5. Recovery and retention volume

The recoveries from enrichment experiments at 10 and 100 ml min⁻¹ are presented in Fig. 5. In all cases 100 ml of 10 ppb Cd²⁺ at pH 5.5 were enriched on columns of varying volume and capacity. The NH₄⁺ and Ca²⁺ concentrations of the test solutions were also varied. The corresponding values of β' were found by batch experiments and used to calculate V_R. The recovery appears to be a smooth function of V_R. The sample volume has been marked out in the graphs, which indicates that a V_R-value of twice the sample volume is sufficient for quantitative recovery at a flow rate

Fig. 4. The relative change of the activity of the R-H₂ groups as a function of the ammonium ion concentration at three specific adsorbent capacities (in M = 10⁻³ μmol ml⁻¹). The activity at [NH₄⁺] = 0.005 M is used as reference.

of 10 ml min⁻¹, while the V_R -value needs to be about 10 times the sample volume at 100 ml min⁻¹.

The empirical relationship between recovery and V_R is a useful means of selecting the conditions for enrichment of metal ions which can be accumulated at near equilibrium conditions. The β' -values of the ions can be determined simultaneously for all ions in the appropriate matrix using a batch experiment. Calculated V_R -values

can then be used to find preliminary conditions for quantitative enrichment of the analytes at a low total capacity so that the concentrations of the concomitants can be kept low in the eluate.

Fig. 6 shows the enrichment of 1 μg of Cu²⁺ and Cd²⁺ from volumes between 50 and 400 ml on an IDA10 column. The solutions also contain 0.01 M Ca²⁺ and the pH was adjusted to 5.5 by 0.005 M acetate buffer. The V_R value for Cd²⁺ is about 230 ml, > 2000 ml for Cu²⁺ in this matrix. Quantitative retention of the latter ion is observed for all sample volumes as expected. For Cd²⁺ significant losses start at a sample volume of about 175 ml which shows that V_R is a reasonable predictor at low flow rates. The adverse effect of calcium concentration is demonstrated for a sample volume of 300 ml by an increase in recovery from about 75 to 100% when the Ca²⁺ concentration decreases from 0.01 to 0.004 M.

3.6. Matrix elimination

The presence of major matrix ions not only diminishes the sample volumes that can be en-

Fig. 5. The recovery of cadmium by columns of different capacity as a function of the calculated retention volume (logarithmic scale). A 100 ml portion of 10 ppb Cd^{2+} at pH 5.5 in different matrices was enriched at 10 and 100 ml min^{-1} . The matrices were, 0.005 and 0.1 M acetate buffer, 0.01 M Ca^{2+} + 0.005 mM acetate buffer. Columns: 6.5 mm i.d. \times 5 or 9 mm. (■, IDA6; ▲, IDA10; ×, IDA20 and ●, IDA45).

riched by a column, but can also cause disturbances in the spectrochemical finish by ICP-AES. This can be exemplified by the determination of Cd^{2+} in natural waters with preconcentration and determination performed in a flow system. Fig. 7 shows elution profiles from IDA10 and 45 initially in equilibrium with a 0.005 M Ca^{2+} solution at pH 5.5. Before elution the columns were washed with 0, 2 or 4 ml of 0.1 M ammonium acetate–acetic acid buffer. The washing was carried out in an attempt to replace Ca^{2+} with NH_4^+ .

The shape of the initial parts of the elution curves for Ca^{2+} is partly caused by the manifold used in the experiment and can be as such ignored. The important features are the peaks, most clearly seen for IDA45, which follow upon elution of the adsorbent by acid. Incomplete removal of Ca^{2+} by NH_4^+ gives rise to peaks on the elution curve for Cd^{2+} which would lead to errors in the determination of cadmium. With IDA10, 2 ml of the washing solution suffices to remove Ca^{2+} to a level that does not disturb the cadmium signal. The results point to the advan-

Fig. 6. The recovery of Cu^{2+} (■) and Cd^{2+} (▲) enriched on IDA10 at 10 ml min^{-1} , from a matrix of 0.01 M Ca^{2+} and 0.005 M acetate buffer, pH 5.5, as a function of sample volume. Each sample contained $1 \mu\text{g}$ of both metals. The estimated retention volume (V_R) for Cd^{2+} is 230 ml. Two results from solutions containing 0.004 M Ca^{2+} are also included for Cd^{2+} (△).

tage of a low specific capacity, namely easier removal of concomitants, but it must be kept in mind that it only holds as long as the total capacity is large enough for quantitative recovery.

3.7. Dispersion

Since the analytes will be spread out into a larger volume when the adsorbent capacity is lowered, the elution profile might change with the specific capacity. Therefore, such profiles were studied for IDA45, 20 and 10 after enrichment of 60 ml of 20 ppb Cd^{2+} and Cu^{2+} in 0.005 M acetate buffer, pH 5.5. The flow rate was 25 ml min^{-1} , which is known to yield quantitative recovery. The elution of the test ions by 1 ml of 2 M HCl at 4 ml min^{-1} was followed by ICP-AES. The elution profiles did not differ between Cd^{2+} , having a moderate, and Cu^{2+} , having a high affinity to the adsorbent. They were also independent of capacity, resulting in the same peak sensitivity for the three adsorbents. Washing the column before elution with 4 ml of 0.1 M acetate buffer did not effect the shape of the elution peak.

One might argue that the similarities between elution profiles for different capacities is a result of large contributions from the ICP nebulizer and

other parts of the system to total dispersion. This could mask small effects by the sample distribution in the column. The extent of the non-column dispersion was studied by collection of 0.1 ml fractions of the eluate at the column outlet in an off-line experiment. The elution profiles obtained in this way had essentially the same width as the on-line signals (about 1 ml). This indicates that minor extra dispersion is caused by the ICP instrument and the manifold. A narrower column with 3 mm i.d. increased the sensitivity by about 40%, but the increased back pressure made work with this column difficult and it was not further used.

A study of the effect of the nature and concentration of the eluent on dispersion showed that there was no advantage of nitric acid or perchloric acid over hydrochloric acid at a concentration of 1 mol l^{-1} . Increase in the concentration of hydrochloric acid to 2 M resulted in a signal enhancement of about 10%. Hence, 2 M hydrochloric acid was generally used as eluent. The effect of the elution flow rate was studied and signal enhancements of about 5 and 10% were achieved by diminishing the elution flow rate from 4 to 3 and 2 ml min^{-1} , respectively. However, the peak widths, in millilitres, were essentially the

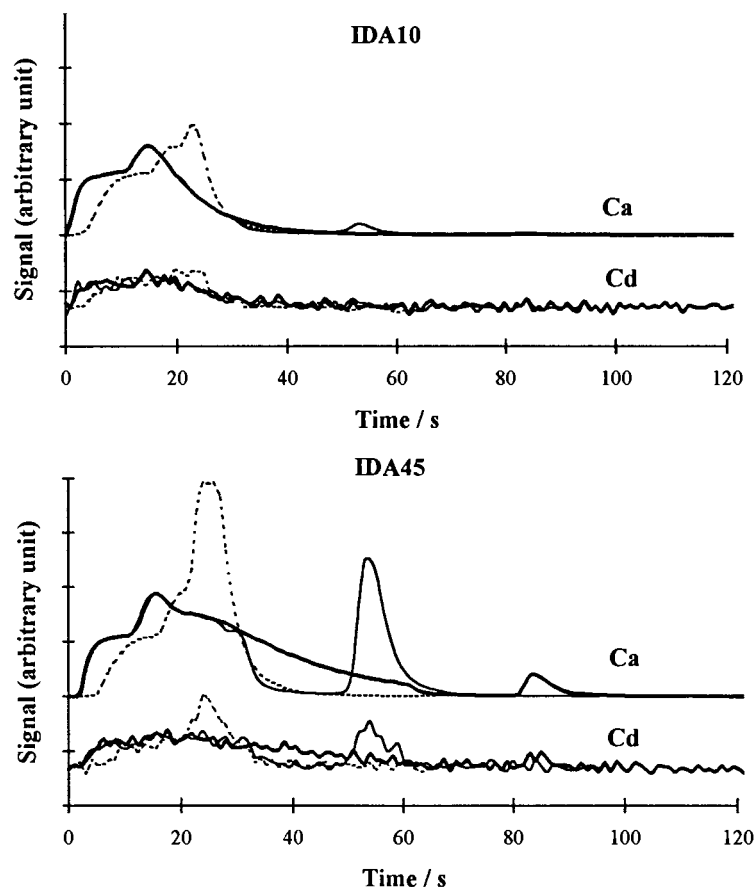

Fig. 7. Calcium and cadmium signals from the solution leaving a calcium saturated enrichment column during washing and elution. Washing was performed with 0, (---); 2, (—) and 4, (— · —) ml of 0.1 M acetate buffer. Calcium was measured by ICP-AES at 317.933 and cadmium at 228.802 nm.

same for the different flow rates indicating that sensitivity enhancement was due to limitations in the ICP input capacity at higher flow rates rather than by a change in the peak dispersion.

4. Conclusions

The general properties and simple preparation of an IDA-Novarose adsorbent with a desired specific capacity make this adsorbent suitable for studies and applications in which specific capacity can be an important parameter.

Conditional metal ion—sorbent stability constants pertaining to the sample matrix can be

readily determined in batch experiments. Due to the rapid kinetics of the adsorbent, an equilibrium approach based on the conditional constant can be used to predict proper conditions for an attempted preconcentration.

The negative effect of the ionic strength on the value of the conditional constant implies that any buffering required should be made using as low a buffer concentration as possible.

The peak height and peak area of the ICP-AES signal from on-line eluates are independent of specific capacity. Use of a low capacity adsorbent results in less interference in the analytical finish from matrix ions—these can be easily replaced by a non-interfering ion by simply washing the en-

richment column before elution. Hence the total capacity of the enrichment column should be kept as low as possible. Adjustment of the total capacity can be carried out by varying the specific capacity of the sorbent at a fixed column length or by changing the column length at a fixed specific capacity.

With Cu^{2+} , having great affinity for the IDA-Novarose sorbent permits 100% recovery even at a flow rate of 100 ml min^{-1} and a specific capacity of $6 \mu\text{mol ml}^{-1}$. For Cd^{2+} , with a moderate affinity, the recovery is dependent on the matrix composition, adsorbent capacity and flow rate. In this case proper condition must be chosen for quantitative recovery.

pH-dependent spectral behavior of substituted quinolones: potential fluorophore for metallofluorescent indicators

Geraldine M. Huitink *

Department of Chemistry, Indiana University South Bend, South Bend, IN 46634, USA

Received 4 August 1997; received in revised form 13 October 1997; accepted 14 October 1997

Abstract

The 7-methoxy and 7-hydroxy derivatives of 2,3-dimethyl-4-quinolone have been characterized with respect to absorbance, steady-state fluorescence excitation and emission, and acid-base behavior in perchloric acid ($H_0 = 5.68$ —pH 2.0) and aqueous buffers (pH 2.2–14.2); susceptibility to alkaline hydrolysis has been examined absorptometrically. 7-Hydroxy-2,3-dimethyl-4-quinolone is resistant to attack by hydroxide ion. Aqueous solutions of it exhibit moderate to high fluorescence emission, which is dependent on solution acidity. It is recommended for incorporation into metallofluorescent indicators of the Calcein Blue type. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: pH-dependent spectral behavior; Substituted quinolones; Potential fluorophore; Metallofluorescent; Indicators

1. Introduction

Metallofluorescent indicators of the Calcein Blue type consist of a fluorophore and one or more methyleneiminodiacetic acid groups. When an indicator of this type is used in spectrofluorometric determinations of metal ions that form weak complexes with methyleneiminodiacetic acid an alkaline medium must be employed. The alkaline medium eliminates competition between protons and metal ions for methyleneiminodiacetic acid; however, if the fluorophore is susceptible to alkaline hydrolysis, indicator function is compromised.

A study of 7-hydroxychromones [1] has identified

2,3-dimethyl substitution as providing the 7-hydroxybenzo-4-pyrone nucleus with high fluorescence intensity and high resistance to attack by hydroxide ion. Might this substitution pattern provide the nitrogen analog of 7-hydroxychromone with desired indicator properties also? As a γ -amide the nitrogen analog should exhibit greater resistance to alkaline hydrolysis than the corresponding γ -ester, but is the material sufficiently fluorescent? The parent 4-quinolone, referred to as 4-hydroxyquinoline in the early literature, has been the subject of several investigations [2–8]. In the present study we characterize the 7-hydroxy and 7-methoxy derivatives of 2,3-dimethyl-4-quinolone—structures and numbering shown below—with respect to absorbance, fluorescence excitation and emission, and acid–base behavior.

2,3-dimethyl-4-quinolone

I. R = OCH₃ (7-methoxy-2,3-dimethyl-4-quinolone)

II. R = OH (7-hydroxy-2,3-dimethyl-4-quinolone)

2. Experimental

2.1. Synthesis

7-Methoxy-2,3-dimethyl-4-quinolone (I) was synthesized according to Mallams and Israelstam [9]: m.p. 303–305° (acetic acid); reported 293–295° (ethanol). Found C 70.99%, H 6.18%, N 6.77%; calculated for C₁₂H₁₃NO₂ (*M*_w 203.2) C 70.92%, H 6.45%, N 6.89%.

7-Hydroxy-2,3-dimethyl-4-quinolone (II) was prepared by boiling I (1 g) and hydriodic acid (10 ml; d, 1.7) under reflux for 1 h. After adding 50 ml of water, the pH was adjusted to 7.0 with a concentrated solution of potassium hydroxide which also contained sodium hydroxide. The precipitate was recrystallized four times from aqueous ethanol: m.p. 335–339°d. Found C 69.83%, H 5.90%, N 7.29%; calculated for C₁₁H₁₁NO₂ (*M*_w 189.2) C 69.82%, H 5.87%, N 7.40%.

2.2. Reagents and procedures

All chemicals were of analytical reagent-grade quality.

Water was demineralized and was further purified by passage through a Milli-Q⁵⁰ system until it exhibited resistance of 18 MΩ.

For the acidity range *H*₀ – 5.68 to +0.04 perchloric acid, 70% (GFS) was diluted with water. Weighed samples were assayed by titration with sodium hydroxide that had been standardized against primary standard potassium acid phthalate, and *H*₀ values were obtained through

interpolation of the corrected Hammett acidity scale of Yates and Wai [10]. Perchloric acid, rather than sulfuric acid, was used to avoid the possibility of sulfonating the 4-quinolones.

Solutions in the pH region 0–2.0 were prepared by dilution of 1 M perchloric acid.

For the range pH 2.20–11.60 buffer solutions of ionic strength 0.01 were prepared following the method of Perrin [11].

For the range pH 10.5–14.2, ionic strength 1.60, appropriate masses of 45.7% w/w potassium hydroxide solution (Baker analyzed) and potassium chloride were diluted with water which had been boiled to remove carbon dioxide.

Stock solutions 3.11 × 10^{–3} M in the 4-quinolones were made up in 95% ethanol. Absorption spectra were run on solutions 2.61 × 10^{–5} M in I and 2.24 × 10^{–5} M in II; fluorescence excitation and emission spectra were obtained on solutions 1.9 × 10^{–6} M in the fluorophore. All solutions were prepared by adding appropriate volumes of stock solution to 25 ml volumetric flasks by means of a Micro Metric Model SB2 buret and Model S5Y syringes and diluting to the mark with buffer solution.

Absorbance measurements were obtained using a Perkin–Elmer λ-6 spectrophotometer interfaced with an Epson Equity III+ computer and an Okidata Microliner 320 printer.

Fluorescence measurements were made using a Perkin–Elmer LS-5 spectrofluorometer interfaced with a Model 3600 data station. Excitation and emission spectra were scanned at rates of 120 nm min^{–1}; the resulting peak intensity and wavelength were processor controlled by the Perkin–Elmer PECLS application program and are uncorrected. An Epson Model FX-85 printer was used to record fluorescence spectra.

The spectrophotometer and spectrofluorometer were equipped with water-circulating cell holders and maintained at 25 ± 0.01°C with Lauda RM6 circulating baths (Brinkman); all absorbance and fluorescence spectra were obtained immediately after solution preparation in 10 × 10 μm quartz cuvettes.

An Accumet[®] 925 pH/ion meter equipped with a semi-micro calomel, glass body, combination

electrode was employed for pH measurement; standardization was accomplished using the two-point calibration procedure. Determination of pH was made in the thermostatted cuvette immediately after each spectrum was run.

Acid dissociation constants were determined using the relationship

$$pK_a = \text{pH} + \log \frac{D_I - D}{D - D_M} \quad (1)$$

where D_I is the absorbance or fluorescence of the ionic form, D_M is the absorbance or fluorescence of the molecular form, and D is the absorbance or fluorescence of mixtures of both quinolone forms measured at a wavelength at which the difference in the absorbance or fluorescence emission of the two forms is greatest and $\text{pH} = \text{p}K_a \pm 0.0, \pm 0.2, \pm 0.4, \pm 0.6$. Plots of absorbance or fluorescence emission as a function of H_0 or pH yield sigmoid curves extending over approximately two and one half H_0 or pH units. For fluorescence work excitation was, in all cases, at the long wavelength isosbestic point in the absorption spectrum.

To avoid making measurements in potassium hydroxide solutions more concentrated than 1.60 M, absorbance and fluorescence of the fully deprotonated quinolones were determined indirectly. Recasting Eq. (1) as

$$D = D_I - \frac{[H^+](D - D_M)}{K_a} \quad (2)$$

and plotting D versus $[H^+](D - D_M)$, the absorbance or fluorescence of the fully deprotonated material was obtained as the y intercept [12]. Best straight line fits were obtained by linear regression analysis of the experimental data.

Susceptibility of the compounds to alkaline hydrolysis in pH 13 solution at 25°C was determined by monitoring changes in the absorption spectrum of each compound over a period of 8.5 h.

3. Results and discussion

3.1. 7-Methoxy-2,3-dimethyl-4-quinolone (I)

As solution acidity increases in the interval pH 5.0–1.0 carbonyl oxygen is protonated, and the long wavelength absorption maximum shifts from 310 to 326 nm (isosbestic points: 262.4, 286.9 and 326.5 nm) (Fig. 1; Table 1). Basicity of the carbonyl group is attributed to strong resonance between the neutral molecule and its dipolar ion [4]. Fluorescence emission, which follows the ground state prototropic reaction, shifts from 362 to 385 nm and increases as acidity increases over the same pH interval (Fig. 2). The $\text{p}K_a$ value obtained fluorimetrically (2.68 ± 0.05) is identical, within experimental error, to that obtained absorptometrically (2.64 ± 0.03).

Deprotonation of the ring nitrogen occurs at pH greater than 10.5 and is accompanied by a decrease in molar absorptivity. The long wavelength absorption maximum (310 nm at pH 10.5) shifts to 305.5 nm, and an unresolved peak (321 nm) shifts to 325.5 nm at pH 14.0 (isosbestic point: 328.8 nm); $\text{p}K_a$, 12.46 ± 0.02 ($I = 1.60$). Changes in the emission spectrum parallel changes in the absorption spectrum, an intense band centered at 409 nm emerging above pH 10.5; $\text{p}K_a$, 12.44 ± 0.02 ($I = 1.60$).

Three forms of I were detected: the anion exists at pH 14 and higher, the neutral molecule is the dominant species in the range pH 4.5–10.5, and the cation exists at pH 1 and lower in both the

Fig. 1. Absorption spectrum of 7-methoxy-2,3-dimethyl-4-quinolone (Compound I) at (1) pH 5.0; (2) $H_0 + 0.04$; (3) pH 14.0.

ground and S_1 states. The correspondence of pK_a values obtained absorptometrically and fluorometrically and of maxima shifts suggests that fluorescence proceeds from excited ground-state forms, and prototropic equilibria are not established during the lifetime of the first excited singlet state.

3.2. 7-Hydroxy-2,3-dimethyl-4-quinolone (II)

Below pH 5 ground state acid–base behavior of II parallels that of I. As carbonyl oxygen is protonated the absorption spectrum, which at pH 5 consists of a 314.3 nm maximum, a 306 nm shoulder and a lesser maximum at 326 nm, is red-shifted and transformed into a broader band

having one maximum at 327 nm and a lesser maximum at 301 nm (isosbestic points: 262.6, 286.4 and 330.2 nm) (Fig. 3); pK_a , 2.72 ± 0.06 .

The neutral molecule is the dominant ground state species between pH 4 and 7. With neutralization of the phenolic proton over the range pH 7.0–9.5 the absorption spectrum is red-shifted: the 306 nm shoulder and 314.3 nm peak coalesce into a peak centered at 313.9 nm, and a broad band arises at 339 nm. A short wavelength maximum centered at 245.9 nm shifts to 261.9 nm over the same pH range (isosbestic points: 276.9, 307.8, 322.4, and 330.4 nm); pK_a , 8.20 ± 0.04 .

Deprotonation of the ring nitrogen is accompanied by a decrease in molar absorptivity, the maximum shifting from 313.9 nm at pH 12.0 to

309 nm at pH 14.2 (isosbestic point: 296.3 nm); pK_a , 13.86 ± 0.05 ($I = 1.60$). The N proton of II is a weaker acid than that of I owing to greater difficulty in removing a proton from an anion than an uncharged molecule. The small spectral shift observed upon ionization of the N proton is in agreement with studies on 4-hydroxyquinoline [2]. Both I and II are stable in pH 13 solution; absorption spectra change by less than 1.5 per cent over a period of 8.5 h.

In $H_0 = -3.65$ solution the cation is the dominant species and is responsible for both absorption and fluorescence emission. The shift in the wavelength of maximum emission from 406 to 474 nm in pH 1.0 solution (Fig. 4) is attributed to ionization of the phenolic proton; no corresponding change occurs in the emission spectrum

Table 1

	337	6.9×10^3

of I, which does not contain a phenolic group. The species responsible for fluorescence emission at 474 nm is presumed to be a zwitterion. Absence of change in the absorption spectrum of II over this acidity range indicates that the phenol is a stronger acid than the protonated carbonyl in the S_1 state; the reverse order prevails in the ground state.

Plots of the decreasing 406 nm emission and the rising 474 nm emission as a function of Hammett acidity yield complementary sigmoid curves with inflection points at $H_0 = -1.37 \pm 0.04$ and -1.34 ± 0.05 , respectively (Fig. 5). Identical inflection points indicate that prototropic equilibrium is established within the lifetime of the first excited singlet state [13], the H_0 value at the inflection points being equal to the excited state pK_a .

As acidity continues to decrease between pH 1.0 and 4.0 the 474 nm emission maximum decreases in intensity and shifts to shorter wavelength (470 nm) while a second maximum emerges at 355 nm; isoemissive point, 425.9 nm. Continued decrease in solution acidity between pH 3.8 and 6.0 is accompanied by further shift of the long wavelength emission maximum to 466 nm (isoemissive point: 437.6 nm). There is little change in the emission intensity of either the 355 nm or the 466 nm bands above pH 4.6. The changes in the emission spectrum appear to be linked to changes in the status of the ground-state carbonyl group, the pK_a value determined fluorometrically (2.76 ± 0.05) agreeing with the value determined absorptiometrically.

The 355 and 466 nm emission bands have identical excitation spectra, which indicates that they originate from the same ground state species. Both bands have about equal emission in-

Fig. 2. Fluorescence emission spectrum of 7-methoxy-2,3-dimethyl-4-quinolone (Compound I) at (1) pH 14.2, excitation monochromator set at 323 nm; (2) $H_0 + 0.04$, excitation monochromator set at 322 nm; (3) pH 5.0, excitation monochromator set at 306 nm.

tensity, the 466 nm band being a little more intense than the 355 nm band. Comparison with the 362 nm emission maximum of I suggests that the 355 nm band originates from the excited neutral molecule. The 466 nm band is thought to originate from the excited neutral ketotautomer.

Neutral molecule

Neutral ketotautomer

Emission maximum, 355 nm

Emission maximum, 466 nm

It should be noted that a variety of excited-state species have been proposed to account for long-wavelength emission in similar compounds, and a variety of mechanisms have been posited to explain how a proton may be transferred from a phenolic group to a carbonyl group several atoms away [14–20].

In the pH interval 7.0–9.5 fluorimetric titration of II follows ground-state neutralization of the phenolic proton: emission at 355 nm decreases while the 466 nm band shifts to 431 nm and triples in intensity; pK_a , 8.20 ± 0.04 . Emission at 431 nm is attributed to the excited anion.

Above pH 11 fluorescence emission of II decreases, and the wavelength of maximum emission

intensity appears to shift to shorter wavelength being centered at 428 nm in pH 14.2 solution. The data are insufficient to provide an excited-state pK_a , but it is presumed to be greater than 14.

7-Hydroxy-2,3-dimethyl-4-quinolone exhibits complex excited-state behavior. Strongest fluorescence is observed in perchloric solutions of $H_0 - 3.65$ and higher, emission being from the excited cation. Fluorescence from what is presumably a zwitterion is strongest near pH 1, but, with conversion of the ground-state cation into the neutral molecule, the dominant excited-state species is converted to the neutral molecule and neutral ketotautomer, and moderate fluorescence is observed. Molecular formulas of the zwitterion, uncharged molecule and ketotautomer are identical. Each has the same number of protons. In the zwitterion and ketotautomer the protons are attached to the same atoms, but the two forms have different electronic arrangements. The emission maxima of the species tentatively identified as zwitterion and ketotautomer differ by only 8 nm, and each may possess a certain amount of the others character. The anionic form of II is approximately 15 percent as fluorescent as the anionic form of 7-hydroxy-4-methylcoumarin, the fluorescent moiety of Calcein Blue, still II is strongly fluorescent. This strong fluorescence and resistance to attack by hydroxide ion indicate that II is an excellent candidate for incorporation into metallofluorochromic indicators.

Neotetrazolium chloride: a new reagent for spectrophotometric determination of manganese

M. Kamburova

Department of Chemistry, Higher Institute of Agriculture, BG-4000 Plovdiv, Bulgaria

Received 24 March 1997; received in revised form 4 August 1997; accepted 20 October 1997

Abstract

The interaction of Mn(VII) and the Neotetrazolium chloride has been examined. The ion-associate formed is extracted into 1,2-dichloroethane. The optimum conditions have been established. The molar absorptivity of the complex is $(9.1 \pm 0.08) \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$. The sensitivity of the method is $6.04 \times 10^{-5} \mu\text{g cm}^{-2}$. It is possible to extract and determine manganese in the presence of large number of cations and anions. The characteristic values for the extraction and the aqueous phase equilibria were determined: extraction constant $K_{\text{ex}} = 3.21 \times 10^9$, distribution constant $K_D = 33$ and association constant $\beta = 9.72 \times 10^7$. The method is applicable to analysis of soils and steels. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Extraction-spectrophotometry; Manganese determination; Soils; Steels

1. Introduction

The determination of microquantities of manganese in soils and other naturally occurring materials is of particular importance in connection with the growing interest in environmental problems. New accurate and reliable methods for analysis of various objects containing traces of manganese should be searched for this element.

Manganese is a microelement actively absorbed by plants and has an effect on the fertility of soils [1]. The reagents suggested for determination of manganese include: ethylenebis(triphenylphosphonium) [2]; isophthalaldihydroxamic acid [3]; 1,10-phenantroline [4]; 8-hydroxyquinoline [5]; 4-(2-pyridylazo)resorcinol

[6]; 1-(2-pyridylazo)-2-naphthol [7,8]; *N*-diphenyl benzamidine [9]. Some of the above mentioned extraction methods are characterized by a long procedure, are not very selective [4–8], low stability of the complexes obtained [2,3], low sensitivity [3].

In the literature there is data on the use of Neotetrazolium chloride for determination of chromium(VI) [16], zinc(II) [17,18], cobalt(II) [19] and molybdenum(VI) [20]. No data about determination of manganese with Neotetrazolium chloride can be found in the literature. The tetrazolium salt Neotetrazolium chloride we suggest is a new reagent for determination of microquantities of manganese. Mn(VII) forms stable an ion-pair with NTC. This can be used in developing an extraction-photometric

method for determination of manganese. The nature of the interaction between the manganese(VII) with the cation of the tetrazolium salt should be studied. The present paper represents the conditions needed for determination of manganese with Neotetrazolium chloride (NTC). This is an extremely simple and direct extraction for determination of microquantities of manganese.

The goal is to develop an extraction–photometric method using NTC for determination of manganese in soils and steels, superior, in some respects, to the existing methods.

2. Experimental

2.1. Reagents

All the chemicals used were of analytical grade. A 1×10^{-3} M stock solution of Neotetrazolium chloride (NTC) Fluka was prepared by dissolving 0.0702 g of NTC in distilled water and diluting to 100 ml. Other NTC concentrations were prepared by appropriate dilution. The solutions were stable for several months.

Stock manganese(VII) solution. A 1×10^{-2} M aqueous solution was prepared by dissolving 0.395 g of KMnO_4 in 250 ml of distilled water. After 8 days the exact concentration of manganese(VII) was checked by oxalate titration. Working solution containing 1×10^{-4} M Mn(VII) was prepared by dilution.

Solutions of ions for interference studies were prepared by dissolving the amount of each compound needed to give 10 mg ml^{-1} of the ion concerned.

Phosphoric, nitric, hydrochloric, sulfuric and perchloric acids at concentrations of 2, 1.55, 1.2, 2 and 9 M, respectively, were used; 1,2-Dichloroethane.

2.2. Apparatus

Absorbance measurements were made with spectrophotometer VSU 2-P (Carl Zeiss, Jena, Germany), 1 cm light path cuvette, 240 nm.

2.3. Procedures

2.3.1. Calibration

In a 100 ml separatory funnel place 0.5 ml of 2 M phosphoric acid, 2 ml of 1×10^{-4} M Neotetrazolium chloride, and a known volume of manganese(VII) solution containing up to $\sim 17 \mu\text{g}$ of manganese. Dilute to 10 ml with distilled water and shake with 3 ml of dichloroethane for 5 s. Transfer the organic layer through a dry filter paper into a 1-cm cuvette and measure the absorbance at 240 nm against a reagent blank similarly prepared.

2.3.2. Determination of manganese in steel

Samples of 0.1 g of steel types were dissolved in 50 ml HNO_3 (1:3) and evaporated to remove vapours of nitric oxides. 0.1 g of ammonium persulphate was added, and boiled for 10 min for oxidation of the carbon compounds and the destruction of the excess of the persulphate. It was diluted up to 70 ml with water and portions of 3 ml conc. H_2SO_4 , 2 ml conc. H_3PO_4 and 0.2 g potassium periodate were added for the oxidation of Mn(II) to Mn(VII) [10,11]. It was heated to boiling point and the temperature was maintained for 10 min. Then the solution was cooled. It was transferred into a volumetric flask of 100 ml and diluted to the mark with distilled water. Aliquot parts of this solution were taken for analysis with addition of 0.5 ml of 2 M phosphoric acid, 2 ml of 1×10^{-4} M NTC and 2 ml of saturated ascorbic acid solution (to mask interfering ions). It was diluted to a volume of the aqueous phase of 10 ml with distilled water, extracted with 3 ml of dichloroethane for 5 s, and the organic layer was then transferred through paper filter into 1 cm cuvette and absorbance was measured at 240 nm.

The determination of manganese was carried out using the analytical graph.

2.3.3. Determination of manganese in soils

4 g of the air-dried soil sample is weighed and introduced into a platinum crucible, then heated for 3 h in a muffle furnace at 500–550°C to digest the organic matter. After cooling, the sample is transferred into a platinum bowl and 5 ml conc. H_2SO_4 , 5 ml of conc. HNO_3 and 2 ml H_2O_2 are

added. The sample was heated until the white fumes of SO_3 appeared. Next, 1 ml of H_2SO_4 and 3 ml of HNO_3 was added and evaporated to dryness. 5 ml of conc. HCl and 2 ml of conc. HClO_4 were added to the dry residue, then heated to dryness evaporating chromium as chromylchloride with destruction of the organic compounds [12]. The dry residue is then dissolved in bidistilled water and acidified with hydrochloric acid. The solution obtained is then neutralized with concentrated ammonia solution to precipitate the iron(III) and aluminium(III) as the hydroxide. The precipitate is filtered through filter paper and the filtrate is evaporated until the volume is 30 ml. 3 ml of conc. H_2SO_4 , 2 ml of conc. H_3PO_4 and 0.2 g of potassium periodate are added, the solution is heated to the boiling point and the temperature maintained for 10 min [13]. Then the solution was cooled and transferred into a 50 ml volumetric flask, and diluted to the mark with distilled water. To mask the interfering ions 0.5 ml of 2 M phosphoric acid, 2 ml of 1×10^{-4} M NTC and 3 ml of ascorbic acid saturated solution were added to 3 ml of soil solution. The solution was diluted to 10 ml with distilled water, then shaken for 5 s with 3 ml 1,2-dichloroethane. The organic phase was filtered through a dry paper into a 1-cm cuvette and the absorbance was measured at 240 nm. A blank was run in parallel in the absence of the soil sample. A calibration graph was constructed with standards similarly treated.

3. Results and discussion

3.1. Extraction of the complex into organic solvents and determination of the wavelength of maximum absorption

Manganese(VII) forms an ion-pair with Neotetrazolium chloride. The solubility of the ion-associate in various organic solvents was investigated. Benzene, chloroform, 1,2-dichloroethane, dimethyl ketone, isobutanol, toluene, alcohols, ethers, xylene were tested. Our studies showed that the ion associate of MnO_4^- with NTC was quantitatively extracted into 1,2-dichloroethane. The absorption spectra of solutions of tetrazolium

salt and ion-association complex in phosphoric acid show that the absorption maxima are around 260 nm (Fig. 1).

3.2. Stability and composition of the ion-association complex

The organic phase containing 1.78×10^{-5} M manganese was extracted as described in Section 2.3. The absorption was measured at 260 nm against time in 1-cm cells with dichloroethane in the reference cell. It was established that the ion-pair had high stability. The absorption did not change for 20 days. Variations in temperature of the test solution from 18 to 24°C had a negligible effect on the light absorption.

The stoichiometric coefficients of the ion-associate were established by various methods [14]: the method of molar ratios, the method of isomolar series. The results show that in the ion-associate, the reagent ratio is $\text{NTC}:\text{MnO}_4^- = 1:2$. The extraction equilibrium was reached in 5 s.

3.3. Photometric characteristics

The molar absorptivity of the complex, calculated by the method of Komar-Tolmatchov [14] is $(9.1 \pm 0.08) \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$. This demonstrates the high sensitivity of the given reaction. A

Fig. 1. Absorption spectra of ion-association complex (1) and NTC (2) in dichloroethane: $C_{\text{Mn(VII)}} = 1.33 \times 10^{-5}$ M, $C_{\text{NTC}} = 1 \times 10^{-5}$ M, $C_{\text{H}_3\text{PO}_4} = 0.1$ M.

Fig. 2. Investigation of the influence of acidity on the extraction of Mn(VII) with NTC: $C_{\text{Mn(VII)}} = 1.78 \times 10^{-5}$ M, $C_{\text{NTC}} = 1 \times 10^{-5}$ M; (○)— H_3PO_4 , (●)— HCl , (×)— H_2SO_4 , (△)— HNO_3 .

plot of the concentration of aqueous phase manganese(VII) vs. absorbance of the organic layer showed good linearity in the range 0.1–1.7 μg of manganese(VII) per 1 ml of aqueous phase. The sensitivity of the method according to Sandell [13] is 6.04×10^{-5} $\mu\text{g cm}^{-2}$. The relative standard deviation (12 determinations with 1 μg of Mn(VII), 95% confidence level) is $\pm 0.85\%$.

3.4. Effect of reagents and conditions on absorbance measurements

The effect of the acidity of the solution on the extraction of the ion associate of manganese is given in Fig. 2. The optimum acidity of the extraction was over a rather wide range: pH 3–8 and 0.2×10^{-1} – 1×10^{-1} M H_3PO_4 . The effect of various acids (H_3PO_4 , H_2SO_4 , HCl , HNO_3 and HClO_4) on the extraction equilibrium was studied. In the presence of perchloric acid, the manganese associate could not be extracted by the organic phase. The change of the absorbance of the ion-associate in the pH range 2–9 was also studied with buffers.

The influence of Neotetrazolium chloride concentration on the ion-associate absorbance was studied. At an aqueous phase acidity 1×10^{-1} M of H_3PO_4 , the maximum extraction of the ion-associate was reached at a concentration of NTC in the range 1.5×10^{-5} – 3.5×10^{-5} M (Fig. 3).

3.5. Interferences

Analyses were performed as described in Section 2.3 with 1 μg of manganese and the amounts of the various elements shown in Table 1. The results obtained show the possibility of extractive-photometric determination of manganese(VII) in the presence of numerous ions without separation beyond the extraction procedure described above. Ascorbic acid was used to eliminate the interference of W(VI) and Mo(VI). $\text{S}_2\text{O}_3^{2-}$ is serious interference. The ratios of the accompanying ions at which the deviations in the results reached $S_r = 0.04\%$ ($n = 3$) are given in Table 1.

3.6. Quantitative characteristics of the extraction equilibrium

The quantitative investigation of the interaction in the aqueous phase and extraction of the ion-associate complex with dichloroethane has been performed.

W(VI)	0.02 and 0.4*
S ₂ O ₃ ²⁻	Interfere

* In the presence of ascorbic acid as masking agent.

$$K_D = \frac{\{NTC[MnO_4]_2\}_0}{NTC[MnO_4]_2} \quad (1)$$

(2) The entire process of the extraction is described by the corresponding equilibrium constant which is regarded as the extraction constant

$$K_{ex} = \frac{\{NTC[MnO_4]_2\}_0}{[NTC^{2+}] \cdot [MnO_4^-]} = K_D \cdot \beta \quad (2)$$

(3) The formation of the ion associate in aqueous phase is characterised by the corresponding equilibrium constant

$$\beta = \frac{NTC[MnO_4]_2}{[NTC^{2+}] \cdot [MnO_4^-]} \quad (3)$$

The following solutions are introduced into 100 ml separating funnels: 4 ml of 1×10^{-4} M NTC, 0.5 ml of 2 M phosphoric acid and the corresponding amounts of manganese(VII). The volume of the aqueous phase is brought to 10 ml with distilled water, then is extracted with 3 ml of dichloroethane for 5 s. After the separation of the two phases, the organic phase is transferred through filter paper into a 25 ml flask and is diluted to the mark with dichloroethane. The light

absorption of the organic phase is measured at 240 nm with a 1-cm light path cuvette.

To determine the distribution coefficient of NTC, the absorptions obtained are compared to the one obtained after three extractions of the aqueous layer:

$$D_{NTC} = A / (A_{max} - A)$$

(A = light absorption for a single extraction, A_{max} = light absorption for three extractions.)

Using the logarithmic values of D_{NTC} and the concentration of manganese, the plot $\log D_{NTC}$ vs. $\log C_{Mn}$ (Fig. 4), allows determination of the distribution constant graphically by extrapolation of the straight line parallel to the X -axis up to the point of intersection with the Y -axis [21]. The value obtained was:

$$K_{D \text{ NTC}[MnO_4]_2} = 33.00 \pm 0.09$$

The extraction constant was determined by the method of Likussar and Boltz [15] by means of an isomolar series and their equation for a 1:2 complex. The extraction constant found was

$$K_{ex \text{ NTC}[MnO_4]_2} = (3.21 \pm 0.05) \times 10^9$$

The stability constant of the ion-association complexes in the aqueous phase was calculated from $K_{ex} = K_D \cdot \beta$. The value found was

$$\beta_{NTC[MnO_4]_2} = (9.72 \pm 0.15) \times 10^7$$

The results show that the ditetrazolium salt Neotetrazolium chloride is superior in terms of completeness of extraction.

Fig. 4. Logarithmic dependence of D_{NTC} on the manganese concentration: $C_{NTC} = 4 \times 10^{-5}$ M, $C_{H_3PO_4} = 0.1$ M.

Table 2
Determination of manganese in steels and soils

Steel	NTC method (%)	Certified manganese (%)	RSD* (%)
CO-C 14a	0.320	0.305	1.5
CO-C 37	1.25	1.35	1.8
Soil	NTC method (%)	Atomic absorption	RSD* (%)
Pseudopodzolic	6.15×10^{-3}	6.30×10^{-3}	1.2
Black	7.0×10^{-3}	7.18×10^{-3}	1.5
Deluvial	4.50×10^{-3}	4.35×10^{-3}	1.9

* Relative standard deviation (based on three determinations).

3.7. Applications

The developed method with NTC has been used for determination of manganese in standard samples of steels. Steel type CO-C 14a contains (%): Mn—0.305, V—0.208, Cu—0.128, Cr—1.84, Ni—0.162, W—0.293, Al—0.56, S—0.0058, P—0.0074, C—0.364, Si—0.50; steel type CO-C37: Mn—1.35, Cr—17.6, Si—0.5, C—0.05, Ni—12, Cu—0.2, Nb—1.2. The results obtained for standard steel samples are given in Table 2. The relative standard deviation of the method was $S_r = 2.0\%$ in the analysis of the standard sample CO-C 14a and $S_r = 1.4\%$ in the case of CO-C 37.

The method was used for the determination of microquantities of manganese in soils. A few types of soils were studied: pseudopodzolic, black, deluvial (Table 2).

The data obtained were checked up by the atomic absorption method. The good agreement of the results obtained by both methods shows that NTC can be used as a reagent for determination of microquantities of manganese. Preisolation of manganese or most other ions is not necessary. The method we developed has a high selectivity and sensitivity.

Abstract

The formation and stability of protonated diamines–carboxylic ligand complexes was studied potentiometrically (H^+ -glass electrode). Species formed are ALH_r (A = cadaverine, putrescine, L = acetate, malate, tartrate, malonate, citrate, 1,2,3-propanetricarboxylate, 1,2,3,4-butanetetracarboxylate and glutamate; $r = 1 \dots m + 1$, where m is the maximum degree of protonation of the carboxylic ligand), and their stability is a function of charges involved in the formation reaction. For the equilibrium $H_i A^{i+} + H_j L^{(j-z)} = ALH_{i+j}^{(i+j-z)}$ the following linear relationships can be written: $\log K_{1j} = -0.25 + 0.75 |j - z|$, $\log K_{2j} = 0.50 + 0.90 |j - z|$ (by also considering some ethylenediamine and 1,2-diaminopropane complexes). Medium effects were considered. Comparison was made with analogous inorganic polyanion complexes. The simplest relationships $-\Delta G^0 = 6.5 \pm 0.3$ and $-\Delta G^0 = 7.9 \pm 0.6 \text{ kJ mol}^{-1} n^{-1}$ (n = number of possible salt bridges) were found for carboxylic and inorganic anions, respectively. © 1998 Elsevier Science B.V. Keywords: Biogenic amines; Carboxylic ligands; Anion coordination chemistry; Speciation of biological fluids

1. Introduction

Carboxylic acid anions (including those of aminocarboxylic acids) form complexes with protonated polyamines whose stability is proportional to the charges of the reagents. In our own laboratories and in those of colleagues, 32 + 13 at

other universities, this type of complex, in particular with $C_{(2n-2)}N_nH_{(5n-2)}$ type amines, has been studied [1,2].

In the first of this series of studies [1] we included stability data relative to the formation of biogenic diamine–inorganic anions complexes. Here we examine the same diamines with organic polyanions [acetic (*ac*), 32 + 13 malonic (*mal*), malic (*mala*), tartaric (*tar*) and glutamic acids (*glu*)] potentially involved in biological cycles. In

* Corresponding author. Tel.: +39 90 393659; fax: +39 90 392827; e-mail: destefano@chem.unime.it

addition, in order to give a fuller picture of amine–anion interactions we also considered other diamines, and 1,2,3-propantricarboxylate (tricarallylate, *tca*) and 1,2,3,4-butanetetracarboxylate (*btc*) polyanions.

2. Experimental

2.1. Materials

Amines [1,4 diaminobutane (putrescine, *ptr*), 1,5 diaminopentane (cadaverine, *cdv*), ethylenediamine (*en*), Sigma] were purified by transformation into the corresponding hydrochlorides, and were used in this form. Carboxylic acids (Fluka and/or C. Erba pure or puriss.) were used without further purification. Their purity, checked by potentiometric titrations, was always >99.5%. Other experimental details, apparatus, procedure and calculations are as reported previously [1].

3. Results and discussion

3.1. Protonation constants

Protonation constants of amines, carboxylic ligand and glutamic acid have already been reported [1,3–7]. In all the calculations we have taken the formation of protonated amine-Cl⁻ and carboxylic ligand-Na⁺ complexes into account. Note that, owing to the fairly high formation constants of high charged polyanion-Na⁺ complexes, interferences with the sodium cation must be avoided, and this is why we worked in the absence of background salt.

3.2. Protonated amine–carboxylic ligand complexes

Table 1 shows overall formation constants of mixed species studied in this work together with the equilibrium constants relative to the reaction

In this Table some other systems of protonated diamines [ethylenediamine (*en*) and histamine

(*hm*)] and carboxylic anions [succinate (*succ*), oxalate (*ox*), 1,2,4,5-benzenetetracarboxylate (pyromellitate, *pymel*) and benzenhexacarboxylate (mellitate, *mlt*)] are shown too [8–12]. In all the systems investigated we found the formation of ALH_r species ($r = 1 \dots m + 1$, $m =$ maximum degree of protonation of carboxylic ligand), with a maximum formation constant value corresponding to reactions which involve the maximum value of $[i + (j - z)]$. This is in accordance with previous results for similar systems (see Table 1 and refs. [2,4–7]). Glutamic acid behaves as a dicarboxylic ligand (such as malate, tartrate and malonate). Figs. 1 and 2 show the distribution of the species vs. pH for the system H⁺-*ptr-cit*³⁻ and H⁺-*cdv-btc*⁴⁻.

3.3. Charge–stability relationships

As can be seen in Table 1, log K_{ij} equilibrium constants mainly depend on the charges involved in the formation reaction. This behaviour has already been observed for several other protonated amine–polyanion systems [1,2]. In Table 2, we give log K_{ij} mean values for each type of reaction considered, and in Fig. 3 these values are reported vs. polyanion charge. For these data we can use the linear relationship

$$\log K_{ij} = a + b|j - z| \quad (2)$$

$a = -0.25, 0.50$ and $b = 0.75, 0.90$, for $i = 1$ and 2 , respectively. Alternatively we can write the equation

$$\log K_{ij} = -1.83 + 1.18i + 0.88|j - z| \quad (3)$$

The above results are in accordance with the basic hypothesis of the non-covalent nature of protonated amine–polyanion interaction. Recent calorimetric measurements for similar systems [8] showed that ΔH^0 values associated to reaction in Eq. (1) are also consistent with this hypothesis, being positive and dependent on charges.

3.4. Comparison with inorganic complexes

In order to compare the stability of inorganic [1] and organic complexes, we may use the very simple relationship

Table 1
Formation constants^a of diamines^b with anions^b at $I = 0 \text{ mol dm}^{-3}$ and $T = 25^\circ\text{C}$

$$\log K_{ij} = a\xi \quad (4)$$

where $\xi = |z_{\text{anion}}z_{\text{cation}}|$

If we make the rough assumption $\xi = 2n$ (n = number of possible salt bridges), the following equation is valid for the ΔG^0 value of a single bond (as mean) $-\Delta G^0 = 11.42a$. We found $a = 0.69 \pm 0.05$ and 0.57 ± 0.03 ; $\Delta G^0 = -7.9 \pm 0.6$ and $-6.5 \pm 0.3 \text{ kJ mol}^{-1} n^{-1}$, for inorganic and organic anions, respectively. In a recent review [8] this analysis was performed for several amine–inorganic and organic polyanion complexes, and it was found that $\Delta G^0 = -7.5 \pm 0.3$ (inorganic) and -6.4 ± 0.4 (organic), in excellent agreement with our own findings. In the first work of this series [1] it was found that the stability of protonated diamines–inorganic polyanion complexes is a function of $n[\text{NH}_2 - (\text{CH}_2)_n - \text{NH}_2]$, whilst this is not true (as a first approximation) for organic

experimental conditions; in fact, it is not possible to exclude the formation of other species when concentrations of reactant are higher than those used in the present work. Moreover, it is possible that some quaternary species such as $AL(Cl)H_r$, $AL(Na)H_r$ are formed if NaCl is added in significant amounts. Nevertheless, the speciation model proposed in this work can be considered satisfactory, since other possible minor species may account for at least 5% with respect to total concentration of amines and anions. The formation of major species in protonated amine–polyanion systems has also been confirmed recently by UV–CD measurements [8]. Errors associated with overall formation constants are reported in Table 1 as three times the standard deviation. In general these uncertainties can be considered satisfactory, but we must consider that by including small systematic errors, formation constants may be affected by substantially higher uncertainties. Values of $\log K_{ij}$ (Table 2) are reported with only one decimal figure since they are affected by an error $3s > 0.1$ ($s = S.D.$).

3.6. Ionic strength and medium effects

The dependence on ionic strength of effective formation constants can be taken into account by a Debye Hückel type equation (see ref. [1] and references therein), when considering the formation of Na^+ –polyanion with Cl^- -protonated

amine complexes. Often in literature only apparent formation constants, which do not consider the formation of these species, are reported. Apparent formation constants are lower than effective ones and can be calculated as previously reported [8]. As an example, the interfering effect of Cl^- can be seen in Figs. 1 and 2 (high percentage of chloride complexes). For the main species (i.e. those of diprotonated amines with unprotonated polyanions, $\log K_{20}$) we have, at $I = 0.1 \text{ mol dm}^{-3}$ (NaCl) [8]:

$$\log K_{\text{effective}}(I = 0.1) = \log K(I = 0) - 0.34|z|$$

$$\begin{aligned} \log K_{\text{apparent}}(I = 0.1) \\ = \log K(I = 0) + 0.12 - 0.40|z| \end{aligned}$$

3.7. Relevance of protonated diamine–organic polyanion complexes

The relevance of these complexes can be deduced from Figs. 1 and 2. As one can see, high formation percentages are obtained even in very low concentration conditions. In the system H^+ - ptr - cit^{3-} , for $C_{ptr} = 0.1$ and $C_{cit} = 1 \text{ mmol dm}^{-3}$, at $pH = 7-8$, the species $(ptr)(cit)H_2^-$ accounts for $\sim 10\%$ of total ptr , and if we also consider chloride complexes, $\%[(ptr)(cit)H_2^- + (ptr)ClH_2^+] > 30$. Similar considerations can be made for the system H^+ - cdv - btc^{4-} (note that for this system Na^+ causes strong interferences, since Na^+ - btc^{4-} complexes are fairly stable, refs. [3–7]).

3.8. Comparison with analogous Na^+ and Ca^{2+} complexes

Inorganic anion–protonated diamine complexes show similar stability with respect to analogous Na^+ and Ca^{2+} species. As regards organic anions, we have a similar trend for double charged cations, Ca^{2+} and H_2A^{2+} (refs. [3,5,6] and this work), whilst there is a remarkable difference for Na^+ and HA^+ , as reported in Fig. 4. At present, too few data are available to make any inference from this fact. Nevertheless, since $\log K(\text{ammonium cation}) \geq \log K(Na^+, Ca^{2+})$, it is possible to affirm that the competitive interaction of the ammonium cation must be taken into account in biological fluids.

Fig. 4. Formation constants vs. anion charge for the reactions, $\text{M}^{2+} + \text{L}^{z-} = \text{ML}^{(2-z)}$, $\text{M}^+ + \text{L}^{z-} = \text{ML}^{(1-z)}$, ($\text{M}^+ = \text{Na}^+$, HA^+ ; $\text{M}^{2+} = \text{Ca}^{2+}$, H_2A^{2+} ; L = carboxylic anion).

3.9. Conclusions

The conclusions of this study can be summarized in the following points.

1. Organic polyanions form (as do inorganic ones) fairly stable complexes with protonated diamines (Table 1).
2. The stability of these species is strictly dependent on the charges involved in the formation reactions [Eqs. (2) and (3), Fig. 3, and Table 2].
3. For analogous species of inorganic and organic systems we have higher stability for inorganic species.
4. A simple relationship for ΔG^0 of single bond is proposed [Eq. (4)].

Abstract

The formation and stability of proton diamine-inorganic anion [Cl^- , SO_4^{2-} , HPO_4^{2-} , $\text{P}_2\text{O}_7^{4-}$ and $\text{Fe}(\text{CN})_6^{4-}$] complexes was studied potentiometrically [(H^+) -glass electrode] at 25°C. Several general formula ALH_r complexes are formed in these various systems. The stability of complexes formed between H_2A^{2+} and different anions ranges from one to six (log formation constants). The formation constants are slightly dependent on the length of the alkylic chain whilst they strongly depend on the anion charge. A general relationship [$\log K = -0.85 + 1.81z - 0.055n$] was found for the reaction $\text{H}_2\text{A}^{2+} + \text{L}^{z-} = \text{ALH}_r^{(2-z)}$ [L = inorganic anions, $\text{A} = \text{NH}_2 - (\text{CH}_2)_n - \text{NH}_2$ diamines with $n = 2 \dots 8$]. © 1998 Elsevier Science B.V. 1. Introduction

Biogenic amines are low molecular weight, highly charged polyamines and are present in all the cells of animal organisms and in those of many micro-organisms. The positively charged sites make the polyamines highly reactive towards a series of cellular molecules including DNA and RNA in all its forms. It has been demonstrated

that the addition of polyamines causes the accelerated entry of cells into the DNA duplication phase. Indeed, in vivo synthesis of biogenic amines manifests itself as soon as cells begin to replicate their own DNA and is due to the activity of the ornithine decarboxylase enzyme. Polyamines are, therefore, critical to the functioning of the cellular cycle, their main biological function being to stabilize the structure and activity of DNA and RNA. The most straightforward explanation of the stabilizing effect of polyamines on DNA is the neutralization of phosphate

* Corresponding author. Tel.: +39 90 393659; Fax: +39 +90 392827; e-mail: destefano@chem.unime.it

groups through the formation of very stable complex species. This hypothesis is confirmed, moreover, by the precipitation of DNA in the presence of high concentrations of polyamines because of the formation of intermolecular complexes. On the other hand, in highly concentrated (high ionic strength) cellular liquids, the presence of large amounts of Mg^{2+} hinders the protective action of these molecules presumably as a result of competition with it against phosphate groups.

Interactions between polyamines and phosphate groups have been demonstrated by Labadi et al. [1] who studied interactions between the pyrophosphate ion and various polyamines in aqueous solution using potentiometric and calorimetric methods. Their findings show that the presence of wholly protonated amines significantly increases the apparent acidity of the $\text{HP}_2\text{O}_7^{3-}$ and $\text{H}_2\text{P}_2\text{O}_7^{2-}$ ions. The most straightforward explanation for these apparent changes in protonation seems to be the formation of an adduct among the negatively charged phosphate ions and protonated ions. These results have been confirmed by a recent study in our laboratories [2]. The higher the charge of the interacting ions is, the more stable one can expect the adduct to be.

The stabilizing effect of mono and polycharged cations, and therefore of polyamines too, has also been demonstrated for the various forms of RNA including tRNA. The tRNA molecule in particular is converted from an inactive to an active form by the addition of monovalent cations (Na^+ , K^+) or Mg^{2+} and polyamines, the latter two in lower concentrations [3]. The tRNA molecule presents up to five strong bond sites for magnesium with formation constants in the order of $10^5 \text{ mol}^{-1} \text{ dm}^3$ [3], which proves the importance of this cation to the maintenance of the original structure and biological functions of tRNA. In vitro trials have shown that certain polyamines can replace magnesium, at least partially, in the stimulation of the biological activity of tRNA [4]. In general, all polyamines increase the stabilization of the structure and activity of nucleic acids, but the concentration necessary to achieve maximum stabilizing capacity varies according to the amines. Spermine has been shown to have the greatest stabilizing capacity with a maximum con-

centration of $1.67 \times 10^{-5} \text{ mol dm}^{-3}$, while higher concentrations of spermidine and diamines (cadaverine and putrescine) are necessary. A similar stabilizing effect is demonstrated by bivalent cations: Mg^{2+} and Mn^{2+} are always present in the stabilizing processes of phosphate groups as an effect of the formation of complex species. It is interesting to note that the protective effect of spermine is reduced in the presence of citrate. The formation of a particularly stable spermine–citrate complex would explain this behaviour. The free cellular concentration of polyamines can be estimated to be in the range $10\text{--}100 \text{ mmol dm}^{-3}$; however, considering that those present are in the main bonded with nucleic acids, it can be estimated that their overall concentration in cells is in the order of mmol dm^{-3} .

Despite the well recognized biological importance of polyamines (having been amply proven), few studies have been performed on their chemical behaviour, and in particular into their acid–base behaviour in biological fluids. Recently we reported several data on the formation of protonated amine-organic and inorganic polyanions [2,5–13].

This study describes an investigation of the formation and stability of the diamines putrescine (1,4-diaminobutane, *ptr*) and cadaverine (1,5-diaminopentane, *cdv*) with inorganic anions (Cl^- , SO_4^{2-} , HPO_4^{2-} , $\text{P}_2\text{O}_4^{4-}$ and $\text{Fe}(\text{CN})_6^{4-}$). Some other diamines were also considered [ethylenediamine (*en*), 1,2-diaminopropane (1,2-*dap*), 1,3-diaminopropane (1,3-*dap*), 1,6-hexanediamine (1,6-*d*) and 1,8-octanediamine (1,8-*d*)] for comparison. The study was performed using the (H^+ -glass electrode) potentiometric technique, at 25°C .

2. Experimental

2.1. Materials

Amines (ethylenediamine, 1,3-diaminopropane, 1,4-diaminobutane, 1,5-diaminopentane, Sigma products) were purified by transformation into the corresponding hydrochlorides, and were used in this form. Tetrasodium diphosphate (Analar BDH), hexacyanoferrate(II) [used in the form of

tetrasodium salt (Fluka, puriss.), sulphuric and phosphoric acids (Fluka purum.) were used without further purification. The purity of all the ligands, checked by potentiometric titrations, was always > 99.5%. Solutions of NaOH and HCl were prepared by diluting concentrated Fluka ampoules and were standardized against potassium biphthalate and sodium carbonate, respectively. Grade A glassware and twice distilled water were used for all solutions.

2.2. Apparatus

Potentiometric measurements were carried out with two different equipments: a) an Amel 337 potentiometer coupled with a Metrohm glass saturated calomel electrode; b) a Metrohm 654 potentiometer coupled with a combination Ross type electrode 8102; the titrant was delivered by a Metrohm Dosimat 665 dispenser. The estimated accuracy of both systems was ± 0.15 mV and ± 0.003 cm³ for e.m.f. and titrant volume readings, respectively. A computer program was used for the acquisition of the potentiometric data. The titration program allows the evaluation of equilibrium potential values and determines the amount of titrant based on the actual buffering properties on the titrated solution, so that there is a difference in pH values of 0.05–0.08 between two successive readings; the e.m.f. was considered to be stable when the variation was less than 0.1 mV within 5 min.

2.3. Procedure

25 ml of the solution containing the inorganic ligand, and the amine hydrochloride under study were titrated with standard NaOH up to 80–90% neutralization. Titrations were performed without adding background salt (except for the protonation of amines) in order to minimize the interference of Na⁺ (which forms complexes with polyanions) and Cl⁻ (which forms complexes with amines, see Section 3, Results). Concentrations used in the experiments were: $C_{\text{amine}} = 5\text{--}20$ mmol dm⁻³, $C_{\text{anion}} = 2.5\text{--}40$ mmol dm⁻³ (lower concentrations for higher charged polyanions; for Cl⁻ 0.1–1 mol dm⁻³). Separate titrations of HCl

at about the same ionic strength (adjusted with NaCl) as the sample under study, were carried out to determine the standard electrode potential E^0 . A stream of purified and presaturated N₂ was bubbled through all solutions in order to exclude the presence of CO₂ and O₂. Small quantities of Na⁺ (titrant NaOH) and Cl⁻ (amine hydrochlorides) are brought into the solution and the relative interactions with polyanions and diamines were taken into account in the calculations.

2.4. Calculations

The computer program ESAB2M [14] was used to calculate the purity of the reagents and to refine all the parameters related to the calibration of the electrode system. The computer programs BSTAC [15] and STACO [11] were used to calculate the formation constants. The dependence of formation constants on ionic strength was taken into account by using the Debye–Hückel type equation [11,16]

$$\log \beta = \log {}^T\beta - z^* \frac{\sqrt{I}}{(2 + 3\sqrt{I})} + CI + DI^{3/2} \quad (1)$$

$$C = c_0 p^* + c_1 z^*$$

$$D = d_1 z^*$$

$$p^* = \sum p_{\text{reactants}} - \sum p_{\text{products}}$$

$$z^* = \sum z_{\text{reactants}}^2 - \sum z_{\text{products}}^2$$

(β = formation constants; ${}^T\beta$ = formation constant at zero ionic strength; p and z are the stoichiometric coefficients and the charges, respectively). For the calculations performed in this work we used the values of $c_0 = 0.10$, $c_1 = 0.23$ and $d_1 = -0.1$ [16]. The computer programs STACO and BSTAC are able to perform calculations in non constant ionic strength. The different equilibria considered in this work were expressed as follows:

$$(K_{ij}, \quad r = i + j) \quad (2)$$

3. Results and discussion

3.1. Protonation constants

Protonation constants of polyanions have already been studied [17–20]. As is known, these polyanions form weak complexes with the sodium ion [21], whose stability increases with the negative charge. These complexes were taken into account in the calculation relative to the formation of mixed proton–polyanion–amine species (experiments were performed without adding background salt, but Na^+ (coming from titrant NaOH). Protonation constants of 1,3-*dap*, *ptr* and *cdv* were determined in this work and are reported in Table 1, together with those of *en*, 1,2-*dap*, 1,6*d*, and 1,8*d* previously reported [5,7,22]. The dependence on ionic strength of amines was taken into account in two ways, i.e. a) by considering the formation of chloride complexes (see below) and b) by considering only apparent protonation constants. Apparent protonation constants vs. I can be expressed by Eq. (1) with $D = 0$ and $C(\log K_1^{\text{H}}) = 0.31 \pm 0.01$, 0.33 ± 0.02 and 0.26 ± 0.02 ; $C(\log \beta_2^{\text{H}}) = 0.61_5 \pm 0.015$, 0.57 ± 0.03 and 0.59 ± 0.03 for 1,3-*dap*, *ptr* and *cdv*, respectively.

3.2. Chloride complexes

Protonated diamines form weak complexes with chloride (AClH^0 and AClH_2^+), whose stability constants are reported in Table 1. These constants follow the general trend found for several other amine–chloride complexes [21]. A mean value $\log K_{20} = 0.73$ is observed which is equal to that of analogous species of some other amines [22–24] (diethylenetriamine, triethylenetetramine, tetraethylenepentamine and pentaethylenhexamine), i.e. $\log K = 0.73$. Though quite weak, AClH ,

complexes may be relevant in the speciation of natural fluids where Cl^- ions are generally present in high concentrations. As an example, in Fig. 1 we report the distribution of the species in the system $\text{H}^+ - \text{ptr} - \text{Cl}^-$ ($C_{\text{Cl}} = 0.5 \text{ mol dm}^{-3}$), vs. pH. As can be seen the species $(\text{ptr})\text{ClH}_2^+$ is present in a large pH range (< 8) in a very high percentage, $> 50\%$, with respect to putrescine.

3.3. Sulphate and hydrogen phosphate complexes

Protonated amines form two species with SO_4^{2-} , i.e. $\text{A}(\text{SO}_4)\text{H}^-$ and $\text{A}(\text{SO}_4)\text{H}_2^0$, and three species with HPO_4^{2-} , i.e. $\text{A}(\text{PO}_4)\text{H}_2^-$, $\text{A}(\text{PO}_4)\text{H}_3^0$ and $\text{A}(\text{PO}_4)\text{H}_4^+$, whose formation constants are reported in Tables 2 and 3. The mean value $\log K_{20} = 2.5$ is in accordance with the values found for several diprotonated amines with L^{2-}

type anions, both organic and inorganic [13]. For the complex $(\text{tetren})(\text{HPO}_4)\text{H}_2^0$ (tetraethylenepentamine, *tetren*) we found previously $\log K_{20} = 2.3$. As regards the complex $\text{A}(\text{HPO}_4)\text{H}^-$ and $\text{A}(\text{SO}_4)\text{H}^-$, it is interesting to note that the value of $\log K_{10}$ for both anions is fairly close to the values of NaSO_4^- and $\text{NaH}(\text{PO}_4)^-$ stability constants ($\log K = 0.73$ and 1.1 respectively) [17,18].

3.4. Pyrophosphate complexes

Diamines form four species with $\text{P}_2\text{O}_7^{4-}$, namely $\text{A}(\text{P}_2\text{O}_7)\text{H}_r^{(r-4)}$, $r = 1 \dots 4$. The stability of these complexes (Table 4) is quite high, as can be seen in the speciation diagram (Fig. 2). In a previous work [2] we reported the stability of several protonated amine–pyrophosphate complexes, where we found that for the equilibrium $\text{H}_2\text{A}^{2+} + \text{P}_2\text{O}_7^{4-} = \text{A}(\text{P}_2\text{O}_7)\text{H}_2^{2-}$ $\log K = 5.4, 5.5,$

^d This work

4.7 and 5.0 for diethylenetriamine, triethylenetetramine, tetraethylenepentamine and pentaethylenhexamine, respectively, in excellent agreement with values reported here for diamines. It is to be noted that stability decreases appreciably with n (n = number of $-\text{CH}_2-$ in the alkylic chain) and this will be discussed later. Labadi et al. [1] studied 1,3-*dap*, *ptr* and *cdv*- $\text{P}_2\text{O}_7^{4-}$ complexes potentiometrically and calorimetrically, in $(\text{CH}_3)_4\text{NCl}$ 0.5 or 1 mol dm^{-3} . In their experimental conditions only the species $\text{A}(\text{P}_2\text{O}_7)\text{H}_2^{2-}$ was found. At $I = 0.5 \text{ mol dm}^{-3}$ log K_{20} was 2.5, 2.1 and 1.9 for the three amines, respectively. Also for pyrophosphate complexes we observe that the formation constants of amine species have values similar to those of Na^+ species [19] (in particular for *en*, 1,6*d* and 1,8*d*, log $K_{10} \cong 2.6$; log $K_1 = 2.4$ for Na^+ species).

3.5. Hexacyanoferrate(II) complexes

Diamine complexes formed with $\text{Fe}(\text{CN})_6^{4-}$ are the same as for pyrophosphate. Their stability

(Table 5) is quite high and is comparable to that of mono and diprotonated amines- $\text{Fe}(\text{CN})_6^{4-}$ species already studied [8]. For the reaction $\text{H}_2\text{A}^{2+} + \text{Fe}(\text{CN})_6^{4-} = \text{A}[\text{Fe}(\text{CN})_6]\text{H}_2^{2-}$ we have a mean value log $K_{20} = 4.5$. In a previous work [8], we found log $K_{20} = 4.9$ and 4.4 for diethylenetriamine and triethylenetetramine, respectively. The same remarks, as in Sections 3.3 and 3.4, can be made on the similarity in the stability of Na^+ and HA^+ complexes.

3.6. Triphosphate complexes

These complexes have been studied previously [11] (for *en*, 1,6*d* and 1,8*d*), and their relative formation constants, log K_{ij} , range between 3.3 and 6.9. On the basis of the general trend of data in this work, we also estimated log K_{ij} values for 1,3-*dap*, *ptr* and *cdv*, namely 6.6, 6.3 and 6.0 (log K_{20}); 4.6, 4.5, 4.4 (log K_{21}) and 3.4, 3.4 3.3 (log K_{22}). According to the high charge of $\text{P}_3\text{O}_{10}^{5-}$, the species formed with diammonium cations are very stable. The stability of these complexes fol-

lows the same trend as HPO_4^{2-} and $\text{P}_2\text{O}_7^{4-}$; it increases linearly with the anion charge.

3.7. Structure and charge-stability relationships

The amines studied here have a general formula $\text{NH}_2 - (\text{CH}_2)_n - \text{NH}_2$ (except 1,2-diaminopropane, which can be assimilated to ethylenediamine, $n = 2$). In a previous work [7], on the basis of much fewer data, it was hypothesized that the stability of $\text{ALH}_r^{(r-z)}$ complexes is an inverse function of n , (i.e. the distance between the two aminogroups negatively influences the formation of anion complexes). In Fig. 3, where $\log K_{2j}$ ($j = 1$ for all the systems, but pyrophosphate

where, $j = 1$ and 2) is reported vs. n , we can see that this hypothesis is confirmed. The $d \log K_{ij}/d n$ slope is about -0.1 , which is quite significant. Moreover, one can observe that this slope is rather more negative for complexes of polyanions with higher charges. Data from ref. 1 are also in accordance with this trend, $\log K_{20} = 3.4 - 0.3n$ (diamine–pyrophosphate complexes, $I = 0.5 \text{ mol dm}^{-3}$). However, the most important factor influencing the stability of protonated amine–polyanion complexes is the charge of the polyammonium cation. The relationship between $\log K_{ij}$ and z is linear, and an example is shown in Fig. 4 (cadaverine complexes). In this Figure, and in the subsequent calculations, hexacyanoferrate(II) complexes are neglected (see below). Data in Fig. 4 can be expressed by the equation

$$\log K_{2j} = -1.0 + 1.63 (\pm 0.10)z$$

with a correlation coefficient > 0.99 and a mean deviation (in $\log K_{2j}$) < 0.1 . Now dependence on both z and n can be taken into account together, by the equation

$$\log K_{ij} = -0.85 + 1.81 (\pm 0.03)z - 0.05 (\pm 0.005)n \quad (3)$$

with a mean deviation (in $\log K_{2j}$) < 0.15 .

The stability of hexacyanoferrate(II) complexes is considerably lower than expected on the basis of Eq. (3). This is not surprising since in $\text{Fe}(\text{CN})_6^{4-}$ anion charge dispersion must be higher than in the other polyanions.

3.8. Relevance of inorganic polyanion-protonated diamine complexes

Data reported in this work, together with previous findings, confirm that in solutions containing protonated diamines and polyanions a significant part of these components form mixed species, $\text{ALH}_r^{(r-z)}$. In particular, biogenic amines having high $\log K^{\text{H}}$ values, form stable mixed diprotonated species in the physiological pH range. In the speciation diagram of the pyrophosphate–putrescine system, we see that even for very low concentrations (Fig. 2B, $C_{\text{ptr}} = C_{\text{pyrophosphate}} = 10 \mu\text{mol dm}^{-3}$), very high percentages of mixed species are found: at $\text{pH} = 7.4$ % $[(\text{ptr})(\text{P}_2\text{O}_7)\text{H}_3^-] +$ %

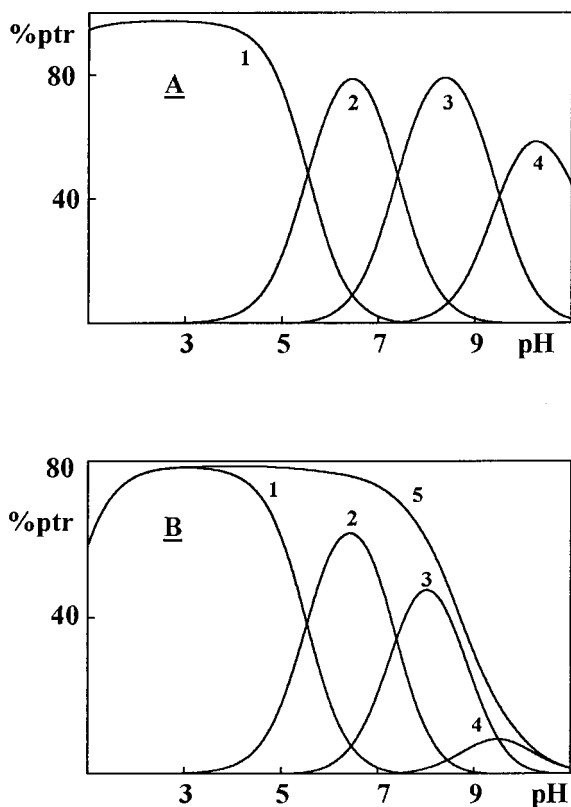

Fig. 2. Distribution of species in the system H^+ –putrescine– $\text{P}_2\text{O}_7^{4-}$ vs. pH. ^a For symbols, see footnote to Table 1.^b A = amine;^c Ref. [8];^d This work.

$[(ptr)(\text{P}_2\text{O}_7)\text{H}_2^{2-}] > 70\%$ of total components. This means that the hypothesis that in vivo these reactions can be of some interest, is now quantitatively confirmed. Moreover, if we consider other important natural fluids, such as seawater ($\text{pH} = 8.2$), it is possible to infer that low molecular ligands containing aminogroups interact significantly with polyanions. Data reported in this work refer to a temperature of 25°C , whilst natural and biological fluids generally have very different temperatures (e.g. 37°C). A few calorimetric

measurements [1,25] showed that for the reaction in Eq. (2) we have fairly low ΔH^0 values, and therefore quantitative data at $T \neq 25$ should be not very different from ours. The relevance of inorganic anion–diamines cation complexes can also be considered in comparison with the relative alkali and alkaline earth cation complexes. As discussed in preceding sections, Na^+ complexes have similar stability in comparison with diammonium complexes studied here. As regards Ca^{2+} and Mg^{2+} complexes for SO_4^{2-} $\log K = 2.29$ and

Fig. 3. Values of $\log K_{ij}$ vs. n , amines: $\text{NH}_2-(\text{CH}_2)_n-\text{NH}_2$ (1,2-diaminopropane $n = 2$) [$i = 2$; $j = 1$ for all anions, but for pyrophosphate, $j = 1$ and 2].

Fig. 4. Values of $\log K_{ij}$ vs. z (charge of polyanions), for cadaverine-anion species, at $I=0 \text{ mol dm}^{-3}$ and $T=25^\circ\text{C}$ [$i=2$; $j=1$ for all anions, except for pyrophosphate, $j=1$ and 2].

2.31 [26], and for $(en)(\text{SO}_4)\text{H}_2$ $\log K = 2.42$, i.e. in this case too stability is similar. Therefore the hypothesized competition between inorganic and ammonium cations in biochemical reactions is explained here quantitatively.

3.9. Conclusions

The main conclusions of this investigation are as follows:

1. Different diamines $\text{NH}_2-(\text{CH}_2)_n-\text{NH}_2$ ($n = 2\dots 8$) form complexes $\text{ALH}_r^{(r-z)}$ with polyanions L^{z-} having similar stability.
2. The stability of $\text{ALH}_r^{(r-z)}$ species depends on n (fairly) and z (strongly), [see Eq. (3)].
3. Mixed proton-amine-polyanion species are formed in significant amounts even at very low concentrations (see Fig. 2B).
4. The stability of Na^+ and Ca^{2+} complexes with inorganic anions is comparable to that of corresponding protonated amine complexes.

Abstract

1,5-Bis[(2-pyridyl)-3-sulphophenyl methylene] thiocarbonohydrazide (PSTH) immobilized on an anion-exchange resin (Dowex) has been used for the on-line preconcentration of mercury from biological samples and waters prior to its determination by inductively coupled plasma atomic emission spectroscopy. The metal was eluted from the column using a solution of 2 M HNO₃ and mixed on-line with SnCl₂. The optimum experimental conditions were evaluated for the continuous preconcentration of Hg, the direct generation of mercury vapour and the final determination of this element by ICP–AES. The enrichment, together with low blank levels of the optimized procedure, allow the simple determination of this toxic element at concentrations down to a few nanograms per milliliter. The proposed method has a linear calibration range 5–1000 ng ml⁻¹ of mercury, with a detection limit of 4 ng ml⁻¹ (*S/N* = 3) and a sampling rate of 40 h⁻¹, investigated with a 9 ml sample volume. The precision of the method (evaluated as the relative standard deviation obtained after analyzing ten series of ten replicates) was ± 3.6% at the 10 ng ml⁻¹ level of Hg(II) and ± 1.3% at the 100 ng ml⁻¹ level. The accuracy of the method was examined by the analysis of certified reference materials. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Mercury; Preconcentration; Ion-exchange; Inductively coupled plasma atomic emission spectrometry

1. Introduction

The toxic effects of mercury are well known. For this reason, sensitive, fast, reproducible and

accurate analytical methods are required for the determination of this element. In routine laboratory measurements, Hg is determined in its atomic form in the vapour phase using atomic spectroscopic methods. However, the direct determination of (ultra)trace amounts of mercury in complicated matrices is usually difficult owing to

* Corresponding author. Tel.: +34 5 2131887; fax: +34 5 2132000; e-mail: jm_cano@uma.es

matrix interferences and/or insufficient detection power. Consequently, a preliminary preconcentration and/or separation is required. Thus, recently, Burrini et al. [1] have developed a sensitive and accurate method for the determination of mercury in urine by ET–AAS using complexation with dithizone and extraction with cyclohexane. However, this extraction procedure cannot be combined with ICP–AES due to the difficulties of introducing organic solvents into the plasma of an ICP spectrometer. In addition, the use of a common batch-type solvent extraction procedure was found to be time consuming and incompatible with the intrinsic speed of ICP–AES analysis.

Column solid-phase extraction has some advantages over liquid–liquid extraction: the possibility of combination with AAS as well as with ICP–AES, allows preconcentration from a larger sample volume, establishing higher concentration factors, simple storage and transportation of the pre-treated samples [2–5]. Column preconcentration using chelating resins such as Chelex-100 [6,7], quinolin-8-ol immobilized on porous glass [8], or silica [9] and poly(dithiocarbamate) [10] have been used for the enrichment of natural waters and biological materials. However, some resins, such as those based on poly(dithiocarbamate), are reluctant to release the bound analyte, and the resin is usually dissolved prior to analysis [11,12]. Thus, Alexandrova et al. [13] report a method for the preconcentration of trace metals prior to their measurements by AAS or ICP–AES; for ICP–AES measurements a quantitative elution was obtained with 4 M HNO₃ permitting the determination of Cd, Mn, Cu, Fe, Ni and Pb, however, the procedure was found to be inappropriate for Hg or Co determination, owing to the formation of stable dithiocarbamate complexes, which cannot be destroyed at an HNO₃ concentration of 4 M. Arpadjant et al. [14] presented an alternative method for preconcentration of Hg from water samples, for ICP–AES measurements the physically immobilized organic chelating ligand together with the analyte–dithiocarbamate complex were completely dissolved in methanol; the methanol solution was diluted with water and then nebulized into the ICP–AES system. For each sample a new sorption column was applied.

From data presented it can be concluded that a detection limit of 0.12 ng ml⁻¹ can be achieved by processing 150 ml samples. However, this type of elution, or more correctly, of dissolution of the preconcentrated element is undesirable as it is labour intensive, time consuming and a potential source of contamination.

Chelation exchange resins containing iminodiacetate functional groups have been used extensively to isolate the first-row transition metals and analytes such as cadmium and lead from complex matrices such as sea-water and biological samples. Such uses have been reviewed [15]. However, many of these techniques were performed off-line.

The incorporation of column solid-phase extraction in the FI systems coupled on-line to atomic spectrometers offer some interesting improvements. The major improvements are, in general, the possibility of working in a closed system with a significant reduction of airborne contamination and a fairly high sampling frequency, which justifies current trends towards an increasing use of this preconcentration technique. To date, various kinds of separation techniques have been adapted to FI on-line separation and preconcentration ICP–AES systems, these procedures were compiled in a recent monograph [16]. The majority of work conducted in this area has been associated with preconcentration on packed columns either by exchange or by adsorption. Of particular importance, is the use of chelating resins as packing materials due to their ability to preconcentrate metal ions from very dilute solutions, thus allowing detection limits to be greatly improved [17]. For this reason, synthesis of chelating resins having good selectivity is a subject of continuing interest and importance. Thus, in the last years, a number of chelating resins containing various functional groups have been reported [18–21].

In this article, a FI-ICP–AES method for the determination of trace amounts of mercury is described. A new chelating ion-exchange resin was prepared for the separation and preconcentration of mercury from different matrices. The efficiency of the resin for Hg(II) preconcentration was studied in detail, with respect to pH, flow rate, precision, interferences of the other ions, etc. The

manifold used involve a column included within the sample loop of an injection valve, in this FI system the metal was eluted from the column and mixed on-line with SnCl_2 , mercury vapour was generated directly and separated via a gas–liquid separator. The accuracy of this automatic method was examined by the analysis of certified reference materials.

2. Experimental

2.1. Apparatus

The ICP–AES system used was a Perkin–Elmer 40 sequential emission spectrometer equipped with the Perkin–Elmer AS-90 autosampler and controlled by an IBM XT-486 personal computer. The spectrometer output was connected to a PE Nelson Model 1020 personal integrator. The plasma operating conditions used in this work are summarized in Table 1.

Table 1
Optimum operating conditions for FI-ICP determination of Hg

ICP system	
Wavelength	253.652 nm
R.f. generator	
Frequency	40 MHz
Incident power	1.1 kW
Photomultiplier voltage	600 V
Plasma gas flow rate	12 l min ⁻¹
Auxiliary gas flow rate	0.6 l min ⁻¹
Plasma viewing height	15 mm (above the induction coil)
FI system	
Internal diameter of coils	0.8 mm
Mixing coil length	100 cm
Sample flow rate	9 ml min ⁻¹
Elution flow rate	5 ml min ⁻¹
Argon carrier flow rate	80 ml min ⁻¹

A schematic diagram of the automatic on-line preconcentration system modified from the Perkin–Elmer FIAS 400 is presented in Fig. 1. Pump P_2 was connected to the sampler capillary and the microcolumn through the four-way rotary valve, this valve had the column connected within the sample loop. The micro-column was a glass tube (3 cm × 3 mm i.d.), and packed with the chelating resin to a height of 1 cm, in both ends of microcolumn polyethylene frits (Omnifit) were fixed to prevent material losses. Transport lines and mixing coils were made using 0.8 mm i.d. PTFE tubing. A classical gas–liquid separator [22] was used. The mini-column was initially flushed with 2 M nitric acid; subsequent use of 2 M HNO_3 as eluent in each operating cycle was sufficient to make it ready for re-use.

For sample digestion, a microwave oven, Pro-labo TX-32, was used.

All glassware used were washed with 10% nitric acid for one day and rinsed with deionized water just before use.

2.2. Reagents

Analytical-reagent grade chemicals were used throughout. Doubly de-deionized water prepared from a Milli-Q purification system (Millipore) was used throughout this work.

A stock solution of Hg(II) was prepared from the nitrate (Merck) and standardized complexometrically; standards of working strength were made by appropriate dilution as required, immediately prior to use.

1,5-bis[(2-pyridyl)-3-sulphophenyl methylene] thiocarbonohidrazide (PSTH) was prepared and purified as described under Synthesis of the chelating agent. The anion-exchange resin used was Dowex 1 × 8–200, 100–200 mesh (Aldrich). The 0.03 M tin(II) chloride solution was prepared from $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ (Carlo Erba). A pH 4.7 buffer was prepared by mixing 25 ml of 0.5 M sodium acetate and 25 ml of 0.5 M acetic acid and diluting to 100 ml with deionized water.

2.3. Synthesis of the chelating agent

A 2 g mass of 2-benzoylpyridine (Aldrich) was

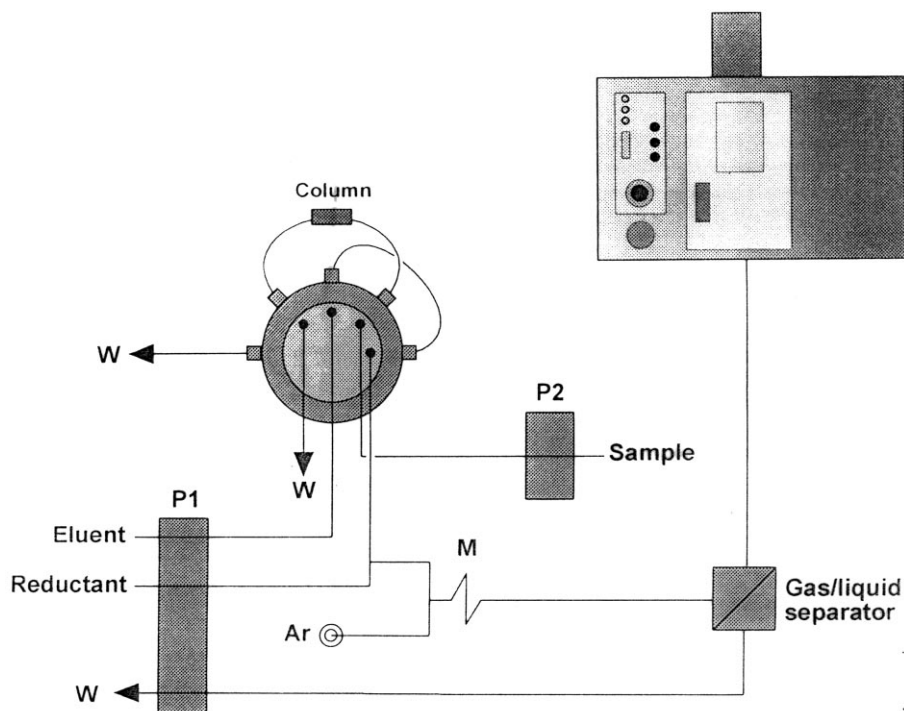

Fig. 1. Schematic diagram of FI manifold for the determination of mercury: P₁, P₂, peristaltic pumps; M, mixing coil (length 100 cm, i.d. 0.8 mm); Ar, stream of argon (80 ml min⁻¹); W, waste. See text for other details.

dissolved in 20 ml of concentrated sulphuric acid (Merck) at 0°; the solution was allowed to stand for about 2 h. and mixed with 180 ml of ether. The mixture was then cooled in a refrigerator and the product that formed, 2-benzoyl(3-sulphonyl) pyridine, was filtered, washed with ether, recrystallized from ethanol:water (1:1) and dried. A solution of 1.54 g of this product in 75 ml of deionized water was mixed with a solution of 0.12 g of thiocarbonohydrazide (Aldrich) in 10 ml of deionized water, then ten drops of glacial acetic acid were added. The mixture was refluxed and stirred for 2 h. After cooling to room temperature, the reaction mixture was placed in a refrigerator and, after a short time, orange crystals were formed. The solid (PSTH) was filtered, washed with deionized water, dried and stored in a vacuum desiccator. Yield is about 78%. Elemental analysis confirmed the purity of the reagent and its structure was verified by IR and NMR spectroscopy.

2.4. Preparation of the chelating resin

After removal of the fines, the Dowex ion-exchange resin was treated with 1 M HCl, collected by filtration and washed with deionized water until pH 7. Then was coupled to PSTH by adding to it 10 ml of a 0.01 M solution of PSTH in 5 M NaOH for each gram of resin. The mixture was stirred and allowed to stand for about 24 h.

2.5. General procedure

2.5.1. On-line preconcentration and elution

With the manifold described in Fig. 1 and under the optimum instrumental conditions show in Table 1. During the 1 min sample loading period, valve in the 'fill' position, a 9 ml min⁻¹ flow of sample (standard or blank) at pH 4.7 buffered with sodium acetate-acetic acid is pumped (via pump P₂) through the microcolumn (located in the loop of the valve) The metal is adsorbed on the sorbent mini-column and the

sample matrix sent to waste. During preconcentration, a 5 ml min^{-1} flow of eluent (2 M HNO_3) and reductant (0.03 M SnCl_2) are being aspirated from the containers by the pump P_1 to establish the baseline of the readout and to stabilize the plasma. At the beginning of the 30 s elution stage, the valve position is changed and the sample pump P_2 is stopped. When the valve is in the 'inject' position, the eluant passes through the column. Thus, the accumulated mercury ion is eluted at an elution rate of 5 ml min^{-1} and merges with a 5 ml min^{-1} flow of reductant in the mixing coil M (length 100 cm, i.d. 0.8 mm), where direct generation of mercury vapour takes place. The gas generated and the solvent are then passed into the gas-liquid separator which provides a separation of gases from liquid. The liquid is drained and the generated mercury vapour is swept into the ICP torch by a stream of argon (80 ml min^{-1}). Calibration plots for Hg were measured from six standard solutions within the concentration range $5\text{--}1000 \text{ ng ml}^{-1}$. Peak heights were used as analytical measurements.

2.5.2. Sample preparation

The certified reference materials (CRMs) analyzed to determine the accuracy of the proposed procedure were: Community Bureau of Reference (BCR), CRMs 397 Human Hair; Institute of Standards and Technology (NIST), Standard Reference Materials (SRMs) 2670 freeze-dried urine. The samples were first dried in accordance with the instructions of the respective analysis certificates and were prepared by microwave digestion. The working conditions of the microwave oven are listed in Table 2. After digestion, the pH of the solutions were adjusted to 4.7 with concentrated NaOH and buffer solutions and finally, the samples were diluted to 50 ml with deionized water in a calibrated flask. Analysis of each sample, in triplicate, was carried out as described in Section 2.5, General procedure, using a calibration graph.

Sea water was collected in polypropylene bottles previously cleaned by soaking in 0.1 M hydrochloric acid. Samples were filtered by using a membrane of $0.45 \mu\text{m}$ pore size, acidified to 0.1% (v/v) with concentrated HNO_3 and stored frozen until analysis.

3. Results and discussion

3.1. Characteristics of the PSTH

The solubilities in several solvents of the organic ligand was determined. The reagent is easily soluble in polar organic solvents, e.g. dimethylformamide, ethanol, methyl isobutyl ketone and is also soluble in alkaline solution and slightly soluble in water.

Thermogravimetric curves were recorded, the reagent was stable up to 100° ; a decrease occurs between 100 and 200° , this fact can be attributed to the loss of six molecules of water. Thus, elemental analysis gave the following results: C 44.01%, H 4.37%, N 11.99%; $\text{C}_{25}\text{H}_{18}\text{N}_6\text{S}_3\text{O}_6 \cdot 6\text{H}_2\text{O}$ requires: C 44.77%, H 4.47%, N 12.53%.

The infrared spectrum of the reagent (KBr pellet) is complicated because the aromatic portion of the molecule produces numerous bands, the overlap of which makes detailed assignments difficult. The band at 1204 cm^{-1} was attributed to C=S stretching and the bands at 3107 cm^{-1} and at 1503 cm^{-1} were assigned to N-H and C=N stretching, respectively.

The ultraviolet spectra of the reagent in various solvents showed intense $n \rightarrow \pi^*$ bands between 200 and 390 nm, as expected for this system. On the other hand, the ultraviolet spectra of aqueous PSTH solutions are pH dependent. Because sulphonic groups are acid-strong, PSTH acts habitually in solution as a charged compound. The other pK values (pK_2 and pK_3) were calculated from the variation of absorbance with pH applying the customary Stenstrom and Goldsmith [23] and Sommer [24] methods. The values obtained are: $pK_2 = 3.3$ and $pK_3 = 10.2$. The pK values are the arithmetic means of the values obtained from measurements at three different wavelengths. The second ionization constant can be attributed to the deprotonation of the nitrogen atom in the pyridine rings (on comparison with those of similar compounds); owing to the large distance between the two pyridine nitrogen atoms, the values of their ionization constants would be expected to be similar and hence they are not distinguishable by spectrometry. pK_3 is due to the deprotonation

Table 2

of the –SH group (which is in tautomeric equilibrium with the C=S group), this process is typical of all thiocarbonhydrazones and thiosemicarbazones. Since the ligand is an anion above pH 10, it is strongly retained by anion exchange resins.

The reaction of different cations with PSTH were tested at different pH values. The characteristics of the most important complexes are summarized in Table 3. The data were obtained from the appropriate spectra, which were measured in the presence of an excess of the reagent at those pH values which facilitate the formation of the different complexes. Since the reagent reacts with many metal ions forming stable complexes, if a solution of these ions at the appropriate pH are passed through such a column, the metals should be complexed and removed from solution.

3.2. Separation and determination of mercury

To optimize the system, main efforts were focused on the conditions for sample loading and mercury eluting from the column, as well as the analytical flow system which was coupled on-line with the preconcentration and separation unit in order to obtain highly sensitive, accurate and reproducible results.

3.2.1. Optimization of experimental parameters

Chemical parameters including sample acidity, reductant concentration, FI variables (mixing coil, sample flow rate, eluent flow rate, etc) and ICP–

AES parameters were optimized according to the procedure described in Section 2.5.1, On-line preconcentration and elution.

It is known that strong acids are effective in dissociating complexes and releasing free metal ions. In this study a 2 M HNO₃ solution was chosen as eluant. In the initial study the stability of the PSTH–Dowex resin was studied experimentally in acidic, neutral and basic media by observing any physical changes occurring in the material, the results obtained showed that the resin was stable over a wide pH range of pH < 0–13.

Since the solution pH affects the extent of complexation which in turn determines the percentage of metal retained by the resin, the preconcentration of mercury from solutions buffered at different pH was studied. The pH from 2.0 to 5.0 was adjusted using sodium acetate–acetic acid buffer and from pH 5.0 to 11.0 using borax–boric acid buffer. The results (mean ± S.D. for three replicate measurements) are shown in Fig. 2. These results indicated that the optimum pH range was around 4.5–6.5. All subsequent studies were carried out at pH 4.7.

Preliminary tests showed that the sample volume was not an important factor when the mass of analyte arriving at the column was kept constant. The influence of the sample flow rate was studied using a constant flow rate of eluant and reductant. For this purpose, 50 ml of samples containing 800 ng of mercury were brought to pH 4.7 and passed through the column at different sample flow rate (the flow rate was varied by changing the speed of the sample pump). The results were essentially the same for flow rate of 6, 8 and 9 ml min⁻¹. It is probable that even faster flow rates would have been successful with a faster pump.

The effect of sample loading time on the emission signal of 100 ng ml⁻¹ Hg was tested at a sample flow rate of 9 ml min⁻¹. The signal increased almost linearly up to 12 min preconcentration time, after which the slope decreased gradually, presumably as a result of an insufficient capacity of the resin. Sensitivity enhancements gained by increasing the sample loading time, however, the loading time selected in the experi-

Table 3

Fig. 2. Influence of pH on the preconcentration of mercury.

ment was 60 s, in order to achieve high sampling frequency with a reasonable degree of sensitivity. Loading time may be higher for samples with low concentrations of mercury.

The influence of the flow rate of elution on sensitivity and precision for triplicate determinations of 100 ng ml^{-1} Hg was investigated in the range $1\text{--}6 \text{ ml min}^{-1}$. The results (mean \pm S.D., $n = 3$) are shown in Fig. 3. As can be seen, the peak height increases with increasing elution flow rate. The precision, however, worsened at flow rates $> 5 \text{ ml min}^{-1}$, possibly due to the high pressures produced. As a compromise between analytical sensitivity and precision, a elution flow rate of 5 ml min^{-1} was chosen. The recommended dissolution period is 30 s.

The influence of mixing coil length was also examined to ensure a homogeneous mixture between the sample and SnCl_2 solutions. Tubing coils (0.8 mm i.d.) of different lengths (0–200 cm) were tested. The ICP emission signals were constant for coil lengths ≥ 50 cm, so a 100 cm coil was chosen. To determine the reductant concentration necessary to quantitative generation of mercury vapour, 50 ml volumes of sample containing 800 ng of mercury at pH 4.7 were passed

through the resin and the SnCl_2 concentration was varied from 0.0005 to 0.03 M. At each corresponding reductant level, 5 ml min^{-1} flow of reductant was used. The results obtained showed that the peak heights remains constant for reductant concentrations equal or greater than 0.02 M. A concentration of 0.03 M was used in practice.

The effect of the argon carrier flow rate on emission signals was also examined. The results obtained showed that the peak height increased with increasing argon flow rate up to 80 ml min^{-1} ; at values $> 80 \text{ ml min}^{-1}$ the peak decrease. Therefore, an argon flow rate of 80 ml min^{-1} was chosen.

Using the minimum background equivalent concentration, BEC, as the optimization criterion, the following wavelengths were investigated: 194.227, 253.653, 296.728, 435.835, 265.204, 302.150 and 365.483 nm. From these wavelengths, measurement made at 253.653 nm produced the most intense emission, thus, this Hg line was selected for this work. Other operating ICP–AES variables such as photomultiplier voltage and plasma observation height were established to achieve the best signal-to-noise (S/N) ratios. The results are given in Table 1.

Fig. 3. Influence of eluent flow rate (ml min^{-1}).

3.2.2. Performance of the method

Under the optimum conditions, with the use of a 60 s preconcentration time, a sample flow rate of 9 ml min^{-1} and an elution flow rate of 5 ml min^{-1} , a linear calibration graph was obtained at least from 5 to 1000 ng ml^{-1} of Hg(II) with a regression coefficient of 0.999. The signal appeared 10 s after sample injection. Within 30 s after injection, the FI system was ready for the next injection, thus giving a sampling rate of about 40 per h.

The enrichment factor (EF), defined as the ratio of the slopes of the linear section of the calibration curves before and after the preconcentration, was 10.1. The concentration efficiency (CE) defined as the product of the enrichment factor EF and the sampling frequency in number of samples analyzed per hour was 7.8 and the consumptive index defined as the volume of sample, in milliliters, consumed to achieve a unit EF, was 0.8 ml. The phase transfer factor (P), defined as the ratio between the analyte mass in the original sample and in the concentrate was 0.6.

The detection limit defined as the concentration of analyte giving a signal equivalent to three times the standard deviation of blank signal plus the net blank intensity was measured to be 4 ng ml^{-1} , the absolute blank value was obtained by using the preconcentration and determination procedures with deionized water buffered at pH 4.7.

The results of including significant levels of possible interferences are presented in Table 4. The elements which can be chelated by the column will compete with mercury for the active sites. If the interferent is more strongly chelated on the column, or in a sufficiently high concentration, the preconcentration of mercury will be reduced.

The precision of the method (evaluate as the relative standard deviation obtained after analyzing ten series of ten replicates) was $\pm 3.6\%$ at the 10 ng ml^{-1} level of Hg(II) and $\pm 1.3\%$ at the 100 ng ml^{-1} level.

^a Values in µg g⁻¹.

In order to test the accuracy and applicability of the proposed method to the analysis of the real samples, two biological reference materials were analyzed. The results, as the average of three separate determinations are shown in Table 5. These results showed that this automatic system provides analytical data within the ranges of the certified values.

In view of the application of the method to the determination of mercury in water, standard solutions containing Hg(II) were added to tap-water, sea water and synthetic sea water. The results, shown in Table 5, indicate excellent recovery.

4. Conclusion

Two of the most frequently stated advantages of the ICP as a source for emission spectrometry are its multi-element capability and low detection limits. However, in certain instances the detection limits possible with the ICP are still inadequate, especially when the sample has a complex matrix. There are also many sample matrices that present difficulties in their own right. Problems may arise due to the high dissolved solids content of the sample solution, other matrix-induced problems include spectral interferences, which result in measurement errors. In these circumstances, a preliminary preconcentration and/or separation is required. Conventional off-line procedures for separation and preconcentration, although, effective, are usually time consuming and tedious, and are vulnerable to contamination and analyte loss.

This study has shown that the FI-ICP method described allows the rapid determination of Hg.

The analytical scheme of the proposed system is more simple than other off-line procedures due to the fact that it combines trace enrichment, derivation and detection in one analytical set-up. The high speed, ease of use and automation, selectivity and relative freedom from random contamination by sample handling make this method suitable for Hg determination in waters and biological samples. The detection limit, obtained with a 60 s loading time at a sample flow rate of 9 ml min⁻¹, was 4 ng ml⁻¹, which compares favourably with other obtained using column solid-phase extraction in FI systems coupled on-line to conventional atomic spectrometers. For example, detection limits obtained by Greenway et al. [17] using different chelating agents (quinolin-8-ol-5-sulfonic acid, dithiocarbamate, dithizone and cysteine) ranged from 10 to 50 ng ml⁻¹ Hg.

Abstract

Cobalt-2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP)-tetraphenylborate ion associated complex is quantitatively adsorbed on microcrystalline naphthalene in the pH range 3.5–9.5 from a fairly large volume of the aqueous samples (preconcentration factor ~30). After filtration, the solid mass consisting of the cobalt complex and naphthalene was dissolved with 5 ml of dimethylformamide (DMF) and the metal determined by first-derivative spectrophotometry. The cobalt-5-Br-PADAP complex can alternatively be quantitatively retained on ammonium tetraphenylborate-naphthalene adsorbent filled in a column (preconcentration factor 120) in the same pH range and determined similarly. The detection limit is 30 ppb (signal-to-noise ratio = 2) and the calibration curve is linear over 0.3–8.0 µg of cobalt in 5 ml of the final DMF solution. Eight replicate determinations of 1.0 µg of cobalt gave a mean peak height of 0.208 (at 611.5 nm) with a relative standard deviation of 1.2%. The sensitivity of the method is 1.04 (dA/dmm) ml µg⁻¹ found from the slope of the calibration curve. The interference of a large number of anions and cations on the determination of cobalt has been studied and the optimized conditions developed were utilized for its trace determination in various standard alloys and biological samples. © 1998 Elsevier Science B.V. 1. Introduction

Sodium tetraphenylborate has been used as a counter ion in the extraction and adsorption of some metal complexes into molten naphthalene

* Corresponding author. e-mail: bkpuri@chemistry.iitd.ernet.in

[1–3] and microcrystalline naphthalene respectively [4–6]. A survey of the literature reveals that metal ions may be preconcentrated using various adsorbents [7]. Although some of these adsorbents are fairly effective for the preconcentration of metal ions, but their methods of preparation are lengthy and involve rigid control of conditions. The desorption of the metal is carried out by the slow process of elution, hence the procedure is time consuming. Solvent extraction is another technique which may be used for the preconcentration of metal ions, but it can not be applied directly to metal ions which form stable complexes with the chelating agents at elevated temperature. This difficulty can be overcome by using molten naphthalene as the extractant for thermally stable metal chelates [8]. Solid–liquid separation after adsorption of metal chelates on microcrystalline naphthalene is more rapid and convenient and can be applied to many types of metal complexes [4–6]. The preconcentration of metal ions is also possible by passing their aqueous solutions over naphthalene-NH₄-TPB adsorbent taken in a column. The microcrystalline naphthalene method is rapid but the column method gives a better preconcentration factor (four times in the present case).

In the present communication, we have developed a simple, rapid, sensitive and highly selective first-derivative spectrophotometric method for the trace determination of cobalt in various complex materials using 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) as the complexing agent, tetraphenylborate as the counter ion and naphthalene as the absorbent. In general, spectrophotometry lacks sensitivity and selectivity. This preconcentration technique is very simple, economical and practical. It not only concentrates the metal ions from large volume (~150 ml in case of microcrystalline method and 600 ml in the column method) to 5 ml of the final solution for the analysis but also improves the selectivity of the method because different metal ions are adsorbed at different pH. The combination of this preconcentration technique and derivative spectrophotometry further improve the selectivity and sensitivity of the method. Various reagents may be used for the spectrophotometric

determination of cobalt [9–11] but 5-Br-PADAP and its derivatives are highly sensitive and selective [12]. The other metal ions also react with the reagent under these conditions and may interfere in the determination of cobalt. However, the cobalt complex of this reagent once formed is highly stable in the acidic solution while the other metal complexes are completely decomposed under these conditions and will not interfere in its determination. Moreover, in the acidic conditions, the nitrogen atom of diethylamino group of 5-Br-PADAP is protonated readily. The resultant quaternary ammonium ion forms instantaneous water insoluble ion-pair with TPB and makes the column method free from the control of flow rate. Various parameters have been evaluated and the optimized conditions utilized for the trace determination of cobalt in certified alloys, ores and biological samples.

2. Experimental

2.1. Apparatus

An Unicam 8700 series UV-Vis spectrophotometer with 1.0 cm quartz cell were used. A Beckman pH meter was employed for pH measurements. The glass column used for the preconcentration was 50 mm long and had an i.d. of 6 mm. All atomic absorption measurements were made with an atomic absorption spectrometer (Shimadzu AA670). All glasswares were washed with a mixture of concentrated sulphuric and nitric acids (1 + 1) before use.

2.2. Reagents

All the reagents were of analytical reagent grade. Cobalt (II) chloride was dissolved in distilled water and standardized complexometrically [13]. A 2 ppm solution of cobalt was prepared by appropriate dilution of the standard solution. A 0.05% solution of 5-Br-PADAP in methanol was prepared. Buffer solutions of pH ~4.5 was prepared by mixing appropriate volume of a 0.5 M acetic acid–0.5 M sodium acetate. A 1% solution of sodium tetraphenylborate (TPB)

Fig. 1. Zero order spectrum of the naphthalene-Co-(5-Br-PADAP)-TPB complex. Co: 1 μg ; buffer: 2.0 ml; (pH: 4.5); 5-Br-PADAP: 2.0 ml(0.05%); Flow rate: 1 ml min^{-1} ; solvent: 5 ml DMF; reference: reagent blank.

and 20% solution of naphthalene were prepared in water and acetone, respectively. The naphthalene-ammoniumtetrphenylborate adsorbent was prepared as described in our previous paper [7].

2.3. Pre-treatment of standard alloys and biological samples

The solution of standard alloy was prepared by dissolving 0.5 g of the alloy in 20 ml of hydrochloric acid (1 + 1) by heating on a water bath and then 2 ml of 30% hydrogen peroxide was added to it. The excess of peroxide was decomposed by heating the solution on a water bath. The solution was cooled, filtered if needed and the filtrate was diluted to 100 ml with double distilled water in a calibrated flask.

A 0.2 g of biological sample was taken in a beaker and dissolved in concentrated nitric acid (~5 ml) by heating. The solution was cooled, diluted and filtered. The filtrate was made to 100 ml with water in a calibrated flask.

2.4. General procedure

An aliquot of solution containing 0.3–8.0 μg of cobalt was taken in a 150 ml conical flask and the total volume was adjusted to ~25 ml. A 2 ml of buffer solution (pH ~4.5) and 2.0 ml of 0.05% 5-Br-PADAP were added and it was allowed to

stand for 3–5 min. Then its acidity was re-adjusted to ~2.0 N with the addition of 6.5 ml of Concentrated hydrochloric acid and 2 ml of 1% solution of TPB was added to it with shaking. Then a 2 ml of 20% naphthalene in acetone was added to it and the solution shaken continuously for 2–3 min. The solid mass was separated by filtration on a Whatman filter paper (No. 1041), dried in folds of a filter paper, and dissolved in 5 ml of DMF. While in the case of column method, the Co-5-Br-PADAP complex in acid medium was passed through the column containing ammonium tetrphenylborate-naphthalene adsorbent at a flow rate of 2–3 ml min^{-1} . Finally, the column was aspirated strongly for 2–3 min and the solid mass was dissolved out with 5 ml of DMF. In both the cases, the first-derivative spectrum with $\Delta\lambda = 1$ for the final DMF solution was recorded against the reagent blank prepared in the similar way. The peak height at 611.5 nm was measured from the base line at various concentrations to construct a calibration curve.

3. Results and discussion

3.1. Spectrophotometric measurements

The zero order and first order derivative spectra of the complex are shown in Figs. 1 and 2,

Fig. 2. First-derivative spectrum of the naphthalene-Co-(5-Br-PADAP)-TPB complex. For conditions, see Fig. 1.

respectively. As can be seen, the higher wavelength peaks of the derivative spectra are more significant. Derivative leads to sharper zero-order bands and gives higher signals in the resulting spectra. The characteristics of derivative spectra, such as peak height and noise level depend on the choice of various parameters [14]. The optimum

Fig. 3. Effect of pH. For conditions, see Fig. 1.

Fig. 4. Calibration curve for Co by first-derivative spectrophotometry. For conditions, see Fig. 1.

parameters were chosen from the preliminary experiments. The best results were obtained from first-derivative with wavelength interval ($\Delta\lambda$) 1 nm and with the scan speed of 120 nm min^{-1} . In the present work, the peak height at 611.5 nm was measured from the base line in all instances against the reagent blank because the reagent does not absorb at this wavelength at all. Although at 575 nm the intensity is high but the peaks are not well defined and at the same time blank is high too.

3.2. Reaction conditions

These were established with the use of $1 \mu\text{g}$ of cobalt. The adsorption of cobalt was found to be maximum in the pH range 3.5–9.5 (Fig. 3). In the subsequent studies, the pH was maintained at approximately 4.5 to avoid interferences of other metals. Addition of 0.5–8.0 ml of the buffer (pH 4.5) did not affect the retention of cobalt and the use of 2.0 ml was recommended. Various amounts of 0.05% alcoholic solution of 5-Br-PADAP were tried. Cobalt was quantitatively adsorbed on the absorbent over the range 0.1–5.0 ml of the reagent. Therefore, 2 ml of the reagent is recommended in the present study (Co:reagent mole ratio is 1:170). The acidity was varied from 0.1 to

^a Column method was applied.

^b Microcrystalline naphthalene method was applied.

5.0 M with concentrated HCl. The peak height was constant and maximum in the range 0.1–3.0 M. Therefore, the acidity was maintained ~2 M with the addition of 6.5 ml of concentrated HCl.

In the case of microcrystalline naphthalene method, the concentration of TPB solution was varied. The retention of cobalt was maximum between 0.2–4.0 ml of 1% TPB, 1 ml was recommended. Various amounts of naphthalene (20% solution of naphthalene in acetone) were added to the sample solution keeping other variables constant. It was observed that the signal height remained constant with the addition of 1.0–5.0 ml of 20% naphthalene solution and 2.0 ml of 20% naphthalene solution was recommended in the present work. The effect of shaking time on the adsorption indicated that the signal height remained constant over a range of 0.5–7.0 min. Therefore, 1.0 min of shaking time was maintained in the present work. While in the case of column method, the flow rate was varied. It was found that a flow rate of 0.5–10.0 ml min⁻¹ did not affect the retention of the complex. A flow rate of 2–3 ml min⁻¹ was recommended in the present study. Various solvents were tried to dissolve the solid mass containing the metal complex. DMF was found to be best and it was used in the present work due to the high absorbance and stability of the metal complex (5 days). The

volume of the aqueous phase was varied in the range of 10–700 ml under the optimum conditions, keeping other variables constant. It was observed that the signal height was almost constant up to 150 ml (preconcentration factor of 30) in microcrystalline method and 600 ml (preconcentration 120) in the case of column method. The column material can be dissolved out with 2–3 ml of DMF. Hence a preconcentration factor of ~200 may be achieved.

3.3. Retention capacity of the adsorbent

The retention capacity of the adsorbent was determined by a batch method. The experiment was performed by taking 500 µg of cobalt, 2 ml of buffer solution (pH = 4.5), the suitable amount of reagent 5-Br-PADAP solution and 40 ml of water in a beaker. This solution was transferred into a separating funnel and then a suitable amount of the naphthalene-NH₄-TPB adsorbent was added. The separatory funnel was shaken vigorously on a mechanical shaker for 5 min. The solid mass was separated by filtration and cobalt was determined from the filtrate by AAS. The solid mass on the filter-paper was dried in an oven, kept in a desiccator and then weighed to determine the mass of the adsorbent. The maximum amount of cobalt retained was 1.5 mg g⁻¹ of adsorbent.

^c Standard addition method was applied.

3.4. Calibration, sensitivity and precision

On the basis of the optimum conditions developed above a calibration graph was constructed according to the general procedure. It was linear over the concentration range 0.3–8.0 μg of cobalt in 5 ml of the final DMF solution (Fig. 4). Eight replicate determinations of 1.0 μg of cobalt in 5 ml of the DMF solution gave a mean intensity in the first-derivative spectrum, measured from the peak height at 611.5 nm, of 0.208 with a relative standard deviation of 1.2%. The sensitivity was 1.04 (dA/dmm) $\text{ml } \mu\text{g}^{-1}$ from the slope of the calibration curve and the detection limit was 30 ppb (signal-to-noise ratio = 2).

3.5. Effect of diverse ions

Various salts of anions and cations were added individually to a solution containing 1.0 μg of cobalt and the general procedure applied. The tolerance limit was set as the ion concentration required to cause a $\pm 3\%$ error in the determination. The following amounts shown in the parentheses did not interfere: Sodium acetate, sodium chloride, potassium nitrate (1 g); ammonium chloride, ammonium bromide, ammonium sulphate (500 mg); thiourea (600 mg); potassium iodide

(400 mg); potassium carbonate (100 mg); potassium sodium tartrate (10 mg); potassium thiocyanate, trisodium citrate (5 mg); disodium EDTA (5 μg); Ca(II), Mg(II), Al(III) (5 mg); Pb(II), Zn(II), Fe(III), Ni(II) (300 μg); Rh(III), Cr(III), Cd(II), Mn(II) (2.0 mg); Zr(IV), Bi(III), Ga(III), (250 μg); Ir(III), W(VI), Ag(II), Pt(IV) (600 μg); Cu(II) (400 μg after masking with 500 mg of thiourea). Palladium interfered seriously. However, it can be eliminated by pre-extraction using dimethylglyoxime [13].

3.6. Analysis of cobalt in standard alloys and biological samples

The accuracy and applicability of the proposed method was evaluated by the analysis of cobalt in Nippon Keikinokogyo (NKK) CRM 916 and NKK No.920 aluminium alloy and Japanese standards of iron and steel (JSS) CRM 651-7, 653-7 stainless steel, National Institute of Environmental Studies Reference Materials (NIES) No. 1 pepperbush; No. 5 human hair, No. 3 chlorella and No. 7 tea leaves. An aliquot (10–50 ml) of the pre-treated sample solution was taken and analyzed by the general procedure. The results are given in Tables 1 and 2 which are in good agreement with the certified values.

4. Conclusion

A solid ion-pair compound produced from 5-Br-PADAP and TPB⁻ on naphthalene provides a simple and economical method for the preconcentration of cobalt from a large volume of alloys and biological samples using 5-Br-PADAP as the complexing agent. This reagent is fairly sensitive and selective for cobalt. With the preconcentration step and the use of derivative spectrophotometry its sensitivity and selectivity have been further improved and thus the developed method can be used safely for the estimation of cobalt in a number of complex materials such as environmental samples. Since the adsorbent provides TPB⁻ as the counter anion, therefore it may be used for the preconcentration of various types of cationic metal complexes. As a whole the proposed method is highly sensitive, selective, simple and highly economical (it requires simple glassware, and a small volume of the organic solvent to dissolve the solid mass) for the estimation of cobalt.

Abstract

The extractable contents of U, Th, Ce, La, Cu, Cr, Ni and Zn in two sediment samples collected from the Ortigas river have been analysed using the three step sequential extraction procedure (SEP) described by BCR, Community Bureau of Reference (now Standards Measurements and Testing Programme) of the European Union. In order to perform a mass balance, a fourth step has been included, i.e. digestion of the residue from the third extraction step. ICP-AES was used for the determination of Cu, Cr, Ni, Zn, Th, Ce and La. Because of the inadequate sensitivity of ICP-AES for the analysis of uranium, ICP-MS was used for the determination of this element. Standard addition method was required, because of the matrix effects. Finally, SEP was applied to the Ortigas river sediments, showing that most of the elements were found mainly associated with the residual sediment fraction, except for uranium, which was found as an exchangeable species in approximately 60% of its total content. Recoveries of 86–108% have been obtained. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Speciation; Sequential extraction; Sediment; ICP

1. Introduction

The study of metal distribution in different sediment phases, by applying sequential extraction schemes, may help to predict metal behaviour, giving information about the mobility of metals and the possible transfer from sediment to the aquatic media [1,2]. Thus, not only the total concentration but the concentration of the differ-

ent forms of metals must be determined in these materials in order to evaluate their bioavailability and related eco-toxicity [3].

Sequential extraction procedures (SEP) are operationally defined methods proposed for speciation in solid samples.

The European Communities Bureau of Reference (BCR) recently proposed a SEP for use throughout the E.U. [4]. It harmonizes different extraction schemes for sediment analysis [5–7] and allows the comparison between results obtained in different laboratories [8], because the

operation conditions (i.e. extractant agents, time and form of shake, operation sequence, etc.) are concentered. This protocol is usually applied to the study of heavy metal distribution in sediments.

This paper describes the development of methods for the determination of Cu, Cr, Ni, Zn, U, Th, Ce and La in nitric acid, acetic acid, hydroxylammonium chloride and ammonium acetate extracts by ICP-AES and ICP-MS. Due to the presence of reagents and co-extracted species from the sediment, the matrix standard addition method was required to correct for interference effects observed.

The methods developed were applied to the determination and speciation study of analytes in two sediment samples taken from the Ortigas river, Spain. This river is located in a granitic zone near to two uranium mines (the El Lobo and Pedregal mines).

The uranium content of these sediments comes from two sources: (1) from uranium mines and (2) from some accessory minerals in the granitic host rocks of these U deposits (e.g. xenotime and/or uraninite). Thorium is held in inherited monazite. La and Ce are closely associated with Th in some accessory granitic minerals, mainly in monazite. Cu is associated with U in secondary uranyl minerals (e.g. torbernite). Zinc is present in granitic rocks as sulphides (e.g. sphalerite).

To validate the applied methodology, and assess the quality of the results, a sediment LS-1, supplied by the University of Barcelona has been analysed and the results obtained of total and extractable contents of some of the heavy metals have been compared with those obtained by Fiedler [9].

2. Experimental

2.1. Instrumentation

Sequential spectrometer induction coupled plasma Jobin Ivon JY38PLUS (France) with radiofrequency generator JY2300 with 2.3 KW of power and frequency of 40.68 MHz.

Mass spectrometer with plasma source Finnigan MAT SOLA (UK).

2.2. Reagents

All reagents used were of analytical grade, Merck (Germany), and their dilutions were made with double deionized water, of conductivity < 18 Ω cm, obtained by purification of deionized water in a MILLI-Q system (Millipore, Molsheim, France).

2.3. Standard solutions

Monoelemental solutions 1000 mg l⁻¹ of Ce, La, Th and U in HNO₃ 5% (ALFA, Johnson Matthey, Karlsruhe, Germany).

Zn, Cu, Cu and Cr standard solutions were obtained by digestion of 1.0000 g of each metal (Johnson Matthey, Germany) with nitric acid and made up to 100 ml.

Low concentration solutions were obtained by successive dilutions with MILLI-Q water.

2.4. Sampling points description

The studied area is located in the central-west of Spain Fig. 1. This area is composed of granitic materials with two uranium mines and three streams flowing parallel to these mines. The Ortigas river collects water from these three streams [10].

Two sediments, S-1 and S-2, were taken of the Ortigas river upstream and downstream respectively, at the confluence of the three streams. About 500 g of each sample were taken

Sediments were dried at 110°C during 24 h period, ground and homogenized in agate mortar, and sieved with an AISI-304 mesh to obtain a particle size < 63 μ m (Norm UNE 7050) which retains trace metals [11]. They were stored in PTFE containers until the analyses were performed.

2.5. Procedure

2.5.1. Sample digestion for total contents analysis [12]

Dried sediment (0.5 g) was transferred into teflon PFA microwave reactors. HF/HCl/HNO₃ (12 ml of (5/5/2)) acid mixture was added. The

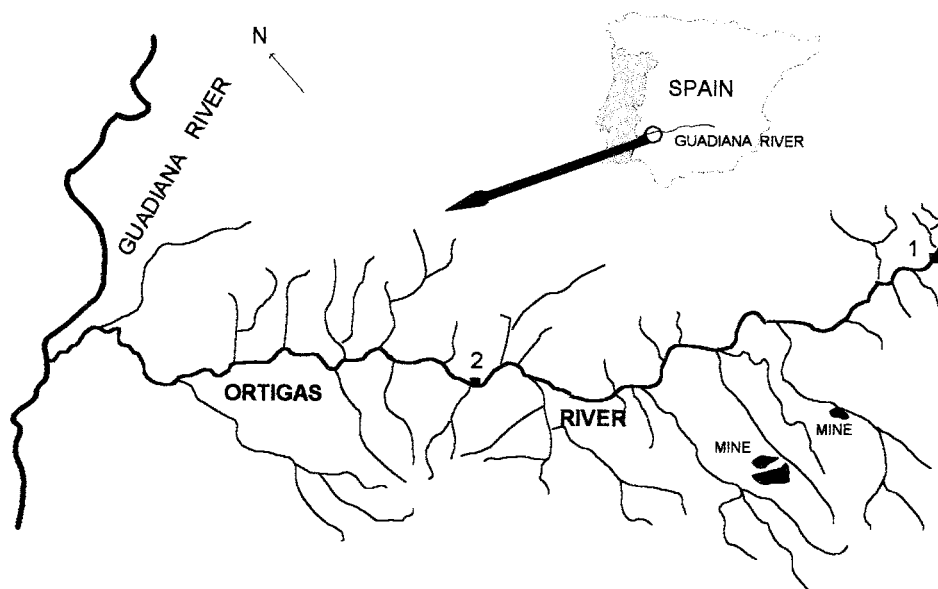

Fig. 1. Sampling point sites.

reactors were sealed and heated in the microwave oven. The program followed was:

1st step: 630 W Power, 80 psi Press during 20 min

2nd step: 630 W Power, 100 psi Press during 60 min

The digests, when cooled, were transferred to teflon capsules. Then 2 ml of HClO_4 was added, and heated to dryness to remove HF completely. Followed by the addition of 2 ml of HNO_3 , to dissolve dry residues, and heated until complete dissolution. They were finally made up to 25 ml with MILLI-Q water. The digests were analysed using the standard addition method.

Table 1
Reagents used in the sequential extraction procedure (SEP)

Reagent	Extracted specie
$0.11 \text{ mol l}^{-1} \text{ CH}_3\text{COOOH}$	Exchangeable and soluble in water and acids
$0.1 \text{ mol l}^{-1} \text{ NH}_2\text{OH} \cdot \text{HCl}$ (pH 2)	Reducible
$8.8 \text{ mol l}^{-1} \text{ H}_2\text{O}_2$ followed by $1 \text{ mol l}^{-1} \text{ CH}_3\text{COONH}_4$ (pH 2)	Oxidizable

2.5.2. Sequential extraction procedure (SEP)

The reagents used in the BCR sequential extraction procedure together with the nominal sediment phases dissolved at each step are given in Table 1. The experimental procedure is summarized below:

Step one: treatment of 0.5 g of sediment in a centrifuge tube with 20 ml 0.11 mol l^{-1} acetic acid solution, shaken for 16 h at room temperature, using an end-over-end shaker. The residue is separated by centrifugation and the supernatant retained for analysis.

Step two: treatment of residue obtained in step one with 20 ml of 0.1 mol l^{-1} hydroxylamine chloride solution (adjusted to pH 2 with nitric acid) and operated as described above.

Third step: treatment of the residue from step two with 5 ml of $8.8 \text{ mol l}^{-1} \text{ H}_2\text{O}_2$ (adjusted to pH 2 with nitric acid) keeping 1 h at room temperature and another hour at 85°C . It was evaporated to near dryness, the treatment was repeated with H_2O_2 heating until dryness. Ammonium acetate (25 ml of 1 mol l^{-1}) was added (adjusted to pH 2 with nitric acid) and the operations were repeated as described in previous steps.

Uranium calibration graphs by ICP-MS is ($I = f(\text{conc.}(\mu\text{g l}^{-1}))$). Calibration graphs of the rest of the elements by ICP-AES are ($I = f(\text{conc.}(\text{mg l}^{-1}))$). The errors quoted are ± 1 s.

To obtain an indication of the concentration of these elements associated with the residual components of the sediment matrix a fourth step was introduced, which involves the total digestion of the residue from the third step, with 12 ml of (5/5/2) HF/HCl/HNO₃ acid mixture in a microwave oven, following the program described in the sample digestion for analysis of total contents.

All the extracts were made up to 25 ml with MILLI-Q water.

3. Results and discussion

3.1. Development of the analytical methodology

Analytical wavelengths for determination of Cu

Ce	0.36	0.90	1.2	0.84

Detection limits were calculated on the basis of 3 s (blank solution).

(327.396 nm), Cr (357.870 nm), Ni (232.003 nm), Zn (206.200 nm), Th (401.913 nm), Ce (456.236 nm) and La (408.672 nm) by ICP-AES, were chosen taking into account their sensitivity and the absence of interferences.

Because of the inadequate sensitivity of ICP-AES for uranium analysis, ICP-MS was chosen for determination of this element.

To determine the matrix effects of reagents used in the extraction, slopes of calibration graphs for each element obtained from standards in 0.5 mol l⁻¹ HNO₃, were compared with those obtained in different reagents (0.11 mol l⁻¹ acetic acid, 0.1 mol l⁻¹ hidroxilamonium chloride and 1 mol l⁻¹ ammonium acetate). In all cases, the correlation coefficients were $r \geq 0.9999$. Results are shown in Table 2. The analytical signals were affected by

the presence of reagents. In the case of Zn and Ni an increase in the signal was observed, whereas for other elements a decrease in the signal occurred. The higher effects were caused by ammonium acetate.

To evaluate the matrix effects of the components associated with each particular sediment fraction, S-2 sediment was chosen. After application of SEP, standard addition calibrations were

made for all the extracts. The slopes obtained were compared with those from direct calibrates (Table 2). In all cases the differences were higher than 8%. Some authors [13] consider that there will be matrix effects when the differences between direct and standard addition slopes are higher than 6%. In this work, with a 't' statistic assay, for a 95% level confidence, significant differences were found between standard addition

Fig. 2. Distribution of contents in S-1 and S-2 fractions sediments

slopes and direct calibration slopes. This confirms the matrix effects which will have some influence on the determination of the analytes. The standard addition method was necessary to carry out the analysis.

Detection limits for each analyte in each of the reagents, calculated as three times the standard deviation of results obtained in the analysis of 10 blank solutions, are shown in Table 3. Higher detection limits were obtained using ammonium acetate for all the analytes owing to the poorer precision of the ICP signals.

A study following the same previous process, was carried out for the determination of U in the extracts and in total digestion sediments solutions by ICP-MS. Detection limits were established and calibrated slopes were calculated for each medium (Tables 2 and 3).

By comparison of direct calibrated slopes and standard addition slopes, interfering effects were observed (Table 2) as such the standard addition method was necessary to determine this element.

Validation of the method was carried out using the sediment LS-1 from Flumendosa lake, Cerdèña, Italy, and prepared by J.R.C. Ispra, Italy. Sequential extraction procedure was carried out with this sediment. Cu, Cr, Ni and Zn, were analysed in the extracts. The results were compared with those obtained by Fiedler [9] (Table 4).

There were no significant differences found between values with 95% of confidence level found.

3.2. Distribution of contents in S-1 and S-2

The extractable contents of Zn, Ni, Cu, Cr, Th, Ce, La and U from SEP applied to S-1 and S-2 Ortigas river sediments are shown in Table 5.

All the elements suffer with some differences, along a distribution of the four phases, they are basically retained in the residual sediment fraction. The distribution obtained for each element along different extraction phases are shown in Fig. 2.

The distribution of Zn, Ni and Cr is similar in the two sediments. They are retained in the residual fraction approx. 70–80% of their total content.

With respect to Cu and Ce, 60% of Cu and 80% of Ce are associated with residual fraction in S-1. Otherwise, there is an increase in more labile forms of these elements, particularly reducible species in S-2, 50% in the residual fraction.

Th and La in S-2 are shown to be more extractable than in S-1 increasing the proportion of these elements associated with the oxidizable sediment fraction.

In the case of uranium, the obtained results clearly show that the proportion retained in residual fraction is significantly lower than in the case

of other elements. Approx. 60% of the total content of this element is exchangeable. In addition, the distribution of uranium between sediment fractions is slightly different in each sediment. In S-1, the percentage in extractable and oxidizable sediment fractions increase, while the proportion of U associated with the reducible sediment fraction in S-2 is higher than S-1.

Comparison of the sum of metal concentrations in the individual fractions after application of SEP (Table 5) with total metal concentration shows good agreement for all trace metals. The total recovery percentages obtained were 86–108%.

Acknowledgements

The authors are grateful to Dr R. Rubio of the University of Barcelona for supplying the sediment LS-1, Dr M.T. Crespo and Dr J.L. Gascon for supplying the sediment samples S-1 and S-2 and Dr L. Perez del Villar for information on geological materials.

Supercritical fluid extraction of phenol compounds from olive leaves

F. Le Floch, M.T. Tena, A. Ríos, M. Valcárcel *

Department of Analytical Chemistry, Faculty of Sciences. University of Córdoba, E-14004 Córdoba, Spain

Received 14 July 1997; received in revised form 21 October 1997

Abstract

A clean, highly selective supercritical fluid extraction (SFE) method for the isolation of phenols from olive leaf samples was examined. Total phenol extracts were determined using the Folin-Ciocalteu reagent. Dried, ground, sieved olive leaf samples (30 mg) are subjected to SFE, using carbon dioxide modified with 10% methanol at 334 bar, 100°C (CO₂ density 0.70 g ml⁻¹) at a liquid flow-rate of 2 ml min⁻¹ for 140 min. Diatomaceous earth is used to reduce the void volume of the extraction vessel. The influence of extraction variables such as modifier content, pressure, temperature, flow-rate, extraction time, and collection/elution variables, were studied. Supercritical fluid extracts were screened for acid compounds such as carboxylic acids and phenols using Electrospray-MS (in the negative ionization mode). SFE was found to produce higher phenol recoveries than sonication in liquid solvents such as *n*-hexane, diethyl ether and ethyl acetate. However, the extraction yield obtained was only 45%, using liquid methanol. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Supercritical fluid extraction; Phenol; Olive leaves

1. Introduction

The determination of polyphenols in plants is of great interest because of the natural antioxidant activity of these compounds. Phenol compounds are synthesized by plants as a defence mechanism against microorganisms and strong UV radiation [1]. Antioxidants are added to fat-containing foods to prevent the formation of off-flavour and toxic compounds resulting from lipid oxidation. Plant extracts are natural alternatives

to synthetic antioxidants as they possess similar or even higher antioxidant activity.

Several studies on the chemical composition of the olive leaf and oil have been carried out [2–7]. Very little information is available on the chemical composition of olive leaves, the primary site of plant metabolism for primary and secondary plant products. Luteolin, luteolin-7-glucoside, rutin, quercitrin and chlorogenic acid have been identified in methanol extracts from the olive leaf [2]. Extraction of highly-hydroxylated flavonoids using supercritical methanol-modified carbon dioxide is difficult [8]. In fact, compounds in SFE extracts that react with the Folin-Ciocalteu

* Corresponding author. Tel.: +34 57 218614; fax: +34 57 218606; e-mail: qalricaa@uco.es

reagent are more likely to be phenolic acids such as salicylic, hydroxybenzoic, coumaric, caffeic, protocatechuic or ferulic acid. These compounds have been found in aqueous hydrochloric acid and ethyl acetate extracts from olive leaves [3]. Montedoro et al. [4], using HPLC-UV, identified hydroxytyrosol, tyrosol, vanillic acid, caffeic acid, syringic acid, *p*-coumaric acid and ferulic acid in methanol extracts from virgin olive oil; the major peaks in the chromatogram, correlated with total phenol, autoxidation stability, could not be assigned. In a subsequent study [5], these compounds were characterized as oleuropein aglycon and three hydrolysable phenols containing hydroxytyrosol or tyrosol. Angerosa et al. [6], using GC-MS, also detected the presence of linked phenols containing tyrosol and hydroxytyrosol in virgin olive oil.

Polyphenols in leaves are different from those in flowers, stems, roots and fruits. Indeed, the types of phenols present on the surface (e.g. in leaf waxes), are usually different from those occurring within the plant. Surface flavonoids are usually highly methylated and lack sugar substitution [9], so they should be more readily extracted using SC-CO₂.

SFE [10–14] offers special advantages over conventional liquid-solvent extraction such as increased selectivity, expeditiousness, automaticity and environmental safety, in addition to dramatically decreased use of organic solvents. Several SFE-based methods for determining phenol pollutants in environmental samples including waters, dust and waste solids have been proposed [15–17]. Also, SFE with carbon dioxide is the most favored method for the isolation of phenol compounds with antioxidant properties from spices and agricultural by-products [18–21].

The Folin reagent is widely used in this context and is recommended for the determination of total phenols; it reacts with compounds other than the target phenols, as such interfering reductants must be removed prior to the assay [22,23]. Solution-ionizable polar compounds not suitable for gas chromatography analysis can be detected by mass spectrometry following electrospray ionization [24,25]. Electrospray-MS in the ion mode

has been used to detect phenolic diterpenes in rosemary SFE extracts [18].

The aim of this work was to develop an SFE-based method for the determination of total phenols in plant samples. Olive leaves were chosen as the plant model because they are by-products of olive farming, one of the most important agricultural activities in the Mediterranean region, and because phenols with a high pharmacological activity are particularly commonplace in plants of warm, dry regions.

2. Experimental

2.1. Apparatus

All SFE experiments were performed on a 7680T Hewlett Packard supercritical fluid extractor equipped with a Hewlett Packard 1050 isocratic modifier pump and furnished with a 7 ml extraction vessel, an automated variable restrictor and a solid-phase trap packed with octadecylsilica (ODS) or PorapakQ material. A Hewlett Packard 8453 diode array spectrophotometer was used to determine the total phenol content in olive leaf extracts. A Fisons VG Platform electrospray and a Fisons VG Autospec mass spectrometer were used to screen acid compounds in the SFE extract.

2.2. Chemicals

Caffeic acid and diatomaceous earth (acid-washed, approximately 95% SiO₂) were purchased from Sigma and used as received. All solvents and reagents were HPLC-grade and analytical reagent grade, respectively. SFC-grade carbon dioxide from Air Liquide (Paris, France) was used as extraction fluid.

Calibration solutions containing 1, 2, 4, 6, 8 and 10 µg ml⁻¹ caffeic acid were prepared from a 1 g l⁻¹ stock solution in ethanol by appropriate dilution in *n*-hexane. Appropriate volumes of ethanol were also added in order to equalize its content in all calibration solutions. Since no significant differences were found between the signals produced by hexane, diethyl ether or ethyl

acetate solution containing the same amount of caffeic acid, calibration solutions prepared in *n*-hexane were used to determine total phenol in water-immiscible solvents. For methanol extracts, calibration solutions containing 10, 25, 50, 75 and 100 $\mu\text{g ml}^{-1}$ caffeic acid were prepared from 1 g l^{-1} methanol stock solution by appropriate dilution in methanol.

An aqueous solution of 2% (v/v) Folin-Ciocalteu phenol reagent (Merck) and a 0.2 M aqueous solution of sodium bicarbonate (Merck) adjusted to pH 12.4 with sodium hydroxide (Merck) was also used.

Olive (*Olea europaea* L.) leaves were collected from trees in the surrounding countryside, dried at 100°C for 2 h, ground and sieved $\leq 500 \mu\text{m}$.

2.3. Supercritical fluid extraction

CO_2 was aspirated from a cylinder furnished with a dip tube, pressurized to 155–334 bar (corresponds to 0.35–0.70 g ml^{-1} density at 100°C) and mixed on-line with 0–20% (v/v) methanol. Ethanol was also assayed as CO_2 modifier. The flow-rate of liquid carbon dioxide was varied from 1 to 4 ml min^{-1} . The sample amount used was 30–200 mg. Extractions were conducted in 7 ml thimbles that were filled with diatomaceous earth in most cases in order to reduce the void volume. Each extraction was carried out in duplicate and the extraction recoveries reported are the averages of the two. Samples were subjected to dynamic extraction for 5–140 min, depending on the particular experiment. A static extraction period of 1 min was used. Extraction curves at different temperatures were obtained by performing consecutive extractions of the same sample and plotting the cumulative concentration obtained. Extracted analytes were collected on an ODS or PorapackQ trap. After extraction, the analytes were eluted from the trap at 20°C with 1.5 ml of HPLC-grade methanol or *n*-hexane. When the rinse solvent was methanol, an additional rinse with *n*-hexane was necessary in order to remove methanol non-soluble coextractives from the trap. The trap temperature was raised to 70°C in order to avoid undesirable modifier condensation on the trap during extraction/collection.

2.4. Sonication with a liquid-solvent

Ground, sieved olive leaf sample (100 mg) was extracted four times with *n*-hexane (4 ml + 3 \times 2 ml). The extraction was performed using ultrasonication at room temperature and the duration of the first and subsequent steps was 30 and 15 min, respectively. The same procedure was followed for ethyl acetate, diethyl ether and methanol extractions; the amount of sample and volume of solvent used in the first step was 30 mg and 6 ml, respectively. After each step, the mixture was centrifuged and the supernatant separated. The amount of total phenol was determined using the water-immiscible solvent calibration procedure for *n*-hexane, diethyl ether and ethyl acetate, and the water-miscible solvent calibration procedure for methanol.

2.5. Photometric determination

Total phenol in the SFE and liquid-solvent extracts was quantified using the Folin-Ciocalteu reagent and either of two procedures depending on the particular rinse/extraction solvents used. Amounts of phenols are given in micrograms of caffeic acid.

Water-immiscible solvents (*n*-hexane, diethyl ether and ethyl acetate): Two aliquots of Folin-Ciocalteu and buffer solutions (2.5 ml) were mixed in a test-tube and 1 ml of *n*-hexane solution containing the phenols was added. The mixture was stirred for 1 min and allowed to stand for 30 min. The absorbance of the aqueous phase was measured at 750 nm after centrifugation.

Water miscible solvent (methanol): Two aliquots of Folin-Ciocalteu and buffer solutions (2.5 ml) were mixed in a test-tube and a volume of 0.5 ml of methanol solution containing the phenols was added. The mixture was stirred for 1 min and allowed to stand for 30 min before its absorbance at 655 nm was measured.

2.6. Mass spectrometric screening of the SFE extract

The SFE extract was screened by electrospray MS (in the negative ionization mode) in order to

detect acid compounds such as carboxylic acids and phenols from their M-1 peaks. A volume of 10 μl of SFE extract was injected into a 50:50 methanol/water carrier solution at 20 $\mu\text{l min}^{-1}$. The source temperature and cone voltage were 60°C and 30 V, respectively. The voltage of the capillary and high-voltage lenses were 3 kV and 0.5 kV, respectively. The M-1 peaks obtained by Electrospray MS of an SFE extract are listed in Table 1. Those compounds previously found in olive leaf or virgin olive oil [2–6] that could have provided an M-1 signal at each m/z ratio are also tabulated. Obviously, tentative assignments are

Fig. 1. Effect of the extraction temperature on the SFE efficiency of phenols. Amount of sample, 100 mg. SFE conditions: CO₂ modified with 10% methanol; CO₂ pressure, 334 bar; flow-rate, 2 ml min⁻¹; ODS trap; nozzle and trap temperature during collection 45 and 70°C, respectively; rinse solvent, *n*-hexane; rinse volume, 1.5 ml; nozzle and trap temperature during rinse, 20°C. Amounts of phenols per gram of sample expressed as milligrams of caffeic acid.

only an approximation and should be further investigated by HPLC fractionation followed by electron impact mass spectrometry analysis.

3. Results and discussion

Preliminary experiments demonstrated that the addition of a modifier to CO₂ was mandatory in order to extract phenols, the extraction yield was strongly influenced by pressure and, especially, the extraction temperature. The restrictor was plugged and overloaded by samples larger than 100 mg (especially at high temperatures) which caused overpressure problems.

3.1. Influence of the extraction temperature on the SFE efficiency

The effect of the extraction temperature on the amount of phenols extracted was studied at con-

stant pressure (334 bar). Fig. 1 shows the extraction curves obtained at three different temperatures (80, 100 and 120°C), corresponding to CO₂ densities of 0.78, 0.70 and 0.63 g ml⁻¹, respectively. Although the solvating power of methanol-modified carbon dioxide decreased with decreasing density, raising the temperature increased both the extraction rate and extraction efficiency through increased diffusion and desorption. The amount of phenols extracted at 80°C increased with increasing extraction time up to 40 min beyond which it remained constant. However, greater amounts were extracted at 100 or 120°C and no plateau was observed over the period studied (1 h). The datum for 60 min at 120°C could not be obtained owing to the short lifetime of the thimble cap. Indeed, the manufacturer recommends that thimble caps be used only once, if the extraction is performed at 120°C. In fact, caps were dramatically deformed and became useless after five extractions. An extraction temperature of 100°C was selected for further experiments as a compromise between extraction efficiency and thimble cap lifetime.

3.2. Void volume

Since the extraction vessel volume (7 ml) was much larger than the sample size (< 0.5 ml), an inert solid (diatomaceous earth) was added to the vessel in order to fill any extra void volume. The void volume was thus reduced and no additional extraction time was required to sweep the SC-extract out of the vessel. Diatomaceous earth was placed at the thimble edge of the CO₂ inlet. Diatomaceous earth (1 g) was extracted under the same conditions in order to check for the absence of interferents extracted from this material. The amount of phenols extracted was markedly increased by the addition of 1 g of diatomaceous earth to the thimble (see Table 2).

3.3. Influence of collection variables

ODS and PorapackQ were tested as packing materials for the analyte trap. Methanol and *n*-hexane were used as rinse solvents with both packings. The amounts of phenols found in the

SFE extracts obtained under the same conditions with the four collection/elution systems are shown in Table 2. As can be seen, the amounts eluted from ODS and PorapackQ trap were much larger (34–21 fold) with methanol than with *n*-hexane. Methanol proved to be a better rinse solvent than *n*-hexane with both traps. However, methanol was not efficient enough to completely remove other extracted substances (yellow/green pigments), so a subsequent rinse using *n*-hexane was mandatory in order to make the trap ready for a new extraction. Indeed, the use of an ODS/methanol or PorapackQ/methanol collection system to extract phenols allowed on-line clean-up of the supercritical extracts. It seems that methanol dissolves the more polar phenols, which may be insoluble in *n*-hexane. A volume of 1.5 ml of rinse solvent (*n*-hexane or methanol) at 2 ml min⁻¹ and 20°C was sufficient to remove all soluble phenols from the trap. No analytes were detected after a subsequent rinse. The nature of the trap packing affected the amount of phenols to a lesser extent than the nature of the rinse solvent. Slightly greater amounts of phenols (about 10%) were obtained with ODS than with PorapackQ. However, PorapackQ provided cleaner extracts, so it was selected for subsequent experiments.

Table 2

Influence of the collection system (trap/rinse solvent) and void volume used on the SFE efficiency of phenols from olive leaves

SFE conditions	Concentration in olive leaves ^a (mg g ⁻¹)
PorapackQ/MeOH, no DE	2.6
PorapackQ/MeOH, DE	3.8

Addition of 1 g of diatomaceous earth.

^a Expressed as caffeic acid.

3.4. Influence of pressure

The effect of extraction pressure on the amount of phenols dynamically extracted from olive leaves using CO₂ modified with 10% methanol for 20 min was studied at a constant temperature of 100°C. The amounts extracted increased linearly with increasing CO₂ density (Table 3, intercept -2.2 mg g⁻¹, slope 8.1 mg ml g⁻², *r*² 0.9996). An extraction pressure of 334 bar and a temperature of 100°C (viz. a CO₂ density of 0.70 g ml⁻¹) were chosen for subsequent extractions.

3.5. Influence of the modifier

The amount of total phenols extracted from olive leaves with pure CO₂ and various methanol-CO₂ mixtures is shown in Fig. 2. The effect of the modifier content on the extraction yield was examined at 100°C and 334 bar. As can be seen, the addition of methanol to CO₂ was mandatory in order to fully extract these compounds. A 10% methanol-CO₂ mixture provided the highest recovery of phenols while a modifier content of 20% produced undesirable methanol condensation on the analyte trap.

Because the proposed SFE of phenols could be implemented by the food, cosmetic and pharmaceutical industry provided the modifier used is non-toxic, the feasibility of replacing methanol with ethanol as modifier was investigated. Ethanol was found to be useful as a modifier, but less effective than methanol: the extraction yield of phenols obtained with 10% ethanol as modifier was 2.0 mg g⁻¹ (rsd 2.5%), the yield obtained

with 10% methanol under the same conditions was 3.6 mg g⁻¹ (rsd 5.6%).

3.6. Influence of the flow-rate and extraction time

There was no significant difference between the results obtained at a flow-rate of 1 and 2 ml min⁻¹ at 80°C; however, the extraction yield in-

Fig. 2. Influence of methanol content on the SFE efficiency of phenols from olive leaves. Amount of sample, 30 mg. SFE conditions: pressure, 334 bar; extraction temperature, 100°C; flow-rate, 2 ml min⁻¹; extraction time, 20 min; PorapackQ trap; nozzle and trap temperature during collection 45 and 70°C, respectively; rinse solvent, methanol; rinse volume, 1.5 ml; nozzle and trap temperature during rinse, 20°C. Addition of 1 g of diatomaceous earth. Amounts of phenols per gram of sample expressed as milligrams of caffeic acid.

Fig. 3. Influence of the extraction time on the SFE efficiency of phenols from olive leaves. Amount of sample, 30 mg. SFE conditions: CO₂ modified with 10% methanol; pressure, 334 bar; extraction temperature, 100°C; flow-rate, 2 ml min⁻¹; PorapakQ trap; nozzle and trap temperature during collection, 45 and 70°C, respectively; rinse solvent, methanol; rinse volume, 1.5 ml; nozzle and trap temperature during rinse, 20°C. Addition of 1 g of diatomaceous earth. Amounts of phenols per gram of sample expressed as milligrams of caffeic acid.

creased with increasing flow rate at 100°C (from 6.4 mg g⁻¹ at 1 ml min⁻¹ to 8.0 mg g⁻¹ at 2 ml min⁻¹). Extraction from plant materials at low temperature seems to be limited primarily by desorption/diffusion since the flow rate has no effect on the extraction rate. However, the process is solubility-controlled at increased extraction temperatures. The behaviour of spiked phenols [8] was different at 50°C; increasing the flow-rate resulted in increased recoveries because solubilization was the limiting step. Undesirable methanol condensation on the analyte trap that could result in analyte loss (by ejection of methanol drops) was observed above 2 ml min⁻¹.

In order to ensure complete methanol evaporation, the trap temperature was raised from 70 to 100°C, which reduced collection efficiency. The extraction yields fell from 7.6 to 6.7 mg g⁻¹ as a result.

Fig. 3 shows the extraction curve obtained under the optimal SFE conditions. Exhaustive extraction was achieved after 140 min of dynamic extraction. A comparison of the cumulative amount of phenols per gram of sample obtained after seven 20-min extractions (6.7 mg g⁻¹) with that obtained in a single 140-min extraction (8.0 mg g⁻¹) revealed the absence of analyte losses after a long extraction time. In absence of losses, the amount obtained by seven 20-min extractions or by a single 140-min extraction must be the same. Determination of low phenol concentrations was difficult, particularly in extracts obtained from the last 20-min steps. It may explain the decreased result of 6.7 mg g⁻¹.

The precision of the whole method (SFE + colorimetry), expressed as percent relative standard deviation (extraction time = 20 min, $n = 5$) was 5.6%.

3.7. Comparison of SFE and sonication in a liquid solvent

SFE and liquid solvent extraction were compared in terms of phenol yields (Table 4). The data for liquid solvents was obtained in four successive extractions of triplicate samples. Only

Table 4
Concentration of total phenols found in olive leaves using the Folin-Ciocalteu reagent after SFE or sonication in a liquid solvent

Solvent	Concentration in olive leaf ± SD ^a ($n = 3$) (mg g ⁻¹)
<i>n</i> -Hexane	0.18 ± 0.03
Diethyl ether	1.1 ± 0.3
Ethyl acetate	1.6 ± 0.4
Methanol	16.8 ± 0.8
CO ₂ + 10% Methanol	7.6 ± 0.5

Sonication time: 75 min, SFE conditions: pressure, 334 bar; extraction temperature, 100°C; flow-rate, 2 ml min⁻¹; extraction time, 140 min; PorapakQ trap; nozzle and trap temperature during collection, 45 and 70°C, respectively; rinse solvent, methanol; rinse volume, 1.5 ml; nozzle and trap temperature during rinse, 20°C. Addition of 1 g of diatomaceous earth. Amount of sample, 30 mg.

^a Expressed as caffeic acid.

with methanol was the olive leaf sample exhaustively extracted. The results reveal that the higher the solvent polarity, the higher the phenol extraction yield. Thus, SFE provided much greater amounts of phenols than extraction with *n*-hexane, diethyl ether or ethyl acetate; however, carbon dioxide modified with 10% methanol recovered 45% of the amounts extracted by liquid methanol.

4. Conclusions

A clean, highly selective, automated method for the isolation of phenols from olive leaves was investigated. Because solvent polarity increases extraction rate and efficiency, the addition of a polar modifier (e.g. methanol or ethanol) to non-polar supercritical CO₂ is essential. Modifier contents and flow-rates higher than 10% and 2 ml min⁻¹, respectively, give rise to methanol condensation on the trap. Ethanol was found to be a less efficient modifier than methanol. PorapackQ packing and methanol was the best combination for collecting and eluting extracted analytes. This collection system affords on-line clean-up of plant extracts. Supercritical CO₂ modified with 10% methanol was found to be a more efficient solvent than *n*-hexane, diethyl ether and ethyl acetate, but was surpassed by liquid methanol in terms of yield.

Abstract

The electrochemical methods cyclic, differential pulse and square wave voltammetry were applied to develop an electroanalytical procedure for the determination of the herbicide bentazon in a commercial product, containing bentazon as the active ingredient, used to treat rice and corn crops. The oxidation mechanism is complex, consisting of an electrochemical step followed by chemical dimerization reaction of the products, which causes severe adsorption problems and consequent poisoning of the electrode surface. The effect of adding Triton surfactant is to enable determinations with good reproducibility to be carried out; the analytical conditions were studied and optimized. The limit of detection obtained was 10^{-5} M. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Bentazon; Herbicides; Square wave voltammetry

1. Introduction

Bentazon is the common name for the herbicide 3-isopropyl-1H-2,1,3-benzothiadiazin-4-(3H)-one-2,2-dioxide and is used as a post-emergence herbicide to control broadleaf and sedges in beans, rice, corn, peanuts and mint [1]. It is a contact herbicide, which means that it only functions in

the part of the plant where it is applied and its activity is short-lived [2]. Commercially, it is available in the form of soluble concentrate which contains the sodium salt of bentazon as the active ingredient and is referred to as sodium bentazon. Bentazon has the following structure

* Corresponding author. Tel./fax: + 351 39 35295; e-mail: brett@cygnus.ci.uc.pt

¹ Present address: Instituto Superior de Engenharia do Porto, 4200 Porto, Portugal.

Analytical techniques used for the determination of bentazon in water, soils and fruits are gas chromatography [3–6] and high performance liquid chromatography (HPLC) [7–14]. The latter has the advantage of not requiring derivatization to obtain good resolution. However, the UV detector employed has low sensitivity and selectivity, making preconcentration and clean-up steps necessary.

The electrochemical oxidation properties of bentazon were studied and an electrochemical method was developed for determination of bentazon in a commercial product used to protect rice and corn crops.

2. Experimental

2.1. Reagents and solutions

Bentazon was from Riedel de Haen. All reagents were of analytical grade and aqueous solutions were prepared using purified water from a Millipore Milli-Q system (conductivity $< 0.1 \mu\text{S cm}^{-1}$). The stock solution of bentazon was prepared in ethanol at a concentration of 9.6×10^{-3} M. The buffer solutions used were in the pH range 1.2–12.8. Quantitative determinations were carried out in a 0.2 M acetate buffer of pH = 3.4.

2.2. Commercial sample preparation

In the commercial product (Basagran, BASF), bentazon is in the basic form; therefore, the sample stock solution was prepared by accurately weighing 0.46 g of the commercial sample and adding a few drops of glacial acetic acid until complete precipitation of the acid form of bentazon occurred. Ethanol was added to the mixture until complete dissolution occurred and the total volume was adjusted to 100.0 cm³. The sample stock solution was diluted with buffer electrolyte in order to obtain a concentration within the calibration curve range.

2.3. Apparatus

All experiments were performed using a 663 VA Metrohm system containing a glassy carbon working electrode (Metrohm 6.1204.000) ($d = 3.0$ mm), a glassy carbon rod counter electrode (Metrohm 6.1247.000) and an Ag/AgCl reference electrode (Metrohm 6.0728.000) attached to a Autolab PSTAT 10 potentiostat/galvanostat running with model GPES version 3 software (Eco-Chemie, The Netherlands). The potential range studied was from +0.2 to +1.2 V.

The glassy carbon working electrode was polished every day using a polishing kit (Metrohm 6.2802.010), first with $\alpha\text{-Al}_2\text{O}_3$ (0.3 mm) and water for 60 s and then with water only, for 60 s. After polishing, the electrode surface was thoroughly washed with purified water.

The pH measurements were obtained with a pH-meter E 520 from Metrohm with a combined glass electrode (Metrohm 6.0202.000).

HPLC experiments for the AOAC Method were carried out using a HPLC Sykan system, model A1210 with a variable wavelength detector.

3. Results and discussion

The oxidation of bentazon was first studied by cyclic voltammetry in order to probe the oxidation mechanism. The electrochemical oxidation of bentazon occurs at +0.96 V vs Ag/AgCl in 0.2 M acetate buffer of pH = 3.4 (Fig. 1) and is an irreversible process. The oxidation products adsorb very strongly on the electrode surface, causing irreproducibility. A plot of I vs $\nu^{1/2}$ is a straight line passing through the origin, indicating that the oxidation is a diffusion-controlled process.

Due to the high adsorption of the products formed during the oxidation of bentazon and in order to attain good reproducibility and increase the sensitivity, an electrochemical cleaning procedure was developed. This electrochemical treatment of the electrode surface was carried out after mechanical polishing and consisted of applying a constant potential of -1.0 V for 60 s and $+1.0$ V for 60 s, followed by a square wave scan at 50

Fig. 1. Cyclic voltammogram of bentazon, 1.0×10^{-4} M, in 0.2 M acetate buffer of pH = 3.4. Scan rate 100 mV s^{-1} , pulse amplitude 50 mV.

Hz between +0.6 and +1.2 V, the potential range of interest for bentazon, in a 0.2 M acetate buffer solution of pH = 3.4. The use of potentials more negative than -1.0 V or more positive than +1.0 V leads to worse reproducibility and longer conditioning times did not improve the results further.

The best results were obtained when, in addition to this mechanical/electrochemical cleaning, a surfactant (Triton) was added to the solution in order to prevent adsorption of the oxidation products. Table 1 shows the results obtained for the peak current for different % V/V Triton added to the solution. It was possible to use high concentrations of Triton without problems of foam formation. For low percentages of Triton, adsorption effects occur and the reproducibility was not

Table 1
Dependence of the peak current on the % (v/v) of Triton for a bentazon solution of 1.90×10^{-5} M

Triton added % (v/v)	$I_p \mu\text{A}^{-1}$
0.1	0.447
1.0	0.338
5.0	0.106

good; at high percentages greater adsorption of the surfactant itself on the electrode surface caused diminution of the peak current, but good reproducibility was obtained. Addition of 1% Triton to the solution was found to be most suitable and in these optimized conditions of 0.2 M acetate buffer of pH = 3.4 with 1% Triton the detection limit was 10^{-5} M.

3.1. The effect of pH

The electrochemical behaviour of bentazon was studied over a large pH range between 1.2 and 12.8, using differential pulse voltammetry (Fig. 2) and scanning from +0.6 to +1.2 V. Plots of E_p vs pH for 2×10^{-5} M solutions of bentazon (Fig. 3) show that the peak potential is dependent on pH in acid media, becoming independent above pH ~ 3.5 ; no peak was observed for pH values greater than 8.4. Bentazon is a weak acid with $pK_a = 3.2$ [14], corresponding to the intersection of the two lines. The dependence of the peak potentials on pH in acid media corresponds to 40

mV per unit of pH, meaning that it is likely that the reaction mechanism corresponds to an electron transfer followed by a chemical reaction, probably a dimerization, leading to irreversible product adsorption on the electrode surface. A plot of I_p vs pH (Fig. 4) shows that higher currents are observed for $\text{pH} \sim \text{p}K_a$.

3.2. Application of the method to a commercial product

The electroanalytical method developed for the determination of bentazon was used to analyse a commercial compound, Basagran, that contains bentazon as the active ingredient. The sample and calibration standards, between 1.51×10^{-5} and 2.26×10^{-5} M were prepared according to the description in Section 2. The square wave voltammograms obtained for both sample and standards are shown in Fig. 5. The calibration plot gave a straight line ($r = 0.998$, $n = 5$) for bentazon.

These results were compared with those obtained using the AOAC method [15]. This method is an isocratic reversed-phase liquid chromatogra-

Fig. 3. Plot of E_p vs pH for 2.0×10^{-5} M solutions of bentazon in 0.2 M buffer electrolyte.

phy (LC) procedure for measuring bentazon in commercial herbicide products and aqueous formulations. The samples are dissolved in LC eluent (0.075 M sodium acetate + methanol (60 + 40)) and analysed by LC on a 30 cm \times 3.9 mm octadecylsilyl column with detection by UV absorption at 340 nm. The quantity of active ingredient is determined by comparing the mean response factor (RF) of the sample to the mean RF of the standards injected immediately before and after each pair of sample injections.

The results obtained with the electrochemical and AOAC methods were in good agreement and the reproducibility was good. The mean and standard deviation obtained for eight determinations by the electrochemical method were 41.61% w/w and 1.42%, respectively and by the AOAC procedure 42.36% w/w and 0.72%. The recovery data for these eight determinations using the electrochemical method was $99 \pm 4\%$. The accuracy of these results was assessed by comparing the electrochemical results with those obtained by the AOAC method, the relative error being 2.4%.

4. Conclusions

Electrochemical methods can be successfully used to quantify the herbicide bentazon in a commercial product. The electrochemically-developed method is simple, enables faster determinations and also permits the study of the oxidation mech-

anism of bentazon which is complex and involves the formation of strongly adsorbed products on the electrode surface. A comparative evaluation of the data showed that the results obtained electroanalytically were in good agreement with those obtained by the AOAC chromatographic method.

Received 18 July 1997; received in revised form 23 October 1997; accepted 24 October 1997

Abstract

Ni(II) and Co(II) have been determined simultaneously by means of adsorptive cathodic stripping voltammetry (AdCSV) in a computerised flow injection system. The working electrode was a glassy carbon disk that was fitted in a wall-jet flow cell. The electrode was initially electrochemically coated with a mercury film at -1.0 V by injecting a Hg(II) solution in the flow stream. Then, the sample, containing Ni(II) and Co(II), was mixed on-line with a solution containing dimethylglyoxime (DMG) at pH 9 in order to selectively complex the metal ions and was injected in the flow system. After a number of successive injections during which accumulation took place under controlled potentiostatic conditions, the surface-bound complexes were reduced in ammonia buffer at pH 9 by a cathodic scan of the potential of the working electrode in the square wave mode and the current-potential response was recorded. Finally, the electrode surface was regenerated by a potentiostatic polarisation at -1.4 V in the same buffer. The apparatus could be easily converted for continuous flow accumulation in order to increase the sensitivity; in this mode of operation, instead of performing discrete injections, the sample was continuously pumped through the cell. Various parameters associated with the preconcentration, stripping and regeneration steps were optimised for the determination of Ni(II) and Co(II). The selectivity of the method was demonstrated for the analysis of high purity iron; the accuracy for the determination of Ni(II) and Co(II) was 11 and 3%, respectively while the coefficient of variation was 10 and 8%, respectively. © 1998 Elsevier Science B.V. 1. Introduction

Since the discovery of the analytical utility of the adsorptive properties of the Ni(II) and Co(II) complexes with dimethylglyoxime, methodologies have been developed to determine Ni(II) and Co(II) by AdCSV in various matrices (for example [1,2]) that make use of the HMDE and con-

ventional batch measuring configurations. Mercury film electrodes (MFEs) can replace the HMDE for adsorptive stripping measurements in the reductive regime [3]. While MFEs are mechanically stable and simple to make and to maintain, their main drawback lies with the difficulty in regenerating the active mercury surface after the irreversible adsorption of surface active compounds after prolonged use [4]. Despite these complications, MFEs plated on a rotating disk electrode have been applied previously with success to the AdCSV analysis of various samples for their Ni(II) and Co(II) content [5–7]. However, the recent trend is towards the use of flow analysers on account of the ease of use, cost, throughput and reliability that such systems typically offer. The HMDE has been occasionally used in flow-through systems [8,9] but is not particularly well suited to operate in flowing systems due to the practical problems of its limited mechanical stability and the difficulty associated with the disposal of liquid mercury. On the other hand, several applications exist that make use of MFEs for the selective accumulation of the Ni(II) and Co(II) complexes with different oximes in flow systems [10–12] or in the batch injection analysis (BIA) mode [13].

In this work, Ni(II) and Co(II) have been determined simultaneously by square wave AdCSV (SWAdCSV) and flow injection analysis (FIA) with high selectivity and sensitivity. The square wave modulation, combined with AdCSV, offers speed, high analytical sensitivity, low background current and insensitivity to dissolved oxygen compared to other scanning waveforms [14]. On the other hand, operation in the FIA mode allows convenient medium exchange in the stripping step and removes the need for the time consuming deoxygenation stage. The cleaning-regeneration of the mercury film working electrode was exhaustively assessed and optimised. Other parameters affecting the combined stripping signal (such as the accumulation time, the concentration ratios of the two metals, the preconcentration potential and the sample volume injected) were also investigated. The selectivity of the method was demonstrated for the analysis of an iron sample for its nickel and cobalt content.

2. Experimental

2.1. Reagents-apparatus

1000 ppm Ni(II) and Co(II) atomic absorption standard solutions were purchased from BDH (Poole, England) and used for the preparation of standards by serial dilution. DMG was also purchased from BDH and a 0.1 M stock solution was prepared in 95% ethanol. A 0.1 M Hg(II) stock solution was prepared by dissolving the appropriate amount of $\text{HgCl}_2 \cdot 6\text{H}_2\text{O}$ (BDH) in 1 mM HNO_3 and the 1 mM mercury plating solution was prepared by dilution with 0.1 M $\text{KNO}_3/0.01$ M HNO_3 . The 0.1 M ammonia buffer (pH 9) was prepared by dissolving the appropriate amounts of concentrated HCl and NH_3 (BDH, Aristar grade). Distilled and deionised water (resistance > 18 M Ω) was used for the preparation of the solutions.

The flow system was a modified version of an earlier FIA apparatus [15]. The configuration of the system for the present work is schematically illustrated in Fig. 1(a). Sampling was carried out for 8 s under stopped-flow conditions and the sample loop was flushed with carrier for 22 s in order to transport the sample to the cell. This timing resulted in a sampling rate of 2 samples min^{-1} . The potentiostat and the wall jet flow cell have also been reported earlier [15]. The loop volume was 200 μl .

2.2. Preparation of the sample

The iron sample (0.250 g) was weighed, dissolved in 10 ml of 4 M HNO_3 and diluted to 100 ml in a volumetric flask. For the analysis, 0.5 g of potassium tartrate was added to a 5.0 ml portion of this solution (in order to complex Fe(III) and avoid precipitation as $\text{Fe}(\text{OH})_3$ in the later stages in alkaline pH). Then 40.0 ml of the ammonia buffer (pH 9) was added and the pH adjusted to 9 with concentrated ammonia. Finally, the solution was diluted to 100.0 ml and was ready for the analysis. A blank solution not containing iron was prepared in the same way.

(1), (2), (3) and (4) correspond to 0, 10, 20, and 40 s cleaning at -1.4 V. $[\text{Ni}(\text{II})]$ and $[\text{Co}(\text{II})]$ 100 nM; DMG 1 mM; deposition at -0.7 V; 3 sample injections; SW frequency 40 Hz, pulse height 10 mV, scan increment 2 mV. (b) Voltammograms demonstrating the efficiency of the mercury stripping from the surface of the glass carbon electrode after electrochemical cleaning in 0.1 M HNO₃ and 0.8 V at different cleaning times. (1), (2), (3) and (4) correspond to 0, 30, 60, and 120 s cleaning at 0.8 V. Scan rate 0.1 V s⁻¹.

2.3. Experimental procedure

The different steps of the experimental procedure together with the physical parameters used for the determination are schematically illustrated in Fig. 1(b).

2.3.1. Coating of the mercury film

The electrode was polished as described previously [6] and then was coated with mercury by injecting three aliquots of the 1 mM Hg(II) plating solution at a potential of -1.0 V using 0.1 M nitric acid as the carrier with a flow rate of 2 ml l⁻¹.

Fig. 3. Plot of the magnitude of the stripping peak current of Ni(II) (◆) and Co(II) (■) as a function of the total injected sample volume. [Ni(II)] and [Co(II)] 50 nM. Other conditions as in Fig. 2(a).

2.3.2. Preconcentration and measurement

The blank solution was mixed with the 1 mM DMG solution and injected into the carrier stream of ammonia buffer while the potential of the electrode was maintained at the preconcentration potential (ranging from -0.3 to -0.7 V). After three successive injections, the flow was stopped and, after a 10 s rest period, the square

wave scan was initiated from the preconcentration potential to -1.4 V with a frequency of 40 Hz, pulse height 10 mV and scan increment 2 mV while the current-potential response was recorded and stored. After measuring the background, the same procedure was repeated by replacing the blank with the sample and the spiked sample solutions.

Table 1

Calibration parameters for the determination of Ni(II) and Co(II) by SWAdCSV using FIA and continuous flow accumulation

Metal	Deposition mode			
	FIA		Continuous flow	
	Ni(II)	Co(II)	Ni(II)	Co(II)
Sensitivity ($\mu\text{A mol l}^{-1}$)	5.2×10^6	1.0×10^7	2.2×10^7	4.8×10^7
Intercept (μA)	0.12	0.14	0.14	0.22
LOD (nM) at 3σ	4.3	2.9	0.76	0.68
Linear range (mol l^{-1})	From LOD to 1×10^{-6}	From LOD to 1×10^{-6}	From LOD to 1×10^{-7}	from LOD to 1×10^{-7}
Correlation coefficient	0.998	0.997	0.995	0.999

Continuous flow involved 30 s adsorption of the sample flowing through the cell at 2 ml min^{-1} .

Fig. 4. (a) Current components of a SW voltammogram of Ni(II) and Co(II) after preconcentration of a deoxygenated sample. [Ni(II)] 100 nM and [Co(II)] 50 nM. Other conditions as in Fig. 2(a) (b) Effect of oxygen on the SW and SC voltammograms of Ni(II) and Co(II). SW after deoxygenation for: (1) 0 s; (2) 60 s; (3) 240 s. SC after deoxygenation for (4) 60 s; (5) 240 s. Other conditions as in Fig. 2(a).

2.3.3. Cleaning of the mercury film

After each measurement, the mercury film was reactivated by potentiostatic polarisation at -1.4 V

in a stream of ammonia buffer flowing at 2 ml min^{-1} . The mercury film was stripped by polarisation at $+0.8$ V in 0.1 M nitric acid flowing at 2 ml min^{-1} .

Fig. 5. (a) Analysis of the 149/3 BCR iron sample for its Ni and Co content. (1) blank; (2) sample; (3), (4) successive additions of $6 \mu\text{g l}^{-1}$ Ni(II) and $12 \mu\text{g l}^{-1}$ Co(II). Deposition at -0.5 V. Other conditions as in Fig. 2(a).

3. Results and discussion

3.1. Mercury film cleaning/regeneration

In order to develop the analytical procedure, a stable and renewable electrode surface was required. Despite the recognition of the fact by most authors that the cleaning/regeneration method of the mercury deposit is one of the most important factors determining the precision of the results in AdCSV, no comprehensive study exists related to this subject. In this work, both the reactivation of the electrode after each measurement and the stripping of the mercury film were assessed.

Initial experiments demonstrated that plating of a new mercury film before each measurement resulted in poor reproducibility in the Ni(II) and Co(II) stripping peaks (coefficient of variation for repetitive measurements was 20–25%). This lack of precision associated with MFEs is attributed to variations in the active surface of these electrodes (i.e. the ‘between-film’ precision is poor). For this reason, it was decided to investigate in situ regeneration of the mercury film as suggested in earlier work and it was found that efficient reactivation could be achieved by polarisation of the electrode

at -1.4 V in flowing ammonia buffer. Under these conditions, the complexes of Ni(II) and Co(II) with DMG were reduced and desorbed from the electrode surface. No memory effects from the reduction and amalgamation of the liberated Ni(II) and Co(II) at -1.4 V were observed. It was assumed that the ions were swept downstream by the flowing solution after desorption and reduction of the complex before they could be reoxidised to the zero oxidation state, in view of the low solubility of nickel and cobalt in mercury. It must be noted that the nickel complex took longer to desorb than the cobalt complex but complete removal of both species could be eventually achieved. The time of the cathodic polarisation depended on the amount of complexes adsorbed but, in general, a cleaning time ranging from 40 to 60 s was sufficient. Fig. 2(a) illustrates the effect of the in situ cleaning time on the magnitude of the stripping response. This procedure decreased the coefficient of variation of successive determinations on the same mercury film (referred to as ‘within-film’ reproducibility) to around 3%. To summarise, in contrast to the method based on the formation of a new film before each analysis resulting in significant ‘between-film’ uncertainty, in situ regeneration of the

same film enabled to achieve a much lower 'within-film' uncertainty and the overall precision of results increased. Each electrode could be used for twenty or more complete preconcentration/stripping/regeneration cycles, depending on the matrix. In situ deposition of the mercury film achieved by adding Hg(II) in the sample solution was found to be unsuccessful, probably due to the alkaline pH of the sample that causes the hydrolysis of Hg(II).

The stripping of the mercury from the electrode surface was also investigated. The objective of this study was the efficient, rapid and reproducible removal of the old coating from the electrode surface. The efficiency of the cleaning was monitored by scanning the potential of the electrode from 0.0 to +1.0 V and recording the magnitude of the stripping peak for the oxidation of mercury. Three cleaning methods were studied: i) the first method was based on the strong complexing activity of tetraethylpentamine (tetren) towards mercury [16]. For this purpose a 0.1 M tetren solution was allowed to flow through the cell while the potential of the working electrode was maintained at +0.4 V. Despite efficient and fast removal of mercury (cleaning time was 60 s for a typical film) this method was found to be unsatisfactory because tetren itself is a strong surface active compound. As a result, tetren fouled the active sites of the electrode surface and subsequent mercury plating to form a new film was erratic as demonstrated by small plating currents and small and irreproducible stripping peaks for Ni(II) and Co(II); ii) the second method involved oxidation and complexation of mercury in the form of the very stable $[\text{HgI}_4]^{2-}$ complex in a medium containing iodide and I^- ions [17]. To carry out the cleaning, a solution containing 0.005M I_2 /0.5 M KI was allowed to flow through the cell. It was found that short cleaning times (cleaning time 40 s for a typical film) were sufficient to remove the mercury coating. However, thorough rinsing (~3 min) of the cell was necessary before plating a new mercury film in order to expel any remaining I^- ions and, thus, avoid the formation of insoluble Hg_2I_2 on the electrode surface and tubings [16]. A common practical disadvantage of both the methods mentioned

above was that they require a more complex flow system (i.e. additional pumps and valves) capable of providing the cleaning medium; iii) the third method involved electrochemical oxidation of mercury at +0.8 V in a 0.1 M HNO_3 solution [15]. Although this method was more time consuming (a cleaning time of 120 s was required for a typical film), any risk of contamination or poisoning of the electrode surface and the flow manifold was eliminated and the experimental procedure was simplified as the nitric acid medium was also used as the carrier for the mercury plating. The traces in Fig. 2(b) demonstrate the cleaning efficiency after polarisation at +0.8 V in 0.1 M HNO_3 for different cleaning times. Electrochemical cleaning was selected for all the subsequent experiments.

3.2. Effect of the total injected sample volume and the flow rate

In batch analysis, the effective preconcentration time is calculated as the total time during which accumulation of the adsorbable species is carried out. In this case, the bulk concentration of the species is assumed to be constant with time. In FIA, preconcentration occurs only when each injected sample plug passes over the electrode and, even then, preconcentration is more efficient at the centre of the plug rather than at the edges where diffusion is predominant. So, In FIA it is more meaningful to relate the stripping current on the volume of the injected sample (or, equivalently, to the number of injections) rather than on the total preconcentration time. The relevant plot for the simultaneous determination of Ni(II) and Co(II) is illustrated in Fig. 3. The response, typically for an adsorptive process, increased with the

Table 2
Analysis of the 149/3 BCR iron sample for its nickel and cobalt content by SWAdCSV ($n = 5$)

Certified content (%)		Content found (%)	
Ni	Co	Ni	Co
0.0036	0.0073	0.0040	0.0075
± 0.0008	± 0.0005	± 0.0008	± 0.0006

total injected volume and levelled off at higher preconcentration times for both Ni(II) and Co(II). The pattern is that the equilibrium surface concentration for Ni(II) was lower and was achieved earlier for Ni(II) than for Co(II) and it was similar to the pattern obtained for the rotating disk electrode and the HMDE [6,18]. This is probably due to the fact that the adsorption coefficient of Ni(II) is larger than the adsorption coefficient of Co(II) at the preconcentration potential of -0.7 V, as already noted in earlier studies [6,18].

Varying the carrier flow rate between 1 and 3 ml min⁻¹ did not affect the peak currents significantly, probably because the increase in the preconcentration efficiency afforded at higher flow rates was counterbalanced by the decreased residence time of the sample in the flow cell. However, higher flow rates enabled higher sampling frequencies and faster rinsing of the cell. A flow rate of 2 ml min⁻¹ was adopted for most of the experiments in this work.

3.3. Calibration parameters—FIA vs continuous flow preconcentration

The calibration curve for the determination of Ni(II) and Co(II) with FIA was linear up to 1 μ M. For higher concentrations the electrode surface saturated and the calibration curve levelled off. The calibration parameters are shown in Table 1. While the linear range was extended to higher concentrations, the limit of detection was higher than in batch analysis using the HMDE or the rotating disk electrode [6,18]. This sensitivity was not sufficient to determine Ni(II) or Co(II) in ultratrace levels (e.g. seawater) without some sort of preconcentration but was enough for the determination of traces of the two metals in pure iron samples. The sensitivity can be increased by employing continuous flow, instead of FIA, preconcentration. This preconcentration mode involves continuous flow of the sample through the cell during the accumulation period rather than discrete injections of sample. Conversion of the FIA manifold to continuous flow

manifold can be achieved in a matter of minutes by repositioning the electrochemical flow cell in the flow manifold, as reported earlier [19]. The calibration parameters with continuous flow preconcentration are also, shown in Table 1.

3.4. Optimisation of the background response

In most reductive voltammetric procedures, dissolved oxygen interferes by producing a wide reduction irreversible peak and capacitive currents arise as a result of the potential scan. In this work two methods were combined to alleviate the deterioration in the background due to these effects: i) the SW potential scanning waveform, and; ii) the medium exchange approach. A third method, involving the use of concentrated CaCl₂ (which has a low oxygen content) [20] was considered impractical due to the possibility of calomel formation on the electrode surface.

The SW provides a means of discrimination of reduction processes according to their reversibility because it enhances the redox current of reversible processes and suppresses less reversible processes. In this case, since the reduction of Ni(II) and Co(II) is irreversible [6], the SW modulation affords no improvement on the classical digitally generated staircase waveform (SC) as far as the sensitivity (peak heights) is concerned. This is due to the same polarity of the forward, I_p , and reverse currents, I_r , which result in a decreased differential current, I_d , (Fig. 4(a)). This is further demonstrated by inspection of the traces in an unpurged solution which clearly demonstrate that no discrimination against oxygen is provided by the SW scan (Trace 1 in Fig. 4(b)). Thus, not only is sensitivity compromised by the use of SW but also the oxygen interference remains. In view of these results, the utility of the SW mode can be questioned. However, a significant improvement in the capacitive component can be obtained as a result of the differential nature of this technique (Fig. 4(a) and Traces 3 and 5 in Fig. 4(b)). On the other hand, the effect of oxygen can be eliminated by exchanging the sample solution with purged ammonia buffer (Trace 3 in Fig. 4(b)).

3.5. Analytical application

The method developed was applied to the analysis of high purity iron for its nickel and cobalt content. The sample was dissolved in nitric acid to oxidise the metals and convert them to their cations, Ni(II) and Co(II). Tartrate was added to the sample solution to prevent Fe(III) from precipitating as Fe(OH)₃ when making the pH alkaline. As explained in the previous section, the sample was not deliberately deoxygenated since the stripping was carried out in the purged buffer. The method of standard additions was used for the quantitative evaluation of the nickel and cobalt content in order to avoid any matrix effects. In agreement with the findings of previous work and, since cobalt is in excess of nickel in the sample, the preconcentration was carried out at -0.5 V in order to increase the ratio of Ni(II)-to-Co(II) peak heights [6]. The peaks for Ni(II) and Co(II) were well defined and no interfering peaks due to other constituents of the sample were present. A series of traces after standard additions in the sample is illustrated in Fig. 5(a). The results for the standard additions analysis are shown in Table 2. It was noted that, after repetitive measurements without in situ electrode cleaning an increase in the background current close to the Co(II) peak was observed. This effect was not investigated further as cleaning of the electrode at -1.4 V restored the background to its initial value.

Non-protected fluid room temperature phosphorescence of several naphthalene derivatives

Longdi Li *, Yu Zhao, Yingguang Wu, Aijun Tong

Received 8 May 1997; received in revised form 27 October 1997; accepted 28 October 1997

Abstract

In our previous work, we reported that with TINO_3 as a heavy atom perturber and Na_2SO_3 as a deoxygenator, room temperature phosphorescence (RTP) emission of dansyl chloride and its amino acid derivatives can be induced directly from their aqueous solution without a protective medium. Is this kind of fluid luminescence phenomenon unique for the dansyl chloride compounds? The present work has shown that many naphthalene derivatives can also exhibit RTP emission in their aqueous solutions under similar conditions in the absence of a protective medium. Such an RTP emission phenomenon could be denoted as nonprotected fluid room temperature phosphorescence (NP-RTP). In order to further understand this new luminescence phenomenon, the substituent group effects and the favorable chemical structure of compounds for NP-RTP emissions are discussed in detail. © 1998 Elsevier Science B.V. Keywords: Naphthalene derivatives; NP-RTP; Substituent group

1. Introduction

As $S_0 \rightarrow T_1$ is a spin-forbidden transition, the triplet state has a long lifetime. During this moment, the nonradiative decay processes of luminophores, the collisions with solvent and conversion of energy, as well as the possibility of photochemical reaction, can easily take place. As a result, the intensity of the phosphorescence will be attenuated and the detection of phosphorescence in solution or gas phases becomes very difficult.

Donkerbroek et al. [1,2] investigated the room temperature phosphorescence (RTP) of various phosphorescent compounds in solution, concluding that RTP intensities of solutes in liquid solution are generally too low to be useful in direct analytical work. This is mainly due to the long lifetime of the triplet state, which favors collision quenching by oxygen and other quenchers in solution at room temperature.

Turro et al. [3] first reported that RTP in fluid solution could be observed in the presence of micelles, heavy atoms and deoxygenation by nitrogen. On the basis of that report, Cline Love [4] established the micelle-stabilized room temperature phosphorescence (MS-RTP) as an analytical

method. The phase behavior of micelles changes the microscopic environment and raises the stability of the triplet state, so that phosphorescence intensity increases to a remarkable degree. Following the successful application of protected medium in fluid RTP, cyclodextrin-induced RTP (CD-RTP) [5], vesicle-stabilized RTP (VS-RTP) [6], microemulsion-stabilized RTP (ME-RTP) [7] etc., have been developed subsequently.

Therefore, it seems necessary to provide a protective ordered medium to minimize self-quenching and bimolecular quenching (for example, in CD-RTP, cyclodextrins are the microscopically ordered medium and phosphors are protected in their cavities) and to organize reactants on a molecular level to increase the proximity of heavy atoms and analyses which can increase the quan-

tity of the triplet state and lead to a intense phosphorescence emission. Using these methods, RTP can be observed after deoxygenation.

However, based on the recent discovery, our group has reported that the RTP emission of dansyl chloride (DNS-Cl) and its derivatives can be directly induced in aqueous systems only by the addition of thallos nitrate as a heavy atom perturber and sodium sulfite as the deoxygenator [8,9]. In order to discover whether this phenomenon occurs only for some unique compounds or if the others also display this characteristic, the properties of RTP emission in a series of solutions of naphthalene derivatives without protective medium (the chemical names of these derivatives studied and their respective codes in this paper are shown in Table 1) were

studied in the present work. The experimental results demonstrated that DNS-Cl is not the only compound to produce RTP without protective ordered medium. The RTP of many derivatives can also be induced under the same conditions. Following our research into the mechanism of this phenomenon, the name non-protected fluid room temperature phosphorescence (NP-RTP) is suggested for this new type of RTP emission.

2. Experimental

2.1. Chemicals

Aqueous solutions (2.0 mmol l^{-1}) were prepared for the code 7, 12, 15, 18, 19, 20 and 22 compounds, 2.0 mmol l^{-1} acetone–water (1:9 v:v) solutions were prepared for code 2, 3, 6, 9, 16 and 23 compounds and 2.0 mmol l^{-1} acetone solutions were prepared for the remaining compounds. Thallous nitrate (TlNO_3 , CP), sodium sulfite (Na_2SO_3 , AR) were purchased from Beijing Chemical Plant (China) and a 0.25 mol l^{-1} solution of TlNO_3 and a 0.1 mol l^{-1} solution of Na_2SO_3 were used in experiments. The water used was sub-boiled and distilled twice.

2.2. Instruments

All spectra and luminescence intensities were obtained with a Perkin–Elmer LS-50B luminescence spectrometer. Data acquisition and manipulation were facilitated by a King computer interfaced directly to the spectrometer.

2.3. Methods

All glassware used was washed with analytical grade acetone or doubly distilled water before use.

2.3.1. Determination of fluorescence

A 0.1 ml aliquot of 2.0 mmol l^{-1} naphthalene derivative solution was added to a 5 ml quantitative tube and the solution was filled to the mark with water. After shaking, the fluorescence spectra were measured with a 1 cm quartz cell (Ex slit = Em slit = 3 nm).

2.3.2. Determination of phosphorescence

A 0.1 ml aliquot of 2.0 mmol l^{-1} naphthalene derivative solution was added to a 5 ml quantitative test tube. A 1.0 ml aliquot of 0.25 mol l^{-1} TlNO_3 and 0.5 ml aliquot of 0.1 mol l^{-1} Na_2SO_3 were added and the solution was filled to the mark with water. Following shaking, the phosphorescence and mixed spectra (fluorescence spectra in the presence of a heavy atom perturber) were measured with a 1 cm quartz cell (for phosphorescence spectra: Ex slit = 15.0 nm ; Em slit = 20.0 nm ; delay time = 0.1 ms ; gate time = 2.0 ms ; for mixed spectra: Ex slit = Em slit = 3.0 nm).

3. Results and discussion

3.1. NP-RTP spectra of naphthalene derivatives

Under the above conditions, the NP-RTP spectra and characterization of several naphthalene derivatives are shown in Fig. 1 and Table 2. In particular, we choose 1-amino-5-naphthalenesulfonic acid sodium salt as a typical example (see Fig. 2). It can be seen that the phosphorescence emission wavelength is much longer than that of the fluorescence, but the excitation wavelengths are very similar. Moreover, it is well known that fluorescence lifetime is 10^{-8} s order of magnitude; however, the RTP life time of naphthalene derivatives that were measured was 10^{-4} s . These results clearly illustrate that what we observed is indeed RTP.

Therefore, the conclusion is drawn that with TlNO_3 as a heavy atom perturber and Na_2SO_3 as a chemical deoxygenator, many derivatives can emit RTP without a protective medium. Furthermore, the RTP intensities are high enough to be useful in analytical work.

3.2. Effect of TlNO_3 on the NP-RTP of dansyl chloride

With fixed concentrations of dansyl chloride and Na_2SO_3 , the intensities of fluorescence and RTP of DNS-Cl change with the change in TlNO_3 concentration (Fig. 3). While increasing TlNO_3 content, its fluorescence intensity decreases and

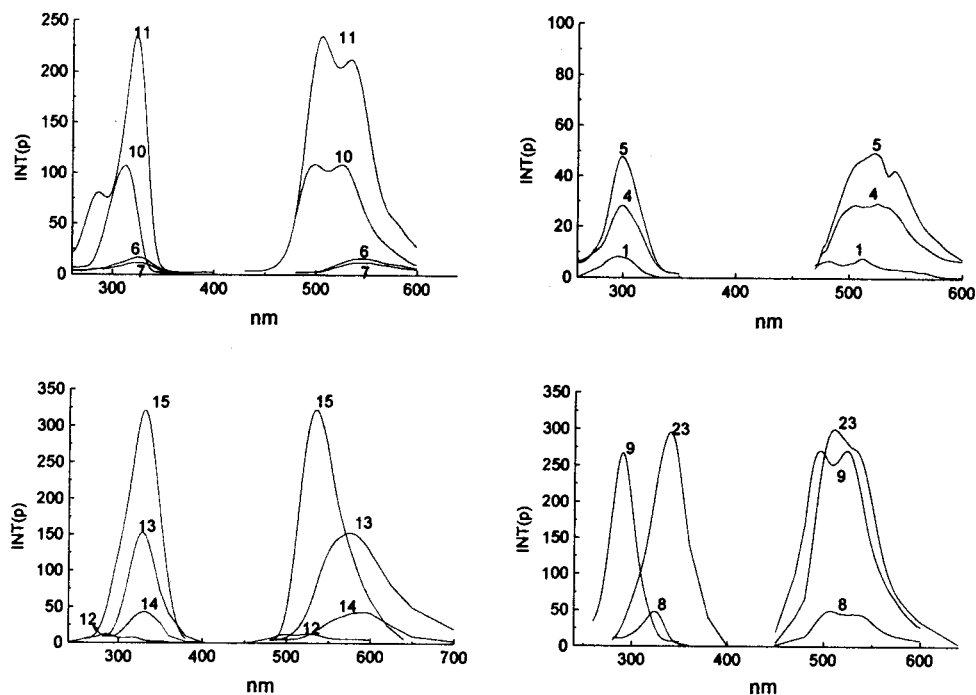

Fig. 1. RTP spectra of partial naphthalene derivatives (code as in Table 1; $C = 4.0 \times 10^{-5} \text{ mol l}^{-1}$).

the RTP intensity increases. Therefore, TINO_3 is a spin-forbidden transition enhancer, increasing intersystem-crossing efficiency.

3.3. Time-stability of RTP emission

For the purpose of using NP-RTP properties of naphthalene derivatives as an analytical tool, the time stability of RTP emission was studied. As shown in the time-scanning spectrum (Fig. 4), there are three cases for the compounds studied: (1) for dansyl chloride in acetone solution, it is necessary to irradiate for 30 s with the apparatus light source in order to obtain a stable RTP signal; (2) for 1-amino-5-naphthalene-sulfonic acid sodium salt in aqueous solution, the RTP intensity is stable; and (3) for some derivatives, including β -naphthoxyacetic acid and α -naphthylacetic acid, the intensity falls with increasing irradiative time. The mechanisms leading to these differences remain to be further investigated.

3.4. Analytical curve and detection limit

Since the RTP intensities of 1-hydroxy-2-naphthoic acid, α -naphthalic acid and 1-amino-5-naphthalenesulfonic acid sodium salt are quite strong under the experimental conditions, the relationship between NP-RTP intensity and the concentration of these derivatives has been investigated and a good linearity has resulted (Table 3).

3.5. Discussion

All the experimental results show that in the presence of a heavy atom perturber to increase the efficiency of the triplet state and a deoxygenator to decrease the quenching of oxygen, the NP-RTP of many naphthalene derivatives without microscopically ordered medium can be observed.

As shown in the literature [10,11], a few compounds such as bridged biphenyls, octahelicene

etc., can produce RTP emission without protective medium. This was attributed to the specific rigidity of the luminophor or the existence of a spin-forbidden transition enhancer. It was regarded as a particular phenomenon belonging to this kind of compound. However, our studies show NP-RTP is not an exceptional phenomenon of certain derivatives but a regular characteristic of naphthalene derivatives. Clearly, the existence of a specific intersystem-crossing enhancement reagent is an important external condition. After studying the structure of naphthalene derivatives, we concluded that RTP emission depends mainly on the chemical structure of the derivatives and the nature of the lowest excited triplet state.

3.5.1. Favorable chemical structure and the nature of the lowest excited triplet state

The basic structure of naphthalene derivatives is the naphthalene nucleus, which has a specific rigidity. The molecular configuration is planar, leading to a high fluorescence efficiency. If the conjugated system grows with the substituent group, the electron is easily excited and fluorescence and phosphorescence are engendered. Turro [12] has pointed out that if phosphorescence can be obtained at 77 K, it can also generally be observed in fluid solution at room temperature, if two conditions are fulfilled: (1) impurities capable of quenching triplet states are rigorously excluded; (2) the triplet state does not undergo an

Fig. 2. NP-RTP and fluorescence spectra of 1-amino-5-naphthalenesulfonic acid sodium salt ($C = 1.6 \times 10^{-6} \text{ mol l}^{-1}$). 1, NP-RTP (Ex slit = 15 nm, Em slit = 20 nm); 2, fluorescence (Ex slit = Em slit = 3.0 nm).

activated unimolecular deactivation having a rate constant (3k_m) greater than or equal to 10^4 times the rate constant for phosphorescence (k_p). In other words, phosphorescence can be observed at room temperature in fluid solution provided that ${}^3k_m < 10^4 k_p$ and that the phosphorescence quantum yield (Φ_p) can be expressed approximately by Eq. (1) based on the dynamic graph (Fig. 5)

$$\Phi_p = \frac{k_p}{{}^3k_m + k_q[q]} \quad (1)$$

where k_q is the rate constant for bimolecular deactivation of the triplet state and $[q]$ is the concentration of quencher. A typical value of k_p for a molecule in an (n, π^*) triplet state (T_1) is 10^2 s , while in a (π, π^*) triplet state is 10^{-1} s [13]. With these k_p values and other assumptions, it is

Fig. 3. Effect of TINO_3 on Fluorescence and RTP of DNS-Cl. 1, fluorescence; 2, RTP.

Fig. 4. Time-scanning spectra of RTP. 1, dansyl chloride; 2, 1-amino-5-naphthalenesulfonic acid sodium salt; 3, β -naphthoxyacetic acid; 4, α -naphthylacetic acid.

possible to calculate the limiting concentration of quencher for the observation of phosphorescence if the quenching is diffusional controlled, such as oxygen. To observe phosphorescence, the Φ_p should be at least 10^{-4} , while for non-viscous organic solvent, the rate constant of diffusion (k_{dif}) is about $10^{10} \text{ l mol}^{-1} \text{ s}^{-1}$. In general, it is assumed that $k_{\text{dif}} = k_q$, then the condition for observing phosphorescence is: for $T_1(n, \pi^*)$, $k_{\text{dif}}[q] < 10^6 \text{ s}$, therefore $[q] < 10^{-4} \text{ mol l}^{-1}$; and for $T_1(\pi, \pi^*)$, $k_{\text{dif}}[q] < 10^3 \text{ s}$, therefore $[q] < 10^{-7} \text{ mol l}^{-1}$.

A concentration of $10^{-4} \text{ mol l}^{-1}$ for q can be readily obtained experimentally, but to obtain a concentration of $10^{-7} \text{ mol l}^{-1}$ is more difficult. Thus, it is easy to observe fluid RTP of compounds with $T_1(n, \pi^*)$ states, whereas it is quite difficult with $T_1(\pi, \pi^*)$ states. This conclusion is in accordance with our experimental results. For example, the NP-RTP emission of naphthalene, anthracene, phenanthrene and pyrene are very weak or cannot be observed because their triplet states are $T_1(\pi, \pi^*)$ states, even in very pure solvents (impurity level including oxygen below $10^{-9} \text{ mol l}^{-1}$), the quantum yields of phosphorescence (Φ_p) are in the order of 10^{-6} .

3.5.2. The substituent group effects

1. Electron-donating substituent groups, particularly those with an n electron, tend to increase the phosphorescence intensity, since they can increase the mobility of the electrons of the naph-

Table 3
Characterization of analytical curve

Compound	Linear range (mol l ⁻¹)	Slope	Intercept	Correlation co- efficient	Detection limit (mol l ⁻¹)
1-Hydroxy-2-naphthoic acid	4.0×10^{-7} $\sim 2.0 \times 10^{-5}$	1.16×10^7	2.10	0.997	1.5×10^{-7}
α -Naphthylacetic acid	8.0×10^{-6} $\sim 8.0 \times 10^{-5}$	4.02×10^6	3.44	0.990	5.9×10^{-7}
1-Amino-5-naphthalenesulfonic acid sodium salt	1.6×10^{-7} $\sim 4.0 \times 10^{-6}$	3.84×10^7	5.30	0.999	3.0×10^{-8}

thalene ring and can form a $T_1(n, \pi^*)$ state such as 1-naphthylamine, β -naphthyl ethyl ether etc...

2. Substituent groups with a negative charge can enhance the phosphorescence intensity. In aqueous solution, the proximity between luminophor and inorganic heavy atom perturber Tl^+ can be increased owing to attraction based on static electricity and can increase the efficiency of intersystem crossing to the triplet state, such as for the code 15 compound, 1-amino-5-naphthalenesulfonic acid sodium salt, which contained not only the electron-donating (with n electron) group $-NH_2$ but also contained the SO_3^- group at position 5. Therefore, its NP-RTP intensity is the highest in the compounds studied.

3. For heavy atom substituted compounds, phosphorescence intensity is relatively strong. In molecules containing heavy atoms, this condition favors a higher probability of intersystem-crossing $S_1 \rightarrow T_1$. Frequently, one sees a decrease in the fluorescence quantum yield Φ_f and an increase in

the phosphorescence quantum yield Φ_p when the heavy-atom effect occurs, such as the Φ_f and Φ_p are 0.55, 0.0016 and 0.051, 0.27 at 77 K for naphthalene and α -naphthalenebromide, respectively [14]. The introduction of additional halogen atoms into naphthalene nuclei also results in a red-shift in the phosphorescence.

4. If the carbonyl group is present, the lowest excited singlet state of derivative is the $S_1(n, \pi^*)$ state. The $S_1 \rightarrow T_1$ intersystem crossing efficiency is high [15] and the NP-RTP of the compound is usually observed, such as code 9, 10, 11 and 23 compounds.

5. Compounds with $-NO$ or $-OH$ groups substituted, such as code 16, 20, 2 and 3 compounds, do not favor phosphorescence emission in solution. When the substituted group is $-NO$, it is easy to produce $T_1 \rightarrow S_0$ non-irradiative intersystem-crossing or photochemical reaction, owing to the reactivity of $-NO$. In aqueous solution, there are hydrogen bonds between the $-OH$ substituent group and H_2O and this may lead to quenching of the phosphorescence. If a suitable amount of β -CD is added into the corresponding α - or β -naphthol (code 2, 3) system, the phosphorescence may be observed as a result of the protective effect of CDs, which isolates luminophor and water.

6. For 1,8-ANS, the group at position 8 is phenylamine, which is connected with naphthalene nucleus through single bond. Since rotation configuration causes energy dissipation, not only can NP-RTP not be detected, but the fluorescence intensity is also very weak.

Fig. 5. The dynamic graph of fluorescence and phosphorescence.

Although it is problematic to illustrate the mechanism of NP-RTP clearly at present, we can predict, based on the above, whether a compound with an n electron and negative charge substituent group, 1-dimethylamino-5-naphthalenesulfonate, it will give intensive NP-RTP emission.

Compared with CD-RTP, MS-RTP etc., NP-RTP has some unique advantages:

1. First and most important, without the microscopically ordered protective medium, NP-RTP not only makes the method itself simple, but also can avoid interference with the analysis due to the addition of the medium. It is particularly suitable for biological samples.

2. RTP can be a useful and powerful technique for detection in liquid chromatography and flow injection analysis (FIA). The investigated system is a transparent, stable solution, which makes it possible to associate it with these analytical techniques and perform automatic on-line analysis.

NP-RTP is a new method for fluid RTP technique. The scope of this luminescence technique is very broad. For example, DNS-Cl, DNS-NH₂ etc., are important and widely used fluorescence derivative reagents, whose derivatives can also be used for NP-RTP. In addition, for sensitized/quenched-RTP (S/Q-RTP) [16], the NP-RTP quantum yield of naphthalene derivatives is high and they can be used as acceptors. Thus, the limits of acceptors for S/Q-RTP will be extended.

Determination of tin in marine materials by using hydride generation–high resolution inductively coupled plasma mass spectrometry

Yong-Lai Feng, Hisatake Narasaki *

Department of Chemistry, Faculty of Science, Saitama University, Shimo-Okubo, Urawa 338, Japan

Received 7 July 1997; received in revised form 28 October 1997; accepted 29 October 1997

Abstract

A hydride generation system combined with high-resolution inductively coupled plasma mass spectrometry was used to determine tin in marine materials. The optimization conditions for determination of tin in this system are 0.015 M of sulfuric acid solution as medium, 0.2% (w/v) of sodium tetrahydroborate(III) in 0.015 M of sodium hydroxide solution as a reductant and argon as the carrier gas at a flow rate of 1.1 l min⁻¹. In order to remove the interferences from transition element ions, a strongly basic anion exchanger was used in this method. Tin was converted to its chlorostannate with 2 M hydrochloric acid followed by passing to an anion exchanger. The tin absorbed on the column was then eluted with 1 M nitric acid. Under the optimized conditions, the detection limit of the method was 12 ng l⁻¹ without using the anion column as preconcentration method. The results obtained using this method were in good agreement with the certified values of marine standard reference materials. The recoveries for the method when applied to determine trace tin in river water were 95–115%. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Inductively coupled plasma mass spectrometry; Tin; Strongly basic anion exchanger

1. Introduction

Hydride generation, as a separation and pre-concentration technique for the determination of hydride-forming elements, has been used recently for the rapid determination of the presence of tin by combination with atomic absorption spectrometry (AAS), inductively coupled plasma

atomic emission spectrometry (ICP-AES) or inductively coupled plasma mass spectrometry (ICP-MS). Of these methods, ICP-MS is the most highly-sensitive. However, with marine materials, because of interference from large amounts of matrix, especially from transition element ions, it is difficult to determine tin by the hydride generation method without interference removal or matrix separation. In the literature on hydride generation technique combined with atomic spectrometry, masking agents [1–8] and ion exchange

* Corresponding author. Tel.: +81 488 522111; fax: +81 488 583378.

resins [9,10] are usually used to reduce or remove the interference from transition element ions. Strongly basic anion exchanger resin such as Amberlite CG400 [9] and Dowex 1-X8 [10] are usually used in the separation column to remove these interferences. Silica gel was also described as a cleanup method for removal of the interferences from transition element ions and preconcentration of trace amounts of tin [11]. Many other masking agents were reported to mask the interference ions in order to reduce their interference in the hydride generation system [1–8]. In a previous paper [12], L-cysteine hydrochloride monohydrate was used as a masking agent to reduce interference from transition metal ions in the hydride generation ICP-AES. In this paper, tin in marine materials and river waters was determined by high-resolution inductively coupled plasma mass spectrometry combined with hydride generation technique. Since tin can be converted into chlorostannate anion in concentrated hydrochloric acid and reconverted into cation with dilute nitric acid, prior to analysis, DIAION PA316, a strongly basic anion exchanger, was used to remove the interferences from transition ions as well as some other hydride-forming elements and CrO_4^- etc. DIAION PA316 is composed of polystyrene crosslinked with 8% divinylbenzene and has functional groups of trimethylammonium.

2. Experimental

2.1. Apparatus

The schematic diagram of the hydride generation system is described elsewhere [13]. A high resolution inductively coupled plasma-mass spectrometer (JMS PLASMAX2, Japan Electron Optics Laboratory, Akishima, Japan) equipped with a computer with a 'HUeLine' operating system to control the instrument operations, data conversion and storage, was used in this study. Two single-channel peristaltic pumps (SJ-1211H, Atto Corporation, Tokyo, Japan) were used to pump the sample and sodium tetrahydroborate(III) solutions, respectively. The waste solution was

drained by an electromagnetic solenoid valve (Pinch Valve PK-305-NO, 13W, Takasago Electric Industries, Nagoya, Japan). The operating conditions of the spectrometer are listed in Table 1. The setup of the electric circuit for this hydride generation system was described elsewhere [13].

2.2. Reagents

The stock standard solution ($1000 \mu\text{g ml}^{-1}$) of Sn(IV) was obtained from Wako Pure Chemical Industries (Tokyo, Japan). The working standard solution (20 ng ml^{-1}) of Sn(IV) and four point calibration solutions composed of blank, 0.2, 0.4 and 0.6 ng ml^{-1} of Sn(IV) in 0.015 M sulfuric acid solution were prepared daily from the stock solution. All acids used were Tamapure-AA-100 (Tama Chemical Industries, Tokyo, Japan). Milli-Q ultrapure water (Japan Millipore, Tokyo, Japan) was used throughout in this study. The stock solution of sodium tetrahydroborate(III) (2% w/v) was prepared by dissolving sodium te-

trahydroborate(III) powder (Morton International, Tokyo, Japan) in 0.15 M sodium hydroxide solution and storing in a polyethylene bottle in a refrigerator at 4°C. The usage period for the stock solution of sodium tetrahydroborate(III) is within 1 week. The working solution of sodium tetrahydroborate(III) (0.2% w/v) with 0.015 M sodium hydroxide was prepared by diluting the stock solution daily. Stock solutions of interference ion ($1000 \mu\text{g ml}^{-1}$ and $10 \mu\text{g ml}^{-1}$) were prepared from their corresponding salts. The column (8 mm i.d. \times 100 mm high) was loaded with a strongly basic anion exchange resin DIAION PA 316 (Mitsubishi Chemical, Tokyo, Japan). The resin was used in the chloride form without any conditioning and was discarded after use. All other reagents used were of analytical reagent grade or better.

2.3. Sample pretreatment

For Marine Sediment Reference Material, PACS-1 (National Research Council, Ottawa, Canada), 0.1 g of the material was weighed in a 100-ml platinum dish. Nitric acid (10 ml; 68% w/w Tamapure-AA-10), 2 ml of perchloric acid (70% w/w Tamapure-AA-100) and 0.5 ml of sulfuric acid (98% w/w) were added to the dish. The mixture was left overnight at room temperature. Then 5 ml of hydrofluoric acid (38% w/w) was added and the platinum dish was heated at 80°C on a temperature controllable electric heater plate for 2 h followed by heating continuously at about 150°C until white fumes of perchloric acid were produced, indicating the end of the digestion procedure. The residue was diluted to 100 ml with water and 1 ml of this solution was diluted to 25 ml with 2 M hydrochloric acid followed by passing through the anion exchanger column and washing the column with 15 ml of 2 M hydrochloric acid three times. The tin adsorbed on the column was then eluted with 18 ml of 1 M nitric acid. After the pH of the eluate was adjusted to about 6 with 6 M sodium hydroxide, 0.5 ml of 1.5 M sulfuric acid was added and finally diluted to 50 ml with water.

For Marine Biological Reference Material, TORT-1 (National Research Council, Ottawa, Canada), 0.015 g of the material was treated following a similar procedure to that for the Marine Sediment, but without using hydrofluoric acid.

For river water, 20 ml of concentrated hydrochloric acid was added to 100 ml of river water, giving it an acidity of 2 M. The acidified river water was left overnight, before undergoing a procedure similar to that described above. Finally, the solution was diluted to 50 ml.

3. Results and discussion

3.1. Effect of sulfuric acid concentration on the tin peak area

Prior to optimization of the other conditions, the effect of sulfuric acid concentration on the tin peak area was investigated. Fig. 1 shows the effect of sulfuric acid concentration on the area at 400 ppt of tin. The area increased and reached a maximum with increasing concentration of sulfuric acid. Thereafter in the experiment, 0.015 M sulfuric acid was used. High acidity of sample solution can cause the corrosion of sampling and skimmer cones. The pH values of hydride reaction solution caused by mixing the sample solution with the sodium tetrahydroborate(III) solution decreased with increasing acidity, as shown in Fig. 1. This indicates that the pH of the mixing solution may be a key factor for the hydride generation of tin, the kind of acid being immaterial.

3.2. Effects of concentrations of sodium tetrahydroborate(III) and sodium hydroxide on the tin peak area

The effects of sodium tetrahydroborate(III) concentrations and sodium hydroxide on the tin peak area were investigated. As a result of several experiments, it was found that both concentrations of sodium tetrahydroborate(III) and sodium hydroxide affect the determination of tin. However, when compared with sodium hydroxide, the concentration of sodium tetrahydroborate(III) has

Fig. 1. Effect of concentration of sulfuric acid on the tin peak area. $[\text{Sn(IV)}] = 400$ ppt, concentration of sodium tetrahydroborate(III) is 0.2% in 0.015 M NaOH solution. The flow-rate of the carrier gas (argon) is 1.04 l min^{-1} . ■, concentration of H_2SO_4 versus peak area; ●, concentration of H_2SO_4 versus pH.

a key effect on the area of tin in this system. Finally, 0.2% (w/v) of sodium tetrahydroborate(III) and 0.015 M sodium hydroxide were found to be most suited to the system. To investigate the factor controlling the hydride generation reaction in this system, the pH value of the hydride reaction solution from mixing sample and sodium tetrahydroborate(III) solutions was sur-

Fig. 2. Effect of concentration of NaBH_4 and NaOH on the pH of the mixed solution. $[\text{Sn(IV)}] = 400$ ppt, concentration of sulfuric acid 0.015 M, flow-rate of carrier gas 1.04 l min^{-1} , concentration of sodium hydroxide: ■, 0.008 M; ●, 0.015 M; ▲, 0.025 M; ◆, 0.035 M.

veyed during the hydride generation procedure. From Fig. 2, it can be seen that the pH value of the mixed solution increased with increasing concentration of sodium hydroxide and sodium tetrahydroborate(III). However, when compared with sodium tetrahydroborate(III), the concentration of sodium hydroxide has little influence on pH in this system, meaning that the variation in pH of the mixed solution may be mainly caused by sodium tetrahydroborate(III), rather than by sodium hydroxide, under the above conditions.

3.3. Effect of carrier gas flow-rate on the tin peak area

The effect of the carrier gas flow-rate on the tin peak area is shown in Fig. 3. It can be seen that the area of tin varied considerably with variation of the carrier gas flow-rate and reached a maximum at about 1.1 l min^{-1} . Separation of the hydride gas from the liquid in the gas-liquid separator may be greatly affected by the flow-rate of the carrier gas. Therefore, in this work, a 1.1 l min^{-1} flow-rate was chosen for the following experiment.

Fig. 3. Effect of carrier gas (argon) flow-rate on the tin peak area. [Sn(IV)] = 400 ppt. The concentrations of sulfuric acid, sodium tetrahydroborate(III) and sodium hydroxide are 0.015 M, 0.2% (w/v) and 0.015 M, respectively.

3.4. Optimization of flow-rate of the sample and sodium tetrahydroborate(III) solutions

Under above optimization conditions, the effect of flow-rates of the sample and sodium tetrahydro-

Fig. 4. Effect of flow rate of sodium tetrahydroborate(III) solution and sample solution on the tin peak area. [Sn(IV)] = 400 ppt, the concentrations of H₂SO₄, NaBH₄ and NaOH are 0.015 M, 0.2% (m/v) and 0.015 M, respectively. The carrier gas (argon) flow rate is 1.1 l min⁻¹. The flow rate of sodium tetrahydroborate(III): ■, 0.86 ml min⁻¹; ●, 2.15 ml min⁻¹; ▲, 3.8 ml min⁻¹; ◆, 6.0 ml min⁻¹.

droborate(III) solutions was investigated (Fig. 4). It can be seen that the optimization flow-rates of the sample and sodium tetrahydroborate(III) solutions are 3.6 and 2.15 ml min⁻¹, respectively.

3.5. Effect of kinds of plastic tube on conveyance of stannane

Several plastic tubes (silicone, PVC and Tygon) were checked for their ability to convey stannane from the separating trap to the ICP torch. A silicone tube was found to be most suitable for that purpose, while a PVC tube absorbed stannane and decreased the area.

3.6. Interference study

Table 2 shows the interference from transition metal ions. It can be seen that they greatly affect the determination of tin in this system without using any masking method or separation technique, especially from copper, cobalt and iron. During the investigation of interference from the transition metal ions, the pH values of the mixed solution were also investigated. However, the results showed that the pH values changed little in the presence of interference ions, meaning that the interference from transition metal ions may not be mainly due to reaction of the transition metal ions with sodium tetrahydroborate(III) causing the change in pH value of the mixed solution, but may be due to some other mechanism. In PACS-1, a marine sediment reference material, concentrations of copper, cobalt and iron are about 452 mg kg⁻¹, 17.5 mg kg⁻¹ and 6.96% (as Fe₂O₃), respectively and in TORT-1, a marine biological reference material, concentrations of copper and cobalt are about 439 mg g⁻¹ and 0.42 mg g⁻¹, respectively. Therefore, it is indispensable to eliminate these metals from the materials prior to determination of tin using the hydride generation method. For this reason, a strongly basic anion exchanger resin was investigated to separate and preconcentrate tin, thereby removing interference from transition metal ions. Tin can be converted to the form of anionic chlorostannate complexes in 2 M hydrochloric acid medium, which can be

adsorbed to the strongly basic anion exchanger resin. This adsorbed tin can then be eluted out when 1 M nitric acid is passed through the anion exchanger resin column [14]. In this study, 2 M hydrochloric acid and 1 M nitric acid were chosen separately and the strongly basic anion exchanger was DIAION PA 316. Fig. 5 shows the elution

curve of DIAION PA 316 column using 1 M nitric acid as the eluant. It can be seen that the adsorbed tin can be completely eluted with 16 ml of the eluant. Therefore, from this point onwards 18 ml of 1 M nitric acid was used to elute the tin chlorostannate. Also evident from Fig. 5, is the long tail of the elution curve, which is similar to

Fig. 5. Elution curve for tin by using 1 M nitric acid. The quantity of Sn(IV) is 4 ng.

Dowex 1X8 described by Fang et al. [10]. Table 2 shows that this anion exchanger resin column can remove interference from transition metal ions, as well as anions which cannot be converted to the form of cations when eluted with 1 M nitric acid.

3.7. Sample analysis

Since there are three kinds of organotins in PACS-1, before the method was applied to determine tin in PACS-1, two kinds of organotins, tributyltin and triphenyltin, were investigated to determine whether they can be converted to inorganic tin by using the same pretreatment conditions. The results (Table 3)

Table 3
Recoveries of organotins

Organotin	Added as tin (ppm)	Recovery (%)
Tributyltin	2.0	96
	0.5	105
	0.1	103
Triphenyltin	2.5	97
	0.5	108
	0.1	94

showed that both kinds of organotins can be completely converted to inorganic tin from 0.1 to 2.5 ppm under the pretreatment conditions. Based on the above investigation, the method was applied to determine tin levels in marine materials and river water. As shown in Table 4, the results obtained by this method are within the certified values of marine standard reference materials.

The river water samples were taken from several sites along the River Arakawa which flows through the Saitama District and into Tokyo Bay. The contents and recoveries of tin in the river water by standard addition are shown in Table 5. The results showed that the recoveries were within the range of the standard deviation.

Abstract

A new method has been developed for the fluorometric determination of 3,4-dihydroxyphenylalaine (L-dopa) in pharmaceutical formulations. The reaction product, belonging to fluorescent species, has the excitation and emission maxima at 410 and 510 nm, respectively. Under the optimum conditions, responses were linear between 0.06–4.0 and 4.0–12.0 $\mu\text{g ml}^{-1}$. The detection limit, corresponding to a signal-to-noise ratio of 3, was 1 ng ml^{-1} . The relative standard deviation ($n = 10$) was 0.6%. The proposed method was applied to determination of L-dopa in pharmaceutical formulations. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Potassium periodate; Paracetamol; L-dopa; Fluorometry

1. Introduction

L-3,4-dihydroxyphenylalaine is also named L-dopa, which is a forerunner of L-dopamine, and it is a catecholamine which is important in neurotransmitter. L-dopa was employed in the treatment of Parkinson disease which is in relation to lack of dopamine in brain tissue, but dopamine can not permeate into brain tissue. In order to increase the concentration of dopamine, we can administer L-dopa which can permeate into brain

tissue and then be converted into dopamine in the presence of decarboxylase.

So it is important to determine L-dopa and its metabolites in biological and pharmaceutical formulations. At present, many methods have been developed for its determination. Spectrophotometry [1] has been used for the determination of L-dopa in pharmaceutical formulations, at 280 nm. Double-wavelength spectrophotometry [2] and derivative spectrophotometry [3] can deplete the interference of carbidopa or benserazida.

Chromatography techniques and thinlayer chromatography has also been used for the separation and determination of L-dopa [4]. Gas chromatography has been used to study the effect of

L-dopa in rat brain [5]. High performance liquid chromatography has been widely used for the determination of L-dopa in brain, plasma, urine, liver, serum, tissues and biological fluids using electrochemical detection [6–11], or fluorescence detection [12].

Fluorometry has also been used to determine L-dopa and its metabolites. L-dopa reacts with ethylenediamine to product the fluorescent species [13]. L-dopa can also be oxidized to fluorescent species by I_2 [14], $NaIO_4$ [15] or $K_3[Fe(CN)_6]$ [16].

The purpose of the present investigation is to develop a new simple and sensitive method for the determination of L-dopa in pharmaceutical formulations by fluorometry. Compared with other methods, the proposed method is more sensitivity, precise, simple. The recovery and determination results are satisfactory.

2. Experimental

2.1. Apparatus

All fluorescence measurements were made with a 850-spectrofluorometer (Hitachi, Japan).

2.2. Reagents

All reagents were of analytical grade and demineralized distilled water was used throughout.

L-dopa solution ($100 \mu g$ ml^{-1}) was prepared by dissolving 0.0100 g L-dopa (Beijing) in 100 ml of distilled water.

Paracetamol solution (1×10^{-2} mol l^{-1}) was prepared by dissolving 0.1510 g Paracetamol (Beijing) in 100 ml of distilled water.

Potassium periodate stock solution (1.67×10^{-2} mol l^{-1}) was prepared by dissolving 0.9584 g Potassium periodate (Tianjin University) in 250 ml distilled water.

Nitriilotriacetic acid (NTA) (5×10^{-2} mol l^{-1}) was prepared by dissolving 0.9557 g NTA (Beijing) in 100 ml of 2 mol l^{-1} NaOH solution

L-dopa sample (Guangxi Donglan). A L-dopa tablet includes 0.25 g L-dopa

H_2SO_4 solution (6.0 mol l^{-1}) and propanone solution

2.3. Procedure

In a 10 ml volumetric flask, adding 1 ml of 1×10^{-2} mol l^{-1} PRT, 1 ml of 6.0 mol l^{-1} H_2SO_4 , 2.5 ml of 1.67×10^{-2} mol l^{-1} KIO_4 . The mixture was heated in a boiling water-bath for 10 min, then was cooled with tap water. Appropriate volumes of L-dopa standard solution ($100 \mu g$ ml^{-1}) to give a final concentration between 0.06 and $12 \mu g$ ml^{-1} , 3.6 ml of 2 mol l^{-1} NaOH (including 5×10^{-2} mol l^{-1} NTA) were added into the solution. The mixture was in a boiling water-bath for 30 min, then cooled with tap water to room tempera-

ture. Adding 2 ml propanone to the solution, then the solution was diluted to 10 ml. The fluorescence intensity was measured in a 1 cm quartz against reagent blank at excitation and emission wavelengths of 410 nm and 510 nm, respectively.

The experimental procedure of determination of L-dopa was as following: Random sampling five tablets L-dopa, lapped to powder, weight out 0.0130 g, dissolved in water and diluted to 100 ml. Determine the concentration by standard addition method.

3. Results and discussion

3.1. Fluorescence spectra

The excitation and emission spectra of the system were shown in Fig. 1. The fluorescent species has excitation and emission maxima at 410 and 510 nm, respectively. The reagent blank is no fluorescence at above wavelength.

3.2. Factors affecting the fluorescence intensity of the system

3.2.1. Effect of the PRT concentration on the reaction

The influence of the concentration of PRT on the fluorescence intensity of the system was

Fig. 2. Effect of PRT concentration. Condition: H_2SO_4 0.6 mol l^{-1} , KIO_4 4.2×10^{-3} mol l^{-1} , NTA 1.75×10^{-2} mol l^{-1} , NaOH 0.7 mol l^{-1} , L-dopa 10 $\mu\text{g ml}^{-1}$.

Fig. 3. Effect of sodium hydroxide concentration. Condition: PRT 1.0×10^{-3} mol l^{-1} , H_2SO_4 0.6 mol l^{-1} , KIO_4 4.2×10^{-3} mol l^{-1} , NTA 1.75×10^{-2} mol l^{-1} , L-dopa 10 $\mu\text{g ml}^{-1}$.

shown in Fig. 2. It can be seen that the fluorescence intensity of the system remained constant and reached a maximum value in the range of 6.0×10^{-4} – 1.2×10^{-3} mol l^{-1} PRT. When the concentration of PRT was less than 6.0×10^{-4} or more than 1.2×10^{-3} mol l^{-1} , the fluorescence of the system was decreased. So 1.0×10^{-3} mol l^{-1} PRT solution was selected. The hydrolysate of PRT is of stronger fluorescence, and the reagent blank is increase in presence of an excess of PRT, therefore the excess of PRT have the negative effect on the fluorescence of the system.

Fig. 4. Effect of periodate concentration. Condition: PRT 1.0×10^{-3} mol l^{-1} , H_2SO_4 0.6 mol l^{-1} , NTA 2.0×10^{-2} mol l^{-1} , NaOH 0.85 mol l^{-1} , L-dopa 10 $\mu\text{g ml}^{-1}$.

Fig. 5. Effect of heating time. Curve 1 for the hydrolysis time of PRT. Curve 2 for the reaction time. Condition: PRT $1.0 \times 10^{-3} \text{ mol l}^{-1}$, H_2SO_4 0.6 mol l^{-1} , KIO_4 $4.2 \times 10^{-3} \text{ mol l}^{-1}$, NTA $1.75 \times 10^{-2} \text{ mol l}^{-1}$, NaOH 0.85 mol l^{-1} , L-dopa $10 \mu\text{g ml}^{-1}$.

3.2.2. Effect of sodium hydroxide solution

The effect of sodium hydroxide solution was shown in Fig. 3. The result indicated that the fluorescence intensity of the system increased with increasing NaOH concentration up to about 0.6 mol l^{-1} , the fluorescence intensity of the system remained constant and reached a maximum value in the range of $0.6\text{--}0.8 \text{ mol l}^{-1}$. Concentration of NaOH above 0.8 mol l^{-1} caused a decrease in the fluorescence intensity of the system. So 0.7 mol l^{-1} NaOH was selected.

3.2.3. Effect of periodate concentration

Fig. 4. showed that the fluorescence intensity

of the system increased from zero with increasing KIO_4 concentration. The fluorescence intensity of the system remained constant and maxima when the concentration of periodate is above $3.84 \times 10^{-3} \text{ mol l}^{-1}$. So $4.2 \times 10^{-3} \text{ mol l}^{-1}$ KIO_4 was selected.

3.2.4. Effect of heating time

The effect of heating time on the fluorescence intensity was shown in Fig. 5. (Curve 1 for the first heating time, Curve 2 for the second heating time). It was found that heating for 10 min (first time) and 30 min (second time) in a boiling water-bath gave maximum fluorescence intensity.

3.2.5. Effect of solvents

In this study, the following solvents were examined: methanol, ethanol, isopropanol, propanone, ammonia water. The result indicated that in presence of methanol, ethanol, isopropanol and propanone, the fluorescence intensity of the system was increased. The propanone is the best one. The sensitivity of the system with the propanone as solvent can increase by 1.5-fold as compared with that with water as solvent. The result also showed that the ammonia water can decrease the fluorescence intensity of the system to zero. The quenching effect of NH_3 probably owing to the formation of hydrogen bond of benzoquinoneimine and NH_3 , which prevent forming fluorescent product of benzoqi-

Table 1

Effect of ions, amino acids and excipients (L-dopa $10 \mu\text{g ml}^{-1}$)

Ions, amino acids	Ratio to L-dopa ($\mu\text{g}/\mu\text{g}$)	Amino acids and excipients	Ratio to L-dopa ($\mu\text{g}/\mu\text{g}$)

^b Obtained using spectrophotometric method [2].

noneimine with L-dopa. In this study, we also examined the effect of surfactants, such as β -CD, CTMAB, OP, SDS, CTAB, Triton x-100. The results showed that the surfactants have no effect on the fluorescence intensity of the system.

3.2.6. Stability of the fluorescent species

The fluorescent species can remain stable for more than 2 h.

3.2.7. Standard curve and detection limit

The fluorescence intensity of the system exhibits linear responses towards 0.06–4 and 4–12 $\mu\text{g ml}^{-1}$ L-dopa. The detection limit is 1 ng ml^{-1} with a signal-to-noise ratio (S/N) of 3.

A calibration graph of a series of standard solutions of L-dopa (0.06–4 and 4–12 $\mu\text{g ml}^{-1}$) provided two typical calibration line with the following analytical regression features.

$$0.06 - 4 \mu\text{g ml}^{-1}: \Delta F = -0.049 + 8.64C_{\text{L-dopa}}$$

$$4 - 12 \mu\text{g ml}^{-1}: \Delta F = 18.23 + 4.08C_{\text{L-dopa}}$$

with regression coefficient r of 0.9999 and 0.9999 respectively.

The relative standard deviation for ten replication measurements was 0.6%.

3.2.8. Interference of some ions, amino acids and excipients

The effect of some other ions, amino acids and excipients on the determination of L-dopa was shown in Table 1. An error of 5% in the intensity values was considered tolerable. Table 1 indicates

that ions almost have no interference, but Cys, leu, Try, Tyr, Pro caused severe interference.

3.2.9. Sample analysis

The standard addition method was applied in the recovery test and for the determination of the sample. The results of recovery test and sample analysis were shown in Table 2. From Table 2, it can be seen that the precision and accuracy of the proposed method are satisfactory.

3.2.10. Mechanism of the reaction

PRT hydrolyzes in acidic medium, then is oxidized by periodate:

The product is benzoquinoneimine which reacts readily with the free *para*-position of phenolic compounds by an electrophilic attack [17]. The product is fluorescent species:

Abstract

A tubular silicone membrane interface has been developed for trace detection of benzene, toluene, ethyl benzene, and xylene (BTEX) compounds in water with a portable ion mobility spectrometer. Effects of flow rate, membrane length and stirring conditions on the IMS signals have been systematically investigated. Besides conventional dynamic mode operation, static mode sampling has been demonstrated for the first time and high sensitivities were achieved by sampling of BTEX contaminated water with static mode operation. A toluene concentration of 0.101 mg l^{-1} in purified water, corresponding to a headspace concentration of $2.75 \text{ } (\mu\text{g m}^{-3})$, was determined by static mode sampling. Headspace sampling without the membrane interface could not detect toluene at this concentration. This method has high sensitivity for trace concentrations of gasoline components in river water with a response time of several seconds. The apparatus developed is portable and can be used for sensitive detection of organic contaminants in water, with improved performance compared to conventional modes of IMS sampling. © 1998 Elsevier Science B.V. 1. Introduction

Gasoline contamination of ground and surface water by leaking gas tanks, pipelines and vehicles is a recognized environmental and health problem [1]. For fuel as well as some other petroleum products, benzene, toluene, ethyl benzene and xylene (*o*-, *m*-, *p*-) (BTEX) compounds are useful

for detecting contamination. Various analytical methods have been employed for water analysis. The common methods include gas chromatography/flame ionization detection (GC/FID) analysis with direct aqueous injection [2], GC/FID with solid-phase micro-extraction [3], GC/FID with headspace solid-phase micro-extraction [4], gas chromatography/mass spectrometric detection (GC/MSD) analysis with solid-phase micro-extraction [5], capillary GC with membrane extraction [6] and gas chromatography/infrared

detection (GC/IRD) [7,8]. These GC related methods offer high resolution and low detection limits, however they are generally time-consuming and sample preparation may be required. Laser induced fluorescence has been investigated for on-line oil contamination analysis in an industrial sewage system [9], but this method suffers from its complex data and expensive instrumentation.

With the implementation of Phase II of the Clean Air Act [10], the development and deployment of portable instruments with satisfactory detection limits is growing in importance for routine on-line water contamination analysis. Ion mobility spectrometry (IMS) offers instruments that may satisfy this demand. IMS instrumentation are sensitive to volatile organic compounds (VOC) and offer the advantages of portability, low cost, rapid response and high sensitivity.

A typical IMS instrument [11] consists of a reaction region and a drift region, with both regions maintained at ambient pressure. An ionization source such as a ^{63}Ni foil or a corona discharge element is used to produce reactant ions in the reaction region. These ions will exchange charge with the analyte through competitive charge transfer reactions. The ions are directed from the reactant region and through the drift region by external electric fields.

The IMS instrument used in this work can detect ions in either positive or negative modes. The positive ion mode was used for BTEX compounds, because their chemistries favored the formation of positive ions. For positive mode, the reactant ions formed from air tend to be protonated water clusters $\text{H}^+ \cdot (\text{H}_2\text{O})_n$. These ions are formed by the atmospheric pressure reaction sequence outlined by Good et al. [12] and Shahin [13], which are given in Eq. (1) and Eq. (6).

The IMS spectrum is a measure of ion current at the detector with respect to ion drift time. The instrument readout is typically converted to voltage. When a blank air sample is measured by IMS, only the reactant ion peak (RIP) appears in the spectrum. When analyte vapors (M) enter the reaction region through the IMS inlet, they may be ionized to form monomer product ions by proton transfer:

As a result of conservation of charge and competitive charge transfer among ions, the RIP intensity decreases while the monomer product ion peak intensity increases with concentration. For high concentrations of analytes, cluster ions may appear. The dimer product ion may form by the procedure below:

The analytes may be identified by their characteristic drift times. Ions with different charge to size ratios will have different drift times. The product ion peak intensity or area provides a means for measuring the analyte concentration [14–16].

Typical IMS instruments are convenient for vapor sampling, but they are not amenable to liquid phase samples. For IMS measurements of liquids, headspace sampling may be used. However, in some cases the analyte concentration in the headspace may not be high enough to be detected by the IMS. For example, toluene in water of concentration 0.101 mg l^{-1} is not detectable by headspace sampling with a chemical agent monitor (CAM), a hand-held IMS developed for use by the US army. By employing a membrane interface, aqueous samples can be sampled and pre-concentration may be achieved. Additional advantages of the membrane interface are that the ion mobility spectrometer is less susceptible to contamination and pre-concentration by the membrane may allow detection of analytes of lower concentrations than headspace sampling. For example, previous studies have used a tubular membrane-based inlet coupled with an ion mobility spectrometer to monitor aniline in hexane or

Fig. 1. Schematic of the experimental setup.

water [17]. Also, a sheet silicon membrane interface coupled with an ion mobility spectrometer has been used for on-line monitoring aqueous ammonia [18]. Also, IMS coupled with a solid phase enrichment and thermal desorption apparatus has been used for field screening of phthalate esters in water [19]. Despite this work, BTEX compounds in environmental samples have not been studied with a membrane interfaced ion mobility spectrometer. This paper extends the previous studies by developing a tubular silicon membrane interfaced sampling apparatus to screen BTEX compounds in water with a handheld ion mobility spectrometer. The effects of experimental parameters on the performance of the system and its feasibility for real-time ground water monitoring of gasoline contamination are presented.

2. Experimental

2.1. Description of the system

The schematic diagram of the system is given in Fig. 1. Silicone tubular membranes (i.d. 0.034 cm, o.d. 0.040 cm; VWR cat. no. 62999-199) of various length (5.0–200.0 cm) were used. The membrane interface was constructed by connecting a silicone membrane to a dry airline (i.d. 0.60 cm), in which house air was dried using a Whatman Model 76-02 air drying tower. The air pressure

was maintained at 20 psig with a regulator. The drying line connected two drying towers (i.d. 4.0 cm, length 17.0 cm) in series that are used to scrub the air of residual organic compounds. The drying towers were packed with 2–3 cm layers of grade 44 indicating silica gel (3–8 mesh size), a 1:1 mix of 13X and 5A molecular sieves, and Pyrex Fiberglas glass wool.

The ion mobility spectrometer used in this work was a CAM (NSN, Serial No. 1420, Type 482-301N, GIL 1995, Graseby Ionics, Watford, Herts, UK) unless otherwise specified. This instrument was used with a single modification. Typically, a CAM uses acetone chemistry for the production of ions, whereas for this work, water chemistry was used. This modification was accomplished by removing the reagent gas source from the re-circulating gas system of the instrument and replacing the internal molecular sieves in the CAM.

A wide mouth glass bottle (500 ml) was used as a sample compartment. A rubber stopper (4.70 cm) with two holes (0.53 cm) was used to seal the bottle. Two Pyrex glass tubes (0.56 cm), bent at right angles, were used for carrier gas input and output. The ends of the glass tubes were tapered by drawing the tubes in a flame. The diameter of the tapered glass tip is slightly smaller than the membrane inner diameter. The glass tubes were inserted into the holes in the rubber stopper. The membrane connects the two tapered ends of the glass tube inside the glass bottle. The membrane and the tubes form a gas-tight connection.

The air flow rate through the membrane was regulated with a Cole-Parmer flow meter (part number FM064-62). Flow rates from 5 ml s^{-1} to 50 ml s^{-1} were verified using a soap bubble flow meter (P/N 29-000086-00, Varian). Stirring of the solution is controlled by a Thermix stirring hot plate (Model 310T, Fisher Scientific).

2.2. Sample preparation

Standard solutions of toluene (AR, Mallinckrodt Chemical Works, St. Louis, USA) were prepared using a $500.00 \pm 0.15 \text{ ml}$ volumetric flask and an analytical electronic balance ($\pm 0.1 \text{ mg}$; Model BP210s, Sartorius). Water purified by reverse osmosis was used to prepare standard solutions unless indicated otherwise and toluene standards of 0.101, 0.202 mg, 1.01, 2.02, 5.05, 10.1 and 20.2 mg l^{-1} were prepared. The standard solutions for other BTEX compounds were prepared in a similar manner. Benzene was obtained from Andover, MA. *m*-Xylene (lot no. 782730) and *p*-xylene (lot no. 952739) were from Fisher Scientific. *o*-Xylene (lot no. IFI 151) was from Spectrum Chemical, CA and Ethyl benzene (CAS no. 100-41-4) was purchased from Mallinckrodt.

Fresh river water from the Hocking River was collected near the campus of Ohio University, Athens for analysis. BTEX spiked river water was prepared using the method mentioned above. Gasoline samples obtained from a local gas station were used to prepare spiked river water standards for analysis.

Upon initial testing, the membrane, as obtained from the manufacturer, gave three product ion peaks at IMS drift times of 11.00, 12.03 and 13.56 ms, indicating the existence of residual volatile organic compounds in the membrane. Heating the membrane in a vacuum oven (Model 5830, National Appliance) at 373 K for 1 h removed these peaks. The clean membrane was stored in a desiccated vessel for later use. The bottle, glass tubes and rubber stopper were cleaned with hot water and concentrated cleaning solution (Micro, cat. no. 6731), following which the apparatus was flushed with tap water, purified water and dried before use.

2.3. Data collection procedures

Data was collected using the WASP software package (Graseby Ionics). All spectra were collected in positive ion mode and each spectrum was the average of 50 instrument scans. Baseline correction of each spectrum was applied by calculating the average intensity from 1.50 to 3.00 ms and then subtracting the average intensity from all spectral intensities. Each spectrum had 900 points that were collected with an 80 kHz data acquisition rate. The gating pulse frequency was 40 Hz with 180 μs pulse width and 1.00 ms delay. IMS was used to evaluate the cleanliness of the cell and membrane before use. A volume of 500 ml of purified water was imported to the bottle and ten background spectra were collected. Subsequently, the water was poured out and the bottle dried by compressed air. For dynamic mode operation, the standard solution was transferred to the bottle and data was immediately collected for 15 min with the carrier gas turned on; approximately 300 spectra were collected. The toluene product ion peak area or peak intensity of the 110th spectrum, which is obtained 5 min after the start of spectra collection, was used for the construction of the calibration curve. For the static mode operation, the membrane is immersed in the solution for some time (optimum 10 min) with the carrier gas turned off, then the carrier gas is turned on and data is collected for 15 min.

3. Results and discussions

3.1. Selectivity of the membrane

To demonstrate that toluene contaminated water can be distinguished from uncontaminated water, the spectrum of a blank sample (Fig. 2(a)) is compared with that of purified water (Fig. 2(b)). It was observed that under the conditions used, sampling water through the membrane interface did not affect the RIP intensity or drift time. In contrast, a product ion peak (Fig. 2(c)) can be rapidly detected when sampling purified water spiked with toluene, indicating that toluene vapor can selectively pervaporate through the membrane.

Fig. 2. IMS spectrum of: (a) blank; (b) purified water; and (c) toluene in water (10.1 mg l^{-1}).

To verify that the product ion peak in Fig. 2(c) is due to toluene, the toluene vapor from a small vial containing toluene was flushed into the tip of the ion mobility spectrometer by dry air. A product ion peak at 6.85 ms was observed and the RIP drift time of 6.00 ms did not

change. Another product ion peak at 8.66 ms was also observed when the toluene vapor concentration was high. The product ion peak at 6.84 ms is due to the toluene monomer ion, while that at 8.66 ms may be due to the toluene dimer ion.

Fig. 2. (Continued)

3.2. Effects of experimental parameters

It was observed that many experimental parameters influence toluene peak intensity. Among the most important of these parameters are the carrier gas flow rate, the membrane length and stirring conditions. Each of these parameters was studied to determine the optimal configuration for the proper analysis of BTEX compounds in water.

Carrier gas flow rate is potentially the most important parameter affecting detection using the membrane interface. The effects of flow rate on the peak area are given in Fig. 3(a) for 8.4 mg l^{-1} of toluene in purified water. The peak area reached a maximum when the carrier gas flow rate was 50 ml s^{-1} . The toluene peak area was smallest for 5 ml s^{-1} , largest for 50 ml s^{-1} and decreased for flow rates greater than 50 ml s^{-1} . At carrier gas flow rates of 5 ml s^{-1} , dilution from the surrounding ambient air decreased the peak area. Furthermore, interference from the ambient air gave spurious peaks when the carrier gas flow rate was at 5 ml s^{-1} . The interface between the instrument and the sampling apparatus was open to the surrounding air.

The IMS instrument samples air through its inlet at a rate of 8 ml s^{-1} . Carrier gas (i.e. dry air) flow rates below the instrument sampling rate results in a dilution of the carrier gas by the surrounding air. At carrier gas flow rates above the IMS sampling rate, only a portion of the carrier gas and the entrained toluene vapor is directed into the instrument. However, the mass of toluene delivered to the instrument is increased at flow rates of up to 50 ml s^{-1} . This increase is due to the relatively fast diffusion of toluene through the membrane. At flow rates greater than 50 ml s^{-1} , the analytical signal was attenuated. This decrease is probably due to dilution of toluene in the carrier gas, because the flow rate exceeds the diffusion rate of the membrane. Thus, the optimal carrier gas flow rate was approximately 50 ml s^{-1} for the membrane.

Membrane length is another important measurement parameter. The effect of membrane length was studied using a toluene solution of 1.01 mg l^{-1} (the results of this study are given in Fig. 3(b)). Immersion of the membrane into the solution interferes with the mixing of the solution. When the membrane is not long enough to signifi-

Fig. 3. (a) Effects of flow rate on the analyte signals (toluene concentration: 10.1 mg l^{-1} ; membrane length: 20.0 cm); (b) effects of membrane length on the analyte signals (toluene concentration: 1.01 mg l^{-1} ; flow rate: 50 ml s^{-1}).

cantly interfere with the mixing, the sensitivity increases with the membrane length for membrane lengths between 10.0 and 20.0 cm (Fig. 3(b)). However, it can be seen that the analytical signal is almost constant for membrane lengths between 20.0 and 50.0 cm . Longer membranes interfere with the mixing of the solution and offset the benefit of the increased membrane surface area. The adverse effects of membrane length on solution stirring are further exhibited by using membranes longer than 50.0 cm . In these experiments, the analytical signal was decreased. When the membrane is approximately 2 m long, there is almost no mixing of the solution and almost no toluene peak is observed. For this system, a membrane length of 20.0 cm was considered optimal. It should be noticed that stirring of the solution and membrane length influence toluene peak with different mechanisms. Stirring of the solution increases the diffusion rate of the toluene molecules in the membrane, while a longer membrane has a greater sampling surface area. These results depend on the geometry of the sample cell. Long membrane lengths may be useful for cylindrical flow through cell designs.

Using the optimized system, toluene peak intensities and area with respect to the toluene concentration in water are given in Fig. 4. The intensities and area are obtained in the dynamic mode of operation. In the dynamic mode of operation, the carrier gas flow is maintained when the sample solution is added to the sample cell. Two linear

ranges for the curve of peak area with respect to toluene concentration may be observed in Fig. 4. The sensitivity is greater at low concentrations. At lower concentrations, only toluene monomer ion is present and the curve is linear. As the concentration increases, toluene dimer ions begin to appear. The peak areas now exhibit a more complex relationship with concentration, because the contribution of monomer and dimer must be included. At even higher concentrations, the contribution to the spectrum is dominated by the dimer ion and a new linear range is realized. Similarly, the curve of peak intensity with respect to toluene concentration shows the same effect. At higher concentrations of toluene, silicone membranes have been known to swell, which decreases the pore size and the pervaporation rates of toluene through the tubular membrane. This behavior would result in a loss of sensitivity for this sampling method.

3.3. Static mode operation

In addition to the dynamic mode operation described above, a static mode operation was also studied. In static mode operation, the tubular membrane is immersed into a stirred toluene solution for a preset period of time to achieve pre-concentration. The effect of immersion time on the analytical signal is given in Fig. 5a. It can be seen that higher IMS signal intensities can be obtained with static mode operation than dy-

Fig. 4. Calibration curves of toluene in water obtained by dynamic mode operation (flow rate: 50 ml s^{-1} ; membrane length: 20.0 cm).

dynamic mode operation, with the strongest signal obtained with an immersion time of 10 min. The reproducibility of the static mode operation was evaluated with two separate toluene solutions of 20.0 mg l^{-1} . The two solutions were analyzed several days apart using two different membranes of the same length. The reproducibility in this paper is defined as the difference of peak area or peak intensities between two measurements and a reproducibility of 121 mV was obtained for standard toluene solutions of 20.0 mg l^{-1} . This reproducibility is considered satisfactory, because the difference of the peak area has relative standard deviation of 6.2% for the two replicate measurements. Based on the results of reproducibility research, only a single measurement was made for a standard toluene solution of 1.01 mg l^{-1} and no abnormality was noticed during the experiments. Pre-concentration of the sample may be achieved with static mode operation, as the membrane is saturated by toluene vapor in 10 min. For dy-

dynamic mode operation, no equilibrium is ever achieved due to the continuous flow of carrier gas. Thus, signals are smaller than those of static mode operation. It is therefore concluded that higher sensitivity can be achieved with static mode operation.

Fig. 5(b) shows the difference in toluene peak area between static mode operation and dynamic mode operation. It can be seen that the difference decreases with increasing toluene concentration. Little difference is observed for the samples with toluene concentrations higher than 20.0 mg l^{-1} . Note that a toluene peak is observed for 0.101 mg l^{-1} of toluene in static mode, corresponding to a headspace concentration of $2.75 \mu\text{g m}^{-3}$. Toluene was undetected with either dynamic mode operation or headspace sampling of the solution. Therefore, static mode is an effective pre-concentration method for trace analysis of the BTEX in aqueous solution.

Fig. 5. (a) Effects of immersion time on the toluene peak area in static mode (toluene concentration: 1.01 mg l^{-1} ; membrane length: 20.0 cm ; flow rate: 50 ml s^{-1}); (b) difference of peak area between static mode operation and dynamic mode operation (membrane length: 20.0 cm ; flow rate: 50 ml s^{-1}).

3.4. Detection of toluene in Hocking River water

The peak intensity of product ions in an IMS spectrum changes not only with the concentration of the product itself, but also with the concentration of the other matrix compounds present, due to competitive charge transfer reactions. For purified water, matrix effects are not problematic, because only a single analyte is competing for charge with the reactant ions. However, river water contains organic compounds that may deleteriously affect the product ion peak intensity or generate interfering peaks in the spectrum.

This study used dynamic mode sampling with the spectra acquired 10 min after the solution is added to the sample cell. With the membrane interface, the background IMS spectrum indicates that no detectable contamination is present (Fig. 6(a)). An untreated river water sample was spiked with toluene to generate a 1.04 mg l^{-1} concentration. This solution has a peak intensity of 67 mV (Fig. 6(b)), which is about 20 mV lower than the spiked purified water obtained from the same concentration (Fig. 4). The reproducibility, defined as above, is typically 5 mV for the pure water measurement. The attenuation of the toluene in the river water sample may be due to organic speciation (e.g. adsorption to humic substances). This technique may be a useful measurement tool for studying organic species directly in environmental samples.

3.5. Analysis of other BTEX compounds and gasoline in Hocking River water

To explore the feasibility of detecting other BTEX compounds and gasoline in river water, standards BTEX and gasoline solutions were prepared with Hocking river water. The static mode operation was used for all spectra collection. IMS spectra of ethyl benzene, *m*-xylene and benzene that obtained with a CAM (NSN, Serial No. 216-M-00002, Type 482-310N, GIL 1994, Graseby Ionics¹, Watford, Herts, UK) are given in Fig. 7(a–c), respectively. The ethyl benzene at 0.668 mg l^{-1} produces a single peak at 7.38 ms with an RIP at 6.21 ms (Fig. 7(a)) and the drift time of *m*-xylene (0.112 mg l^{-1}) is 7.30 ms (Fig. 7(b)). The intensities of the product ion peaks indicate that ethyl benzene and *m*-xylene can be detected at even lower concentrations.

Low concentrations of benzene in river water were readily detected with static mode operation, as demonstrated by the monomer and dimer peaks in the spectra (Fig. 7(c)). Dimer ions are indicative of higher concentrations. The membrane was immersed in benzene river water solutions spiked to 0.416 mg l^{-1} for 10 min with carrier gas disconnected to achieve pre-concentration. A peak at 7.05 ms (not shown) with this CAM was obtained when a toluene/river water

¹ A different ion mobility spectrometer than described previously.

solution of 0.104 mg l^{-1} was sampled. Again, headspace sampling and dynamic mode sampling of the same concentration of toluene produced no

Fig. 6. IMS spectrum of: (a) background; and (b) toluene in the river water (toluene concentration: 1.04 mg l^{-1} ; flow rate: 50 ml s^{-1} ; membrane length: 20.0 cm).

detectable peaks, indicating the higher sensitivity of the static mode operation.

For the IMS scan of river water spiked with gasoline to 0.748 mg l^{-1} (Fig. 7(d)), the spectrum has two broad product ion peaks. Wide peaks are obtained from complex mixtures such as gasoline. The integrated product ion peak area may be a useful indicator of gasoline contamination levels. IMS can also yield a general analysis method by measuring the decrease in RIP. Furthermore, the advantages of portability and low cost of the detection units offer the potential for sensitive detection of contaminants at remote sites that may be hostile or inaccessible by other methods.

4. Conclusions

A simple tubular membrane interfaced ion mobility spectrometer apparatus has been developed for trace analysis of BTEX compounds in water. Effects of experimental parameters such as carrier gas flow rate, membrane length and stirring conditions on analyte signals have been systematically investigated. The optimal carrier gas flow rate is 50 ml s^{-1} for the presented design. The optimal membrane length is related to stirring conditions and sample cell geometry. An optimal membrane length of 20.0 cm was found for this design. Higher sensitivity was achieved by operating the apparatus in static, rather than dynamic mode. BTEX compounds in purified and river water at sub-ppb level were detected with this method when operated in static mode. Benzene gave the greatest sensitivity compared to toluene, ethyl benzene and *m*-xylene. Detection of a gasoline spike in river water at 710 ppb was demonstrated. Similar results were obtained using two different IMS instruments. The developed apparatus is portable and inexpensive and the detection limits for BTEX compounds are better than those obtainable with conventional IMS or other competitive methods. This methodology may be adapted to real-time monitoring of water streams. Although semi-quantitative models may be possible, this method may be useful for the direct screening of environmental water samples for organic pollutants, such as BTEX.

Solvent extraction separation of tin (IV) with 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A)

Sunita V. Bandekar, P.M. Dhadke *

Department of Chemical Technology, Inorganic Chemistry Laboratory, University Of Mumbai, Matunga, Mumbai 400 019, India

Received 28 July 1997; received in revised form 24 October 1997; accepted 30 October 1997

Abstract

Solvent extraction of tin(IV) from hydrochloric acid media was carried out with 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A) in toluene. Tin(IV) was quantitatively extracted with 2.5×10^{-2} M PC-88A in toluene from 0.1–0.3 M HCl when equilibrated for 5 min. Tin(IV) from the organic phase was stripped with 4 M HCl and determined spectrophotometrically by both the morin and pyrocatechol violet method. The nature of the extracted species was determined from the log–log plots. Various other diluents such as xylene, hexane and cyclohexane also gave quantitative extraction of tin. The metal loading capacity of the reagent was found to be 0–15 ppm of tin(IV). The extraction of tin(IV) was carried out in the presence of various ions to ascertain the tolerance limit of individual ions. Tin(IV) was successfully separated from commonly associated metal ions such as antimony(III), bismuth(III), lead(II), thallium(I), copper(II), nickel(II), etc. The method was extended for determination of tin in real samples. © 1998 Elsevier Science B.V. Keywords: Solvent extraction; Separation; Stripping agent; Tin(IV); Phosphonic acid

1. Introduction

Since the last decade, organophosphorus compounds have been widely used as extractants for solvent extraction of various metal ions. An acidic organophosphorus extractant, 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A) has been used for various transition and rare earth metals [1].

Bis(2-ethylhexyl) hydrogen phosphate was used for extraction of tin(IV) but masking agent [2],

longer period of equilibration and salting out agent [3] were required. Tin(IV) was extracted with various reagents such as 2-(salicylideneamino) benzenethiol [4], methyltrioctylammonium chloride [5], trioctylphosphine oxide [6], trialkyl ammonium nitrate and bis(2-ethylhexyl) hydrogen phosphorodithioate [7], as well as 8-hydroxy-7-iodoquiniline-5-sulfonic acid and tribenzylamine [8]. However, with these methods interference and co-extraction of commonly associated ions was observed. Extraction of tin was also carried out with reagents such as quinoline-8-ol [9], salicylaldehyde [10], 1,1,1-trifluorotridecan-1,3-dione [11] and tetrabromophenolphthalein

* Corresponding author: Tel.: +91 22 4145616; fax: +91 22 4145614.

ethyl ester [12], but these suffered from the limitations of critical pH conditions.

In the present investigation, tin(IV) has been quantitatively extracted from hydrochloric acid media with PC-88A in toluene. The method is applied for the separation of tin from commonly associated metals and analysis of tin in real samples.

2. Experimental

A UV-visible spectrophotometer (model GBC 911A) with 10 mm matched quartz cells was used for absorbance measurement and a digital pH meter (model LI-120) was used to adjust the required pH of the solution.

The stock solution of tin(IV) was prepared by dissolving stannic chloride in 2 M HCl and was standardised by known method [13]. The required solution concentration of tin(IV) was prepared by diluting the stock solution with 2 M HCl. The extractant 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester was kindly supplied by Dai-hachi Chemical Industries, Japan and it was used without further purification. All chemicals used were of analytical grade.

An aliquot of the solution containing 60 μg of tin(IV) was taken in a separating funnel, hydrochloric acid concentration was adjusted to 0.2 M on dilution to 10 ml and equilibrated with 10 ml of 2.5×10^{-2} M PC-88A in toluene for 5 min. The two phases were allowed to settle and separate. Tin(IV) from the organic phase was back extracted with 4M HCl and determined spectrophotometrically using the morin [14] or pyrocatechol violet method [15].

Fig. 1. Effect of hydrochloric acid concentration on percentage extraction of tin(IV) with 2.5×10^{-2} M PC-88A in toluene.

3. Result and discussion

3.1. Effect of acid concentration

The hydrochloric acid concentration of the aqueous phase was varied from 0.05–3.0 M and the extraction was found to be quantitative with 0.1–0.3 M HCl (Fig. 1). Hence, the acidity of the aqueous phase was maintained at 0.2 M HCl for other experimental studies.

Table 1
Effect of PC-88A concentration

[PC-88A] 1×10^{-2} M	0.10	0.25	0.50	0.75	1.00	2.00	2.50	5.00	10.00
%E	6.06	24.20	54.54	62.96	81.81	93.94	99.22	99.22	99.22
D	0.06	0.32	1.20	1.70	4.50	15.50	127.21	127.21	127.21

3.2. Effect of reagent concentration

Tin(IV) was extracted with varying concentrations of PC-88A ranging from 1×10^{-3} – 1×10^{-1} M dissolved in toluene. The minimum concentration of PC-88A required for quantitative extraction was 2.5×10^{-2} M (Table 1).

3.2.1. Nature of the extracted species

The nature of the extracted species was investigated by the slope analysis method. A graph of $\log D$ vs $\log [\text{PC-88A}]$ was plotted and the slope was found to be 1.88. Therefore, metal to reagent stoichiometry of the tin(IV):PC-88A complex was 1:2. A graph of $\log D$ vs $\log [\text{Cl}^-]$ was also plotted and the slope was equal to 2.05. These results suggested that tin(IV) was extracted by PC-88A from HCl media as $\text{Sn}^{+4}\text{R}_2\text{Cl}_2 \cdot 2\text{HR}$. It has already been found that tin(IV) was extracted by bis(2-ethylhexyl) phosphoric acid (HR) as a complex of the type $\text{Sn}^{+4}\text{R}_2\text{X}_2 \cdot 2\text{HR}$ from aqueous HCl or HBr solution where $\text{X} = \text{Cl}$ or Br [16].

The probable reaction mechanism may be given as,

where HR represents PC-88A which is dimeric in toluene [1].

3.3. Effect of diluents

Various diluents were used for the extraction of tin(IV) with PC-88A. The extraction was quantitative with toluene, hexane and cyclohexane, whereas with xylene (83.64%), benzene (65.45%), chloroform (84.85%), carbon tetrachloride (80.6%) and dichloromethane (89.7%) it was incomplete. Toluene was preferred as it gave better phase separation.

3.4. Effect of stripping agents

Tin(IV) from the loaded organic phase was stripped with different concentrations of mineral acids such as HCl, HClO_4 , HNO_3 and H_2SO_4 .

Table 2

Effect of stripping agent on the percentage extraction of tin

Concentration (M)	% Stripping of Sn(IV) with various mineral acids			
	HCl	HClO_4	H_2SO_4	HNO_3
1.0	4.85	18.88	22.93	6.45
2.0	49.25	34.4	40.0	17.36
3.0	76.82	—	—	30.42
4.0	100	—	—	45.16
5.0	91.96	—	—	—
6.0	86.2	—	—	—

The quantitative stripping was only observed with 4 M HCl (Table 2).

3.5. Effect of equilibrium time

The aqueous phase containing tin(IV) was shaken with 2.5×10^{-2} M PC-88A in toluene for different periods of equilibration from 1–20 min. and the minimum equilibrium time required was 5 min. It was observed that there was no decrease in the percentage extraction of tin when shaken for a longer time period.

3.6. Effect of metal loading

The concentration of tin(IV) was varied to determine the loading capacity of PC-88A. The loading capacity was found to be 0–15 ppm of tin(IV) with 2.5×10^{-2} M PC-88A in toluene.

3.7. Effect of various diverse ions

The effect of various diverse ions was tested when tin(IV) was extracted with PC-88A in toluene. The tolerance limit of the individual diverse ion was determined with an error of $\pm 1\%$. Alkali metal ions (Li^+ , Na^+ , K^+ , Rb^+ , Cs^+) were tolerated in the ratio 1:30 while alkaline earth metal ions (Be^+ , Mg^{2+} , Ca^{2+} , Ba^{2+} , Sr^{2+}), transition metal ions (Hg^{2+} , Cu^{2+} , Zn^{2+} , Co^{2+} , Fe^{3+} , Mn^{2+} , V^{5+} , Ni^{2+}) and some main group metal ions such as Al^{3+} , Ga^{3+} , In^{3+} were tolerated in the ratio 1:10. Cr^{3+} , Cd^{2+} , Au^{3+} , Bi^{3+} and Pb^{2+} were tolerated in the ratio 1:5.

Table 3
Effect of diverse ions

Ratio of ions (Sn:ions)	Cations	Anions
1:50	—	SO ₄ ²⁻ , SO ₃ ²⁻ , Cl ⁻
1:30	Li ⁺ , Na ⁺ , K ⁺ , Rb ⁺ , Cs ⁺	—
1:20	Hg ²⁺ , Al ³⁺ , Be ²⁺ , Cu ²⁺ , Zn ²⁺ , Co ²⁺ , Mg ²⁺ , Ca ²⁺ , Ba ²⁺ , Sr ²⁺ , Fe ³⁺ , Mn ²⁺ , Ga ³⁺ , In ³⁺ , V ⁵⁺ , Ni ²⁺	NO ₂ ⁻ , NO ₃ ⁻ , Br ⁻ , I ⁻ , citrate
1:10	Ru ³⁺ , Rh ³⁺ , Pd ²⁺ , Pt ⁴⁺ , Tl ⁺	HPO ₄ ²⁻ , SCN ⁻ , EDTA, oxalate, tartrate, thiourea
1:5	Cr ³⁺ , Cd ²⁺ , Au ³⁺ , Bi ³⁺ , Pb ²⁺	—
1:1	Sb ³⁺	—
1:0	As ³⁺	—

The amount of tin(IV) is 60 µg.

Sb³⁺ was tolerated in the region of 1:1 while As³⁺ was found to interfere. Anions such as SO₄²⁻, SO₃²⁻ and Cl⁻ were tolerated in the ratio 1:50 whereas NO₂⁻, NO₃⁻, Br⁻, I⁻ and citrate were tolerated in the ratio 1:20. Anions such as HPO₄²⁻, SCN⁻, EDTA, oxalate, tartarate and thiourea were tolerated in the ratio of 1:10 (Table 3).

3.8. Separation of tin(IV) from associated metals

Tin(IV) was separated from commonly associated metal ions by taking advantage of the difference in the extraction conditions between metals. Tin(IV) and antimony(III) were quantitatively ex-

tracted with 1.5×10^{-1} M PC-88A in toluene from 0.1 M HCl. These two metal ions were quantitatively separated by differential stripping. Tin(IV) was first stripped with 4 M HCl followed by antimony(III) with 8.5 M H₂SO₄. Tin(IV) was separated from bismuth(III), lead(II), thallium(I) and nickel(II) by taking advantage of the fact that these metal ions were unextracted when tin(IV) was extracted with 2.5×10^{-2} M PC-88A in toluene from 0.2 M HCl. Tin(IV) was separated from Copper(II) in the presence of thiourea with 2.5×10^{-2} M PC-88A in toluene when the acidity was maintained at 0.1 M HCl. Tin(IV) was also separated from ternary mixtures. An aliquot con-

Table 4

taining tin(IV), antimony(III) and bismuth(III) was equilibrated with 1.5×10^{-1} M PC-88A in toluene in the presence of 0.1 M HCl. Tin(IV) and antimony(III) were extracted in the organic phase, while bismuth(III) was unextracted. Tin(IV) from the organic phase was first stripped with 4 M HCl followed by antimony(III) with 8.5 M H_2SO_4 . Similarly, tin(IV) was separated from the mixtures of tin(IV), antimony(III) and lead(II), as well as tin(IV), antimony(III) and thallium(I), where lead(II) and thallium(I) were unextracted (Table 4).

3.9. Applications

3.9.1. Determination of tin in alloys

The proposed method was tested by analysing tin in leaded gunmetal. Alloy (50 mg) was dissolved in aqua regia, followed by the addition of

5 ml of perchloric acid. The solution was evaporated to dryness, leached with water and diluted to 100 ml with 2 M HCl. An aliquot of each solution was taken for extraction and determination of tin by the recommended procedure.

3.9.2. Determination of tin in canned foods

The sealed tins of various canned food samples such as pineapple slices and orange pulp were collected from local shops. The canned food samples were treated by the HNO_3 -HCl digestion procedure described previously [17].

A 5 g sample was dried in an oven at 120°C for 24 h in a 250 ml beaker. 30 ml of concentrated nitric acid was added, the mixture was gently heated on a hot plate to initiate digestion and then boiled down to about 3 ml. Following this, 25 ml of concentrated hydrochloric acid was added and gently boiled down to 10–15 ml. It

was cooled, transferred into a 100 ml standard flask and diluted with distilled water. Aliquots of each sample were taken and the tin content was determined using the proposed method. The results obtained with this method were compared with the AAS method. Recovery of tin in these real samples was found to be in good agreement with the theoretical values (Table 5).

4. Conclusion

The present method permits quantitative extraction of tin with a very low concentration of PC-88A within a short period of equilibration. Tin is quantitatively separated from commonly associated metals. The proposed method is used to separate and determine tin in real samples.

Received 24 April 1997; received in revised form 30 October 1997; accepted 31 October 1997

Abstract

The extraction behaviour of copper(II) and silver(I) with 2-(3,6,10,13-tetrathiacyclotetradec-1-oxy)hexanoic acid (TTCTOHA) was investigated at $25 \pm 0.1^\circ\text{C}$ and ionic strength of 0.1. The value of the logarithmic distribution coefficient, $\log K_{\text{DR}}$ of TTCTOHA between octan-1-ol and aqueous phases was determined to be 4.13. Copper(II) was extracted with TTCTOHA into octan-1-ol as CuL_2 , where L represents the anionic species of TTCTOHA. The logarithmic extraction constant, $\log K_{\text{ex}(10)}$, was determined at -7.42 . Silver(I) was extracted with TTCTOHA into octan-1-ol as AgL and Ag_2L_2 . The logarithmic distribution constant, $\log K_{\text{DC}}$, of AgL was estimated to be 0.49. On the other hand, silver(I) was extracted into 1,2-dichloroethane as AgL and the logarithmic extraction constant, $\log K_{\text{ex}(10)}$, was determined to be -2.24 . © 1998 Elsevier Science B.V. Keywords: Extraction; Copper(II); Silver(I); Thiacycrown ether carboxylic acid

1. Introduction

The complexing properties of macrocyclic polythioethers (thiacycrown ethers) have been studied and metal complexes with macrocyclic polythioethers have been isolated and characterized [1–12]. Thiacycrown ethers have also been studied as analytical reagents which are selective for soft metal ions [13–16]. The extraction behaviour of some metal ions with thiacycrown ethers has been

examined stoichiometrically [17–21]. Chromogenic thiacycrown ethers which contain a dissociative group such as hydroxyl or picrylamino group functioning as a counter anion have been synthesized and the extraction of metal ions with chromogenic thiacycrown ethers has been detailed [22–24]. As acid dissociation constants of the chromogenic thiacycrown ethers are small, high extraction efficiency of metal ions was obtained under alkaline media. In general, extraction of metal ions from alkaline media is unfavourable because of metal ion hydrolysis. Thiacycrown ethers with a dissociative group in acidic media, such as

* Corresponding author. Fax: +81 78 8031261; e-mail: saito@natura.h.kobe-u.ac.jp

a carboxyl group, are expected to extract metal ions from acidic media. Although crown ether carboxylic acids have been synthesized and the separation of alkali-metal and alkaline-earth cations from aqueous solutions has been reported by Bartsch et al. [25–33], there are few studies carried out on thiacycrown ether carboxylic acids. Recently, we synthesized two new thiacycrown ether carboxylic acids and examined their characteristics as extracting reagents for various metal ions [34]. It was found that copper(II) and silver(I) are selectively extracted with 2-(3,6,10,13-tetrathia-cyclotetradec-1-oxy)hexanoic acid (TTCTOHA, Fig. 1). The extraction efficiency of copper(II) and silver(I) with TTCTOHA differed from that previously studied with thiacycrown ethers. Although copper(II) is classified as a borderline Lewis acid [35], the extractability was higher than that of soft metal ions such as silver(I) and copper(I). Therefore, it is of interest to study the extraction equilibria of copper(II) and silver(I) with TTCTOHA. Moreover, the results of equilibrium studies should provide significant information in devising a procedure for copper and silver separation from various metal ions and designing new polythioether carboxylic acids for metal ion extraction. Thus, the extraction behaviour of copper(II) and silver(I) with TTCTOHA was stoichiometrically examined in this study. The distribution of TTCTOHA between octan-1-ol and aqueous phases and the back-extraction of copper(II) and silver(I) from octan-1-ol into aqueous acid solutions were also examined.

2. Experimental

2.1. Reagents

The thiacycrown ether carboxylic acid was synthesized and purified using a method previously described [34]. Copper and silver sulphate (analytical-reagent grade) were used to prepare 1×10^{-2} M copper(II) and 2×10^{-2} M silver(I) stock solutions. Their concentrations were determined by EDTA titration and potentiometric titration with sodium chloride, respectively. Octan-1-ol and 1,2-dichloroethane were purified as previously de-

scribed [34]. Other reagents were of analytical-reagent grade.

2.2. Apparatus

Extraction was performed in a Taiyo M-100 incubator at $25 \pm 0.1^\circ\text{C}$. A Seiko SAS-725 atomic absorption spectrometer was used for the determination of copper(II) and silver(I). The UV-vis absorption spectra were measured with a Hitachi U-3200 spectrophotometer. The pH of the aqueous phase was measured with a Toa HM-5ES pH meter.

2.3. Distribution of TTCTOHA between octan-1-ol and aqueous phases

An aqueous solution (10 ml) containing acetic acid and sodium acetate buffer solution (1×10^{-2} M) and sodium sulphate to maintain the ionic strength at 0.1 and an octan-1-ol solution (10 ml) containing 5×10^{-3} M TTCTOHA were placed in a 50 ml glass cylindrical tube and shaken for 30 min at 200 inversions min^{-1} at $25 \pm 0.1^\circ\text{C}$. After shaking the solution it was then centrifuged for 5 min at 2000 rounds min^{-1} , the aqueous phase was separated. A definite volume of the aqueous phase, buffer solution (sodium tetraborate and sodium hydroxide, pH 9.4) and bis[2-(5-chloro-2-pyridylazo) - 5 - diethylaminophenolato]cobalt(III) chloride (Co-5-Cl-PADAP) were placed in another glass cylindrical tube and diluted to 10 ml with water. The final concentrations of the buffer solution and Co-5-Cl-PADAP were 1×10^{-2} and 1×10^{-4} M, respectively. The residual aqueous solution was used for measuring pH. The hydro-

Fig. 1. The investigation of thiacycrown ether carboxylic acid.

gen ion concentration, $-\log[\text{H}^+]$, was calculated from the pH value [36]. After the addition of chlorobenzene (10 ml) the mixture was shaken for 5 min at 200 inversions min^{-1} and then centrifuged at 2000 rounds min^{-1} . The absorbance of the chlorobenzene phase was measured at 566 nm against a reagent blank. The concentration of TTCTOHA in the aqueous phase was determined from the calibration graph which was a straight line passing through the origin.

2.4. Distribution of copper(II) and silver(I)

An aqueous solution (10 ml) containing the metal ion and a buffer solution was placed in a 50 ml glass cylindrical tube. The buffer solution was prepared with disodium hydrogenphosphate and potassium dihydrogenphosphate (5×10^{-3} M) or acetic acid and sodium acetate (1×10^{-2} M). The ionic strength was maintained at 0.1 with sodium sulphate. After the addition of an organic solution (10 ml) of TTCTOHA the mixture was shaken for 30 min at 200 inversions min^{-1} at $25 \pm 0.1^\circ\text{C}$ and then centrifuged for 5 min at 2000 rounds min^{-1} . After the two phases had separated the pH of the aqueous phase was measured. The concentration of the metal ion in the aqueous phase was determined by atomic absorption spectrometry. The metal ion concentration in the octan-1-ol phase was determined as follows: Copper(II) or silver(I) in the organic phase was back-extracted into nitric acid (0.1 M) or hydrochloric acid (3 M), respectively, and the concentration in the stripped solution was determined by atomic absorption spectrometry. The concentration of silver(I) in the 1,2-dichloroethane phase was determined as previously outlined [20].

3. Results and discussion

3.1. Distribution coefficient of TTCTOHA between octan-1-ol and aqueous phases

The distribution ratio, D_R , of TTCTOHA between octan-1-ol and the aqueous phases was examined at various hydrogen ion concentrations. After the octan-1-ol solution containing TTC-

Fig. 2. Distribution ratio of TTCTOHA as a function of $-\log[\text{H}^+]$. Initial TTCTOHA concentration, 5×10^{-3} M. Ionic strength, 0.1 (Na_2SO_4). The solid line is the calculated curve based on $K_a = 10^{-4.05}$ and $K_{DR} = 10^{4.13}$.

TOHA (5×10^{-3} M) was equilibrated with an aqueous phase at a certain hydrogen ion concentration, the total concentration of TTCTOHA in the aqueous phase, $[\text{HL}]_t$, was determined spectrophotometrically by extraction as the ion associate with Co-5-Cl-PADAP. The value of D_R was calculated from the following equation.

$$D_R = (C_{\text{HL}} - [\text{HL}]_t)/[\text{HL}]_t$$

where C_{HL} denotes the initial concentration of the ligand.

Fig. 2 shows the logarithmic distribution ratio as a function of $-\log[\text{H}^+]$. Since carboxylic acid does not form a dimer in octan-1-ol [37], the distribution ratio of TTCTOHA between octan-1-ol and aqueous phases can be expressed as Eq. (1) and is rewritten as Eq. (2) using the proton dissociation constant, K_a , and the distribution coefficient, K_{DR} ,

$$D_R = [\text{HL}]_o/([\text{HL}] + [\text{L}^-]) \quad (1)$$

$$D_R = K_{DR}/(1 + K_a/[\text{H}^+]) \quad (2)$$

where subscript o denotes the concentration in the organic phase. Eq. (3) gives the logarithmic expression,

$$\log D_R = \log K_{DR} - \log(1 + K_a/[\text{H}^+]) \quad (3)$$

The value of K_a has been determined [34], $\log K_{DR}$ can be calculated from $\log D_R$ and the

hydrogen ion concentration. The value of $\log K_{DR}$ was determined as 4.13 from Eq. (3) and data from Fig. 2.

3.2. Back-extraction of copper(II) and silver(I)

Since TTCTOHA is a weak acid, the metal ions in the organic phase should be back-extracted into an aqueous acid solution by adjustment of the acid concentration. Copper(II) was quantitatively back-extracted into nitric acid (0.1 M) from octan-1-ol phase. However, silver(I) was rarely back-extracted into nitric acid (1 M). This may be due to the formation of the ion associate. Therefore, sulphuric acid and hydrochloric acid solutions were tested as stripping solutions for silver(I). Silver(I) was back-extracted to some degree (40%) into sulphuric acid (1 M) from the octan-1-ol phase. Silver(I) was quantitatively back-extracted into hydrochloric acid (1.2 M or above). This is due to the formation of a complex—silver(I) with chloride ions i.e. $[\text{AgCl}_2]^-$.

3.3. Equilibria of the extraction of complexes with TTCTOHA

3.3.1. Extraction of copper(II) with TTCTOHA.

If the extracted species in the organic phase are represented by $\text{Cu}_j\text{L}_{2j}(\text{HL})_a$ the extraction equilibrium and the extraction constant are given by,

where (o) and subscript o denotes the species in the organic phase. When only $\text{Cu}_j\text{L}_{2j}(\text{HL})_a$ is responsible for the extraction of the total concentration of copper(II) in the organic phase it can then be expressed as:

$$\log C_{\text{Cu,o}} = j(\log[\text{Cu}^{2+}] - 2 \log[\text{H}^+]) + (2j+a) \log[\text{HL}]_{\text{o}} + \log j + \log K_{\text{ex}(ja)} \quad (5)$$

If copper(II) species other than the Cu^{2+} ion

in the aqueous phase can be neglected compared with Cu^{2+} ion concentration Eq. (5) becomes,

$$\log C_{\text{Cu,o}} = j(\log C_{\text{Cu,w}} - 2 \log[\text{H}^+]) + (2j+a) \log[\text{HL}]_{\text{o}} + \log j + \log K_{\text{ex}(ja)} \quad (6)$$

The degree of polymerization of the extracted species can be determined from the slope of the plot $\log C_{\text{Cu,o}}$ against $(\log C_{\text{Cu,w}} - 2 \log[\text{H}^+])$ at constant concentration of TTCTOHA. The result is shown in Fig. 3. The plot in Fig. 3 falls on a straight line with a slope of 1.0. Then only the monomeric species were expected to be responsible for the extraction of copper(II) with TTCTOHA. When the monomeric copper(II) species is extracted the following relation can be derived:

$$\log C_{\text{Cu,o}} - \log C_{\text{Cu,w}} + 2 \log[\text{H}^+] = \log K_{\text{ex}(1a)} + (2+a) \log[\text{HL}]_{\text{o}} \quad (7)$$

From the plot of the left-hand side value in Eq. (7) against $\log[\text{HL}]_{\text{o}}$, the number of ligand molecules involved in the monomeric copper(II) species can be estimated. Fig. 4 shows the value of the left-hand side in Eq. (7) as a function of TTCTOHA concentration in the organic phase. A straight line with a slope of 2.0 was obtained, which indicates $a=0$. This result shows that the

Fig. 3. Determination of the degree of polymerization of copper(II) TTCTOHA complex. Initial TTCTOHA concentration, 5×10^{-3} M. The solid line is straight with a slope of 1.0.

Fig. 4. Determination of the number of TTCTOHA involved in the monomeric complex. Initial copper(II) concentration, 5×10^{-5} M. The solid line is straight with a slope of 2.0.

monomeric species is CuL_2 , the extraction equilibrium and constant is given by Eqs. (8) and (9), respectively.

$$K_{\text{ex}(10)} = [\text{CuL}_2]_{\text{o}}[\text{H}^+]^2 / ([\text{Cu}^{2+}]_{\text{a}}[\text{HL}]_{\text{o}}^2) \quad (9)$$

From Eq. (7) and the results in Fig. 3 and 4, the logarithmic value of $K_{\text{ex}(10)}$ was found to be -7.42 .

3.3.2. Extraction of silver(I) with TTCTOHA.

When the concentration of the complex, silver(I) with TTCTOHA in the aqueous phase is negligible compared with the Ag^+ ion concentration, the extraction equilibria of silver(I) with TTCTOHA can be dealt with using the same method as the extraction of copper(II). However, the dependence of silver(I) extraction on the concentration of TTCTOHA indicates that the same treatment used for the extraction of copper(II) can not be applied. Fig. 5 shows the logarithmic distribution ratio of silver(I)— $\log D_{\text{Ag}}$ as a function of the logarithm of TTCTOHA concentration in the organic phase. When the concentration

of the complex of silver(I) with TTCTOHA in the aqueous phase is negligible compared with the concentration of Ag^+ ion the value of $\log D_{\text{Ag}}$ should depend on ligand concentration. Even though the value of $\log D_{\text{Ag}}$ gradually increases with increasing ligand concentration at $\log[\text{HL}]_{\text{o}} > -3.0$, it is substantially independent of ligand concentration at $-3.5 < \log[\text{HL}]_{\text{o}} < -3.0$. This result indicates that the species of silver(I) in the aqueous phase is similar to that in the organic phase at $-3.5 < \log[\text{HL}]_{\text{o}} < -3.0$. The composition of the extracted species at $\log[\text{HL}]_{\text{o}} < -3.0$ was examined using the molar ratio and the continuous variation method. As can be seen from Fig. 6, the results obtained using both methods indicates that the extracted species is the 1:1 complex, AgL , at $\log[\text{HL}]_{\text{o}} < -3.0$. As stated previously, the value of $\log D_{\text{Ag}}$ was almost constant at $-3.5 < \log[\text{HL}]_{\text{o}} < -3.0$ so that the species of silver(I) in the aqueous phase seems to be the AgL complex in this ligand concentration range. In order to confirm this, after the extraction of silver(I) (5×10^{-5} M) with 5×10^{-4} M TTCTOHA at $-\log[\text{H}^+] = 5.1$, the aqueous phase (8 ml) was shaken with octan-1-ol (8 ml) containing no TTCTOHA. When silver(I) predominantly exists as the hydrated ion, silver(I) should not be extracted. However, 51% of silver(I) in the aqueous phase was extracted into octan-1-ol. The extraction percentage was approximately analogous to that of the extraction of silver(I) with octan-1-ol, containing TTCTOHA in the same concentration as silver(I). This result sup-

Fig. 5. Distribution ratio of silver(I) as a function of $\log[\text{HL}]_{\text{o}}$ at $-\log[\text{H}^+] = 5.1$ in octan-1-ol system. Initial silver(I) concentration: 5×10^{-5} M.

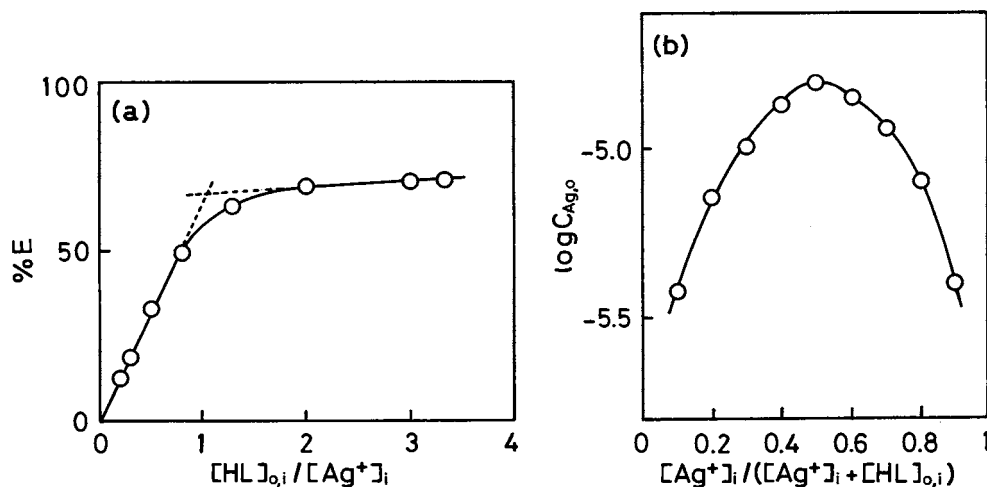

Fig. 6. Determination of the composition of the extracted silver(I) species at $\log[HL]_o < 3.0$ in octan-1-ol system. (a) Molar ratio method at $-\log[H^+] = 5.1$. Initial silver(I) concentration, 5×10^{-5} M. (b) Continuous variation method at $-\log[H^+] = 5.1$. $[Ag(I)]_i + [HL]_{o,i} = 5 \times 10^{-5}$ M.

ports the above consideration. The logarithmic distribution coefficient, $\log K_{DC}$, of AgL was estimated to be 0.49 from the values of $\log D_{Ag}$ at $-3.5 < \log[HL]_o < -3.0$. As shown in Fig. 5, the value of $\log D_{Ag}$ gradually increases with increasing TTCTOHA concentration at $\log[HL]_o > -3.0$. This suggests that the extracted species separate from AgL can be presented together with AgL. The formation of the monomeric adduct complex, $AgL(HL)_a$, in the organic phase could be a cause of ligand concentration dependence. In such a situation, the equilibrium and formation constant of $AgL(HL)_a$ are given by:

$$K_{add(a)} = [AgL(HL)_a]_o / ([AgL]_o [HL]_o^a) \quad (11)$$

From Fig. 2, the ligand concentration in the aqueous phase at $-\log[H^+] = 5.1$ is extremely low so that the formation of AgL_2 in the aqueous phase is negligible and the total concentration of silver(I) in the aqueous phase can be expressed as $C_{Ag,w} = [AgL]$ under the present condition. The logarithmic distribution ratio of silver(I) is given by:

$$D_{Ag} = C_{Ag,o} / C_{Ag,w} \\ = ([AgL]_o + [AgL(HL)_a]_o) / [AgL] \quad (12)$$

at constant $-\log[H^+]$. With appropriate substitutions using the expressions for K_{DC} and $K_{add(a)}$, Eq. (12) becomes Eq. (13).

$$\log C_{Ag,o} = \log K_{DC} + \log(1 + K_{add(a)}[HL]_o^a) \\ + \log C_{Ag,w} \quad (13)$$

The term $\log(1 + K_{add(a)}[HL]_o^a)$ is constant at constant ligand concentration so that the plot of $\log C_{Ag,o}$ against $\log C_{Ag,w}$ should be a straight line with a slope of unity. Fig. 7 shows the relationship between $\log C_{Ag,o}$ and $\log C_{Ag,w}$ at ligand concentration 1×10^{-3} and 5×10^{-3} M at constant $-\log[H^+]$. A straight line with a slope of 1.0 was obtained at 1×10^{-3} M of TTC-TOHA. On the other hand, the slope of the plot at 5×10^{-3} M of the ligand became progressively greater than unity with an increase in $\log C_{Ag,w}$, a straight line with a slope of 1.0 was obtained at lower $\log C_{Ag,w}$. These results indicate that the increase of $\log D_{Ag}$ at $\log[HL]_o > -3.0$ is not due to the formation of the $AgL(HL)_a$ complex. Another reason for this increase of $\log D_{Ag}$ at $\log[HL]_o > -3.0$ could be the formation of polymeric species. In this case, the value of $\log D_{Ag}$ should depend on ligand concentration, the slope of the plot of $\log C_{Ag,o}$ against $\log C_{Ag,w}$ should become greater than unity. Since the dependence

Fig. 7. Plots of $\log C_{Ag,o}$ vs. $\log C_{Ag,w}$ at $-\log[H^+] = 5.1$ in octan-1-ol system. Initial TTCTOHA concentration, (○) 1×10^{-3} M and (●) 5×10^{-3} M. The solid line is straight with a slope of 1.0.

of $\log D_{Ag}$ on ligand concentration is small and the slope of the plot of $\log C_{Ag,o}$ vs. $\log C_{Ag,w}$ is greater than unity but smaller than two, the dimeric species, Ag_2L_2 , is presumed to be ex-

tracted with the monomeric one. Even though silver(I) forms the stable AgL complex with TTC-TOHA and is extracted into octan-1-ol to some degree, the distribution constant between octan-1-ol and the aqueous phases is not as high as that of silver(I) and exists as the AgL complex in the aqueous phase. Furthermore, the dimeric species, Ag_2L_2 , seems to form with increasing concentrations of the AgL complex in the organic phase.

The extraction behaviour of silver(I) in 1,2-dichloroethane was also examined. The results are shown in Fig. 8. Considering the sharp O–H stretching absorption in the IR spectrum of TTC-TOHA [34], the rather high dielectric constant of 1,2-dichloroethane and the low ligand concentration—it is thought that TTC-TOHA exists predominantly as a monomer in the organic phase. Therefore, the value of $\log D_{Ag}$ was plotted against $\log[HL]_o$ in Fig. 8(a). A straight line with a slope of 1.0 was obtained, which is different from the extraction into octan-1-ol. After the extraction of silver(I) (5×10^{-5} M) with ligand (5×10^{-3} M) at $-\log[H^+] = 5.1$ the aqueous phase was shaken with the same volume of 1,2-dichloroethane (containing no TTC-TOHA). Silver(I) was not extracted, which also differs from the extraction in octan-1-ol. These results indicate that silver(I) exists predominantly as the hydrated

Fig. 8. Plots of (a) $\log D_{Ag}$ vs. $\log[HL]_o$ at $-\log[H^+] = 5.0$ and (b) $\log D_{Ag}$ vs. $-\log[H^+]$ in 1,2-dichloroethane system. Initial concentrations: Silver(I), 5×10^{-5} M for (a) and (b); TTC-TOHA, 5×10^{-3} M for (b). Solid lines are straight with a slope of 1.0.

ion in the aqueous phase when 1,2-dichloroethane was used as the organic solvent. From the results see Fig. 8(a) and 8(b), the extraction equilibrium and constant can be represented as follows:

$$K_{\text{ex}(10)} = [\text{AgL}]_{\text{o}}[\text{H}^+] / ([\text{Ag}^+][\text{HL}]_{\text{o}}) \quad (15)$$

The logarithmic distribution ratio of silver(I) is given by

$$\log D_{\text{Ag}} = \log K_{\text{ex}(10)} + \log[\text{HL}]_{\text{o}} - \log[\text{H}^+] \quad (16)$$

From Eq. (16) and the results in Fig. 8, the value of $\log K_{\text{ex}(10)}$ was calculated as -2.24 , when 1,2-dichloroethane was used as the organic solvent.

Abstract

Accurate qualitative and quantitative results were obtained by the application of parameter estimation methods, viz. Classical Least Squares 'CLS', Inverse Least Squares 'ILS' and Kalman Filter 'KF' algorithms. These methods were used to separate strongly overlapping electrochemical peaks produced by binary, ternary and quaternary mixtures of traces of cited poisonous heavy metals stripped from the hanging mercury drop electrode in an acetate–bromide electrolyte using the square wave anodic stripping voltammetry. The analysis was achieved using a single standard addition, the concentrations studied were down to 50 nM and molar ratios up to 1:6 for binary mixtures. A statistical analysis of the results was reported. The method was applied for the ultratrace analysis of the cited cations in a sample of sodium hydrogen carbonate AR. © 1998 Elsevier Science B.V. Keywords: Multivariate anodic stripping voltammetry; Cd(II), In(III), Tl(I), Pb(II)

1. Introduction

The polarographic and voltammetric methods are one of the well-known analytical tools used to give qualitative and quantitative information of electroactive species in a sample. Recent reported methods for the determination of both Pb and Cd in a variety of samples and matrices are numerous as their electrochemical peaks are separate enough to be estimated simultaneously. This is exem-

plified by the stripping voltammetry of both elements in unpurged sea water [1], in neutral zinc-plant electrolyte [2], in ammonium fluoride [3], in thioglycolic acid [4], in whole blood [5], in human gallstone [6] and in the urine of steel production workers [7]. Square-wave stripping voltammetry was also utilised in the determination of both elements [8,9]. Differential potentiometric stripping analysis was applied to determine Pb and Cd in serum [10].

When In or Tl are incorporated with either Pb, Cd or both, overlapping peaks are observed. To overcome this problem, various chemical and

statistical methods were employed to resolve the analytical data.

In and Cd were simultaneously determined by differential pulse polarography in the presence of poly- β -cyclodextrin [11] which increases the difference in their reduction potentials. The determination selectivity of traces of Cd, Pb, Tl and In is improved by direct coupling of liquid/liquid extraction and anodic stripping voltammetry [12,13]. Mutual interference of Pb and Tl was diminished by pre-electrolysis in the presence and absence of EDTA [14].

On the basis of chemometrics, Turnes et al. [15] used differential pulse polarography to resolve binary, ternary and quaternary mixtures of Cd, In, Tl and Pb in micromole levels using the generalized standard addition method with multiple linear regression. However, unsatisfactory results were obtained, especially with the binary mixture of Cd and In. Inadequate results were also achieved by the same authors [15] when a more sensitive technique, namely the linear anodic stripping voltammetry was applied with concentrations down to 50 nmol. Kalman filtering was used as a parameter estimator for the analysis of Cd/In and Cd/In/Pb systems by linear sweep [16], or analysis of Tl/Pb system by square wave voltammetry [17], both techniques were performed at the micromole scale, i.e. with concentrations down to 16 μ M for Cd and In, 14 μ M for Pb and 7 μ M for Tl. The relative error values obtained by Turnes [15], were significantly high and so the aim of the present work is to investigate the source of these errors, whether being in the electrochemical procedures or the statistical treatments.

2. Experimental

2.1. Reagents

All reagents used were of analytical-reagent grade. Stock solutions of 10 mM Cd(II) nitrate, In(III) chloride, Tl(I) nitrate and Pb(II) nitrate were prepared by dissolving the appropriate amounts of the cited salts in double distilled water acidified with 1 ml l⁻¹ concentrated nitric acid.

Diluted solutions were prepared daily and also acidified.

An acetate–bromide electrolyte [18,19] of pH 4.65 was prepared by dissolving 23.8 g KBr and 2.177 g sodium acetate in 100 ml distilled water. The pH of the solution was adjusted to 4.65 by the dropwise addition of 1 M HCl solution. The final concentrations of bromide, acetate and chloride ions should be 2, 0.16 and 0.08 M, respectively.

A matrix modifier used for Zeeman AAS was prepared by dissolving 0.05 mg ammonium dihydrogen phosphate (AR) and 0.003 mg magnesium nitrate (AR) in 1 l of deionized water.

2.2. Glassware

The glassware was initially allowed to stand (for 24 h) in an alkaline bath containing industrial detergent plus KOH, it was then transferred to an acidic bath of 5% HCl. It was washed with distilled water and then dried in a drying oven. Keeping it away from dust.

2.3. Apparatus

Direct current (DC) and Square wave (SW) anodic stripping voltammetric measurements were obtained from a Metrohm 693 VA processor equipped with a 694 VA stand involving three potentiometric electrodes. The working electrode was a hanging mercury drop electrode (HMDE) with a drop area of about 0.3 mm², while the auxiliary electrode was platinum wire. The reference electrode was Ag/AgCl in 3 M KCl. The instrumental settings used in all techniques are summarised in Table 1.

All voltammetric measurements were made in triplicate and all experiments were performed at room temperature (25°C).

After completing the sweep, the binary file was transferred on-line to an IBM-compatible PC computer and ASCII file was generated through the Metrodata 693 VA Backup program, version 1.1. For resolution of the multicomponent mixtures, the numerical data or ASCII file was entered in-line into the CASAP program [20] which was written in Turbo Pascal Language and com-

piled into an executable file run under MS DOS version 6. The program designed includes classical least squares CLS, inverse least squares ILS and Kalman filtering KF.

A Zeeman atomic absorption spectrometer, model 4100 of Perkin Elmer, was used for reference determinations.

2.4. Procedure

An appropriate volume of sample and 1 ml of the acetate–bromide electrolyte were placed in a 10 ml measuring flask, completed to the mark with distilled water and then transferred to the voltammetric vessel. The solution was stirred and de-aerated for 2 min by bubbling nitrogen gas at 1 atmospheric pressure. Cathodic reduction was then carried out at -900 mV for 1 min with continuous stirring. The stirrer was stopped and the solution was allowed to rest for 10 s, then the voltage was scanned using the selected mode in the anodic direction. The experiment was repeated three times with a fresh new mercury drop on the electrode in order to check the reproducibility up to 3%. A single standard addition, i.e. an individual standard for each sample, of 300 nM component was added to the sample and the procedure was repeated for each component. The vessel was washed thoroughly with 10% hydrochloric acid and then with double distilled water for each analyte.

Table 1
Experimental conditions used for DC and SW at hanging mercury drop electrode

Parameter	DC	SW
Stirring speed (rpm)	2000	2000
Purge and stirring time (s)	120	120
Deposition potential (mV)	-900	-900
Deposition time (s)	60	60
Delay before sweep (s)	10	10
Pulse Amplitude (mV)	—	10
Frequency (Hz)	—	25
Scan rate (mV s^{-1})	40	40
Initial potential (mV)	-900	-900
Final potential (mV)	-200	-300

The proposed method was applied to the ultra trace analysis of cations in sodium hydrogen carbonate 'ANALAR', reported to contain 99.5% NaHCO_3 and heavy metals in terms of Pb of $\approx 0.001\%$ (Batch No. 2093200, 500 g net). An aliquot of 5 ml solution of 10 g sample in 100 ml bidistilled water, was diluted to 10 ml and the same parameters of square wave technique illustrated in Table 1, were applied except for the time of preconcentration which was increased to 5 min.

3. Results and discussion

Using a thin mercury film on a glassy carbon electrode (MFGCE) in conjunction with SWASV reduces the detection and determination levels of poisonous metals to ppb and sub-ppb range, the hanging mercury drop electrode (HMDE) is still the most versatile and reliable method. Resurfacing of the glassy carbon support and replating the mercury film were not very successful, and often failed to restore the initial perfect response [21]. Furthermore, the HMDE is less sensitive to solution chemistry than the MFGCE and in fact suffers less from interference caused by the formation of intermetallic compounds [18].

Using direct current anodic stripping voltammetry (DCASV) leads to stripping peaks with a drawn-out shape, as shown in Fig. 1, owing to the slow diffusion of metal from the interior to the surface of the mercury drop. For this reason, it is necessary to use high-frequency waveforms for ASV at the HMDE [22,23]. The high effective scan rates of square wave technique responds only to dissolved metal at the surface of the mercury drop, and so the stripping peaks have a sharp, symmetrical and relatively high shape compared with that obtained by DCASV (Fig. 1). It is clear that peak widths obtained by SWASV are narrower than those produced by DCASV and so the degree of peak overlapping is less using the first method. Also, the peak currents obtained by SWASV are higher, nearly four fold higher than DCASV.

The optimum compositions required for the supporting electrolyte used in the determination of Cd, In, Tl and Pb at the HMDE were reported

Fig. 1. Standard curves of 100 nM analyte in acetate–bromide medium after subtraction of the blank.

in the literature. The determination of In(III) by stripping voltammetry in aqueous solution at the HMDE requires a weakly acidic medium as well as the presence of halide or pseudohalide ions [18,19]. The most sensitive peaks were obtained in an acetate–bromide electrolyte [18,19] of pH 4.65, which is chosen for the present work. In non-complexing media such as nitrate and perchlorate electrolytes, In(III) did not produce a polarographic reduction wave [19]. Similar requirements must apply to the deposition and stripping of Cd(II) which produces much larger waves at the HMDE in halide ions than in perchlorate media [18]. These requirements may explain why the results achieved for the analysis of binary mixtures of Cd and In were unsatisfactory [15,16].

Errors due to the shift in peak position, may be caused by ligand concentration effects or by unknown synergistic effects in the mixture, these errors can be alleviated using a standard addition rather than calibration methods.

In the anodic stripping voltammetric techniques, the peak current i_j measured at a HMDE

and at a given potential ' $j = 1, 2, \dots, p$ ', is proportional to the electroactive analyte concentration ' c_i ' over a given concentration range and can be expressed as

$$i_j = k_j c + e_j \quad (1)$$

where k_j is the response constant of the analyte and e_j is the chemical and instrumental errors. For n components in a mixture, the total peak current, i_p , at a given potential will be

$$i_j = \sum_{i=1}^n k_{ij} c_i + e_j \quad (2)$$

where $i = 1, 2, \dots, n$ is the number of components. For a series of single standard additions ' $l = 1, 2, \dots, m$ ', i.e. an individual standard for each mixture component, each measured potential will provide an equation system in the form

$$i_{jl} = \sum_{i=1}^n k_{ij} c_{il} + e_{jl} \quad (3)$$

or in matrix notation, the empirical model is

$$I = \mathbf{K} \mathbf{C} + \mathbf{E} \quad (4)$$

Fig. 2. Binary mixture square wave stripping peaks after subtraction of the blank (solid lines) and the corresponding fit components (dotted lines).

which involves \mathbf{K} ($p \times n$) matrix whose elements are response coefficients relating current I to analyte concentration C at given potential. The matrix \mathbf{E} is ($p \times m$) residual or error matrix in estimating the concentration of analytes. Most approaches to peak resolution rely on curve fitting of the standard empirical models to the overlapped electrochemical responses. In this work, three different multivariate calibration and prediction methods have been selected, which include classical least squares (CLS), inverse least squares (ILS) and Kalman filtering (KF).

The CLS and KF are capable of full-voltammogram calibration accounts for errors in the current measurements, while the ILS, sometimes called the P -matrix method, is a sensor-limited method, i.e. the number of sensors are selected and limited in order to avoid collinearity problems, and is inverse of CLS or KF models which account for errors in the concentration measurements and can be represented as a model by

$$C = \mathbf{P}I + \mathbf{E} \quad (5)$$

where \mathbf{P} is ($n \times p$) matrix with response coefficients relating analyte concentration C to current I at a given potential.

In most cases, the full-voltammogram methods are significantly better than the sensor-limited ILS method, since they have ability to achieve signal averaging effect over many or all the potentials included the analysis, while ILS is not capable of signal averaging [23]. However, all components of overlapping peaks should be known for optimal performance of CLS and KF, whereas at only one component needs to be known for ILS calibration.

An important consideration in the application of the least squares algorithms is the accurate estimation of the measurement model or empirical matrix \mathbf{K} or \mathbf{P} . This matrix was constructed by selecting the responses of every pure single component closest to the zero baseline. These were after background subtraction to remove the capacitive current component, by re-scanning anodically after the stripping step [16,17], or by scanning the blank.

To start the Kalman recursion KF, initial estimates of $x(0)$, $P(0)$ and $R(0)$ in the present case were assigned, according to Poulisse proposal [24], as 0, 1 and 1×10^{-6} , respectively. Figs. 2 and 3 and Fig. 4 shows the experimental voltammograms obtained for binary, ternary and quaternary mixtures, respectively, and the

Fig. 3. Ternary mixture square wave stripping peaks after subtraction of blank (solid lines) and the corresponding fit components (dotted lines).

computer-fitted curves (dotted lines) of each component after resolving the multicomponent system by the KF method. As can be seen, the fitting is quite satisfactory and the problems encountered in the resolution of different components mentioned by Turnes [15] are improved by the KF. The same results might be obtained by employing full-voltammogram CLS as demonstrated in Table 2. Attempts to improve the error of propagation by minimisation of $\text{Cond}(K)$ [25] has been

Fig. 4. Quaternary mixture square wave stripping peaks after subtraction of blank (solid lines) with the corresponding fit components (dotted lines).

made over the potential range lower than -700 to -300 mV, but results have not improved.

The optimal number of potentials used for ILS depends on the presence or absence of a random linear voltammetric base line, the degree of peak overlap of different electroactive components and the magnitude of the voltammetric noise [23]. Accordingly, the smallest error amplification, i.e. the smallest condition number of calibration, $\text{Cond}(K)$ [25], was a criterion to choose the optimal set of stripping potentials used for ILS analysis of Cd(II), In(III), Tl(I) and Pb(II). The potentials selected were -680 , -571 , -555 , -454 , -450 , -446 and -406 mV vs Ag/AgCl. Based on these selected potentials, the results are given in Table 2.

The metals can be identified as being Cd, In, Tl and Pb on the basis of their high estimates of concentrations obtained by parameter estimator (Table 3). If one component is not present in the sample, but its pure coefficients exist in the K matrix, the filter will produce a very small value for that component with respect to other components of the concentration.

In order to evaluate whether there are significant differences between the concentration found for each analyte and each method, the variance

Table 3
Relative standard error of prediction (SEP) in validation data

	df	F_{critical} at $\alpha = 0.05$	CLS	ILS	KF
Cd	41	1.68	11.37	7.97	11.48
In	41	1.68	34.48	6.94	7.01
Tl	41	1.68	20.96	8.91	11.43
Pb	41	1.68	36.05	31.23	36.39

ratio test, F -test, was used to compare the relative standard error of prediction (SEP) [26] at the 95% confidence level. The values of SEP are shown in Table 3. It is clear that ILS gave the lowest SEP values for all components studied, this method offered the best results. This can be explained by the computational advantage that ILS has over CLS and KF in multicomponent data where wider potential ranges do not add any relevant analytical information, but noise. The results show no significant differences in any of the calibration methods for Pb determination. For In and Tl estimation, no significant differences have been found using ILS and KF. For Cd, there were significant differences between ILS and other calibration methods.

Applying the present method to a real sample of NaHCO_3 (ANALAR), it was possible to detect and determine the ultra traces of Pb, Cd and Tl present in the sample after 5 min preconcentration at -900 mV. As for In, it was clear that the bicarbonate medium is not suitable for its complexation similar to the effect of the previously mentioned anions [19]. This was confirmed by the standard addition of the cation itself where the In peak failed to develop in the predominantly bicarbonate medium, either in the presence or absence of the acetate–bromide electrolyte. Thus, subsequent measurements of Pb, Cd and Tl were performed in the absence of this supporting electrolyte to exclude the possibility of its contamination.

The peak potentials of Cd and Pb were shifted to a more negative value, -618 and -525 mV, respectively, while the Tl peak, at -445 mV, remained unaffected by the bicarbonate medium.

The baseline correction of the bicarbonate sample was performed through rapid square wave sweep after the stripping step.

Fig. 5 shows the voltammogram of the sample and the resolved peaks of Cd, Pb and Tl after applying the CLS method. The optimal set of stripping potentials used for ILS analysis of Cd(II), Pb(II) and Tl(I) was -618 , -525 and -445 mV. Comparative results obtained by CLS, ILS and KF for five replicate samples are outlined in Table 4.

The signal-to-noise ratio of the stripping peak, especially thallium, is generally very low, the relatively higher values of standard deviation (SD) obtained using the three techniques were expected, cf. Table 4. However, they still exist within the permissible limits for the determination of such ultra trace quantities. SD improvement may be attained if the enrichment time step was longer than 5 min.

For reference determinations, a Zeeman AAS, model 4100 of Perkin Elmer, was used. The measurements of cadmium, thallium and lead in sodium bicarbonate solution was carried out by adding a solution of ammonium dihydrogen phosphate and magnesium nitrate to the sample as matrix modifier [27]. The mean (and SD) values obtained are 26.202 (5.004), 0.716 (0.288), 1.180 (0.245) for lead, thallium and cadmium, respectively. The results are in accordance with those

Abstract

The dithizone-anchored poly (EGDMA-HEMA) microbeads were prepared for the removal of heavy metal ions (i.e. cadmium, mercury, chromium and lead) from aqueous media containing different amounts of these ions (25–500 ppm) and at different pH values (2.0–8.0). The maximum adsorptions of heavy metal ions onto the dithizone-anchored microbeads from their solutions was 18.3, Cd(II); 43.1, Hg(II); 62.2, Cr(III) and 155.2 mg g⁻¹ for Pb(II). Competition between heavy metal ions (in the case of adsorption from mixture) yielded adsorption capacities of 9.7, Cd(II); 28.7, Hg(II); 17.6, Cr(III) and 38.3 mg g⁻¹ for Pb(II). The same affinity order was observed under non-competitive and competitive adsorption, i.e. Cr(III) > Pb(II) > Hg(II) > Cd(II). The adsorption of heavy metal ions increased with increasing pH and reached a plateau value at around pH 5.0. Heavy metal ion adsorption from artificial wastewater was also studied. The adsorption capacities are 4.3, Cd(II); 13.2, Hg(II); 7.2, Cr(III) and 16.4 mg g⁻¹ for Pb(II). Desorption of heavy metal ions was achieved using 0.1 M HNO₃. The dithizone-anchored microbeads are suitable for repeated use (for more than five cycles) without noticeable loss of capacity. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Dithizone; Poly(EGDMA-HEMA) microbeads; Heavy metal removal, cadmium, mercury, chromium and lead

1. Introduction

Dithizone (diphenylthiocarbazon) is considered a selective and sensitive ligand to prepare specific sorbents for heavy metal removal and preconcentration. Polymeric supports loaded with

dithizone were used for preconcentration of mercury from seawater but with little success [1–3]. Garcia et al. made a comparative study of silica, amberlite XAD2 and amberlite XAD7 loaded with diethyldithiocarbamate, pyrrolidine-1-ylthioformate and dithizone for on-line preconcentration of mercury [4]. Chow and Buksak have reported the use of dithizone-treated polyurethane foams for the preconcentration of ionic mercury from aqueous samples [5]. Griesbach and Lieser

reported 15 sorbents, including one loaded with dithizone [6]. Uchiumi et al. utilized porous polymeric resin loaded with dithizone, thionalide and bismuthol II for the removal of As(III), Sb(III) and Cu(II) ions from industrial waste water [7]. Chwastowska and Kosiarska reported the anchoring of dithizone to a diazotised styrene-divinyl benzene support [8]. This chelating resin was utilized for the sorption of Ag(I), Cd(II), Cu(II), Pb(II), Ni(II), Co(II) and Zn(II) at different static and dynamic conditions. More recently, Shah and Devi attempted to apply dithizone anchored poly(vinyl pyridine) support for selective separation of mercury from binary and ternary mixtures of mercury, palladium, zinc and cadmium [9].

Recently, we produced microbeads (swell with water) made of ethylene glycol dimethacrylate (EGDMA) and hydroxyethyl methacrylate (HEMA) copolymer as a carrier matrix to prepare specific sorbents [10]. Several dye-ligands were attached covalently to these sorbents and used for selective removal of heavy metal ions from aqueous media [11–17]. In this study, we anchored dithizone on poly(EGDMA-HEMA) microbeads and attempted to use it in the adsorption of some selected heavy metal ions, i.e. Cd(II), Hg(II), Pb(II) and Cr(III). This study reports on the preparation and characterization of these dithizone-anchored poly(EGDMA-HEMA) microbeads and discusses the applicability of these sorbents in the adsorption/desorption/reuse of these heavy metal ions.

2. Experimental

2.1. Dithizone-anchored poly(EGDMA-HEMA) microbeads

Details of the preparation and characterization of the plain poly(EGDMA-HEMA) microbeads was previously detailed [10]. Ethyleneglycoldimethacrylate (EGDMA) (Röhm and Haas, Germany) and 2-hydroxyethylmethacrylate (HEMA) (Sigma, St. Louis, MO) were polymerized in suspension using benzoyl peroxide (BPO) and poly(vinylalcohol) (PVAL; M_w : 100000, 98%

hydrolyzed, (Aldrich)) as the initiator and stabilizer, respectively. Toluene (Merck, Germany) was included in the recipe as a pore former. Table 1 gives the polymerization conditions needed to obtain copolymer microbeads with a swelling ratio of 55%, in the size range of 150–200 μm .

In order to prepare microbeads containing 105.5 μmol dithizone g^{-1} polymer, the following procedure was applied: 10 ml of aqueous solution containing 500 mg dithizone (BDH, Poole, UK) was poured into 90 ml of the poly(EGDMA-HEMA) microbeads suspension in distilled water (containing 3.0 g of microbeads), 4.0 g of NaOH was then added. The medium was heated in a sealed reactor for 24 h at a stirring rate of 400 rpm, and at 80°C. The dithizone-anchored poly(EGDMA-HEMA) microbeads were filtered, and washed with distilled water and with 0.1 M NaOH several times until all of the physically adsorbed and/or absorbed dithizone molecules were removed. The extent of dithizone attachment was determined by elemental analysis data of the dried samples obtained using an elemental analysis device (Leco, CHNS-932, USA).

FTIR spectra of dithizone, untreated and dithizone-anchored microbeads were obtained using a FTIR spectrophotometer (FTIR 8000 Series, Shimadzu, Japan). The dry microbeads (about 0.1 g) were thoroughly mixed with KBr (0.1 g, IR Grade, Merck, Germany), and pressed into pellet form, the spectrum was then recorded.

Stirring rate, 600 rpm	
Heating program, 65°C for 4 h, followed by 90°C for 2 h	

2.2. Heavy metal adsorption/desorption

Heavy metal ion adsorption from the single metal (nitrates were used) aqueous solutions was investigated in batch adsorption-equilibrium experiments. The effects of the initial concentration of metal ions and the pH of the medium on the adsorption rate and capacity was studied. Aqueous metal ion solutions of 20 ml with different concentrations (in the range of 25–500 ppm) was treated with the untreated and/or dithizone-anchored microbeads (100 mg microbeads per batch) at different pH values (in the range of 2.0–8.0, adjusted with universal buffer solution) at room temperature, in flasks magnetically agitated at 600 rpm. The adsorption time was selected as 60 min in preliminary experiments, which was assumed the equilibrium adsorption time, because there was no significant change in the amount of adsorption after 60 min. The microbeads were separated from the adsorption medium at the end of each adsorption experiment, and the concentration of the metal ions in the aqueous phase was measured by graphite furnace atomic absorption spectrophotometer (AAS, GBC 932 AA, Australia). Hg(II) concentration was determined by AAS connected with a Hydrid Generator (GBC HG 3000). All instrumental conditions were optimized for maximum sensitivity as described by the manufacturer. For each sample, the mean of 10 AAS measurements was recorded. The amount of adsorbed heavy metal ions was calculated as:

$$Q = [(C_o - C_A) \cdot V]/m \quad (1)$$

Where Q is the amount of metal ions adsorbed onto unit amount of the microbeads (mg g^{-1}); C_o and C_A are the concentrations of metal ions in the initial solution and in the aqueous phase after adsorption, respectively (mg ml^{-1}); V is the volume of the aqueous phase (ml); and m is the weight of the microbeads (g).

Competitive adsorption of heavy metal ions from their mixture was also investigated in batch wise form. A solution (20 ml) containing 50 ppm from each metal ions was treated with the dithizone-anchored microbeads at a pH of 7.0 at room temperature, in flasks stirred magnetically at 600

rpm. After adsorption, the concentration of the metal ions in the supernatant was acquired using an atomic absorption spectrophotometer.

Adsorption of heavy metal ions from artificial wastewater was also performed in batch wise form. A solution (20 ml) containing 50 ppm of each metal ion [i.e. Cr(III), Cd(II), Hg(II) and Pb(II)] was treated with the dithizone-anchored microbeads at a pH of 6.8 at room temperature, in flasks stirred magnetically at 600 rpm. Artificial wastewater also contains Ni(II), Cu(II), Zn(II), Fe(II), Co(II), Sn(II) and Ag(I). The concentration of each metal ion in artificial wastewater is 5 ppm. In order to adjust the salinity, 700 ppm NaCl was added to artificial wastewater. After adsorption, the concentration of metal ions in the supernatant was obtained using an atomic absorption spectrophotometer.

In order to determine the reusability of the dithizone-anchored microbeads, consecutive adsorption-desorption cycles were repeated five times using the same microbeads. Desorption of heavy metal ions was achieved using 0.1 M HNO_3 . The dithizone-anchored microbeads carrying 7.60 mg Cd(II) g^{-1} ; 14.05 mg Cr(III) g^{-1} ; 32.01 mg Pb(II) g^{-1} ; 12.30 mg Hg(II) g^{-1} were placed in this desorption medium and stirred at 600 rpm for 30 min at room temperature. The final metal ion concentration in the aqueous phase was determined using an atomic absorption spectrophotometer. The desorption ratio was calculated from the amount of metal ions initially loaded on the microbeads and the final metal ion concentrations in the desorption medium.

3. Results and discussion

3.1. Structure of chelating resin

The poly(EGDMA-HEMA) based microbeads which were prepared in this study have a rather hydrophilic structure. The equilibrium swelling ratio was about 55% [10]. As mentioned before, dithizone was selected as the chelating agent, and attached to the poly(EGDMA-HEMA) microbeads. Fig. 1 gives a schematical view of dithizone attachment to the carrier microbeads—the

Fig. 1. Synthesis of the sorbent.

reaction of hydroxyl groups (coming from HEMA) on the carrier and the nitrogen atom of dithizone.

Fig. 2 gives the FTIR spectra of the untreated and dithizone-anchored microbeads. The bands observed at 3220 cm^{-1} are due to stretching of N–H, adjacent to the C=S functional group. The absorption band observed at 3370 cm^{-1} is assigned to the stretching of N–H that is adjacent to the aromatic ring. The N–H scissor absorption band is seen at 1500 cm^{-1} . The absorption band at 1625 cm^{-1} represents conjugation of the aromatic ring. The weak absorption band at 1575 cm^{-1} shows a N=N stretching band in the structure of dithizone. The absorption bands at 1100 cm^{-1} and 1450 cm^{-1} represent stretching of S=C and S=C–NH vibration, are due to the dithizone bonded to the poly(EGDMA-HEMA) microbeads. It is probable that not all of the OH

functional groups on the carrier reacted with dithizone. Therefore, the absorption band at 3370 cm^{-1} representing these unassociated OH groups is fairly broad in FTIR spectra of the dithizone-anchored poly(EGDMA-HEMA) microbeads. All of these absorption bands show the attachment of dithizone onto/into the microbeads.

Elemental analysis of untreated and dithizone-anchored microbeads was also carried out, the attachment of dithizone was found as $105.5\text{ }\mu\text{mol g}^{-1}$ from sulphur and nitrogen stoichiometry. This was the maximum attachment value achieved.

Dithizone leakage from the anchored microbeads was also studied. There was no dithizone leakage in any of the adsorption and desorption media used, a guarantee that the washing procedure was adequate for removal of physically adsorbed dithizone molecules from the microbeads.

3.2. Heavy metal adsorption

3.2.1. Effects of initial concentration of metal ions

The heavy metal ion adsorption capacities of the dithizone-anchored microbeads are given as a function of the initial concentration of metal ions within the aqueous phase in Fig. 3. These adsorption curves were obtained from experiments where adsorptions from the single metal aqueous solutions were studied. It was observed that the amount of adsorption was significantly increased with the initial heavy metal concentration especially in the case Pb(II) and also for Cr(III), in the studied concentration range. In order to eliminate the contribution made by the precipitation of heavy metal in the form of hydroxides, we did exceed metal ions concentrations of 500 ppm. The maximum adsorption capacities of the dithizone-anchored microbeads in the studied range are 18.3, 43.1, 62.2 and 155.2 mg g^{-1} for Cd(II), Hg(II), Cr(III) and Pb(II), respectively, at pH 7.0, which corresponds to an initial concentration of 500 ppm. The affinity order (weight basis) is Pb(II) > Cr(III) > Hg(II) > Cd(II). It should be noted that the maximum adsorption capacities (molar basis) of the dithizone-anchored microbeads are 160, 214, 749 and $1192\text{ }\mu\text{mol g}^{-1}$ of

Fig. 2. FTIR Spectra of: (A) Dithizone; (B) Dithizone-anchored poly(EGDMA-HEMA) microbeads.

polymer for Cd(II), Hg(II), Pb(II) and Cr(III), respectively. The order of affinity based on micro-mole uptake by the sorbent differs according to weight base and is as follows: Cr(III) > Pb(II) > Hg(II) > Cd(II).

As mentioned previously, 1 g of sorbent carries 105.5 μmol dithizone which was determined by elemental analysis. From the stoichiometry, it

seems that one immobilized dithiozone molecule interacts with one to ten metal ions depending on the type of metal. The S and N atoms of dithiozone are available for interaction with heavy metal ions. The number of available active sites does not match the number of heavy metal ions adsorbed. Heavy metal ion adsorption on plain microbeads (carrying no dithiozone) is relatively low, about 8.3×10^{-3} , Cd(II), 10.5×10^{-3} , Hg(II), 59.3×10^{-3} , Cr(III) and $59.3 \times 10^{-3} \mu\text{mol g}^{-1}$ for Pb(II). Note that these microbeads are prone to swelling and are also porous, and therefore may absorb (or entrap) heavy metal ions within the matrix of the swollen microbead. In addition, the hydroxyl groups may interact with heavy metal ions (similar to solvation with water), causing these non-specific-adsorption capacities. These values do not explain the high adsorption (up to ten heavy metal ions per one dithiozone molecule, i.e. Cr(III) ions). It seems that the adsorbed heavy metal ions interact with heavy metal ions that arrive at the same adsorption site during the adsorption process, as such adsorption is not monolayer, but rather multilayer (non-Langmuir type).

Fig. 3. Heavy metal ions adsorption capacity of the dithizone-anchored microbeads. Temperature 20°C; pH 7.0.

Different sorbents having a wide range of adsorption capacities for heavy metal ions have been used. Chwastowska and Kosiarska achieved 5.6 mg Cd(II) g⁻¹ and 10.4 mg Pb(II) g⁻¹ with dithizone loaded poly(styrene-divinylbenzene) copolymer [8]. Shah and Devi used dithizone-anchored poly(vinyl pyridine) support and they reported a specific mercury adsorption capacity of up to 144 mg Hg(II) g⁻¹ polymer [9]. Shreedhara-Murthy and Ryan found 3.9–14.4 mg Cd(II) g⁻¹ removal by cellulose-dithiocarbamate resins [18]. Roozmond et al. reported 40 mg Cd(II) g⁻¹ with pyrazole-containing poly(styrene-divinylbenzene) sorbents [19]. Konishi et al reported 4.8–96.3 mg Cd(II) g⁻¹ with alginic acid gels [20]. Liu et al. achieved 22.4 mg Cd(II) g⁻¹, 72.2 mg Hg(II) g⁻¹ and 93 mg Pb(II) g⁻¹ adsorption capacity with *N*-hydroxymethyl thioamide resin [21]. Sağ and Kutsal used *Zoogloea ramigera* microorganisms for heavy metal adsorption [22]. The maximum adsorption capacities achieved were 85 mg Pb(II) g⁻¹ dry weight of microorganisms. Denizli et al. used alkali blue 6B-attached P(EGDMA-HEMA) sorbents, in which the maximum adsorption capacities were 5.5 mg Cd(II) g⁻¹ and 125 mg Pb(II) g⁻¹ [13]. Dev and Rao reported 51.7 mg Cd(II) g⁻¹ and 80.8 mg Pb(II) g⁻¹ adsorption capacity for polystyrene-divinylbenzene macroreticular resin functionalized with bis-(*N,N'*-salicylidene)1,3-propanediamine [23]. Denizli et al. reported 136.2–174.2 mg Pb(II) g⁻¹ for diamine glow discharge treated polyhydroxyethylmethacrylate microbeads [15]. Aksu and Kutsal used *Chlorella vulgaris* microorganisms [24]. They reported 42.1 mg Cr(VI) g⁻¹ and 90 mg Pb(II) g⁻¹ maximum adsorption capacity. Jose and Pillai used ethylenediamine–triethyleneglycoldimethacrylate crosslinked polyacrylamide resin and reached 68 mg Cd(II) g⁻¹, 69 mg Cr(III) g⁻¹ and 164 mg Pb(II) g⁻¹ [25]. The adsorption capacities achieved in this study compare well with values reported in previous publications.

3.2.2. Effects of pH

Metal ion adsorption onto non-specific and specific sorbents is pH dependent [12–15]. In the absence of complexing agents, the hydrolysis and

Fig. 4. Effect of pH on adsorption of heavy metal ions on the dithizone-anchored microbeads. Temperature 20°C. Initial concentrations of metal ions, 50 ppm.

precipitation of metal ions are affected by the concentration and form of soluble metal species. The solubility of metal ions is governed by hydroxide or carbonate concentration. As discussed in detail by Reed and Matsumoto [26], the hydrolysis of metal ions becomes significant at a pH of approximately 7.5–8.5. Therefore, in this study the pH range was adjusted to between 2.0 and 8.0. The effect of pH on heavy metal adsorption is illustrated in Fig. 4. It was noticed that the adsorption capacities increased with increasing pH, reaching plateau values at around pH 4–6 depending on the metal ions [8]. Our plateau values are 7.6, Cd(II), 12.3, Hg(II), 14.1, Cr(III) and 32 mg g⁻¹ for Pb(II), which correspond to initial metal ion concentrations of 50 ppm. The difference in adsorption values can be explained by the different affinities the heavy metal ions have for the donor atoms in the ligand dithizone.

3.3. Competitive adsorption

Adsorption capacities of dithizone-anchored microbeads for metal ions under competitive conditions (adsorption from solutions containing all heavy metal ions) for Cd(II), Hg(II), Cr(III) and Pb(II) are given in Table 2. Adsorption values are given both on a weight and molar basis. It should be noted that the competitive adsorption capac-

ities of the dithizone-anchored poly(EGDMA-HEMA) microbeads for all metal ions was much higher than non-competitive conditions. The non-competitive adsorption capacities are 7.60, Cd(II); 12.30, Hg(II); 14.05, Cr(III) and 32.01 mg g⁻¹ for Pb(II) at 50 ppm initial concentration. The competitive adsorption capacities are higher than the non-competitive adsorption capacities. They are 9.7, Cd(II); 28.7, Hg(II); 17.6, Cr(III) and 38.3 mg g⁻¹ for Pb(II). The dithizone-anchored microbeads exhibit the following metal ion affinity sequence (molar basis) under competitive adsorption conditions: Cr(III) > Pb(II) > Hg(II) > Cd(II). Contrary to previous publications, we did not observe any dithizone groups specificity for mercury ions, this maybe due to the adsorption conditions we studied [9].

3.4. Adsorption from artificial wastewater

Adsorption capacities of the dithizone-anchored microbeads from artificial waste-water for Cd(II), Hg(II), Cr(III) and Pb(II) are shown in Table 3. Adsorption values are given both in weight and molar basis. It is worth noting that the adsorption capacities of the dithizone-anchored microbeads from artificial wastewater for all metal ions was much lower than competitive conditions. The adsorption capacities are 4.3, Cd(II); 13.2, Hg(II); 7.2, Cr(III) and 16.4 mg g⁻¹ for Pb(II). The dithizone-anchored microbeads exhibit the following metal ion affinity sequence (molar basis): Cr(III) > Pb(II) > Hg(II) > Cd(II). Dithi-

Table 2

Competitive adsorption of heavy metal ions on the dithizone-anchored microbeads:

Ions	mg Adsorbed ion g ⁻¹ polymer ^a	μmol Adsorbed ion g ⁻¹ polymer ^a
Cd(II)	9.7 (7.60)	86.3 (67.6)
Hg(II)	28.7 (12.3)	143.1 (61.3)
Pb(II)	38.3 (32.01)	184.5 (154.5)
Cr(III)	17.6 (14.05)	338.5 (270.2)

^a Adsorptions from single metal ion solutions are given in parantheses.

Concentration of each metal ions, 50 ppm; pH 7.0, temperature 20°C.

Table 3

Adsorption of heavy metal ions from artificial wastewater on the dithizone-anchored microbeads

Ions	mg Adsorbed ion g ⁻¹ polymer	μmol Adsorbed ion g ⁻¹ polymer
Cd(II)	4.3	38.3
Hg(II)	13.2	65.6
Pb(II)	16.4	79.2
Cr(III)	7.2	138.4

Concentration of each metal ions, 50 ppm; pH 6.8, temperature 20°C.

zone-anchored microbeads adsorbed other metal ions. Therefore adsorption of other metal ions reduces the adsorption capacities of the microbeads for Cd(II), Hg(II), Cr(III) and Pb(II).

3.5. Regeneration of microbeads

To be of use in metal ion recycling processes, metal ions chelated should be easily desorbed under suitable conditions. Desorption experiments were performed with 0.1 M HNO₃ as the desorption agent. The dithizone-anchored microbeads loaded the maximum amounts of the respective metal ions when placed within the desorption medium, the amount of metal ions desorbed in 30 min was measured. Table 4 shows the adsorption-desorption values of heavy metal ions by dithizone-anchored microbeads after several cycles of consecutive adsorption and desorption. This table clearly shows that the dithizone-anchored microbeads can be used repeatedly without losing their adsorption capacities for all metal ions studied here.

4. Conclusion

Poly(EGDMA-HEMA) microbeads containing 105.5 μmol dithizone g⁻¹ polymer were used for adsorption/desorption of Cd(II), Hg(II), Cr(III) and Pb(II) ions from aqueous solution under non-competitive and competitive conditions. The maximum desorption capacities of these affinity microbeads from their single metal ions solutions were 18.3 mg g⁻¹ (160 μmol), Cd(II); 43.1 mg

Table 4
Adsorption-desorption cycles for heavy metal ions

Cycle no.	Cd(II)		Cr(III)		Pb(II)		Hg(II)	
	Adsorption (mg g ⁻¹)	Desorption (%)	Adsorption (mg g ⁻¹)	Desorption (%)	Adsorption (mg g ⁻¹)	Desorption (%)	Adsorption (mg g ⁻¹)	Desorption (%)
1	7.60	91.6	14.05	94.4	32.01	89.2	12.30	91.4
2	7.43	94.2	13.88	96.8	31.86	95.6	12.16	89.6
3	7.29	95.4	13.65	95.2	31.72	97.3	11.89	92.5
4	7.11	93.3	13.44	93.5	31.40	98.4	11.71	88.7
5	6.96	92.8	13.02	93.2	31.05	91.5	11.62	88.9

g^{-1} (214 μmol), Hg(II); 62.2 mg g^{-1} (1192 μmol), Cr(III) and 155.2 mg g^{-1} (749 μmol) for Pb(II). When the heavy metal ions competed (in the case of adsorption from their mixture) the amounts of adsorption was 9.7 mg g^{-1} (86.3 μmol), Cd(II); 28.7 mg g^{-1} (143.1 μmol), Hg(II); 17.6 mg g^{-1} (338.5 μmol), Cr(III) and 38.3 mg g^{-1} (184.5 μmol) for Pb(II). Dithizone-anchored microbeads exhibit the following metal ion affinity sequence under non-competitive and competitive conditions, Cr(III) > Pb(II) > Hg(II) > Cd(II). The adsorption capacities of the dithizone-anchored microbeads from artificial wastewater for all metal ions was much lower than competitive conditions. The adsorption capacities are 4.3, Cd(II); 13.2, Hg(II); 7.2, Cr(III) and 16.4 mg g^{-1} for Pb(II). Consecutive adsorption and desorption cycles showed the feasibility of these dithizone-anchored microbeads for heavy metal adsorption.

Book reviews

Semiconductor Nanoclusters—Physical, Chemical and Catalytic Aspects by P.V. Kamat and D. Meisel (Eds.), Elsevier, Amsterdam, 1996, x + 474 pp. US\$272.00. ISBN 0-444-82064-7.

This book takes a wide-angle view of the rapidly expanding applications and greater sophistication in our understanding of the fundamentals of nanoparticles and nanostructured materials. Size quantization is defined and discussed in relation to single-size clusters, quantum dots, quantum wells and layered structures. Changes in electronic, optical, magnetic, catalytic, and mechanical properties in the nanometer regime are explored. Preparation, spectroscopic and electrochemical characterization of porous silicon, semiconductor metal oxide, II–VI, III–V nanoparticles, metal clusters and size-quantized structures, as well as devices based on them, are covered (e.g. H. Weller and A. Eychmüller). Some of the topics are only dealt with somewhat superficially, but through the references this book will be a good springboard to exploration of topics surrounding nano-materials.

The articles go beyond studies of isolated nanoparticles, describing a variety of nanoparticulate films and assemblies which employ the unique properties of nano-materials to develop electrodes (J.J. Fendler, P.V. Kamat, S. Gorer and G. Hodes), to imbed II–VI nanocrystals and carbon clusters in conducting polymers producing novel photoconductive imaging materials (Y. Wang) and to combine porous silicon with conducting polymers for displays (M.J. Sailor et al.). Electron transfer, carrier diffusion and relaxation are discussed (e.g. D. Meisel). Techniques for calculating

size quantization of optical properties in metal and semiconductor particles are presented (P. Mulvaney), and a good development of the use of a pseudopotential method for calculating optical and electronic properties of silicon quantum dots is included (L.-W. Wang and A. Zunger). An overview of applications of semiconductor nanostructures for solar energy conversion, electrochromic windows, luminescent diodes and intercalation batteries is given by M. Grätzel, while E. Pelizzetti and C. Minero describe applications in sensor technology, filtration, total organic carbon analysis and ferrofluids for medical imaging. Simple fabrication techniques are emphasized, with chemical solution deposition and electrodeposition utilized in most studies of films, although a nice treatment of molecular beam epitaxy in the fabrication of quantum wells is included (A.J. Nozik). Utilization of metal and semiconductor nanoparticles as catalysts for organic synthesis are discussed (Y. Li and L. Wang), as well as uses in environmental remediation of pollutants. A detailed study of the electronic states and carrier dynamics in TiO₂ and good introduction to application of TiO₂ to environmental photocatalysis in water (N. Serpone and R.F. Khairutdinov) and in air (X. Fu et al.) are presented. This book is recommended reading for both practitioners and newcomers who wish to keep up with the rapid developments in nano-materials, especially those treading the line between fundamental and applications.

Restoration and Rehabilitation of the Desert Environment. N. Al-Awadhi, M.T. Balba and C. Kamizam (editors), Elsevier, Amsterdam, 1996. xiii + 29 pp. US\$265.75. ISBN 0-444-824725.

This volume is the proceedings of the joint Kuwait–Japanese Symposium 3–4 March 1996. Nineteen papers are presented, and these are divided into three main categories: (1) Soil Bioremediation, (2) Greenery Development and (3) Water Utilisation for Greenery. It primarily focuses on rehabilitation of the desert environment in Kuwait post-Gulf War, and reflects current understanding of the technologies used to bioremediate oil-contaminated environments and of the ‘greening’ of desert environments. The connection between Japan and Kuwait in terms of rehabilitation of desert environments is not immediately obvious, but it appears that Japan does have water shortage problems and there are several good contributions by Japanese delegates on technologies for cleaning oil-contaminated soil and reuse of urban water. An author index and list of delegates are included.

The first section outlines the environmental problems facing Kuwait. During the Gulf War, large amounts of crude oil were released to the surface environment, forming huge oil lakes in the desert. While some of this oil has been extracted for processing, the remainder forms an oily sludge which must be degraded. An additional problem is that hundreds of oil wells were set on fire, necessitating the use of millions of gallons of sea water to put the fires out. This has resulted in oil sludges where microbial degradation is difficult because of the high salinity and desert environment. Various bioremediation treatments are detailed. These include composting to breakdown the heavier components of crude oil, allowing microbial degradation of the remaining light fraction. The overall conclusion is that bioremediation is aided by inoculation with a variety of bacterial strains to break down the different components of oil. Addition of nutrients increases bacterial activity, as does oxygenation (aerobic heterotrophs are far more efficient at oil degradation than anaerobic microorganisms). This first

section also includes an interesting paper on the use of photocatalysts such as TiO_2 to decompose crude oil spills. This method offers a promising approach to the remediation of heavier crudes.

The second section details strategies that can be employed to encourage plant growth in arid environments. This is of importance, not only in the rehabilitation of native plants in areas affected by oil contamination but also for dune stabilisation, agriculture and the urban environment. An interesting paper describes the propagation, via tissue culture, of individual plants that have tolerated conditions of fire and oil pollution. The authors hope that this will lead to tolerant ecotypes that can be planted in affected areas. Other topics covered include the role of microorganisms, notably VA (vesicular-arbuscular) mycorrhizal fungi and *Rhizobium* bacteria, in establishing plant growth. A plan for the ‘greening’ of Kuwait and Kuwait City is detailed. This plan is to create greenbelts and to improve the visual character of metropolitan areas. Planting will also aid energy conservation by providing shade for buildings.

The third sections deals with the implications of the ‘greening’ to water resources. There are two basic approaches: one is to plant indigenous species that are drought tolerant, and the other is to irrigate. Irrigation can be achieved through the reuse of reclaimed water from sewage treatment plants. Waste water is recycled using a combination of ultrafiltration and biological treatment. The efficiency of irrigation can also be improved with new technology.

This book is an interesting account of how the problems of oil contamination are currently being addressed by Kuwait. The results of these studies will underpin the treatment of any further man-made oil disasters. However, the sequence of papers could have been better thought about with introductory chapters at the beginning of each section. It is also very expensive for such a short book.

Water Disinfection and Natural Organic Matter—Characterization and Control. R.A. Minear and G.L. Amy (editors), ACS, Washington, DC, 1996. Xi + 394 pp. US\$109.55. ISBN 0-8412-3464-7.

This book is one of the ACS Symposium Series and was developed from the proceedings of a symposium presented at the 210th National Meeting of the American Chemical Society held in Illinois on 23–24 August 1995.

Twenty papers are presented and these can be divided into four categories: (1) History, Overview and Regulatory Impact Analysis; (2) Chlorination–Chloramination Products and Reaction; (3) Natural Organic Matter Relationships and Characterization; (4) Other Processes—namely Bromate. A number of the authors contribute to more than one paper. Author, affiliation and subject indices are included.

This book may be of interest to scientists and engineers in the water industry as the concern and debate over disinfection by-products (DBPs) continues, and to water treatment companies themselves as they attempt to develop strategies to minimize and control the formation of DBPs. In Chapter 1, as a means of introduction, there is a review by the editors of the historical developments of water disinfection and an overview of the issues surrounding DBPs and natural organic matter. The second chapter discusses the use of regulatory impact analysis for disinfectants/disinfection by-products using total organic carbon (TOC) as a surrogate for DBP precursors. It was predicted that reductions in DBPs would parallel TOC reduction. A number of control strategies are reviewed using either precursor removal technologies such as coagulation, granular activated carbon or membranes, or alternative disinfectants such as chloramines, ozone or chlorine dioxide.

In Chapters 3–9, papers are presented on chlorination–chloramination reactions and products. Chloramines versus chlorine for the control of

dissolved organic halogens (DOX, i.e. all organic halogen-substituted DBPs) is examined and the influence of operational variables on their formation. Although chloramines are less reactive than free chlorine and produce fewer THMs, they are inherently unstable due to a complex set of reactions. Reaction pathways of chloramines and analytical techniques are considered in Chapters 7 and 8. Analytical techniques for the determination of cyanogen chloride, one particular chloramine DBP, are compared in Chapter 9.

Chapters 10–16 present papers dealing with natural organic matter relationships and characterization, including a case study of precursor removal using granular activated carbon compared to treatment by ozone–biological carbon. Significant improvements in the reduction of trihalomethanes, haloacetic acids and TOC were observed with the latter treatment.

Chapters 17–20 are a group of papers which relate to a number of issues which do not readily fall into the category of the other sections. Bromate formation from ozonation is the focus of Chapter 18, in particular the kinetic rate of formation which may be crucial in reactor design, ozone dose and other operational considerations. Chapter 19 outlines the development of an ion chromatography technique for the determination of oxalic, formic and acetic acids following the treatment of water in an ozonation and biofiltration pilot plant.

This book should provide a good reference and appeal for those with an interest in water treatment and to those analysts whose task is to identify and quantify the by-products and side-reactions associated with the disinfection of potable water.

Abstract

Biosensing methods utilize the intrinsic selectivity of a biorecognition process to create relatively simple, low cost, analytical alternatives for a variety of research investigations. Here, biosensor applications of the piezoelectric quartz crystal (PQC) are reviewed. The discussion is divided into sections focusing on the development of PQC based analytical techniques, applications in solution phase sensing pertaining to PQC biosensors, and the current state of knowledge in PQC biosensing applications. Immobilization procedures, dip and dry assay techniques, and solution phase sensing methods are considered in detail. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Review; Piezoelectric quartz crystal; Biosensor

1. Introduction

Research trends suggest newly developing chemical and biological sensors, which are simple and inexpensive to design, will likely gain popularity over more complicated traditional techniques. Biological sensors, or biosensors, are measuring devices which incorporate a biologically active sensing element with an electronic transducer. Thus, biosensors harness the biological recognition processes created through evolution, providing enhanced selectivity capabilities. The biological component interacts with or senses

substance being investigated. The transducer recognizes the signal and converts the biological event into a response that can be further processed and displayed, such as a digital output. A variety of biological components (including enzymes, antibodies, antigens, nucleic acids, isolated receptors, whole cells, microorganisms, and plant and animal tissues) have been applied to sensing systems. Examples of signal transducing elements include electrochemical, optical, calorimetric, and acoustic sensors. The biological layer and the transducer in conjunction with the conditions of the assay environment dictate the overall applicability and sensitivity of biosensing systems. The design of an acoustic sensor, such as a piezoelectric quartz crystal (PQC) is relatively simple. Gen-

erally, analyte detection is based on adsorbate recognition where selective binding causes a mass change which is identified by a corresponding change in the acoustic parameters of the PQC.

2. Development of PQC mass sensing

The piezoelectric effect occurs in crystals without a center of symmetry [1]. When pressure is applied to the crystal, the crystal lattice is deformed in such a manner that a dipole moment arises in the molecules of the crystal. Many types of crystals exhibit the piezoelectric effect, but the electrical, mechanical, and chemical properties of quartz make it the most common crystal type used in analytical applications [2]. PQC are quartz wafers sliced from a single crystal. Typically, alpha quartz is used for crystal fabrication [3]. The PQC is sandwiched between two electrodes which are generally composed of gold or silver and are prepared by thermal evaporation onto the quartz surface [2]. An alternating electric field is developed in the PQC by applying a potential difference between the electrodes. With this applied voltage, the physical orientation of the crystal lattice is distorted, resulting in a mechanical oscillation of a standing shear wave across the bulk of the quartz disk at a characteristic vibrational frequency (i.e. the crystal's natural resonant frequency). The direction of the oscillation depends on the orientation of crystal lattice in the electric field; in turn, the orientation of the crystal lattice depends on the exact geometry of the quartz disk with respect to the crystalline axes of the quartz from which the crystal is cut. Oscillation in the thickness shear mode (TSM) creates a displacement parallel to the surface of the quartz wafer. Only the region between the electrodes is piezoelectrically active; thus oscillation is maximum where the electrode pads overlap and diminishes rapidly from that point [4–6].

The frequency of the PQC vibration depends on parameters associated with the phases adjacent to the crystal and on the physical properties of the crystal itself (e.g. size, cut, density, and shear modulus). Of particular importance for analytical sensing devices is the proportional relation be-

tween the resonant frequency and the overall mass of the crystal. Most piezoelectric analytical applications utilize this mass relationship. The TSM of vibration is the mode most sensitive to mass change [3]. Two crystal orientations vibrate exclusively in the TSM, AT- and BT-cut crystals [7]. For the majority of piezoelectric work in analytical chemistry, AT-cut crystals have been used [1,3]. The AT-cut refers to quartz wafers cut at $+35^{\circ}15'$ angle from the z -axis. AT-cut crystals have a temperature coefficient of nearly zero, indicating the resonant frequencies are stable over a wide range of temperatures [1,3].

There are two methods to generate a signal using PQC [8,9]. In the first and most common method the crystal itself is part of an oscillator circuit. Here, the crystal vibrates at a frequency controlled by properties of the crystal. In the second method, the crystal is connected to an external instrument which applies an alternating voltage at various frequencies across the crystal. Here, the vibrational frequency is not determined by the crystal; the phase and amplitude of the crystal in response to electrical excitation is measured, e.g. monitoring the equivalent circuit parameters of a PQC. Subsequent discussions will focus primarily on the first analysis method since it represents the majority of experimental designs used.

There are two general classes of piezoelectric devices: BAW (bulk acoustic wave) and SAW (surface acoustic wave). PQC, as described in this paper, are BAW devices. Other terms used to reference (i.e. name) or describe these same PQC or BAW crystals are: QCM (quartz crystal microbalance) and TSM (thickness shear mode). The QCM term is often used because it describes the mass sensitivity of the crystal. TSM is used because it describes the motion of the crystal's vibration. SAW devices are an entirely different class of acoustic sensor. In a SAW device, electrodes are on the same side of the crystal. Interdigital transducers act as a transmitter and receiver to excite a wave that travels across the crystal face. The physical deformation of the wave is confined to the surface of the crystal. SAW devices have been applied to a number of sensing systems, including uses as biosensors [10–13].

SAW devices are more mass sensitive than PQC, but some SAW devices exhibit a variety of problems when applied to a biological sensing system because biological solutions can severely attenuate surface acoustic waves [14]. PQC sensing systems are used most in biological applications and thus will be the focus of subsequent discussion.

In 1959 Sauerbrey developed an empirical equation (equation 1) to describe the mass sensitivity of gas phase mass deposition on an PQC [15].

$$\Delta F = \frac{-2f_0^2 \Delta m}{A \sqrt{\mu_q \rho_q}} = -C \Delta m \quad (1)$$

where ΔF = measured frequency shift, in Hz; f_0^2 = the fundamental resonant frequency (squared), in Hz; Δm = mass change, in g; A = piezoelectrically active area (area of electrode surface), in cm²; μ_q = shear modulus of quartz = 2.947×10^{11} g cm⁻²; ρ_q = density of quartz = 2.648 g cm⁻³; C = mass sensitivity constant (based on type of crystal used), in (sg)⁻¹.

Sauerbrey's work demonstrated a thin film applied to a PQC could be treated as an equivalent mass change of the crystal. This approach is based on the deposition of rigid layers that are infinitesimally thin and, thus, dampen the propagation of the bulk shear wave in a fashion identical to quartz itself. A change in the mass of the crystal per unit area results in a change in resonant frequency. This equation forms the basis for the analytical use of PQC. As an analyte is physically or chemically adsorbed onto the PQC surface, it adds mass to the crystal. The change in mass is identified by a corresponding change in the frequency of vibration of the crystal. The Sauerbrey relation is based on the overall mass sensitivity of the PQC. Only the region under the electrode is piezoelectrically active; at the bare quartz, the mass sensitivity is negligible [4–6]. To interpret data based on Sauerbrey's relation the mass should be uniformly deposited over the entire active area of the PQC (i.e. the electrode surface). Also, there is a limit to the amount of mass that can be added to the PQC. When this limit is exceeded, the crystal ceases its oscillation.

Gas phase mass sensitivity is determined by the PQC's fundamental frequency as described in equation 1. Mass sensitivity increases as the fun-

damental frequency of the PQC increases; the fundamental frequency increases as the PQC thickness decreases. Thus, one approach to increase sensitivity is to fabricate thinner crystals, which in turn increases the operating frequency and sensitivity. Clearly, miniaturization can only be performed within physical limits. The size cannot be reduced below a certain value without affecting the durability of the device [14]. However, recent fabrication designs have been tested that provide fundamental frequencies of 30 MHz [16]. The most commonly used crystals are 5–15 MHz quartz disks with a 10–16 mm diameter. For a fundamental frequency of 10 MHz and an electrode surface area of 0.22 cm², the gas phase mass sensitivity is approximately 1 Hz per nanogram. Piezoelectric gas phase mass sensing is a well established technique and is currently applied to investigations in science and engineering in a wide array of assay conditions [1–3,17–22].

King, in 1964, is recognized as the first to utilize a PQC in an analytical chemical application [23]. PQCs were implemented into a gas chromatography system for detection of hydrocarbons. The detector selectivity was based on coatings on the PQC surface. The next two decades saw intensive research using PQC to monitor a number of gas phase species. For information on PQC techniques other than biosensing applications refer to the reviews by Alder and McCallum [1], Guibault and Jordan [3], McCallum [20], and Janta et al. [17].

Recent advances in gas phase detection schemes focus on modification of the crystal surface with organic compounds or biological components that will bind a particular gaseous substrate which can provide enhanced detection sensitivity. Guibault, in 1983, was the first to use a biological coating for direct assay in the gas phase [24]. Here, gas phase formaldehyde was monitored with an enzyme coated PQC. Ngeh-Ngwainbi et al. introduced gas phase immuno-sensing through a PQC coated with antibodies against parathion [25]. Wu and Wang immobilized an olfactory receptor protein on the PQC surface for quality assessment of sorghum liquor from measurement of head-space gas [26]. It is questionable whether gas phase biosensing can truly occur, however [27,28].

The structure of the immobilized biological component may retain waters of hydration when outside of their aqueous environment, but it is questionable if this is enough to ensure the integrity of the binding sites. Rajakovic et al. demonstrated gas phase adsorption of organics and pesticides to antibody coated PQC was completely reversible [28]. No signal corresponding to selective immunochemical binding was found. The true focus for PQC biosensing applications is in solution sensing, as discussed below.

3. PQC solution phase sensing

Early attempts to apply the PQC sensing system to liquid phase measurement failed because the crystal ceased to oscillate when submerged in solution. To sense solution phase analytes either the sample was converted into a gas or a tedious dipping procedure was used [1,3,20]. These problems have been addressed by developing oscillator circuits that allow for crystal immersion in solution [29] or through the use of specially designed crystal flow through and/or batch reaction cells where solution contacts only one crystal surface [30–38]. The first attempt to use an acoustic device as a liquid phase sensor was by Konash and Bastiaans in 1980 [39]. PQCs were used as a liquid chromatography detector where one crystal face was exposed to a flowing organic solution. The system had poor sensitivity and reproducibility, but they demonstrated the PQC could produce stable oscillations in liquid.

Sauerbrey's mass relation cannot be applied to a solution sensing system since the equation is applicable to only gas phase mass deposition of rigid layers. Pioneering studies to define what parameters govern the change in frequency seen for a PQC in liquid sensing systems have been conducted by a number of investigators. A summary of their findings follows.

Nomura and Okuhara were the first to attempt to characterize solution phase piezoelectric sensing [40]. The resonant frequency of a PQC in air was compared with the frequency response when the whole crystal was immersed in 17 non-conducting organic liquids. They developed an empir-

ical equation which related the frequency change to the square root of viscosity and density of a solution.

In 1985, Kanazawa and Gordon reported a theoretical model which described the frequency response in fluid phases in terms of the physical parameters of the PQC and analyte solution by considering the coupling of PQC shear wave to a dampened shear wave propagating into the fluid [41,42]. The depth of the shear wave penetration varied with the square root of the bulk liquid viscosity. The decay length corresponded to the effective thickness of the liquid in motion with the PQC. This liquid layer was treated as a sheet of mass attached to the PQC. The model treated the fluid layer as continuous; no slip boundary between the PQC surface and the fluid was allowed. The equation was verified by contacting a single PQC surface with solutions of glucose and ethanol. The oscillation frequency in pure water was taken as a reference. The decrease in frequency varied as the solution viscosity and density product increased.

In the same year, Bruckenstein and Shay described a model similar to that of Kanazawa and Gordon [43]. They assumed the liquid in contact with the PQC provided a viscous boundary layer at the PQC surface. The mass of this layer was considered as an additional mass load on the PQC. This mass is determined from the viscosity and density of solution. Therefore, the frequency change was again described in terms of the viscosity and density product. Here, the model was applied to solutions in contact with one or both surfaces of a PQC and they demonstrated good agreement between experimental results and the theoretical model. In the articles by both research groups, the additional mass load from the liquid layer was treated in the same manner as in the Sauerbrey relation. Although the physical properties of the liquid affect the operating frequency, the mass sensitivity was essentially unaffected.

Subsequent investigators experimentally demonstrated the validity of the equations for selected solutions but found deviations for highly viscous or conducting solutions [29,36,44–46]. Although they clearly showed the frequency response is affected by the viscosity and density of

the solution, the response is not controlled exclusively by these factors. Later work identified many parameters associated with the physical and chemical nature of the interfacial environment that influence the frequency. The frequency response is mediated by interfacial interactions such as the structure of the solid/solution interface with respect to surface roughness and surface stress [47–49]; conductivity, solution polarity, and temperature [36,45,50]; interfacial viscosity and surface free energy described in terms of hydrophilicity and hydrophobicity [9,38,46,51,52]; crystal coating uniformity [6]; and the extent of crystal contact with the solution phase [4].

Kurosawa et al. [45], Barnes [29], and Cavic-Vlasak and Rajakovic [46] found the change in PQC frequency was a linear function of the viscosity and density product except for high viscosity solutions, salt solutions, and solutions with high polymer concentrations. Since viscosity and density are temperature sensitive, this indicates the frequency may be temperature dependent. In 1987 Muramatsu et al. monitored the PQC frequency response in air, ethanol, sodium chloride solution, and purified water [36]. The response was evaluated in terms of the equations by Bruckenstein and Shay and Kanazawa and Gordon. They found the oscillating frequency was affected by the density, viscosity, temperature, and conductivity of the liquid, but they indicated each of the equations cannot predict all of the experimental factors involved. The deviations from the predictions were attributed to the solution conductivity and the dielectric polarization of water. Although, the difficulty in reading the frequency for high conductivity solutions may be associated with their method of solution contact. Both PQC electrodes were immersed in a conductive solution which may lead to short circuiting. In a later publication, Muramatsu et al. found the change in frequency responded linearly to the square root of the viscosity · density product for alcohol–water solutions but non-linearly when in contact with highly viscous solutions [44].

Yao and Zhou also found conductivity influenced the PQC frequency response [50]. The analyses were performed with the crystal submerged in liquids. They measured the frequency

when in contact with 47 pure organic liquids, water–organic mixtures, and electrolyte solutions and developed an empirical model similar to that of Nomura and Okuhara. Their equation identified a similar dependence on the square root of the density and viscosity but they improved their correlation by including terms for dielectric constant and conductivity. If the density and viscosity do not vary significantly with the electrolyte concentration, they suggested the influence of density, viscosity, and dielectric constant could be considered negligible. Thus, they proposed a method to describe the change in frequency in terms of specific conductance.

Other investigators found the frequency depends also on properties of the liquid/solid interface such as hydrophilicity and hydrophobicity of the metal electrodes and interfacial viscosity of the metal-to-water interface. Thompson et al. actually measured an increase in frequency with binding [38]. This result is contrary to what is expected based on all previous equations developed to describe mass addition to the PQC surface [15,40–43]. This frequency increase was attributed to differences between the hydrophilic and hydrophobic coating surfaces on the PQC. Thompson indicated hydrophilicity affects the interfacial viscosity which in turn affects the frequency. For PQC hydrophilic coatings, the resonant frequency required a greater time to stabilize due to equilibration of the boundary structure. Other investigators question whether Thompson's coatings were too thick to resonate in an aqueous environment [32]. However, Thompson's results did indicate the assumption of Bruckenstein and Shay and Kanazawa and Gordon of a no-slip boundary between the solid and liquid is invalid [38]. Hayward experimentally demonstrated the assumptions of continuity and no surface slip are groundless [53]. Rajakovic et al. found physical conditions of the interface mediate the transfer of acoustic energy into the liquid [51]. Hydrophobic surfaces have lower interfacial viscosity because of interfacial slip than hydrophilic surfaces. The PQC sensor responds to the extent to which the acoustic wave is propagated into the surrounding medium and to an alteration in interfacial viscosity. This indicates

the response to the addition of a rigid layer will differ from the response to the addition of a deformable layer like a protein. Duncan-Hewitt and Thompson proposed a theory to describe the PQC sensor response in polar liquids [52]. The paper characterizes the solid/liquid interface with respect to four liquid layers that wet the PQC surface to different extents. This model allows for a partial slip boundary condition at the interface. Yang and Thompson interpreted the PQC response in terms of kinetic energy transfer, acoustic energy dissipation, and formation of interfacial structures [9]. The structure of the solid/liquid interface can change if liquid properties (ionic strength, pH, buffer composition) change. The interfacial structure defines the interfacial viscosity; interfacial viscosity can influence the slip boundary condition at solid–liquid interface which in turn affects the resonant frequency.

To date, no unifying equation has been developed to describe the PQC response in a liquid medium since the response depends greatly on the exact interfacial structure formed between the coatings on the PQC surface and the solution environment. If the solutions are not highly viscous and only one electrode is in contact with the solution, good experimental agreement with the predictions of Bruckenstein and Shay and Kanazawa and Gordon can generally be expected. However, calibration of the PQC is vital for accurate use of the device. Ward and Delawski determined the radial mass sensitivity of a PQC in contact with a liquid [6]. The greatest sensitivity is in the center of the crystal, decreasing with increasing radius. Their results suggested coating uniformity is extremely important for accurate measurements. In 1992, Hillier and Ward determined mass changes occurring on the non-electrode portion of a PQC cannot be calibrated because the sensitivity constant would not be accurate due to field fringing [4]. These fringe effects can be minimized by contacting only the electrode portion of the PQC with solution. This suggests the best means of solution contact is through the use of crystal flow cells. In any case, the PQC response must be calibrated.

In summary, Sauerbrey demonstrated the PQC resonant frequency depends on the material

parameters of the PQC and on its overall mass [15]. This is strictly applicable to rigid layer behavior of gas phase mass deposition. Recent advances in solution sensing indicate the viscoelastic properties of the hydrodynamic layer in addition to mass deposition influence the frequency response. When vibrating in a liquid matrix, a layer of liquid moves with the PQC oscillation due to viscous drag. Binding of an analyte to the PQC surface will likely change the viscoelastic properties of the interface, but the overall change in frequency is likely to be different than that predicted by Sauerbrey. This indicates the need for characterizing the PQC system with the respective sensing environment. Application of solution phase sensing is paramount to the applicability of using PQC in biosensing systems.

4. PQC biosensors

The general approach to exploiting the piezoelectric effect for use in a biosensor is to coat a PQC with a material that interacts selectively with a target substance. Two general experimental designs are used in most PQC biosensing applications. In each, a biological entity is first immobilized on the crystal surface. One method is to measure the dry frequency of the crystal after the biological component is immobilized. Then the PQC is immersed in the reaction solution for a time period sufficient to allow for the target substance in solution to bind to the immobilized biological constituent. As the analyte interacts with the material coated on the PQC, it physically or chemically absorbs onto the PQC thereby adding to its overall mass. The PQC is then removed from the solution, rinsed, and dried. The additional mass is identified by measuring the corresponding change in the vibrational frequency of the PQC after the drying step. The limitations of this approach center on the tediousness of the dip and dry method. Additionally, the method provides no real-time data. The second approach addresses these limitations. Here, a PQC flow cell or some type of batch reaction cell is used to provide real-time data on the time course of binding events on the PQC surface. The analysis is

conducted wholly in the solution phase. Adsorption of the analyte on the PQC surface causes a change in the viscoelastic properties of the interfacial structure which are recognized by a decrease in the resonant frequency.

4.1. Immobilization methods for PQC biosensor applications

Optimization of immobilization techniques will need to be addressed before biosensors are used on a large scale [54]. There are four basic immobilization procedures used in which the species is bound to the PQC electrode or to an inert support on the electrode surface [54,55]. The first method utilizes crosslinking through glutaraldehyde. The second involves covalent attachment through a silane or via an avidin/biotin complex. The third uses entrapment in a matrix such as a gel or polymer. The fourth implements direct physical adsorption to the crystal's electrode surface. In many cases, a combination of these methods is used. Regardless of the procedure, it is advisable to clean the electrode surface prior to immobilization to remove any substances that may hinder the immobilization process. The cleaning procedure of Davis and Leary [32], or some modification of this general method, has been used in numerous cases.

Shons et al. immobilized albumin and gamma globulin through glutaraldehyde crosslinking to create the first PQC biosensor [56]. Many piezoelectric biosensors use crosslinking [18,38,55,57–66]. Chemical attachment through avidin and biotin has been conducted but is not routinely used [55,66,67]. Covalent binding through a thin silane layer is commonly employed [13,35,36,46,68–75]. Attachment via entrapment in a gel [33,34,38,76] or through a polymer [18,55,57–66,75,77] is also customary. Other procedures involve attachment to an immobilized Protein A layer [55,58–66,75,78]. The shortcomings of these immobilization procedures of crosslinking, covalent attachment, entrapment, or linking through Protein A rest in the large size and mass added to the PQC prior to analyte detection. This can increase the interfacial viscosity which will decrease the sensitivity and/or the

mass load may approach the PQC's limit for stable oscillation.

Many investigators have developed PQC sensors used for multiple dip and dry assays. Guilbault and Schmid indicated for multiple liquid assays immobilization through a stable layer is desired so the biological elements can withstand abrasive regeneration steps, such as contact with a solution of 8 M urea [18]. Prusak-Sochaczewski and Luong conducted multiple albumin assays and evaluated immobilization through protein A or a polyethylenimine layer with subsequent glutaraldehyde crosslinking [65]. In terms of reusability, pre-coating the crystal with protein A was superior to the polymer coating. In publications by Konig and Gratzel [58–63], Suri et al. [75], and Plomer et al. [64] three immobilization procedures were evaluated: through a silane layer (APTES) with subsequent glutaraldehyde crosslinking in addition to the above two methods. Based predominantly on their requirement for biosensor regeneration, Konig and Gratzel found the polymer coating to be superior in the case of detecting human T-lymphocytes [58], erythrocytes [60,62], and granulocytes [61]. For analysis of viruses and bacteria Konig and Gratzel found immobilization through protein A was the best [59,63]. Similarly, Plomer et al. and Suri et al. determined protein A was the best immobilization method for determination of insulin and enterobacteria, respectively [64,75]. Guilbault et al. [55] and Prusak-Sochaczewski et al. [66] tested the above three methods in addition to attachment via a biotin-avidin interaction. For *Salmonella typhimurium* detection, polyethylenimine was superior and the biotin-avidin procedure was far inferior to the other three immobilization methods. Again, the predominant qualifying factor was the ability to withstand harsh regeneration steps.

Immobilization via direct attachment to the PQC surface has also been conducted. Davis and Leary monitored the attachment of protein A to the surface of a gold electrode [32]. They indicated gold-protein A complexes are highly stable with an association constant of 10^8 M^{-1} ; the attractive forces are Van der Waals in nature. In general, protein adsorption to solid surfaces decreases as protein hydrophobicity decreases [79]. Subsequent

to Davis and Leary, a wide range of biological elements have been immobilized directly on a PQC electrode, including anti-human serum albumin [37], IgG [35], goat anti-ricin antibody [31], anti-vibro cholera [80], Herpes simplex virus type one [81], and recombinant protein fragments of HIV specific antibodies [82,83]. Bare PQC have also been used to monitor attachment of cells to its surface [84–86]. To date, no uniform immobilization standard has been identified. This indicates that for any particular method, the ‘best’ procedure should be identified and verified experimentally. Extensive details on immobilization techniques are provided in the literature mentioned above.

4.2. Dip and dry PQC biosensor applications

The fundamental procedure used for essentially all ‘dip and dry’ methods includes attachment of a selective binding agent to the PQC surface and quantifying the frequency of the PQC with the immobilized binding agent before and after interaction with the target analyte. Thus, the reaction occurs in the solution phase, but analysis and quantification occur under gas phase conditions. Before the frequency is measured, the PQC is subjected to one or more washing steps to remove non-specifically bound substances and dried by some means. In some cases measurement steps before immobilization of the biosensing element are also taken. The time allowed for interaction between the immobilized entity and the analyte is determined by the assay conditions and the type of analyte examined. The wash and dry conditions vary.

Shons et al. was the first to attempt to construct a PQC biosensor in 1972 [56]. Five MHz PQCs were coated with albumin or gamma globulin and immersed in anti-sera of varying concentration and specificity to determine antibody activity. They found the sensitivity was equal to or better than the conventional detection method of the day, passive agglutination. PQC biosensors did not receive any further research attention until the 1980s. An indirect, competitive binding assay for the determination of antigens was patented by Oliveira and Silver in 1980 [87]. Also in 1980, Rice

disclosed a method for identifying antibody subclasses [88]. Other microgravimetric PQC immunoassays have been developed for the detection of albumin [65], atrazine [57,89,90], human transferrin [78], insulin [75], cocaine [91], and IgM [71,76]. An enzymatic assay was designed by Grande et al. for detection of galactosyltransferase [92]. This work discussed some of the complications associated with conducting dip and dry PQC assays, such as solvent retention.

PQC biosensors have also been applied to the detection and quantification of cells. Muramatsu et al. were the first to perform a piezoelectric microbial assay [93]. *Candida albicans* concentrations were detected in the concentration range of 10^6 to 5×10^8 cells ml^{-1} . Assay specificity was confirmed; there was no reaction with other yeast species or other type of antigen. Subsequently, a number of bacterial, viral, and cellular entities have been analyzed: *Salmonella typhimurium* [66], *Listeria monocytogenes* [94], enterobacteria [64], granulocytes [61], human T-lymphocytes [58], human erythrocytes [60,62], viruses and bacteria that play a role in diarrhea [59], herpes viruses [63], and vibrio cholera [80]. In the work conducted by König and Gratzel a number of sample replicates were analyzed and thorough statistical analysis was performed [58–63]. Unfortunately, for many PQC studies this is the exception rather than the norm.

Reusable detectors for microbial assays have been reported [58–66]. Carter et al. also suggested their PQC sensor could be regenerated but indicated this was inadvisable due to contamination hazards associated with detection of cholera [80]. In most cases, the PQCs were regenerated by immersion in 8 M urea. König and Gratzel improved the reusability of a PQC immunosensor by developing a novel, competitive–regeneration step [62]. A PQC with an immobilized antibody and attached antigen was placed in a solution containing a synthetic peptide corresponding to the antigenic region of the antibody. After the peptide bound to the antigen, the antigen/peptide complex was removed from the antibody immobilized on the PQC with several washing steps. In a subsequent study for the determination of viral and bacterial agents, they were able to regenerate a single PQC for up to 18 analyses [63].

DNA hybridization studies have been conducted using the dip and dry method [72,74,77,95]. Fawcett et al. conducted the first study in 1988 where short, synthetic, single stranded nucleic acids were covalently attached to the PQC surface through a styrene–acrylic acid copolymer [77]. The PQC mass to frequency relationship was determined by adding 20 μl of polyvinyl alcohol to the surface of one PQC. Calibration was not performed on each PQC used in the analysis. Although their method of quantitation may be questionable, they did demonstrate the PQC biosensor could identify DNA hybridization. Later, Campbell et al. conducted a similar assay for monitoring Poly(U) hybridization to Poly(A) immobilized on a PQC [74]. The reusability of their sensor was demonstrated through sequential hybridization and denaturing steps. Wu et al. developed another hybridization assay [95]. Here, single stranded DNA isolated from salmon sperm were immobilized on the PQC through electro-blotting. In this procedure, the crystal electrode acts as positive electrode; the negatively charged DNA phosphate backbone is attracted to this positive electrode. Then, the PQC was irradiated with UV to covalently link the DNA probe to the PQC surface. Yamaguchi et al. monitored the direct adsorption of DNA onto gold and graphite PQCs modified with a silane (GPTMS) [72]. This portion of their assay was conducted in real-time but subsequent methods for monitoring hybridization used dip and dry procedures. Impedance measurements which can differentiate between mass addition to the crystal surface and solution viscosity changes were utilized to detect hybridization. All the above methods offer the opportunity to monitor DNA hybridization without the use of radio-isotopes.

Dip and dry piezoelectric sensing applications are advantageous in that the frequency signal can in some cases be interpreted through the use of the Sauerbrey relation; although, the method is sensitive to errors due to hydration, humidity, and solvent retention. The time consuming and tedious nature of the analysis scheme suggest the dip and dry method is not likely to ever become a routinely used analytical procedure. Furthermore, the application of solution phase piezoelectric

sensing is far superior in that real-time data analysis can be conducted and the system can be configured for on-line analysis.

4.3. Solution phase sensing PQC biosensor applications

Solution phase PQC sensing systems are designed using a myriad of conditions. The most common method employs the use of a contact cell where one crystal surface is adjacent to the solution. The contact cell is configured in a flow or batch mode and the solution is typically introduced using a peristaltic or syringe pump. In flow cells, the volume of solution flowing over the crystal surface is commonly less than 100 μl [31,35,38] but some flow cells have been designed for solution contact volumes of up to 7 ml [37]. No generalities can be made concerning the volume of solution in a batch contact cell; volumes range from a few microliters to nominally one liter. Alternatively, the whole crystal can be in contact with the solution phase. Here, either the PQC surface is masked to avoid solution contact [45,96,97] or the oscillator circuit is designed to allow the crystal to oscillate while immersed in solution [36,44,68,69]. Many conventional PQC's designs do not allow for dual electrode contact with a solution to avoid short-circuiting due to exposure to a common conductive solution. Further, with full solution contact more than just the piezoelectrically active surface interacts with the solution. This may cause calibration inconsistencies [4]. On the other hand, immersion in solution allows for detection of changes in solution conductivity. This could be advantageous, or a serious draw back, depending on the type of analysis performed.

For most biosensor techniques, a biological component is immobilized on the PQC surface. The signal is generated in response to adsorbate recognition. The sensitivity of direct analyte detection through an immobilized ligand is limited by the number of binding sites available to interact. This is beneficial for characterization of conditions associated with a reaction but may be a limitation in terms of detection sensitivity. One technique used to increase the sensitivity of PQC

biosensors is to relate the first-derivative of the change in frequency versus time to the analyte concentration [26,97–100]. Additionally, a number of analysis schemes have been proposed that do not rely on direct mass attachment to the crystal surface [32,50,67,85,86,96–106]. A summary of solution phase piezoelectric bio-sensing systems follows.

Roederer and Bastiaans were the first to conduct a piezoelectric immunoassay completely in solution phase [13]. A SAW device was coated with goat anti-human IgG for detection of IgG in solution in the range 0.0225–2.25 mg ml⁻¹. Thompson et al. were the first to study interfacial immunochemistry with a PQC in contact with a liquid phase [38]. Contrary to what was expected based on a microgravimetric signal, the binding of antibody to antigen (IgG) produced a frequency increase. The frequency increase was explained in terms of the change in surface free energy associated with binding. To our knowledge, no other frequency increase upon binding to the PQC surface has been documented in the literature. Muramatsu et al. determined antibody subclasses of IgG using a protein A modified crystal [36]. Their detection range of 10⁻⁶–10⁻² mg ml⁻¹ was markedly improved over Roederer and Bastiaans. Their measurements were conducted in the liquid phase, but their study was not in real-time. The crystal was washed with purified water before the frequency was measured; frequencies were not recorded over the time-course of the reaction. Minunni et al. conducted real-time detection of human-IgG adsorption directly to the PQC crystal surface [35]. A decrease in frequency was noted for successive increases in human-IgG concentrations; however, physical attachment to the crystal surface was never demonstrated. An indirect, competitive binding assay was also conducted. Antigen was covalently immobilized on the crystal and the assay solution contained both antigen (the target analyte) and antibody. The immobilized and free antigens competed for the antibody binding site. Thus, the frequency signal was inversely proportional to the analyte concentration. Muratsugu et al. determined microgram concentrations of human serum albumin [37]. The detection range for albumin was from 0.1 to 100 µg

ml⁻¹. They proposed using this detector for albumin in urine (normal range from 8.84 to 9.15 µg ml⁻¹) but all their analyses were conducted in purified solution. Selectivity for human albumin against bovine serum albumin was substantiated. Carter et al. detected ricin concentrations as low as 0.5 µg l⁻¹ [31]. Davis and Leary continuously monitored the reaction of immunoglobulins with protein A and the subsequent attachment of antibody to the immunoglobulin [32]. All investigations discussed above utilized adsorbate recognition through direct antibody–antigen interactions.

Binding interactions between lipopolysaccharide (LPS), an endotoxin, and LPS-binding peptides were monitored by Chang et al. [107]. The method allowed for crystal regeneration with an acidic buffer. Their work indicated the procedure may be useful for some drug screening studies. A cholestyramine coated PQC was used to determine bile acid concentrations in deionized water and phosphate buffer saline [108]. The detection limits were as low as 0.2–9 nmol in purified solution; however, no actual biological samples were assayed. The method showed excellent promise and the results even suggested the need for a drug modification that may increase the effectiveness of bile-salt sequestering drugs.

PQC sensing systems have been configured to determine protein analyte concentrations without immobilizing a biological constituent on the PQC surface. Imai et al. quantified total urine protein concentrations by a PQC technique based on sedimentation of proteins [103]. A protein precipitating agent was added to a protein solution; the protein consequently precipitated on the PQC surface causing a frequency decrease corresponding to the protein concentration. However, it is questionable whether simple precipitation, not physical or chemical bond formation, can be reliably correlated to the change in frequency [84,85].

The relationship between the PQC response and solution density and viscosity was applied to sensing gelation and agglutination. Muramatsu et al. determined endotoxin concentrations by monitoring the gelation of *Limulus ameobocyte* lysate [99]. Muramatsu et al. analyzed fibrinogen through a coagulation reaction with thrombin [98]. An assay

for C-reactive protein was developed by Kurosawa et al. based on the detection of changes in viscosity and density that occur when an antigen binds to an antibody coated on the surface of latex in solution [96]. The antigen induces an agglutination reaction of the antibody-bearing latex. Muratsugu et al. applied the latex assay to the detection of antistreptolysin O antibody [97]. Here, the first derivative of the change in frequency versus time was related to the analyte concentration. This concentration correlation greatly enhanced the method's sensitivity. Ghouchian and Kamo examined the effects of interfacial properties on the latex assay and found PQC surface modifications greatly affected the response to viscosity changes [105]. The latex assay was improved by developing a crystal cell allowing for a single PQC electrode to contact the solution [106]. Chu et al. developed an assay similar to the latex based assay where complement III was determined through another agglutination assay [109]. Again, detection was based on a change in the viscosity of the assay solution.

Escherichia coliform concentrations have been detected in solution [100,110]. Muramatsu et al. reported detection in the concentration range of 10^6 – 10^8 cells ml^{-1} [110]. To amplify the signal, polystyrene particles modified with anti-*E. coli* were added to the reaction mixture. After *E. coli* attached to the antibody immobilized on the PQC, anti-*E. coli* attached to polystyrene particles complexed to *E. coli*. Fengjiao et al. decreased the detection range to 10^1 – 10^6 cells ml^{-1} by implementing a frequency detection time method based on the detection of a change in conductivity of the solution [100]. The frequency detection time (FDT) was defined as the time required to see a shift in frequency above a threshold level where no response could be seen. A range of concentrations were analyzed and the FDT was determined for each concentration. The resulting calibration curve related the initial concentration to the FDT. Conductivity changes have also been used to determine aspirin and salicylic acid concentrations [104] and urease activity [111].

Herpes simplex virus type 1 was evaluated with a PQC biosensor [81]. HIV antibodies have been detected in rabbit immunosera at different anti-

serum dilutions [30] and in human sera [82,83]. Barnes et al. assayed for sugars and erythrocytes with a piezoelectric crystal coated with lectin [69]. Erythrocytes detection was based on recognition of the terminal sugar of the carbohydrate chains attached to the erythrocyte membranes as glycoproteins or glycolipids. Lasky and Buttry [33,34] developed a system for glucose sensing through immobilized hexokinase. This represents one of the few PQC biosensors based on an enzymatic interaction.

In situ piezoelectric techniques for monitoring cellular process have been described [84–86,101]. A cell growth sensor was developed by Ebersole et al. to detect metabolites without immobilization of a biological entity [101]. This was the first sensor capable of detecting metabolic responses and division rates of viable cells. The authors indicated production of metabolic acids is a useful marker of cell metabolism and growth and utilized this relation in their sensor design. Detection of metabolic processes was based on adhesion of a polymer to the PQC. The polymer precipitated from solution in response to titration of its carboxylate groups by the metabolic acids which converted the polymer to its isoelectric form. Ebersole et al. also reported solution phase detection of DNA hybridization [67]. The hybridization assay was based on an earlier method by the same primary author, amplified mass immunosorbent assay [102]. The signal is amplified enzymatically through production of a precipitate that settles on the crystal surface after the binding reaction occurs. Again, there is some question whether precipitate formation on the PQC surface can be reliably correlated to the change in frequency [84,85]. Matsuda et al. monitored real-time platelet adhesion in plasma [84]. The frequency decrease was associated with direct adhesion onto the crystal surface. When cell suspensions settled on the crystal surface, without forming a direct attachment, no measurable frequency decrease was observed. Gryte et al. monitored anchorage dependent cell adhesion and detachment to the surface of a PQC [85]. Here, the investigators demonstrated the decrease in frequency was a function of physical cell attachment not simple sedimentation. The frequency

change for cell attachment was compared to the frequency change for sedimentation of latex beads onto the crystal surface. The beads did not change the frequency appreciably. The formation of a biofilm of *Pseudomonas cepacia* was monitored by Nivens et al. [86]. The study was designed to simulate contamination in a sterile water system. The change in frequency was related to the number of attached cells; the number of attached cells was determined with a scanning electron microscope. This relationship was used to determine the number of cells attached over time by correlating the results with the change in frequency over time. Also, the rate of biofilm formation was determined from the first derivative of the change in frequency versus time.

Davis and Leary proposed using PQC biosensors to characterize reaction kinetics; however, no kinetic parameters were calculated [32]. Skladal et al. [73] and Steegborn and Skladal [112] utilized PQC methods to determine association and dissociation rate constants to characterize the affinity binding of an antibody to two herbicides, 2,4-dichlorophenoxyacetic acid and atrazine, respectively. Su et al. monitored DNA hybridization in solution in real-time by recording the PQC equivalent circuit parameters [113]. The actual mass added to the crystal through hybridization was quantified using radio-labels. The change in frequency correlating to this mass addition was approximately 18 times larger than that predicted by the Sauerbrey relation. This further substantiates the complexities associated with solution phase sensing. The authors indicated their analysis scheme could be used to study the kinetics of hybridization. Subsequently, two of the researchers from this group characterized the hybridization kinetics of a cDNA probe to single stranded DNA immobilized on a PQC [114].

5. Summary

PQC biosensing systems have been applied to a number of analytical problems because of the many advantages associated with using the detector. These advantages include the potential for on-line, automated, real-time analysis out-put;

high sensitivity and specificity; reduced influence of interferences; rapid response time; ease of use; small, readily transportable instrumentation; and cost effectiveness. The primary limitations of piezoelectric sensors are in the challenges associated with immobilization procedures; the lack of an exact correlation between mass addition and frequency change for solution phase sensing; and sensitivity to environmental conditions. These disadvantages can be addressed by investigating and determining the most appropriate immobilization procedure to use; through characterization and calibration of the sample matrix; and minimizing background effects through analysis of blanks and controls and with the use of reference crystals. Although a large body of work already exists, the potential applications yet to be investigated are exhaustive. Future studies will likely be applied to solving research problems in biochemical investigations, clinical diagnostics, and in environmental and industrial process monitoring.

Gravimetric determination of tin with sodium cyclotetramethylenedithiocarbamate and its applications in metal analysis

Zhou Nan *

Shanghai Research Institute of Materials, 99 Handan Lu, Shanghai 200437, People's Republic of China

Received 27 June 1997; received in revised form 10 September 1997; accepted 11 September 1997

Abstract

A gravimetric determination of tin is proposed with sodium cyclotetramethylenedithiocarbamate as precipitant at pH 5.0–5.5. By optimizing the reaction conditions the theoretical conversion factor 0.1687 can be used for determining $\geq 5\%$ of Sn. Its standard deviation ($n = 10$) at the level of 20 mg of Sn was found to be 0.08 mg. Effects of diverse cationic species can be eliminated by a clear-cut group precipitation at pH 9 with DDTC in the presence of tartrate and subsequent masking with EDTA. Provision is also made for removal of individual species in occasional cases. Hence, the proposed method is flexible and versatile and was successfully applied to the macro-determination of Sn in diverse alloys. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Gravimetric determination; Tin; Metal analysis

1. Introduction

Oxidimetry of Sn(II) with KIO_3 [1] is generally used for the macro-determination of tin, an important component of industrial alloys. This method is empirical, needs thorough exclusion of air, the titre of the titrant should be standardized each time [2] and its values may be inconsistent if different CRM's are used for standardization. The chelatometric titration of Sn is poorly selective [3]. More so are its gravimetric methods hitherto published which are time-consuming, hence, rarely

used. It reacts with *N*-benzoyl-*N*-hydroxylamine only in an ice bath for 4 h [4]. The precipitates formed with benzoate [5], phenylarsonic acid or *N*-nitroso-*N*-phenylhydroxylamine or as metatannic acid should be ignited to SnO_2 . Owing to the disproportionation of Sn(II) its electrodeposition is not quantitative. Indeed its macro-determination remains a problem and deserves further study.

Sodium cyclotetramethylenedithiocarbamate (TDTC) is proposed in this paper for precipitating Sn(IV). High selectivity can be achieved by incorporating a preliminary clear-cut group precipitation at pH 9 in the presence of tartrate with DDTC and a subsequent masking with EDTA.

2. Experimental

2.1. Reagents

Deionized water was used for the preparation of all reagents and for dilutions. Analytical-reagent grade chemicals, supplied by Shanghai Reagent Chemicals, were used, unless otherwise specified. TDTC solution, 10% was prepared freshly from a product of Heyl, Germany. It was filtered through a 0.45 μm membrane before use. DDTC (sodium diethyldithiocarbamate) solution, 4% was prepared freshly and filtered before use. Tartaric acid solution, 0.5 M. HCl (3 M) and concentrated H_2SO_4 (9 M). Ammonia solution, 25% NaOH solution, 5 M TiCl_3 solution, ca. 15% in 3 M HCl. Al(III) solution, 0.1 M in 0.15 M NaOH by alkaline dissolution of $\geq 99.9\%$ pure Al metal. EDTA solution, 0.03 M. Buffer solution, pH of 5.2; containing 10 M of sodium acetate and 2 M of HCl. *m*-Nitrophenol solution, 0.3%. Screened indicator of pH 5.1, containing 0.08% of methyl red and 0.06% of bromocresol green in ethanol.

2.2. Wash solution A

To 100 ml of water add 2 ml of HCl conc., one drop of *m*-Nitrophenol solution and dropwise ammonia solution till the indicator colors yellow.

2.3. Wash solution B

To 100 ml of water add 2 ml of buffer solution and 1 ml of TDTC solution.

2.4. General procedure

Take 200 mg of the sample containing $\geq 5\%$ of Sn, weighing to the nearest 0.1 mg. Transfer it to a 250 ml conical flask and decompose with HCl alone or together with a few drops of HNO_3 (note 1). Cap the flask loosely and warm gently at 50–60°C till decomposition is complete (note 2). Dilute to 30 ml with water, add TiCl_3 solution in excess, cap the flask as before and boil gently for 10 min (note 3). Add an appropriate amount of tartaric acid (note 4), one or two drops of *m*-

Nitrophenol solution (note 5), neutralize with NaOH solution to pH 6–7, then with ammonia solution till yellow color appears (ca. pH 9) and dilute to 80–100 ml. Add DDTC solution dropwise with vigorous stirring till the precipitate forms slowly. Add 5 ml of Al solution (note 6), adjust the pH with HCl if necessary and continue the addition of DDTC till no further precipitate appears, then one or two drops more. Digest the precipitate in a water bath thermostated at 60°C for 5 min. Cool and filter off the precipitate through a 0.45 μm membrane and wash the precipitate and the original flask three or four times with wash solution A (note 7).

To a 250 ml beaker containing 1 ml of 9 M H_2SO_4 and 5 ml of HCl conc., pour in quantitatively by portionwise the combined filtrate and washings while stirring vigorously to make a clear solution. Boil to decompose the residual DDTC and concentrate the volume of the analyte solution to 60–70 ml. Add, while hot, 5–10 ml of EDTA solution (note 8), adjust pH to 4 with ammonia solution, then add one or two drops of the screened indicator solution and sufficient buffer solution till the indicator just turns green. Finally, add 10–30 ml (note 9) of TDTC solution dropwise with constant stirring.

Digest the precipitate in a water bath thermostated at 70°C for 15 min. Cool to room temperature, filter the precipitate quantitatively to an IG 4 filter crucible dried and weighed to constant mass at 95°C and wash the glass crucible and the original beaker three or four times with wash solution B. Dry the crucible at 95°C to constant mass and calculate the content of Sn in the sample as follows (note 10):

$$\text{Sn}\% = \frac{(m_2 - m_1) \times 0.1687}{G} \times 100 \quad (1)$$

where m_1 is the mass of the crucible itself, mg; m_2 is the mass of the crucible and precipitate, mg; G is the mass of the sample or its aliquot taken for the determination, mg; 0.1687 is the conversion factor of the precipitate to Sn (vide infra).

2.4.1. Note 1

For Ti alloys add 10 ml of HCl conc. alone; for Al-Sn alloys add 8 ml of HCl(1 + 3) first, then 8

ml each of water and HCl conc. only after vigorous reaction subsides. For Cu, Pb, Sn and fusible alloys add 10 ml of HCl conc. and a few drops of HNO₃ (just sufficient but no more) [6].

2.4.2. Note 2

If there is any insoluble matter left, filter it off through a medium-texture filter paper and wash the paper thoroughly with HCl.

2.4.3. Note 3

If As is present, transfer the analyte solution to a distillation flask in a smaller size, and distil till the temperature of the vapor in the flask reaches 108°C under standard pressure.

2.4.4. Note 4

Its optimum amount is 9 ml for Pb, Sn and fusible alloys; 13 ml for Cu alloys; 17 ml for Ti alloys; 30 ml for Al–Sn alloys. Sometimes heating is necessary, e.g. to complex Cr(III). If the sample contains ≥ 35% of Sn; or Mo or V or both, dilute its solution to a definite volume. For the determination take therefrom an appropriate aliquot (to which 3 ml of tartaric acid solution should be added) estimated after analyzing the other major elements.

2.4.5. Note 5

Omit its addition whenever colored species is present.

2.4.6. Note 6

Omit or reduce its addition if the analyte solution contains Al. This addition may raise the pH of the analyte solution.

2.4.7. Note 7

If V is present, add 10 ml of ethanol to the filtrate.

2.4.8. Note 8

Its amount depends on that of the species to be masked.

2.4.9. Note 9

Its amount depends on: (a) mg of Sn(IV) to be determined; (b) mg of Mo or V or both in the

analyte solution; 10 ml of it suffices to precipitate ≤ 30 mg of Sn alone.

2.4.10. Note 10

If Mo or V or both are present, the mass of the precipitate in the sintered glass crucible on drying is the sum of these two or three chelates. Hence, a correction for this co-precipitation should be made and Eq. (1) is modified as follows:

$$\text{Sn}\% = \frac{(m_2 - m_1 - 4.382m_a - 7.390m_b) \times 0.1687}{G} \times 100 \quad (2)$$

where m_a is the mass of Mo co-precipitated, mg; 4.382 is its conversion factor to MoO₂L₂ (L stands for the TDTC anion here), i.e. 420.453/95.94; m_b is the mass of V co-precipitated, mg; 7.390 is its conversion factor to VO(OH)L₂, i.e. 376.463/50.942.

Once m_1 and m_2 are known, m_a and m_b can be determined as follows. Dissolve the precipitate in aqua regia, dilute to a definite volume and take aliquots for determining Mo by photometry with thiocyanate and V by oxidimetry or 2,2'-iminodibenzoic acid method [8], respectively.

3. Results and discussion

3.1. Choice of the precipitant for Sn(IV)

Sn(IV) is the stable species in the aqueous medium, ligands of O,O-or S,S-donor type can react with it. Unfortunately, these reactions are poorly selective. Ligands of the latter type would be preferred, however, because reaction selectivity can be achieved by making use of the fact that they, like sulfide ion, do not precipitate Sn(IV) in an alkaline medium; but do most of the other precipitable species. Among them dithiocarbamates would be the candidates. It should be noted that those of the mono-substituted group tend to decompose readily in acidic and alkaline media [9], whereas the disubstituted group do so in the acidic medium only. Hence, the latter group would seem recommendable. The Sn(IV)-DDTC chelate was reported to be a mixture as the result

of its decomposition or simultaneous redox reaction between its components [10,11]. On the other hand, TDTC has the following special features: (1) very soluble in water, much more so than the corresponding ammonium salt [12]; (2) slight solubility of its chelates [13]; (3) stable to a considerable extent toward gently heating in the weakly acidic medium; (4) much less oxidizable than other dithiocarbamates, hence, precipitation in the absence of any accompanying redox reaction. Accordingly it was chosen as the precipitant.

3.2. Optimum conditions for quantitative precipitation of Sn(IV)

Our preliminary experiments showed that TDTC precipitates at $\text{pH} \leq 6$. Generally the decomposition rate of dithiocarbamates increases with increasing acidity of the medium, a pH range over 5.0–5.5 was chosen for the precipitation. This is easily controlled by the use of an acetate buffer of pH 5.2 with the aid of a screened indicator. Under such conditions the protonation effects of TDTC and the masking agent used would be minimized too. It is an added advantage.

An auxiliary complexing agent should be first chosen to meet the following requirements: It can prevent the hydrolysis of Sn(IV) and keep all the concomitant species in solution, yet exerts little effect on the main reaction. It was found that tartaric acid serves the purpose and in the presence of 0.5–1.0 g of it the precipitation of Sn(IV) runs normally. As it complexes cationic species in moles, its amount of addition vary widely for different kinds of alloys, as specified in note 4 of Section 2.4.

As revealed by our preliminary experiments, the mass of the precipitate $\approx 6 \times$ the mass of Sn added. Therefore, it can be inferred that the precipitate would be $\text{Sn}(\text{C}_5\text{H}_8\text{NS}_2)_4$, because its relative molecular mass, calculated on the basis of values of relative atomic mass of elements recently recommended by IUPAC [13] would be 703.74, which divided by 118.71, the relative atomic mass of Sn, gives the quotient 5.928.

This inference seems theoretically sound, because DDTC reacts with Sn(IV) in the same mole ratio [11]. Hence, the conversion factor from SnL_4 (L stands for the TDTC anion here) to Sn should be $1/5.928 = 0.1687$. With a view to applying this theoretical factor the reaction conditions were optimized as follows.

Different temperatures for drying the precipitate to constant mass were tested and their results are shown in Table 1. Evidently 95°C would be the optimum one, whereas low recovery of Sn was found if dried at higher temperatures, presumably owing to thermal decomposition of the precipitate. Drying at $< 95^\circ\text{C}$ takes much more time.

The optimum volume of the analyte solution for precipitating was found to be 80–100 ml. The precipitate formed at room temperature is difficult to filter. On the other hand, high precipitation temperature favors its filtrability, but accelerates the decomposition of the precipitant. As a compromise, 70°C was specified and found to be optimum. The precipitate should be aged for 15 min at this temperature and filtered only after cooling to room temperature. Otherwise the results may be poorly reproducible.

Different amounts of the precipitant were added for precipitating different amounts of Sn(IV) and the results are shown in Table 2.

Obviously addition of a large excess of TDTC does no harm. Its optimal amounts were specified to be 1–3 g. One g of it suffices to precipitate quantitatively ≤ 30 mg of Sn when present alone.

Table 1
Effect of drying temperature on determination of 15 mg of Sn

Drying temperature (°C)	Mass of precipitate (mg)	Sn found (mg)
105	87.7	14.8
	88.3	14.9
100	88.1	14.9
	88.5	14.9
95	89.2	15.0
	88.9	15.0

Table 2
Effect of amount of TDTC on the determination of Sn

Sn added (mg)	TDTC added (g)	Mass of precipitate found (mg)	Mass of Sn found (mg)
15.0	0.5	88.9	15.0
		89.1	15.0
30.0	0.8	178.4	30.1
		177.5	30.0
75.0	1.7	443.9	74.9
	3.0	444.3	75.0
		444.9	75.0

3.3. Effects of diverse ions and preliminary separation

As the preparation reaction with TDTC is not selective, most of other cationic species, if present, should be removed in advance. DDTC was reported to precipitate Sn(IV) over the whole pH range of 2–14 [14]. It is surely invalid. As an analog of TDTC, it has the same donor system, hence should behave similarly. Our experiments confirmed this since at $\text{pH} \geq 7$ no precipitate was found. Accordingly a preliminary group separation can be made by precipitation with DDTC at pH 9 in the presence of tartrate to remove at a single stroke: Ag(I), Au(III), Bi(III), Cd(II), Co(II), Fe(III), Hg(II), Mn(II), Ni(II), Pb(II), Sb(III), Te(IV), Tl(I) and Zn [14]. Although the removal of Se(IV) and Te(VI) is not quantitative, yet only a part of their residual portions would react with TDTC under the specified conditions [14]. Fortunately, they are usually present in very small amounts, hence, their interference might be ignored. The ionic species of platinum metals, if present, would be removed also. Once the filtrate is acidified to pH 2–6, the excess of DDTC left would precipitate Sn(IV) immediately. Therefore, it is advisable to overstep this pH region by pouring the alkaline filtrate portionwise to strong acids.

The possibly remaining species after this group separation would be: (a) cationic species of alkali and alkaline earth metals; (b) soluble tartrate complexes of B(III), Be(II), Al(III) and Ti(IV). All of them are tolerable even in macro amounts. Interferents are Cr(III), Ga(III), In(III) [14]. They can be masked, however, by EDTA, the excess of

which then reacts with Al(III) to constitute a ligand buffer, as their formation constants $\lg K_f$ were reported to be 23.4, 20.3, 25.0 and 16.3, respectively. Zr(IV), Hf(IV), Th(IV), U(VI) and most of the cationic species of rare earth metals would behave similarly, since they also form stronger chelates [15] with EDTA than Al(III). It was found that the precipitation of Sn(IV) runs normally in the presence of this ligand buffer, and that in the presence of Ce(III) or La(III), which itself is a non-interferent, a slight turbidity appears sometimes, and addition of EDTA helps to clear the solution.

Nb as an interferent may be present in some Ti alloys. If HCl alone is used for sample decomposition, it would remain undissolved and thus removed from the analyte solution [7]. So do W, Si and the platinum metals [7]. If necessary, the trace amount of Sn which might be occluded in the insoluble matter, can be recovered and determined separately as reported elsewhere [16].

Up to 1% of As may be present in some alloys of interest. As it is not separated by the preliminary group precipitation and reacts with TDTC, it would cause a positive error. Even 0.1 mg of it would increase the mass of the Sn-precipitate by 0.7 mg. Hence, it seems advisable to keep it in the trivalent state and distil off as AsCl_3 . Ge(IV) is an interferent [14] of rare occurrence. If present, it can be removed together with As.

Generally speaking, oxidants can oxidize TDTC, and hence interfere. The only oxidant introduced to the analyte solution is nitric acid. Accordingly its addition should be kept as small as possible. Its remnant can be completely removed by adding Ti(III):

Ti(III) was chosen for this purpose, since it serves to reduce also the higher valence states of As and Sb quantitatively to their trivalent ones, the presence of its excess is indicated by its own color and both Ti(III) and Ti(IV) are non-interferents. If sodium sulfite were used instead, the separation of Sb(III) would be incomplete owing to reoxidation [17]. Moreover, sulfite would react with hydrogen sulfide, one of the acid decomposition products of DDTC [18] to form colloidal elemental sulfur, and hence is the only interferent possibly used among the reductants.

The reaction between Mo(VI) and DDTC was reported to take place over the pH range of 2–9 [14]. This statement is questionable, as our experiments showed that it, like Sn(IV), reacts with either DDTC or TDTC at $\text{pH} \leq 6$ only. Hence, Mo(VI) would accompany Sn(IV) in the filtrate after the preliminary separation at pH 9. This interference from Mo can not be eliminated by masking with EDTA or hydroxylamine (which was used to mask the precipitation of MoS_3 in acid solution) [19] alone, nor as Mo(VI)– NH_2OH –EDTA [20].

V, like Mo, would accompany Sn(IV) in the filtrate too. As shown in its predominance-zone diagram, it is at pH 5.0–5.5 in the state of vanadyl vanadate, i.e. partly as V(IV) and partly as V(V) [21]. Hence, effects of both V(V) and V(IV) should be studied. It was found that in the presence of EDTA, TDTC does not precipitate either of them at the stated pH to form the same yellow product. The only difference lies in that this precipitation takes place at once in the case of V(V), but slows down somewhat in the case of V(IV).

It should be noted that at pH 9 V(V) is the predominate species in the filtrate; whereas at $\text{pH} \leq 0$ V(IV) is [21]. Therefore, subsequent acidification of the alkaline filtrate makes the unstable V(V) an oxidant. Under such conditions V(V) would oxidize DDTC or its decomposition products and thus render the analyte solution colloidal. In order to avoid this additional interference ethanol is purposely added prior to acidifi-

cation and preferentially oxidized. It was chosen since it is very pure, harmless and can be readily boiled off.

Attempts were made to eliminate interferences from Mo and V, but failed. Thus, we can not help taking another approach: to precipitate them altogether, determine their co-precipitated amounts and make corrections for them (Eq. (2)). Fortunately, their presence or absence can be readily detected by the naked eye: in their absence the precipitate is pure white; while in their presence it is colored (yellow if V is present and scarlet if Mo present). Their determinations are also an easy matter. Indeed, a clear-cut separation of Mo and V from Sn seems very much difficult, if not impossible, to incorporate conveniently in the proposed method.

For anions, some alloys may contain $\leq 1\%$ of P which is tolerable. Effects of some ionic species on the determination of Sn are shown in Table 3.

3.4. Applications

It should be noted that only Sn(IV) forms a precipitate with TDTC in the highest mole ratio of 1:4. Hence, its conversion factor is very small

Table 3
Effects of cations on the determination of 30.0 mg of Sn

Cation added (mg)	Mass of precipitate found (mg)	Mass of Sn found (mg)
As(III) 2	177.7	30.0 ^b

As 0.5, Cd 2, Cu 3, Pb 73, Sb 15, Sn 6.5	6.55
Cu 83, Pb 4, Zn 6, Sn 7	6.95
Bi 45, In 10, Pb 25, Sn 20	20.10

(0.1687), even smaller than that of the well known nickel diacetyldioximate (0.2031). The proposed method is very suitable for the determination of 10–70 mg of Sn. Its standard deviation ($n = 10$) at the level of 20 mg of Sn was found to be 0.08 mg.

Its special features may be summarized as follows:

1. **Simplicity:** $\geq 5\%$ of Sn can be determined by taking 0.2 g of sample or even an aliquot there from. This makes the separation simpler and easier.
2. **Selectivity:** a single clear-cut precipitation in combination with masking suffices to eliminate most of the interferences and render the determination specific for Sn in most cases.
3. **Versatility:** provision is made for eliminating interferences in special cases, such as correction for Mo and V. This makes it also applicable to the analysis of Ti alloys.
4. **Flexibility:** it is flexible in the technique of sample decomposition and simplifications are possible in the absence of certain interferents.

Owing to these features the proposed method will find many industrial applications. The results for analysis of some simulated and industrial samples are shown in Tables 4 and 5 respectively.

4. Conclusion

A new gravimetric method is proposed for the macro-determination of Sn. It is simple, selective, versatile and flexible, hence would be very promising.

Received 27 August 1997; received in revised form 9 October 1997; accepted 10 October 1997

Abstract

FI spectrophotometric determination of calcium using murexide has been developed. The problem of the color of the dye fading and/or its complex in an alkaline medium in the batch method can be overcome by taking advantage of FIA. A calcium solution is injected into an ethylenediamine–ethylenediamine hydrochloride buffer (1 M, pH 11) which also serves as a masking agent, and is then merged with the aqueous murexide (0.005%, w/v) and continuously monitored. Simple FIA manifolds, including an LED colorimeter detector hooked up to a PC-based data acquisition and evaluation system are described. Optimization of FIA systems has been made. The proposed procedures have been validated by using reference materials and comparing the results with the standard methods, and then applied to ores and drug samples. © 1998 Elsevier Science B.V. Keywords: Calcium; Murexide; Flow injection; Spectrophotometry; Ores analysis; Drug analysis

1. Introduction

Calcium compounds are of concern to various industries, such as cement, pulp and paper, pharmaceutical, metallurgy and mining [1]. Determination of calcium is required for the quality control of raw material, process and/or product. Various techniques have been applied, for example titrimetry [2], spectrophotometry [3], atomic absorption

spectroscopy [4], ion-selective electrode [5] and ion chromatography [6]. In dealing with a large number of samples, a method which is rapid, accurate, precise and with low operation cost is required.

Flow injection (FI) techniques have increasingly served the above purposes. FI procedures for determination of calcium have been reported. Although some other techniques have also incorporated FI, such as flame AAS [7], flame photometry [8], ICP-AES [9], ISE [10], fluorimetry [11] and enthalpimetry [12], FI spectrophotometry has gained most attention owing to its simplicity.

A number of color reagents have been employed for FI determination of calcium. They

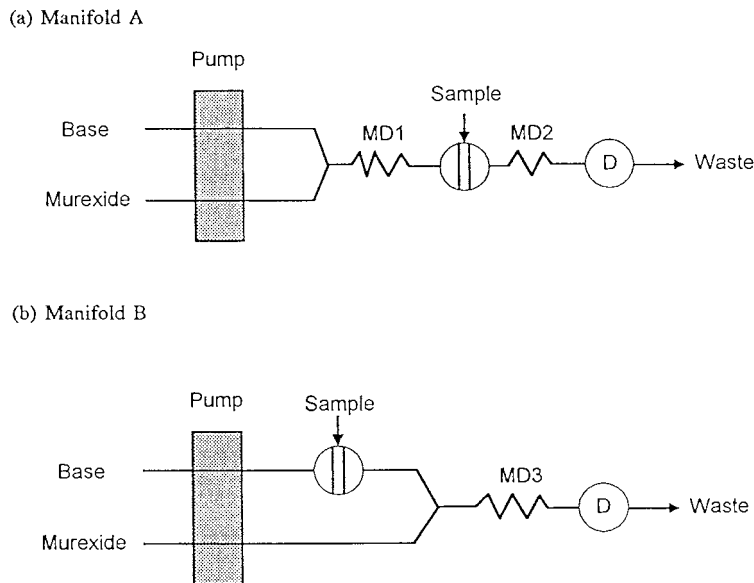

Fig. 1. The flow systems for the determination of calcium using murexide; MD1, MD2 and MD3, mixing devices (see text).

include complexon [13], chlorophosphonazo III [14], *o*-cresolphthalein [15], 3,3-bis[*N,N*-bis(carboxyl methyl)-*o*-cresolphthalein [16], 1-(2-hydroxy-4-diethylamine-1-phenylazo)-2-hydroxynaphthalene-3,6-disulfonic acid [17] and Arsenazo III [18].

Some reported FI procedures are based on chelatometric titration for calcium using EDTA and a color indicator, such as calmagite [19] or murexide [20].

Murexide is a metal ion indicator, commonly used in conventional EDTA titration determination of calcium. It was also proposed to be used as a chromogenic reagent for conventional spectrophotometric determination of calcium. The Ca(II)–murexide complex is formed in an alkaline solution, but its color fades rapidly [21].

In this work, attempts have been made to make use of the advantages of FI to overcome the problem on fading in the conventional method. Spectral characteristics of murexide and its metal complexes were re-investigated. FI direct spectrophotometric determination of calcium using murexide, which is a commonly available indicator, as a complexing color agent is proposed. A simple FI system with an LED detection device,

interfaced with a PC using 'CMUFIA II' software for data acquisition and evaluation, has been developed. The proposed system provides a simple, economical and precise determination of calcium using a cost-effective instrumentation. The procedures were validated by the analysis of reference materials, and applied for ores and pharmaceutical samples, and the results compared with standard methods.

2. Experimental

2.1. Reagents

All chemicals were analytical-reagent grade, except where otherwise stated; de-ionized water was used.

A stock standard calcium solution of 1000 mg l^{-1} was prepared by dissolving calcium carbonate (puriss, Fluka, 2.5800 g) in 50 ml of 0.1 M hydrochloric acid (proanalysis, Merck). The solution was boiled for a few minutes to remove carbon dioxide and diluted to 1 l with 0.1 M hydrochloric acid. Further dilutions with water were made for appropriate concentrations.

The stock color reagent was murexide solution (0.05%, w/v), obtained from murexide (ammonium purpurate, purum, Fluka, 0.05 g) dissolved in 100 ml of water. The stock was diluted with water for various concentrations.

Ethylenediamine–ethylenediamine hydrochloride (en/enHCl) buffer solution (1 M, pH 11) was prepared by dissolving ethylenediamine (purum, Fluka, 68.0 ml) in water (500 ml), mixing with concentrated hydrochloric acid (8.3 ml) and making up to a 1-l volume with water.

Certified reference materials for limestone, CRM1-J1s and CRM2-440/38, were obtained from The Geological Survey of Japan (GSJ) and The Department of Mineral Resources, Thailand, respectively. A mixed standard solution certified

for: Ca $1000 \pm 50 \text{ mg l}^{-1}$ (containing As, B, Be, Fe, Se and Zn, $100 \pm 5 \text{ mg l}^{-1}$; Ag, Al, Ba, Bi, Cd, Co, Cr, Cu, Ga, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Rb, Sr, Te, Tl, U and V, $10.0 \pm 0.5 \text{ mg l}^{-1}$) was obtained from Merck.

2.2. Sample preparation

2.2.1. Calcite and limestone samples

Powdered sample (0.1000 g; ≥ 250 mesh USS) was put in a 50-ml beaker. One ml of water was added and concentrated hydrochloric acid was carefully added dropwise, until about 2 ml of the acid was used. The solution was evaporated until nearly dry. Then 20 ml of 0.1 M hydrochloric acid was added and the solution was filtered. The filtrate was made up to 100 ml with 0.1 M HCl. The solution for injecting into the FI system was prepared by suitable dilution of this solution with deionized water [22].

2.2.2. Drug samples

The samples were taken from drug stores then ground and accurately weighed, followed by dissolving with 5 ml of 1 M HCl. The solution was boiled on a hot plate until a clear solution was obtained. The solution was filtered and diluted to 100 ml with deionized water [23].

2.3. Apparatus

All spectrum measurements of the solutions of murexide and its metal ion complexes were made using a Shimadzu UV-265 spectrophotometer.

2.4. Flow manifold

The manifolds used are depicted in Fig. 1. The systems were assembled by using a peristaltic pump (FIALab, Alitea USA, or EVA pump, Eppendorf), an injection valve (Alitea) or a home-made two-loop injection valve with a suction system using an aquarium pump as described previously [8], a mixing device consisting of single-string glass beads (3.0 mm diameter) in a column of silicone tubing (3.2 mm I.D.) [24]. The detector was a Spectronic 21 (Bausch & Lomb, USA) with a flow-through cell (Hellma, 1 cm,

Suprasil I window) or an LED colorimeter. Output signals were recorded by either a chart recorder (Omniscrite, Houston Instrument) or via a home-made 8-bits interface card linking with a PC using the 'CMUFIA II' software program [25] developed for data acquisition and evaluation.

3. Results and discussion

3.1. Spectral characteristics of murexide and its Ca complex

Three absorption maxima were observed in sodium hydroxide solutions for each dye spectrum

(Fig. 2) at 530 ± 15 , 335 ± 10 and 240 ± 5 nm, similar to the ones in a solution of en/enHCl buffer (1 M, pH 11).

Spectra of the Ca–murexide complex were also observed for three absorption maxima at 505 ± 5 , 335 ± 5 and 246 ± 5 nm in all the above alkaline solutions, except in the sodium hydroxide medium of pH 9, in which only the spectrum of the reagent was observed, but not that of the Ca–murexide complex. This agrees with the previous report [26].

Absorption spectra of the complexes of the dye with metal ions (Cu²⁺, Ni²⁺, Zn²⁺, Co²⁺, Fe²⁺, Mg²⁺, Ba²⁺ and Ca²⁺) were also recorded in sodium hydroxide (0.002 M) and in the en/enHCl

Fig. 4. Stability study (absorbance–time dependence at 520 nm (vs. H₂O)) of murexide solutions in (a) H₂O (pH 6), (b) 0.005 M NaOH (pH 11.7), and (c) en/enHCl buffer (1 M, pH 11), and of Ca–murexide complex in (d) 0.005 M NaOH and (e) en/enHCl buffer (1 M, pH 11); (a), (b) and (c) at 520 nm, and (d) and (e) at 505 nm Ca, 10 mg l⁻¹; murexide, 0.005% (w/v).

buffer (1 M, pH 11) as represented in Fig. 3. The dye complexes of some metal ions, such as Cu²⁺, Co²⁺ and Ni²⁺, also absorbed strongly at the absorption maximum wavelength of the Ca complex (505 or 498 nm against water or reagent blank, respectively). But absorbances of the com-

Fig. 6. FIA peaks observed when using (a) mixing coils and (b) glass bead columns as mixing devices.

plexes in the en/enHCl buffer were much less; only just about that of the reagent blank. This could be due to the fact that the metal ions form more stable complexes with en than the ones with murexide. The formation constants for the murexide complexes, log β , are 4.36, 3.11, 3.0, 2.66, 2.2, 2.0 and 2.68 for Cu²⁺, Ni²⁺, Zn²⁺, Co²⁺, Mg²⁺, Ba²⁺ and Ca²⁺, respectively [27], while those of the en complexes, log β , are 24.53, 21.29, 16.84, 16.76 and 0.37 for Cu²⁺, Ni²⁺, Zn²⁺, Co²⁺ and Mg²⁺, respectively [28]. This indicates that en could be used as a masking agent for the determination of calcium.

Fig. 5. Effect of reagent concentration on calibration curves: (A) murexide solution ((a) 0.0005, (b) 0.001, (c) 0.005 and (d) 0.010% (w/v)); [NaOH] = 0.01 M and (B) sodium hydroxide solution ((a) 0.01, (b) 0.02, (c) 0.03, (d) 0.04 and (e) 0.10 M); [murexide] = 0.005% (w/v).

Fig. 7. Effect of sodium hydroxide concentration: (a) 0.001 M, pH 10.9; (b) 0.005 M, pH 11.7; (c) 0.010 M, pH 12.1; and (d) 0.050 M, pH 13.0.

Using the continuous ratio and the mole ratio methods, a 1:1 complex of Ca–murexide was confirmed as previously reported [26].

Fig. 4 represents a study on the stability of the Ca–murexide complex. A murexide solution (0.005%, w/v) in water was found to be stable for at least 6 h, while its solutions in sodium hydroxide (0.005 M) or in the en/enHCl buffer (1 M, pH 11) decomposed rapidly. Its Ca complex was observed to be more stable than the murexide alone.

Fig. 8. Stopped-flow signal profile of FI stopped-flow experiment; (I) injection point; (S) stop the flow; and (F) start flow again.

3.2. Optimisation of the FI systems

3.2.1. The Manifold A

3.2.1.1. Effects of murexide and sodium hydroxide concentrations. Using manifold A (Fig. 1a) with mixing coils, MD-1 (145 cm long; 0.8 mm I.D.) and MD-2 (90 cm long; 0.8 mm I.D.); a flow-rate of 2.2 ml min^{-1} for each stream, effects of murexide concentration (0.0005–0.01%, w/v) and alkalinity of the medium (0.001–0.04 M NaOH) were studied. A series of standards ($2\text{--}10 \text{ mg Ca l}^{-1}$) was injected. From the results obtained (Fig. 5), 0.005% (w/v) murexide and 0.01 M NaOH were chosen for further study as the condition providing a good compromise between sensitivity and linearity of the signal.

3.2.1.2. Effect of mixing devices. The manifolds using mixing coils as the mixing devices yielded a doublet peak not found in usual FIA measurements. The peak height of each of them depended on the calcium concentration, but the first peak was consistently lower than the second one, as depicted in Fig. 6a. The second peak was better

Table 1

	6.0	6.6	209.3	36
	8.25	5	274.4	18

^a Mean of triplicate injections of 8 mg l⁻¹ standard calcium solution (R.S.D. <4%).

correlated to calcium quantities than the first one. The doublet peak may be due to too high injected volume of sample; thus, when passing the second mixing coil of 90 cm length, the reagent cannot disperse well into the middle of the sample plug and the reaction will not occur there. The peaks may have been the result of the complex that formed at the beginning and the end zones of the sample plug. The glass bead column (GBC) mixing device provides better mixing of sample and reagent than mixing coils alone [24]. By using a 15-cm long GBC for MD-1 and a 10-cm long GBC for MD-2, the doublet peak profiles disappeared (Fig. 6b).

Doublet peaks may also be caused by pH gradi-

ent, i.e. a dispersion of NaOH solution into a sample plug. Fig. 7 shows that the higher concentration of sodium hydroxide decreased the depth of the valley of peaks. This would be due to the fact that the high concentration of NaOH solution would cause the NaOH to disperse into the middle of sample plug. The stopped-flow experiment indicated that no kinetic effects of reaction are responsible for the observed shapes (Fig. 8).

GBC was then chosen for use as a mixing device.

3.2.1.3. *Effect of GBC length.* The length of the MD-1 using a 15-cm GBC was fixed, while the

0.1	10.4	65	88.4	116.3	97.6	106.9	—	88.4
		250	283.6	227.8	186.0	69.8	46.5	4.6

^a Mean of duplicate injections (R.S.D. <5%).

MD-2 GBC length was varied (3–30 cm long). A mixing chamber (0.8 ml) was also tried.

The results indicate that the longer GBC provided a wider linear determination range, but caused a longer residence time, thus reducing sample through-puts. As expected, the mixing chamber provided a wider linear range but broader peaks and lower sensitivity. Either 5- or 10-cm GBC could be suitable for the MD-2.

3.2.1.4. Reagent flow-rate. The flow-rate of each line was varied from 0.8 to 8.25 ml min⁻¹. It was found that 2.0 ml min⁻¹ was suitable for both manifolds, with and without MD-2, as reasonable peak height and acceptable residence time were obtained (Table 1).

Fig. 10. Calibration curves of calcium standard in 0.1 M HCl using the en (1 M) buffers containing; (a) 0.001, (b) 0.01 and (c) 0.1 M HCl.

3.2.1.5. Sample volume. Injection volumes of three different loop lengths were measured by means of a spectrophotometric method using bromothymol blue as dye [29]. The effects of the injection volumes (108, 144 and 188 μl) of a series of Ca standard solutions were studied. Less volume injected provided good correlation in the calibration range of 0–10 mg Ca l⁻¹, although lower peak heights were obtained. Higher volumes cause doublet peaks (Fig. 9), possibly due to the fact that the reagent did not sufficiently disperse into the middle of the sample zone, as previously discussed.

3.2.2. Manifold B

To achieve a more efficient mixing, a sample was injected into a stream of buffer (Fig. 1b), followed by merging with a murexide solution stream before passing through a 10-cm long GBC. Only single positive peaks were obtained. By comparison with the same conditions for manifold A, a calibration curve of $y = 34.0x + 19.0$, $r = 0.96076$, resulted; manifold B yielded a calibration curve of better linearity, but with about 40% lower sensitivity ($y = 20.8x + 13.0$, $r = 0.99956$).

3.2.2.1. Effects of sample volume and mixing device length for manifold B. Three different volumes (45, 125 and 250 μl) were investigated for a series of Ca standards (0–10 mg l⁻¹) injected into a stream of the en/enHCl buffer (1 M, pH 11). The following calibration curves were obtained: for 45 μl , $y = 34.9x + 57.8$, $r = 0.99427$; for 125 μl , $y =$

 A.U.

Fig. 11. FIAgram for the determination of calcium.

$40.2x + 40.0$, $r = 0.99810$; and for $250 \mu\text{l}$, $y = 55.2x + 79.7$, $r = 0.98173$. A volume of $125 \mu\text{l}$ provided a compromise of sensitivity and linearity in the determination.

The length of mixing device MD-3 was varied; GBC of 10–25 cm in length. The 15-cm GBC was found to give the most sensitivity and linearity, according to the calibration curves obtained: for the 10-, 15- and 25-cm GBCs, $y = 29.9x + 80.3$ ($r = 0.97826$), $y = 36.4x + 33.0$ ($r = 0.99396$) and $y = 25.5x + 25.9$ ($r = 0.99360$), respectively.

3.2.2.2. Effect of flow-rate. Using manifold B with the LED colorimeter detector, three flow-rates (3.7 , 5.0 and 8.0 ml min^{-1}) were tried for calibration curves (0 – 100 mg Ca l^{-1}). The flow-rate of

8.0 ml min^{-1} yielded high sensitivity with less residence time.

3.2.3. Effects of sample pH and of hydrochloric acid concentration for the en/enHCl buffer

As found earlier, a high pH medium favored the formation of a Ca–murexide complex and affected the observed absorbance. A sample solution is normally acidic since acids (especially HCl in this work) are used for dissolving samples. This affects the pH of the final mixture, after the sample solution is mixed with the reagent solution. The peak height observed decreased with decreasing pH values. The buffer solution, instead of NaOH solution, was required for maintaining the high pH conditions in the mixture. Ethylene-

diamine–ethylenediamine hydrochloride (pH 11) was introduced for this purpose, as well as being a masking agent. A HCl solution was added to the en solution (kept constant at 0.1 M en) to produce the required ethylenediamine salt. The buffer capacity and the pH of the buffer depend on the quantity of the HCl added, i.e. the ratio of

the en and the chloride salt.

Three different concentrations (0.001, 0.01 and 0.1 M) of HCl in the en (1 M) buffer resulted in pH values of 11.4, 11.2 and 10.4, respectively (Table 2). Solutions containing 2 mg Ca l^{-1} in various HCl concentrations were injected with two injection volumes (65 and 250 μl). It was found that the larger the volume injected, the more pronounced was the effect of the acidic sample. However, for the sample volume of 65 μl , a peak height due to 2 mg Ca l^{-1} in different concentrations of HCl did not yield significantly different results.

A calibration curve was constructed for each buffer by injecting a series of Ca standards in 0.1 M HCl (Fig. 10). Sensitivity was less when a high concentration of HCl was present in the buffer. This is due to the pH of the buffer being more acidic, a condition not suitable for calcium–murexide complex formation.

Table 4
Tolerance limit of some interfering ions for 4 mg Ca l^{-1} in the presence of 1 M en/enHCl buffer (pH 11) (see text)

3.3. The FIA system for calcium using an LED colorimeter

A less-sensitive FIA system using an LED colorimeter can be used instead of a spectrophotometer for a sample containing high calcium contents, such as limestone, a raw material in the ceramic and cement industries. The system could be either hooked up to a recorder or to a computer-based data acquisition system controlled by the 'CMUFIA II' software [25]. Fig. 11 depicts an example of the FIAGram recorded.

3.4. Recommended conditions

The conditions and analytical characteristics of the FIA systems developed for calcium are summarized in Table 3.

3.5. Interference study

The interference of some expected ions was studied using condition 4 described in Table 3. Solutions of a 4-mg Ca l⁻¹ standard containing varying concentrations of diverse ions were injected. The tolerance limit for the given ions is defined as the amount of an interfering ion to cause a 5% deviation of calcium concentration alone. The tolerance limits of ions are summarized in Table 4.

All the ions studied interfered when 0.001 M NaOH was used as the alkaline medium. When 1 M ethylenediamine buffer was used, the tolerance limits of most ions increased. Therefore, ethylenediamine is effective as a masking agent. The properties of magnesium ion are similar to those of calcium, so the tolerance limit for magnesium ion was found to be very low. Despite the fact that 8-quinolinol has been reported as a masking agent for magnesium ion [13], it was not applied because, in the case of calcium minerals/ores samples that contain large amounts of calcium, magnesium contents are usually relatively low (Table 5). So this additional masking agent was avoided.

3.6. Accuracy and application of the methods

The accuracy of the FIA methods was checked by analysis of a certified standard solution and certified reference materials, and by comparison to the results obtained with the standard methods; flame atomic absorption spectroscopy (FAAS) [30] for ores samples (Table 5) and the British Pharmacopoeia titrimetric method for drug analysis (Table 6) [23].

The calcium contents obtained by the FIA methods agreed with the certified values and/or the standard methods.

Comparison of the results for calcite and limestone samples (Table 5) can be expressed by the following relationship: FI-SPEC = 0.98 × FAAS + 2.35, $r = 0.99362$; FI-LED = 1.12 × FAAS - 3.78, $r = 0.99158$ and FI-LED = 1.14 × FI-SPEC - 6.13, $r = 0.98962$.

The results for the drug analysis can be represented as follows: FI-SPEC = 1.00 × titrimetry + 0.66, $r = 0.99338$; FI-LED = 1.00 × titrimetry + 0.16, $r = 0.99999$ and FI-LED = 0.98 × FI-SPEC - 0.23, $r = 0.99360$.

4. Conclusion

The flow injection spectrophotometric method which has been developed for calcium, using a murexide color agent, is inexpensive and readily available, allows fast determination at low operating costs, and is simple. Use of an unstable reagent, alkaline murexide, for determination of calcium with the aid of FIA has been successfully applied. This emphasizes an additional advantage of FIA, even by using a very simple instrument. The application of the method to ores and pharmaceutical samples has been demonstrated.

Discrimination between arabica and robusta green coffee varieties according to their chemical composition

María J. Martín, Fernando Pablos, A. Gustavo González *

Department of Analytical Chemistry, Faculty of Chemistry, University of Seville, 41012, Seville, Spain

Received 14 July 1997; accepted 3 November 1997

Abstract

Arabica and robusta green coffee varieties have been differentiated by using pattern recognition procedures. Chlorogenic acid, caffeine, trigonelline, aqueous extract, amino acids and polyphenols have been analysed in 41 samples of green coffee and used as chemical descriptors. Principal component and cluster analysis in addition with the *K*-nearest neighbours method have been applied. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Coffee; Pattern recognition

1. Introduction

The two most important varieties of commercial coffee are *Coffea arabica* and *Coffea canephora*, usually known as arabica and robusta, respectively. Commercial coffee beverage is made from arabica or robusta beans or blends of them, the arabica being considered of better quality [1] and is therefore more expensive. Accordingly, it is interesting to have methods for differentiating between those two coffee varieties. Chemometric procedures applied to the data of chemical composition of the samples provide an interesting approach to the food quality control [2]. Within this realm several works on the discrimination of coffee varieties based on differences of their chem-

ical composition have been published. Some of them use as descriptors sterols [3,4], diterpenic alcohols [4], volatile components [5] and metals [6].

In the present paper the content of chlorogenic acid, caffeine, trigonelline, amino acids, polyphenols and aqueous extract have been determined in 41 samples of green coffee. By using these chemical data, principal component analysis (PCA), cluster analysis (CA) and the *K*-nearest neighbours (KNN) method have been applied to discriminate between arabica and robusta varieties.

2. Experimental

2.1. Reagents and solutions

Tannic acid (Fluka), Folin–Ciocalteu reagent (Fluka), glycine (Merck), ninhydrine (Sigma), 2-

* Corresponding author. Tel.: +34 5 455173; fax: +34 5 4557168; e-mail: agonzale@cica.es

metoxietanol (methylcellosolve) (Fluka), caffeine (Merck), chlorogenic acid (Fluka), trigonelline (Sigma) and concentrated hydrochloric acid (Merck) were of analytical grade. Methanol (Romil) of HPLC quality was also used. Milli-Q water (Millipore) was used throughout.

Glycine (0.3 g l^{-1}), tannic acid (0.1 g l^{-1}) and ninhydrine (10 g l^{-1}) in methylcellosolve with 0.03% of ascorbic acid were used. HPLC analysis was performed by using a mixture of 20:80 (v/v) methanol:water, buffered at pH 4.5 with a formate–formic acid buffer, as mobile phase. Ionic chromatography analysis was performed by using a 2 mmol l^{-1} aqueous hydrochloric acid (pH 3) as mobile phase.

2.2. Apparatus

A UV-V Phillips PU 9720 spectrophotometer equipped with 1.0 cm silica cells was used for absorption measurements. The HPLC equipment consisted of a 510 Waters HPLC pump, a Waters AGC-680 pump controller, a Rheodyne injection valve 7120 with a $20 \mu\text{l}$ sample loop, a Waters 440 UV detector operated at 254 nm and a CE Instruments DP700 integrator. A $150 \times 4 \text{ mm}$, $5 \mu\text{m}$ Lichrosorb RP-18 column was used and the flow rate of the mobile phase was 1.5 ml min^{-1} . The ion chromatographic system consisted of a 510 Waters HPLC pump, a Waters 440 absorbance detector (254 nm), a Rheodyne injector with a $100 \mu\text{l}$ loop and a Hewlett Packard HP3395 integrator. A $150 \times 3.9 \text{ mm}$, $5 \mu\text{m}$ Waters IC Pack C M/D column (silica base coated with polybutadiene-maleic acid) was used and the flow rate of the mobile phase was 1 ml min^{-1} .

2.3. Analytical procedures

Aqueous extract, total polyphenols, total free amino acids, caffeine, chlorogenic acid and trigonelline contents were carried out from assay solutions obtained by refluxing 3 g assay portions of dried sample with hot water (80°C) for 1 h. Before analysis, sample moisture was determined by drying at 103°C [7] until constant weight.

The aqueous extract was analysed by a gravimetric method according to the AOAC protocol [8].

The total polyphenols and the total free amino acids were determined by spectrophotometry using the Folin–Ciocalteu method [9] and a method based on ninhydrine [10], respectively.

Trigonelline was analysed by a single column ionic chromatography [11] with UV detection at 254 nm.

Caffeine and chlorogenic acid contents were evaluated by means of reversed-phase HPLC with UV detection at 254 nm. The procedure is a modification of previously reported works [12,13], performed at isocratic mode and using a mobile phase 20% v/v methanol/water (pH 4.5). Caffeine and chlorogenic peaks are well resolved and enable us to easy quantitation from calibration graphs based on peak heights.

The results were referred to dry base and expressed as the average weight percentage from triplicated measurements.

2.4. Coffee samples and data analysis

41 samples of green coffee, kindly provided by Kraft Jacobs Suchard, were studied. Arabica and robusta varieties from different geographic origin were included. Accordingly, they were labelled with a code. Table 1 shows the analysed samples with their origin and the assigned codes. All samples were ground, powdered and stored in polyethylene flasks.

Each green coffee sample (case) was considered as an assembly of six variables, i.e. the contents of aqueous extract (EXT), total polyphenols (POL), total free amino acids (AA), trigonelline (TRIG), chlorogenic acid (CHLOR) and caffeine (CAF) as chemical descriptors. A data matrix whose rows are the cases or samples and whose columns are the analysed variables was built as shown in Table 2.

Pattern Recognition (PR) techniques used in this paper were PCA [14], CA [15,16] and non parametric KNN [17,18]. The software packages and programs used for calculations were: CSS STATISTICA from Statsoft for performing PCA and CA. Software developed by us was used for KNN.

3. Results and discussion

Before the PR analysis, the selected variables were tested for normality. In all cases, they did not follow the normal distribution according to the χ^2 criterion and the Kolmogorov test [19]. Therefore, this address us to call on non-parametric PR procedures as the best choice.

A preliminary study based on PCA and CA has been applied for a better understanding of the discriminating efficacy of the selected descriptors and, while, visualising samples trends.

3.1. PCA-based display methods

Biplots [20] are often used to observe the structure present in the data matrix. In these plots, both scores for samples (Q-mode) and scores for variables (R-mode), are represented in the space of the two principal components (PCs) obtained from PCA. Thus, relationships between samples, descriptors and between samples and descriptors can be seen on the same plot. Fig. 1 shows the biplot corresponding to our data, explaining the

57.1% of the total information. The first PC, PC1, explains 36.5% and the second, PC2, explains 10.6% of the total variance. At a glance, one can see that variables POL, CHLOR and CAF appear with similar loadings and they are the descriptors of highest contribution to PC1. So, these features happen to be the most discriminating ones and apparently, they are going to give the same kind of information. Descriptor AA has intermediate loading. Remaining variables such as EXT and TRIG have less importance since their loading is close to the zero value of PC1. On the other hand, robusta samples are situated at positive scores of PC1, except sample 40R, that appears at negative scores near to zero. Most of the arabica samples are at negative values of PC1 but there are four samples, 30A, 23A, 29A and 20A, which are at positive scores close to the robusta ones. As it can be seen, the biplot did not lead to a complete separation of the studied samples, although it enables us to assume that the descriptors with more discriminant power are POL, CHLOR and CAF. Moreover, these features appear at the right side of the plot with the robusta samples, that

present higher contents of the mentioned descriptors.

In order to obtain a good separation of the coffee samples, a hierarchical agglomerative CA of samples was done.

3.2. Cluster analysis

In spite of the a priori knowledge of the class membership of the coffee samples, CA has been carried out to find the natural grouping of the data trend. According to PCA, the most discriminating features are POL, CHLOR and CAF. They appeared with similar loadings, so it can be thought that these variables will provide similar information. Besides, from a non-parametric correlation study, the most correlated variable pairs according to the Spearman criterion are: CHLOR/CAF, POL/CHLOR and POL/CAF. Consequently, we have applied CA selecting only one of these three descriptors, CAF, together with AA, that appeared with intermediate loading.

Taking the Euclidean distance as a basis and the Ward's method as amalgamation rule [21], two clusters were obtained. Fig. 2 shows the corresponding dendrogram, where all arabica samples are grouped in one cluster and the rest of the cases, robusta samples, are forming a different cluster. Only cases 40R and 41R appear in the opposite group, but in the borderline between both clusters.

3.3. K-nearest neighbours

Aside from the results obtained by the display methods and CA, we have applied a supervised-learning PR technique, the KNN classification. KNN is a non-parametric classification procedure recommended when the descriptors do not follow the normal distribution. The validation procedure for evaluating the classification performance was the leave-one-out method [22]. The selected variables were AA and CAF. The results obtained as percentage of hits, against different *K* values, are

Fig. 1. PCA biplot for the first PCs.

presented in Table 3. As one can see, KNN leads to fairly good performances of classification. However, some samples are badly classified occasionally (40R, 41R for $K \geq 3$) or always (20A).

To assess that the performance cannot be improved by adding other descriptors, the KNN procedure was repeated using the following sets of

Table 3
Percentage of hits in the classification performance^a of coffees versus the number of K neighbours selected

K	% hits	Conflicts
1	97.6	Sample 20A is badly classified
2	97.6	
3	92.7	Samples 20A, 40R and 41R are badly classified
4	92.7	
5	92.7	

^a According to the leave-one-out method and using AA and CAF as descriptors.

non-correlated variables: {AA, CAF, EXT}, {AA, CAF, TRIG} and {AA, CAF, EXT, TRIG}. In all cases, similar results were obtained. This seems to emphasise that, in fact, the most discriminant descriptors are AA and CAF indeed. On the other hand, samples 20A, 40R and 41R exhibit some outlying features. Case 20A belongs to the arabica variety but presents a high content of caffeine, 1.8%, and samples 40R and 41R are robusta coffees with a very low content of caffeine, 1.7 and 1.6%, respectively.

Fig. 2. Dendrogram of coffee samples by using CAF and AA variables.

4. Conclusion

After applying PR methods, with the exception of three outliers, green coffee varieties (arabica and robusta) can be easily differentiated according to their contents in caffeine and total free amino acids.

Received 18 June 1997; received in revised form 24 October 1997; accepted 7 November 1997

Abstract

The development of two-stage control systems is of great interest when a large number of samples are analysed in order to check that they fulfil certain requirements. If the first stage is carried out using an inexpensive method with a high throughput which makes it possible to filter out the majority of the samples that fulfil the requirements, the procedure is not only less time-consuming but also more economical. Direct determination of metals in solid samples by graphite furnace atomic absorption spectrometry (GFAAS) appears, in principle, to be a suitable analytical technique for screening purposes since it provides sufficiently reliable results in a reasonably short time. In this paper it is applied with satisfactory results to antimony content control in a PVC sample. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Direct analysis; Solid samples; Antimony screening; Graphite-furnace atomic absorption spectrometry

1. Introduction

In the development of inspection or control procedures a number of factors which are not merely analytical (sensitivity, precision etc.) are increasingly important, such as expeditiousness, cost-effectiveness or personnel safety and comfort [1] and so the choice of an analytical method for a given purpose is not currently always dictated by accuracy but in many cases by throughput,

economic considerations and various other factors.

In many practical situations a large number of samples have to be analysed and what is important is not so much the exact content of the analyte but to determine whether it is higher or lower than a certain value. In these cases, a two-stage control system is recommendable from an economic viewpoint, with investigation of the samples in the first stage by an inexpensive method with a high throughput to filter out the majority of samples which fulfil the requirements [2].

The first analytical procedure is usually a screening method characterised by a high sample

* Corresponding author. Tel.: + 34 76 761175; fax: + 34 76 761292.

throughput, which enables a large number of samples to be sifted [3]. Screening methods based on immunochemical techniques are numerous [4] and are also used for the control of organic compounds, usually by chromatographic methods [5]. Their use in inorganic analysis, however, is far more limited [6].

Graphite furnace atomic absorption spectrometry (GFAAS) for direct determination of metals in solid samples [7] is, in principle, a suitable analytical technique for screening purposes as it provides sufficiently reliable results in a relatively short time, thus fulfilling the typical requirements of chemical analysis for industrial product control [8]. With this technique a result can be obtained in about 15 min and although the RSD values may well be higher than 10% [9], they can be kept within a range of 5–10% by correct control of the operating conditions. Although some papers pointed out that these characteristics meet the demands of those of a screening method [10,11] we have not found in the literature any practical application of the direct determination of metals from solid samples by GFAAS for screening purposes.

In order to obtain quick results the calibration should be carried out using aqueous solutions and too much time should not be spent on the preparation of the sample (homogenisation), although this could have a negative effect on precision [12].

In this paper we report the control of the concentration of antimony, used as a flame retardant to delay the initiation and burning in the production of polyvinyl chloride (PVC). The confirmatory technique may be flame-AAS after dissolution of the sample [13]. The minimum concentration of the product in this case should be 2.5%. Although this antimony content in the PVC is fairly high, which usually complicates the direct determination of metals in solid samples by GFAAS, [14,15] this sample was chosen because it is well known and so as to be able to compare the results with those obtained with a similar magnesium content in another PVC sample which had been previously homogenised [16].

2. Experimental

2.1. Reagents and sample

2.1.1. Antimony standard

1000 $\mu\text{g ml}^{-1}$, 2.74 g of potassium antimonyl tartrate hemihydrate were dissolved in water and diluted to 1 l with redistilled water.

2.1.2. Poly(vinyl chloride) resin and real sample

A commercially available PVC sample with an antimony content provided by the manufacturer of ca. 2.6% was used.

All solutions were prepared with analytical reagents and redistilled water and were stored in polyethylene vessels. Further dilutions of these elements were prepared from the standard solutions immediately prior to use.

2.2. Instrumentation

A Perkin–Elmer Model 3030 atomic absorption spectrometer was used together with a Perkin–Elmer HGA-400 graphite furnace furnished with a temperature programmer and an autosampler (Perkin–Elmer AS40) for liquid samples. The hollow-cathode lamp employed was purchased from Instrumentation Laboratory. Pyrolytic-coated graphite tubes with a platform were used; their dosing hole was mechanically enlarged to a diameter of about 4 mm.

Solutions and real samples were atomised electrothermally and the atomic absorption (integrated absorbance) of antimony was measured under the operating conditions summarised in Table 1.

Flame-AAS measurements were made on a Perkin–Elmer Model 2380 atomic absorption spectrometer.

2.3. Procedure for flame AAS

The procedures used to treat PVC samples and to determine antimony by flame-AAS are described in detail elsewhere [13].

^b Calculated as in ref. [20] (*n* = 4).

^c Without stop-flow in atomization step.

2.4. Procedure for the solid sampling technique

Small pieces of roughly the required mass of the PVC sample were cut off using stainless steel scissors while the plastic was handled with stainless steel pincers. The PVC pieces were weighed to within 1×10^{-5} g. Samples of 1.5–4 mg were used in different experiments.

Calibration graphs were run using aqueous solutions of antimony with the amounts given in Table 1. Each measurement was carried out three times.

An amount of ca. 2.5–3.5 mg solid PVC sample was introduced directly into a pyrolytic graphite tube through an inverted paper cone with its apex pierced and this was inserted into the enlarged

hole of the tube [16]. The antimony content of the sample was calculated as the median of five results obtained by interpolation on the pertinent calibration graph.

3. Results and discussion

3.1. Simplification of the procedure

The advantage of obtaining quick results due to the non-dissolution of the sample is lost to a considerable extent if the sample needs to be homogenised. Although in a recent work [17] we have proved that the non-homogeneity of the subsamples used is the principal cause of the poor

precision of the technique and so, atomisation in non-optimum conditions or possible changes in the deposition of the samples in the atomiser are hardly significant, the homogenisation process of the PVC was eliminated in order to give priority to obtaining quick results. Furthermore, the use of the median minimised the influence of possible anomalous results [18]. If the results obtained in the determinations of antimony (see median in Table 3) and magnesium [16] (for which the sample was homogenised) are compared, no significant differences can be seen with regard to precision.

Although the effect of the drying step on the time needed to carry out the measurements is considerably less than the influence of sample homogenisation, this step was omitted in the atomisation of the solid samples.

3.2. Solid sampling-GFAAS optimisation

The rapid determination of metals using GFAAS by direct atomisation of the solid samples poses three problems of a general nature: (1) adapting the sensitivity of the technique to the analyte content of the sample; (2) establishing the conditions for carrying out the calibration using aqueous solutions; and (3) establishing the range of sample mass which provides correct results.

Given the high antimony content in the sample, the lines proposed for the determination of the antimony by GFAAS [19] are too sensitive (see

Fig. 1. Typical peaks for antimony: (a) 80 μg of Sb in water; and (b) 3.3 mg of PVC sample (82 μg of Sb).

Fig. 2. Relationship between the antimony content found and the amount of sample used. (A) Average value $\pm 10\%$; (●) median of ten results.

Table 2). The line of 211.4 nm was therefore used and even with this wavelength it was necessary to maintain the gas flow during the atomisation step. Judging by the results obtained for tin [20], these non STPF working conditions should not cause a notable increase in imprecision, providing atomisation takes place from a platform. This is confirmed by the RSD_{x_0} value (6.3 ± 0.5 ; $n = 4$) which is similar to that of the least sensitive lines of tin [20].

In order to carry out the calibration using aqueous solutions, most of the matrix must be eliminated during the pyrolysis step. From previous work with PVC it was known that this elimination takes place at temperatures higher than 700–800°C [16,18], so a temperature of 800°C was used directly. The great similarity between the signals obtained with a solid sample and those obtained with an aqueous solution can be seen in Fig. 1. It can also be observed that no non-specific absorption is produced. The integration time was reduced to 0.5 s as marked instrumental noise appeared after 1 s because of d.c. emission from the tube.

With regard to the dependence of the results obtained on the amount of sample used, it was necessary to make a specific study as this dependence cannot be deduced from previous data [21]. By means of 60 measurements using masses of 1.5–4 mg, it was concluded that results which are

Standard deviation (g per 100 g)	0.33	0.17	0.13
RSD (%)	12.6	6.4	4.8

$F = 1.79$.

$t = 0.015$.

in agreement with those provided by Flame-AAS can only be obtained in a range of 2.5–3.5 mg as can be seen in Fig. 2. Sample amounts greater than 3.5 mg lead to overestimated results while by using less than 2.5 mg the results obtained are very scattered.

3.3. Temperature programme-GFAAS optimisation

Apart from the problems of a general nature previously mentioned, each determination may pose specific problems. Although Frech et al. [22] report that antimony is stable up to 900°C, in the case under study there may well be antimony losses as $SbCl_3$ due to the high chloride content in the sample [23]. However, as can be seen in Fig. 3, the pyrolysis and atomisation curves of antimony

in the absence and in the presence of the PVC matrix are practically identical and no loss of antimony is observed below 800°C. Dahl et al. had previously reported that in the presence of chlorides antimony was more stable in some complex samples than in aqueous solution [24].

3.4. Screening of antimony

Over a 2-week period 14 determinations of antimony were carried out on seven different days. The result of each determination was taken as the median of five consecutive measurements carried out with a sample mass of 2.5–3.5 mg. The average of the 70 measurements carried out confirmed that the method has no systematic error (2.63% of antimony as an average value) and imprecision is high (RSD = 23.2%), although, ow-

Fig. 4. Control chart for antimony screening (c.a. 2.6%): (A) Average value $\pm 10\%$; (B) Average value $\pm 5\%$; (○) Individual results; (●) Median; (◆) Average value.

Fig. 5. Control chart for antimony screening (c.a. 2.25%): (A) Average value $\pm 10\%$; (B) Average value $\pm 5\%$; (○) Individual results; (●) Median; (◆) Average value.

ing to the large number of measurements, the confidence interval at a confidence level of 95% is small (2.49–2.78% of antimony). The proposed method has good reproducibility, as the ANOVA showed that there are no statistically significant differences at a confidence level of 95% between the results obtained on the seven days ($F = 1.62$; $p = 0.16$).

The results of the 14 determinations, taken as the mean and the median of the five replicates carried out in each case, are gathered in Table 3. The results are compared with those obtained

after aqueous dissolution of the sample. When either the mean or the median is used, the mean value is practically the same as that obtained after sample dissolution. However, as happened in the determination of cadmium [18], the median reduces the influence of anomalous results, so that the RSD is half the RSD obtained when the mean is used and is comparable to that obtained after sample dissolution.

Unfortunately, this RSD value cannot be extrapolated to all the series. If we observe the results gathered in Fig. 4 as a whole, it can be

Fig. 6. Control chart for antimony screening (ten measurements): (A) Average value $\pm 5\%$ for the sample with a Sb content of c.a. 2.6%; (B) Average value $\pm 5\%$ for the sample with a Sb content of c.a. 2.25%; (○) Median for the sample with a Sb content of c.a. 2.6%; (●) Median for the sample with a Sb content of c.a. 2.25%.

seen that they are highly dispersed and each series displays a different behaviour from the others, with RSD values ranging from 5% in series 8 to 40% in series 9 and an average value of 20%. Despite this dispersion, the method carries out the screening task satisfactorily as only one (series 6) of the 14 controls has a value of antimony lower than 2.50%. Once again, the results obtained with the mean are worse: four series are lower than the reference value. The same conclusions can be reached more rapidly without carrying out a calibration curve. It is sufficient to compare the specific absorption ($3 * Q_A/\text{sample mass}$) of each measurement with that of a solution containing 75 μg of antimony (equivalent to 2.5% in 3 mg of the sample) measured three times.

The usefulness of a screening method depends on the characteristics of the method and the margin of tolerance accepted, which is understood as the difference between the real value and the maximum or minimum tolerated value (in this case c.a. 5%). The best way of generalising the benefits of this method is to evaluate the results on the basis of the frequency of their deviation above the mean value, which will also indicate whether there are false negatives [3]. With this method, if only the median is used,

ten of the 14 results are within the range of $\pm 5\%$, another two within the $\pm 10\%$ range, and only two are outside this interval. One of them is a false positive result and the other a false negative result. If a margin of error of $\pm 10\%$ is considered reasonable for these screening methods, the efficiency of the proposed method can be considered satisfactory. Although to obtain a result is necessary to carry out five measurements, the process is accomplished in less than 10 min and therefore is adequate for a screening purpose.

To check the former conclusions another sample of PVC with a content of ca. 2.25% in antimony (10% lower than the critical value) was subjected to the same control process. Results are shown in Fig. 5 and corroborate the performance of the method. Again only one (series 10) of the 14 controls has a value of antimony higher than 2.50%.

Naturally, the performance of the method improves if the number of replicates is increased, although this is logically more time-consuming. If, for example, the median of the ten replicates measured daily is taken as a result, all the results are within the interval of $\pm 10\%$ and only three lies outside the $\pm 5\%$ interval (see Fig. 6).

4. Conclusions

Atomic absorption spectrometry with direct atomisation of solid samples is efficient as the first stage in two-stage analysis design. It enables us to rapidly filter out a significant number of samples, which would otherwise need more careful determination, provided the tolerance limit is approximately 10%. Its application to the content control of antimony in a PVC sample is satisfactory.

As the method requires a previous study of the atomisation conditions in order to be able to calibrate using aqueous solutions and to determine the amount of sample to be used, the process is not suitable if only a small number of samples are to be analysed. However, it is highly profitable for routine control over a long period of time.

Abstract

High purity fluorapatite (FAP) was prepared by solid state reaction, in flowing argon gas, at 1370°C for 60 min. For chemical characterization of $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$, the accuracy and reproducibility of different analytical methods were assessed. Methods with a good accuracy for the determination of Ca, P and F content were: titrations with EDTA for Ca determination (accuracy: -0.8%), spectrophotometric method for P determination (accuracy: $+0.6\%$) and measurements with fluoride-selective electrode (accuracy $+5.4\%$) for F determination. © 1998 Elsevier Science B.V. Keywords: Fluorapatite; Preparation; Chemical characterization

1. Introduction

Synthetic fluorapatites are important materials for different applications like: preparation of phosphor for fluorescent lamps, laser host for neodymium, biocompatible materials. They are also used as humidity sensors, ion exchangers and dispersive additives for suspension polymer polymerization. For all these applications high purity fluorapatite is needed. This requirement can be assured by a well controlled preparation method and a sound and secure quality controlling of the final product. It is known that stoichiometric

apatite powders with high crystallinity could be prepared by solid state reaction by heating a mixture of $\text{Ca}_3(\text{PO}_4)_2$ and CaF_2 of 1:3 molar ratio at temperatures between 1100 and 1370°C and the reaction times could be about 1 for 4 h [1,2]. There is no data in the literature for optimal heat treating procedure (heat treating temperature and heat treating time). On the other hand, for the quality controlling of these materials is important to identify the most adequate analytical methods for their chemical characterization. Different authors refer to different methods, but the various methods used for determination of Ca, P and F content differ in their accuracy and precision, which depends strongly on the nature of analyzed samples. The aim of present study is to demon-

* Corresponding author. Tel.: +36 88 423091; fax: +36 88 423091; e-mail: kts040@almos.vein.hu

strate a solid state preparation method of good reproducibility and to compare, based on statistical calculations, the different analytical methods for each element, in terms of their accuracy and precision.

2. Experimental

2.1. Preparation

$\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$ (fluorapatite) was prepared by solid state reaction, by heating a stoichiometric (3:1 molar ratio) mixture of $\text{Ca}_3(\text{PO}_4)_2$ (Merck, 96.2% purity) and CaF_2 (Merck, 99.2% purity), in the presence of some CaF_2 upstream, to minimize volatilization of fluorine (as CaF_2) from the reaction mixture. Homogenization of raw materials was made using ethanol (abs. alcohol). The mixture of raw materials was heated at five different temperatures (1000, 1100, 1200, 1300, 1370°C) for two different heat treating times (30, 60 min). The furnace was first rinsed with H_2O - and CO_2 -free Ar gas (99.998%) and than a flush rate of 20 l h^{-1} of Ar was maintained during the heat treatment. Water-free character of the heating atmosphere was checked by scrubbing the gas leaving the furnace in P_2O_5 and by detecting the mass increase (if any) after the heating period. Prevention of CO_2 contamination was done by flowing the Ar gas through a KOH trap. Mineralogical composition of the samples was determined with a Philips PW 1825 type X-ray diffractometer. For identification of samples the following designations were made: FAP, T (°C), t (min), where FAP is fluorapatite.

2.2. Chemical analyses

2.2.1. Determination of Ca content

The calcium content of samples was determined by two different methods: by ICP [3] and by EDTA-titration in the presence of Fluorexon indicator [4]. Stock solutions were prepared as follows: the samples (approx. 0.1 g) were dissolved in 10 ml 1:1 HNO_3 solution and than were diluted to 100 ml (for ICP) and to 500 ml (for EDTA titrations). The measurements were carried out at

FAP,1370,30	38.7 ± 0.7

317.993 nm, with an ARL 3410 MINITORCH type ICP.

2.2.2. Determination of P content

Two different methods were used for the determinations: ICP [3] and spectrophotometric method [5]. ICP measurements were carried out at 213.618 nm, with an ARL 3410 MINITORCH type ICP. The reagents used for spectrophotometric determinations were as follows:

1. 0.25% NH_4VO_3 pur. spec. solution
2. 5% $(\text{NH}_4)_6\text{Mo}_7\text{O}_{21} \cdot 4\text{H}_2\text{O}$ pur. spec. solution
3. 1:1 HNO_3 a.r. solution
4. 1 mg ml^{-1} KH_2PO_4 pur. spec. stock solution

The stock solutions were prepared as follows: the samples (approx. 0.07 g) were dissolved in 10 ml 1:1 HNO_3 solution and than the volume of solutions were adjusted to 200 ml. Measurements were done at 400 nm with a LAMBDA 20 UV/VIS, Perkin Elmer type spectrophotometer.

FAP,1370,30	19.00	1.00	19.00	1.27

2.2.3. Determination of *F* content

The methods used for fluoride determination were as follows:

1. Pyrohydrolytic method (distillation at 1000°C in the presence of Al₂O₃) [6]
2. Distillation with conc. H₂SO₄ (water vapor distillation at 165 ± 2°C) [7]. In both cases the fluoride content of the condensate was measured by thorium nitrate titration [8].
3. By ionchromatographic method [9]. The samples were dissolved in 4 ml 10% H₂SO₄ solution at 50°C. Ionchromatographic determinations were done with a DIONEX (DX 1000) ionchromatograph, using Na₂CO₃/NaHCO₃ eluent and AS9 column.
4. With fluoride selective electrode [10]. The samples (approx. 0.1 g) were dissolved in 10 ml 1:1 HNO₃ solution. The solutions were adjusted to pH = 5–6 using 1:1 NaOH solution, than 100 ml of TISAB was added and diluted to 500 ml.

According to some authors [11] the use of TISAB as buffer in fluoride determinations leads to an apparently lower result than by other methods. The use of citrate–hydrochloric acid buffer appears to avoid the fluoride loss that occurs with TISAB. The measurements were carried out using citrate–hydrochloric acid buffer too, but no differences were observed in the results. The pF values were obtained with the help of an OP-F-07 fluoride-selective electrode connected to a pH/ion Analyser OP-271 Radelkis. The reference electrode was a double-junction silver/silver chloride OP-0820P electrode (Radelkis).

3. Results and discussion

The following results were calculated based on 3–5 parallel measurements. The confidence intervals were determined considering a 95% confidence level and the convenient values of standard deviations and Student's *t*-test. The different analytical methods were compared based on *t*-test. The normal distribution of the results was supposed. Comparison of the standard deviations was done using *F*-test.

3.1. Ca determination

The theoretical value of calcium content was found to be 38.4% (wt), which value was calculated considering the purity of raw materials. Determination of Ca and P content of apatites by ICP is a routine method. The accuracy of this method is already mentioned in the literature to be ± 1–3% both for the Ca and the P determination [3]. However, for evaluation of the method's reproducibility and comparison with other methods, parallel measurements were necessary (Table 1).

Using EDTA titration method for Ca determination was mentioned in the literature [12], but no data for accuracy were available. To estimate the accuracy of the method, determination of the Ca content of a standard sample was needed. Selection of the most relevant standard was troublesome. It was necessary to find a standard sample containing all the elements which were present in the analyzed samples and having the same dissolution properties in 1:1 HNO₃ solution. Because

	<i>t</i> (95)	<i>t</i> _{calculated}	<i>t</i> (95)	<i>t</i> _{calculated}
FAP,1100,60	2.776	0.931	2.776	2.501
FAP,1200,60	2.776	0.000	2.776	2.430
FAP,1370,60	2.447	0.884	2.447	0.000
FAP,1370,30	2.776	0.873	2.776	0.364

of the different dissolution properties, the stoichiometric mixture of the raw materials was ruled out. The same problem was faced also with $\text{Ca}_3(\text{PO}_4)_2$. In both cases the measured values of Ca and P contents were lower than the theoretical values. Based on the X-ray diffractograms of the samples prepared at different heating temperatures, unit cell parameters were calculated [13]. Unit cell parameters of sample FAP, 1000, 60 were found to be $a = 9.35 \pm 0.00296 \text{ \AA}$, $c = 6.86 \pm 0.00267 \text{ \AA}$, whereas those of the sample FAP, 1370, 60 were $a = 9.36 \pm 0.00243 \text{ \AA}$, $c = 6.87 \pm 0.0022 \text{ \AA}$, respectively. In Kanazawa's monography [1] $a = 9.36\text{--}9.37 \text{ \AA}$, $c = 6.87\text{--}6.89 \text{ \AA}$ parameters were given. Relying upon these findings, the sample prepared by heating at 1370°C for 60 min had a composition which best approaches the stoichiometric composition of fluorapatite. This sample was used as a standard for different analytical methods. Dissolution properties of the standard sample were identical to those of the other samples.

Using the sample mentioned above as a standard, the accuracy of the Ca content determination by EDTA titration method were found to be

Table 5
 P% (wt) content of the samples determined by spectrophotometric method at 400 nm

Sample	P% (wt)
FAP,1000,60	17.7 ± 0.8
FAP,1100,60	17.7 ± 0.9
FAP,1200,60	17.9 ± 0.8

FAP,1370,60	17.8 ± 0.8
FAP,1370,30	17.7 ± 0.9

–0.8% (Table 2), better than that of the ICP method. For a comparative evaluation of these two methods statistical calculations were done. Based on *F*-test was established that no differences among the standard deviations of the two methods, $F_{\text{calculated}} < F(95)$ (see Table 3). The results of *t*-test showed with an uncertainty at 95% confidence level that no differences among the average values of the two determinations, $t_{\text{calculated}} < t(95)$ (see Table 4). This results show that both of the methods (ICP and EDTA titration) are suitable for determination of Ca content if their accuracy is taken into consideration.

3.2. P determination

The theoretical P content was found to be: 17.7% (wt). The accuracy of the spectrophotometric method was found to be +0.6% (Table 5), better than experienced with ICP, $\pm 1\text{--}3\%$ (Table 6). Results of *F*-test and *t*-test showed no differences among the standard deviations and average values of P content determination by two different methods. Difference between the two methods was found only in their accuracy as compared to the standard sample.

 P% (wt) content of the samples determined by ICP at 213,618 nm

Sample	P% (wt)
FAP,1100,60	18.4 ± 0.8
FAP,1200,60	18.5 ± 0.7
FAP,1370,60	17.8 ± 0.7
FAP,1370,30	17.8 ± 0.8

Table 7
F% (wt) content of the samples determined with fluoride-selective electrode

Sample	F% (wt)
FAP,1000,60	3.6 ± 0.2
FAP,1100,60	3.4 ± 0.2
FAP,1200,60	3.5 ± 0.2
FAP,1300,60	3.4 ± 0.3
FAP,1370,60	3.5 ± 0.2
FAP,1370,30	3.4 ± 0.2

3.3. F determination

The analysis of fluoride is one of the most difficult in analytical chemistry. The experiments demonstrated a strong dependence between the applicability of the methods and the nature of the samples as well as the quality of sample preparation. The difference between the first two methods (i.e. pyrohydrolytic method and distillation with conc. H₂SO₄) were merely in the sample preparation. Fluoride content of the solutions was determined by thorium nitrate titration. The results showed that neither of the methods is adequate for fluoride analysis, because the total fluoride content can not be extracted. The measured values were 45% (wt) less than the theoretical value 3.72% (wt).

3.3.1. F determination by ionchromatography

The precision of this method was satisfactory, but the accuracy was poor: –23%. This poor accuracy could be explained by the non-adequate sample preparation. The samples were dissolved in H₂SO₄ at 50°C, when a part of the fluoride content could be evaporated in the form of HF. Sample preparation by dissolution using an other acid (e.g. HNO₃) was not applicable because of the disturbing effect of NO₃[–] ions for the fluoride determination in this method.

3.3.2. F determination with a fluoride-selective electrode

Accuracy of the method was found to be: –5.4%. This method was of good precision but a moderate accuracy (Table 7). Nevertheless this latter method seems to be an acceptable compromise between precision and accuracy, especially in comparison with the formerly listed methods.

4. Conclusions

Fluorapatite with a composition (Ca:P:F = 10:6:1.9) which best approximates the theoretical stoichiometry (Ca:P:F = 10:6:2) was prepared by solid state reaction, heating a mixture of Ca₃(PO₄)₂ and CaF₂ of 3:1 molar ratio. Heating run was performed in flowing argon gas (20 l h^{–1}) with some CaF₂ upstream, at 1370°C for 60 min. Considering that this sample had the same unit cell parameters as the theoretic values, this one was selected for reference for Ca, P and F determination. Accuracy and precision of different analytical methods were determined. Methods with a good accuracy for the determination of Ca, P and F content were: titrations with EDTA for Ca (accuracy: –0.8%), spectrophotometric method for P (accuracy: +0.6%) and measurements with fluoride-selective electrode (accuracy: +5.4%) for F determination. Statistical results (*t*-test) demonstrated that all of the presented analytical methods (ICP, EDTA titrations, spectrophotometric method) were suitable for determination of Ca and P content in fluorapatites provided their accuracy, as compared to a standard sample, is considered during evaluation of results.

Abstract

The use of ICP/AES for the determination of zinc, in low concentration levels, in matrices containing high levels of copper is difficult because copper interferes in the zinc main emission wavelength (213.856 nm). In the present work, a separation of zinc from copper matrices was possible, using the reaction of zinc(II) cation with 1-(2-tiazolylazo)-2-naphthol (TAN), in the pH range of 6.5–8.0, resulting in a stable red complex. Copper also reacts with TAN but its interference was avoided by the addition of ascorbic acid and thiosulphate in the reaction medium. In this way, the aqueous solution was passed through a SEP PAK C18 cartridge, in which the zinc(II)–TAN complex was quantitatively retained, but it did not occur with copper which passes through the cartridge, as $[\text{Cu}_2(\text{S}_2\text{O}_3)_2]^{2-}$, with the aqueous solution. The cartridge was washed with water and the complex eluted with ethanol. Then, the alcohol was evaporated and the complex decomposed by nitric acid. It results in both zinc pre-concentration and separation from copper. The zinc quantification was carried out by ICP/AES at 213.856 nm. The relative standard deviations, for ten different aliquots, were 5.7% and the average recovery found for zinc was 96%, even when the concentration ratio Cu/Zn was up to 500/1 ($\text{mg l}^{-1}:\text{mg l}^{-1}$). Other metals, like nickel, for example, can react with TAN in the same way as zinc but they do not interfere in the emission wavelength 213.856 nm. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: ICP/AES; Zinc; Copper-base alloys

1. Introduction

The determination of zinc in low concentration levels has been widely done by spectroscopic methods such as ICP–AES and/or AAS. How-

ever, the determination of zinc traces in copper matrices using these analytical methods is difficult because of the spectral interference, due to the overlapping of the copper line at 213.853 nm with the zinc main emission wavelength (213.856 nm) [1–3]. A lack in *sensitivity* does not allow the quantification of zinc in its second emission wavelength at 334.502 nm. Thus, the determination of

* Corresponding author. e-mail: jailsong@ufba.br

zinc traces in copper matrices, by spectroscopic methods, requires a prior separation [4,5], which can be done by several ways. For example, Wunderlich and Haedeler [4] had determined zinc in pure copper, by atomic absorption spectrometry, after copper separation either as its sulfide with hydrogen sulfide, or by electrolysis. On the other hand, McCrackan et al. [5] determined zinc, cadmium and tin, at low concentration levels, in copper after copper separation by ion exchange.

In the present work, a new method for zinc separation from copper was investigated. It is based on the quantitative reaction between Zn(II) and TAN [6] and retention of the zinc(II)–TAN complex on a SEP PAK C18 cartridge. Copper also reacts with TAN, however, this reaction was masked with ascorbic acid and thiosulphate. After elution from the cartridge, zinc was quantified by ICP/AES, in the emission wavelength 213.856 nm, without any interference due to copper or other metals.

2. Experimental

2.1. Reagents

All reagents were analytical grade unless otherwise stated. Double distilled water was used in the preparation of the solutions. Nitric acid and hydrochloric acid were of Suprapur quality (Merck). The laboratory glassware was kept overnight in a 5% nitric acid solution. Before use, the glassware was washed with deionized water and dried in a dust-free environment.

The reagent solutions were prepared as follows: zinc stock solution [$1000 \mu\text{g ml}^{-1}$], by dissolving 1.000 g of granulated zinc metal (Baker) in concentrated nitric acid and taken up to 1000 ml, with water; Triton-X100 [10%], by dissolving 20.0 g in 200 ml of water; TAN [0.05%], by dissolving 0.10 g of 1-(2-tiazolylazo)-2-naphthol (Merck) in 5 ml of ethanol and taken up to 100 ml with the Triton-X100 solution; Hexamine buffer solution [pH 6.8], by dissolving 70 g of hexamethylenetetramine in 800 ml of deionized water and pH adjust with nitric acid and/or sodium hydroxide; Thiosulfate solution [10%], by dissolving 10.0 g of

sodium thiosulfate pentahydrate in 100 ml of deionized water; Ascorbic acid solution [10%], by dissolving 10.0 g in 100 ml of deionized water; Ethanol p.a. (Merck), SEP PAK C18 cartridges (Millipore Waters).

2.2. Apparatus

An Applied Research Laboratories model 3410 minitorch sequential inductively coupled plasma spectrometer, equipped with an IBM PC–AT computer was used. The emission intensity measurements were made under the conditions shown in Table 1. The calibration curves (five points) for zinc (without copper and using this method) concentration in the range of $0\text{--}2.0 \mu\text{g ml}^{-1}$ are shown in Table 2. The limit of detection and background equivalent concentration (BEC) were 16 and $98 \mu\text{g l}^{-1}$, respectively.

A 300 analyser pH meter was used to measure the pH values.

Table 1

Fig. 1. Reaction between Zn(II) and TAN.

Fig. 2. Effect of acidity in Zn retention/recovery on SEP PAK C18 Cartridges.

2.3. Method

0.100 g of the sample was placed in conical flasks and 10 ml of concentrated nitric acid and 2 ml of concentrated hydrochloric acid per gram of sample were added. The system was heated up to promote the sample dissolution. The dissolved sample was placed in a volumetric flask and taken up to 1000 ml. Aliquots of 10.00 ml were placed in a 250 ml beaker. Then, 2.0 ml of ascorbic acid solution, 10.0 ml of hexamine buffer solution pH 6.8, 2.0 ml of 10% thiosulfate solution and 1.0 ml of TAN solution were added. Aliquots of 10.00 ml of the aqueous solution was passed through a SEP PAK C18 cartridge (using a 10 ml syringe) at an approximate

flow rate of 3 ml min⁻¹. In this way, the zinc(II)–TAN complex was quantitatively retained, but it did not occur with the copper which passes through the cartridge with the aqueous solution. Thus, the cartridge was washed with water and the complex was eluted with ethanol. Then, the alcohol was evaporated and the complex decomposed by nitric acid and sulfuric acid under heating. This solution was transferred to a 10.00 ml volumetric flask and taken up with water. The zinc quantification was carried out by ICP/AES at 213.856 nm. The samples can be pre-concentrated, if necessary, by passing a whole aqueous solution through a SEP PAK C18 cartridge, instead of aliquots of 10.00 ml.

Fig. 3. Zinc determination in the presence of copper (the relative standard deviations for ten different aliquots were 5.7%).

3. Results and discussion

3.1. Characteristics of the zinc(II)-TAN complex

The zinc(II) cation reacts instantaneously with TAN, in the pH range of 6.5–8.0, in the presence of Triton-X100 to form a red complex (Fig. 1) [6], which is stable for at least 2 h. Both, TAN and its zinc(II) complex have low solubility in water but

the reaction in the presence of Triton-X100, increases the solubility. Due to the non polar character of the Zn–TAN complex it can be quantitatively retained on reversed phase SEP PAK C18 cartridges. The pH conditions did not affect the retention capacity if it were kept in pH range of 6.5–8.0, as can be seen in Fig. 2. In this conditions no breakthrough was observed in the Zn–TAN complex retention on the cartridges, even when the amount of zinc retained was up to 0.1 mg. A study showed that 5.0 ml of ethanol was sufficient to elute quantitatively the complex from the cartridge. Because the conditions (pH 6.5–8.0) are not aggressive to the reversed phase C18, the cartridge can be reused several times.

3.2. Masking of copper

Thiosulphate forms a strong complex with cuprous ion and has been used as masking agent for copper in zinc determinations by spectrophotometric methods and complexometric titrations with EDTA [7,8]. This is based on the reduction of copper(II) to copper(I) and complexation of copper(I) with thiosulfate $[\text{Cu}_2(\text{S}_2\text{O}_3)_2]^-$ [7,8].

However, this masking is efficient only up to pH 6.0, which is too low for optimum use with TAN. In this way, the use of a masking solution containing ascorbic acid and thiosulfate avoided the copper interference in pH range of 6.2–7.2 [6]. As $[\text{Cu}_2(\text{S}_2\text{O}_3)_2]^{2-}$, copper did not react with TAN and passed throughout the SEP PAK C18 cartridges without any retention. Fig. 3 shows the efficiencies in the recovery of zinc from solutions containing variable amounts of copper. The recovery efficiency was high (>90%) even in the presence of considerable amounts of copper (500 to 1 in relation to zinc concentration).

3.3. Zinc determination in copper-base alloys

In Table 3 it is shown the emission intensity measured when different zinc solutions are quantified, by ICP/AES, with and without copper. As can be seen in Table 3 the presence of $250 \mu\text{g ml}^{-1}$ can increase the signal up to 2.7 times depending on the zinc concentration. An alternative way *is to* quantify zinc at 334.502 nm, but it revealed a lack in sensitivity with the signal dropping up to 40 times depending on the zinc concentration (Table 3). Meanwhile, when copper is separated using the procedure proposed in this study, zinc can be quantified accurately and precisely in its main emission wavelength (213.856 nm), with a detection limit of $16 \mu\text{g l}^{-1}$. The relative standard deviations for ten different aliquots were 5.7%.

The method validation was made with three different copper-base alloys. The results are shown in Table 4, the application of the $t_{95\%}$ test in the result obtained at NIST and CEPED and in this work (Table 4) did not show significant differences. In the analyzed sample the concentra-

tions (%) of copper were in the range of 88.96–90.48% (Table 5) and its interference was avoided. Other metals like nickel, tin, iron, lead, aluminum, manganese and arsenic were present (Table 5) but they do not interfere in the emission wavelength 213.856 nm.

4. Conclusions

Copper is a serious interference in the determination of zinc by ICP/AES in the zinc main emission wavelength. The method proposed in the present work allows the determination of low levels of zinc in copper alloys by ICP/AES, at 213.856 nm.

Received 23 June 1997; received in revised form 10 November 1997; accepted 12 November 1997

Abstract

The acid dissociation constants (K_a), base dissociation constants (K_b) and the autoprotolysis constants (K_s) for 2,2'-bipyridyl in water and in water + alcohol (methanol, ethanol, iso-propanol) mixed solvents have been determined at 25°C and an ionic strength of 0.1 mol l⁻¹, from a direct potentiometric method based on the treatment of the data of a single pH titration. It has been shown that K_a increases, whereas K_b and K_s decrease, with increasing proportion of the alcohol in the mixed solvents. Linear relations between p K_a , p K_b , p K_s and the mole fraction of the alcohol were observed in the composition range investigated. These results are discussed in terms of the properties of solvent and the interactions of the different species existing in dissociation equilibrium with solvents. It is concluded that the higher stabilization of both 2,2'-bipyridyl and its protonated form by dispersion forces and of the proton by its interaction with solvent molecules in the mixed solvents compared with that in water are largely responsible for the observed changes of p K_a with composition. On the other hand, the low stabilization of OH⁻ in the mixed solvents relative to that in water and the electrostatic effect are the main factors in determining the solvent effect on p K_b . © 1998 Elsevier Science B.V. Keywords: Acid dissociation constant; Base dissociation constant; Autoprotolysis constant; Water + alcohol mixed solvent; 2,2'-bipyridyl

1. Introduction

In recent years, non-aqueous and mixed solvents have been widely used in analytical chemistry with the rapid development of non-aqueous analytical techniques and methods. Choosing acid-base titration as an example, there are essentially three reasons for this: (i) weak acid or weak base whose acid dissociation constant is less than

10⁻⁷ can not be titrated accurately in aqueous solution; (ii) the small solubility for a large number of organic compounds makes the titration impossible in water; (iii) the strong acids or bases in a mixture can not be titrated respectively, because of the leveling effect in aqueous solutions. Usually, these problems can be partially or entirely resolved by using proper non-aqueous solvents as the reaction medium.

Acid dissociation constant and base dissociation constant of organic compounds as well as the

autoprotolysis constant of solvent are the important basic data for non-aqueous titration. They may be used to choose the optimum analytical conditions and the best medium in which the titration is carried out [1,2]. Although a number of such constants in non-aqueous or mixed solvents have been determined and accumulated in literature [3–5], much more work in this respect is indispensable in order to meet the needs of practical applications and to clarify the nature of medium effect on the acid–base dissociation constants. As a part of the continuing studies on the use of ion selective electrode (ISE) in mixed solvents [6–9], we report here the acid dissociation constants, base dissociation constants and the autoprotolysis constants for 2,2'-bipyridyl in water and in water + alcohol (methanol, ethanol, iso-propanol) mixed solvents at 25°C and an ionic strength $I = 0.1 \text{ mol l}^{-1}$. These constants were determined from a direct potentiometric method [10] by which the acid, the base as well as the autoprotolysis constant can be obtained simultaneously from the data of a single pH titration. The effect of the solvents on the dissociation constants of 2,2'-bipyridyl have been discussed in terms of properties of the solvents and the interactions of the different species existing in dissociation equilibrium with the solvents.

2. Experimental

2.1. Reagents and stock solutions

2,2'-bipyridyl (A.R., Beijing) was used after drying for 3 h under vacuum at 50°C. Methanol (MeOH), ethanol (EtOH) and iso-propanol (*i*-PrOH) (A.R., all from Shanghai) were dried over 4 Å type molecular sieves before use. Hydrochloric acid, potassium Chloride and sodium hydroxide (G.R., all from Shanghai) were used without further purification.

Stock solution of hydrochloric acid (0.2 mol l^{-1}) was obtained by direct dilution of the commercial hydrochloric acid with redistilled water, and that of sodium hydroxide (0.12 mol l^{-1}) was prepared by dissolving an accurate amount of sodium hydroxide in CO_2 free redistilled water.

The accurate concentration of these two stock solutions is determined by potentiometric titration. In order to prepare the stock solution of 2,2'-bipyridyl (0.05 mol l^{-1}) + hydrochloric acid (0.1 mol l^{-1}), the required amount of 2,2'-bipyridyl and pure water were added into a portion of the stock solution of hydrochloric acid. Generally, dilute solutions were prepared by appropriate dilution of the respective stocks. Water + alcohol mixed solvents were prepared by weight. The ionic strength in all solutions was supported with 0.1 mol l^{-1} potassium chloride.

2.2. Apparatus

The cell used in this work was

where SH denotes water + alcohol mixed solvent. The pH electrode was a pH glass electrode of type 231 (Shanghai). Ag–AgCl reference electrode without liquid junction was home-made by the thermal electrolytic method [11], the potentiometric titrations were carried out at $25 \pm 0.05^\circ\text{C}$ in a water jacketed glass cell as described in a previous paper [6]. The cell potentials were recorded by means of a precise pH meter (pHS-2D, Chengdu) readable to 0.2 mV. Before measurements, the glass electrode was prepared according to the manufacturer's instruction and calibrated with the standard aqueous potassium acid phthalate and sodium tetraborate buffers.

2.3. Procedure

Into two 50 ml volumetric flasks, transfer 5.00 ml of the stock solutions of 2,2'-bipyridyl + hydrochloric acid and sodium hydroxide, respectively. Add the required amount of alcohol and solid potassium chloride, dilute to the marks with redistilled water. Thus obtained solution containing 2,2'-bipyridyl + hydrochloric acid was used as the titrand, and that containing sodium hydroxide as the titrant. Here, the titrand and the titrant have the same proportion of the alcohol and the same ionic strength. Before measurements, Ag–AgCl and pH electrodes were soaked over night in a portion of the titrand.

^a The uncertainty in e.m.f. measurements is about ± 0.3 mV.

A 20.00 ml of the titrand was added to the cell. After thermal equilibrium was reached, the cell solution was titrated with small additions of the titrant. During titrations, the excess hydrochloric acid in the cell solution was titrated firstly before the first stoichiometric point. Then, 2,2'-bipyridyl hydrochloride was titrated up to the second stoichiometric point. E.m.f. readings were taken after every titrations when cell potential was constant within 0.5 mV for at least 3 min. $E-V$ (volume of the titrant added) data obtained (as shown in Table 1, column 1 and 2) are used firstly for the determination of the volume of the titrant, V_2 , added into the cell solution when the second stoichiometric point is reached. This is performed very accurately by

means of the second derivative method [12]. Since the mole ratio of 2,2'-bipyridylhydrochloride and hydrochloric acid in the titrand is exactly 1:1, the volume of the titrant added corresponding to the first stoichiometric point, V_1 , can be easily calculated from the V_2 value obtained.

3. Results

The whole titration process can be divided into three stages. Titration before the first stoichiometric point belong to the first stage. At this stage, the cell potential at 25°C is given by the following equation [13]

$$E = E_a^0 - 59.16 \log[\text{SH}_2^+] \quad (1)$$

Where E_a^0 is the specific constant of the cell in the acidic range, and includes the standard electrode potential of the glass electrode, the potential of the Ag–AgCl electrode and the activity factors. $[\text{SH}_2^+]$ is the concentration of solvated proton and can be expressed by

$$[\text{SH}_2^+] = c_{\text{HCl}} - c_{\text{NaOH}} \quad (2)$$

here c_{HCl} is the total analytical concentration of hydrochloric acid in the cell solution, constant throughout the experiment, c_{NaOH} is the total analytical concentration of the added sodium hydroxide.

Introducing Eq. (2) into Eq. (1), it follows that

$$E = E_a^0 - 59.16 \log(c_{\text{HCl}} - c_{\text{NaOH}}) \quad (3)$$

Using the measured E and c_{NaOH} values in every titration point before the first stoichiometric point, E_a^0 can be easily calculated from Eq. (3).

Titrations between the first and the second stoichiometric points belong to the second stage. The measured cell potential in every titration point in this range can be used to calculate the hydrogen ion concentration $[\text{H}^+]$ and the acid dissociation constant K_a by the following relations [14]

$$-\log[\text{H}^+] = \frac{(E - E_a^0)}{59.16} \quad (4)$$

and

$$\begin{aligned} \text{p}K_a &= -\log[\text{H}^+] \\ &+ \log \left\{ \frac{([\text{BH}^+] - [\text{SH}_2^+] + [\text{S}^-])}{([\text{B}] + [\text{SH}_2^+] - [\text{S}^-])} \right\} \\ &= -\log[\text{H}^+] + \log \left[\frac{(V_2 - V)}{(V - V_1)} \right] \end{aligned} \quad (5)$$

where $[\text{B}]$, $[\text{BH}^+]$ and $[\text{S}^-]$ are the equilibrium concentrations of 2,2'-bipyridyl, the protonated form of 2,2'-bipyridyl and the lyate ion in solution, respectively. V is the volume of the titrant (NaOH) added in every titration point.

Titrations after the second stoichiometric point are in the range of the third stage. The titrand at this region becomes 2,2'-bipyridyl and sodium hydroxide in the mixed solvent studied. The cell potential in every titration point is given by

$$E = E_b^0 + 59.16 \log[\text{S}^-] \quad (6)$$

where E_b^0 is the specific constant of the cell in the alkaline region, and includes also the standard electrode potential of the glass electrode, the potential of Ag–AgCl electrode and the activity factors. Under the conditions investigated here, the concentration of the lyate ion can be calculated by

$$[\text{S}^-] = c_{\text{NaOH}} - 2c_{\text{HCl}} \quad (7)$$

From Eqs. (6) and (7), it is evident that

$$E_b^0 = E - 59.16 \log(c_{\text{NaOH}} - 2c_{\text{HCl}}) \quad (8)$$

Similarly, using the measured E and c_{NaOH} values for every titration point after the first stoichiometric point, values of E_b^0 can be computed. Once E_a^0 , E_b^0 and $\text{p}K_a$ are known, the autoprotolysis constant K_s for the solvent and the base dissociation constant K_b can be obtained by means of the known relations [10]

$$\text{p}K_s = \frac{(E_b^0 - E_a^0)}{59.16} \quad (9)$$

and

$$\text{p}K_b = \text{p}K_s - \text{p}K_a \quad (10)$$

As an example, Table 1 lists the titration data for the three stages in aqueous solution of 34.3 wt% methanol as well as the calculated E_a^0 , E_b^0 , $\text{p}K_a$, $\text{p}K_s$ and $\text{p}K_b$ values. Values of $\text{p}K_a$, $\text{p}K_b$ and $\text{p}K_s$ ($I = 0.1$) for 2,2'-bipyridyl in water and in different water + alcohol mixed solvents are presented in Table 2.

4. Discussion

It is evident from Table 1 that E_a^0 and E_b^0 are constant throughout the experiment within the experimental error. This suggests that strong acid in the acidic range can be leveled to the strength of the solvated proton SH_2^+ and that strong base in the alkaline range can be leveled to the strength of the lyate S^- , in the investigated water + alcohol mixed solvents.

It can be seen from Table 2 that $\text{p}K_a$ value for 2,2'-bipyridyl obtained in water was 4.47, which is in excellent agreement with the values 4.48 or 4.44 reported in the literature [15,16]. The autoprotoly-

sis constant p*K*_s obtained for water was 13.70, which also agrees satisfactorily with the value 13.73 determined by Tencheva and co-workers [10]. As far as the dissociation constants in aqueous alcohol solutions are concerned, El-Gyar et al. [17] determined pH-metrically the acid dissociation constants of the protonated 2,2'-bipyridyl in aqueous media containing 30, 40, 50 and 60 wt% alcohol (methanol, ethanol) at 25°C

and $I = 0.1 \text{ mol l}^{-1}$. The standard deviations of our p*K*_a values and those determined by these authors in water + methanol and water + ethanol mixed solvents are 0.08 and 0.14, respectively. Data in Table 2 show that for 2,2'-bipyridyl, the acid dissociation constant (*K*_a) increases, whereas the base dissociation constant (*K*_b) and the autoprotolysis constant (*K*_s) decrease, with increasing proportion of the alcohol in the mixed solvents. A

careful analysis of these results reveals that in the composition range investigated, pK_a , pK_b and pK_s change linearly with the mole fraction (x_2) of the alcohol in aqueous solutions. These linear equations with correlation coefficients were listed in Table 3. As an example, the variation of pK_a , pK_b and pK_s as a function of x_2 in water + methanol mixed solvents was illustrated in Fig. 1.

It is generally recognized that the acid–base dissociation constants of acids and bases may be affected by electrostatic effect associated with the change in dielectric constant, acidic or basic strength of the solvents and the interactions of different species existing in dissociation equilibrium with solvents. The acid dissociation equilibrium of the protonated form of 2,2'-bipyridyl in mixed solvent can be represented by

If we disregard all participation of the solvent and the effect of ion activity coefficients, the difference of pK_a in mixed solvent and in water can be related to the Gibbs energy of transfer, $\Delta G_t^0(i)$, from water to the mixed solvent by

$$2.303RT[pK_a(SH) - pK_a(H_2O)] = \Delta G_t^0(H^+) + \Delta G_t^0(B) - \Delta G_t^0(BH^+) \quad (12)$$

It is known that electrostatic effect operates only on the charged species. Its contribution to $\Delta G_t^0(i)$ is inversely proportional to the radius of the ionic species considered [3]. Consequently, the electrostatic term of $\Delta G_t^0(H^+)$ is larger than that of $\Delta G_t^0(BH^+)$, and K_a is expected to decrease with increasing proportion of the alcohol in aqueous medium. This is at variance with the observed changes in pK_a . Accordingly, electrostatic effect is of considerably less importance in explaining solvent effects on the isoelectric dissociation reaction, as indicated previously [3,17–19].

Wells [20–23], Popovych [24] and Lahiri et al. [25–27] determined the Gibbs energies of transfer of H^+ , B and BH^+ from water to water + alcohol (MeOH, EtOH, *i*-PrOH) mixtures. The results shown that values of $\Delta G_t^0(H^+)$, $\Delta G_t^0(B)$ and $\Delta G_t^0(BH^+)$ are increasingly negative with increasing proportion of the alcohol in aqueous solution, and that values of $\Delta G_t^0(B)$ are close to those of $\Delta G_t^0(BH^+)$ at the same composition in water-rich region. Thus, the magnitude of $pK_a(SH)$ relative

to $pK_a(\text{H}_2\text{O})$ is mainly determined by the sign of $\Delta G_i^0(\text{H}^+)$. Accordingly, K_a should increase with increasing proportion of alcohol in aqueous solution, which is in accordance with the results given in Table 2.

It has been stressed [25] that the basicity of the solvent mixtures and the H^+ -solvent interactions can best be determined from the Gibbs energy of transfer of H^+ from water to aquo-organic mixtures. The negative values of $\Delta G_i^0(\text{H}^+)$ indicate that the water + alcohol mixed solvents are more basic than water and that proton is more stable in the mixed solvents than in water. Similarly, the negative values of $\Delta G_i^0(\text{B})$ and $\Delta G_i^0(\text{BH}^+)$ means that B and BH^+ have lower energies or higher stabilization in the mixed solvents than in water. This is mainly due to their dispersion interaction with the alcohol in the mixed solvents because the effective density of dispersion centers of methanol, ethanol and propanol is higher than that of water [28,29]. Therefore, it is concluded that the higher stabilization of both 2,2'-bipyridyl and its protonated form by dispersion forces and of the proton by its interaction with solvent molecules in the mixed solvents compared with that in water are largely responsible for the observed changes of pK_a with composition of the mixed solvents.

The base dissociation equilibrium of 2,2'-bipyridyl in mixed solvent can be expressed by

As an approximation, $\Delta G_i^0(\text{S}^-)$ can be replaced by $\Delta G_i^0(\text{OH}^-)$ in the water-rich region. Under this condition, if we disregard the effect of ion activity coefficients, difference of pK_b in mixed solvent and in water is related to $\Delta G_i^0(i)$ by

$$2.303RT[pK_b(\text{SH}) - pK_b(\text{H}_2\text{O})] \\ = \Delta G_i^0(\text{BH}^+) + \Delta G_i^0(\text{OH}^-) - \Delta G_i^0(\text{B}) \quad (14)$$

Considering the fact that the Gibbs energies of transfer for OH^- from water to the water + alcohol solvents are increasingly positive with increasing proportion of the alcohol in aqueous media [20–23], it can be deduced from the similar analysis as above that electrostatic effects and low stabilization of OH^- in the mixed solvents

relative to that in water played major role in determining the solvent effect on the base dissociation process of 2,2'-bipyridyl.

Furthermore, it is interesting to note that at the same mole fraction of alcohols, K_a varies in the sequence $i\text{-PrOH} + \text{H}_2\text{O} > \text{EtOH} + \text{H}_2\text{O} > \text{MeOH} + \text{H}_2\text{O} > \text{H}_2\text{O}$, while K_b varies in the order $i\text{-PrOH} + \text{H}_2\text{O} < \text{EtOH} + \text{H}_2\text{O} < \text{MeOH} + \text{H}_2\text{O} < \text{H}_2\text{O}$. This behavior is expected as a result of increase in the basicity of the solvents or in the H^+ -solvent interaction, on going from H_2O , $\text{MeOH} + \text{H}_2\text{O}$, $\text{EtOH} + \text{H}_2\text{O}$ to $i\text{-PrOH} + \text{H}_2\text{O}$ mixed solvents. It has been observed [20–23] that at the same composition of different water + alcohol system, $\Delta G_i^0(\text{H}^+)$ is increasingly negative, while $\Delta G_i^0(\text{OH}^-)$ is increasingly positive, from $\text{MeOH} + \text{H}_2\text{O}$, $\text{EtOH} + \text{H}_2\text{O}$, $i\text{-PrOH} + \text{H}_2\text{O}$ mixtures. This strongly supports the above suggestion.

Abstract

The concentration of potassium was determined by a combination of flow injection analysis (FIA) with an all-solid-state potassium sensor detection. The all-solid-state potassium-selective electrode possessing long-term potential stability was fabricated by coating an electroactive polypyrrole/poly(4-styrenesulfonate) film electrode with a plasticized poly(vinyl chloride) membrane containing valinomycin. The simple FIA system developed in this laboratory demonstrated sensitivity identical to that in the batch system and achieved considerably rapid assay (150 samples h⁻¹). Analyses of soy sauce and control serum samples by this FIA system yielded results in good agreement with those obtained by conventional measurements. © 1998 Elsevier Science B.V. 1. Introduction

Determination of potassium contents of serum, urine, and foods is very important in clinical and medical fields [1], since the potassium contents are related to renal diseases. These diseases restrict patients to a diet containing a large amount of potassium. From the potassium determination,

medical information concerning physical conditions of the patient can be obtained. In the case of hypokalemia, alkalosis, cirrhosis of liver, diuretic drugs, etc. are suspected. On the other hand, when potassium concentration in human serum becomes higher than 9 mmol dm⁻³, heart often stops. Hence, accurate, easy and rapid sensing of potassium ions is very important.

Miniaturization of an ion-selective electrode (ISE) will bring improvements in determining ion contents in clinical and medical fields. Recently,

we reported on the highly stable response of the all-solid-state K^+ ISE with an electropolymerized film [2,3], which, in general, is known to provide various functionalities [4–8]. This solid state electrode can be easily miniaturized. On the other hand, the method of flow injection analysis (FIA) allows fast and simple sample treatment, e.g. ion-selective electrodes have been employed previously as an FIA detector for analyses of real samples [9]. Because of the use of small diameter tubings, small volume injectors, flow-through detectors and fast flow rates, the FIA system offers rapid assay with high precision [10–14]. In this work, we combined the all-solid-state K^+ ISE with the simple flow injection system developed in this laboratory.

2. Experimental details

2.1. Reagents

Reagent grade pyrrole, valinomycin (Wako), poly(sodium 4-styrenesulfonate) (Aldrich, M_w ca. 70000 $g\ mol^{-1}$), poly(vinyl chloride) (PVC) (Kanto, $n = 1000 \pm 40$), *o*-nitrophenyl octyl ether (*o*-NPOE), and potassium tetrakis(*p*-chlorophenyl) borate (KTpCIPB) (Tokyo Kasei Kogyo) were used without further purification. A 2-amino-2-hydroxymethyl-1,3-propanediol (Tris) ($50\ mmol\ dm^{-3}$)-HCl ($0.1\ mol\ dm^{-3}$) buffer solution was used as pH buffer. All other chemicals used were of analytical-reagent grade. Deionized and distilled water was used in all experiments.

2.2. Preparation of solid state K^+ ISE

Details of the fabrication of the all-solid-state potassium ion selective electrode have been described in our previous papers [2]. A polypyrrole/poly(4-styrenesulfonate) (PPy/PSS) composite film was deposited potentiostatically on a Pt disk (1 mm in diameter) from an aqueous solution containing pyrrole and poly(sodium 4-styrenesulfonate) at 0.8 V vs. Ag/AgCl by passing a charge of $10^\circ C\ cm^{-2}$. After electropolymerization, the PPy/PSS composite film electrode was condi-

tioned in $1\ mol\ dm^{-3}\ KCl$ for 2 h and dried in laboratory atmosphere. The potassium-selective PVC membrane was formed on the PPy/PSS film electrode by casting from a tetrahydrofuran solution containing 7.0 wt.% valinomycin, 62.7 wt.% *o*-NPOE, 1.1 wt.% KTpCIPB and 29.2 wt.% PVC.

2.3. Flow injection analysis with K^+ ISE

A schematic diagram of the potentiometric flow system equipped with the K^+ ISE is illustrated in Fig. 1. Tris buffer (pH = 7.5 at room temperature) was continuously pumped through the system with a peristaltic pump (ATTO, AC-2120) at a flow rate of $2.8\ ml\ min^{-1}$. Sample solution was introduced via a rotary injection valve (Rheodyne, 7010). Fig. 1b shows a schematic drawing of the sensing part. A carrier stream was directed against the side of the reference electrode glass vessel. Employing this sensing configuration enabled

Fig. 2. Dependence of injection volume on potential response to 10 mmol dm^{-3} KCl with the use of the K^+ ISE based-simple FIA system. Carrier stream, 50 mmol dm^{-3} Tris (pH 7.5 adjusted with 0.1 mol dm^{-3} HCl); flow rate, 2.8 ml min^{-1} .

rapid assay owing to the absence of dead volume at the probe.

3. Results and discussion

3.1. Response properties and calibration

The all-solid-state K^+ ISE responded to the K^+ ion selectively even in a test solution containing Na^+ ion [2] and showed high stability as a potassium ion sensor in the batch system [3]. This K^+ ISE electrode displayed low potential drift in the response to potassium ion. First, by operating the K^+ ISE in the simple FIA system, injection volume was optimized as $200 \mu\text{l}$ for more sensitive and rapid determination as shown in Fig. 2. And more, flow rate and valve switching timing were optimized. The K^+ ISE based-simple FIA system demonstrated rapid potential responses with good sensitivity as shown in Figs. 3 and 4. In Fig. 3, a linear relationship was obtained in the range of K^+ activity from 10^{-5} – 10^{-1} with a slope of $57.6 \text{ mV decade}^{-1}$. The apparatus allowed 150 samples to be assayed per hour with a precision of 2.0% as illustrated in Fig. 4. As summarized in

Table 1, although the analytical precision varied with the concentration of potassium chloride, it was possible to determine potassium contents with satisfactory precision in the range of 10^{-5} – $10^{-1} \text{ mol dm}^{-3}$ potassium chloride. As previously analyzed by ac impedance for the batch system [3], the long-term stability of the K^+ ISE in the simple FIA was also confirmed, i.e. low potential drift and low impedance. We also evaluated time dependence of the sensitivity. Table 2 shows that the slope of the calibration curve remained almost independent of time during the period of 8 days after fabrication.

The results described above demonstrate that the simple FIA system equipped with the K^+ ISE allows rapid determination of potassium in KCl standard solutions with high precision.

3.2. Assay of food and serum samples

Figs. 5 and 6 show response curves obtained with two samples of Japanese soy sauce and one sample of control serum. In these determinations, soy sauce and control serum were diluted by factors of 200 and 20, respectively, in order to avoid interference by the presence of protein con-

Fig. 3. Calibration graph for potassium ion using the FIA. Carrier stream, 50 mmol dm^{-3} Tris (pH 7.5 adjusted with 0.1 mol dm^{-3} HCl); flow rate, 2.8 ml min^{-1} ; injection volume, $200 \mu\text{l}$.

Fig. 4. Typical FIA peaks for 1 mmol dm⁻³ KCl standard solution. Operational, $n = 25$; carrier stream, 50 mmol dm⁻³ Tris (pH 7.5 adjusted with 0.1 mol dm⁻³ HCl); flow rate, 2.8 ml min⁻¹; injection volume, 200 μ l.

tained in the samples. Potassium concentrations estimated from the FIA analyses were; 0.143 mmol dm⁻³ (sample A) and 0.124 mmol dm⁻³ (sample B). These results agreed with flame photometric data. Furthermore, the potassium content of the control serum was determined to be 4.06 mmol dm⁻³, which also agreed with that listed for the specific serum lot used. In addition,

Table 1
Reproducibility of assay for standard potassium ion solution with various concentrations

KCl (mol dm ⁻³)	Precision (%)
1.0×10^{-1}	0.16
1.0×10^{-3}	2.00
1.0×10^{-5}	4.73

Table 2
Variations in the slope of calibration plots for potassium ion

4. Conclusions

The potentiometric determination of potassium ions in the range between 10^{-5} and $10^{-1} \text{ mol dm}^{-3}$ was possible with the use of the simple flow injection cell equipped with the all-solid-state K^+ ISE developed in this laboratory. We achieved rapid ($150 \text{ samples h}^{-1}$) and continuous assay of potassium ions with good precision. It was demonstrated that samples of soy sauce and control serum can be assayed by this FIA system.

Received 21 July 1997; received in revised form 3 November 1997; accepted 12 November 1997

Abstract

The vanadium content in chloride rich hydrogeochemical samples has been determined through a modification in the existing standard gallic acid oxidation method which has severe interference problem from halides. The modification incorporates a preliminary fume-drying of the sample aliquot with a mixture of perchloric and sulphuric acids. This ensures total removal of halides and hence their interference. The estimation is completed as per the standard method after taking the sample in 10 ml of 1% nitric acid. Also mercuric nitrate addition which forms a part of the standard procedure to prevent halide interference, is also dispensed with keeping in view the toxic nature of mercury. The method has been tried on a number of samples having varying chloride content. The results obtained compare well with the standard PAR method. The method can be used to determine vanadium down to 1 ppb. The relative standard deviation obtained for vanadium contents in the range 400–10 ppb is in the range 4–8.2%. © 1998 Elsevier Science B.V. Keywords: Catalytic–photometric method; Determination; Vanadium; Chloride

1. Introduction

The determination of vanadium content at ppb level in potable water and hydrogeochemical samples has an important role to play because, (i) its presence in the range 20–150 ppb in drinking water has been reported to have beneficial role in the prevention of heart disease, and (ii) for locating the calcrite type of uranium deposit contain-

ing carnotite (a secondary mineral of uranium in association with vanadium and potassium having the composition $K_2O \cdot 2U_2O_3 \cdot V_2O_5 \cdot 2H_2O$). The procedure followed for the determination of vanadium is the catalytic–photometric method [1,2] that is based on the catalytic action of vanadium on the oxidation–coloration reaction of gallic acid by ammonium persulphate in acid medium. This method being highly sensitive is considered superior to other methods, [3–9] wherein different oxidizing agents and reagents that generate coloured product on oxidation, have

* Corresponding author. Fax: +91 265 432669.

been used. Although the persulphate–gallic acid procedure is accepted as the standard method, inherent defects of the method like reproducibility, accuracy and susceptibility to interference, calls for a cautious acceptance of the results. Weiguo [10] after a critical study suggested certain modifications which helped to achieve better reproducibility and improved sensitivity. However, the method continued to have serious interference problems from some cations and anions. Of the halides, chloride bromide and iodide, the latter two interfere seriously even when present at low levels. The tolerance limit for chloride, bromide and iodide are 100 ppm, 0.1 and 0.001 ppm respectively. Addition of mercuric nitrate (350 ppm) raises the tolerance limit for bromide and iodide to 0.25 ppm. However, when the levels of halides exceed the above limits, dilution of the sample solution is recommended so as to have the optimum suggested level of the halides, to pursue the determination. Mercuric ion itself acts as an interference when used beyond the suggested quantity of 350 ppm. Thus the knowledge of the halide content is essential to proceed with the vanadium determination.

During the analysis of hydrogeochemical samples from the semi-arid zones of Rajasthan, India, while surveying for carnotite mineralization, samples with high chloride contents ranging upto one lakh ppm and beyond, were encountered. Determination of vanadium in these chloride rich samples could not be carried out by the dilution technique as the dilution of the sample, many folds, resulted in bringing down the level of vanadium to an extent that was below the determination limit of the method. Also there is no easy way to ascertain the bromide and iodide content of the sample. In order to overcome the above problem, the present work has been developed after suitable modification of the existing method. It describes a simple and reliable procedure for determining vanadium in chloride rich hydrogeochemical samples. The procedure also excludes the use of mercury which is known for its toxicity.

2. Experimental

2.1. Apparatus

A cryostatic constant temperature waterbath model CB-701 from M/S Remi Instruments, Mumbai, India, with temperature control of $\pm 0.2^\circ\text{C}$ was used.

An ultrasonic cleaner IS-120 W/F from M/S IMECO ultrasonics, Mumbai, was used for cleaning glass ware.

A Elico (India) UV-Visible spectrophotometer ultraspecmodel CL-540 was used for making absorbance measurements.

2.2. Reagents

All chemicals used were of analytical reagent grade and the solutions were prepared using doubly distilled water.

2.3. Standard vanadium solution

100 $\mu\text{g ml}^{-1}$. It is prepared by dissolving 0.23 g of ammonium metavanadate in 1 l of water containing 7.5 ml of concentrated nitric acid. Working solutions of 1 and 0.1 $\mu\text{g ml}^{-1}$ were prepared fresh daily, for the work.

2.4. Ammonium persulphate–phosphoric acid solution (reagent A)

Prepared by dissolving 2.5 g of ammonium persulphate in 50 ml of 1:1 orthophosphoric acid solution. The solution is to be used after 29 h but is to be discarded after 48 h.

2.5. Gallic acid, 1% solution (reagent B)

1 g of gallic acid was dissolved in 100 ml of water and filtered before use. The solution is prepared fresh daily.

2.6. Mercuric nitrate solution

Prepared by dissolving 350 mg of mercuric nitrate in 1 l of water (350 $\mu\text{g ml}^{-1}$).

2.7. Procedure

The glass ware to be used are all initially cleaned in the ultrasonic cleaner using dilute nitric acid (3% v/v).

A known quantity of the sample aliquot containing not more than 0.4 μg of vanadium is taken in 50 ml beaker. It is treated with 0.5 ml of 1:1 sulphuric acid and 0.5 ml of perchloric acid (70% v/v) and heated on a hot plate till the evolution of dense white fumes ceased. The residue is taken up in 10 ml of 1% nitric acid which is added in small lots. The solution is transferred after warming, to vials having 10 ml marking. The final volume is adjusted to 10 ml with 1% nitric acid. A blank and a series of standards ranging from 0.05 to 0.4 μg vanadium were also processed similarly to obtain a calibration graph. The vials were stoppered and kept in the cryostatic bath set to 25°C along with the stoppered bottles containing ammonium persulphate–phosphoric acid solution (reagent A) and gallic acid [reagent B] for equilibration at the set temperature. After 45 min, 1 ml of reagent A is added to each of the vials, they are kept back in the water bath after swirling, for thorough mixing. After 15 min, 1 ml of reagent B is added to first vial which after mixing is placed again in the cryostatic bath. Addition of reagent B to other vials were continued at intervals of 2 min and were returned to the bath for equilibration. Exactly 60 min after the addition of reagent B, the absorbance of each solution was measured at 415 nm against distilled water as the blank. The vanadium content of the sample is computed from the calibration plot drawn for the standards. Beers law obeyed in the range 0.05–0.40 μg in 12 ml of the solution.

3. Results and discussion

Since it is known that the only effective way of driving out halides is by fuming with sulphuric acid, an attempt has been made in the present work to overcome the problem of interference of chloride in the vanadium determination. Fume drying of the sample with perchloric–sulphuric acid combination has been introduced as a pre-

liminary step in the existing procedure. This step ensures destruction of the dissolved organic matter with simultaneous conversion of all forms of vanadium to the pentavalent state and total removal of halides, thus paving way for vanadium determination. The following studies were also carried out to know the implications of the modification suggested.

3.1. Effect of sulphate ions

Varying quantities of sulphate ions were added to a series of solutions containing 0.1 μg vanadium and the absorbance of the solutions were measured after processing them as suggested in the procedure. It is noticed that presence of even upto 100000 ppm of sulphate, has no effect on the absorbance. Quantities beyond this were not tried. In order to fix the quantity of 1:1 sulphuric acid to be used and also to know their effectiveness for displacing chloride ions, experiments were carried out by adding 0.25, 0.50, 0.75 and 1.00 ml of 1:1 sulphuric acid along with 0.5 ml of perchloric acid, on solutions of 0.1 μg vanadium containing 5000–1 lakh ppm of chloride. After fume drying and processing as suggested above, the absorbance of the solutions were measured at 415 nm. In all the cases it is noticed that the fuming is effective in displacing the chloride ions as evidenced from the net absorbance values obtained which were comparable with the absorbance value of pure 0.1 μg vanadium solution, processed in a similar fashion. It was also noticed that, where quantities of sulphuric acid above 0.50 ml was used, there was a slight increase in absorbance values of both blank as well as that of the 0.1 μg vanadium solution.

Thus keeping in view the fuming time and the blank value, use of quantities beyond 0.5 ml of 1:1 sulphuric acid was discarded. Use of 0.25 ml of 1:1 sulphuric acid was also not continued as it may not be able to effectively displace chlorides in chloride rich samples. Hence a quantity of 0.50 ml was selected as the optimum quantity for further work. Further experiments also revealed that, use of 0.5 ml 1:1 sulphuric acid can comfortably fume of even around 1 lakh ppm of chloride. Fig. 1 shows the absorbance values obtained for solu-

Fig. 1. Effect of chloride ion on absorbance of 0.1 µg vanadium.

tions containing 0.1 µg of vanadium, in presence of chloride and absorbance values obtained after fuming with perchloric and sulphuric acid.

3.2. Effect of metal ions

A fresh study was made with regard to the tolerance to various metal ions that are likely to interfere in view of the fact that certain modifications have been made. Table 1 gives the tolerance

Table 1
Tolerance limit for various cations and anions

Ions	Concentration (ppm)
U(VI)	10.0
Cr(VI)	1.5
Fe(III)	6.0
Mo(VI)	0.2
Co(III)	1.0
Cu(II)	0.05
Ni(II)	3.0
Ag(II)	1.0
F ⁻	15.0
Cl ⁻	100.0
Br ⁻	0.10
I ⁻	0.001

limits for various ions. It is seen that there is improved tolerance for iron. Further, the samples taken up for estimation of vanadium, were found to have the concentration of the interfering metal ions well below the tolerance limit given in the Table 1. From the results of the experiments carried out. It is evident that chlorides can effectively be removed from samples by simple fuming with a combination of perchloric and sulphuric acids. This obviously should ensure the removal of traces of bromides and iodides that may be present along with the chlorides. This aspect was confirmed by recording the absorbance value, after fuming with perchloric acid–sulphuric acid mixture, of a solution containing 0.10 µg vanadium along with 5000 ppm chloride, 10 ppm bromide and 10 ppm iodide. The absorbance value matched with that of the vanadium solution, not containing halides. Thus the suggested modification gets rid of the interference from the halides totally. The advantage of the modification suggested is that, there is no need to know the halide content of each sample, which however was a prerequisite for determining vanadium in the existing method for carrying out optimum dilutions in order to prevent halide interference. Yet

Table 2
Comparison of the values obtained by present method with standard PAR method

12	187 120	0.5	63	6.5	69	67

* Based on average of four determinations.

an other consequence of the modification suggested is that since there is total removal of halides, addition of mercuric nitrate, it was felt was unnecessary and superfluous. This in fact was confirmed experimentally, by processing a set of samples in duplicate and comparing the absorbance values of the set to which mercuric nitrate is added, with that of the set to which mercuric nitrate is not added. It was noticed that there was no difference in the absorbance values. Thus in the present work, use of mercuric nitrate has been dispensed with, completely. The exclusion of the use of mercuric nitrate is an added advantage in view of its poisonous nature and its possible pollution of the environment.

In order to validate the suggested method, the values obtained have been compared with the values obtained by standard PAR [11,12] method after preconcentration. Further validation was made by standard addition technique. The results obtained on a batch of 12 samples has been incorporated in Table 2 along with the relative standard deviation. The results obtained by PAR method and the standard addition technique are also given along with. Typical plots obtained for five random samples by standard addition technique are given in Fig. 2. It is seen that results compare well.

4. Conclusions

A simple, precise and accurate method has been suggested as a modification to the existing standard method, for determining vanadium in the chloride rich hydrogeochemical samples. It involves a preliminary fume drying of the sample with a mixture of perchloric and sulphuric acids. The procedure helps in overcoming the interference effects caused due to presence of halides. Depending on the nature (high or low total dissolved salt content) and quantity of the sample aliquot taken, the method can be extended to determine vanadium down to 1 ppb. The relative standard deviation ranges from 8.2 to 4.0% for the concentration range 10 to 400 ppb. Also the use of mercuric ion has been dispensed with.

Acknowledgements

The authors wish to thank the Regional Director, western region and the Head Chemistry Group, for their kind encouragement to carry out the above work. Sincere thanks are also due to Shari PK Shrivastava, Dr Ravikumar and Shri Hanumanthappa for providing water samples.

Applying magnesium hydroxide coprecipitation method for trace analysis to dialysis concentrate

Latif Elçi *, Sibel Saraçoğlu

Chemistry Department, Art and Sciences Faculty, Erciyes University, 38039 Kayseri, Turkey

Received 28 July 1997; received in revised form 17 November 1997; accepted 20 November 1997

Abstract

A magnesium hydroxide coprecipitation technique for determination of Cd, Co, Cu, Mn, Ni in dialysis concentrate is described. The analytes are concentrated from 10 ml of dialysis concentrate into 1 ml of 1 M HNO₃ and subsequently determined by graphite furnace atomic absorption spectrometry. Coprecipitation parameters and matrix effects are discussed. The precision, based on replicate analysis, is around 5% for the analytes, and recovery is quantitative, based on analysis of spiked samples and solutions including matrix components. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Coprecipitation; Magnesium hydroxide; Dialysis concentrate

1. Introduction

Coprecipitation by hydroxides of metals is frequently used in the preconcentration of trace amounts of analytes, generally using a milligram quantity of carrier element [1,2]. Among metal hydroxides, magnesium hydroxide is the most attractive gathering precipitate due to the quantitative trace recovery of some elements and sufficient separation factors for alkaline elements [3–5]. It is especially useful for high salinity samples, such as sea water, dialysis concentrate, etc., including

magnesium ions at high enough concentration levels.

To the best of our knowledge, a magnesium hydroxide coprecipitation system has not been applied to the analysis of dialysis concentrate. Whereas, such a coprecipitation system would be ideal for analysis of dialysis concentrate because of an appropriate magnesium content. Furthermore, the contamination for the analysis would be significantly decreased, as it would only be from the sodium hydroxide solution used for pH adjustment.

In this study, the method of determination of the concentrations of cadmium, cobalt, copper, manganese and nickel in a dialysis concentrate has been critically discussed and extended.

2. Experimental

2.1. Apparatus

A Hitachi Model Z-8000 atomic absorption spectrometer with a Zeeman background corrector was employed for the determination of analytes ions in the aqueous solution. An air–acetylene flame was used for the determinations related to model workings. The sample solutions were introduced into the nebulizer using an injection technique [6]. A Hitachi Model graphite furnace atomizer (Part no. 180-7400) was used for the determination of Cd, Co, Cu, Mn and Ni in the dialysis concentrate. The conditions for AAS measurements were as recommended by the instrument manufacturer.

A pH meter, Delta 320 Mettler, was employed for measuring pH values in the aqueous phase.

2.2. Reagents and solutions

Stock standard solutions of analytes, 1000 mg l⁻¹, were diluted daily for obtaining reference and test solutions. Water, redistilled in a quartz apparatus, was used in all the experiments. Sodium hydroxide (suprapure grade, Merck) was used for preparation of 6 M NaOH solutions and pH adjustment. Two mg ml⁻¹ Mg²⁺ as nitrate salt was prepared freshly from solid magnesium nitrate hexahydrate (suprapure grade, Merck). Nitric acid (65%) used for preparation of dilute acid solution was suprapure grade from Merck.

3. Procedures

3.1. Test working

The coprecipitation method was tested with model solutions prior to its application to dialysis concentrate. Five hundred microliters of 2 mg ml⁻¹ magnesium solutions were added to 10.0 ml of a solution containing 1–0.5 µg of Cd, Co, Cr, Cu, Mn, Ni and Pb. Then, a certain amount of 6 M NaOH solution was added to adjust the pH or NaOH concentration. After 10 min, the solution was centrifuged at 3500 rpm for 30 min. The

supernatant was removed. The precipitate remaining adhered to the tube was dissolved with 1 ml of 1 M HNO₃. To determine the analytes, 100 µl of this final solution was injected into the flame AAS nebulizer. There were three replicates for the test workings.

3.2. Analysis of dialysis concentrate

Exactly 10.0 ml of dialysis concentrate is placed into a 15-ml glass centrifugation tube. To form a magnesium hydroxide precipitate and to run coprecipitation, the pH of the concentrate is adjusted to 12.7 with 6 M NaOH solution. A certain amount of the NaOH solution is previously determined with a pH meter using a reference dialysis solution. The tube is slowly and carefully shaken for several seconds and allowed to stand for 10 min. The precipitate is centrifuged at 3500 rpm for 30 min, and the supernatant is discarded. A small precipitate adheres to the bottom of the tube. Then, 1 ml of 1 M HNO₃ is added to dissolve the precipitate. The analytes in this solution are determined with graphite furnace AAS using matrix matching standards.

4. Results and discussion

4.1. Coprecipitation of some metal ions with magnesium hydroxide

Initially, an attempt was made to examine the effect of magnesium concentration, due to the magnesium matrix, on the determination of the desired elements, using flame atomic absorption spectrometry. The absorbances for the elements remained almost constant up to about 40 mg ml⁻¹ Mg²⁺, however, above this concentration a decrease in the absorbances (increase for Pb) was observed. This indicates that the concentration of magnesium in the final solution for the combination of coprecipitation with flame AAS must be a maximum of 40 mg ml⁻¹.

The amount of magnesium ion needed for coprecipitation was selected experimentally. As can be seen from Table 1, the recoveries of desired metal ions from solution prepared with increasing

Table 1
Effect of magnesium amount on coprecipitation ($n = 3$)

Amount of Mg (μg)	Recovery (%)						
	Cd	Co	Cr	Cu	Mn	Ni	Pb
0	63	67	52	73	69	72	30
250	80	80	86	99	90	82	89
500	82	96	88	97	96	87	94
750	83	95	93	97	96	95	96
1000	85	98	97	100	98	95	95
1250	86	97	97	99	98	96	95
1500	88	96	95	99	96	97	96
3000	85	96	98	98	97	98	96
4500	89	97	95	97	95	100	95

amounts of magnesium ion in 0.05 M NaOH (pH 12.7) were quantitative after 0.25 mg Mg^{2+} for Cu, 0.50 mg Mg^{2+} for Mn and Co, 0.75 mg Mg^{2+} for Ni and Pb, and 1.0 mg Mg^{2+} for Cr. With these amount of Mg^{2+} , as the recoveries decrease, the precision of the results was also poor. The recoveries for Cd were lower than 88%. Magnesium hydroxide was precipitated at different pH values from test solution containing 1 mg magnesium and fixed trace amount of desired elements, such as 1 μg for Cu, Co, Cr, Mn, Ni, Pb and Fe, and 0.5 μg for Cd. pH values were adjusted with 6 M NaOH solution. A bulky precipitate of magnesium hydroxide formed with 0.005 M NaOH (pH 11.7), collecting significant amounts of Cu, Mn and Co as shown in Table 2. However, all metal ions of interest were virtually completely coprecipitated in the range of 0.01–1 M NaOH. In this work, the optimum concentration of NaOH was taken as 0.05 M (pH 12.7).

4.2. Effect of matrix ions

To detect potential interference on the coprecipitation of examined elements, various amounts of NaCl, KCl, CaCl_2 , CH_3COONa and dextrose, as the major components of dialysis concentrate, were added to a solution containing the examined elements at the fixed amounts, and then the procedure was followed. The maximum concentrations of the components were selected, based on the data given in Table 3 [7,8]. The results are listed in

Table 4. Of all the components (except NaCl) in the concentration ranges investigated, Pb and Cr were the ones which were generally affected. The others were not affected. From the comparison of dialysis concentrate compositions given in Table 3 with the tolerable concentrations found in Table 4, it can be concluded that Co, Cu, Mn and Ni will be recovered quantitatively from the dialysis concentrate. The tolerable concentrations for the matrices are defined as the concentration causing a relative error smaller than $\pm 5\%$ in relation to the determination of examined analytes. However, Cd can be determined with 85% recovery. The results are desirable in view of application to the dialysis concentrate sample. On the other hand, the precipitation of calcium ion, as a hydroxide in the dialysis concentrate, can be expected at the optimum pH 12.7. However, it may be concluded that this is not important because of the quantitative recoveries of the analytes. The coprecipitation of calcium hydroxide with analytes was not investigated in this work.

4.3. Accuracy, precision and detection limits

To ensure that this procedure was valid for real sample analysis by GFAAS, the recoveries of analytes spiked into dialysis concentrate as a real sample were also studied; satisfactory results were obtained, as shown in Table 5. The analytical errors for Cd, Cu, Mn, Ni are in the range of -4.1 to $+5.6\%$. The relative error in the deter-

Table 2
Effect of NaOH concentration on coprecipitation ($n = 3$)

NaOH Conc. (M)	Recovery (%)						
	Cd	Co	Cr	Cu	Mn	Ni	Pb
0.005	10	35	5	69	40	20	5
0.01	86	97	98	98	97	98	98
0.05	85	97	97	99	98	97	96
0.1	85	98	96	100	100	98	96
1	79	100	95	100	99	100	40

mination of Cd was higher than 10%. Also, the errors found from the test solutions with or without the matrix ion were at the same level as Cd (Tables 1, 2, 4 and 5). However, the results for the determination of cadmium are considerably replicable (R.S.D., 6.2%). Also, the accuracy of results was confirmed by use of a Co-DDTC coprecipitation method [9]. As seen from Table 6, there is no significant difference between the concentrations of analytes, except for Ni, obtained by the two methods.

The relative standard deviations for graphite furnace atomic absorption spectrometric measurements are between 4.7 and 7.7% in the case of $0.87\text{--}3.29 \mu\text{g l}^{-1}$ of analytes.

The detection limits, defined as the concentration equivalent to three times the standard deviation ($n = 10$) of the reagent blank, for graphite furnace atomic absorption spectrometric measurements, were $0.08 \mu\text{g l}^{-1}$ for Cd, $0.24 \mu\text{g l}^{-1}$ Co,

$0.33 \mu\text{g l}^{-1}$ Cu, $0.15 \mu\text{g l}^{-1}$ Mn and $0.74 \mu\text{g l}^{-1}$ Ni.

4.4. Analysis of dialysis concentrate

Based on the above findings, the procedure was applied to a dialysis concentrate analysis. The results are summarized in Table 6. The analytes in the final solution obtained with the coprecipitation were determined using a graphite furnace atomic absorption spectrometer using matrix matching standards. Previously, the magnesium content of dialysis concentrate was determined with flame AAS. The content of Mg^{2+} was found to be $390 \mu\text{g ml}^{-1}$. Accordingly, the standard solutions used for the calibration curves include $4 \text{ mg ml}^{-1} \text{ Mg}^{2+}$, calculated according to 10 ml of dialysis concentrate.

The concentrations given in Table 6 have been calculated on the assumption of 100% recovery of the analytes. The results from magnesium hydroxide coprecipitation are compared with results obtained by the Co-DDTC coprecipitation method [9], using a *t*-test at 95% C.L. The dialysis concentrates, having the same production date, analysed in this work and given in Ref. [9], are from the same company. With the exception of Ni, no significant difference is indicated between the results obtained by two techniques. For nickel, there is also a significant difference between the concentrations at 99% C.L. If the results in Ref. [9] are acceptable as a true value, the analytical errors for Cd, Cu and Mn (except Co and Ni) are less than 8%.

Table 3
Composition of typical dialysis concentrate

Determination of arsenic content in natural water by graphite furnace atomic absorption spectrometry after collection as molybdoarsenate on activated carbon

Toshio Kubota *, Tetuya Yamaguchi, Tadao Okutani

College of Science and Technology, Nihon University, 7-24-1, Narashinodai, Funabashi-shi, Chiba 274, Japan

Received 16 September 1997; received in revised form 20 November 1997; accepted 21 November 1997

Abstract

A sample solution containing less than 0.5 μg of As was adjusted to pH 2. As in the solution was collected on activated carbon (AC) as molybdoarsenate. The AC was directly introduced as an AC suspension into a graphite furnace atomizer, and the concentration of As was determined by atomic absorption spectrometry (AAS). This method is relatively free from interference caused by coexisting ions. The calibration curve was linear up to 0.1 mg l^{-1} , and limit of detection of As was 0.004 mg l^{-1} . When 1000 ml of sample solution is preconcentrated to 5 ml (enrichment factor is 200-fold) 0.02 $\mu\text{g l}^{-1}$ of As could be determined, and relative standard deviation was below 4.0% (by the deuterium background correction system). The method was applied to sea water and well water, and the sum of As(III) and As(V) was determined with satisfactory results. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Arsenic; Natural water; Graphite furnace atomic absorption spectrometry; Molybdoarsenate; Activated carbon

1. Introduction

Arsenic causes severe poisoning in man, and a chronic effect can appear from it in the body even at a low intake level. Carcinogenicity of the skin and the lungs has been attributed to As [1]. Therefore, accurate determination of As has become of increasing importance.

Determination of As content was previously carried out by spectrophotometry of 12-molybdoarsenic acid [2] and silver diethyldithiocarba-

mate [3]. For the determination of low concentrations of As, the extraction of 12-molybdoarsenic acid into 1-butanol [4], adsorption with thionalide loaded on silica gel [5], and preconcentration of molybdoarsenate–malachite green aggregate [6] were combined with the spectrophotometry.

Atomic absorption spectrometry (AAS) is an easy, rapid method and has been widely used for the determination of trace elements in natural water. However, it has not been used for direct determination of As because of poor sensitivity. The sensitivity is greatly enhanced by coupling a

* Corresponding author. Fax: +81 474 695324

hydride generation method with flame [7–10] and flameless [11,12] atomic absorption spectrometry. Walcerz et al. [13] and Sturgeon and Gregoire [14] reported unique preconcentration methods. That is, generated hydrides were transferred to the inner wall of the graphite furnace, then the furnace was heated at a high temperature, vaporized As was determined by AAS [13] and ICP-MS [14]. However, the hydride generation method has a tendency to interference by coexisting ions [15]. To remove this drawback, a flotation was reported [16] by which As is coprecipitated with Fe(III) hydroxide and determined by hydride generation AAS.

Other preconcentration methods for As without using the hydride generation method have been published. Hata et al. [17] reported that the As in natural water was preconcentrated on a membrane filter as an ion associate of molybdoarsenate and tetrapentylammonium, and the As was determined by inductively coupled plasma atomic emission spectrometry. Peräniemi et al. [18] reported that the As in aqueous solution was adsorbed onto zirconium-loaded AC and was determined by X-ray fluorescence spectrometry.

In this report, a trace level of As in natural water was collected as molybdoarsenate onto AC. The AC suspension was directly introduced into a graphite furnace (GF), and As was determined by AAS. This method is free from interference caused by coexisting ions, and furthermore, the sum of As(III) and As(V) in clean water was simultaneously determined without digestion. This method was applied to sea water and well water.

2. Experimental

2.1. Apparatus

A Seiko Model SAS 727 atomic absorption spectrometer equipped with a Model SAS 705V graphite furnace (GF) atomizer, an As hollow-cathode lamp and a deuterium background corrector were used. The optimum operating conditions are listed in Table 1. A Hitachi Model Z8270 polarized Zeeman atomic absorption spec-

trometer was also used for comparison with of another background corrector. An ultrasonic cleaner Model B2200 (Bransonic) was used for the preparation of the AC suspension.

2.2. Reagents

The standard As(III) solution (1000 mg l^{-1}) was prepared by dissolving 0.1320 g of As_2O_3 (Wako) in 5 ml of 6 M NaOH solution, neutralizing with 6 M HCl and diluting it to 100 ml with deionized water. The standard As(V) solution (1000 mg l^{-1}) was prepared by dissolving 0.4165 g of $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$ (Nakarai Tesque) in deionized water and diluting to 100 ml. Five percent (w/v) Mo solution ($0.52 \text{ mol Mo l}^{-1}$) was added to 9.20 g of $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$ (Wako, super special grade) dissolved in deionized water and diluted to 100 ml. One percent (w/v) Zr solution was prepared by dissolution of 2.93 g of $\text{ZrO}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ in deionized water and was diluted to 100 ml. Activated carbon (AC, Merck No. 2186, smaller than 300 Tyler mesh) was soaked in 3 M HCl for 1 day, washed with deionized water until it was neutral, and was then dried at 120°C for 2 h and kept in a desiccator. All other reagents were of analytical grade.

2.3. Preconcentration and determination procedure

Up to a 1000-ml portion of the sample solution containing less than $0.5 \mu\text{g}$ of As was placed in a

beaker. Acetic acid (3 M) was added to the sample solution to make 0.1 M acetic acid, which was adjusted to pH 2.0 with 1 M HCl. Then 0.1 ml of 5% (w/v) Mo solution per 100 ml of sample volume and 0.1 g of AC were added. The solution was stirred for 10 min with a magnetic stirrer. The AC with adsorbed As was separated from the aqueous phase through a membrane filter (MF, 3- μ m pore size), and the AC on the MF was dispersed in 5 ml of 0.1 M acetic acid (containing 0.1 ml of 1% (w/v) Zr solution) using an ultrasonic cleaner for 30 s (AC suspension). Ten μ l of magnetically stirred AC suspension was pipetted into the GF. The peak height of AAS was measured under the conditions shown in Table 1.

3. Results and discussion

3.1. Analytical conditions

As is an easily volatilized element in GF-AAS. However, in this method, As is not easily lost by volatilization without matrix addition, because there is up to 840 μ g Mo in 5 ml of the AC suspension and it should act as a matrix modifier. However, the peak height of As decreased according to the heating time of exposure in the GF. Therefore, 0.1 ml of 1% (w/v) Zr solution (1 mg of Zr) was added to 5 ml of the AC suspension as a matrix modifier in a manner similar to that described in the previous paper [19]. Under these conditions, using a pyrocoated graphite tube as the GF, the effects of the ashing and atomization temperatures were investigated at from 400 to 1400°C and from 2300 to 2800°C, respectively. The conditions under which stable and maximum peak heights were obtained were an ashing temperature of 1200°C and an atomization temperature of 2600°C. Atomic absorption measurement of As has been recommended using resonance lines at 193.7 and 197.2 nm. The line at 193.7 nm was more sensitive than at 197.2 nm according to this method. However, the absorbance of blanks at 193.7 and 197.2 nm, respectively, were 0.032 and 0.0064. This phenomenon did not occur without molybdenum. Therefore, there should be a spectral interference with molybdenum. From this

reason, the line at 197.2 nm was used for measurement of the atomic absorption of As.

3.2. Effect of pH on the adsorption of As onto the AC

The effects of pH on the adsorption of As(III) and As(V) onto the AC in 100 ml of sample solution were investigated from pH 1.0 to 6.0 with the procedure described in Section 2.3. The results are shown in Fig. 1. As was not contained in 5 ml of the filtrate obtained by the adsorption procedure of As(III) and As(V) in 5 ml of sample solution at pH 1.0 to 3.0. Furthermore, As contents in the AC suspension from 5 and 100 ml of the sample solution were in agreement. Therefore, As(III) and As(V) were quantitatively adsorbed onto AC in the pH range from 1.0 to 3.0. The method does not tend to suffer from interference from coexisting ions in a strong acidic range. Consequently, the optimum pH of 2.0 was employed for the adsorption of As(III) and As(V) onto the AC.

3.3. Effect of amount of Mo and AC

The suitable amount of Mo for the adsorption of As(III) and As(V) onto AC was determined. A 0.02–1.0-ml portion of 5% (w/v) Mo solution (1–50 mg Mo) was added to 100 ml of sample solution (containing 0.25 μ g of As) at pH 2.0, and the solution was stirred for 10 min. The amount of As(III) and As(V) adsorbed onto the AC was examined. The results are shown in Fig. 2. As(III) and As(V) were not adsorbed on AC without addition of Mo but were quantitatively adsorbed with the addition of 0.04–0.2 ml of 5% (w/v) Mo solution (2–10 mg of Mo). The recovery of As(III) and As(V) gradually decreased as the amount of Mo increased by more than 10 mg. Similarly, the amount of Mo necessary for the adsorption of As(III) and As(V) in 500 ml of sample solution was determined. The results are shown in Fig. 3. As(III) and As(V) were quantitatively adsorbed by the addition of 5–40 mg of Mo per 500 ml. The recovery of As decreased in the presence of more than 50 mg of Mo. Based on these results, 0.1 ml of 5% (w/v) Mo solution (5

Fig. 1. Effect of pH on the adsorption of As onto the AC. (○) As(III); (△) As(V); As, 0.25 μg ; 5% (w/v) Mo solution: 0.1 ml. AC: 100 mg; stirring time, 10 min; 100 ml of sample solution was concentrated to 5 ml of sample suspension.

mg of Mo) per 100 ml of sample solution was employed for the proposed procedure.

The effects of the amounts of AC for adsorption of As(III) and As(V) at pH 2.0 were investigated. As(III) and As(V) were quantitatively adsorbed by the addition of 50–150 mg of AC. Therefore, 100 mg of the AC was employed for the proposed procedure.

3.4. Effect of the sample volume

The effect of the sample volume on the recovery of As(III) and As(V) onto AC was investigated by the proposed procedure. When 5 mg of Mo per 100 ml of sample solution was added and stirred for 10 min or more, As(III) and As(V) in 50–1000 ml of sample solution were quantitatively adsorbed onto AC.

3.5. Calibration curves

The values of the absorbance of As with matrix-matched standard solution without AC and the AC suspension differed according to the heating time of exposed GF. Therefore, a calibration curve was prepared from the AC suspension which was preconcentrated from 50 ml of the standard solution. The value of absorbance of the AC suspension did not change after 10 days. The calibration curves obtained by the AC suspension of As(III) and As(V) were in agreement and were linear up to 0.1 mg l^{-1} of As. The linear regression equation (absorbance and As concentration mg l^{-1}) was $y = 3.08x + 0.004$, and the correlation coefficient was 0.9997. Using this equation, the limit of detection of As was calculated to be 0.004 mg l^{-1} ($\bar{X}_{bl} + 3\sigma_{bl}$). When 1000 ml of sam-

ple solution was preconcentrated to 5 ml, 0.02 $\mu\text{g l}^{-1}$ of As could be determined.

3.6. Effect of foreign ions

The effect of foreign ions coexisting in sea water on the determination of As(III) and As(V) was investigated. A 100-ml portion of sample solution containing 0.25 μg of As and the foreign ions was concentrated to 5 ml of AC suspension, and the As content was determined by the proposed method. Because the recovery of As was $100 \pm 10\%$, the presence of foreign ions was regarded as having no effect. The experimental results are shown in Table 2. The sum of As(III) and As(V) in natural water which contains a sea water level concentration of foreign ions should be determined by the proposed method.

3.7. Determination of As in natural water

The proposed method was applied to the determination of As in natural water. The water samples were first filtered under pressure (0.8–1.0 atm) through a MF (0.45- μm pore size) to remove the suspended matter. The filtrate without digestion was then preconcentrated by the proposed method, and the sum of As(III) and As(V) was determined by AAS with the deuterium background correction system, and with the polarized Zeeman background correction system. The analytical results of the original sample solution and of this sample solution, to which a known amount of As(III) and As(V) was spiked, are shown in Table 3. The sum of As(III) and As(V) values with both systems was in good agreement. The recoveries of the spiked As(III) and As(V) were in the range of 95–110% for well water and in the

range of 92–97% for the sea water. Sturgeon et al. [20] quantified As species in river water reference material. According to their data, the sum of As(III) and As(V) was about 65% of the total arsenic value. It is assumed that organic arsenic

As, 0.25 μg ; 5% (w/v) Mo solution, 0.1 ml. AC, 100 mg; 100 ml sample solution was concentrated to 5 ml of the sample suspension. When the recovery of As is within $100 \pm 10\%$, the foreign ion is regarded as having no effect.

species, such as disodium methyl arsonate, are also contained in sea water. Therefore, a digestion method for sea water was investigated. The tested digestion procedure [21] was as follows: 100 ml of filtrate, which had been filtered through a MF to remove the suspended matter, was placed in a beaker. Seven ml of 9 M H_2SO_4 and 5 ml of conc. HNO_3 were added and evaporated on an aluminum dry bath (bath temperature was about 155°C) until dense white fumes of SO_3 just appeared. The wall of the beaker was rinsed with a small amount of deionized water, and evaporation to the point fumes of SO_3 appeared was repeated. The sample was not dried during digestion. After cooling, the sample was diluted to about 100 ml of 0.1 M acetic acid and heated to almost boiling to dissolve the slowly soluble salt, and the solution was adjusted to pH 2.0 with 3 M HCl. The sample and blanks were analyzed with the procedure described in Section 2.3. The results are shown in Table 3. The obtained total As value was about 95% relative to the value of the sample without digestion. Kohno et al. [22] pointed out that As tends to be lost by volatilization during H_2SO_4 and HNO_3 digestion. From these results, further investigation of digestion should be done.

3.8. Discussion of the adsorption mechanism

It is well-known that 12-molybdoarsenate is formed by the reaction of As(V) and molybdate ions [17], but the reaction of As(III) and molybdate ions is little known. However, the proposed method in which As(III) and As(V) were adsorbed onto AC involved the presence of molybdate ions. Therefore, the mole ratio of As and Mo adsorbed onto AC was investigated. A 0.05-ml Mo solution (5% (w/v), 2.5 mg Mo) and 0.1 g of AC were added to 50 ml of pH 2.0 sample solution containing 0–0.5 μg of As, and the solution was stirred for 10 min. The AC with adsorbed As and Mo was separated from the solution through a MF. Mo and As on the AC were dissolved with successive conc. HCl and aqua regia treatment by heating at 145°C in the same manner shown in the previous paper [19]. According to this dissolution method, the Mo content was about 840 μg in 0.1 g of AC, and was independent of the As content.

^f Sea water was digested with H₂SO₄ and HNO₃.

^g RSD, relative standard deviation.

Therefore, the adsorption ratio of As and Mo onto AC could not be determined.

Next, in order to clarify the adsorption mechanism in the proposed method, the addition order of As, Mo and AC was varied. Method A: the solution containing As and Mo was adjusted to pH 2.0, and AC was immediately added. Method B: the solution containing As and Mo was adjusted to pH 2.0, stirred for 5 min, and then AC was added. Method C: AC was added to the Mo solution at pH 2.0 and stirred for 20 min. The AC with adsorbed Mo was separated from the solution through a MF. The wet AC on the MF was added to the As solution of pH 2.0. In methods A, B and C, each solution was stirred for the prescribed time and treated with the procedure described in Section 2.3. The results are shown in Fig. 4. As(V) is quantitatively adsorbed on the

AC within 2 min or above in every method. On the other hand, As(III) is adsorbed within 2 min or above in methods A and B, but in method C it is adsorbed at less than 15% of recovery up to 10 min. The molybdate ions are easily adsorbed on AC, and the AC adsorbs As(V), but it does not adsorb As(III) up to 10 min in method C. Based on these results, it is assumed that As(III) is oxidized to As(V) and is adsorbed as an molybdoarsenate complex onto AC. This assumption was investigated. The effects of dissolved oxygen in aqueous solution and adsorbed oxygen on AC for the oxidation of As(III) were examined. The procedure was as follows: dissolved oxygen in 1 mg l⁻¹ As(III) in pH 2.0 solution and in 5% (w/v) Mo solution were replaced separately with H₂ gas by blowing for 1 h. A 50-ml portion of pH 2.0 suspension containing 100 mg of AC was placed

Fig. 4. Effect of addition order of As, Mo and AC. (○) Method A: the solution containing As and Mo was adjusted at pH 2.0, and AC immediately mixed. (△) Method B: the solution containing As and Mo was adjusted to pH 2.0, stirred for 5 min, and then AC is mixed. (□) Method C: AC was added to Mo solution at pH 2.0 and stirred for 20 min. The AC-adsorbed Mo was separated through a MF. The wet AC on the MF was added to the As solution at pH 2.0. *In methods A, B and C each solution was stirred for the prescribed time and treated with the procedure described in Section 2.3. *As, 0.25 μg ; 5% (w/v) Mo solution, 0.05 ml; AC, 100 mg; 50 ml sample solution were concentrated to 5 ml of sample suspension.

in a 100 ml cylindrical flask. The flask was covered with a rubber stopper, which was equipped with a H_2 gas inlet, an outlet glass tube with a stopcock, and a sample injection glass tube with a

rubber stopper. The suspension in the flask was replaced with H_2 gas by blowing for 1 h and by evacuating five times with an aspirator and then filled with H_2 gas. Then, 250 μl of 1 mg l^{-1}

As(III) solution and 50 μl of 5% (w/v) Mo solution were injected into the suspension in the cylindrical flask, stirred for 5 min, and finally treated by the procedure described in Section 2.3. Dissolved oxygen in the solution and physically adsorbed oxygen on the AC should be substantially removed by blowing H_2 gas and five evacuations. However, the investigation showed that As(III) was quantitatively adsorbed onto the AC. Kamegawa et al. [23] reported the catalytic oxidation of 50 ml of 1 mg l^{-1} As(III) in aqueous solution by 50 mg of AC (stirred for 24 h). They concluded the overall reaction mechanism to be: the dissolved oxygen oxidizes As(III) to As(V), and the active surface oxide of AC acts as a catalyst. The authors proposed a method in which As(III) and As(V) are adsorbed onto AC in the presence of molybdate ion, the concentration of As(III) solution is very dilute (0.005 mg l^{-1}), and the stirring time is very short (10 min). With regard to oxidation, the method also differs from the report of Kamegawa et al. [23]. Based on these results, As(V) and molybdate ions in solution and molybdate ion adsorbed on AC form a molybdoarsenate complex and adsorb onto the AC. On the other hand, As(III) is oxidized to As(V) by the surface oxide on the AC, and this As(V) reacts with molybdate ion in solution, forms a molybdoarsenate complex, and is adsorbed onto the AC. If the molybdate ion has already been adsorbed on the surface of the AC, this interferes with the oxidation of As(III).

Determination of total thallium in fresh water by electrothermal atomic absorption spectrometry after colloid precipitate flotation

Trajče Stafilov *, Katarina Čundeva

Institute of Chemistry, Faculty of Science, St. Cyril and Methodius University, P.O. Box 162, 91001 Skopje, Macedonia

Received 25 April 1997; received in revised form 26 November 1997; accepted 2 December 1997

Abstract

Tl(I) and Tl(III) are preconcentrated simultaneously from aqueous solutions by colloid precipitate flotation using two collectors: hydrated iron(III) oxide ($\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$) and iron(III) tetramethylenedithiocarbamate ($\text{Fe}(\text{TMDTC})_3$). After the coprecipitation step and the addition of foaming agents, Tl(I) and Tl(III) were separated from the water by a stream of air bubbles. Various factors affecting Tl(I) and Tl(III) recoveries during the separation from water, including the collector mass, the nature of the supporting electrolyte, pH, ζ potential of the collector particle surfaces, type of tenside, etc., were investigated. Within the optimal pH range (6–6.5), establishing by a recommended procedure, Tl(I) and Tl(III) were separated quantitatively (94.9–100.0%) with 30 mg Fe(III). Both Tl ions were simultaneously separated without any previous conversion of one type of Tl ion to the other. Total Tl determination was performed by electrothermal atomic absorption spectrometry by previous matrix modification of the concentrated samples. The determination limit of Tl by this method is $0.108 \mu\text{g l}^{-1}$. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Determination; Electrothermal atomic absorption spectrometry; Precipitate flotation; Thallium; Water

1. Introduction

Thallium can be found in nature as Tl(I) and Tl(III) ions. The total Tl quantity in fresh water is $0.01\text{--}14 \mu\text{g l}^{-1}$ [1]. Because the level of this element in uncontaminated fresh water is very low, it needs to be preconcentrated before its instrumental analysis. Among the preconcentra-

tion procedures, such as liquid–liquid extraction, ion-exchange, coprecipitation, etc., flotation techniques prove to be very simple. They allow handling of large volumes of sample and considerable saving in reagents and time [2–4]. Flotation studies have been performed on most elements [4], but there is only one report for flotation of Tl ions [5]. Hualing and Side's work [5] describes ion flotation of Tl(I) and Tl(III) from hydrochloric–nitric acid solution prior to determination by spectrophotometry, overlooking the interference of chlorides on Tl(I) recoveries.

The present paper is the first attempt of a precipitate flotation preconcentration of total Tl, previously establishing the experimental conditions for successful separation of both Tl ions. Similar to a previously suggested method for total chromium preconcentration [6], electrothermal atomic absorption spectrometry (ETAAS) has been applied. The determination of total Tl has been performed without previous reduction or oxidation of one type of Tl ion to the other. The procedure involves the use of two collectors: hydrated iron(III) oxide ($\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$) and iron(III) tetramethylenedithiocarbamate ($\text{Fe}(\text{TMDTC})_3$). The same combination of collectors has been applied for the separation of several metals from sea water using neutron activation [7] or atomic absorption spectrometry [6,8], but not for Tl(I) and Tl(III). The coprecipitation efficiency of Tl(I) and Tl(III) with $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ was investigated. The effect of $\text{Fe}(\text{TMDTC})_3$, as a compound with a bigger hydrophobicity than $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$, on flotation recoveries of Tl(I) and Tl(III) was investigated. The interferences of chlorides on Tl(I) and Tl(III) flotation recoveries were studied. The method developed is simple, rapid and applicable to total Tl separation at $\mu\text{g l}^{-1}$ levels from a large volume of water.

2. Experimental

2.1. Apparatus

The apparatus employed in this work has been described previously [6]. A Tl Perkin-Elmer hollow cathode lamp was used as a source. The optimal instrumental parameters for ETAAS determination of Tl are given in Table 1. Inductively coupled plasma atomic emission spectrometry (ICP–AES) was performed using a Varian spectrometer Model Liberty 110 (Table 2). The flotation cell used to carry out the preconcentration and the equipment applied for electrophoretic determination of electrokinetic (ζ) potentials of the collector particle surfaces are the same as those used previously [6].

2.2. Reagents and standards

All chemicals used for preparation of solutions were of analytical-reagent grade except for ten-sides, sodium dodecyl sulfate (NaDDS) and sodium oleate (NaOL). The aqueous solutions were prepared in redistilled water. Stock solution of Tl(I) was made by dissolving a commercial standard solution (Titrisol, Merck) containing 1 g of Tl(I) in the form of TlNO_3 in 1 l water. The same commercial standard solution of TlNO_3 containing 1 g of Tl(I) was oxidized to Tl(III) with several drops of bromine. The solution was evaporated nearly to dryness (to expel the excess bromine) and the residue was diluted to 1 l. Before each investigation, series of Tl(I) and Tl(III) standards were freshly made by diluting these stock solutions of Tl(I) and Tl(III). Stock solution of $\text{Fe}(\text{NO}_3)_3$ was prepared by dissolving high purity Fe metal (21 g) in 60 ml conc. HNO_3 solution by heating. Thus all Fe was converted into the three-valent state. After cooling, redistilled water (500 ml) was added and the solution was filtered through the thickest filter paper. The

Peristaltic pump	12 rollers, 1 turn min^{-1} increment
Integration time	2 s, smart integration 5 s, direct reading instrument

mass concentration was $\gamma(\text{Fe}) = 30 \text{ g l}^{-1}$. The stock solution of FeCl_3 ($\gamma(\text{Fe}) = 30 \text{ g l}^{-1}$) was prepared in the same way as described previously [6]. Series of standards with the mass concentration of Fe ranging from 2.5 to 100 mg ml^{-1} were obtained by diluting these Fe stock solutions. The solution of ammonium tetramethylenedithiocarbamate (NH_4TMDTC) was prepared as 0.1 mol l^{-1} dissolving an appropriate quantity of NH_4TMDTC in water. Before each investigation

it was filtered. The 0.5% solutions of tensides were prepared by dissolving appropriate amounts of NaDDS and NaOL in 95% ethanol. Solutions of HNO_3 (0.1 mol l^{-1}) and KOH (2.5% and 10%) were used to adjust the medium pH. Solutions of KCl (3.57 mol l^{-1}) and KNO_3 (2.78 mol l^{-1}) were used to regulate the ionic strength of the medium, i.e. the coagulation of the collector precipitates.

2.3. Recommended procedure

The procedure is for uncontaminated fresh water. The samples investigated were tap water from the city of Skopje and water from Lake Ohrid. Immediately after sampling, the lake water was filtered through a Sartorius membrane filter (0.5 μm pores) to remove plankton. The tap water was not filtered. To prevent the possible hydrolytic precipitation of some mineral salts present in natural water with standing, a few millilitres of concentrated HNO_3 had to be added to 1 l of natural water. The pH had to be 2.5–3.

An acidified water sample (1 l) was placed in a 1000 ml beaker. After adding 6 ml of KNO_3 and 1 ml of 30 g l^{-1} $\text{Fe}(\text{NO}_3)_3$ solution, pH was adjusted to 6.3 with a solution of KOH (2.5% or 10%). To the solution with yellow–brown precipitate of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$, 2 ml of NH_4TMDTC solution were added. The precipitate changed colour to black $\text{Fe}(\text{TMDTC})_3$. After stirring for 15 min (induction time), 0.6 ml of NaDDS and NaOL alcoholic solutions were added and the contents of the beaker were transferred quantitatively into the flotation cell with a small portion of 0.1 mol l^{-1} NH_4NO_3 . Air (50 ml min^{-1}) was passed through from the perforated bottom of the cell for 1–2 min. Then, a glass pipette was introduced into the cell through the foam layer and the water phase was sucked off. Hot concentrated HNO_3 solution (10 ml) was added to the cell to destroy the scum. The solution was sucked off and collected in a volumetric flask (25 ml) through the bottom of the cell. The cell was washed with 4 mol l^{-1} HNO_3 solution. The flask was filled up to the mark with the same solution of HNO_3 and the sample was ready for AAS measurement. Before ETAAS determination of total TI, a matrix mod-

ification with H_2SO_4 of each sample concentrated by flotation should be made by adding 0.5 ml concentrated H_2SO_4 to 10 ml of each Tl solution concentrated by flotation.

3. Results and discussion

3.1. Coprecipitation with hydrated iron(III) oxide

The coprecipitation of Tl(I) and Tl(III) in the sublate particles of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$, as the first collector, was investigated through the mass of Fe, as a constitutive element of this collector. The series of flotations were carried out by addition of different Fe quantities (2.5–100 mg l⁻¹) to the working solutions at a constant pH (5.5) and ionic strength (0.02 mol l⁻¹) regulated with KNO_3 . Fe was added as $\text{Fe}(\text{NO}_3)_3$. At pH 5.5, there is not any coprecipitation of Tl(I) and the coprecipitation of Tl(III) is insignificant (62%). These data show that the role of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ as collector in the recommended procedure with two collectors at pH 5.5 was not decisive for Tl(I) and Tl(III) separation from water matrix. The first induction time used in the previous paper [6] can be reduced or omitted. The omission of the first induction time had shortened the performing of the method.

3.2. Influence of the $\text{Fe}(\text{TMDTC})_3$ mass and the presence of chlorides on flotation recoveries of Tl(I) and Tl(III)

Similarly as the previous investigations about the dependence of colligends recoveries on $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$, the dependence of Tl(I) and Tl(III) recoveries on $\text{Fe}(\text{TMDTC})_3$ was determined through the mass of Fe. The influences of Cl^- were investigated, floating each colligend separately in the presence and in the absence of Cl^- . In the presence of Cl^- , Fe was added as a solution of FeCl_3 and a solution of KCl served as a ionic strength adjuster. To perform the investigations without Cl^- , Fe was added as a solution of $\text{Fe}(\text{NO}_3)_3$ and a solution of KNO_3 was used to regulate the ionic strength.

When FeCl_3 and KCl were used, Tl(I) was not quantitatively separated (maximum up to 84.6%). This means that Cl^- interfere with the Tl(I) recoveries. However, if $\text{Fe}(\text{NO}_3)_3$ and KNO_3 were used (Table 3), Tl(I) recoveries became quantitative (94.9–100.0%). In this case, the minimum mass of Fe used for flotation of Tl(I) was 30 mg.

The investigation of the influence of Fe mass on Tl(III) recoveries in the presence of chlorides and nitrates show that Tl(III) could not float successfully at pH 5.5 independently of that if the combination FeCl_3 – KCl or the combination $\text{Fe}(\text{NO}_3)_3$ – KNO_3 was used. Probably the proper

Fig. 1. Dependence of Tl(I) flotation recovery R (%) on medium pH values in the presence and in the absence of chlorides. In the presence of chlorides: \times , $\gamma(\text{Tl}^+) = 1 \mu\text{g ml}^{-1}$; $*$, $\gamma(\text{Tl}^+) = 2 \mu\text{g ml}^{-1}$. In the absence of chlorides: \square , $\gamma(\text{Tl}^+) = 1 \mu\text{g ml}^{-1}$; \circ , $\gamma(\text{Tl}^+) = 2 \mu\text{g ml}^{-1}$.

preconcentration of Tl(III) in the presence of nitrates might be carried out within another pH range.

All obtained results are the mean of three replicates. Relative standard deviations of these measurements vary from 1.2% to 2.9% and the confidence intervals (95%) of the recovery values vary from 0.4% to 1.9%.

3.3. Influence of pH

The influence of medium pH on the Tl(I), i.e. Tl(III) recoveries, was studied floating series of solutions containing 25 and 50 μg Tl, within the pH range 3.5–6.5, with 30 mg Fe at constant ionic strength (0.02 mol l^{-1}). Investigation of pH values higher than 6.5 was not performed because at pH higher than 6.5 the compound $\text{Fe}(\text{TMDTC})_3$ did not exist because of its hydrolysis. Fe was added as solutions of FeCl_3 or $\text{Fe}(\text{NO}_3)_3$. The ionic strength was regulated with KCl and KNO_3 , respectively.

When the combination $\text{Fe}(\text{NO}_3)_3$ – KNO_3 was used, the Tl(I) recoveries within the range 5.5–6.5

are 95.5–100.0% (Fig. 1). As expected, when FeCl_3 –KCl was applied, the Tl(I) recoveries, within the same pH range, are insufficient (a maximal value is 86.0%). The proper preconcentration of Tl(III) was carried out with 30 mg Fe(III) within the pH range 6–6.5, when Tl(III) recoveries are 98.9–100.0% (Fig. 2). The use of the combination FeCl_3 –KCl or $\text{Fe}(\text{NO}_3)_3$ – KNO_3 had no appreciable effect on the flotation efficiency of Tl(III). The presence of Cl^- did not interfere with Tl(III) preconcentration.

The Tl(I) as well as Tl(III) recoveries within the pH range 3.5–5 were lower because of the hydrolysis of NaDDS and NaOL as anion. Within this pH interval the medium acidity influenced the function of these tensides. At lower pH values they were not in the form of anions, but in the form of molecules which were not able to perform their function as surfactants. Thus, lower pH values decrease their efficiency as surfactants, the foaming is not good and both the Tl(I) and the Tl(III) recoveries obtained within the pH range 3.5–5 are poor.

Fig. 2. Dependence of Tl(III) flotation recovery R (%) on medium pH values in the presence and in the absence of chlorides. In the presence of chlorides: ○, $\gamma(\text{Tl}^{3+}) = 1 \mu\text{g ml}^{-1}$; □, $\gamma(\text{Tl}^{3+}) = 2 \mu\text{g ml}^{-1}$. In the absence of chlorides: *, $\gamma(\text{Tl}^{3+}) = 1 \mu\text{g ml}^{-1}$; ×, $\gamma(\text{Tl}^{3+}) = 2 \mu\text{g ml}^{-1}$.

3.4. ζ potential of the collector flocs and choice of tenside

According to the signs of the $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ flocs (26.05 mV) as well as the ζ potentials of the $\text{Fe}(\text{TMDTC})_3$ flocs (46.5 mV), the two collectors needed anions for flotation. The anions NaDDS and NaOL were shown to be successful. The detergent NaDDS provides good foaming in hard water because of its soluble calcium and magnesium salts. The long flexible tail (the hydrocarbon chain) of NaOL increases the aerophilicity of collector particles. When NaOL was added to the system the air bubbles attached and fixed more easily to the collector particles surrounded by anions of tensides and the foaming was much better.

The more positive ζ potential of $\text{Fe}(\text{TMDTC})_3$ flocs than ζ potential of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ flocs has indicated that the froth layer obtained by the second collector $\text{Fe}(\text{TMDTC})_3$ should be more stable [9]. Namely, the anions of NaDDS and NaOL, orientated with their negatively charged sides (the head groups) to the positive surface of

the floc particles, should create stronger association with $\text{Fe}(\text{TMDTC})_3$ than with $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$. The experiment has demonstrated that if $\text{Fe}(\text{TMDTC})_3$ was used as collector the time of air bubbling during the step of flotation would be shorter (only 1 or 2 min). The froth layer obtained on the top of the liquid phase in the cell was better fixed at the gas–liquid interface and less exposed on reflux with standing. The separation of the froth layer of $\text{Fe}(\text{TMDTC})_3$ from the processed water phase was easier than the separation of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$.

3.5. Matrix modification of solutions concentrated by flotation

To destroy and dissolve the froth layer containing Tl(I) and Tl(III), a suitable acid should be used. The use of concentrated H_2SO_4 was unsuccessful. This acid helped to decompose the black $\text{Fe}(\text{TMDTC})_3$ compound but did not destroy the tensides. They hydrolysed, stood out as yellowish precipitate, made the system turbid and inappropriate for AAS determination. On the other hand,

when concentrated HNO_3 was used, due to its oxidizing properties the scum was destroyed and dissolved properly. A homogeneous clear yellow solution, suitable for AAS, was obtained, so the procedure was carried out using concentrated HNO_3 . However, it was shown that the nitrate form of Tl is inappropriate for ETAAS [10–13]. Namely, Tl nitrates start to atomize during the thermal pretreatment steps (drying and charring). So, before each Tl determination by ETAAS it was necessary to convert its compounds into more thermostable forms, i.e. to make the matrix modification. Because Tl sulfates are more thermostable than Tl nitrates [10–13], they should be transformed to sulfates. It was found experimentally that a matrix modification of the final solutions of Tl could be performed by adding 0.5 ml concentrated H_2SO_4 to 10 ml of each Tl solution concentrated by flotation.

3.6. Influence of Fe mass on Tl absorbance

The concentration of Tl made it possible to move its detection limit towards lower concentrations. However, it was important to examine the interferences resulting from the high Fe concentrated in the final testing solutions on the Tl absorbance during ETAAS determinations. For this purpose, a series of solutions with the same concentration of Tl ($0.05 \mu\text{g ml}^{-1}$) and different concentrations of Fe (from 0–1.6 mg ml^{-1}) were prepared and absorbance was measured. These investigations (Table 4) showed that the Tl absorbances changed insignificantly up to 1.6 mg ml^{-1} Fe, confirming the results of Dulski and

Table 4
Influence of iron mass on thallium absorbance

Sample no.	$\gamma(\text{Tl}) (\mu\text{g l}^{-1})$	$\gamma(\text{Fe})$ (mg l^{-1})	$(A/A_0) \cdot 100$
1	0.50	0	—
2	0.50	10.0	100.0
3	0.50	20.0	99.3
4	0.50	30.0	99.8
5	0.50	35.0	99.8
6	0.50	40.0	97.9

Bixler [14] and our previous results [12,13] about Fe interferences on Tl determination by ETAAS. This means that 30 mg of Fe added to 1 l of investigated water does not interfere in the final enriched solution.

3.7. Determination limit

To evaluate the detection limit of the method ten successive blank measurements were made. The detection limit ($0.08 \mu\text{g l}^{-1}$) was estimated as three values of the standard deviation ($0.027 \mu\text{g l}^{-1}$). The relative standard deviation for the blank was 5.02%. We found that the determination limit for Tl is $0.108 \mu\text{g l}^{-1}$ (as four values of standard deviation).

3.8. Analysis of natural water

The applicability of the proposed procedure has been verified by the ETAAS analysis of natural water samples with the method of standard additions. For this purpose, known amounts of Tl were added to 1 l aliquots of lake and tap water samples and then were floated and tested by ETAAS. The recoveries of 95.0–101.4% show that the preconcentration and separation of Tl are satisfactory (Table 5). The results obtained by ETAAS were compared with the results obtained by ICP–AES determinations. The samples for ICP–AES were prepared by concentration by evaporation (from a volume of 1 l to 25 ml) of tap and lake water (containing from 1–20 $\mu\text{g l}^{-1}$ Fe). A calculation of Student's *t*-test for the ETAAS and ICP–AES results gives the values in the range 2.04 for water sample from Labino to 2.65 for sample from Ljubaništa, whereas the theoretical value (95%) of *t* was 2.78. As can be seen, *t* values are smaller than theoretical values, there is no significant difference between the two methods.

4. Conclusion

The experimental conditions for ETAAS determinations of total Tl following colloid flotation have been established. To avoid the Cl^- interfer-

ences on the Tl(I) recoveries, reagents containing Cl^- should not be used. The use of $\text{Fe}(\text{TMDTC})_3$, as a second additional collector, improves separation of Tl(I) and Tl(III) from processed water phase. The dithiocarbamate added increases the hydrophobicity of the sublate which is the most important criterion for successful flotation. The value of ζ potential of the $\text{Fe}(\text{TMDTC})_3$ flocs is more positive than the ζ potential of $\text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ flocs, resulting in better separation efficiency. Matrix modifications of Tl salts of nitrates in sulfates improve the ETAAS determination.

Abstract

Multi-wavelength detectors offer improved detection capabilities for liquid chromatographic methods, but require multivariate approaches to utilise all the available information. The photodiode-array detector in high-performance liquid chromatography (HPLC) generates a three-dimensional data matrix, which is conventionally presented as an isometric projection or a contour plot. In this work, a new graphical technique is described for improving the quantitative results obtained from HPLC, using the available spectrochromatographic information in both the time and wavelength domains. The technique consists of performing cross-sections through the data matrix to obtain the maximum analytical information for each of the analytes. Hence, the resolution of overlapping peaks and the sensitivity in the determination are optimised. In order to demonstrate the validity and simplicity of the approach, the method has been applied to the resolution of synthetic mixtures of iprodione, procymidone and chlorothalonil. Also, the method has been satisfactorily applied to the simultaneous determination of the pesticides in environmental groundwater samples. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Multi-wavelength detectors for liquid chromatography have become increasingly available in analytical laboratories. UV-visible and, to a lesser extent, fluorescence based array detectors have

been used to gain more relevant analytical information from the mixtures of interest [1–3]. For example, the possibility of examination of the whole absorption spectrum at the peak allows the assignment of peak purity, and the investigation of homogeneity of a chromatographic peak.

In this context, it is very common to describe, as the most significant applications or advantages of high-performance liquid chromatography

* Corresponding author. Tel.: + 34 24 289378; fax: + 34 24 289375; e-mail: arsenio@unex.es

(HPLC) with diode-array detection, the following: (1) the simultaneous detection of two kind of compounds absorbing at different wavelengths, avoiding the need of performing two injections of the sample; (2) the development of methods of amplification and/or dilution of the sample, based on the reading of the absorbance of the standards at diverse wavelengths; (3) the verification of the spectral purity of the peaks, by scanning several absorption spectra at different zones of the chromatographic peaks. However, this multi-wavelength information is often not used for quantification, but instead a single wavelength is selected to obtain the calibration models. Much of the quantitative information available from these three-dimensional multi-wavelength (A, λ, t) data matrices is therefore wasted.

The spectrochromatographic data are usually represented as a three-dimensional projection, where slices in the time domain generate the elution profile at a fixed wavelength, while slices in the wavelength domain generate the absorption spectra at specified elution times. Alternatively, the data can be presented in two dimensions by using the cartographer's technique of contour plotting. Thus, the isoabsorptive contours are mapped in the (λ, t) plane. In this way, computer-aided manipulation of spectral and chromatographic data allows a number of digital methods to be exploited for enhanced detection sensitivity and selectivity [1,4], and opens up new approaches for the resolution of mixed solutes. Many of the algorithms developed for analytical spectroscopy can be used for data analysis in HPLC–UV-visible, and novel algorithms can be developed to exploit the combination of wavelength and time-domain data in the spectrochromatogram to extend the capabilities of liquid chromatography [5]. Various computer-aided graphical presentations such as spectral normalisation to aid visual assessment of the spectrochromatographic data matrix (A, λ, t) [6,7] and differentiation of the spectrochromatographic data have been applied [8–11]. A number of chemometric methods have also been proposed [7,12,13].

The objective of the present work is to examine the properties, limitations and potential applications of a new methodological approach, to extract the maximum analytical information from the data generated by a diode-array detector in HPLC. The method consists of the generation of cross-sections through the three-dimensional (A, λ, t) matrix, in a way similar to the several linear and non-linear synchronous techniques applied in luminescence spectroscopy, where a trajectory is performed through the three-dimensional (intensity, $\lambda_{\text{excitation}}, \lambda_{\text{emission}}$) luminescence matrix [14–17]. The proposed method allows the use of the spectral information for the deconvolution of overlapping peaks of analytes showing different absorption spectra, extending the potential applications of diode-array detectors in HPLC.

This method has been applied to the determination of iprodione, procymidone and chlorothalonil fungicides, in the presence of each other, in environmental groundwater samples. Generally, these compounds are determined by chromatographic methods, gas chromatography (GC) or HPLC. Methods of GC determination of iprodione, procymidone and chlorothalonil have been reported with thermoionic N-P [18], flame ionisation [19], electron-capture [20,21] and mass detection [22,23]. HPLC methods have been used with UV [24] and mass detection [22]. However, problems of selectivity can occur in multicomponent analysis because of the overlapping of peaks. Frequently, these pesticides are determined by using an a priori separation step [21,25,26], which is time consuming for routine analysis, and in some instances requires special and expensive instrumentation.

2. Experimental

2.1. Reagents

Analytical standards of known purity (99%, w/w) of iprodione, procymidone and chlorothalonil, were obtained from Riedel-de Haën (Seelze, Germany), and used without further purification. Acetonitrile (ACN) of analyti-

cal grade purity obtained from Panreac (Barcelona, Spain) was also used. Milli-Q water, obtained from Millipore Milli-Q filtration/purification system (Millipore, Bedford, MA) was used throughout.

2.2. Apparatus

A Waters (Milford, MA) 990 liquid chromatographic system was used, consisting of a Waters 600 E pump, a Rheodyne injection valve provided with a 20 μl loop, and a LC Waters 991 diode-array photometric detector. The spectral resolution used was 1.4 nm per diode in the range 200–250 nm.

2.3. Software

A compatible personal computer, provided with a 386 microprocessor and mathematical co-processor, was used for acquisition and treatment of the data. The LC system allows the acquisition of a series of chromatograms at different wavelengths (λ). The 991 Waters software controlling the instrument generates a three-dimensional file (A, λ, t) in binary format. Then, the three-dimensional file is converted in a series of n individual spectra, each of them corresponding to an absorption spectrum, acquired at a different time, with the ASCII converter included in the 991 Waters program. The resolution used in the time domain is 1.4 s.

A converter program in BASIC, developed by us, was used to transform the bidimensional files in ASCII format, to the software package SURFER [27]. The three-dimensional spectrochromatograms are obtained and presented as isometric plots (A, λ, t). Alternatively, the data are presented as a contour plot in the two dimensions of time and wavelength, by linking points of equal intensity to form the contour map. The SURFER program allows to generate cross-sections, and shows the trajectory followed in the contour or isometric plot. Cross-section data are plotted to produce a profile from the bidimensional data projection [$A-f(\lambda, t)$]. When the data are plotted, the absorbance value is plotted as the Y co-ordinate.

2.4. HPLC procedure

The column used was a Lichrospher[®] RP-C₁₈ 250 mm \times 4 mm (5 μm particle size) from Merck (Darmstadt, Germany). The mobile phase, under isocratic conditions, was ACN–water (70:30, v/v). This mobile phase composition was used to reduce the time of analysis and avoid too much dispersion of peaks. The solvents were daily filtered through a 0.45 μm cellulose acetate (water) or polytetrafluoroethylene (ACN) membrane filter before use, and de-gassed with helium during and before use.

Mixtures of iprodione, procymidone and chlorothalonil pesticides were prepared, in the concentration range 0.5–8.0 $\mu\text{g ml}^{-1}$. Sample volumes of 20 μl were injected into the HPLC system at a solvent rate of 1 ml min^{-1} and the spectrochromatographic data were recorded between 200 and 250 nm over an integration period of 1.4 s per spectrum. A cross-section was defined through the data matrix by the initial and final co-ordinate (λ, t) pairs (200, 300)–(210, 400) and (210, 400)–(250, 300). Cross-section data were plotted on the wavelength domain to produce a bidimensional projection that was used to determine the concentrations of iprodione, procymidone and chlorothalonil through the adequate calibration lines.

2.5. Procedure for the analysis of iprodione, procymidone and chlorothalonil in environmental groundwater samples

Three extractions with methylene chloride were carried out. Groundwater samples (500 ml) were filtered and shaken with 50 ml of the organic solvent for 2 min each. The combined organic extracts were dried, by passing them through anhydrous Na_2SO_4 and evaporated using a rotary vacuum evaporator. The samples thus concentrated were eluted with 1 ml of ACN. Amounts of 20 μl were injected in the chromatograph and the pesticides were determined as described above.

3. Results and discussion

The objective of the work is the investigation of the possibilities and limitations of a novel technique, taking advantages of the multivariate information produced by a diode-array detector in HPLC. For that, a mixture of three pesticides, iprodione, chlorothalonil and procymidone, has been selected for the discussion of the proposed approach.

The UV absorption spectra of each of the selected pesticides were recorded and are represented in the Fig. 1. The corresponding absorption maxima are located at 207.5 nm for iprodione, at 206.0 nm for procymidone, and at 233.5 nm for chlorothalonil. From the observation of the corresponding absorption spectra, it is evident that iprodione and procymidone present their absorption maxima at very close wavelengths, while chlorothalonil presents its maximum absorption at a longer wavelength, but its wide absorption spectrum overlaps in part with those of procymidone and iprodione.

Taking into account the absorption data of the mixture of interest, 220 nm was first selected as the monitoring wavelength, as a compromise value for the detection of the three compounds

Fig. 1. Absorption spectra of: (1) $4 \mu\text{g ml}^{-1}$ iprodione; (2) $3 \mu\text{g ml}^{-1}$ chlorothalonil and (3) $4 \mu\text{g ml}^{-1}$ procymidone.

Fig. 2. Chromatogram at 220 nm of a sample containing: (1) $3 \mu\text{g ml}^{-1}$ iprodione; (2) $4 \mu\text{g ml}^{-1}$ chlorothalonil and (3) $5 \mu\text{g ml}^{-1}$ procymidone.

after the HPLC separation. The chromatogram corresponding to a mixture of iprodione, procymidone and chlorothalonil, using ACN–water (70:30, v/v) as the mobile phase, and monitoring the absorbance at 220 nm, is presented in Fig. 2. With these conditions, the complete chromatogram is obtained in 7 min.

The obtained retention times are 5.3 min for iprodione, 5.6 min for chlorothalonil and 5.7 min for procymidone. It is evident that, in the chromatographic profile taken at the fixed wavelength selected (220 nm), the peaks corresponding to chlorothalonil and procymidone are strongly overlapping, and that the complete resolution of the mixture is not accomplished. It can be observed in Fig. 2 that iprodione is well resolved from the other two components of the mixture, and that its determination would be possible from the chromatogram at 220 nm. Alternatively, to maximise the iprodione signal, 207.5 nm (wavelength of its maximum of absorption) can be selected for the analysis. In these conditions, the calibration graph found was $y = 0.02122I + 0.00195$ ($n = 10$) for iprodione concentrations ranging between 0.5 and $8.0 \mu\text{g ml}^{-1}$, where y is the peak height and I is the iprodione concentra-

tion. The standard deviations of the slope and the intercept were 0.00019 and 0.00080, respectively. Several synthetic mixtures were analysed for iprodione in these conditions, and the recoveries obtained ranged between 95.0 and 100.3%.

However, procymidone and chlorothalonil show overlapping peaks in the chromatographic profile, and the resolution of these two compounds is not possible by measuring at a fixed wavelength of 220 nm. A possible solution of the problem, in the case of using a diode-array detector, or a conventional photometric detector allowing the simultaneous measurement at two different wavelengths, would be the measurement of chlorothalonil at its absorption maximum at 233.5 nm. By measuring at 233.5 nm, the interference of procymidone on the analytical signal corresponding to chlorothalonil should be smaller, as its absorption maximum is at 206.0 nm. To explore this possibility, chromatograms of samples containing $0.5 \mu\text{g ml}^{-1}$ procymidone or $0.5 \mu\text{g ml}^{-1}$ chlorothalonil were recorded under the same chemical conditions, monitoring the absorbance at 233.5 nm.

The corresponding chromatograms are presented in Fig. 3. From an inspection of the chromatograms, it is evident that the presence of 0.5

Fig. 3. Chromatogram at 233.5 nm of a sample containing: (1) $0.5 \mu\text{g ml}^{-1}$ procymidone and (2) $0.5 \mu\text{g ml}^{-1}$ chlorothalonil.

$\mu\text{g ml}^{-1}$ procymidone produces a small signal, practically at the same retention time, that would interfere in the determination of chlorothalonil at 233.5 nm. The reason is that, although the absorption maximum corresponding to procymidone is located at 206.0 nm, its wide spectrum still shows a small absorption signal at 233.5 nm.

We have found that the determination of chlorothalonil in mixtures with procymidone in concentration ranges between 0.5 and $2.0 \mu\text{g ml}^{-1}$ is only possible by measuring the absorbance at wavelengths higher than 250 nm, where procymidone absorption is negligible. However, the method suffers a dramatic decrease in sensitivity with respect to chlorothalonil determination, as its absorption at those wavelengths is much smaller than at 233.5 nm.

On the other hand, procymidone determination is not possible at any wavelength in the presence of chlorothalonil as, even at 200 nm, the wide absorption spectrum of chlorothalonil is overlapping, as can be observed from the corresponding absorption spectra profiles (Fig. 1).

This situation, with overlapping of peaks of several analytes of interest, or between analytes and interference substances, is frequent in multi-residue methods. The change of both stationary or mobile phases may resolve the problem, but with a multi-residue method applied to a high number of samples it is preferable to complete the determination without changing the analytical conditions. In consequence, the possibility of an approach to optimise the resolution of the peaks, avoiding as much as possible loss in sensitivity, seems interesting.

3.1. Three-dimensional spectrochromatograms

With the object of resolving the overlapping problem, using the total analytical information provided by the diode-array detector, the three-dimensional (A, λ, t) spectrochromatograms of each of the pesticides, and that of their mixture, were obtained.

In the Fig. 4, the spectrochromatographic profile of the mixture has been represented as an isometric projection. The spectrochromatogram of the selected mixture has been also represented,

Fig. 4. Isometric (A , λ , t) representation of the spectrochromatogram of a mixture of (1) iprodione ($3 \mu\text{g ml}^{-1}$), (2) chlorothalonil ($4 \mu\text{g ml}^{-1}$) and (3) procymidone ($5 \mu\text{g ml}^{-1}$), captured at 1.4-s intervals during elution, and photometric detection effected in the range 200–250 nm.

in two dimensions, as a contour plot, where concentric isoabsorptive lines are plotted in the (λ , t) plane, so that all the data can be observed simultaneously. In the contour plots, the two normal axes represent time and wavelength, while absorbances are expressed as a series of contours connecting points of equal absorbance by contour lines. In the Fig. 5 the contour plot of a mixture of the three pesticides is presented.

From the three-dimensional representations, it is clearly evident that the signals corresponding to iprodione and procymidone show the absorption maxima at very close wavelengths, but at different retention times. However, the signals corresponding to procymidone and chlorothalonil appear at different wavelengths, but the chromatographic peaks are very overlapped in the time domain, and because of the wide spectral profiles some overlapping also exists in the wavelength domain.

3.2. Cross-sections optimisation through the three-dimensional data matrix

The contour presentation of the three-dimensional data matrix is more convenient than the isometric presentation, especially where quantitative data are needed. The contour plots are specially useful to make cross-sections through the

data matrix, in a way allowing to pass as close as possible to the wavelength maxima and elution times of the different peaks, with the object of optimising the resolution of the overlapping peaks in both, selectivity and sensitivity. Two trajectories have been selected through the contour plots to define the corresponding cross-sections. These trajectories have been defined by the initial and final co-ordinate (λ , t) pairs, that describe the different linear paths, of the corresponding cross-section.

The contour plot of a mixture containing $3 \mu\text{g ml}^{-1}$ iprodione, $4 \mu\text{g ml}^{-1}$ chlorothalonil and $5 \mu\text{g ml}^{-1}$ procymidone, in which the trajectories of the selected cross-sections are indicated, is presented in Fig. 6. In the present case, the two cross-sections selected are defined by two linear paths. In the cross-section I, the wavelength is first varying linearly from 200 to 210 nm, while the retention time is varying linearly between 300 and 400 s in the first path. In the second path, the wavelength is varying linearly between 210 and 250 nm, while the retention time is varying between 400 and 300 s. In this way, the initial and final co-ordinates (λ , t) are (200, 300)–(210, 400) for the first path, and (210, 400)–(250, 300) for the second path. Similarly, the co-ordinates for the cross-section II are (200, 300)–(215, 400) and (215, 400)–(250, 300).

The bidimensional projections on the wavelength domain, generated by the selected cross-sections through the data matrix, are represented in Fig. 7a, cross-section I, and Fig. 7b, cross-section II. The analytical signals obtained after this process are very different from the ones of the original chromatograms obtained at 220 nm. The separation of three peaks, corresponding to each one of the mixture components, is evident in both cross-section projections selected. In this way, the resolution of the mixture is accomplished, allowing the quantification of each of the analytes through the adequate calibration lines.

The two cross-sections tested have been selected in order to get bidimensional projections with the

Fig. 5. Contour plot representation of the spectrochromatogram of standards of (1) iprodione ($3 \mu\text{g ml}^{-1}$), (2) chlorothalonil ($4 \mu\text{g ml}^{-1}$) and (3) procymidone ($5 \mu\text{g ml}^{-1}$), captured at 1.4-s intervals during elution, and photometric detection effected in the range 200–250 nm.

Fig. 6. The trajectories (I and II) and the two cross-sections selected for the analysis, plotted across the contour plot, of the spectrochromatogram of a mixture containing $3 \mu\text{g ml}^{-1}$ iprodione, $4 \mu\text{g ml}^{-1}$ chlorothalonil and $5 \mu\text{g ml}^{-1}$ procymidone.

best analytical characteristics (resolution and sensitivity). It is evident that the two trajectories selected in this work are not the unique possibilities. More complicated trajectories, with more than two linear paths, or even non-linear paths, may be selected for the analysis. Apart from maximising resolution, in order to obtain the highest sensitivity possible, in each particular case, the selected trajectories should pass as close as possible to each absorption maximum. In our case, comparing the results found for the two trajectories tested, the best bidimensional projection is the cross-section I. In Fig. 8, the isometric projection of the complete spectrochromatogram

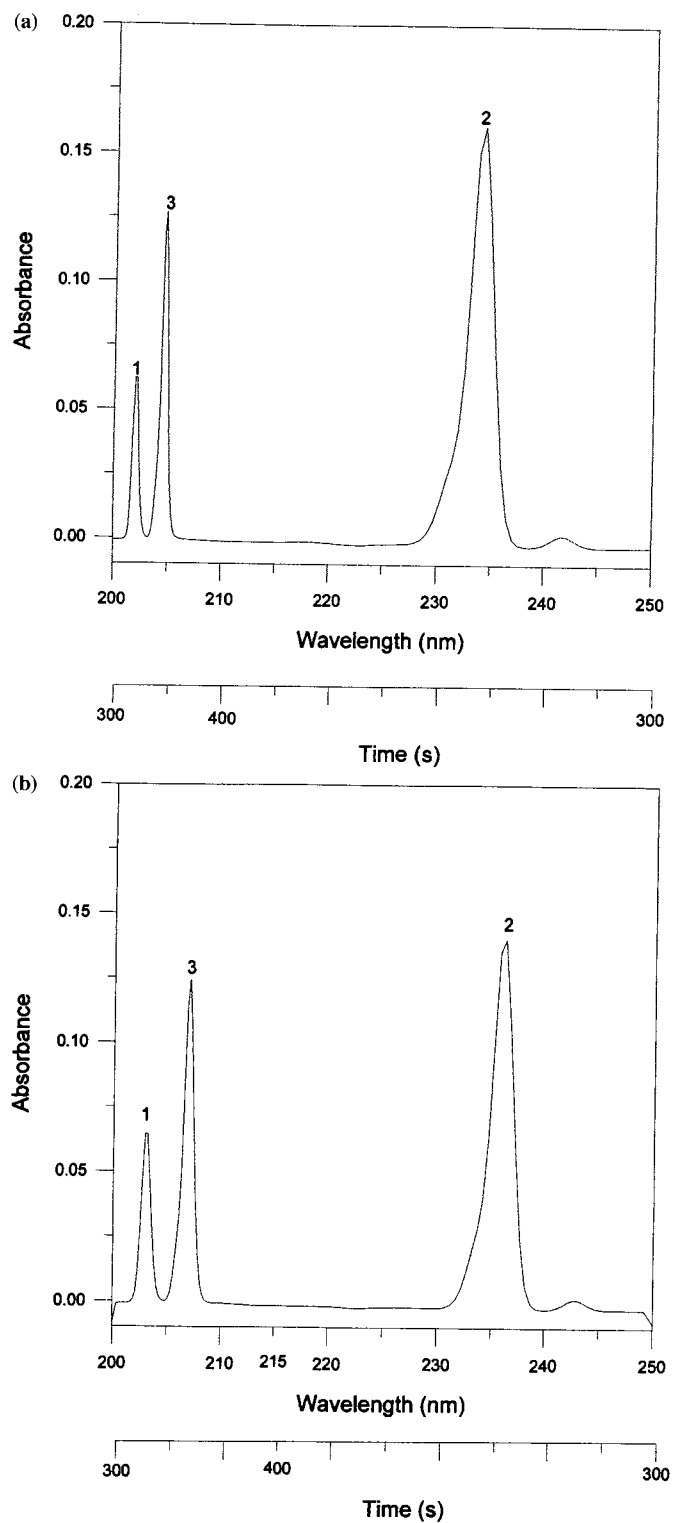

Fig. 7. Bidimensional projections of the cross-sections produced from the three-dimensional data, by plotting absorbance versus a function of wavelength and time: (a) trajectory I, (b) trajectory II.

Fig. 8. Isometric projection of the spectrochromatogram of the mixture analysed, in which the trajectory of the selected cross-section, I, is marked.

of the mixture analysed, in which the trajectory of the selected cross-section I is marked, is presented.

With the aim of demonstrating that the trajectory taken is free from interferences, the selected cross-section I was applied to individual standards of iprodione, procymidone and chlorothalonil. The suitable bidimensional projections in the wavelength domain are superposed and represented in Fig. 9. It is clear that there is not interference in the determination of any analyte with the proposed cross-section. Hence, the combined use of chromatographical and spectral information allows to carry out the quantitation of each analyte, as the signal from one analyte is free from interferences from the other analytes. The above proves the advantage of this approach over the classic techniques of cutting through the three-dimensional matrix at constant wavelength, obtaining chromatograms, or at constant time, obtaining absorption spectra.

3.3. Calibration graphs

Calibration graphs, for the respective analytical signals constructed by measurement of the peak heights, were taken from the corresponding cross-section throughout the selected trajectory, for

samples of mixtures of the three compounds, containing different concentrations of iprodione, procymidone and chlorothalonil. Good linearity was obtained for all pesticides, in the range $0.5\text{--}8.0\ \mu\text{g ml}^{-1}$. Table 1 lists the straight-line equations obtained for the concentration intervals tested, and the corresponding statistical parameter values. The detection and quantitation limits [28], calculated statistically, are summarised in Table 2. In order to study the repeatability of the method, a series of six samples were prepared, containing $2.0\ \mu\text{g ml}^{-1}$ iprodione, $2.0\ \mu\text{g ml}^{-1}$ procymidone and $2.0\ \mu\text{g ml}^{-1}$ chlorothalonil, with results of 1.20, 0.85 and 0.78%, respectively, for the relative standard deviations. The values obtained show the high repeatability of the method.

3.4. Resolution of synthetic ternary mixtures

Mixtures of iprodione, procymidone and chlorothalonil, in the concentration range $1\text{--}8\ \mu\text{g ml}^{-1}$, were prepared, and the spectrochromatograms were recorded according to the described procedure. Table 3 presents the results of the analysis of different mixtures. Satisfactory results were obtained, with recovery values ranging from 95.0 to 99.8% for iprodione, from 96.7

Fig. 9. Superimposed bidimensional projections of the cross-sections produced from the three-dimensional data, by plotting absorbance versus a function of wavelength and time, following the trajectory I.

to 103.7% for procymidone, and from 98.0 to 108.8% for chlorothalonil. The results indicate that the complete resolution of the mixture has been accomplished by the proposed approach, showing the high resolving power of the technique.

Table 1

Calibration graphs for the determination of iprodione (I), procymidone (P) and chlorothalonil (C) in mixtures, by measuring the peak heights at the selected projection of cross-section I

Pesticide	Equation ^a	R ²	Standard deviation	
			Slope	Intercept
Iprodione	$y = 0.02256I + 0.00260$	0.9997	0.00020	0.00090
Procymidone	$y = 0.02423P + 0.00199$	0.9999	0.00012	0.00056
Chlorothalonil	$y = 0.03850C + 0.00102$	0.9998	0.00025	0.00110

The results were obtained from ten calibration standards.

^a I, P, C are concentrations in $\mu\text{g ml}^{-1}$.

Table 2

Detection and quantitation limits

Pesticide	Detection limit ($\mu\text{g ml}^{-1}$)	Quantitation limit ($\mu\text{g ml}^{-1}$)
Iprodione	0.04	0.09
Procymidone	0.13	0.17
Chlorothalonil	0.10	0.16

3.5. Analysis of pesticides in environmental groundwater samples

To check the procedure in a real situation, the method was applied to determine the three pesticides in environmental samples of groundwater. The preconcentration step was carried out as described in Section 2. The study was performed with uncontaminated spiked groundwater samples.

Table 4 summarises the composition and the results of the analysis of different samples. Satisfactory recoveries were obtained, with values ranging from 90.0 to 108.0% for iprodione, from 93.7 to 107.7% for procymidone and from 87.0 to 107.0% for chlorothalonil. The results obtained indicate the suitability of the proposed approach to determine the pesticides in environmental water samples.

4. Conclusions

The determination of iprodione, procymidone and chlorothalonil mixtures has been performed by means of a novel technique with good re-

Table 3

peatability and sensitivity. The proposed technique is particularly useful for determining mixture of analytes in complex samples, as it is the case in multi-residue pesticide analysis. The usefulness of the proposed methodology is the resolution of overlapping chromatographic peaks maintaining, at the same time, as much sensitivity in the determination as possible. The technique presented here is applicable for such purpose if there exists at least one cross-section of the spectrochromatogram along which the peaks are resolved. In addition, the approach would allow a reduction in the time of analysis in certain cases. This can be the case in the separation of several analytes with similar polarities, from one of very different polarity. In con-

clusion, the combination of advanced computational capability, with the diode-array detector technology applied in HPLC, offers a powerful approach for the resolution of highly overlapping peaks, maximising at the same time the sensitivity of the method, as it is demonstrated in the particular case studied.

Abstract

A PVC membrane electrode for lead ions based on 5,5'-dithiobis-(2-nitrobenzoic acid) as membrane carrier was prepared. The electrode exhibits a Nernstian response for Pb^{2+} over a wide concentration range (1.0×10^{-2} – 4.0×10^{-6} M). It has a relatively fast response time and can be used for at least 3 months without any divergence in potentials. The proposed electrode revealed good selectivities for Pb^{2+} over a wide variety of other metal ions and could be used in a pH range of 2.0–7.0. It was used as an indicator electrode in potentiometric titration of lead ions and in direct determination of lead in water samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: 5,5'-Dithiobis-(2-nitrobenzoic acid); Lead ion selective electrode; PVC membrane; Potentiometry

1. Introduction

Ion-selective electrodes based on solvent polymeric membranes with incorporated ion carriers are well known as very useful tools for clinical, chemical and environmental analyses [1,2]. During the last two decades, a large number of neutral ionophores with high selectivities for specific metal ions have been developed and have found widespread applications in potentiometric and optical sensors for the determination of the respective metal ions in a variety of real samples [3,4].

Because of the increased industrial use of lead, on one hand, and its serious hazardous effect to

human health, on the other [5], the electrochemical properties and preparation of the lead ion selective membrane electrodes have been extensively studied by using different active materials. Besides the solid-state membranes [6–11] and liquid ion-exchange membranes [12,13], there has been recently increasing interest to the use of ionophore ligands as sensing materials for neutral carrier type lead ion selective electrodes, mainly due to the unique selectivities of these compounds [14–18].

We have recently prepared a lead-selective membrane electrode based on dibenzopyridino-18-crown-6 [18]. Since the sulphur donor atoms are well known to coordinate strongly with heavy metal ions [19,20], in this paper we employed 5,5'-dithiobis-(2-nitrobenzoic acid) (DTBNBA) as

* Corresponding author. Tel.: +98 831 94066; fax: +98 831 831618.

a suitable ion carrier to construct a PVC-based membrane electrode which exhibits significantly high selectivity to lead ion over alkali, alkaline earth and several transition metal ions.

2. Experimental

2.1. Reagents

Reagent grade dibutyl phthalate (DBP), oleic acid, 5,5'-dithiobis-(2-nitrobenzoic acid) (DTBNBA) and tetrahydrofuran (THF) were purchased from Merck and used as received. The nitrate salts of the cations used (all from Merck) were of the highest purity available and used without any further purification except for vacuum drying over P_2O_5 . Triply distilled deionized water was used throughout.

2.2. Electrode preparation

The general procedure to prepare the PVC membrane was to thoroughly mix 40 mg powdered PVC and 50 mg plasticizer DBP in 10 ml THF. To this mixture was added 20 mg oleic acid and 10 mg ionophore DTBNBA and the solution was mixed well. The resulting mixture was transferred into a glass dish of 2 cm diameter. The THF was evaporated slowly until an oily concentrated mixture was obtained. A Pyrex tube (3–5 mm o.d.) was dipped into the mixture for about 10 s so that a non-transparent membrane of about 0.3 mm thickness was formed. The tube was then pulled out of the solution and kept at room temperature for 1 h. The tube was filled with internal filling solution (1.0×10^{-3} M $Pb(NO_3)_2$ + 1.0×10^{-3} M NH_4Cl). The electrode was finally conditioned for 24 h by soaking in a 1.0×10^{-2} M solution of lead nitrate. A silver/silver chloride coated wire was used as an internal reference electrode.

2.3. e.m.f. measurements

All e.m.f. measurements were carried out with the following assembly: $Ag-AgCl/1.0 \times 10^{-3}$ M $Pb(NO_3)_2$, 1.0×10^{-3} M NH_4Cl/PVC membrane/test solution/ $Hg-Hg_2Cl_2$, KCl (satd.).

A Corning ion analyser 250 pH/mV meter was used for the potential measurements at $25.0 \pm 0.1^\circ C$. The e.m.f. observations were made relative to a double-junction saturated calomel electrode (SCE, Philips) with the chamber filled with an ammonium nitrate solution. Activities were calculated according to the Debye–Hückel procedure[21].

3. Results and discussion

Due to its negligible solubility in water and the existence of two donating sulphur atoms in its structure, DTBNBA seemed to be a potential ion carrier for soft heavy metal ions in the PVC membrane electrodes. Thus, in preliminary experiments, it was used to prepare PVC membrane ion-selective electrodes for a wide variety of metal ions, including alkali, alkaline earth, transition and heavy metal ions. The potential responses of these electrodes are illustrated in Fig. 1. As seen, among these cations, those of hard acid character

(i.e. alkali, alkaline earth and UO_2^{2+} ions [22]) show negligible responses, due to their weak interactions with the sulphur atoms of the carrier as soft bases. On the other hand, the metal ions of soft acid character (i.e. Tl^+ , Ag^+ , Cd^{2+} , Hg^{2+} and, especially, Pb^{2+} [22]) show the most sensitive potential response in the series, among which Pb^{2+} provides the most suitable ion-selective electrode. It is thus obvious that the Pb^{2+} ions are more easily attracted to the PVC–DTBNBA membrane which results in a Nernstian potential–concentration response over a wide range.

Since the sensitivities and selectivities obtained for a given ionophore depend significantly on the membrane ingredients and the nature of solvent mediators and additives used [18,23–25], we investigated the influence of membrane composition on the potential response of the Pb^{2+} sensor. The results are summarized in Table 1. It is seen that the increased amount of ionophore, up to a value of 9%, results in the best sensitivity and linear range, although the slope of e.m.f. versus log concentration plot in this case is about one-third of the expected Nernstian value. However, addition of 16% oleic acid will increase the sensitivity of the electrode response considerably, so that the membrane electrode demonstrates a Nernstian behavior. It is well known that the presence of lipophilic anions in cation-selective membrane electrodes not only diminishes the ohmic resis-

tance [26] and enhances the response behaviour and selectivity [27], but also, in cases where the extraction capability is poor, increases the sensitivity of the membrane electrodes [3].

In general, the thickness and hardness of the membrane depend upon the amount of PVC used. At higher PVC content, the membrane becomes too dense, which makes the transport of cations into the membrane more difficult and results in the increased resistance. A decrease in PVC causes an increased linear range of the electrode. However, at lower PVC content, the membrane becomes mechanically weak and swells up easily in aqueous solution. Therefore, the optimum composition of membrane 10 was used for further studies.

The concentration of the internal solution $\text{Pb}(\text{NO}_3)_2$ in the electrode was changed from 1.0×10^{-3} M to 1.0×10^{-5} M and the potential response of the Pb^{2+} selective electrode was obtained. It was found that the variation of the concentration of the internal solution does not cause any significant difference in the potential response, except for an expected change in the intercept of the resulting Nernstian plots. A 1.0×10^{-3} M concentration of the reference $\text{Pb}(\text{NO}_3)_2$ solution is quite appropriate for smooth functioning of the electrode system.

The PVC-based membrane of DTBNBA generates stable potentials when placed in contact with

Pb^{2+} solutions. The critical response characteristics of the Pb^{2+} selective electrode were assessed according to IUPAC recommendations [28]. The e.m.f. response of the membrane at varying activity of Pb^{2+} (Fig. 1) indicates a rectilinear range from 1.0×10^{-2} to 4.0×10^{-6} M. The slopes of the calibration curves were 29.0 ± 0.3 mV per decade of lead concentration. The limit of detection, as determined from the intersection of the two extrapolated segments of the calibration graph, was 1.5×10^{-6} M.

The average time required for the Pb^{2+} selective electrode to reach a potential within ± 1 mV of the final equilibrium value after successive immersion of a series of lead ion solutions, each having a 10-fold difference in concentration, was measured. The static response time thus obtained was 70 s for concentration $\leq 1.0 \times 10^{-3}$ M, and potentials stayed constant for more than 5 min, after which only a very slow divergence was recorded. The standard deviation of ten replicate measurements was ± 0.3 mV. The sensing behaviour of the membrane remained unchanged when the potentials recorded either from low to high concentrations or vice versa. The ion-selective membranes prepared could be used for at least 3 months without any measurable divergence.

The pH dependence of the membrane electrode was tested over the pH range 2–11 at Pb^{2+} concentration of 1.0×10^{-3} M and the results are shown in Fig. 2. As seen, the potential was constant from pH 2.0 to 7.0, beyond which a gradual

Fig. 2. Effect of pH of test solution on the potential response of the Pb^{2+} selective electrode.

Table 2
Selectivity coefficients of diverse ions

Diverse ion	$K_{\text{Pb}}^{\text{Pot}}$	Diverse ion	$K_{\text{Pb}}^{\text{Pot}}$
Li^+	1.5×10^{-4}	Co^{2+}	4.4×10^{-3}
Na^+	1.4×10^{-4}	Ni^{2+}	3.0×10^{-3}
K^+	1.3×10^{-4}	Cu^{2+}	9.1×10^{-3}
NH_4^+	1.4×10^{-4}	Zn^{2+}	7.8×10^{-3}
Ag^+	1.0×10^{-2}	Cd^{2+}	1.2×10^{-2}
Tl^+	2.9×10^{-3}	Hg^{2+}	4.3×10^{-2}
Mg^{2+}	2.7×10^{-4}	UO_2^{2+}	9.9×10^{-4}
Ca^{2+}	3.7×10^{-4}	Fe^{3+}	1.2×10^{-3}
Ba^{2+}	3.9×10^{-4}		

drift was observed. The observed drift at higher pH values would be due to the ionization of the ionophore and/or the formation of some hydroxy complexes of Pb^{2+} in solution.

In order to investigate the selectivity of the proposed Pb^{2+} selective electrode, perhaps as the most important characteristic of a membrane sensor, its response was examined in the presence of various foreign ions. The potentiometric selectivity coefficients ($K_{\text{Pb}}^{\text{Pot}}$) were evaluated graphically by the mixed solution method [29,30] from potential measurements on solutions containing a fixed amount of Pb^{2+} (1.0×10^{-3} M) and varying amounts of the interfering ions (M^{n+}) according to the equation:

$$K_{\text{Pb}}^{\text{Pot}} a_{\text{M}}^{1/n} = a_{\text{Pb}} \{ \exp[(E_2 - E_1)F/RT] \} - a_{\text{Pb}} \quad (1)$$

where E_1 and E_2 are the electrode potentials for the solution of Pb^{2+} alone and for the solution containing interfering ions (M^{n+}) and Pb^{2+} ions. According to Eq. (1), the $K_{\text{Pb}}^{\text{Pot}}$ values for diverse ions can be evaluated from the slope of the graph of $a_{\text{Pb}} \{ \exp[(E_2 - E_1)F/RT] \} - a_{\text{Pb}}$ versus $a_{\text{M}}^{1/n}$.

The resulting values are summarized in Table 2. As can be seen, with the exception of Ag^+ , Cu^{2+} , Cd^{2+} , and Hg^{2+} , for all diverse ions used, the selectivity coefficients are in the order of 10^{-3} or smaller, indicating they would not significantly disturb the functioning of the Pb^{2+} selective membrane. However, Ag^+ , Cu^{2+} , Cd^{2+} and Hg^{2+} with the selectivity coefficients in the order of 10^{-2} reveal some reversible interfering effect in the Pb^{2+} selective electrode functioning. It should be noted that an even more severe interference

effect from these cations on the functioning of other Pb^{2+} selective electrodes has been reported in the literature [16,17,31].

The proposed Pb^{2+} membrane electrode was found to work well under laboratory conditions. It was successfully applied to the titration of a Pb^{2+} solution with sodium chromate, and the resulting titration curve is shown in Fig. 3. As seen, the amount of Pb^{2+} in solution can be accurately determined with the electrode.

The electrode was also applied to the direct measurement of Pb^{2+} in local spring waters from the Calsimine lead and zinc mines (Dandi, Zanjan, Iran). The water samples were adjusted to pH of about 5.5 using 0.01 M ammonium nitrate buffer and their potentials were measured by direct potentiometry. The results obtained were compared with those from atomic absorption spectrometric (AAS) analysis (Table 3). The Zn^{2+} and Cd^{2+} contents of the water samples were also determined by AAS. As seen, the agreement is good and we conclude that the membrane electrode may have applications in the environmental monitoring of Pb^{2+} .

Fig. 3. Potentiometric titration curve of 25 ml of 4.0×10^{-3} M Pb^{2+} solution with 1.0×10^{-2} M Na_2CrO_4 , using the proposed sensor as an indicator electrode.

Table 3
Analytical data for the water samples

Method	Ion	\bar{x} (ppm)	S.D. ($n = 4$)	R.S.D. (%)
AAS	Zn^{2+}	21.7	0.4	1.8
	Cd^{2+}	1.8	0.1	5.5
ISE (direct)	Pb^{2+}	14.1	0.3	2.1
	Pb^{2+}	14.9	0.7	4.7
ISE (titration)	Pb^{2+}	14.1	0.6	4.2

4. Conclusions

This work demonstrates that 5,5'-dithiobis-(2-nitrobenzoic acid) as a new ionophore can be used in the development of a PVC-based lead ion-selective electrode. The electrode responds to Pb^{2+} in a Nernstian fashion and presents good selectivity and detection limit. The electrode is characterized by a relatively fast response, reasonable long-term stability and responsive potential stability. The proposed Pb^{2+} -membrane electrode was applied to the titration of Pb^{2+} solution with sodium chromate as well as the direct determination of lead in water samples.

Simultaneous determination of selenium and lead in whole blood samples by differential pulse polarography¹

Recai İnam, Güler Somer *

Gazi Üniversitesi, Fen-Edebiyat Fakültesi, Kimya Bölümü, 06500 Ankara, Turkey

Received 1 August 1997; received in revised form 13 November 1997; accepted 2 December 1997

Abstract

The polarographic reduction of lead in the presence of selenite gives rise to an additional peak corresponding to the reduction of lead (Pb) on adsorbed selenium (Se) on mercury at -0.33 V. The selenium and lead content can be determined using this peak by the addition of a known amount of one of these ions first and then the second ion. The linear domain range of lead is 5.0×10^{-7} – 2.0×10^{-5} M and for selenium 5.0×10^{-7} – 1.0×10^{-5} M. Using this method 4.90×10^{-7} M Se(IV) and 1.47×10^{-6} M Pb(II) in a synthetic sample could be determined with a relative error of $+2.0\%$ and 1.8% , respectively ($n = 4$). A recovery test after acid digestion for a synthetic sample was 97% for selenium and 96.5% for lead. The method was applied to 1 ml of digested blood, and $328 \pm 23 \mu\text{g l}^{-1}$ Se(IV) and $850 \pm 62 \mu\text{g l}^{-1}$ Pb(II) could be determined with a 90% ($n = 5$) confidence interval. © 1998 Elsevier Science B.V. Keywords: Blood; Differential pulse polarography; Selenium and lead determination

1. Introduction

Determination of trace quantities of selenium has become increasingly important due to the important concern about its physiological significance and toxicity. It is an essential trace element in human body. A lack or an excess of selenium will lead to several diseases. A sensitive method of determining selenium is therefore necessary to study selenium deficiency disease or selenium poi-

soning. Blood contains iron (400 – 1000 mg l^{-1}), copper (600 – $1200 \mu\text{g l}^{-1}$), selenium (80 – $400 \mu\text{g l}^{-1}$), lead (100 – $800 \mu\text{g l}^{-1}$) and Sb, As, Bi, Cd, Cr, and Hg in very low quantities [1]. Voltammetric methods such as anodic stripping voltammetry (ASV) [2–5], cathodic stripping voltammetry (CSV) [2,6,7], adsorptive cathodic stripping voltammetry (AdsCSV) [2,8], differential pulse cathodic stripping voltammetry (DPCSV) [9,11] and differential pulse polarography (DPP) [10] have been used with priority because of their high sensitivities and inexpensive instrumentation. Determination of selenium in biological samples is usually difficult, because of long and tedious digestion procedures and risks of interference prob-

¹ Presented at the XIth National Chemistry Congress, 16–20 June 1997, Van, Turkey.

lems. The interfering ions have to be separated by preconcentration techniques such as solvent extraction, ion exchange or hydride generation. These are all time-consuming procedures and losses of selenium are also possible. It is therefore very important to accomplish methods with minimum interference problems. In some voltammetric studies such as ASV [3] and CSV [12,13] it was mentioned that addition of selenite to a sample containing ions such as lead, copper or cadmium had a diminishing effect on their peak heights which would lead to erroneous results. Thorough investigation revealed formation at the mercury electrode surface of an intermetallic compound between selenium and the elements present [12,14]. The same kind of interference was also observed in DPP studies, a phenomenon not yet mentioned before in polarographic work, and was attributed to the formation of an intermetallic compound [15]. In fact, it was shown that, when selenium and lead were present together, a new peak belonging to an intermetallic compound appeared. This peak may be used for the quantitative determination of selenite. The present work takes advantage of this new peak and describes a new method for the determination of selenium in the presence of interfering ions without any separation procedure. It has been applied to blood samples analysis after acid digestion.

2. Experimental

2.1. Apparatus

A PAR Model 174 A polarographic analyser system, equipped with a PAR mercury drop timer, was used. The natural drop time of the mercury electrode was in the range 2–3 s (2.75 mg s⁻¹). A saturated calomel electrode (SCE) was used as the reference, and a platinum wire as the counter electrode. The polarograms were recorded with a Linseis LY 1600 X-Y recorder (Linseis, Selb, Germany). DP polarograms were recorded with drop time 1–2 s, scan rate 1–5 mV s⁻¹ and pulse amplitude 50 mV.

2.2. Reagents

All the reagents used were of analytical-reagent grade. Triply distilled water was used throughout. The mercury (proanalysis) used in the dropping mercury electrode was obtained from Merck (Darmstadt, Germany). Contaminated mercury was cleaned by passing it successively through dilute HNO₃ and water columns in the form of fine droplets. The collected mercury was dried between filter papers. Before use, a polarogram of this mercury was recorded in order to confirm the absence of impurities. A 0.1 M stock standard selenite solution was prepared by dissolving SeO₂ in hot water; 0.1 M lead and cadmium solutions were prepared by dissolving Pb(NO₃)₂ and Cd(NO₃)₂ in water, respectively. Dilute solutions were prepared daily from standard stock solutions to avoid aging.

2.3. Procedure

2.3.1. Sample digestion

To 5.0 ml of blood in a long-necked 100 ml flask, 6.0 ml of acid mixture (3 ml HNO₃ + 3 ml HClO₄) was added and after 10–15 min it was warmed up and evaporated until the half of the mixture was left. Before further warming up (to avoid explosion) 2.0 ml of HNO₃ was added and partly evaporated, then another 2.0 ml of HNO₃ was added. After evaporation to nearly dryness 2.0 ml HClO₄ was added and warmed up until white fumes were nearly finished; then a further 2 ml of HClO₄ were added, the sample became clear and was re-evaporated until nearly dryness. After cooling, 2.0 ml of HCl was added and evaporated until nearly dryness. The acidity was neutralized with 2 M NaOH and then it was diluted to 5.0 ml. After addition of 50 µl of concentrated HCl, the solution was kept as the digested blood sample solution.

2.3.2. Polarographic determination

The 9.0 ml of 0.1 M HCl solution in the polarographic cell was deaerated by passing pure nitrogen gas (99.999%) for about 10 min. Polarogram was taken by scanning the potential from -0.1 V to about -0.8 V. Then 1 ml of digested

blood was added and the polarogram was recorded once more. A small peak at about -0.33 V and larger ones at -0.52 and -0.68 V were observed. The peak at about -0.33 V belongs to the intermetallic compound between lead and selenium. Firstly, a known amount of excess selenite ($50\text{--}200\ \mu\text{l}$ of 1×10^{-3} M Se(IV) solution) were added and the polarogram was recorded. After standard addition of $50\ \mu\text{l}$ of 1×10^{-4} M Pb(II) the peak at -0.33 V increased. Selenium and lead concentration in this peak was calculated from the increments. The conditions were: drop time, $1\text{--}2$ s; current range, 0.1 mA; pulse amplitude, 50 mV; scan rate, $1\text{--}5$ mV s^{-1} .

3. Results and discussion

In our earlier polarographic work [15] we observed that when selenium and lead were present together and when selenium concentration was higher than lead, two peaks were observed in acidic media. One corresponded to free selenium at -0.54 V and the second to an intermetallic compound between lead and selenium at -0.33 V. Fig. 1 shows the formation of the peak at -0.33 V by successive additions of Se(IV) to lead reduction in 0.1 M HCl. When standard additions of selenite were made in this solution, the peak for selenium at -0.54 V also increased. It was not possible, however, to determine selenium from this increment since one part of selenium was reduced to the intermetallic compound (at -0.33 V). In this case, both of these peaks have to be analysed for selenium.

Various solutions in different Pb/Se ratios were prepared in 0.1 M HCl solution. When the ratio was 1, only one peak at -0.33 V which belonged to the intermetallic compound (PbSe) was observed (see Eq. (2)) and since the reaction between selenium and lead is in equilibrium a very small peak at -0.54 V for selenium still existed.

When the lead concentration was larger than that of selenium (Fig. 1c–e), almost all of the selenium was reduced at -0.33 V with the formation of the intermetallic compound, while free lead ion appeared as a peak at -0.41 V. These two peaks are not well separated and therefore

Fig. 1. Effect of selenite ion additions on the lead peak. (a) 10 ml 0.1 M HCl; (b) a + $200\ \mu\text{l}$ 1.0×10^{-3} M Pb(II); (c) b + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (d) c + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (e) d + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (f) e + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (g) f + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (h) g + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV); (i) h + $50\ \mu\text{l}$ 1.0×10^{-3} M Se(IV). Drop life, 1 s; scan rate, 5 mV s^{-1} ; pulse amplitude, 50 mV.

standard additions for selenium determination could not be applied under these conditions.

When the selenium concentration was larger than the lead concentration (Fig. 1g–i), two distinct peaks were observed, one for selenium at -0.54 V and the second for PbSe at -0.33 V. Since selenium reduction occurred in both of these peaks, they have to be analysed for selenium individually. The amount of selenium in the -0.54 V peak can be found by applying the standard addition method since it responds quantitatively to selenite additions in the concentration range 5.0×10^{-7} – 2.0×10^{-5} M. For the selenium content in the intermetallic compound, an indirect method is suggested. According to the above experiments, two conditions have to be considered. Either selenium or lead may be in excess in the solution under investigation. For these two situations two different methods have been suggested.

3.1. Samples containing excess selenite

A DP polarogram of 10.0 ml of 0.1 M HCl containing 1.47×10^{-6} M Se(IV) and 4.90×10^{-7} M Pb(II) was taken. As can be seen in Fig. 2b, two peaks were observed: the first at -0.33 V for PbSe and the second at -0.54 V for selenium. The selenium content in the sample can be determined by two different methods.

In the first method the selenium content in the -0.54 V peak can be calculated by standard additions of Se(IV). For the selenium content in the PbSe peak, a known amount of lead solution was added. As can be seen in Fig. 2d, while the selenite peak decreased, the peak for PbSe at -0.33 V increased. From this increase the lead and selenium content in this PbSe peak can be calculated. The total selenite content is the sum of the selenium present in both of these peaks. The above method was applied to two solutions of different composition. For a solution containing 1.47×10^{-6} M Se(IV) and 4.90×10^{-7} M Pb(II) after four successive measurements, values of $(1.63 \pm 0.01) \times 10^{-6}$ M for Se(IV) and $(5.40 \pm 0.49) \times 10^{-7}$ M for Pb(II) were obtained with relative standard deviations of 0.61% and 9.1%, respectively. The results are summarized in Table 1 as Ia and IIa.

Fig. 2. DP polarogram of Se(IV) and Pb(II) with selenium in excess (first method). (a) 10 ml 0.1 M HCl; (b) a + 150 μ l 1.0×10^{-4} M Se(IV) and 50 μ l 1.0×10^{-4} M Pb(II); (c) b + 200 μ l 1.0×10^{-4} M Se(IV); (d) c + 100 μ l 1.0×10^{-4} M Pb(II). Conditions as in Fig. 1.

In the second method, the DP polarogram of a solution containing 1.94×10^{-5} M Se(IV) and 0.97×10^{-5} M Pb(II) was taken (Fig. 3b). A known amount of lead ion was added. The selenite peak at -0.54 V decreased and the PbSe peak at -0.33 V increased (Fig. 3c,d). From the decrease, the selenium content in the -0.54 V peak was calculated, since lead and selenium reacted in

Table 1
Determination of selenium and lead in synthetic samples in various concentration ratios

t, 90% confidence interval.

a 1:1 ratio. From the increase of the PbSe peak the lead and selenium content in the PbSe peak were determined. Calculations showed that $(2.12 \pm 0.05) \times 10^{-5}$ M Se(IV) and $(0.89 \pm 0.04) \times 10^{-5}$ M Pb(II) were determined from the prepared synthetic sample. The relative standard deviations of selenium and lead were 2.4% and 4.5%, respectively. The result with its relative error is given in Table 1 as IIIb.

3.2. Samples containing excess lead:

A DP polarogram of 10.0 ml of 0.1 M HCl solution containing 4.90×10^{-6} M Se(IV) and 1.47×10^{-5} M Pb(II) was taken. Since the lead concentration was larger than that of selenium, a peak at -0.41 V for lead and a shoulder for PbSe at -0.33 V and the small peak at -0.54 V were observed (Fig. 4b). Because of the overlap of first two peaks, a known excess of selenite was added in order to bring all lead into PbSe phase. Thus, two peaks appeared: one for PbSe and a second one for selenite. With the addition of excess selenite, the first method could be applied. The selenium in the sample solution is equal to the difference between total selenite calculated and the added selenite. Lead and selenium contents of synthetic samples can be determined using this method. The above method was applied to more dilute solutions as encountered in biological samples such as blood where lead and selenite are present in similar molar quantities [1]. For four solutions with a composition of 4.90×10^{-7} M

Se(IV) and 1.47×10^{-6} M Pb(II), selenite and lead concentrations were found to be $(4.99 \pm 0.47) \times 10^{-7}$ M and $(1.50 \pm 0.06) \times 10^{-6}$ M with relative standard deviations of 9.4% and 4.0%, respectively. The results with their relative errors are given in Table 1 as IVc and Vc. As observed, when the lead concentration exceeded the selenium concentration, the peak of lead and the peak of PbSe overlapped. Since in most biological samples [16] lead concentration exceeds selenium concentration, it was decided to work with various solutions in which lead was in excess. The average results for three measurements are summarized in Table 2.

According to the above results, selenium and lead can be determined using DPP in fairly low concentrations with good precision and accuracy. As it was observed before [15], some kind of intermetallic compound formation happened in the presence of cadmium and copper. Although strong interference problems were observed in ASV and CSV studies with copper, in our DPP studies almost no effect was observed even when the copper concentration was more than ten times that of selenium (copper reduction peak is at -0.16 V).

3.3. Samples containing cadmium

A DP polarogram of a solution containing 4.90×10^{-6} M Se(IV) and 1.47×10^{-5} M Cd(II) in 0.1 M HCl showed two peaks. According to our previous [15] studies, the first peak at

−0.42 V belongs to the reduction of Cd(II) with formation of CdSe, and the second peak at −0.62 V belongs to Cd(II) reduction to CdHg (Fig. 5). For the determination of selenium and cadmium, a known amount of selenite was added. As can be seen from Fig. 5, the cadmium peak decreased and the CdSe peak increased. Since

Fig. 3. DP polarogram of Se(IV) and Pb(II) with selenium in excess (second method). (a) 10 ml 0.1 M HCl; (b) a + 200 μl 1.0×10^{-3} M Se(IV) and 100 μl 1.0×10^{-3} M Pb(II); (c) b + 50 μl 1.0×10^{-3} M Pb(II); (d) c + 50 μl 1.0×10^{-3} M Pb(II). Conditions as in Fig. 1.

Fig. 4. DP polarogram of Se(IV) and Pb(II) with lead in excess. (a) 10 ml 0.1 M HCl; (b) a + 50 μl 1.0×10^{-3} M Se(IV) and 150 μl 1.0×10^{-3} M Pb(II); (c) b + 250 μl 1.0×10^{-3} M Se(IV); (d) c + 50 μl 1.0×10^{-3} M Pb(II). Conditions as in Fig. 1.

selenium and cadmium reacted in 1:1 ratio, the cadmium concentration can be calculated from the decrease of the cadmium peak, and the amount of cadmium and selenium in this peak can be calculated from the increase of the CdSe peak. By studying four solutions containing 4.90×10^{-6} M Se(IV) and 1.47×10^{-5} M Cd(II) the concentrations $(5.41 \pm 0.42) \times 10^{-6}$ M Se(IV) and $(1.38 \pm 0.12) \times 10^{-5}$ M Cd(II) were obtained at a 90% confidence interval with relative standard deviations of 7.8% and 8.7%, respectively.

Table 2

Determination of lead and selenium in synthetic samples when lead was in excess or equal to selenite

Pb and Se in synthetic samples (M)		Pb and Se found (M)		Relative error (%)	
Pb	Se	Pb	Se	Pb	Se
1.47×10^{-6}	4.90×10^{-7}	1.51×10^{-6}	4.70×10^{-7}	+2.7	-4.1
1.47×10^{-5}	4.90×10^{-6}	1.49×10^{-5}	4.75×10^{-6}	+1.4	-3.1
2.88×10^{-5}	0.96×10^{-5}	3.13×10^{-5}	0.87×10^{-5}	+8.6	-9.3
1.94×10^{-5}	0.97×10^{-5}	2.02×10^{-5}	1.01×10^{-5}	+4.1	+4.1
2.83×10^{-5}	2.83×10^{-5}	2.70×10^{-5}	2.97×10^{-5}	-4.5	+4.9

3.4. Determination of selenium and lead in whole blood

According to the above investigations, 4.90×10^{-7} M selenium can be determined using DPP in the presence of lead although they interfere with each other. It is known that blood contains lead and selenium, and their concentrations after digestion and dissolution are in the range 10^{-6} – 10^{-7} M. Thus the above method can be used for the determination of both of these ions in blood. Since, prior to the application of this method, blood samples have to be digested, the recovery of the elements during the digestion procedure has to be investigated. For this purpose synthetic samples were prepared and the digestion procedure given in Section 2.3.1 for blood was applied. For a solution containing $800 \mu\text{g l}^{-1}$ selenium and $2070 \mu\text{g l}^{-1}$ lead, recovery efficiencies of 97% for selenium and 96.5% for lead were obtained.

For the determination of lead and selenium in blood, one bag of group O Rh (–) blood (450 ml) was kindly provided from the university hospital. A sample of 5.0 ml was digested according to the digestion procedure. The acidity was neutralized and it was diluted to 5.0 ml; the pH was then adjusted to 1.0 by the addition of 50 μl of HCl. From this solution 1.0 ml was taken and it was added to 9.0 ml of oxygen-free 0.1 HCl solution. A DP polarogram was taken in cathodic potential direction; a small peak at about -0.33 V and two large peaks at about -0.52 and -0.68 V were observed. The peak at -0.33 V may belong to lead or PbSe. The lead ion peak should occur at -0.41 V and the selenite peak at -0.54 V

in this medium. To check whether these peaks (at -0.52 V and -0.33 V) belong to lead or selenium, lead ion addition was made and the polarogram taken once more. Neither the peak at -0.33 V nor the peak at -0.52 V changed by the addition of lead ion; only the peak for lead ion at -0.41 V increased. If the selenite peak were hidden in the -0.52 V peak, the peak at -0.33 V would increase by the addition of lead due to the formation of PbSe. This is an indication that the peak at -0.33 V does not belong to lead and the peak at -0.52 V does not include selenium, otherwise the latter peak would have been decreased because of the possible intermetallic compound formation. The peak at -0.33 V must belong to PbSe since it was shown to occur at this potential. To determine both ions, first 50 μl of 1.0×10^{-3} M Se(IV) was added and the polarogram was taken. (It should be remembered here that one of the ions—lead or selenium—in the solution has to be at a higher concentration than the other to complete the reaction between them). There was no change in the -0.33 V peak, which is an indication that all lead was in the PbSe form and that the lead and selenium molar quantities were similar. To find the quantity of these ions, 50 μl of 1×10^{-4} M Pb(II) additions were made. From the increment at the -0.33 V peak, the lead and selenium concentrations in blood were obtained. The changes in the -0.33 V peak during selenite and lead additions are shown in Fig. 6.

The results obtained for five separately digested blood samples taken from the same person were $328 \pm 23 \mu\text{g l}^{-1}$ Se(IV) and $850 \pm 62 \mu\text{g l}^{-1}$ Pb(II) in a 90% ($n = 5$) confidence interval with relative

Fig. 5. DP polarogram of Se(IV) and Cd(II) in a synthetic sample. (a) 10 ml 0.1 M HCl; (b) a + 150 μl 1.0×10^{-3} M Cd(II) and 50 μl 1.0×10^{-3} M Se(IV); (c) b + 50 μl 1.0×10^{-3} M Se(IV). Conditions as in Fig. 1.

Drop life, 2 s; scan rate 1.0 mV s^{-1} ; pulse amplitude, 50 mV.

standard deviations of 7.0% and 7.3%, respectively.

To check the validity of the method, the same blood sample was analysed for lead using ASV [5] and for selenium using AdsCSV [8] (Table 3). It can be seen that the results obtained with the proposed method are consistent with those given by other methods. The proposed method can be applied safely for many biological samples.

Received 4 September 1997; received in revised form 24 November 1997; accepted 3 December 1997

Abstract

Simple, selective and sensitive spectrophotometric methods are described for the determination of pentoxifylline, based on the haloform reaction with a known and excess of standard iodine solution under alkaline conditions. The excess of iodine is determined at pH 3.0 with metol-isoniazid ($\lambda_{\max} = 620$ nm; method A) or wool fast blue BL ($\lambda_{\max} = 540$ nm, method B). All the variables have been optimised and the reaction mechanisms presented. Regression analysis of Beer's law plots showed good correlation in the concentration ranges 4.0–24.0 and 0.4–2.4 mg ml⁻¹ for methods A and B respectively. No interferences were observed from excipients and the validity of the methods was tested by analysing pharmaceutical formulations. Recoveries were 99.0–100.0%. The concentration measurements were reproducible within a relative standard deviation of 1.0%. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Iodine in alkaline medium; Isoniazid; Metol; Pentoxifylline; Pharmaceutical formulations; Spectrophotometry; Wool fast blue BL

1. Introduction

Pentoxifylline (PTF, 3,7-dimethyl-1-(5-oxo-hexyl)xanthine) is a vasodilator useful in the treatment of peripheral vascular disorders. Pentoxifylline is officially listed in the British Pharmacopoeia addendum as oxypentifylline [1]. Literature cites high-performance liquid-chromatographic methods [2–9], gas-chromatographic methods [10–12], fluorescence polarized im-

unoassay methods [13,14], visible [15] and UV [16] spectrophotometric methods for its determination. The reported visible spectrophotometric methods for pentoxifylline are based on treatment with reagents like picric acid [15] and 3,5-dinitrobenzoic acid [15]. These two methods suffer from disadvantages such as low λ_{\max} or limited sensitivity. It is therefore of interest to develop simple and sensitive procedures with higher λ_{\max} values for the determination of pentoxifylline in pure and pharmaceutical formulations. This paper describes two visible spectrophotometric methods for the determination of PTF, exploiting its structural features (i.e. methyl ketone).

* Corresponding author. Tel.: +91 891 554871; fax: +91 891 555547; e-mail: aulibra@md2.vsnl.net.in

It is well known that methyl ketones react with iodine under alkaline conditions leading to the formation of iodoform [17]. This reaction has been utilised for the quantification of PTF in pure and pharmaceutical formulations. These methods are based on the reaction of PTF with iodine under alkali, followed by the estimation of reacted iodine (amount originally taken minus unreacted) which corresponds to the drug amount, with either colour development with metol (*p*-*N*-methylaminophenol, PMAP)–isoniazid (INH) (method A) [18] or decrease in colour of an oxidizable dye such as wool fast blue BL (WFB, 5,9-dianilo-7-phenyl-4,10-disulphbenzo[α]phenazinium hydroxide inner salt) (C.I. No. 50316) (method B) [19]. We have applied these two sensitive procedures to the determination of PTF (methods A and B) in pure samples and pharmaceutical formulations.

2. Experimental

2.1. Apparatus

A Milton-Roy Spectronic 1201 Spectrophotometer with 1 cm matched quartz cells and an Elico LI-120 model digital pH meter were used for absorbance and pH measurements, respectively.

2.2. Reagents and solutions

All chemicals were of analytical or pharmacopoeial grade and doubly distilled water was used throughout.

Aqueous solutions of iodine 0.089% [0.0035 M I₂ (Merck) in 0.05 M potassium iodide (Merck)], metol (BDH, 0.3%), isoniazid (Wilson, 0.15%), sodium hydroxide (Merck, 1 M), hydrochloric acid (Merck, 1 M), and potassium hydrogen phthalate–HCl buffer (pH 3.0) [20] were prepared in the usual way for method A. Aqueous solutions of iodine 0.02% (0.786×10^{-3} M iodine (Merck) in 1.12×10^{-2} M potassium iodide), sodium hydroxide (Merck 1 M) and WFB (Chroma, 200 $\mu\text{g ml}^{-1}$) were prepared in the usual way for method B. Standard PTF solution (1 mg ml⁻¹) was prepared in distilled water. The working standard

solutions (200 $\mu\text{g ml}^{-1}$ for method A, 10 $\mu\text{g ml}^{-1}$ for method B) were obtained by further dilution of stock solutions with distilled water.

The pharmaceutical sample (tablet powder or injection) equivalent to 100 mg of the drug was accurately weighed or measured, transferred to a 100 ml volumetric flask and solutions were prepared as described for the standard solution and filtered, if insoluble material was present, prior to analysis as described for pure samples.

2.3. Procedures

2.3.1. Method A

Aliquots of a test solution of PTF (0.5–3.0 ml, 200 $\mu\text{g ml}^{-1}$) were transferred into a series of 25 ml graduated test tubes. Then 1.5 ml of the iodine and 1.0 ml of the sodium hydroxide solutions were added and the volume was adjusted to 6.0 ml with distilled water. The mixture was set aside for 5 min at 45–50°C for completion of reaction. Later 1.0 ml of hydrochloric acid, 15 ml of pH 3.0 buffer and 2.0 ml of metol solution were added. After 2 min, 1 ml of isoniazid solution was added. The absorbance was measured at 620 nm after 5 min and before 20 min against distilled water. In the same way a corresponding reference solution was prepared simultaneously, containing the sample, but with 2.0 ml of distilled water instead of 1.0 ml each of sodium hydroxide and hydrochloric acid. The difference in absorbance between the reference and test solutions corresponds to the iodine consumed by the drug. The amount of drug present in each pharmaceutical preparation was computed from the corresponding calibration graph or regression equation.

2.3.2. Method B

To each 25 ml graduated test tubes containing aliquots of a test PTF solution (1.0–6.0 ml, 10 $\mu\text{g ml}^{-1}$), 2.0 ml of 1.0 M NaOH solution was added and the volume was made up to 10 ml with distilled water. The contents were allowed to stand for 5 min at 45–50°C and cooled to room temperature, then 3.0 ml of iodine solution (200 $\mu\text{g ml}^{-1}$) and diluted to 19 ml with distilled water. After 5 min 6.0 ml of dye (WFB) solution was added and measured the absorbance, 5 min

later at 540 nm against distilled water. In the same way a corresponding blank (omitting drug) and dye (omitting drug and iodine) solutions were prepared and their absorbances were measured against distilled water. The decrease in absorbance corresponding to consumed iodine, which in turn corresponds to the drug content, was obtained by subtracting the decrease in absorbance of the test solution (dye-test), from that of the blank solution (dye-blank). The amount of drug present in each pharmaceutical preparation was computed from the corresponding calibration graph or regression equation.

3. Results and discussion

3.1. Method A

This involves two stages, namely oxidation with excess iodine in alkaline medium and the estimation of excess iodine using PMAP–INH reagent. Oxidation of PTF with 1.0–2.0 ml of iodine and 0.6–1.2 ml of 1 M NaOH solutions gave maximum and reproducible absorbance values. The absorption spectra of the reaction products in method A show characteristic λ_{\max} value (Fig. 1). The effect of time and temperature of oxidation on the absorbance of the coloured species was studied by conducting the oxidation at different temperatures for different time intervals. Oxidation times ranging from 5 to 10 min at (45–50°C) gave constant and reproducible absorbance values. Use of 0.6–1.2 ml of 1 M HCl was needed for the neutralization of excess alkali. Maintaining pH of the solution at 2.9 ± 0.3 was found to be best for attaining the highest sensitivity. Hence 15 ml of pH 3.0 potassium hydrogen phthalate–HCl buffer was used. Use of 1.5–2.5 ml of PMAP solution and 0.5–1.5 ml of INH solution afforded the highest absorbance values. A waiting period ranging from 1 to 4 min is necessary between the addition of PMAP solution and INH solution for the generation of *p*-*N*-methyl benzoquinone monoimine (PMBQMI) (by the action of iodine on PMAP). Prolonging the waiting period beyond 4 min results in low absorbance values, probably due to partial hydrolysis of the PMBQMI formed

in situ, to the quinone state. Maximum colour intensity was attained 5 min after the final dilution and remained stable for the next 20 min.

Fixed amount of iodine (1.5 ml, 0.089%), NaOH (1.0 ml, 1.0 M), HCl (1.0 ml, 1.0 M), buffer (15 ml, pH 3.0), metol (2.0 ml, 0.3%) and INH (1.0 ml, 0.15%) were used in a total volume of 25 ml in further investigation.

3.2. Method B

This method involves two stages: oxidation of PTF by iodine in alkaline medium and estimation of unconsumed iodine with wool fast blue BL.

In preliminary experiments, several phenazine and oxazine dyes such as neutral violet (NV; CA 3562-46-7), wool fast blue BL (WFB; CA 6378-88-7), azocarmin G (AG; CA 25641-18-3), lisamine blue BF (LBBF; CA 6448-97-1), gallocyanine (GC; CA 1562-85-2), solochrome prune AS (SPAS; CA 6416-51-9) and cresyl fast violet acetate (CFVA; CA 10510-54-0) were tested for reaction with iodine in alkaline medium. These investigations revealed that NV, WFB,

Correlation coefficient	0.9998	0.9999
% relative standard deviation ^b	0.86	0.32
% range of error ^b (95% confidence limits)	0.91	0.34

^a With respect to $A = a \pm bC$ where C is concentration (mg ml⁻¹) and A is absorbance unit.

^b Six replicate samples (concentrations 20 and 2.0 μg ml⁻¹ of pure drug for methods A and B, respectively).

SPAS and CFVA exhibit quantitative reactions, with iodine in alkaline medium by a definitive decrease in absorbance for a specific concentration of iodine in alkaline medium. As the difference in absorbance was found to be higher in the case of WFB, it was preferred over others in further investigation. The effect of reagent concentration (alkalinity, iodine and WFB), reaction temperature and period in each step were studied by means of controlled experiments varying one parameter at a time.

The above optimum conditions were incorporated in the recommended procedure (B).

3.3. Analytical data

The Beer's law limits, molar absorptivity, Sandell's sensitivity, detection limits [21], regression equation and correlation coefficients, ob-

tained by least squares treatment of these results are given in Table 1. Precision of each method was tested by analysing six replicate samples containing 500 and 50 μg of pure drug for methods A and B, respectively. The percent standard deviation and the percent range of error at 95% confidence level of each method are given in Table 1.

The values obtained by the proposed and reference [15] methods for pharmaceutical formulations are compared in Table 2, and are in good agreement. These results were compared statistically by the *t*- and *F*-tests and were found not to differ significantly. The results of the recovery experiments by the proposed methods are also listed in Table 2. Recoveries were determined by adding standard drug to the pre-analysed pharmaceutical formulations. The ingredients usually present in pharmaceutical formulations did not interfere in the proposed methods.

3.4. Chemistry of coloured species

Methods A or B involves the oxidation of PTF by iodine solution in excess under alkaline conditions which produce iodoform through the hydrolytic cleavage of methyl ketone group. The iodine unreacted at the end of the reaction was determined using metol–INH reagent after bringing the pH to 3.0 (method A) or decrease in the intensity of WFB colour (method B). The coloured complex in method A may be regarded as a charge-transfer [18] complex ($\lambda_{\text{max}} = 620$ nm) type, presumed to be taking place involving electron-transfer from the highest occupied π molecular orbital of INH to the lowest empty π^* molecular orbital of two adjacent *p*-*N*-methylbenzoquinone monoimine (formed in situ from metol and iodine) molecules. The colour intensity decreases at λ_{max} 540 nm in method B, is due to oxidation of WFB with iodine giving mixture of products from the dye with cleavage of conjugate system (i.e. chromophores and auxochromes). Even though the iodine oxidation of PTF or WFB under experimental conditions is not stoichiometric reproducible values are attained.

^c Recovery of 10 mg added to the pharmaceutical formulations.

4. Conclusion

The order of λ_{\max} values among the proposed methods and reference method (R) in the determination of pentoxifyllin is A > B > R. The higher λ_{\max} of the visible spectrophotometric methods over reported UV and visible spectrophotometric methods is a decisive advantage since the interference from the excipients should far less at higher wavelengths than at lower wavelengths. The sensitivity order of the methods is B > A > R.

Thus the proposed methods are simple sensitive (when compared to reported visible spectrophotometric methods) and can be used for the routine determination of pentoxifyllin in pure and pharmaceutical formulations. It is selective to compounds containing a methyl ketone portion in their molecule.

A selective voltammetric method for uric acid detection at Nafion[®]-coated carbon paste electrodes

Jyh-Myng Zen *, Chi-Teng Hsu

Department of Chemistry, National Chung-Hsing University, Taichung 402, Taiwan

Received 26 September 1997; received in revised form 25 November 1997; accepted 3 December 1997

Abstract

A square-wave voltammetric method together with Nafion[®]-coated carbon paste electrodes were used for the selective determination of uric acid in the presence of a high concentration of ascorbic acid. Since the oxidation potential of uric acid is about 200 mV more positive than that of ascorbic acid at the Nafion[®]-coated carbon paste electrode, the selectivity can be greatly improved simply by applying an electrolysis potential of +0.4 V vs. Ag/AgCl where only ascorbic acid is oxidised. The acceptable tolerance of ascorbic acid concentration for the determination of uric acid is as high as 1.5 mM. With 30 s of electrolysis time, a linear calibration curve is obtained over the 0–50 μ M range in 0.05 M citrate buffer solution, pH 4.0, with slope (μ A/ μ M) and correlation coefficient of 0.34 and 0.9984, respectively. The detection limit (3σ) is 0.25 μ M. The practical analytical utility is illustrated by selective measurements of uric acid in human urine without any preliminary treatment. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Carbon paste electrode; Nafion[®]; Uric acid

1. Introduction

Uric acid (UA), the primary end-product of purine metabolism, and ascorbic acid (AA) are both present in biological fluids such as blood and urine. It has been shown that extreme abnormalities of UA levels are symptomatic of several diseases [1]. Earlier electrochemical procedures based on the oxidation of UA at carbon-based electrodes in acidic solutions suffered from interference from AA which can be oxidised at a

potential close to that of UA [2,3]. Various methods, such as an adsorption/medium exchange approach [4,5], enzyme-based techniques [6–10], polymer-modified electrode with and without catalyst [10–13], and electrochemically pretreated carbon paste electrode or clay modified electrode [14,15], were developed to solve the UA detection problem. Indeed, the benefit of an enzyme-based method is that good selectivity is imparted by inclusion of the enzyme. Unfortunately, long-term stability is hardly achieved by any enzyme-based method. Until now, sensitive and selective methods still needed to be developed for the detection of UA due to its clinical significance.

* Corresponding author.

We report here an interesting approach for the selective determination of UA in urine samples using a Nafion[®]-coated carbon paste electrode (Nafion[®]-CPE) and square-wave voltammetry (SWV). The only means of achieving selectivity is by use of the Nafion[®] and applied potential. Since the oxidation potential of UA at the Nafion[®]-CPE is about 200 mV more positive than that of AA, the selectivity can be greatly improved simply by applying an electrolysis potential (P_p) where only AA is oxidised. The Nafion[®] membrane coating on the modified electrode can also prevent the organic interference from reaching the interface. In this paper, the optimal experimental conditions for the determination of UA as well as possible interferents, especially AA, were thoroughly investigated. The transport characteristics of UA in the Nafion[®]-CPE are also discussed.

2. Experimental

2.1. Chemicals and reagents

Nafion[®] perfluorinated ion-exchange powder, 5 wt% solution in a mixture of lower aliphatic alcohols and 10% water, was obtained from Aldrich. All buffers and supporting electrolyte solutions were prepared from Merck Suprapur reagents. Graphite powder (Aldrich), mineral oil (Sigma), UA (Sigma), AA (Wako), and all the other compounds (ACS-certified reagent grade) were used without further purification. Aqueous solutions were prepared with doubly distilled deionised water.

2.2. Apparatus

Electrochemistry was performed on a Bioanalytical Systems (West Lafayette, IN) BAS-100B electrochemical analyser. A BAS Model VC-2 electrochemical cell was employed in these experiments. The three-electrode system consisted of either a CPE or a Nafion[®]-CPE working electrode, a Ag/AgCl reference electrode (Model RE-5, BAS), and a platinum wire auxiliary electrode. Since dissolved oxygen did not interfere with the anodic voltammetry, no deaeration was performed.

2.3. Procedure

The Nafion[®]-CPE was made as follows. Carbon paste was prepared in a conventional fashion by thoroughly hand-mixing 70 wt% graphite powder and 30 wt% mineral oil in a mortar with a pestle. The carbon paste was packed into the hole of the electrode body and smoothed off on a sheet of weighing paper. A Nafion[®] solution (5 wt%) was then spin-coated on the CPE surface at 3000 rpm. The Nafion[®]-CPE was equilibrated in the test buffer solutions, by cyclic voltammetric scanning between 0.0 and +0.9 V until a steady background was attained, before measurements were made. Dependence of the anodic peak current of UA on pH at the Nafion[®]-CPE was evaluated using citrate-hydrochloric acid buffers. SW voltammograms were obtained by scanning the potential from +0.2 to +0.9 V at a SW frequency of 1.0 kHz, SW amplitude of 30 mV, and a step height of 4 mV for most cases. The UA quantification was achieved by measuring the current of the oxidation peak. For most of the experiments, a 0.05 M citrate buffer solution, pH 4.0, was used as supporting electrolyte.

Urine samples were obtained from laboratory personnel. After filtration through membrane filters (0.45 μ m), all samples were stored in the dark at 4°C. In order to fall into the linear range, all samples used for detection were diluted 200 times. The standard addition method was used to evaluate the content of UA in samples. The Nafion[®]-CPE can easily be renewed either by cleaning at +1.0 V in test solutions for 10 s or at +0.9 V for 15 s in 0.02 M NaOH.

3. Results and discussion

3.1. Voltammetric behaviour of UA at the Nafion[®]-CPE

The function of the Nafion[®]-CPE is illustrated in Fig. 1 for 50 μ M UA and 1.5 mM AA recorded at a bare CPE and the Nafion[®]-CPE by SWV. On scanning from 0.0 V towards a positive potential at the bare CPE, the interference from AA, which can be oxidised at a potential close to that

of UA, can be clearly seen, as shown in Fig. 1A(a). For comparison, Fig. 1A(b) shows that an anodic peak at around +0.5 V was observed for 50 μ M UA alone. This result indicates that there is a serious interference from AA in the detection of UA at a bare CPE. The appearance of a small peak at around +0.8 V correlating with the presence of AA will be discussed later. In contrast, separate peaks (at about 200 mV) of UA and AA were observed when the Nafion[®]-CPE was used, as shown in Fig. 1B(a). Similarly, for comparison, an anodic peak at the same peak potential was observed for UA alone at the Nafion[®]-CPE, as shown in Fig. 1B(b).

The basis for the practical utility of the Nafion[®]-CPE in the determination of UA is its discrimination against AA. Since the oxidation potential of UA at the Nafion[®]-CPE is about 200 mV more positive than that of AA, the interference from AA was found to be completely eliminated at the Nafion[®]-CPE by selecting a P_p of +0.4 V as shown in Fig. 2B. Note that such phenomenon, however, was not observed at the bare CPE. As can be seen in Fig. 2A, the shoulder

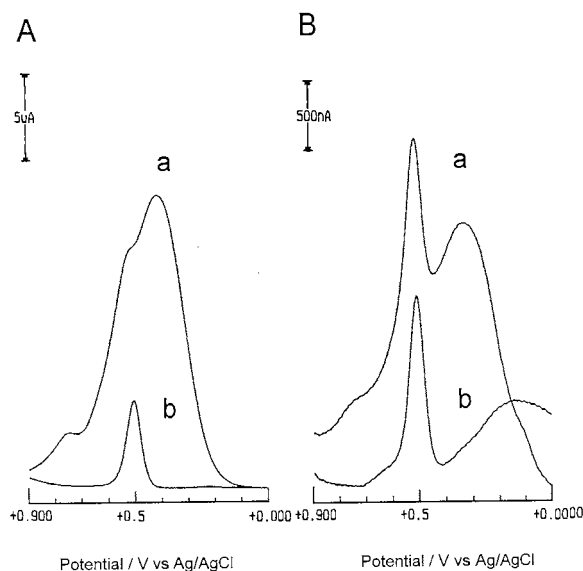

Fig. 1. SW voltammograms at (A) a bare CPE and (B) the Nafion[®]-CPE for (a) 50 μ M UA + 1.5 mM AA and (b) 50 μ M UA alone in 0.05 M citrate buffer solution, pH 4.0. $P_p = 0.0$ V; $t_p = 10$ s; SW amplitude, 20 mV; SW frequency, 50 Hz; step height, 4 mV.

Fig. 2. SW voltammograms at (A) a bare CPE and (B) the Nafion[®]-CPE for (a) 50 μ M UA + 1.5 mM AA and (b) 50 μ M UA. $P_p = +0.4$ V; $t_p = 30$ s; SW amplitude, 30 mV; SW frequency, 1 kHz; step height, 4 mV.

that appears next to the UA peak can still cause interference in UA detection. The reason for this is that, at a bare CPE, even though the AA near the electrode surface is oxidised after the electrolysis step, the AA in the bulk solution can still diffuse rapidly to the electrode surface during the detection step. With the Nafion[®]-CPE, the diffusion process was apparently somewhat restricted by the existence of the Nafion[®] film during the detection step and hence the interference of AA can be completely removed. Note that the small peak at around +0.8 V was also removed at the Nafion[®]-CPE by selecting a P_p of +0.4 V as shown in Fig. 2B. This result further confirms that the appearance of the small peak around +0.8 V is indeed due to the existence of AA.

Further investigation was made into the transport characteristics of UA at the Nafion[®]-CPE. The current response of linear scan voltammetry for 50 μ M UA obtained at the Nafion[®]-CPE was found to be linearly proportional to the square root of the scan rate, indicating that the process was diffusion-controlled. More evidence for the non-adsorptive behaviour of UA was demonstrated by the following experiment. When the Nafion[®]-CPE was switched to a medium contain-

ing only pH 4.0 buffer solution after being used to measure a UA solution, no voltammetric peak signal was observed at all.

3.2. Optimisation of UA detection at the Nafion[®]-CPE

In order to arrive at the optimum conditions for UA determination, the major factors that should be considered are the solution pH, the P_p , the electrolysis time (t_p), and the SWV parameters. The effect of pH on the voltammetric oxidation of UA is shown in Fig. 3. As can be seen, the current response reaches a maximum around pH 4.0. The reason for the large drop in the current response when the pH is higher than 6 is because UA exists in the anionic form (pK_a 5.75) when the pH is higher than 6 and is consequently repulsed by the Nafion[®] film. A pH of 4.0 was therefore chosen for the subsequent analytical experiments. The trend of the peak potential (E_p) shifts linearly towards negative potentials with an increase in pH and indicates that protons are directly involved in the rate determination step of the UA oxidation reaction. The equation relating E_p (in

Fig. 3. Dependence of the anodic peak current and peak potential on pH in SWV for 50 μM UA at the Nafion[®]-CPE. Other conditions as in Fig. 1.

Fig. 4. Effect of P_p in SWV for 50 μM UA at the Nafion[®]-CPE. t_p = 30 s.

volts) and pH, over the pH range 1–6, was found to be: $E_p = 0.73 - 0.06\text{pH}$.

As mentioned earlier, by selecting a P_p of +0.4 V, the interference by AA can be removed at the Nafion[®]-CPE. The effect of the P_p on the SW response for UA detection was thoroughly studied and the results obtained are shown in Fig. 4. As expected, the peak current reaches a maximum at a P_p of +0.4 V for 50 μM UA with a t_p of 10 s. The large drop in peak current when the P_p was more positive than +0.5 V was due to the oxidation of UA since the E_p is around +0.5 V for UA at the Nafion[®]-CPE. The effect of the t_p on the SW response for UA has also been studied and the results are shown in Fig. 5. As can be seen, the peak current increases as the t_p increases and starts to level off around 60 s for 50 μM UA (Fig. 5A). A similar trend except with lower peak currents was also observed for a lower concentration of 10 μM UA as shown in Fig. 5B. For convenience, a t_p of 30 s was chosen for the subsequent analytical experiments. In order to increase the sensitivity of detection, a longer t_p is needed for a lower concentration of UA.

The peak current obtained in SWV is dependent on various instrumental parameters such as SW amplitude, SW frequency, and step height. These parameters are interrelated and have a combined effect on the response. When the SW amplitude was varied between 10 and 70 mV, the peak currents were increased with increasing amplitude up to 30 mV; the peak width was also increasing at the same time. Hence, 30 mV was chosen as the SW amplitude. The step height together with the frequency defines the effective scan rate. An increase of either the frequency or the step height results in an increase in the effective scan rate. The response for UA increases with SW frequency up to 1.0 kHz, above which the peak current was unstable and obscured by a large residual current. By maintaining the frequency at 1.0 kHz, the effect of step height was studied. At step heights greater than 5 mV, too few points were sampled, thus affecting the reproducibility of the detection, whereas the response is more accurately recorded at a step height of 4 mV. Overall, the optimised parameters can be summarised as follows: SW frequency, 1.0 kHz; SW amplitude, 30 mV; step height, 4 mV.

Fig. 5. Effect of t_p in SWV for (A) 50 μM and (B) 10 μM UA at the Nafion[®]-CPE. $P_p = +0.4$ V.

3.3. Analytical characterisations of UA detection at the Nafion[®]-CPE

Under optimal conditions, the SWV current response is linearly dependent on the concentration of UA between 0 and 50 μM in 0.05 M citrate buffer solution, pH 4.0, with slope ($\mu\text{A}/\mu\text{M}$) and correlation coefficient of 0.34 and 0.9984, respectively. The SW voltammograms and the calibration plot observed are shown in Fig. 6. The detection limit (3σ) is 0.25 μM .

To characterise the reproducibility of the modified electrode, repetitive electrolysis–measurement–regeneration cycles were followed. The Nafion[®]-CPE can be easily renewed by cleaning at +1.0 V for 10 s in test solutions or at +0.9 V for 15 s in 0.02 M NaOH. Before the next measurement, the renewed electrode was checked in the supporting electrolyte to ascertain that no peak appeared. The result of 25 successive measurements showed a very small relative standard deviation of 1.7% for 50 μM UA. The results indicate that the electrode renewal procedure gives an excellent reproducible surface. The long-term stability was also examined by measuring the response to various concentrations of UA for a period of 60 days. The result of measurements during this period showed almost no decrease in signal at the end of the lifetime test. Since the activity remains virtually constant during this period of time, the result indicates excellent long-term stability of the electrode.

Various possible interfering substances, such as purine, glucose, cysteine, cytosine, oxalate, hydrazine, and AA, were examined for their effect on the determination of 50 μM UA. The results obtained are summarised in Table 1. It is well known that AA co-exists with UA in many samples; therefore, its interference was investigated in more detail. Since the acceptable tolerance of AA concentration for the determination of UA is as high as 1.5 mM, the method is applicable to urine samples.

Three human urine samples from laboratory personnel were investigated using the method presented above. To fit into the linear range, all the samples used for detection were diluted 200 times. The dilution process can actually help in reducing

Fig. 6. Dependence of the SWV peak current with increasing UA concentrations of 0–80 μM . Other conditions as in Fig. 2.

the matrix effect of real samples. The results obtained are listed in Table 2. To determine the accuracy of the results, the samples were spiked with certain amounts of UA in about the same

concentration as found in the samples themselves. The recovery rates of the spiked samples were determined and found to range between 95.9% and 98.7% for the three human urine samples.

Table 1
Influence of potential interferences on the response of UA

Interferent	Concentration (mM)	Signal change ($i_{\text{UA}} = 100\%$)
AA	0.5	-3.8
	1.5	-6.1
	2.5	-11.4
Cytosine	0.05	-3.3
	0.5	-15.0
Purine	0.05	-7.0
	0.5	-9.2
Oxalate	2.5	0.0
Cysteine	0.05	-1.2
	0.5	-13.7
Glucose	0.5	0.0
	2.5	-2.2
Hydrazine	0.5	2.5
	1.5	-5.7

[UA] = 50 μM .

4. Conclusion

The present study demonstrates a very simple and improved SW voltammetric method to detect UA in the presence of a high concentration of AA at the Nafion[®]-CPE. The acceptable tolerance of AA concentration for the determination of UA is at least as high as 1.5 mM. The Nafion[®]-CPE can be applied to the detection of UA in urine samples with excellent sensitivity and selectivity. The recovery of the spiked UA was observed to be good in urine samples. The Nafion[®]-CPE possesses good selectivity and can be regenerated easily by cleaning at +1.0 V in test solutions for 10 s or at +0.9 V for 15 s in 0.02 M NaOH. The detection can be achieved without deoxygenation. Simplicity and long-term stability are further advantages of this method.

Table 2
Determination of UA in urine samples with the Nafion[®]-CPE

	Urine 1	Urine 2	Urine 3
Detected value, original (μM)	20.25 ± 0.70	15.94 ± 0.53	18.32 ± 0.95
Spike (μM)	10	10	10
Detected value, after spike (μM)	29.84 ± 1.23	25.80 ± 1.24	28.08 ± 1.34
Recovery (%)	95.9	98.7	97.7
Real value ($\mu\text{g l}^{-1}$)	680.8 ± 28.1	535.9 ± 25.8	615.9 ± 29.4

Total value is obtained by multiplying the detected value by the dilution factor of 200.

Number of samples assayed was 3.

Abstract

The determination of a single rare earth element in a mixture with other species of this family is a very challenging problem in analytical chemistry due to the close similarity of their chemical properties. In this work, a liquid–solid extraction procedure for praseodymium, neodymium, samarium and yttrium mixtures and subsequent determination by energy dispersive X-ray fluorescence spectrometry is described. The pre-concentration procedure, which involves the use of silica modified with 1-(2-pyridylazo)-2-naphthol, permits complete recovery of the rare earths and significant sensitivity enhancement in comparison with direct determination in the aqueous phase. Determinations in quaternary mixtures show typical precisions and accuracies of 3% and 5%, respectively. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Pre-concentration; Rare earths; X-ray fluorescence

1. Introduction

Technological progress in recent years has increased the requirements for rare earth elements. Diverse and interesting applications of these elements are promoting their need in many activities, including glass and ceramic processing, metallurgy, nuclear chemistry, electronics, and, more recently, preparation of superconductor materials [1,2]. This massive demand has favored the progress of the analytical chemistry of these strategic

metallic species which is notably complex due to the great similarity of their chemical properties [1,2].

Classical spectrophotometric techniques are only useful for determination of the total amount of rare earth elements [3–6]. Simultaneous determination of several individual species is very troublesome due to the unavailability of selective chromogenic reactants. Other well-known analytical techniques such as atomic absorption and emission flame spectroscopy are of very restricted use, because rare earth elements, besides presenting complex absorption and emission spectra, manifest the important tendency to form refrac-

* Corresponding author. Fax: +55 197 883023; e-mail: lorenacp@iqm.unicamp.br

tory oxides as well as ionization [7,8]. Successful analytical methodologies are found only among modern instrumental techniques. Of these, plasma atomic emission spectroscopy [9,10], radiochemical analysis [11,12], chromatography [13], and fluorescence spectroscopy in the visible and X-ray regions [14,15], are the most efficient.

Energy dispersive X-ray fluorescence (EDXRF) is an instrumental technique with sufficient spectral resolution for the determination of rare earth mixtures without serious spectral interferences [16–21]. Nevertheless, the sensitivity of this technique is not enough for trace analysis. So, the application of pre-concentration procedures is an essential step in rare earth determination by this technique.

In this work, a procedure for pre-concentration and subsequent determination of praseodymium, neodymium, samarium and yttrium by EDXRF is proposed. The pre-concentration methodology involves the use of 1-(2-pyridylazo)-2-naphthol (PAN) immobilized on silica gel. The use of a liquid–solid pre-concentration step is a very favorable procedure, because, beyond permitting the elimination of potential matrix interferences, the solid phase is a convenient substrate for EDXRF measurements.

2. Experimental

2.1. Instruments

X-ray fluorescence measurements were performed using a Spectrace 5000 energy dispersive X-ray fluorescence spectrometer, equipped with a rhodium tube and a Si(Li) semiconductor detector. The samples were introduced on cylindrical plastic devices of about 2 cm in height with 3 cm i.d., using a Mylar film as sample support. Standard solution volumes were taken with a Metrohm microburette, using 0.5000 ml taps.

Analytical lines were: praseodymium, 5034 keV ($L\alpha_1$); neodymium, 5230 keV ($L\alpha_1$); samarium, 5,636 keV ($L\alpha_1$); yttrium, 14957 keV ($K\alpha_1$).

Instrumental conditions were: irradiation time, 100 s; tube voltage, 20 kV; tube current, 0.07 mA; atmosphere, air; filter, 0.127 mm aluminium film.

2.2. Reactants and standard solutions

The praseodymium standard solution was prepared from Pr_2O_3 (99.5%; Koch-Light), the neodymium standard solution from $Nd_2(CO_3)_3$ (reactant supplied by the Brazilian Federal Fiscal Service, without purity specifications), the samarium standard solution from Sm_2O_3 (99.9%; Aldrich) and the yttrium standard solution from Y_2O_3 (99%; Carlo Erba). All these solutions were prepared by direct dissolution of the reactants in $0.2 \text{ mol l}^{-1} \text{ HClO}_4$ (with heating in a water bath), and complexometrically standardized by the use of EDTA and xylenol orange [22].

Silica gel (Baker, 60–200 mesh) and 1-(2-pyridylazo)-2-naphthol (PAN; Baker) were used without further purification.

2.3. Working sample

The sample utilized is commercially distributed by NUCLEMON (Nuclebrás de Monazita e Associados Ltda., Brazil) as ‘rare-earth chloride’, corresponding to a concentrate obtained by chemical treatment of ‘Brazilian monazite’. The monazite is submitted to various physical and chemical processes for the separation of thorium, uranium, lead and other radioactive species. The resulting rare-earth chloride is then concentrated and packed as a final product, containing approximately 250 g of rare-earth oxides per litre of solution. The distribution of rare-earth elements in this product is presented in Table 1. The solution for analysis was obtained by precipitation of the hydroxides with an aqueous solution of NH_3 from a volume of 100 ml of the sample, with later dissolution in 100 ml of $2.0 \text{ mol l}^{-1} \text{ HClO}_4$.

2.4. Preparation of modified silica

A 10 g portion of silica (previously activated at 100°C for 3 h) was added to 50 ml of PAN solution (0.2% m/m in acetone). The mixture was vigorously stirred at room temperature to complete the solvent evaporation (approximately 3 h). The solid mass was homogenized in a mortar and stored in amber glass flasks.

Table 1
Distribution of the rare earths in the working sample

Element	% (as oxide)	g l ⁻¹ (original sample)	µg ml ⁻¹ (2500-fold dilution)
Pr	5.5	11.75	4.7
Nd	18.5	39.65	15.9
Sm	2.5	5.39	2.16
Y	1.3	2.56	1.02
Ce	47.5	101.38	40.55
La	22.0	46.90	18.76
Others	2.7	–	–

2.5. Extraction with modified silica

Aqueous solutions (50 ml) containing the rare earth mixtures were placed in 150 ml beakers and adjusted to suitable pH values with aqueous solutions of HCl or NH₃. To each solution, 0.2 g of the modified silica gel (minimal amount of sample necessary to cover the bottom of the cylindrical plastic device) was added. The mixture was magnetically stirred for 15 min and the solid was recovered by filtration with a Whatman 41 filter paper, washed with deionized water, dried at 60°C for 30 min and directly analysed by EDXRF.

2.6. Analytical curves and reproducibility

Using the optimized experimental conditions and the standard extraction procedure described above, calibration curves were obtained. The concentrations of each element in the rare earth mixtures ranged from 0.2 and 15 mg l⁻¹.

The reproducibility evaluation was performed using five determinations of two synthetic rare earth mixtures containing 4.0 or 10.0 mg l⁻¹ of each element.

3. Results and discussion

3.1. Optimization studies

The effect of pH on the rare earth extraction efficiency is seen in the extraction curves shown in Fig. 1. These curves presented a classical sigmoidal form with a very similar range of maximal extraction between pH 7.5 and 9.5. There is a

possibility of hydrolysis at these pH values since it is a particular tendency of the trivalent lanthanide elements. However, the physical phenomena that characterize the hydrolysis were not observed in our experimental conditions. On the contrary, the distinguishing purple colour that attests the formation of the lanthanide–PAN complexes was always observed. This is not a surprising; other studies have reported quantitative extractions of rare earth elements with PAN at pH values higher than 8 [14,21].

This result implies that there is no additional selectivity by application of the adsorption process. Fortunately, the high spectral resolution of the instrumental system permits the determination of the elements with little interference. A typical spectrum of rare earth elements adsorbed onto modified silica, isolated rare earth oxides and rare earths present in the work sample are shown in

Fig. 1. Effect of aqueous phase pH on extraction of rare earths on silica–PAN. Rare earth concentration 10.0 mg l⁻¹.

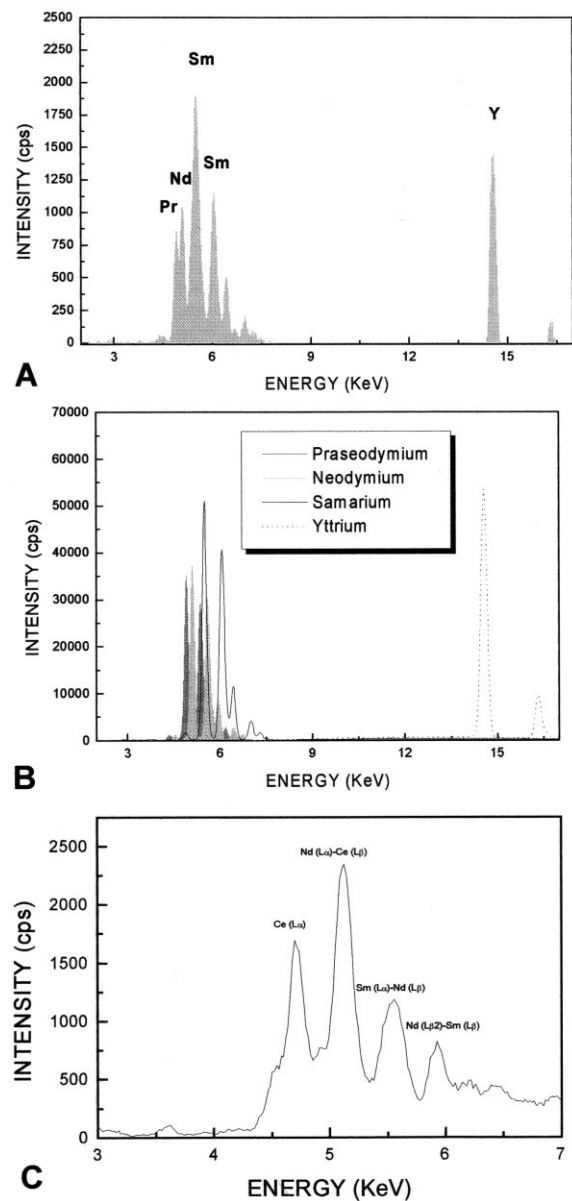

Fig. 2. X-ray fluorescence spectra of the rare earths. (A) Rare earth mixture adsorbed on modified silica. (B) Isolated rare earth oxides. (C) Working sample (expanded view).

Fig. 2A, Fig. 2B and Fig. 2C, respectively. In all these figures, it is possible to observe the existence of some spectral interferences, principally between

praseodymium, neodymium and samarium. Fig. 2C shows this effect of peak superposition most clearly.

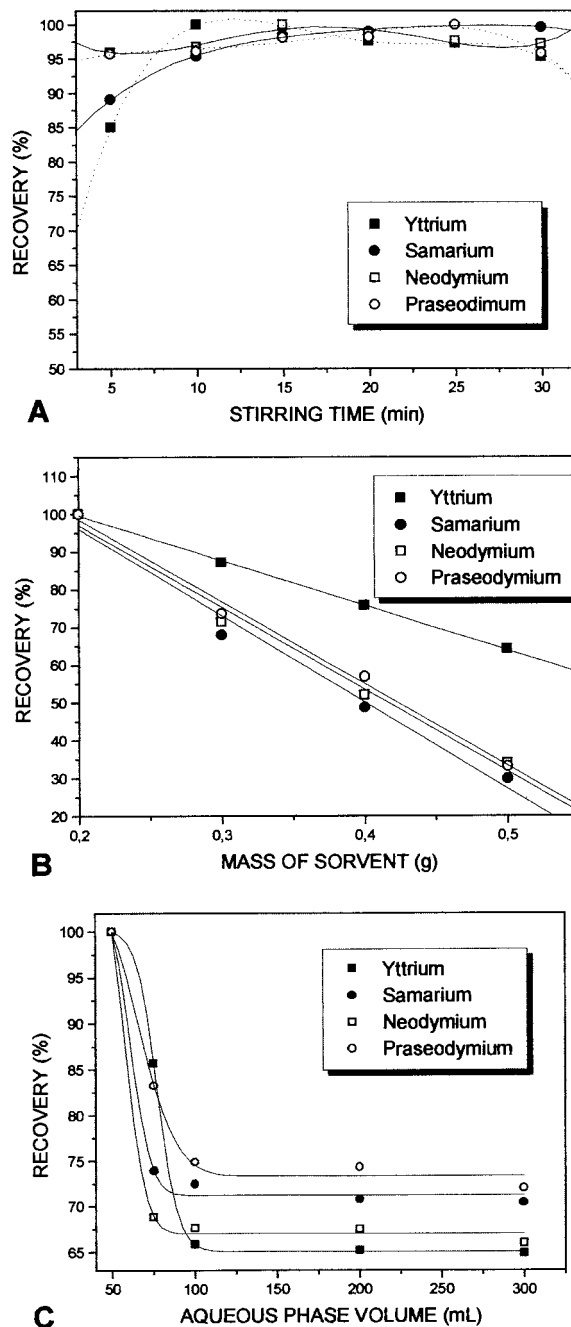

Fig. 3. Effect of stirring time (A), mass of solvent (B) and aqueous phase volume (C) on recovery of the rare earths.

Optimization studies show that the maximum extraction capacity of the sorbent is obtained with a stirring time of between 10 and 30 min (Fig. 3A). For subsequent experiments a stirring time of 15 min was selected. The effect of the variation on the mass of the sorbent (Fig. 3B) is negligible. So, whereas the sorbent mass is increased, the emission intensity of the element decreased in the same proportion, due to its dilution in the increasing mass of sorbent. For higher pre-concentration efficiency, a minimum mass of sorbent is necessary; thus, 0.2 g was selected for further experiments. Lower mass values have not been tested, because 0.2 g is the minimum amount necessary to cover the bottom of the sample device.

The effect of variation of the aqueous volume was tested between 50 and 300 ml. The results (Fig. 3C) show that the extraction is complete with volumes up to 50 ml. The use of volumes higher than 50 ml implies a significant reduction of the extraction efficiency, probably due to the drastic reduction of the contact among the phases. Between 100 and 300 ml the recovery is almost constant, with an efficiency of about 70%.

3.2. Analytical curves

The analytical curves presented in Fig. 4 were obtained using the optimized experimental conditions. These analytical curves are linear between 0.2 and 15 mg l⁻¹ with correlation coefficients higher than 0.999. Considering the sensitivity as a function of the slope of the analytical curves, the proposed method allows an enhancement equal to 176 for Pr, 172 for Nd, 167 for Sm and 84 for Y, compared to direct measurement of aqueous phases of these rare earths. These values are greater than those obtained by other extraction procedures [23].

3.3. Precision and figures of merit

To verify the precision of the proposed methodology, synthetic mixtures at two concentration levels (4.0 and 10.0 mg l⁻¹) were analysed using six replicates for each element. The results (Table 2) indicate that relative standard deviations (R.S.D.) lower than 5% can be obtained for these

Fig. 4. Analytical curves for rare earths.

Praseodymium	$r = 0.9991$; cps = $(1.248 \times \text{mg l}^{-1}) - 0.394$
Neodymium	$r = 0.9990$; cps = $(1.686 \times \text{mg l}^{-1}) - 0.550$
Samarium	$r = 0.9992$; cps = $(12.911 \times \text{mg l}^{-1}) - 4.060$

Table 3

Figures of merit of the developed pre-concentration methodology for the four elements (calculated under IUPAC recommendations)

Parameter	Praseodymium	Neodymium	Samarium	Yttrium
LDL (mg l^{-1})	0.26	0.06	0.06	0.61
R.S.D. (%) for 4.0 mg l^{-1}	2.7	2.9	4.7	2.9
S (cps mg l^{-1})	1.248	1.686	12.911	14.710

LDL (lower detection limit): $(3 \times \text{R.S.D. of blank})/S$.

R.S.D. (relative standard deviation): $S \times 100/\text{average of four replicates}$.

S (sensitivity): slope of analytical curve.

The principal figures of merit are shown in Table 3. The values obtained for the lower detection limit (LDL) and sensitivity (S) are comparable with the results reported in the literature [17,20].

3.4. Analysis of synthetic samples

By applying the proposed method to synthetic samples of variable elemental concentration (Table 4), it is observed that the interelemental spectral interferences are of little significance for those species in relatively high concentration and also when there is no appreciable difference in concentrations among the elements. In these cases the errors are of the same order of magnitude as those reported in the literature for similar procedures [10,18]. Nevertheless, it was verified here that, when one of the element is in relatively low concentration, the interelemental spectral interferences cause higher errors. This last case is critical in the determination of samarium, which suffers strong spectral interference from neodymium (see results of synthetic sample 3). It is important to observe that the error is produced not by the superposition of analytical lines but by the secondary $L\beta$ line of neodymium on the analytical $L\alpha$ line of samarium.

3.5. Analysis of working sample

The results for the quadruplicate analysis of the working sample are presented in Table 5. For samarium and yttrium, the results are very similar to the certified values. For neodymium, a large error was obtained, probably due to the interference of cerium which is present in large concen-

tration. Praseodymium was not detected due to its low concentration and poor sensitivity.

The large error obtained can be attributed to the great dilution factor used, 2500-fold. Nevertheless, the existence of concentrated samples is always provable. If a dilution is not made, the silica phase will be saturated and the extraction will be incomplete.

Another reason for these large errors can be spectral. In this case they can be improved by multivariate calibration, such as neural networks [25] and partial least squares [26] methods. In this sense, studies need to be done to solve the deficiencies in accuracy. So far, the great merit of the methodology described here consists of the high pre-concentration factors.

4. Conclusions

The proposed pre-concentration methodology consists of a simple, fast and low cost procedure which permits the complete recovery of rare earth elements from a large volume of aqueous phase. It permits high pre-concentration ratios for the determination of low concentrations of the rare earth elements by energy dispersive X-ray fluorescence spectrometry (EDXRF). In relation to the direct determination in aqueous phase, the pre-concentration procedure permits an enhancement of sensitivity of about 200 times for praseodymium, neodymium and samarium, and nearly 100 times for yttrium. This significant improvement in sensitivity expands the potential of the EDXRF technique which, by reason of its high spectral resolution, represents a valid alternative for applications in complex analysis.

Table 5
Analysis of working sample

Run	Certified amount (mg l ⁻¹)				Found amount (mg l ⁻¹)			
	Pr	Nd	Sm	Y	Pr	Nd	Sm	Y
1	4.70	15.90	2.16	1.02	ND	36.98	2.46	1.23
2	4.70	15.90	2.16	1.02	ND	35.81	2.47	1.29
3	4.70	15.90	2.16	1.02	ND	34.39	2.20	0.96
4	4.70	15.90	2.16	1.02	ND	36.39	2.46	1.20
Average	–	–	–	–	–	35.89	2.40	1.17
R.S.D. (%)	–	–	–	–	–	3.1	5.4	11.9
Error (%)	–	–	–	–	–	+125	+11	+15

ND, not detected.

The precision of the proposed method (R.S.D. of about 5%) is lower than those obtained by similar procedures [18]. Nevertheless, the accuracy is a function of the relative concentration of the species. For elements in high relative concentrations, the accuracy is satisfactory for analytical purposes. For the low concentration of one element in the presence of higher concentrations of another, the accuracy is prejudiced, probably due to spectral interferences by emission lines of the element present in the larger amount.

Received 7 July 1997; received in revised form 8 December 1997; accepted 8 December 1997

Abstract

A highly sensitive and selective method is described for the determination of trace amounts of nitrite based on its effect on the oxidation of carminic acid with bromate. The reaction was monitored spectrophotometrically by measuring the decrease in absorbance of carminic acid at 490 nm after 3 min of mixing the reagents. The optimum reaction conditions were $1.8 \times 10^{-1} \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$, $3.8 \times 10^{-3} \text{ mol l}^{-1} \text{ KBrO}_3$, and $1.2 \times 10^{-4} \text{ mol l}^{-1}$ carminic acid at 30°C. By using the recommended procedure, the calibration graph was linear from 0.2 to 14 ng ml^{-1} of nitrite; the detection limit was 0.04 ng ml^{-1} ; the R.S.D. for six replicate determinations of 6 ng ml^{-1} was 1.7%. The method is mostly free from interference, especially from large amounts of nitrate and ammonium ions. The proposed method was applied to the determination of nitrite in rain and river water. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Nitrite determination; Catalytic spectrophotometric method; Carminic acid–bromate redox reaction; Natural water

1. Introduction

Nitrite is an active intermediate in the nitrogen cycle, resulting from incomplete oxidation of ammonia or from reduction of nitrates. This ion is an important precursor of nitrosamines, which are potential carcinogens. Nitrite is one of the pollutants found in the atmosphere and natural water [1,2]. Nitrite salts is sometimes used as a preserva-

tive in the food industry and a corrosion inhibitor in industrial process water. Thus, its determination at ng ml^{-1} levels is important in environmental studies.

Many papers have been published on the determination of nitrite in different samples, but not all are suitable for routine trace determination. Among these methods spectrophotometry based on diazotization of an aromatic amine and subsequent coupling to form an azo dye are most widely used. These methods are characterized by high sensitivity but often have drawbacks of inter-

* Corresponding author. Tel.: +98 41 355998; fax: +98 41 340191.

ference by oxidizing and reducing agents, as well as relatively long reaction times and large sample volumes [3–7]. Other methods such as fluorometry [8,9], chemiluminescence [10,11], chromatography [12,13], pulse polarography [14,15] and flow injection [16–18] are also used but suffer from more or less time consuming procedures or complicated instrumentation.

A number of kinetic methods have been reported for nitrite determination [19–28]. Most of these procedures are based on its catalytic effect on bromate oxidation of organic compounds such as thionine [19], pyrogallol red [20], prochlorperazine [21], brilliant cresyl blue [22], methyl orange [23], pyridine-2-aldehyde 2-pyridylhydrazone [24], chlorophosphonazo-pN [25], and Nile blue A [26]. However, many of these methods are time consuming or have high limit of detection or need rigid control of acidity, temperature or reagents. The hydrogen peroxide oxidation of carminic acid has been used for the kinetic determination of cobalt [29] and iron [30], but its oxidation by bromate has not been used for nitrite determination so far.

The aim of this work was to study the catalytic oxidation of carminic acid with bromate in the presence of nitrite and to use the results obtained to develop a catalytic method for nitrite determination. The reaction was monitored spectrophotometrically and the method was successfully applied to the determination of nitrite in rain and river water.

2. Experimental

2.1. Reagents

Analytical-reagent grade chemicals and triply distilled water were used throughout.

A stock standard nitrite solution, $1000 \mu\text{g ml}^{-1}$, was prepared by dissolving 0.150 g sodium nitrite, pre-dried at 110°C for 4 h, in water. A small amount of sodium hydroxide was added to this solution to prevent its decomposition and a few drops of chloroform were also added to prevent bacterial growth. The resulting solution was made up to the mark in a 100 ml calibrated flask and was kept in a refrigerator and used within 2 weeks of preparation.

Potassium bromate solution ($3.8 \times 10^{-2} \text{ mol l}^{-1}$) was prepared by dissolving 1.5866 g KBrO_3 in water in a 250 ml volumetric flask. Carminic acid (Merck) (structure shown in Fig. 1) was used without further purification. A stock solution ($1.2 \times 10^{-3} \text{ mol l}^{-1}$) was prepared by dissolving 0.0591 g of carminic acid in water in a 100 ml standard flask and kept in a refrigerator. Sulphuric acid (1.8 mol l^{-1}) was prepared from concentrated H_2SO_4 (98%, Merck). Stock solutions ($1000 \mu\text{g ml}^{-1}$) of interfering ions were prepared by dissolving suitable salts in water, hydrochloric acid or sodium hydroxide solution.

2.2. Apparatus

A UV-265 FW spectrophotometer (Shimadzu) was used for measurements of absorption spectra. A model UV-120-02 spectrophotometer (Shimadzu) with 1.0 cm glass cuvettes was used to measure the absorbance at 490 nm. A thermostat (Tokyo Rikakika, LTD UA-1) was used to keep the reaction temperature at 30°C . A stop-watch was used for recording the reaction time.

2.3. Recommended procedure

1 ml 1.8 mol l^{-1} Sulphuric acid and 1 ml $1.2 \times 10^{-3} \text{ mol l}^{-1}$ carminic acid were added to each sample or standard solution containing 2–140 ng of nitrite in a 10 ml volumetric flask. Each solution was diluted to ca. 8 ml with water and was kept in a thermostated water-bath at 30°C for 10 min. 1 ml $3.8 \times 10^{-2} \text{ mol l}^{-1}$ Bromate previously brought to 30°C , was added and the solution was diluted to the mark with water. Time was measured from just after the addition of the

Fig. 2. Absorption spectra of the carminic acid– bromate system in the presence of nitrite, conditions: carminic acid, 1.2×10^{-4} mol l^{-1} ; sulphuric acid, 1.8×10^{-1} mol l^{-1} ; bromate, 3.8×10^{-3} mol l^{-1} ; nitrite, 5.0 ng ml^{-1} ; temperature, $30^{\circ}C$; after: a, 0.5; b, 1.5; c, 2.5; d, 3.5; e, 4.5; and f, 5.5 min from initiation of the reaction.

bromate solution. The blank solution was prepared by the same procedure. After 3.0 min, 0.1 g solid urea was added to the solutions to stop the catalysed reaction. The solutions were transferred into 1.0 cm glass cuvettes and after 3.5 min the absorbances of the solutions were measured

against water at 490 nm. The absorbances of the sample and blank were labeled A and A_0 respectively. Then the amount of nitrite was determined from a calibration graph which was constructed by plotting the $\log(A_0/A)$ versus the nitrite concentration.

Fig. 3. Effect of sulphuric acid concentration on the reaction rate, conditions: carminic acid, 1.0×10^{-4} mol l⁻¹; bromate, 4.0×10^{-3} mol l⁻¹; nitrite, 10.0 ng ml⁻¹; temperature, 30°C; reaction time, 3.0 min.

Fig. 4. Effect of carminic acid concentration on the reaction rate, conditions: sulphuric acid, 1.8×10^{-1} mol l⁻¹; bromate, 4.0×10^{-3} mol l⁻¹; nitrite, 10.0 ng ml⁻¹; temperature, 30°C; reaction time, 3.0 min.

3. Results and discussion

Some oxidants such as bromate could oxidize carminic acid irreversibly in acidic media at a

slow rate. This oxidation is increased in the presence of ultra-trace amounts of nitrite. This process was monitored by measuring the decrease in absorbance at 490 nm. Fig. 2 shows absorption

Fig. 5. Effect of bromate concentration on the reaction rate, conditions: sulphuric acid, $1.8 \times 10^{-1} \text{ mol l}^{-1}$; carminic acid, $1.2 \times 10^{-4} \text{ mol l}^{-1}$; nitrite, 10.0 ng ml^{-1} ; temperature, 30°C ; reaction time, 3.0 min.

spectra of carminic acid at different times. As shown in this figure, the change in absorbance at 490 nm with time can be used for the study.

Several acidic media including sulphuric, hydrochloric, nitric and phosphoric acids were investigated for the carminic acid–bromate system. The results indicated that among these four acids, sulphuric acid is the best due to its acidity strength relative to other acids at equimolar concentrations.

3.1. Effect of variables

The effect of sulphuric acid concentration on the rate of the reaction with and without nitrite was studied. The optimum concentration of sulphuric acid is $1.8 \times 10^{-1} \text{ mol l}^{-1}$ as shown in Fig. 3.

Fig. 4 shows the effect of carminic acid concentration on the catalysed and uncatalysed reaction. The results show that the sensitivity increased up to $1.2 \times 10^{-4} \text{ mol l}^{-1}$ carminic acid, whereas a higher concentration of the reagent caused a decrease in the reaction rate. This effect may be due to the change of mechanism of the reac-

tion or deviation from Beer's law. Thus $1.2 \times 10^{-4} \text{ mol l}^{-1}$ carminic acid was used for the study.

The effect of bromate concentration on obtaining maximum sensitivity was investigated. Fig. 5 shows that sensitivity increases up to $3.8 \times 10^{-3} \text{ mol l}^{-1} \text{ BrO}_3^-$. At higher concentrations, the sensitivity decreases, owing to the decrease of A_0 . Thus $3.8 \times 10^{-3} \text{ mol l}^{-1}$ bromate concentration was selected for use.

The effect of the reaction temperature was studied in the range $5\text{--}40^\circ\text{C}$ at optimum conditions. Fig. 6 shows that by increasing the temperature to 30°C , $A_0 - A$ increases with temperature, while at higher temperatures it decreases. This effect is due to the fact that at higher temperatures, the rate of the uncatalysed reaction increases with temperature to a greater extent than the catalysed reaction and the difference between the rates of the catalysed and uncatalysed reactions diminishes. A temperature of 30°C , which gives high sensitivity, was selected.

A chemical inhibitor or rapid cooling is sometimes used to stop the catalytic reaction in practical applications of the fixed time method. It was

Fig. 6. Effect of temperature on the reaction rate, conditions: sulphuric acid, $1.8 \times 10^{-1} \text{ mol l}^{-1}$; carminic acid, $1.2 \times 10^{-4} \text{ mol l}^{-1}$; bromate, $3.8 \times 10^{-3} \text{ mol l}^{-1}$; nitrite, 10.0 ng ml^{-1} ; temperature, 30°C ; reaction time, 3.0 min.

found that urea is a good inhibitor which decomposes nitrite rapidly. In this study urea was used to stop the catalytic reaction. 0.1 g Solid urea suffices for 10 ml of solution and simultaneously quenches the catalysed reaction. The absorbance of the solution remains constant for a few minutes in the presence of urea.

The effect of ionic strength on the rate of reaction was investigated by using NaNO_3 (2 mol l^{-1}). The reaction rate increases very slightly up to $0.5 \text{ mol l}^{-1} \text{ NaNO}_3$.

The effect of measuring time on the rate of the reaction was studied at the optimum concentra-

tions of the reagents at 30°C . The results show that 3.0 min yields the best sensitivity. Thus, a fixed reaction time of 3 min was chosen for this study.

3.2. Calibration, precision and detection limit

Under the conditions chosen, in the concentration range $0.2\text{--}14 \text{ ng ml}^{-1}$ of nitrite the following regression equation was obtained:

$$\log(A_0/A) = 1.6 \times 10^{-3} + 0.011C \quad (r = 0.9995)$$

where C is the ng ml^{-1} of nitrite. The R.S.D. for six replicate determinations is 1.7% for 6.0 ng ml^{-1} nitrite. The experimental limit of detection is 0.04 ng ml^{-1} , which was calculated as three times the S.D. of the blank (3s criterion).

3.3. Interference

The effects of possible interfering species, which commonly accompany nitrite in natural waters, were studied in the determination of 10 ng ml^{-1} of nitrite following the recommended procedure. A foreign ion was considered to interfere seriously when it gave a determination error of more than 5%. The tolerance limit of foreign ions are sum-

Table 1
Tolerance limits of foreign ions in the determination of 10 ng ml^{-1} of nitrite following the recommended procedure

Tolerance limit ($\mu\text{g ml}^{-1}$)	Foreign ion
100	NO_3^- , F^- , SO_4^{2-} , CO_3^{2-} , ClO_3^- , PO_4^{3-} , Cl^- , acetate, tartarate, NH_4^+ , Na^+ , K^+ , Mg^{2+} , Ca^{2+} , Cu^{2+} , Zn^{2+} , Ni^{2+} , La^{3+} , U (VI)

	30.0	84.8	98.7			1.0
	50.0	104.2	98.0			1.2

^a Collected at Iran; the river water was collected from the Talkheroud river on 28 April 1997; the rain water was collected on the roof of the Chemistry building of Tabriz University on 29 April 1997.

^b A sample of 2 ml was used for one measurement. Each result is the average of five determinations.

marized in Table 1. Large amounts of nitrate and ammonium ions have little effect. Thus, the determination of trace amounts of nitrite in nitrate or ammonium salt is possible.

3.4. Determination of nitrite in rain and river water

A freshly collected water sample was filtered through a membrane filter of 0.45 μm pore size into a poly(propylene) bottle, kept in a refrigerator at about 4°C and analysed by recommended procedure within 12 h of collection.

Since the concentration of common pollutants in natural water is generally far below the tolerance levels shown in Table 1, the method was applied directly to the determination of nitrite in rain and river water.

As shown in Table 2, the results obtained with the proposed method agree well with those obtained by the standard method [31]. The reliability of the method to analyse real samples was also checked by recovery experiments. The results show that the method gives good recoveries of added nitrite.

The simplicity, high sensitivity and its freedom from interference effects are significant advantages of the proposed method. The method could be applied to drinking water after removing the chlorine. Furthermore, with the proposed method it is also possible to combine the nitrate and nitrite analysis. This could be feasible by reduc-

tion of nitrate to nitrite by using a copper cadmium reduction column [17] and measuring the sum. Nitrite is determined directly by the proposed method and nitrate can be determined by the difference.

Received 8 August 1997; received in revised form 4 December 1997; accepted 8 December 1997

Abstract

The modified silica gel with 1,10-phenanthroline adsorbed was obtained. The adsorption from aqueous solutions onto loaded silica gel of Fe(II), Cu(II) and Ag(I) and their complexes was studied. The loaded silica gel was applied to Fe(II), Cu(II) and Ag(I) reflectance spectroscopy determinations in water (detection limits 0.08, 0.03 and 0.01 ppm respectively). Visual test scales for Fe, Cu and Ag ion determinations in water were worked out. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: 1,10-Phenanthroline; Adsorption; Loaded silica gel; Fe(II III) determination; Cu(II) determination; Ag(I) determination

1. Introduction

Sorption reflectance spectroscopic methods are known as effective methods to combine metal ions preconcentration and their determination on the surface [1]. Numerous methods for Fe(II), Cu(II) and Ag(I) determination have been based on sorption of metal ions on disks made of polyacrylonitrile fibers filled with KU-2 ion exchanger with detection in the sorbent phase by Rhodasol X, thiocyanate and sodium diethyldithiocarbamate correspondingly [2,3]. The sorbents modified with analytical reagents are the most promising solid phase reagents [4]. Silica gels modified with *p*-dimethylaminobenzylidenerhodanine, in partic-

ular, has been used for Ag(I) preconcentration [5]. 1,10-Phenanthroline (Phen) is known to be one of the effective chelating reagent for some metal ions determination [6]. The possibility of Phen fixation on silica gel in a chemical way was shown in [7]. Adsorption of reagents is a more simple and reliable method of sorbent modification, silica gel (SG) in particular [8]. As far as we know no modification of silica gel by Phen adsorption has been reported.

It is known that the maximum adsorption of metal ions can be obtained during complex with ratio reagent:metal ion = 1:1 forming on a surface of modified sorbent [1]. Ag(I) forms a complex with Phen with a ratio of Ag:Phen = 1:1 in acidic solution [9]. This complex is colourless but with a xanthine dye of the sulfophthalein group it forms a coloured heteroligand complex [9]. Cu(II) also

* Corresponding author. Tel.: + 380 44 2210211; fax: + 380 44 2244188; e-mail: ZUBENKO@analit.chem.univ.kiev.ua

forms a heteroligand complex with ratio Cu:Phen = 1:1 [9]. Fe(II) forms some coloured complexes with Phen in solution and the most stable complex is Fe(Phen)_3^{2+} [10].

In the present work we have studied the possibility of application of silica gel with adsorbed Phen to Fe(II), Cu(II) and Ag(I) determination in water.

2. Experimental

2.1. Reagents

Water was purified according to [11]. Standard Fe(II), Ag(I) and Cu(II) solutions were prepared by dissolving salts $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, AgNO_3 and $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. Potassium citrate (K_3Cit) (0.3 M), ammonium chloride (1 M), urotropin (17%), 1,10-phenanthroline (1×10^{-3} M), bromopyrogallol red (BPR) (1×10^{-4} M), and ascorbic acid water solutions were prepared by dissolving appropriate substances. The standard solutions of metal salts were acidified with sulfuric or nitric acid and further diluted as required. A saturated solution of ascorbic acid (H_2Asc) was used. Acetate citrate buffer solution (pH 5.5) was prepared according to [12]. Ammonium buffer solution (pH 8.8) was prepared by mixing a 1 M solution of ammonium hydroxide and a 1 M solution of ammonium chloride. Hexane was purified by flowing over metallic sodium. A solution of Phen in hexane (1×10^{-3} M) was obtained by dissolving the appropriate amount of substance. All chemicals were of analytical reagent grade. Silica gel L 100/250 for chromatography (Chemapol, Prague, Czech Republic) was digested in hydrochloric acid, washed with purified water and dried at 80°C for 8 h.

2.2. Apparatus

The spectra of solutions and reflectance spectra of sorbents were registered with a UV/Vis spectrophotometer Specord M-40 (Carl Zeiss Jena, Germany). Atomic absorption measurements were recorded on a model Saturn atomic absorption spectrometer (Severodonetsk) equipped with

a standard burner for use with an air–propane–butane flame. Standard hollow-cathode lamps were used as a line source for all elements.

A potentiometer model EV-74 with a glass electrode (Gomel, Belarus) was used for pH measurements.

2.3. Procedures

The batch technique has been used for the research of Phen adsorption onto unloaded silica gel (SG) and metal ion adsorption onto SG and loaded silica gel (Phen–SG).

2.3.1. Adsorption of Phen from hexane solution

SG (0.01 g) was stirred with 5 ml of 0.05–1 mM Phen solution in hexane for 1–60 min. The Phen residue in hexane was controlled spectrophotometrically by the absorbance of the complex Phen with Fe(II) [13].

2.3.2. Adsorption of Fe(II) and Fe(III) onto Phen–SG

This was realized from 3.0 mM K_3Cit . Fe(Phen)_3^{2+} and Fe(Phen)_3^{3+} were adsorbed onto SG from 1.5 mM Phen. All these solutions were buffered to pH 5.5 with acetate citrate buffer. Fe(II) residue in the solution was controlled spectrophotometrically by the colour of the complex ($\lambda = 510$ nm) and Fe(III) residue was controlled spectrophotometrically by the absorbance of Fe(Phen)_3^{2+} after Fe(III) reduction by ascorbic acid.

2.3.3. Adsorption of Cu(II) onto SG and Phen–SG

This was adsorbed from the solution buffered to pH 8.8 with ammonium buffer.

2.3.4. Adsorption of Ag(I) onto Phen–SG

This was done from 0.02 mM BPR and 1.7% urotropin solutions. The Cu(II) and Ag(I) residues were controlled by atomic absorption measurements.

Sorbents with metal ions adsorbed were dried at room temperature for 24 h and analyzed by using reflectance spectroscopy.

Fig. 1. Adsorption of Fe(II) onto Phen-SG (1) and SG (2), and adsorption of Fe(Phen)_3^{2+} onto SG (3) as functions of pH. Initial concentration, $10^{-3} \text{ mol l}^{-1}$: Fe (II), 0.02; Phen, 1.5 (3); Cit, 3.0 (1–2); $V = 10 \text{ ml}$; pH 5.5; $m = 0.15 \text{ g}$; $t = 5$ (1, 2), 10 min (3).

3. Results and discussion

Modification of SG with Phen has been carried out from hexane solution [13]. Phen-SG containing 0.1 and 0.2 mmol g^{-1} Phen were used.

3.1. Fe(II) and Fe(III) adsorption onto Phen-SG

It is well known that Fe(II) forms a coloured complex with Phen in solution at pH 2.5–9.0 [14]. The pH dependences of Fe(II) adsorption from aqueous solution onto Phen-SG and SG are compared in Fig. 1 (curves 1 and 2) and the optimum pH is 5.5. Fe(II) adsorption onto Phen-SG under these conditions was found to be quick. The maximum adsorption was reached in 5 min. The dependence of maximum adsorption on concentration of Fe(II) is shown in Fig. 2 (curve 5) and Table 1. The chelating capacity of Phen-SG is 0.1 mmol g^{-1} Fe(II) for 0.1 mmol g^{-1} Phen. Spectrophotometrically it was proved that Fe(Phen)_2^{2+} had been formed on the surface under these conditions. Fe(III) forms a colourless complex with Phen but in the presence of citrate

ions it is not adsorbed onto the Phen-SG.

3.2. Fe(Phen)_3^{2+} and Fe(Phen)_3^{3+} adsorption onto SG

Dependence of Fe(Phen)_3^{2+} adsorption on pH is shown in Fig. 1 (curve 3). The maximum adsorption was arrived at pH 5.0–6.3 under optimum conditions for Fe(Phen)_3^{2+} formation [14]. Equilibrium of this complex adsorption onto SG was reached in 10 min.

Adsorption of Fe(Phen)_3^{3+} was found to be quick and quantitative on these conditions, too.

The isotherm of Fe(Phen)_3^{2+} adsorption (Fig. 2, curve 2) can be formally described by a Langmuir equation and linearized in the coordinates $[C]/a - [C]$ with the coefficient of correlation $r = 0.993$. The results of such a description are shown in Table 1. The dependences of Fe(Phen)_3^{2+} adsorption ($y, \%$) onto SG on mass (m, g) of the sorbent and volume (V, ml) of solution can be described by the following equation: $y = a + b \cdot m - c \cdot m^2$ and $y = a + b/V$. The values of a, b and c are shown in Table 2.

Fig. 2. Isotherms of Cu(II) (1) and Fe(Phen) $_3^{2+}$ (2) adsorption onto SG; and isotherms of Cu(II) (3) and Ag(I) (4) adsorption onto Phen-SG, and dependence of Fe(II) adsorption onto Phen-SG on the concentration of Fe(II) (5). Initial concentration, mol l $^{-1}$: Phen, 1.5×10^{-3} (2); NH $_3$, 0.2 (1, 3); BPR, 2.10^{-5} (4); Cit, 3.10^{-3} (5); equilibrium concentration [C], mol l $^{-1}$: 10^{-5} (1–3), 10^{-4} (4), 10^{-3} (5); $a_{\text{Phen}} = 0.1$ (5), 0.2 mmol g $^{-1}$ (3, 4); $V = 10$ (2, 4, 5), 20 (1, 3) ml; pH 6.5 (4), 5.5 (2, 5), 8.8 (1, 3); $m = 0.02$ (1–3, 5), 0.01 g (4); $t = 10$ (1–4), 5 min (5).

	SG	S	0.063	—
Ag $^+$	Phen-SG	L	0.23	2.4

a_{Phen} (mmol g $^{-1}$): 0.1 (Fe), 0.2 (Cu, Ag).

3.3. Cu(II) adsorption onto Phen-SG and SG

Cu(II) was not adsorbed from aqueous solution onto Phen-SG. So the adsorption of Cu(II) from ammonia solution was studied. Ammonia was chosen because it has a small radius (it escapes steric hindrance) and its complexes with Cu(II) are coloured. To avoid difficulties with soluble hydroxide of Cu(II) conformation at pH 8–9 a concentration of ammonium ions was calculated from the solubility product and stability constant

of Cu(II) ammonia complexes [15,16]. Optimum concentration of ammonium ions was 0.2 M.

Kinetics experiment of Cu(II) adsorption onto Phen-SG and SG showed that the time taken for maximum Cu(II) adsorption was 10 min in both cases.

Isotherms of Cu(II) adsorption onto SG and Phen-SG are shown in Fig. 2 (curves 1 and 3) and Table 1. The maximum Cu(II) adsorption onto Phen-SG is 3 times more than the complex full adsorption onto SG. The chelating capacity of

Table 2

The dependencies of metal ions adsorption on mass of sorbent and volume of solution

Ion	Coefficients of equation for dependencies on					Optimal		Coefficient of preconcentration
	<i>m</i>			<i>V</i>		<i>V</i> (ml)	<i>m</i> (g)	
	<i>a</i>	<i>b</i>	<i>c</i>	<i>a</i>	<i>b</i>			
Fe(Phen) ₃ ²⁺	19.3	564	1350	1.24	211	50	0.15	500
Cu ²⁺	21.9	323	581	114	0.87	50	0.10	333
Ag ⁺	43.3	858	2660	87.8	0.26	40	0.20	200

Fig. 3. The reflectance spectra of SG (1), Phen-SG (2) with Cu(II) adsorbed, Phen-SG with Ag(I) adsorbed (3) and the optical absorbance spectrum of an aqueous solution of Ag(Phen)⁺ (4).

Phen-SG (Fig. 2, curve 3) and the reflectance spectra of Phen-SG with Cu(II) adsorbed (Fig. 3) show that Phen on the surface had taken part in forming a complex with Cu(II).

The dependencies of Cu(II) adsorption onto SG on the mass of the sorbent and the volume of solution can be described by the equations: $y = a + b \cdot m - c \cdot m^2$ and $y = a - b \cdot V$. The values of *a*, *b* and *c* are shown in Table 2.

3.4. Ag(I) adsorption onto Phen-SG

Ag(I) is adsorbed onto Phen-SG from aqueous solution at pH 2. But such a complex is colourless so the adsorption of Ag(I) was studied from an

aqueous solution in the presence of BPR at pH 6.5 according to [17]. For comparison an attempt to adsorb Ag(I) onto unloaded silica gel was done but there was no effect.

The Ag(I) adsorption equilibrium was reached in 10 min. The isotherm shown in Fig. 2 (curve 4) can be formally described by a Langmuir equation and linearized with $r = 0.999$. The results of such description are shown in Table 1. It is known that in solution Ag(I) with Phen and BPR forms a heteroligand complex with the ratio Ag:Phen = 1:2 [17]. Spectra (Fig. 3) showed that the complex of Ag(I) on the surface differed from the complex in solution. The chelating capacity of Phen-SG is 0.2 mmol g^{-1} Ag(I) for 0.2 mmol g^{-1} Phen. So it

 $P = 95\%$, $n = 5$.

can proved that the complex with the ratio Ag:Phen = 1:1 is formed on the surface of Phen–SG.

The dependencies of Ag(I) adsorption onto Phen–SG on the mass of the sorbent and the volume of solution can be described by following equations: $y = a + b \cdot m - c \cdot m^2$ and $y = a - b \cdot V$. The values of a , b and c are shown in Table 2.

3.5. Application of modified and unmodified SG for Fe, Cu and Ag ion determinations

The possibility of SG and Phen–SG application to Fe, Cu and Ag ion determination in water has been studied.

3.5.1. Fe(II) determination

The concentration of Fe(III) in natural water is > 100 times more than that of Fe(II) [14]. Our investigation has shown that both Fe(Phen)₃³⁺ and Fe(Phen)₂²⁺ have been adsorbed onto SG simultaneously. So Fe(III) interfered with Fe(II) detection. Unloaded SG can be used to the sum concentration of Fe ions determination in water after reduction of Fe(III) to Fe(II) with ascorbic acid.

Phen–SG adsorbed only Fe(II) in the presence of citrate ions. So this sorbent has been applied to Fe(II) detection in the presence of Fe(III).

The colour scale on the base of Phen–SG for visual test determination of Fe(II) in the range of 3–50 µg per sample was obtained. It was prepared by Fe(II) adsorption onto loaded SG from distilled water contained 0, 6, 10, 30 and 50 µg Fe. The scale has been stable for more than 4 months. This sorbent can also be used for visual detection of the sum concentration of Fe ions in solution (when citrate ions are absent) after reduction of Fe(III) with ascorbic acid.

The adsorption reflectance spectrophotometric methods for this purpose were developed, too.

3.5.2. The sum concentration of Fe ion determination in water by using SG

The calibration graph was linear in the range 0.02–10 ppm. The calibration equation was: $R = 0.33 + 1.5 \cdot 10^{-2} C_{\text{Fe}^{2+}}$, (µg per sample), $r = 0.975$. The detection limit was 0.012 ppm (100 ml of the sample solution).

The sample of natural water (100 ml) with the addition of 1 ml saturated solution of ascorbic acid, 10 ml 15 mM Phen, 10 ml buffer solution (pH 5.5) was been stirred with 0.2 g SG for 10 min.

3.5.3. The Fe(II) determination in water by using Phen–SG

The calibration graph was linear in the range 0.1–15 ppm, calibration equation was: $R =$

$0.31 + 1.3 \cdot 10^{-2} C_{\text{Fe}^{2+}}$, (μg per sample), $r = 0.985$. The detection limit was 0.08 ppm (20 ml sample solution). It was shown that 100 times the quantity of Fe(III) in the presence of citrate ions does not interfere with the Fe(II) determination.

The sample of natural water (20 ml) with the addition of 0.2 ml 0.3 M K_3Cit and 0.2 ml buffer solution (pH 5.5) was been stirred with 0.2 g of Phen-SG mechanically for 10 min.

In both cases the sorbents were filtered, dried at room temperature and the sum of the concentration of Fe was determined by diffusion reflectance spectroscopy ($\lambda = 514$ nm).

The results of Fe(II) determination in the model solutions and natural water are shown in Table 3. The content of Fe ions in natural water was controlled by the spectrophotometric method with Phen [14]. It was found that Fe(II) content was 1.8 ± 0.6 ppm.

3.5.4. Cu(II) determination

The colour scale for the Cu(II) visual test determination in the range 15–320 μg per sample was developed. It was prepared by adsorption of Cu(II) onto Phen-SG from 0.2 M ammonium solution contained 0, 30, 50, 200 and 320 μg Cu. The scale has been stable for more than 4 months.

3.5.5. Cu(II) determination in water by using Phen-SG, SG and diffusion reflectance spectroscopy

The calibration graphs were linear in the range 0.04–32 ppm (SG) and 0.03–16 ppm (Phen-SG). The calibration equations were: $R = 0.03 + 0.25 \cdot 10^{-2} C_{\text{Cu}^{2+}}$, (μg per sample), (SG, $r = 0.993$); $R = 0.01 + 0.56 \cdot 10^{-2} C_{\text{Cu}^{2+}}$, (μg per sample), (Phen-SG, $r = 0.995$). The detection limit was 0.04 ppm (200 ml sample solution) using SG and 0.03 ppm (100 ml sample solution) using Phen-SG.

It is known [10] that Ni(II) and Co(II) form complexes with ammonia and can be adsorbed onto SG and Phen-SG. So their influence on the Cu determination was studied. It was shown that Ni(II) and Co(II) do not influence the

Cu(II) determination at a concentration of $\leq 10^{-4}$ mol l^{-1} (Phen-SG) and $\leq 3 \times 10^{-5}$ mol l^{-1} (SG).

The sample of natural water (100–200 ml) buffered to pH 8.8 with ammonium buffer was been stirred with 0.5 g of SG or Phen-SG mechanically for 10 min. In both cases the sorbents were filtered, dried at room temperature and than content of Cu was determined by diffusion reflectance spectroscopy at 685 nm (SG) and 715 nm (Phen-SG).

The results of Cu(II) determination in different types of water are shown in Table 3. The content of Cu(II) in natural water was determined by the atomic absorption method was 2.0 ppm [18].

3.5.6. Ag(I) determination

The colour scale for the visual test determination of Ag(I) in water in the range 0.5–50 μg per sample was developed. It was prepared by adsorption of Ag(I) from 0.02 mM BPR solution (pH 2) contained 0, 1, 5, 25, 50 μg of Ag. The scale has been stable for more than 4 months.

The diffusion reflectance spectroscopic method for Ag(I) determination was developed. The calibration graph was linear in the range 0.05–1.1 ppm. The calibration equation was: $R = 0.2 + 3.24 \cdot 10^{-2} C_{\text{Ag}^+}$, (μg per sample), ($r = 0.998$). The detection limit was 0.003 ppm (200 ml sample solution). The 10 times Cu(II) and 100 times Fe(III) quantities do not interfere with Ag(I) adsorption in presence of EDTA. This method was applied for Ag(I) determination in mineral water.

The samples of mineral water (200 ml) was mixed with 10 ml 0.1 mM BPR, 5 ml 0.25 mM EDTA, 5 ml 17% urotropin, and 0–5 ml 0.04 mM Ag(I) and stirred mechanically with 0.5 g Phen-SG for 10 min. Sorbents were dried at room temperature for 24 h. Ag(I) content in water was determined by use diffusion reflectance spectroscopy ($\lambda = 560$ nm). The results of Ag(I) determination in the model solutions and the mineral water “Cylushcha” are shown in Table 3. The content of Ag(I) in the mineral water determined by the atomic absorption method was 0.005 ppm [18].

Abstract

The construction and electrochemical response characteristics of poly (vinyl chloride) and poly (vinyl chloride) carboxylate membrane sensors for the determination of cyclophosphamide and ifosphamide are described. Based on the formation of an ion-pair complex between the drug cation and sodium tetraphenylborate, two poly (vinyl chloride) sensors, namely a cyclophosphamide membrane sensor and ifosphamide membrane sensor were fabricated. They show a linear response for both drugs over the concentration range 10^{-2} – 10^{-4} M with cationic slopes of 56 and 54.6 mV per concentration decade, for sensor 1 and sensor 2, respectively. Based on the interaction between the drug solution and the dissociated COOH groups in the poly (vinyl chloride) carboxylate, sensor 3 was fabricated. It shows a linear response for both drugs over the concentration range 10^{-3} – 10^{-5} M with a cationic slope of 49.7 mV per concentration decade. The direct potentiometric determination of cyclophosphamide and ifosphamide in their pharmaceutical preparations using the proposed sensors gave average recoveries of 101.3 ± 0.6 , 100.8 ± 10.7 and $102.0 \pm 11.0\%$ for the sensors 1, 2 and 3, respectively, which compares reasonably well with the data obtained using the British Pharmacopoeial method (1993). Sensors 1 and 2 were also used to follow up the stability of the drugs studied in the presence of their degradates. These degradation products have no diverse effect on the responses of sensors 1 and 2. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Cyclophosphamide; Ifosphamide coated wire sensor; PVC matrices; PVC-COOH matrices

1. Introduction

Cyclophosphamide (bis-(2-chloroethyl) amino perhydro-2H-1,3,2-oxazaphosphorine-2-oxide) and its isomer ifosphamide (3-(2-chloroethyl) 2-

chloroethylamino perhydro-2H-1,3,2-oxazaphosphorine-2-oxide) have been used clinically as useful anticancer drugs for more than 30 years [1].

The British [2], Indian [3] and Egyptian [4] pharmacopoeia methods for the determination of cyclophosphamide are based on the monitoring of its phosphorus content via titrimetric procedures.

* Corresponding author. Fax: +20 2 3624105.

The USP [5] recommended assays based on liquid and gas chromatographic techniques for determination of cyclophosphamide and ifosphamide, respectively.

A variety of methods have been also reported for the determination of the two drugs studied and their metabolites. Original studies used nitrobenzylpyridine for the spectrophotometric determination of cyclophosphamide [6]. Other spectrophotometric methods based on the formation of chromogenic species with benzidine [7], cobalt thiocyanate [8] and nitrous acid [9] have been suggested. Infra red [10], nuclear magnetic resonance [11], mass spectrometry [12], polarography [13], flow injection [14], fluorimetry [15,16], analysis via its chloride [17] and phosphorus content [18,19], thin layer chromatography [20,21], gas chromatography [22–24] and high pressure liquid chromatography [25,26] have been also recommended. Only one potentiometric procedure [27] has been reported for the determination of cyclophosphamide using a chloride ion-selective electrode.

Tetraphenylborate was reported as a famous ion exchanger [28] and as a direct titrant [29] for about 17 basic drugs. It has been used in the formation of many sensors [30]. In the present study, it has been found that both cyclophosphamide and ifosphamide react with tetraphenylborate with the formation of water insoluble ion association complexes. The high lipophilicity and remarkable stability of these complexes suggested their use as electroactive materials in PVC matrix membrane sensors for the determination of the two drugs studied, selectively, in the presence of their nine degradation products. The major degradates have been shown to be *N*-(2-hydroxyethyl)-*N*-(3 hydroxypropyl) ethylenediamine, phosphorylated ammonium ion, bis(2-chloroethyl) ammonium chloride, chloride ion and phosphate ion [21,25,31,32].

Another simple and inexpensive procedure for the fabrication of coated wire microelectrodes has been developed using PVC-COOH and plasticizer in the ratio 70:30% as the electroactive membrane.

The advantages of potentiometric sensors is their simplicity, low cost, fast response, wide pH range and applicability to turbid and coloured

solutions, combined with the wide medical use of microsized coated wire design, to form the three investigated potentiometric sensors that offer highly sensitive, selective and a convenient technique for the determination of cyclophosphamide and ifosphamide in their pharmaceutical preparations as well as in the presence of their related substances and degradation products.

2. Experimental

2.1. Apparatus

Potentiometric measurements were made with an Orion Digital ion analyser (model 720A) and an Orion 90–02 Ag/AgCl double junction reference electrode containing 10% w/v KNO₃ in the outer compartment. pH adjustment was made with an Orion 91–20 combination glass electrode. A platinum wire of 1.0 mm diameter was used for the ion selective electrodes.

2.2. Reagents

All chemicals were of analytical reagent grade and bidistilled deionized water was used throughout. Cyclophosphamide and ifosphamide were obtained from Asta Pharma, with a purity of not less than 98% and assayed by the BP (1993) pharmacopoeia method to contain 99.6 ± 1 and

99.6 + 0.9% cyclophosphamide and ifosphamide, respectively.

Aqueous 10^{-3} – 10^{-5} M of the drug solutions were freshly prepared by accurate dilutions of a standard 10^{-2} M stock drug solution. Poly (vinyl chloride) (PVC) (molecular weight \cong 1000, poly (vinyl chloride) carboxylate (PVC-COOH), sodium tetraphenylborate (TPB), tetrahydrofuran (THF), a solvent with a purity of 99%, dioctylphthalate (DOP) and nitrophenyl octyl ether (NPOE), plasticizers with a purity of 99%, 1 M hydrochloric acid.

2.3. Procedures

2.3.1. PVC membrane sensors 1 and 2

We acidified 5 ml 10^{-2} M aqueous drug solution with two drops of 1 M hydrochloric acid and mixed them with the saturated aqueous solution

of TPB. We filtered the resultant precipitate, washed it with cold water, dried it at room temperature and ground it to a fine powder, forming the ion-pair complex. Elemental analysis and infrared data confirmed the formation of 1:1 complexes.

In a glass Petri dish (5 cm diameter), we thoroughly mixed 10 mg of the ion-pair complex with 0.35 ml dioctylphthalate and then added 0.19 g PVC. The mixture was dissolved in 5 ml THF, then the Petri dish was covered with a filter paper and left to stand for 1 h to allow slow evaporation of the solvent, producing the master thick PVC solution.

We removed the cover for a length of about one cm at both ends of an insulated platinum wire. One end of the wire was immersed in the previously prepared PVC solution and was left to stand for 10 min to allow complete air drying,

Fig. 2. Profile of the potential in mV to the $-\log$ concentrations of either cyclophosphamide or ifosphamide using sensor 3.

forming a thin membrane around the wire end. We repeated the immersing and air drying until we obtained a globular membrane of about 3 mm diameter around the wire end. The resultant coated wire membrane sensor had to be conditioned by soaking in 10^{-2} M drug solution for 3 h and had to be stored in the same solution when not in use.

2.3.2. PVC-COOH sensor 3

In a glass Petri dish, we thoroughly mixed 0.2 g PVC-COOH with 0.09 ml NPOE then dissolved the mixture in 1.65 ml THF. The Petri dish was covered with a filter paper and left to stand for 10 min to allow slow evaporation of the solvent, producing a thick solution. We constructed a

globular membrane of about 3 mm diameter around the platinum wire end as described above. The resultant coated wire membrane had to be conditioned by soaking in 10^{-2} M drug solution for 24 h and had to be stored in the same solution when not in use.

2.3.3. Sensors calibration

We calibrated the conditioned sensors with aqueous drug solutions in the range from 10^{-2} to 10^{-6} M by immersing the coated wire membrane sensor and the Orion double junction Ag/AgCl reference electrode in the drug solution, allowing them to equilibrate whilst stirring and recording the emf readings within ± 1 mV. We stored the membrane sensor in deionized bidistilled water

between measurements. We plotted the mV–concentration profile.

2.3.4. Potentiometric titration of phosphamides

We transferred 2, 4, 6, 8 and 10 ml aliquots of 10^{-3} M drug to 50 ml beakers. The sensor to be investigated, in conjunction with the Ag/AgCl reference electrode, were immersed in the solution and titrated with 10^{-3} M standard tetraphenyl borate solution. We recorded the mV readings after each addition of the titrant.

2.3.5. Application to pharmaceutical formulations

2.3.5.1. Endoxan vial and Holoxan vial. The contents of 10 vials were mixed and a quantity of the mixed contents corresponding to about 0.279 g were transferred to a 100 ml volumetric flask and filled to the mark with water to prepare a 10^{-2} M aqueous solution of cyclophosphamide or ifosphamide in the case of Endoxan and Holoxan vial, respectively. They were finished as in Section 2.3.3.

2.3.5.2. Endoxan tablet. We mixed and powdered 20 tablets and calculated the average weight of one tablet. A quantity corresponding to about 0.279 g was transferred to a 100 ml volumetric

Fig. 3. Effect of pH on the responses of sensor 1 (○—○) and sensor 2 (△---△).

Fig. 4. Effect of pH on the response of sensor 3.

flask and filled to the mark with water to prepare a 10^{-2} aqueous solution of cyclophosphamide. It was finished as in Section 2.3.3.

2.3.5.3. Stability study. Degraded samples of 10^{-3} M cyclophosphamide and ifosphamide solutions were prepared by refluxing an aqueous solution for 6 and 10 h, respectively, followed by cooling. A 10^{-3} M standard drug solution was mixed with its degraded sample in different ratios. The emf of these laboratory prepared mixtures were measured and the recorded results were compared with the calibration plots.

3. Results and discussion

The increasing importance of chemotherapeutic drugs in cancer treatment makes the manufacture of microzised sensors an area of interest. The advantages they offer over conventional electrodes are well known [33], their reduced diffusion

layer allows fast response, their small currents lead to low susceptibility to ohmic loss and thus, enable their use in highly resistive biological media and their small physical size allows exploitation of microscopic domains.

In the present work, the microsized coated wire membrane sensors were fabricated with either PVC or PVC-COOH as a polymer matrix. In the PVC sensors fabrication, it was found that both cyclophosphamide and ifosphamide which contain a tertiary amino group, behave as cations in acidic media. This fact suggests the use of anionic type of ion exchangers, tetraphenylborate with its low solubility product and suitable grain size was found to be the optimum for the formation of 1:1 hydrophobic ion association complexes with the two studied drugs of the type shown below.

In the PVC-COOH sensor fabrication, it was found that the tertiary amino groups in the two drug solutions studied undergo some acid–basic interactions with the dissociated carboxylic

groups of the PVC-COOH till reaching chemical equilibria as in the following equation:

Making use of the two recommended properties of PVC-COOH, that is the partial dissociation and the high adhesion, the proposed sensor 3 was simply fabricated without need of ion association complex formation.

Both PVC and PVC-COOH act as regular support matrices for the membrane and reproducible traps for the ions sensed, but their use creates a need for a mediator [34]. In the present investigation, DOP was found to be the optimum available mediator for the PVC membrane sensors. It plasticizes the membrane, dissolves the ion- association complexes and adjusts both of the membranes permittivity and ion-exchanger sites mobility to give the highest possible selectivity and sensitivity. Except for nitroaromatic mediators which had the same effects as DOP, other mediators such as dibutylsebacate, tricresylphosphate and castor oil gave noisy responses with little discrimination for concentration changes (slopes 42, 28 and 8 mV per decade drug concentration, respectively). On the other hand, NPOE, was found to be the optimum available mediator for the PVC-COOH membrane sensor. The use of nonpolar mediators such as DOP leads to insufficient selectivity differences in the sensor response towards foreign cations. The quantity of the mediator used was found to be a critical factor for the reproducibility and life time of sensor 3; increasing the mediator ratio more than 30% led to a decrease in the highly adhesive property of the PVC-COOH polymer giving the membrane limited life time and nonreproducible results.

Electrochemical performance characteristics of the proposed sensors were systemically evaluated according to IUPAC standards [35].

Table 1 shows the results obtained over a period of three months for 10 different assemblies of each sensor. Typical calibration plots are shown in Figs. 1 and 2. The sensors displayed constant potential readings within ± 1 mV from day to day and the calibration slopes did not change by more than 1 mV per decade over a period of 12 and 10 days for the PVC and PVC-COOH sensors, respectively.

In measurements with the three investigated sensors, the experimental conditions were studied to reach the optimum. A pH value within the range 4–7 was found optimum from the point of view of both sensor function and the chemical form of the test solution, i.e. cyclophosphamide and ifosphamide being in the cationic form in acidic media. Figs. 3 and 4 shows the potential pH profiles for 10^{-3} and 10^{-4} M drug solutions. Above pH 8, the potentials displayed by the sensors sharply decreases due to formation of non-protonated cyclophosphamide and ifosphamide. Below pH 4, the potentials displayed by the sensors were noisy and unbalanced due to sensor shocking. It is apparent that the sensors responses are fairly constant in acetate buffer solutions of pH 4–7.

Although the three suggested sensors exhibit a slight gradual increase in their potentials as the temperature increases in the range 25–45°C, the limit of detection and response time do not significantly vary due to change of temperature, indicating reasonable thermal stability of the PVC and PVC-COOH membranes up to 35°C.

It is clear that both PVC and PVC-COOH polymers were affected similarly by pH and temperature.

Although, the investigated coated wire sensors consist of membranes of either PVC/sensing system/mediator or PVC-COOH/mediator in ratios 34:2:64 or 70:30%, respectively, i.e. without an internal reference system, there is a confident view that the coated wire sensors have an inbuilt reference system which is attributed to the permeability of PVC and PVC-COOH to both water and oxygen and, thus, setting up an oxygen electrode at the wire membrane interface to function as an internal reference system [33].

The reliability of the proposed membrane sensors for the quantification of cyclophosphamide and ifosphamide was assessed by determining 10^2 – 10^{-4} M on using sensors 1 and 2 and 10^{-3} – 10^{-5} M on using sensor 3 on the pure powder of the drugs using both the calibration graph and the standard additions method. The results showed average recoveries of 101.3 ± 0.6 , 100.8 ± 0.7 and $102.0 \pm 1\%$, respectively. Typical S-shape titration curves were obtained using sen-

sors 1 and 2, the equivalence points are reproducible. The excellent agreement between the results obtained for the determination of a series of vials and tablets by both the proposed potentiometric procedures and the B.P. (1993) method (Table 2), suggests the successful application of the proposed methods for the pharmaceutical formulations.

Although, the sensors investigated failed in the differentiation between cyclophosphamide and ifosphamide, they succeeded in the quantification of either drug in presence of their degradates and related substances.

The potentiometric selectivity coefficients of the proposed sensors were calculated in presence of the nine recommended degradates of either drug [21,25,29] and also in presence of some organic and inorganic related substances, using separate technique [36]. The results revealed that PVC membrane sensors 1 and 2 displayed higher selectivity and lower response for the potentially interfering species than the PVC-COOH sensor. Sensors 1 and 2 were at least 10–100 times more selective than sensor 3.

It was reported that cyclophosphamide completely disappeared on exposing it to 0.1 M unbuffered aqueous solution to refluxing for 6 h. Ifosphamide was reported to have a slower disappearance rate; it needs refluxing for 10 h to completely disappear, however, its degradation products are similar to that derived from cyclophosphamide [32].

Table 3 shows the results obtained with synthetic mixtures containing different ratios of drug with its degraded sample. The results show that the proposed sensors 1 and 2 can be successfully used for the determination of intact cyclophosphamide and ifosphamide in the presence of up to 50% of their degradates.

Abstract

Screen-printed carbon electrodes have been developed as disposable voltammetric sensors for 2,4,6-trinitrotoluene (TNT). Thick-film electrodes based on various conventional and modified inks have been compared for this task. The operation is based on placing the selected thick-film carbon sensor in the non-deaerated/quiescent sample and using a fast (< 1 s) and sensitive square-wave voltammetric scan. Different experimental variables have been optimized to yield a detection limit of 200 ppb TNT and a wide linear range. The high selectivity, demonstrated in assays of various untreated environmental samples, is attributed to the facts that the reducible nitro group is rare in nature and that most electroactive organic compounds require higher potentials. The new single-use sensor strips should facilitate the on-site environmental screening of TNT. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Electrochemical sensor; Explosive detection; Screen-printed electrode; Square-wave voltammetry; TNT

1. Introduction

Because of upsurge in terrorist and criminal activity, there are urgent needs for reliable methods for the detection of explosives such as 2,4,6-trinitrotoluene (TNT) [1]. In addition to forensic or security considerations, such methods should address the environmental and toxicological significance of various explosives. In particular, with the end of the Cold War, the environmental community is confronted with problems of water and

soil on military sites contaminated with explosives.

Cumbersome and expensive instruments based on X-ray imaging or thermal neutral analysis have been introduced recently for the detection of hidden explosives [1,2]. In addition, bench-top instruments based primarily on chromatographic techniques are commonly used for laboratory measurements of explosives in water samples [3,4]. More compact low-cost instruments, coupled to smaller sensing probes, are highly desired for facilitating the task of on-site monitoring of explosives. Although sniffing dogs can provide high portability and selectivity, they are unpredictable

and require special training. Recent activity at the US Naval Research Laboratory resulted in a portable fiber-optic competitive immunosensor for rapid on-site detection of TNT [5]. Surprisingly, little attention has been given to electrochemical sensing of nitroaromatic explosives, despite their inherent redox activity [4] and the compact nature of electrochemical instruments.

In this paper we describe the characterization and performance of a disposable sensor strip for on-site electrochemical measurements of TNT. The screen-printing (thick-film) technology represents an ideal route for large-scale fabrication of highly reproducible and yet inexpensive electrochemical sensors [6]. While most of

the commercial activity in this direction has focused on 'one-shot' glucose sensors [7], screen-printed electrodes have been shown to be useful for the amperometric biosensing of other metabolites [8] or toxic enzyme inhibitors [9], for decentralized stripping measurements of trace metals [10], or for the specific detection of DNA sequences [11].

In the following sections we will compare various conventional and modified thick-film electrodes for on-site screening of TNT, and will demonstrate the attractive analytical performance accrued from the coupling of disposable carbon strips with rapid square-wave voltammetric (SWV) detection of this important explosive.

Fig. 2. Effect of the SWV frequency (A) and the amplitude (B) upon the voltammetric response of 10 ppm TNT at the screen-printed carbon electrode. Other conditions as in Fig. 1A.

2. Experimental

2.1. Apparatus

Most experiments were performed using a microprocessor-controlled electrochemical analyzer (Model 620; CH Instruments), interfaced with an IBM personal computer. The AutoLab electrochemical system (Eco Chemie) was used for obtaining the background-corrected voltammograms. SWV measurements were carried out in a 5-ml electrochemical cell (Model VC-2; BAS). The screen-printed electrode, the reference electrode (Ag/AgCl (3 M NaCl), Model RE-1; BAS), and platinum wire auxiliary electrode joined the cell through its Teflon cover.

2.2. Ink preparation

Four different inks were used and compared. These included unmodified carbon or gold inks from Ercon (Ercon G-449 (I) and Exp 44281, respectively), and metal-dispersed carbon inks. These were prepared by thoroughly mixing (for 30 min with a spatula) 1.9 g of carbon ink (Ercon, G-449 (I)) with 100 mg iridium powder (Alfa, 325

mesh, 99.9%) or ruthenium powder (Alfa, 325 mesh, 99.95%) to give a 5%wt. metal loading.

2.3. Screen-printed electrode fabrication

A semi-automatic screen printer (Model TF 100; MPM, Franklin, MA) was used for printing the working electrodes. The inks were printed through a patterned stencil onto 10 cm × 10 cm alumina ceramic plates containing 30 strips (of 3.33 cm × 1.00 cm, as defined by a laser pre/semi cut). The resulting 1 mm × 30 mm printed carbon structures were cured for 30 min at 100°C; the gold ink was cured at 150°C for the same period. An insulating ink (Ercon R-488c1, Green) was subsequently printed on a portion of the plate, to leave 1 mm × 5 mm sections on both ends for defining the working electrode and electrical contact. The insulating layer was cured at 100°C for 30 min.

2.4. Reagents and procedure

All solutions were prepared daily with double-distilled water using reagent-grade chemicals. The TNT stock solution (100 ppm in water) was a gift

Fig. 3. Effect of the ionic strength upon the SWV response (peak current (A) and potential (B)) of the carbon strip electrode towards 10 ppm TNT. Other conditions as in Fig. 1A.

from Sandia NL. Potassium phosphates (monobasic and anhydrous) were obtained from Sigma, hydrochloric acid from J.T. Baker and acetic acid (glacial) from Fisher Scientific. A potassium phosphate buffer solution (0.05 M, pH 6.5) was employed in most experiments. The river water (Rio Grande) and groundwater samples were collected at Las Cruces (NM) and the Hanford Site (Richland, A), respectively.

All measurements were performed at room temperature, using non-deaerated quiescent solutions and a rapid Osteryoung SWV scan from 0.0 to -0.70V .

3. Results and discussion

Polynitroaromatic compounds, such as TNT, are readily reduced, particularly at various mercury electrodes. Such compounds undergo stepwise reduction processes, involving initial reduction of the nitro groups to a hydroxylamine, followed by conversion to an amine group. While mercury drop [12] or film [4] electrodes have been traditionally used for laboratory measurements of reducible explosive substances, solid-state 'mercury-free' devices should be more attractive for

single-use field-screening applications. Accordingly, we evaluated various conventional and modified screen-printed electrodes as disposable TNT sensors.

Fig. 1b compares square-wave voltammograms for trace (1 ppm) TNT at carbon (A), gold (B), iridium-dispersed carbon (C) and ruthenium-dispersed carbon (D) screen-printed electrodes. All strip electrodes display a single voltammetric peak (at ca. -0.45V), corresponding to the formation of the hydroxylamine moiety. However, only the unmodified carbon strip results in a well-defined response, suitable for such trace measurements. With the other sensors the peak appears as a shoulder on a rising background current (associated with the reduction of dissolved oxygen). Apparently, the metal-dispersed (Ru and Ir) catalytic centers have a more profound effect on the oxygen background than upon the target TNT signal. In view of its favorable signal-to-background characteristics, the screen-printed carbon electrode was used for all subsequent analytical work. The very low oxygen background current of this sensor eliminates the need for a time-consuming deoxygenation step and hence further simplifies practical field operations. Additional reduction peaks were observed at the carbon strip electrode

Fig. 4. Effect of solution pH upon the SWV response (peak current (A) and potential (B)) of the carbon strip electrode towards 10 ppm TNT. Other conditions as in Fig. 1A.

upon scanning to more negative potentials (up to -1.1 V). However, due to the high background at these negative potentials all analytical work was focused on the first reduction process at -0.45 V.

The data of Fig. 1 indicate that the combination of carbon strip electrodes with rapid SWV yields an attractive analytical behavior. Besides its high sensitivity and speed, SWV offers higher information content compared to the chronoamperometric measurements commonly employed in connection with screen-printed sensors. The effect of different variables of the SWV waveform was explored for further optimization. Fig. 2A examines the influence of the square-wave frequency upon the response to 10 ppm TNT. The peak current rises sharply with the frequency at first up to 50 Hz, and then decays gradually. The effect of the SWV amplitude (height of square-wave component) is shown in Fig. 2B. The TNT signal increases nearly linearly upon raising the amplitude between 5 and 50 mV, and then more slowly. All subsequent work was thus carried out using an amplitude of 25 mV, a frequency of 50 Hz, and a staircase step height of 4 mV (i.e., less than 5 s for the entire scan). We also attempted to increase the sensitivity by employing a preceding adsorp-

tive accumulation of TNT (i.e., an adsorptive stripping operation). However, only a slight (15%) signal enhancement was observed in connection with a 3 min preconcentration at 0.0 V. Such a stripping approach was abandoned considering also its very slow response time.

Field-screening applications will greatly benefit from the minimization of sample pretreatment. Reduced dependence upon solution variables (such as pH or ionic strength) would assure a minimal sample pretreatment and simplified field operations. Fig. 3 displays the dependence of the SWV response upon the solution ionic strength. As desired, the sensor displays a broad ionic strength independence, with minimal changes in the peak current (A) or potential (B) for phosphate buffer concentrations ranging from 10 to 200 mM. As might be expected, a sharp decrease in the current response and large potential shift are observed without any electrolyte. Environmental water samples commonly contain sufficient natural electrolyte, and hence permit convenient and direct monitoring of TNT (see following sections).

Fig. 4 examines the effect of the pH upon the SWV TNT response. The peak current increases nearly linearly with the pH over the 3.5–5.5

Fig. 5. SWV response of the thick-film carbon sensor to TNT solutions of increasing concentration from 1 ppm to 10 ppm (b–k), along with the background voltammogram (a). Other conditions as in Fig. 1A.

range, and then it starts to level off (A). The nearly pH independence over the 5.5–8.5 range indicates great promise for numerous natural water matrices (with quantitation based on calibration in the given matrix). As expected from the

involvement of protons in the redox reaction, the peak potential shifts negatively (in a nearly linear fashion) upon raising the pH from 3.5 to 8.5 (B).

Fig. 5 displays SW voltammograms for increasing levels of TNT in 1 ppm steps (b–k), along

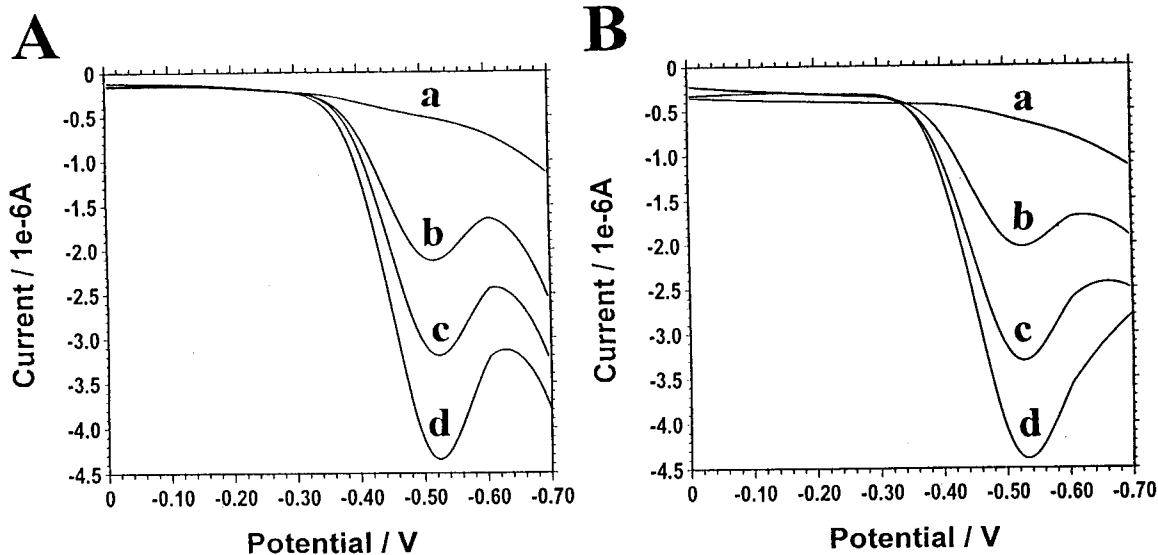

Fig. 6. Assays of untreated river water (A) and groundwater (B) samples. Response to the sample (a), as well as subsequent concentration increments of 3 ppm TNT (b–d). Other conditions as in Fig. 1A.

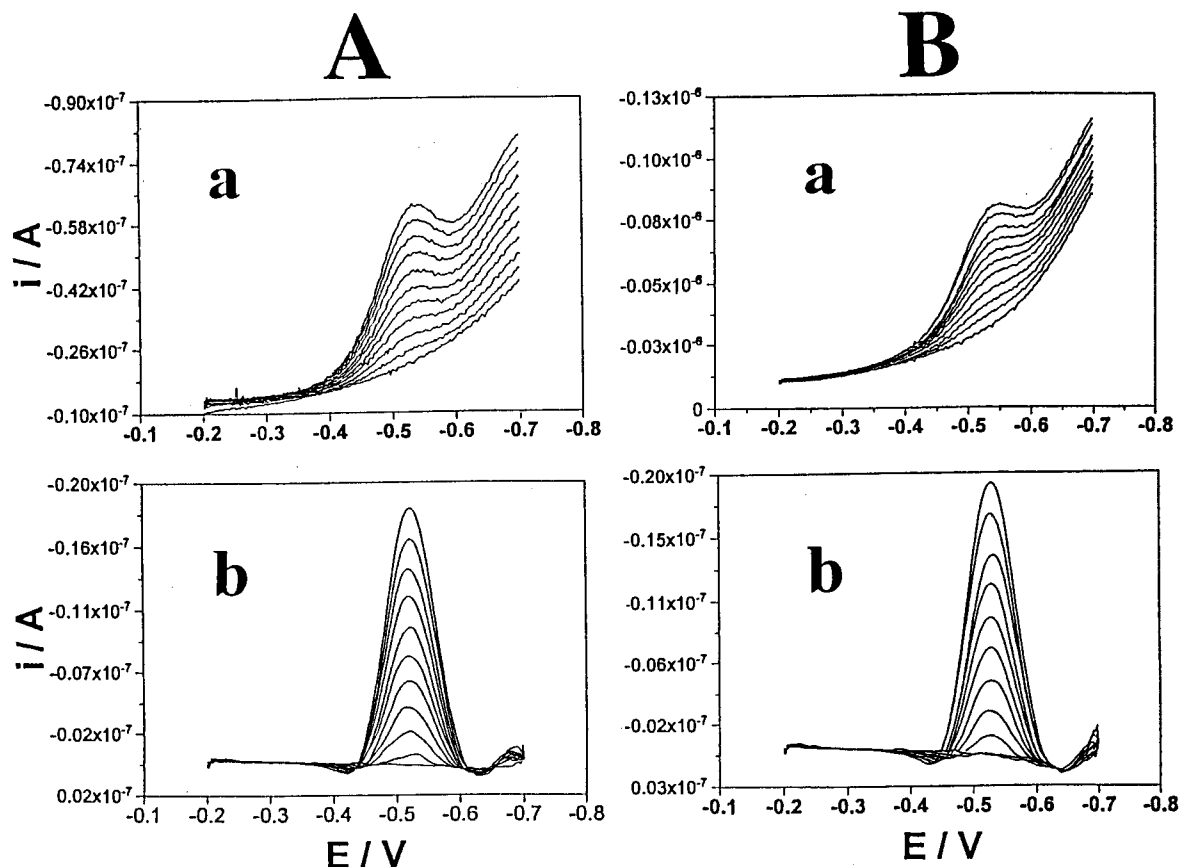

Fig. 7. Conventional (a) and background-corrected (b) square-wave voltammograms for untreated tap water (A) and river water (B) samples containing increasing levels of TNT in 200 ppb steps, along with the sample blank voltammogram. Amplitude, 10 mV; frequency, 30 Hz; step, 2 mV.

with the blank voltammogram (a). Well-defined peaks, proportional to the explosive concentration, are observed, along with the low background response. The resulting calibration plot (also shown) is highly linear (slope, 4.144 $\mu\text{A/ppm}$; correlation coefficient, 0.999). Besides their promise for single-use field applications, the screen-printed electrodes can be used as reusable TNT detecting devices. For example, a prolonged series of 16 repetitive measurements of 10 ppm TNT using the same carbon strip resulted in a highly stable peak current, with a relative standard deviation of 0.6% (not shown).

High selectivity is expected in environmental samples because the nitro group is rare in nature and few other organic compounds are as easily reduced [13]. The screen-printed carbon electrodes

thus holds great promise for direct analysis of relevant water samples, without any prior separation or pretreatment. Fig. 6 displays typical SW voltammograms, illustrating such assays of untreated river water (A) and groundwater (B) samples. A low (nearly flat) baseline is observed for both samples (a), indicating the absence of interfering electroactive species. Three subsequent additions of 3 ppm TNT resulted in well-defined peaks, proportional to the explosive concentration, and similar to those common in synthetic samples. Note again that neither pH nor ionic strength adjustments were required to obtain these high-quality voltammetric data. We also tested the effect of potential organic, inorganic and surface-active interfering materials. The response for 5 ppm TNT was not affected by the presence of 50 ppm of the

similar nitroaromatic compounds nitrophenol and nitrobenzene, by the presence of 1000 ppm of nitrite or nitrate ions, by 1 ppm of the reducible copper, iron(III), lead or zinc ions, or the presence of 10 ppm Triton X-100 or sodium dodecyl sulphate. Yet, it is strongly recommended to employ the new screen-printed voltammetric electrodes as early screening/warning devices (in connection to a high-resolution laboratory confirmation technique). It should be pointed out that even the use of antibodies for imparting selectivity into TNT sensing suffers from cross-reactivity interferences from structurally similar nitroaromatic compounds [5].

Extremely low detection limits can be achieved in connection with a computerized background-correction operation. Fig. 7 compares conventional (a) and background-subtracted (b) square-wave voltammograms for untreated tap (A) and river (B) water samples, containing increasing levels of TNT in 200 ppb steps (along with the blank voltammogram). Such a background-correction operation offers a detection limit of about 100 ppb. Note again the absence of electroactive interferences in these untreated water samples, and the well-defined concentration dependence.

In conclusion, the results presented above demonstrate that the coupling of rapid SWV with screen-printed electrodes results in effective disposable sensors for TNT. As desired for field operations, such coupling leads to a fast, sensitive, simple and low-cost detection of TNT. Although the present work deals with the measurement of TNT, other nitro-containing explosives (e.g. RDX, HMX, picric acid) may be similarly detected on the basis of differences in their peak potentials [4], and in connection with chemometric or on-chip separation schemes. The coupling of these single-use devices with hand-held, battery-operated, instruments should facilitate on-site

environmental screening of TNT.

Remote (submersible) electrochemical sensors, based on the rapid SWV strategy, can also be envisioned for continuous real-time monitoring applications.

Spectral characterization of a novel near-infrared cyanine dye: a study of its complexation with metal ions

Leila Tarazi, Abraham George, Gabor Patonay *, Lucjan Strekowski

Department of Chemistry, Georgia State University, University Plaza, Atlanta, GA 30303, USA

Received 29 April 1997; received in revised form 4 December 1997; accepted 15 December 1997

Abstract

The spectral features of the near-infrared (NIR) dye TG-170 in different solutions and its complexation with several metal ions were investigated. The absorbance maxima of the dye are at $\lambda = 819, 805,$ and 791 nm in dimethyl sulfoxide (DMSO), methanol, and a buffer of pH 5.9, respectively. These values match the output of a commercially available laser diode (780 nm), thus making use of such a source practical for excitation. The emission wavelengths of the dye are at $\lambda_{em} = 822, 812,$ and 803 nm in DMSO, methanol, and the buffer, respectively. The molar absorptivity and fluorescence quantum yield increase accordingly. The addition of either an Al(III) ion or Be(II) ion resulted in fluorescence quenching of the dye. The Stern–Volmer quenching constant, K_{SV} , was calculated from the Stern–Volmer plot to be $K_{SV} = 3.11 \times 10^5 \text{ M}^{-1}$ for the Al(III) ion and $K_{SV} = 1.17 \times 10^6 \text{ M}^{-1}$ for the Be(II) ion. The molar ratio of the metal to the dye was established to be 1:1 for both metal ions. The stability constant, K_S , of the metal–dye complex was calculated to be $4.37 \times 10^4 \text{ M}^{-1}$ for the Al–dye complex and $1.94 \times 10^6 \text{ M}^{-1}$ for the Be–dye complex. © 1998 Elsevier Science B.V. 1. Introduction

Fluorescence spectroscopy has long been established as a versatile, sensitive, and easy-to-use analytical technique [1] for a large variety of applications, including chromatography [2], immunoassay [3], and detection of metals [4–6]. Most of the work reported in the literature related to detection of metals by means of fluorescence

techniques used UV-Vis fluorophores such as rhodamine, fluorescein, 8-hydroxyquinoline, and their derivatives [5,7–9]. Unfortunately, spectral interference is significant in this region. The use of near infrared dyes (NIRDs) absorbing in the region from 700 to 1000 nm is a better alternative because this region exhibits low interference [10–13]. Thus, NIR dyes have great potential for the development of chemical sensors for the detection of metal ions.

We have focused our attention on cyanine dyes, a general structure of which is shown below.

* Corresponding author. Tel.: +1 404 6513856; fax: +1 404 6511416; e-mail: cheggp@panther.gsu.edu

Structure of a typical cyanine dye.

A dye of this class is composed of two heterocyclic systems linked by a polymethine chain, and all three moieties contribute to spectral properties of the chromophore. In particular, the absorption maximum undergoes a bathochromic shift of about 100 nm with elongation of the polymethine chain by one vinyl (CH=CH) group [14]. The heptamethine and higher cyanines absorb in the NIR region with an unusually high molar absorptivity of up to $300\,000\text{ M}^{-1}\text{ cm}^{-1}$. The fluorescence quantum yield is from 0.1 to 0.3 and is structure dependent [15]. Of major concern is the relatively low light fastness of certain cyanines. Indolium derivatives, however, exhibit good light stability that additionally can be improved by incorporating a ring structure into the polymethine chain [16].

The use of semiconductor lasers for excitation further enhances the advantage of the NIR spectral region. The absorbance maxima of most of the NIR dyes are compatible with the output of commercially available laser diodes. The use of laser diodes

for excitation provides a highly powerful monochromatic excitation, which makes detection at extremely low limits possible [13,17].

Recently we have reported synthesis [18] of a heptamethine cyanine dye, 4-carboxy-2-[4'-chloro-7'-(4''-carboxy-5''-hydroxy-1''',3''',3'''-trimethylindolin-2''-ylidene)-3'-5'-(propane-1''',3'''-diyl)-1',3',5'-heptatrien-1'-yl]-5-hydroxy-1,3,3-trimethyl-3H-indolium trifluoroacetate, abbreviated as TG-170. The molecular structure of TG-170 is shown below.

TG 170

This dye is an indolium derivative and contains a six-membered ring in the chromophore for improved light fastness, as discussed. The ortho hydroxy-carboxy functionality, a known selective complexon for Al(III) and Be(II) ions, was incorporated into the molecule for potential use of TG-170 as a sensor for these metal ions. It was reasoned that metal ion complexation would affect spectral properties of the dye chromophore. The results of the complexation studies are presented in this paper.

Fig. 1. Absorption spectrum of TG-170 in: (A) DMSO, (B) methanol, (C) buffer, pH 5.9.

Fig. 2. Emission spectrum of TG-170 in: (A) DMSO, (B) methanol, (C) buffer, pH 5.9.

2. Experimental section

2.1. Reagents and solvents

TG-170 (F.W. 717.12) was synthesized and purified as described previously [18]. Aluminum nitrate, $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, glacial acetic acid (HPLC Grade), and ammonium hydroxide (certified A.C.S. Plus) were used as received from Fisher (Fair Lawn, NJ). Methanol and dimethyl sulfoxide (DMSO) were obtained from Aldrich (Milwaukee, WI). Distilled water was purified with a NANOpure ultrapure water system (Barstead).

2.2. Apparatus

Absorption measurements were done on a Perkin-Elmer Lambda 2 UV/VIS/near-IR spectrophotometer interfaced to a Zenith 386 computer. Fluorescence measurements were done on an ISS K2 spectrofluorometer (ISS, Champaign, IL). Quartz cuvettes of 1 cm path length were used for absorbance and fluorescence measure-

ments. A commercial GaAlAs laser diode (Laser Max, Rochester, NY) was used as the excitation source (780 nm output, 50 mW). The data acquisition and control of the instrument were done with a Gateway 2000 computer equipped with an ISS software program. The slit width was 2 mm and the integration time was 1 s. A PHOM-10 pH meter (Omega Technologies, Broughton Astley, UK) was used for pH measurements. Micropipetters (Rainin, Woburn, MA) were used to prepare the dilutions.

2.3. Stock solutions

A stock solution of 1.00×10^{-3} M Al(III) was prepared by dissolving $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ in purified water. A stock solution of 1.00×10^{-3} M TG-170 was prepared by dissolving the dye in DMSO. All stock solutions were kept in Nalgene containers and were stored at 4°C in the dark for a maximum of one month. Stock solutions were brought to room temperature prior to preparation of the required dilutions. Successive

Table 1
Spectroscopic characteristics of TG-170

dilutions of working solutions were made fresh before each experiment.

2.4. Buffer solutions

To 800 ml of distilled water 40 ml of glacial acetic acid was added. Samples of 40 ml each were taken from the above solution and enough ammonium hydroxide was added to adjust the pH of each sample to the desired value.

3. Results and discussion

3.1. Spectral characteristics

The excitation and emission spectra of TG-170 in DMSO, methanol, and aqueous buffer (pH 5.9) are shown in Figs. 1 and 2, respectively. The various spectral properties of TG-170 that have been investigated are summarized in Table 1. The fluorescence quantum yields (Φ_F)

Fig. 4. Variation with pH of the fluorescence intensity of TG-170.

Fig. 5. Variation with time of the fluorescence intensity of TG-170.

were calculated relative to IR-125, $\Phi_F = 0.13$ in DMSO [19].

As can be seen, both the absorption and emission maxima of TG-170 are solvent dependent and, apparently, are a complex function of solvent polarity and hydrogen-bonding ability. Related observations have been noted [20].

3.2. Influence of pH on the absorption and emission spectra of TG-170

Variations of the absorption and emission spectra of TG-170 with pH are shown in Figs. 3 and 4, respectively. The dye reaches its highest values of absorptivity and fluorescence efficiency at pH 5.9. Titration of TG-170 with standardized sodium hydroxide solution on a Schott TR 600 automated titrating system showed one end point only, also at pH 5.9. At this pH one COOH group of the molecule of TG-170 is deprotonated. Varying the pH of the dye solution did not result in any appreciable shift in the λ_{\max} of absorption and fluorescence.

3.3. Determination of pK_a for TG-170

The pK_a of TG-170 was determined from Fig. 4 by interpolation. When the relative fluorescence intensity was 0.50, the corresponding pH was about 3.82. At this pH value the protonated form of the dye and the form in which one proton has been removed from the molecule are present in equal molar concentrations. This pH value corresponds to the pK_a of the dye. The pK_a of 2-naphthoic acid is 4.17 [21]. The pK_a of 3-hydroxy-2-naphthoic acid, computed using the Hammett equation, is 4.00. This is consistent with the pK_a value for TG-170 determined experimentally. The fact that the pK_a of TG-170 is slightly lower than the pK_a of 3-hydroxy-2-naphthoic acid, a related molecule, can be attributed to the positive charge on the nitrogen atom of TG-170. This charge stabilizes the deprotonated form of the molecule and lowers its pK_a .

3.4. Effect of time on the fluorescence intensity of the dye

The fluorescence intensity of 1.00×10^{-6} M of

Table 2
Effect of temperature on the fluorescence intensity of the metal–dye complex

Temperature (°C)	F_i (dye)	ΔF_i (%)	F_i (dye+Al)	ΔF_i (%)	F_i (dye+Be)	ΔF_i (%)
25	1576		1384		760	
40	1508	(−4.31)	1272	(−8.09)	808	(+6.32)
50	1484	(−5.84)	1091	(−21.2)	1104	(+45.3)

TG-170 kept in a buffer of pH 5.9 in the dark at room temperature was found to be steady over a period of 75 min. However, the fluorescence intensity dropped sharply after a period of 2 h (Fig. 5), indicating the need for fresh solutions for each experiment.

3.5. Effect of metal ions on the fluorescence intensity of TG-170

The spectral properties of TG-170 were investigated in the presence of each of the following metal ions: Na, K, Be(II), Cd(II), Co(II), Fe(II), Ni(II), Mg(II), Zn(II), Al(III), and B(III). To a 9.10×10^{-6} M solution of TG-170 each of the above mentioned metal ions under investigation was added, respectively, in concentrations ranging from 0 to 10-fold that of the dye concentration. The final concentration of the dye was kept constant by adding enough buffer to maintain a constant final volume. Only the presence of Al(III) ion or Be(II) ion affected the fluorescence intensity of TG-170, resulting in both cases in quenching of the fluorescence. Metal ions are known to quench fluorophores in a process which probably involves transfer of electron density from the fluorophore to the metal ion to form a charge-transfer complex. This transfer of charge perturbs the conjugated structure of the dye chromophore and results in quenching of its fluorescence. The Stern–Volmer plot represented by equation (1)

$$F_0/F = 1 + K_{SV}[Q] \quad (1)$$

relates F_0 and F , the fluorescence intensities in the absence and presence of the quencher Q , respectively, to K_{SV} , the Stern–Volmer quenching constant, and to the concentration of the quencher.

3.6. Determination of the Stern–Volmer quenching constants

In the presence of Al(III) ion, a plot of F_0/F versus the concentration of Al(III) ion gave a straight line and a correlation coefficient of 0.989. The slope K_{SV} of this line was $3.11 \times 10^5 \text{ M}^{-1}$. In the presence of Be(II) ion, a plot of F_0/F versus the concentration of Be(II) ion gave a straight line and a correlation coefficient of 0.990. The slope K_{SV} of this line was $1.16 \times 10^6 \text{ M}^{-1}$. The nature of the quenching was established by measuring the fluorescence intensity F at different temperatures. It was observed that increasing the temperature resulted in a decrease in the fluorescence intensity of the dye–Al complex and an increase in the fluorescence intensity of the dye–Be complex (Table 2). These results suggest that quenching by Al(III) ion is dynamic (diffusion dependent), and quenching by Be(II) ion is static. In the case of dynamic quenching, higher temperatures result in larger diffusion coefficients and in an increase in the bimolecular quenching constant k_q , thus causing further decrease in the fluorescence intensity. In the case of static quenching, an increase in temperature may result in dissociation of the ground state complex and, consequently, in an increase in the fluorescence intensity [22].

In dynamic quenching the diffusion-controlled bimolecular rate constant k_0 is calculated using the Smoluchovski equation

$$k_0 = 4\pi RDN/1000 \quad (2)$$

where R is the collision radius, D is the sum of the diffusion coefficients of the fluorophore and the quencher, N is the number of molecules. The term $N/1000$ converts molarity to molecules cm^{-3} . The bimolecular quenching constant k_q is related to k_0 by the quenching efficiency γ :

Fig. 6. Variation with Al(III) concentration of the fluorescence intensity of TG-170.

$$k_q = \gamma k_0 = 4\gamma\pi RDN/1000 \quad (3)$$

Eq. (3) suggests that dynamic quenching at such low concentrations of Al(III) used in this study requires unrealistically high diffusion coefficients and thus, rules out the possibility of dynamic quenching by aluminum ion.

3.7. Detection limits

A plot of the fluorescence intensity of TG-170 versus [Al(III)] was linear in the range 1.82×10^{-6} – 6.40×10^{-6} M, i.e. for amounts ranging from 49.1 to 172 ppb (Fig. 6). Also, a linear

relationship between the fluorescence intensity and the concentration of Be(II) existed for $[\text{Be}^{2+}]$ in the range 2.73×10^{-6} – 9.10×10^{-6} M, i.e. for amounts ranging from 24.6 to 82.0 ppb (Fig. 7). The calculated detection limit, at 3 times the S.D. of the blank, was 1.64×10^{-6} M (or 44.3 ppb) for the Al(III) ion and 3.05×10^{-7} M (or 24.6 ppb) for the Be(II) ion.

3.8. Determination of the molar ratio of the dye to the metal in the metal–dye complex.

The molar ratio of TG-170 to the metal in the

Fig. 7. Variation with Be(II) concentration of the fluorescence intensity of TG-170.

Fig. 8. Job's plot for the Al-dye complex.

dye-metal complex was established by the method of continuous variation. Equimolar solutions of the dye and of the metal ion (9.10×10^{-6} M) were prepared in buffer. At each step the dye and metal ion were mixed such that their initial concentrations varied in such a way that the sum of their concentrations remained constant, after which the mixture was subjected to spectroscopic measurements. A plot of the absolute value of excess absorbance (excess absorbance is equivalent to the total absorbance of the sample solution minus the absorbance of an identical hypothetical solution of the dye and metal ion, except it con-

tains no complex [23]) versus the molar ratio (Job's plot) for the Al ion and the Be ion is shown in Figs. 8 and 9, respectively. The Job's plot for the dye-Al complex showed a 1:1 molar ratio. The Job's plot for the dye-Be complex also showed a 1:1 molar ratio. Fluorescence techniques failed to provide these ratios using the method of continuous variation. However, when plotting the fluorescence intensity against the metal concentration, a monotonous dependence was observed. This indicated a constant 1:1 stoichiometry in the investigated range of concentrations [24]. Since the molecule of TG-170 possesses two hydroxy-

Fig. 9. Job's plot for the Be-dye complex.

Fig. 10. Variation with Al(III) concentration of the fluorescence intensity of TG-170, Al(III) in large excess.

carboxy functions at each end of the molecule, the expected molar ratio of metal to dye in the complex is 2:1. Apparently, the complexation of a metal ion on one end of the molecule impedes the complexation at the second end of the molecule by electronic features [20].

The reaction between the dye and the metal ion (Al or Be) can be represented by the following reaction expressed by Eq. (4)

where D, M, and DM represent the dye, metal ion, and dye–metal complex, respectively. The stability constant of the complex, K_s , is expressed by Eq. (5)

$$K_s = \frac{[DM]}{[D][M]} \quad (5)$$

where the quantities in the square brackets represent molar concentrations at equilibrium.

3.9. Determination of the stability constant of the dye–metal complex

The stability constant of the dye–metal complex was measured by using Eq. (6) [25]

$$\frac{1}{F} = \frac{1}{kD_T} + \frac{1}{kD_T K_s} \times \frac{1}{[M]} \quad (6)$$

where F is the intensity of fluorescence measured,

k is a constant that depends on the quantum efficiency of the fluorescent process and on the instrument, D_T is the total concentration of the dye, and $[M]$ is the concentration of the metal ion. Keeping the total concentration of the dye in each sample constant, 9.1×10^{-6} M, and varying the metal ion concentration from 9.10×10^{-7} to 9.10×10^{-6} M, a plot of $1/F$ versus $1/[M]$ produces a straight line. The stability constant K_s is the quotient of the intercept divided by the slope. The stability constant for the Al complex is $4.37 \times 10^4 \text{ M}^{-1}$. The stability constant of the Be complex is $1.24 \times 10^6 \text{ M}^{-1}$.

The stability constant K_s was also established from the linear portion of the calibration curve obtained by plotting the fluorescence intensity versus the concentration of the dye, with the concentration of the metal ion constant and in large excess. For each metal ion the concentration of the dye was varied from 2.00×10^{-5} to 20×10^{-5} M. The concentration of the metal ion was 2.00×10^{-3} M. A plot of the fluorescence intensity versus the concentration of Al(III) is shown in Fig. 10. A plot of the fluorescence intensity versus the concentration of Be(II) is shown in Fig. 11.

The stability constant K_s can be derived from Eq. (3) by rewriting it as

$$K_s = \frac{[D]_T - [D]}{[D][M]_T - [DM]} \quad (7)$$

Fig. 11. Variation with Be(II) concentration of the fluorescence intensity of TG-170, Be(II) in large excess.

Since $[M]_T$ is in large excess, Eq. (7) can be written as

$$K_s = \frac{[D]_T - [D]}{[D][M]_T} \quad (8)$$

By definition, the fluorescence intensity F is

$$F = k'I_0\Phi_f\epsilon d[D] \quad (9)$$

where k' is an instrumental constant, I_0 is the intensity of the source, Φ_f is fluorescence quantum yield of the dye, ϵ is its molar absorptivity, and d , the thickness of the cuvette, is 1 cm. Since the

parameters I_0 , Φ_f , ϵ , and d are constant, the product $k'I_0$ can be substituted for by K and the product $\Phi_f\epsilon d$ by K' . Substituting the value of $[D]$ from Eq. (7) into Eq. (9) and rearranging:

$$F = \frac{KK'[D]_T}{K_s[M]_T + 1} \quad (10)$$

which can be rewritten as:

$$F = \frac{KK'[D]_T}{K_s[M]_T} \quad (11)$$

K has been established for the ISS K2 spec-

Table 3
Effect of foreign metal ions on the detection of Al or Be ions

Foreign Ion	Limiting molar ratio for the Al method	Limiting molar ratio for the Be method	% Error in fluorescence for Al	% Error in fluorescence for Be

Zn	10	10	-75	-25

trofluorometer to be 1.24×10^4 and K' was calculated from the data in Table 1. A plot of F versus $[D]_T$ is a straight line. The stability constant K_s is the quotient of the slope divided by the product KK' . K_s for the Al–dye complex, calculated from the slope of the linear part of Fig. 10, is $2.24 \times 10^5 \text{ M}^{-1}$. K_s for the Be–dye complex, calculated from the linear part of Fig. 11, is $1.20 \times 10^6 \text{ M}^{-1}$.

3.10. Interference by other metal ions

The effect of foreign metal cations on the determination of each of aluminum and of beryllium was investigated. These foreign metal ions were Na^+ , K^+ , Ba^{2+} , B^{3+} , Cd^{2+} , Co^{2+} , Eu^{3+} , Fe^{2+} , Fe^{3+} , Pb^{2+} , Mg^{2+} , Ni^{2+} , and Zn^{2+} . Mixtures of interferents and 44.3 ppb of Al(III) were evaluated to determine the effect of an ion on the formation of Al–dye complex. Mixtures of interferents and 24.6 ppb of Be(II) were evaluated to determine the effect of the ion on the formation of the Be–dye complex. A 100-fold molar excess of each foreign ion over the Al or Be ion was used. Where the buffer capacity of the ammonia–acetic acid buffer was insufficient, the pH was adjusted to 5.9 using dilute ammonia or dilute acetic acid. When a foreign ion was found to interfere, it was further investigated at a lower molar ratio. The limiting value of the molar ratio of a foreign ion to that of Al or Be was taken as that which caused an error of $\pm 10\%$ in the determination of Al(III) or Be(II). Cationic interferences are noted in Table 3.

A 10-fold molar excess of EDTA with respect to Al(III) was enough to restore the original signal of the dye. When EDTA was added in an amount equal to its tolerance limit in the presence of an interfering foreign ion, it was effective in masking the foreign ion in the Al method. The presence of EDTA did not affect the Be complex. However, at low concentrations of Be EDTA prevented the formation of the TG-170–Be complex. Addition of excess Ca(II), a noninterfering cation, was effective in masking the excess EDTA. Addition of a 100-fold molar excess of EDTA to the beryllium complex and a 125-fold molar excess of Ca(II) was effective in preventing the interference of the foreign cation without affecting the fluorescence signal of the Be complex.

Interference by Fe(III) was not tolerated at the 2-fold level in the Al method and at the 5-fold level in the Be method. When Fe(III) was reduced to Fe(II) by the addition of the required amount of ascorbic acid, the interference by Fe(III) was reduced to approximately -81% and -58% in the aluminum and beryllium method, respectively.

4. Concluding remarks

The NIR dye, TG-170, described in this paper, undergoes fluorescence quenching upon binding with either aluminum or beryllium ion in a large range of concentrations. This outcome can be a result of a charge transfer from the ligand to the metal. Such ligand-to-metal charge transfer disturbs the resonance structure of the conjugated NIRD and results in its quenching [26].

The pH of formation of the complex was found to be 5.9, which is higher than the pH at which aluminum hydroxide precipitates (approximately pH 4.1). Since no precipitate was observed, it appears that the reagent inhibits the formation of insoluble hydroxide species. This can occur by means of a mechanism whereby chemical combination of the ligand through replacement of a hydroxyl group in the hydrated alumina unit terminates the possibility of further aggregation [27].

The two values of the stability constant K_s (1.20×10^6 and $1.24 \times 10^6 \text{ M}^{-1}$) obtained from Eqs. (6) and (11), respectively, for the Be–dye complex agree with each other and match the value of the Stern–Volmer quenching constant K_{SV} ($1.16 \times 10^6 \text{ M}^{-1}$) for the Be method. This, as well as the data from Table 3, confirms that the quenching by Be(II) is static and is connected with the capacity of the ground-state complex formation. On the other hand, the two values of the stability constant K_s (4.37×10^4 and $2.24 \times 10^5 \text{ M}^{-1}$) established from Eqs. (6) and (11), respectively, for the Al–dye complex are not in agreement with each other and neither value matches the value of the Stern–Volmer quenching constant K_{SV} ($3.11 \times 10^5 \text{ M}^{-1}$) for the Al method. This excludes the possibility of static quenching. On the other hand, dynamic quenching by aluminum is ruled out for the reason given previ-

ously. It can be concluded that the mechanism of the quenching of TG-170 by aluminum ion is not fully understood. It could be that both dynamic as well as static quenching is a contributing factor in the aluminum method.

The data presented in this study demonstrate the use of fluorescence quenching measurements for studying NIR fluorophores. Since such fluorophores have found an increasing application as labeling agents in various fields of chemical analysis, it is important to study the effect of different quenchers.

Abstract

Benzeneacetaldehyde-4-hydroxy- α -oxo-aldoxime is proposed as a new sensitive and selective reagent for the spectrophotometric determination of cobalt. The reagent reacts with cobalt in the pH range 8.6–9.4 to form a yellow colored 1:3 chelate which is very well extracted in chloroform. Beer's law is obeyed in the concentration range 0.05–1.3 $\mu\text{g ml}^{-1}$ cobalt. The molar absorptivity of the extracted species is $2.746 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$ at 390 nm. The proposed method is highly sensitive, selective, simple, rapid, accurate and has been satisfactorily applied for the determination of cobalt in synthetic mixtures, pharmaceutical samples, biological samples and alloys. © 1998 Elsevier Science B.V. Keywords: Benzeneacetaldehyde-4-hydroxy- α -oxo-aldoxime; Cobalt; Spectrophotometric determination

1. Introduction

The significance of cobalt as a transition metal lies in its wide spectrum of applications covering many frontier areas of study, particularly in medicine. Even though cobalt is not considered to be as toxic as most of the heavy metals, it is an equally harmful element. Hence owing to the significance of cobalt, its determination from associated elements by extractive spectrophotometry has been of considerable importance [1]. A

wide variety of chelating agents like thenoyl trifluoroacetone [2], isonitroso-4 methyl-2-pentanone[3], isonitrosomalondianilide [4], 3-(4-phenyl-2-pyridyl)-1,2,4-triazine [5], 5-nitrosalicylaldehyde - 4 - phenyl - 3 - thiosemicarbazone [6], phenyl azobenzaldoxime[7], cyanex-272[8], tetrazolium violet [9], *m*-(mercaptoacetamido) phenol [10], nitrosochromotropic acid [11], 2-(8-quinolyazo)-5-*N,N*'-dimethyl-aminobenzoic acid [12], trifluoroacetylacetone [13], malachite green [14], 2-nitroso-1-naphthol-4-sulfonic acid [21], 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol [22], 2-(2-benzothiazolylazo)-2-*p*-cresol [15], isonitroso-propiofenone [16] and *p*-nitroisonitrosoace-

Fig. 1. Absorption spectra of BAHA and its cobalt complex extracted in chloroform.

tophenone [17], etc. have been reported for the spectrophotometric determination of cobalt.

However these methods suffer from limitations such as critical pH [2,11,13], long extraction time [6], long color development time [22] and interference from some ions [2–8,11,13–17,21,22] etc. A method, far superior in sensitivity and selectivity to those reported in the literature [3,5,7–10,12,16,17,21], is developed for the extractive spectrophotometric determination of cobalt with benzeneacetaldehyde-4-hydroxy- α -oxo-aldoxime (*p*-hydroxy isonitrosoacetophenone or BAHA). A close literature survey indicates that BAHA has so far not been employed for either coordination or analytical studies. It forms intensely colored complexes with Fe(III),

Co(III), Cu(II), Ni(II), Pd(II), Pt(IV), Ru(III) and Pb(II) which are extractable in organic solvents under different experimental conditions. The proposed method is free from many limitations.

2. Experimental

2.1. Apparatus

A Shimadzu-140-02 UV-visible spectrophotometer with 10 mm matched cells and a digital ELICO pH meter (model LI-120) with a combined glass electrode assembly were used for the absorbance and pH measurements respectively.

Fig. 2. The effect of pH on the extraction of cobalt with BAHA in chloroform.

2.2. Reagents

All chemicals used were of analytical grade unless otherwise indicated. De-ionised, doubly distilled water was used throughout the experiment.

2.3. BAHA

The ligand was synthesized by the reaction of *n*-amyl nitrite on 4-hydroxy acetophenone (Aldrich), as per the method previously described in the literature [18] using HCl gas. A stock

solution (5 mg ml^{-1}) of BAHA was prepared by dissolving 0.5 g of the reagent in 100 ml absolute alcohol to give a 0.5% reagent solution of BAHA.

2.4. Cobalt(II) solution

A stock solution of cobalt ($10000 \mu\text{g ml}^{-1}$) was prepared by dissolving an accurately weighed amount of Merck cobaltous chloride hexahydrate (10.0930 g) in 250 ml double-distilled water with a few drops of concentrated hydrochloric acid and standardized by a known method [19].

2.5. Buffer solution (pH 9.0)

The pH of aqueous (1.1) NH₃ solution was adjusted to the required pH with 4 N HCl using a pH meter.

2.6. Recommended procedure

To an aliquot of solution containing 1–100 µg cobalt(II) in a separating funnel add 0.4 ml 0.5% alcoholic reagent solution (BAHA) and 1 ml pH 9.0 buffer. Dilute the mixture to 10 ml with double-distilled water and equilibrate the aqueous medium with 10 ml chloroform for 1.5 min. Allow the two layers to separate and measure the absorbance of the organic extract containing the complex at 390 nm against a reagent blank.

3. Results and discussion

3.1. Absorption spectra

The absorption spectrum of the yellow colored cobalt–BAHA complex against a reagent blank in chloroform under optimum condition showed a maximum at 387–391 nm (Fig. 1, curve B). The spectrum of reagent blank against pure solvent 'chloroform' indicates that the ligand practically does not absorb above 380 nm (Fig. 1, curve A). Hence all absorption measurements were carried out at 390 nm against a reagent blank.

1.25	1.250	0.0047	0.38
1.50	1.502	0.0052	0.35

^a Average of five determinations.

3.2. Extraction conditions

A preliminary study showed that the formation of an extractable cobalt–BAHA complex is affected by the hydrogen ion concentration. The optimum pH range for the absorbance was studied by means of the standard procedure. The results are shown in Fig. 2. The final pH of each aqueous solution was measured after extraction. A maximum and constant absorbance was obtained over the pH range 8.6–9.4. Hence all extractions were carried out at pH 9.0.

The effect of BAHA concentration on the extraction of cobalt complex was examined. It was found that a 0.02% alcoholic solution of BAHA sufficed for quantitative extraction of 10 µg cobalt. Hence 0.4 ml of 0.5% BAHA solution was used for the extraction of 10 µg cobalt in further studies.

The shaking time for the extraction was varied from 0.1 to 2 min. The minimum shaking time for complete extraction of 10 µg cobalt with chloroform was found to be 1.5 min at room temperature. A longer extraction time had no adverse effect.

The cobalt–BAHA complex was found to be stable for 3 h. Addition of salting agents like NaCl, LiCl, NH₄Cl etc were found to have no significant effect on the absorbance. Extractions at higher temperatures in the range 30–70°C were found to have no adverse effect.

3.3. Effect of solvents

The effect of various solvents such as chloroform, toluene, benzene, carbon tetrachloride, amyl acetate, benzyl acetate, ethyl acetate, butyl acetate, xylene and monochlorobenzene on the extraction of cobalt with BAHA was studied. Chloroform (99.5%) was selected as the optimum solvent for its convenience and sensitivity. The other solvents in sequence gave only 98.1–84.1% extraction of cobalt.

3.4. Beer's law and sensitivity

Under optimum conditions, the cobalt–BAHA complex complied with Beer's law, the calibration

Fig. 3. Logarithmic plot of the distribution of cobalt vs. concentration of BAHA.

graph being linear over the range $0.05\text{--}1.3\ \mu\text{g ml}^{-1}$ cobalt in chloroform. The molar absorptivity of the system was found to be $2.746 \times 10^4\ \text{l mol}^{-1}\ \text{cm}^{-1}$ in Ringbom's [20] optimum working range of $0.42\text{--}1.05\ \mu\text{g ml}^{-1}$. The minimum detectable limit for an absorbance of 0.001 was $2.191\ \text{ng ml}^{-1}$ of cobalt at 390 nm.

3.5. Precision and accuracy

The precision and accuracy of the method were studied by analysing a series of solutions containing known amounts of cobalt(II). The results

presented in Table 1 show that the R.S.D. for pure cobalt solution is about 0.5%.

3.6. Composition of the extracted species

The composition of the complex was determined by the slope–ratio method, a plot of $\log D$ against $\log [\text{BAHA}]_{\text{org}}$ at a fixed pH where D denotes the distribution ratio of cobalt between the two phases and $[\text{BAHA}]_{\text{org}}$ is the equilibration concentration of BAHA in the organic phase. As shown in Fig. 3, a straight line graph with a slope of about 3 indicates a metal to ligand ratio of 1:3.

Table 2
Effect of foreign ions on the extraction of 10 µg cobalt with 0.02% BAHA in chloroform

Ion added	Tolerance limit (mg)	Ion added	Tolerance limit (mg)

		EDTA	0.250

^a Masked with fluoride.

^b Masked with iodide.

3.7. Effect of foreign ions

Different amounts of diverse ions were added to 10 µg cobalt and were extracted according to the present procedure. The tolerance limit of an ion was taken as the maximum amount (mg)

causing an error not greater than $\pm 2\%$ in the absorbance value of the organic extract. Most of the ions associated with cobalt do not interfere, except Fe³⁺ and Ag⁺. The interference from large amounts of Ag⁺ can be overcome by masking with iodide. Attempts to suppress the interference of Fe³⁺ using citrate were partially successful. Fe³⁺ can be easily masked with fluoride ions. The results are shown in Table 2.

3.8. Preconcentration of cobalt

10 µg cobalt from different volumes of aqueous phase containing 0.4 ml 0.5% alcoholic BAHA was extracted in 10 ml chloroform by the recommended procedure. It was observed that the absorbance of the organic extract was found to remain constant when the aqueous phase taken was up to 70 ml indicating that the preconcentration of cobalt can be achieved up 7.0 times.

3.9. Application to the determination of cobalt in synthetic mixtures

The present method was applied to the determination of cobalt (10 µg) in various synthetic mixtures. The results are shown in Table 3.

3.10. Application to the determination of cobalt in pharmaceutical samples

The proposed method was applied to the determination of cobalt in injectables, liquid formulations and tablets obtained from available sources.

3.10.1. Sample dissolution

To 2 ml of injectable solution, 45 ml of liquid formulation or a tablet/capsule, concentrated sulfuric and nitric acids were added and evaporated until nearly dry. It was treated with hydrogen peroxide (5 ml, 30 V) every time, until the solution became colorless. Finally it was treated with dilute HCl and the solution was evaporated until nearly dry. The residue was dissolved in 10 ml double-distilled water and a suitable aliquot of this solution was used for cobalt analysis by the developed method. The results are shown in Table 4.

3.11. Application to the determination of cobalt in biological samples

The proposed method was applied to the determination of cobalt SRM ray flour (standard reference material supplied by International Atomic Energy) sample.

3.11.1. Sample dissolution

To a 10 g SRM ray flour sample was added distilled 70% nitric and concentrated HCl acids

and evaporated until nearly dry and the residue was extracted in 20 ml distilled water and a suitable aliquot taken of this solution for cobalt analysis by the developed method. The results are shown in Table 4.

3.12. Application to analysis of alloys

The proposed method was applied to the determination of cobalt in high speed steel samples.

3.12.1. Dissolution of high speed steel samples

About 0.2 g of an oven dried (110°C) high speed steel sample was dissolved in 15 ml of aqua regia. It was heated until nearly dry and nitrate expelled from the residue using 5 ml concentrated HCl. The residue was extracted in 20 ml distilled water and a suitable aliquot of this solution was used for cobalt analysis by the developed method. The results are shown in Table 4.

3.12.2. Determination of cobalt in samples

To a suitable aliquot of the above solutions containing cobalt in a separating funnel add 0.5 ml 0.5% alcoholic reagent solution (BAHA) and 1

ml pH 9.0 buffer. To this mixture add 2 ml of a saturated solution of sodium fluoride to mask the interfering ions. Dilute the mixture to 10 ml with double-distilled water and equilibrate the aqueous medium with 10 ml chloroform for 1.5 min. Allow the two layers to separate and measure the absorbance of organic extract containing the complex at 390 nm against a reagent blank.

4. Conclusion

The proposed method is more highly sensitive and selective than the reported methods for the spectrophotometric determination of microgram amounts of cobalt. It offers advantages like reliability and reproducibility in addition to its simplicity, instant color development and suffers from less interference. It has been successfully applied to the determination of cobalt at trace level in synthetic mixtures, pharmaceutical samples, biological samples and alloys. An R.S.D. of about 0.5% for sample analysis underlines the versatility of the developed method.

Second derivative spectrophotometric determination of partition coefficients of phenothiazine derivatives between human erythrocyte ghost membranes and water

Keisuke Kitamura *, Takashi Goto, Tatsuya Kitade

Kyoto Pharmaceutical University, 5 Nakauchicho, Misasagi, Yamashina-ku, Kyoto 607, Japan

Received 23 June 1997; received in revised form 15 December 1997; accepted 17 December 1997

Abstract

The absorption spectra of six phenothiazine derivatives, chlorpromazine, triflupromazine, promazine, promethazine, trifluoperazine and prochlorperazine, measured in the solutions containing various amounts of human erythrocyte ghosts (HEG) showed bathochromic shifts according to the amount of HEG. Due to the strong background signals caused by HEG, the baseline compensation was incomplete, even though the sample and the reference solutions contained the same amount of HEG, hence further spectral information could not be obtained. The second derivative spectra of these absorption spectra clearly showed the derivative isosbestic points, indicating that the residual background signal effects were entirely eliminated. The derivative intensity differences of the phenothiazines (ΔD values) before and after the addition of HEG were measured at a specific wavelength. Using the ΔD values, the partition coefficients (K_p) of these drugs were calculated and obtained with R.S.D. of below 10 %. The fractions of partitioned phenothiazines calculated from the K_p values agreed well with the experimental values. The results indicate that the derivative method can be applicable to the determination of partition coefficients of drugs to HEG without any separation procedures. © 1998 Elsevier Science B.V. 1. Introduction

Partition of drugs between an aqueous phase and biomembranes has been an important subject for study [1–7] since it concerns the drug absorption and/or the direct actions of drugs to biomembranes. Determination of partition coefficients of

drugs to biomembranes has usually been accompanied by separation procedures such as centrifugation or filtration to measure the concentrations of free drugs or the amounts of bound drugs [1–6]. However, the separation procedures are troublesome and may disturb the equilibrium states of sample solutions and also lead to errors due to the possibilities of residue of membrane fragments in the supernatants of sample solutions or nonspecific adsorption of drugs onto filter membranes.

It has been recognized that derivative spectrophotometry can eliminate the effect of background signals and hence does not require optically clear sample solutions [8,9]. We previously applied the second derivative spectrophotometry [10] to the determination of partition coefficients of chlorpromazine and promazine between model membranes (lecithin vesicles) and water (buffer). In this study, we attempt to determine partition coefficients of six phenothiazine drugs between human erythrocyte ghosts (HEG) and water by the second derivative spectrophotometry. The results will show usefulness of the derivative method for the determination of partition coefficients of drugs to HEG. The effect of structural difference of six phenothiazines on their affinity to HEG is also discussed.

2. Theory

The molar partition coefficient of phenothiazine between lipid bilayer of HEG and water is defined as [10],

$$K_p = \frac{([P_m]/[P_t])/[M]}{([P_w]/[P_t])/[W]} \quad (1)$$

where $[P_m]$ and $[P_w]$ represent the concentrations of phenothiazine in the lipid bilayer of HEG membranes and water, respectively, and $[P_t]$ equals to the total amount of phenothiazine added ($[P_t] = [P_m] + [P_w]$), and $[M]$ and $[W]$ are molar concentrations of lipid in HEG membranes and water (55.5 M), respectively.

If the effect of background signal caused by HEG can be entirely eliminated in the derivative spectrum, the derivative intensity (denoted as D) of a phenothiazine at a specific wavelength is represented as follows,

$$D = E_m[P_m] + E_w[P_w]$$

where, E_m and E_w are the molar derivative intensities for $[P_m]$ and $[P_w]$, respectively. With a definition, $E = E_m - E_w$, D can be written as

$$D = E_w[P_t] + E[P_m] \quad (2)$$

A new variable ΔD is introduced to represent the difference between D and $E_w[P_t]$ as below,

$$\Delta D = D - E_w[P_t] \quad (3)$$

From Eq. (2),

$$\Delta D = E[P_m] \quad (4)$$

Thus the ΔD value is proportional to the concentration of phenothiazine in HEG membranes.

Finally, from Eqs. (1) and (4), we can get,

$$\Delta D = \frac{K_p \Delta D_{\max} [M]}{[W] + K_p [M]} \quad (6)$$

where $\Delta D_{\max} = E[Pt]$. The values of K_p and ΔD_{\max} are calculated from the experimental values of $[M]$ and ΔD by applying a non-linear least-squares calculation to Eq. (6) [10].

3. Experimental

3.1. Reagents, materials and apparatus

Chlorpromazine hydrochloride (CPZ), trifluorpromazine hydrochloride (TFZ), promazine hydrochloride (PZ), promethazine hydrochloride (PMZ), trifluoperazine hydrochloride (TFPZ) and prochlorperazine dimaleate (PCPZ) were purchased from Sigma (USA). All other chemicals were reagent grade. Absorption spectra were measured by a spectrophotometer (Hitachi U-3210) equipped with a temperature regulated cell holder. Calculations of second derivative spectra and values of K_p and ΔD_{\max} were performed using BASIC programs on a pc (NEC PC-9801 VX) [10,11].

3.2. Human erythrocyte ghosts

Human erythrocytes were washed three times with 20 volumes of a phosphate buffer (PBS; 10 mM phosphate, 140.5 mM NaCl, pH 7.4) and each time the buffy coat was removed after centrifuged at $900 \times g$ for 5 min. The erythrocytes were suspended in PBS to make 40–50% haematocrit values. HEG were prepared according to the method of Dodge et al. [12]; one volume of the erythrocyte suspension was dissolved in 10 volumes of PBS. Then the obtained suspension was centrifuged at $20000 \times g$ for 20 min, and

hemoglobin and non-sedimentary erythrocytes in the supernatant were removed. These procedures were repeated three times. The HEG obtained were suspended in PBS to make about 1 mM of phosphorous.

3.3. Determination of lipid concentration of HEG

Phospholipid concentration in HEG suspensions was determined from phosphate analysis [13]. Lipid concentration of HEG suspensions was considered to be a sum of the concentrations of phospholipid and sterol assuming that HEG contains 0.90 mol of sterol mol⁻¹ of phospholipid [4]. The other minor lipid contents were ignored.

3.4. Procedure

To each of several 2 ml volumetric flasks, an appropriate amount of a phenothiazine stock solution was added so that the final drug concentration in the sample solutions became 15 μM. Then suitable amounts of HEG suspension were added to the flasks, and the PBS was further added to make up to volume. Each flask was shaken for a short time and incubated at 37°C for 60 min. The sample solution was added in a black micro quartz cuvette having a 1 cm light-pass length and 0.5 cm width and the sample cuvette was set in the cell holder which was maintained at 37°C. After 10 min, the absorption spectrum was recorded against the reference buffer solution containing the same amount of HEG as the sample solution with a band path of 2 nm, wavelength interval of 0.1 nm and a scan speed of 15 nm min⁻¹.

4. Results and discussion

4.1. Absorption and second derivative spectra

The absorption spectra of CPZ and PCPZ in the sample solutions containing various amounts of HEG are shown in Fig. 1A and B, respectively, as the examples of six phenothiazine derivatives studied. The absorption maxima of both drugs

show bathochromic shifts according to the increase in the HEG amounts of the sample solutions, indicating the partition of CPZ and PCPZ into the lipid bilayer of HEG membranes [4]. But, even though the solutions in the sample and reference cuvettes contain the same amount of HEG, the counterbalance of the sample and reference beams is incomplete as seen in Fig. 1. It is usually difficult to cancel the background signal effects completely when the background signal level is very high. Thus, further spectrophotometric data

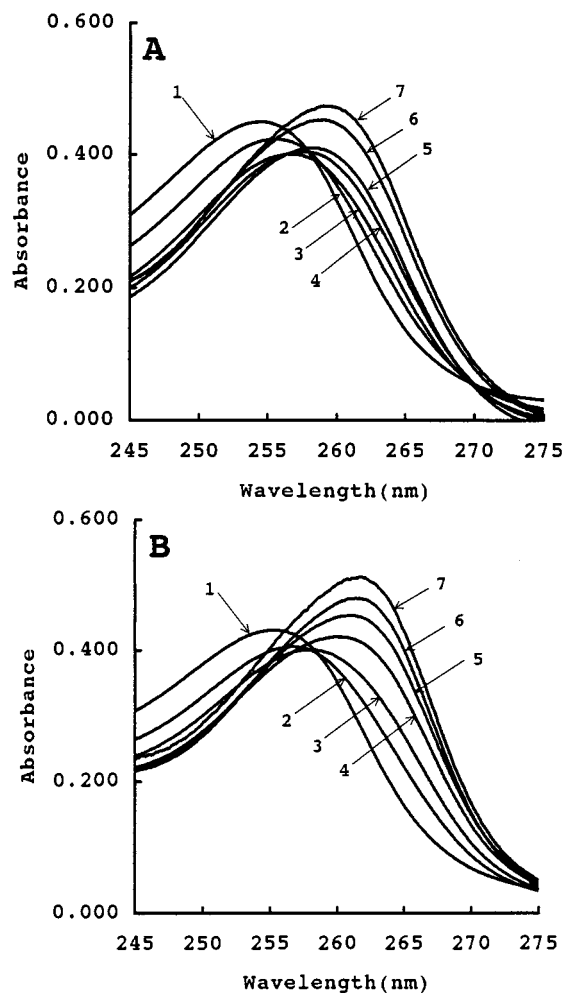

Fig. 1. Absorption spectra of 15 μM chlorpromazine (A) and prochlorperazine (B) in phosphate buffer solutions (pH 7.4, 37°C) containing various amounts of HEG. HEG concentration (mM): 0 (1), 0.060 (2), 0.120 (3), 0.180 (4), 0.240 (5), 0.360 (6), and 0.600 (7).

Fig. 2. Second derivative spectra of chlorpromazine (A) and prochlorperazine (B) calculated from the absorption spectra of Fig. 1A and B, respectively. The numbers in the figures are the same as in Fig. 1.

can not be drawn from these absorption spectra. The absorption spectra of the rest of the phenothiazine derivatives showed similar features.

To eliminate the residual background signal effects, the second derivative spectra were obtained from the absorption spectra. It has been known that in the calculation of second derivative spectra too small $\Delta\lambda$ values (the wavelength interval) enhance the noise in the second derivative spectra, and too large $\Delta\lambda$ values cause signal distortions [10]. As the background signal intensities of HEG suspensions are much higher than those of the lecithin vesicle solutions, a larger $\Delta\lambda$ value of 0.8 nm than the value of 0.5 nm for the lecithin vesicle solutions [10] was employed to suppress the generation of noises in the second derivative spectra.

The second derivative spectra obtained from the absorption spectra in Fig. 1A and B are shown in Fig. 2A and B, respectively. Similarly to Fig. 1, bathochromic shifts are observed with the increase in the amounts of HEG in the sample solutions. A noteworthy difference from the original absorption spectra is that the derivative isosbestic points are clearly observed at the wavelengths near 258 and 268 nm for CPZ in Fig. 2A and 259 and 269 nm for PCPZ in Fig. 2B, respectively. The second derivative spectra of the

sample solutions of the another phenothiazine derivatives studied also showed the derivative isosbestic points. The existence of the derivative isosbestic points indicates that the influences of the residual background signal of HEG are entirely eliminated in the second derivative spectra, and that each phenothiazine exists in two states, [14], i.e. in polar bulk water and non-polar lipid membranes of HEG.

4.2. Calculation of K_p and ΔD_{max}

The ΔD values for CPZ or PCPZ were obtained as the differences of the derivative values between the spectrum 1 and spectra 2–7 in Fig. 2A or B at the wavelength of 262 or 263 nm, respectively, since large ΔD values could be obtained at these wavelengths as seen in Fig. 2. It has been already confirmed that the wavelength at which ΔD values are measured do not largely affect the calculated K_p and ΔD_{max} values and large ΔD values will result in a good precision for the K_p values [10]. The wavelengths at which the ΔD values of the rest of the phenothiazine derivatives were measured are given in Table 1.

Using the experimentally obtained ΔD values, the K_p and ΔD_{max} values were calculated. As summarized in Table 1, the K_p values of six

phenothiazine derivatives were obtained with R.S.D. of below 10 %. The results indicate a good precision of the derivative method.

The K_p value of CPZ (10 μM) obtained by difference spectrometry [4] has been reported to be 6.5×10^5 . The partition coefficient based on the HEG membrane volume has been also obtained for CPZ by filtration [1] and centrifugation [6] methods. The reported values are converted to K_p values according to [4], yielding 4.0 and 2.6×10^5 , respectively. The K_p value of CPZ in Table 1 is within these values.

The K_p values of CPZ and PZ between egg yolk lecithin vesicles and water are reported to be 2.93 and 1.15×10^5 , respectively [10]. It seems interesting that these values show a resemblance to the corresponding results in Table 1.

As the K_p values of six phenothiazine derivatives are obtained with good precision, the effect of the structural difference of these compounds on their affinity to HEG membranes is considered. The phenothiazine derivatives studied can be divided into two types with respect to the polar side chain group: one having a *N*-dimethylaminopropyl group (TFZ, CPZ, PMZ and PZ), and the other is having an *N*-methylpiperazinylpropyl group (TFPZ and PCPZ).

In the former type, the K_p values show that the introduction of halogen atom(s) to phenothiazine rings increased the affinity of the drugs to HEG membranes, according to the order of $\text{CF}_3 > \text{Cl} > \text{H}$. The result is consistent with those obtained from the shape changes of human erythrocytes [2], and a microcalorimetric study [7].

Table 1
 K_p values of phenothiazine derivatives

Compound	Wavelength (nm)	$K_p^a (\times 10^{-5})$
CPZ	262 ^b	3.1 ± 0.2 (6)
TFZ	264 ^b	3.7 ± 0.2 (4)
PZ	259 ^b	1.6 ± 0.1 (4)
PMZ	257 ^b	1.5 ± 0.1 (5)
TFPZ	265 ^b	4.6 ± 0.1 (4)
PCPZ	263 ^b	4.5 ± 0.3 (4)

^a Mean \pm S.D. (number of determination).

^b Wavelength (nm) at which ΔD values were measured.

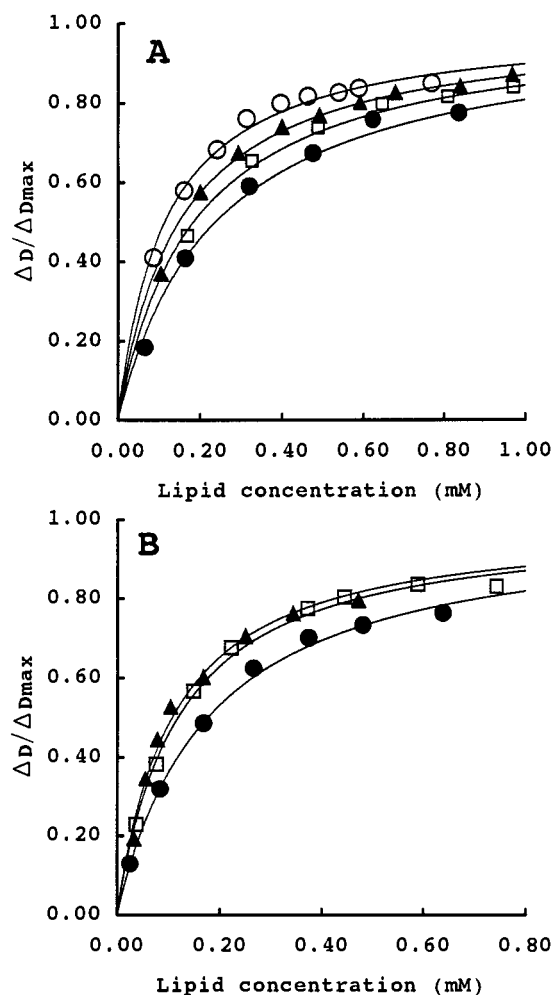

Fig. 3. Fraction ($\Delta D/\Delta D_{\text{max}}$) of phenothiazine derivatives in HEG membranes at various HEG concentrations. The solid lines show the theoretical curves calculated from Eq. (6) using the K_p obtained and ΔD_{max} values. The symbols are the experimental values: CPZ (○), TFZ (●), PZ (△), PMZ (▲), TFPZ (□), and PCPZ (■).

Since the K_p values of the latter type are larger than those of the former type, the partition of the phenothiazine to HEG membranes seems to be affected also by the polar side chain groups. From the results and discussion above it can be seen that not only the hydrophobic interactions of the phenothiazine rings with the acyl chains of the membrane lipids but also the effects of a polar side chain group might contribute to the interac-

tions of the phenothiazine derivatives with HEG membranes.

In Fig. 3, the fractions of six phenothiazine derivatives partitioned in HEG are shown as a plot of the $\Delta D/\Delta D_{\max}$ values versus the lipid concentration of HEG. Solid lines represent theoretical curves calculated from the K_p and ΔD_{\max} values according to Eq. (6). The all curves are well fitted to the experimental data.

Conclusively, it can be emphasized that, when the drugs of interest show spectral changes according to their partition to HEG membranes, the derivative spectrophotometry will be applicable to the determination of their partition coefficients between HEG membranes and water without separation procedures.

Abstract

Formation constants for recrystallized thymol blue were determined in water, using the SQUAD and SUPERQUAD programs. The best model correlating spectrophotometric, potentiometric and conductimetric data was fitted with the dissociation of $HL^- = L^{2-} + H^+ - \log K = 8.918 \pm 0.070$ and $H_3L_2^- = 2L^{2-} + 3H^+ - \log K = 29.806 \pm 0.133$ with the SUPERQUAD program at variable low ionic strength (1.5×10^{-4} – 3.0×10^{-4} M); and $HL = L^{2-} + H^+ - \log K = 8.9 \pm 0.000$, $H_3L_2^- = 2L^{2-} + 3H^+ - \log K = 30.730 \pm 0.032$, $H_4L_2 = 2L^{2-} + 4H^+ - \log K = 32.106 \pm 0.033$ with SQUAD at 1.1 M ionic strength. © 1998 Elsevier Science B.V. Keywords: Aqueous medium; Formation constants; Recrystallized thymol blue

1. Introduction

Determination of equilibrium constants for acid–base indicators has long been a concern in analytical chemistry. Thermodynamic information associated with these constants is mainly useful for determining the end point in acid–base reactions. Because of their binding properties, the applications of indicators have recently been ex-

tended to include their use in the spectrophotometric determination of cations. Therefore, accurate determination of equilibrium constants of the best possible certainty, is of crucial importance.

The sulfonephthalein family of indicators are currently used extensively. Several publications have reported equilibrium constants for the thymol blue family members in aqueous medium: (a) Kolthoff et al. [1–3] determined pK_a values using the limit law of Debye–Hückel, 1.65 and 9.2; (b) Nørgaard [4] reported pK_a values for EFA (evolving factor analysis, 8.87) and for PLS (partial

* Corresponding author. Tel.: +52 5 7244670; fax: +52 5 7244666; e-mail: mtrs218@xanum.uam.mx

least-squares regression, 8.76 and 8.73); and (c) Casula et al. [5] a spectrophotometric method based on the SPECFIT program, reported a pK_a value of 8.47. However at least two pK_a values are reported and in most of the cases the indicator was not purified prior to use.

Kolthoff's studies determined pK_a values for thymol blue in water, in methanol [1], ethanol [2], dimethylsulfoxide [6], *N,N*-dimethylformamide [7], and acetonitrile [3]. Kolthoff proposed a model with three pK_a values in acetonitrile medium. In an attempt to refute or reinforce Kolthoff's model in water, we applied spectrophotometric, conductimetric and potentiometric methods and executed, SQUAD, SUPERQUAD, and SIBYLA (see below for the description of these programs) to determine the equilibrium constant values for purified thymol blue in water over the widest possible pH range.

2. Methods

2.1. Purification

As indicators are not generally of high purity, it is necessary to purify and verify them prior testing because impurities can affect the experimental determinations and the final results. In previously published reports on acidity constants [5] for thymol blue, only Kolthoff [1–3] purified the indicator. In the present study, purification was completed prior to any quantitative experimentation to avoid deviations due to impurities. Thymol blue supplied by Merck was purified and recrystallized in 30% (v/v) acetic acid solution. Purity was assessed by determining the melting point using the Fisher method in a Sybron Powerstat (Thermoline) by the Thiel's Tube method. The IR absorption spectra were obtained for the recrystallized solid in a TF-IR 1600, Perkin-Elmer spectrophotometer, and it was compared with the one reported in the FT-IR spectra catalog [8]. Table 1 shows that the melting point of recrystallized thymol blue agrees with that reported in [8], whereas that of the crude substance does not. The recrystallized thymol blue was then used in its purified form for all experiments.

2.2. Spectrophotometric determination

2.2.1. Absorbance versus time studies

To demonstrate absorbance on time independence during the measurements, absorbance was monitored for 7 days for 2.5×10^{-5} M thymol blue solutions at pH 0.00, 4.84 and 13.00. A maximum variation of 2.7% was observed over this period.

2.2.2. Spectrophotometric data

Two aqueous solutions of 2.50×10^{-5} M thymol blue were prepared, one at pH 0.0 (adjusted with HCl) and the other at pH 13.0 (adjusted with NaOH), each with an ionic strength of 1.1 M NaCl. The experiment was carried out in two steps:

1. The thymol blue 13.0 pH solution was added to the 0.0 pH thymol blue solution until the pH reached 7.0.
2. The thymol blue 0.0 pH solution was added to the 13.0 pH thymol blue solution until the pH reached 7.0.

Absorbance was recorded every 0.25 pH units in a UV-Vis Beckman DU-65 spectrophotometer and pH values were monitored using a Corning model 250 pH-meter equipped with a combined (glass–AgCl/Ag) electrode. These values were corrected for cell efficiency. Constant temperature was kept at $25 \pm 0.1^\circ\text{C}$ with a Lauda temperature controller water bath model T-1.

2.3. Nuclear magnetic resonance (NMR)

Thymol blue NMR spectra were acquired on a Bruker DMX500 NMR spectrometer at a constant temperature (25°C) in CD_3OD (Aldrich),

Table 1
Fusion points for thymol blue using the Thiel tube and Fisher methods

Thymol blue	Fusion point ($^\circ\text{C}$)		
	Reported	Thiel tube	Fisher
As supplied	221	207–208	208–210
Recrystallized		221–222	220–222

using a 5 mm inverse Z-gradient probe. The pH was adjusted by KOH (Merck) or HCl (Mallinckrodt) addition.

2.4. Potentiometric and conductimetric determinations

The titrations of 5.0×10^{-5} , 1.0×10^{-4} or 2.5×10^{-4} M thymol blue solutions were performed under a nitrogen gas inert atmosphere

(Linde Suprapur), with 1.0×10^{-3} or 2.0×10^{-3} M NaOH (Sigma) as the added solutions, at a constant temperature of $25 \pm 0.1^\circ\text{C}$ with a Cole Parmer temperature controller model 12101-10.

The potentiometric response was followed using a Radiometer-Tacussel TTP2 automatic titrator and BX3 automatic burette, or Radiometer-Tacussel LPH430T potentiometer ($\text{pH} \pm 0.001$) equipped with a combined (glass–AgCl/Ag) electrode with inbuilt temperature probe and a Pyrex

burette (10 ± 0.01 ml). Simultaneous spectrophotometric measurements were conducted at some added volumes during these titrations using a Perkin-Elmer Lambda 17 UV-Vis spectrophotometer. Cell potentials were corrected for cell efficiency [9].

The conductimetric response was registered using a Cole Parmer model 19101-00 digital conductivity meter ($\pm 0.1 \text{ m}\Omega^{-1}$) equipped with a dip gold cell and a Pyrex burette (10 ± 0.01 ml).

2.5. Computational programs

SQUAD [10,11] was designed to calculate the best value for stability constants in a proposed model by minimizing the sum of residual squares for absorbance. The program can refine stability constants for complexes such as $M^pM^qL^rL'sH_j$, where $p, q, r, s = 0$ and j is positive (for protons), negative (for hydroxide ions) or zero. For this reason the program is often chosen for acid base equilibria studies in which the species can be weak acids or bases.

SUPERQUAD [11,12] refines equilibrium constant values by minimizing the sum of residual squares for cell potentials. The program also calculates other statistical parameters as χ^2 and the total S.D. (s).

Fig. 2. Thymol blue structure. The carbon atoms in the aromatic rings are labelled.

SIBYLA [13] applies the analysis factor algorithm and Fourier convolution theorem. Principal component analysis (PCA) is the basic multivariate statistical technique of factor analysis. The PCA and factor analysis (FA) techniques involve the analyses of an $m \times n$ data matrix. These can be m spectra (or any others observations) each containing values for n channels (variables). Each 'spectrum' can be represented as a point in a multidimensional space. The FA and PCA techniques are used to find a p -dimensional subspace ($p < n$) in which the spectrum can be approximately represented.

It is important to note that the best model for the programs that use the least squares algorithm (e.g. SQUAD and SUPERQUAD) is the one that reports the smallest value for the sum of square residuals (U). The residuals are the differences between the determined and calculated values of a physicochemical property.

3. Results and discussion

3.1. ^1H NMR and ^{13}C NMR analysis

On the ^{13}C NMR spectrum of thymol blue at $\text{pH} < 2$ (Fig. 1), the broad signal centered at 190.19 ppm was assigned to C-7 (Fig. 2). This low field shift agrees with a carbon having carbocation character. Assignment of C-7 was confirmed by an inverse detection C- H_n long range correlation experiment. The corresponding 2D spectrum (Fig. 3) clearly shows C- H_n correlations between C7-H5 and C7-H13. These data agree with the proposed structure H_3L^+ (Fig. 4 (V)), as proposed by Kolthoff [3]. Nevertheless, the NMR spectra also could be assigned to H_4L_2 species because the techniques used can not distinguish between monomeric or dimeric species.

On the other hand, the ^{13}C NMR spectrum of thymol blue, acquired under alkaline conditions ($\text{pH} > 13$) (Fig. 5), has signals which appear at 180.42 and 179.63 ppm. These were assigned to C-11 and C-11' based on their respective C- H_n long range correlations. Its corresponding ^1H

Fig. 3. Thymol blue 2D inverse detection C-H_n long range correlation spectrum in acid medium at 25°C (only part of the plot is shown).

NMR spectrum (Fig. 6) shows evidence for the presence of tautomeric species. There is a pair of signals for the methyls directly attached to the B and B' rings and for the H-10, H-10', H-13 and H-13' hydrogens. This strongly suggests a structure which is in accordance with L²⁻ (Fig. 4, I).

The NMR studies also confirm the high purity of the recrystallized thymol blue, used in the titrations.

3.2. pH variation of thymol blue—spectrophotometric study

Fig. 7a shows typical absorption spectra behavior for a 2.50×10^{-5} M thymol blue solution as a function of pH. At $\text{pH} \leq 1.22$, two absorption bands appear at 390 and at 545 nm. For pH between 2 and 7.5, absorption bands are observed at 430 and 545 nm, and for pH 8.0, the bands are

Fig. 4. Model proposed by Kolthoff [3] of three acid–base equilibria. ${}_yH_2L$ and ${}_cH_2L$ correspond to two different chemical species.

present at 390 and 600 nm. Fig. 7b shows identical behavior for a 2.5×10^{-4} M thymol blue solution.

3.3. Determination of the number of absorbing species

In order to determine the number of absorbing species, the absorbance matrices were analyzed at different pH and wavelengths values using SIBYLA for the two different concentrations. The program indicated that the absorbance data must have resulted from 3 or 4 different experimental factors. This implies the presence of at least 3 or 4 absorbing species over the pH interval studied. This is consistent with the Kolthoff model [3] (Fig. 4) which proposed three acid–base equilibria.

3.4. Acid–base titrations

Fig. 8 shows the typical behavior of thymol blue titrations with NaOH followed potentiometrically. It can be seen that in the concentration range studied only the first of the titration reaction is quantitative, because the second one has a low equilibrium constant value. In the same way Fig. 9 shows this same typical titrations but followed conductimetrically. In this case both titration reactions are observed. Results for both methods can be compared successfully.

3.5. Chemical models

As the solutions titrated were prepared from neutral species and following the scheme pro-

Fig. 5. Thymol blue ^{13}C NMR spectrum in alkaline medium at 25°C .

posed by Kolthoff [3], the titration reactions should be:

The visible or apparent equivalence point could be assigned to the first titration reaction in Eq. (1). However, the calculated end point differs from the experimental value by a factor of 2 ($v_{\text{ep}}(\text{calculated}) = 2v_{\text{ep}}(\text{experimental})$). A dimerization of the neutral and negatively monocharged

species is proposed to explain this 2-fold factor.

It was then, necessary to consider both possibilities in the refining procedure of the equilibrium constants by the SQUAD and SUPERQUAD.

3.6. Equilibrium constants determination by computational methods

The results for SQUAD and SUPERQUAD for the best refining obtained with several models are reported in Table 2. This information allows us to

Fig. 6. Thymol blue ^1H NMR spectrum in alkaline medium at 25°C .

conclude that models II and III could be considered as statistically equivalent.

It was then necessary to simulate the data obtained by different analytical methods in the present work (spectrophotometric, potentiometric and conductimetric) with the Excel 6.0, using the values refined with SQUAD and SUPERQUAD.

3.7. Simulations

3.7.1. Potentiometric and conductimetric titrations

Fig. 8 shows overlapped experimental and simulated potentiometric curves. Fig. 8a shows the

simulation obtained using the Kolthoff model. The first part of the simulated curve does not predict the experimental behavior, but after the first equivalence point, the simulation agrees very well with the experimental results.

Fig. 8b considers the model with dimeric species. It shows excellent agreement between simulated and experimental data for all titrations.

The same conclusion can be obtained from the conductimetric data, shown in Fig. 9.

The simulated curves reported in Fig. 8b and Fig. 9b, corresponding to the model III of Table 2, consider the acid dissociation of a dimeric

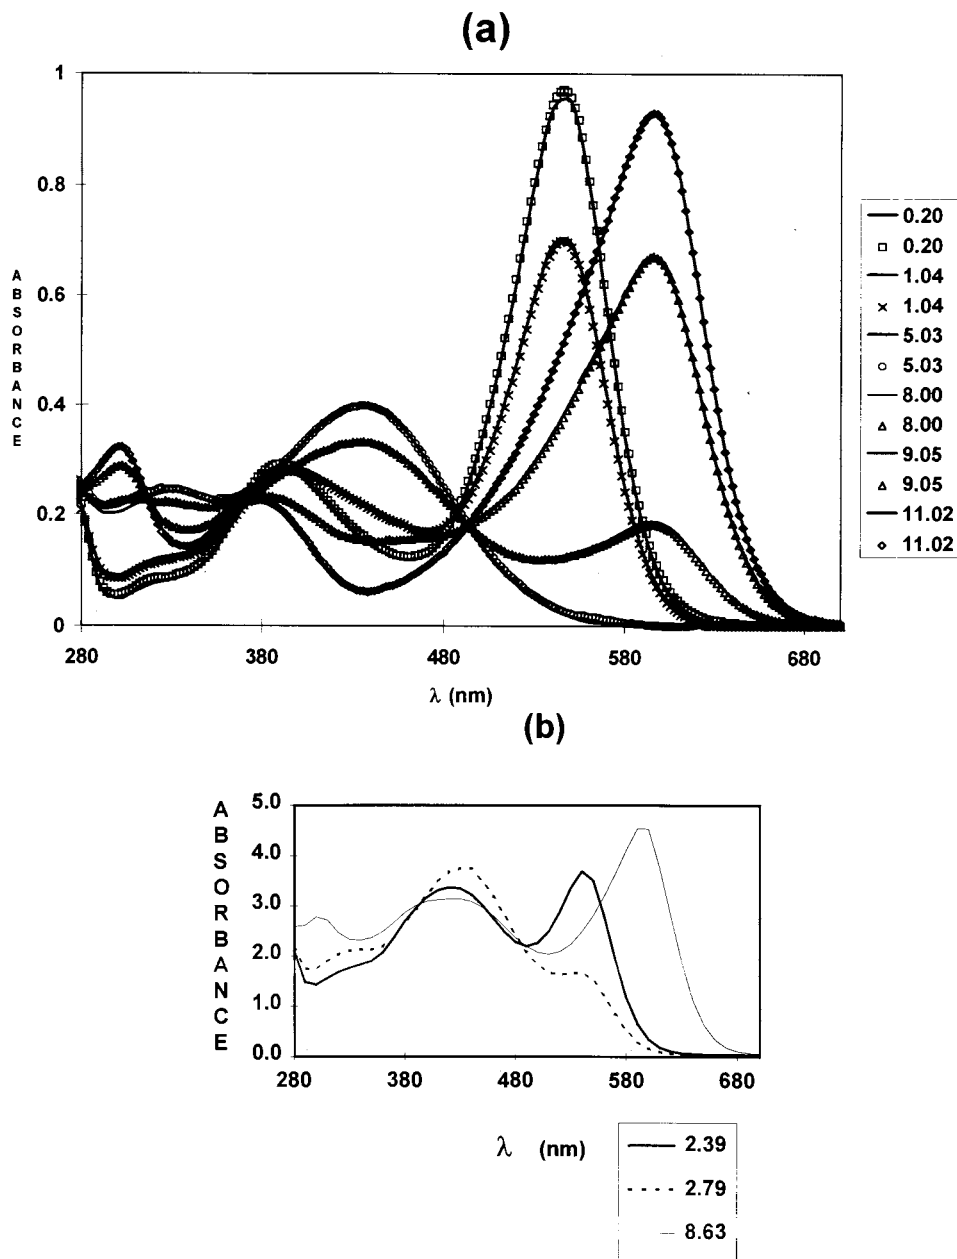

Fig. 7. (a) Absorption spectra simulated and experimental for different values of pH. (b) Absorption spectra for thymol blue at different pH values, the pH values are indicated in the figure, the total concentration of the thymol blue is 2.5×10^{-4} M. (c) Molar absorptivity coefficients calculated for SQUAD program for the thymol blue species.

neutral species in the beginning of the titration, as represented by the equilibrium in Eq. (3).

This first dissociation is strong for the concentrations used in the experimental part of this work. Then, the first titration reaction corresponds to the proton neutralization in Eq. (4):

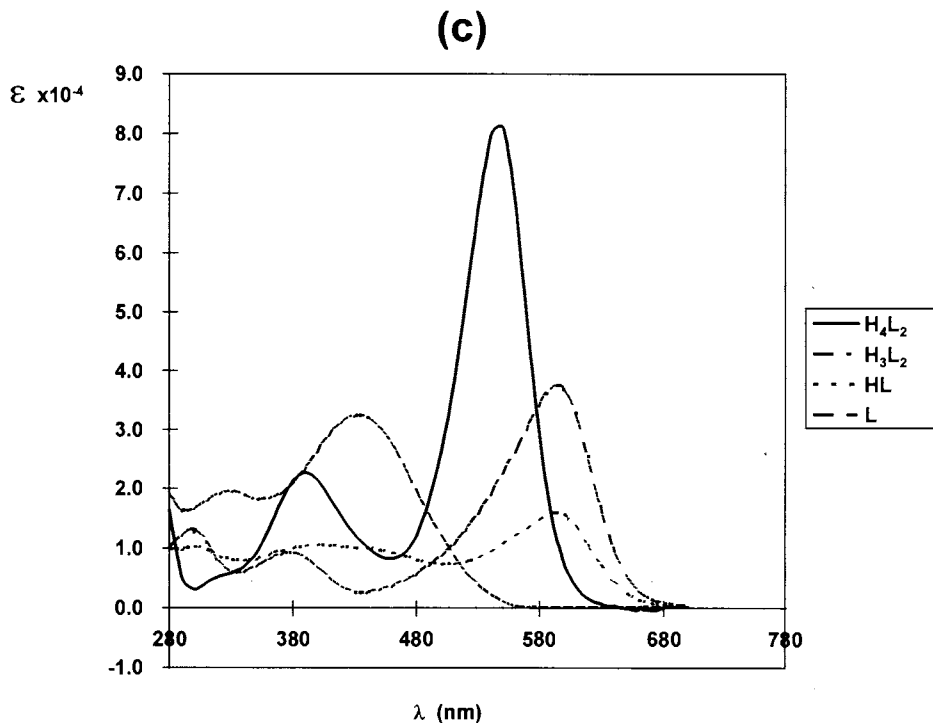

Fig. 7. (Continued)

After the first equivalence point, the reaction of the dimeric charged species H_3L_2^- with NaOH produces the monomeric species HL^- , in agreement with the reaction in Eq. (5):

Finally, the third titration reaction would be the same that is proposed in the Kolthoff model (the reaction in Eq. (6)):

This third reaction could explain why both models fit well the experimental data in the last part of the potentiometric and conductimetric titration curves.

It is interesting to remember that this kind of dimerization–acidic equilibria have been previously suggested [14]. It is known as ‘homoconjugation equilibria’. However, it has been proposed for other reagents in aprotic solvents. The pres-

ence of this equilibria in water for thymol blue could be induced by the big methyl and isopropyl groups residing on the phenyl rings.

3.7.2. Absorption spectra

The best model (III) that can simulate the potentiometric and conductimetric titrations, can be used in order to fit experimental absorption spectra (Fig. 7a).

Fig. 7c shows the absorptivity coefficients calculated with the program SQUAD for each one of the species used in the dimerization model. It is important to note the maximum value for the absorptivity coefficient of H_4L_2 species is achieved at 550 nm, and this fact agrees well with the experimental band observed for a $\text{pH} \leq 1.2$. For the H_3L_2^- species the maximum is achieved at 430 nm this maximum represents well the experimental band observed at $\text{pH} 5.0$. In the same way HL^- shows the maximum wavelength at 590 nm at $\text{pH} 8.0$ and the L^{2-} species at 600 nm at $\text{pH} > 9.0$.

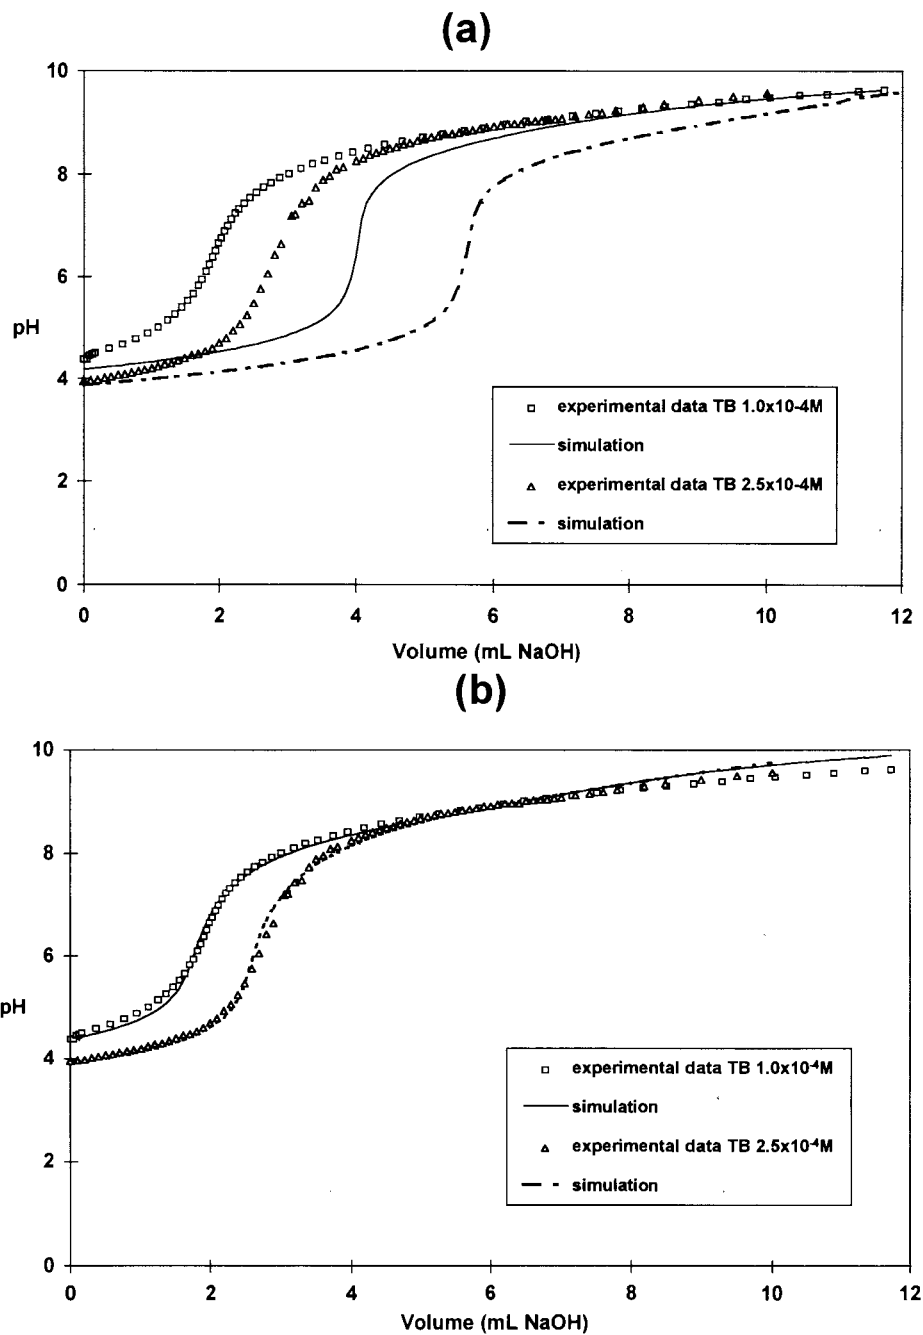

Fig. 8. (a) Simulated and experimental potentiometric curves for two different concentrations of thymol blue, utilizing a model of three acid–base equilibria. (b) Simulated and experimental potentiometric curves for two different concentrations of thymol blue, utilizing a dimeric species model.

Fig. 7a shows the excellent agreement between the simulated and experimental absorption spectra.

4. Conclusions

The $\text{p}K_a$ values determined for thymol blue for a model of three acid–base equilibria (proposed by Kolthoff), statistically corresponded with the best model better than the two acid–base equilibria models proposed in other papers [4–6]. However, this model does not describe all the experimental information. Therefore, a new model considering dimers has been proposed with equilibrium constants ($\text{HL } \log K = 8.918 \pm 0.070$ and $\text{H}_3\text{L}_2 \log K = 29.806 \pm 0.133$ calculated with the SUPERQUAD program at variable low ionic strength (1.5×10^{-4} to 3.0×10^{-4} M); and $\text{HL } \log K = 8.9 \pm 0.000$, $\text{H}_3\text{L}_2 \log K = 30.730 \pm 0.032$ and $\text{H}_4\text{L}_2 \log K = 32.106 \pm 0.033$ calculated with SQUAD program at 1.1 M ionic strength). There is an excellent agreement with this dimerization–acidic scheme and experimental spectrophotometric, potentiometric and conductimetric data.

Abstract

Poly(vinyl chloride) based membranes of di-(2-ethylhexyl)phosphoric acid (DEHPA) and dibutyl-(butyl)phosphonate (DBBP) have been prepared and investigated as VO^{2+} -selective sensors. The membranes containing DEHPA/DBBP and sodium tetraphenylborate, an anion excluder, show near-Nernstian/Nernstian response in the concentration range $\sim 10^{-5}$ – 10^{-1} M. The sensors exhibit a fast response time and good selectivity for VO^{2+} over a number of other cations. Quantitative determination of vanadium in waste V_2O_5 catalyst has been achieved by these sensors and they have also been used as indicator electrodes for the determination of the end point in the potentiometric titration of VO^{2+} against EDTA. © 1998 Elsevier Science B.V. Keywords: Di-(2-ethylhexyl)phosphoric acid; Dibutyl(butyl)phosphonate; VO^{2+} -selective sensors

1. Introduction

In spite of widespread activity in the field of ion-selective electrodes during the last two decades, the efforts to make suitable commercially available sensors for heavy metals have not been successful. This appears to be due to the non availability of suitable sensor materials. As heavy metals are present in most samples, it is desirable to have sensors for their quick determination. This may become possible with the increasing availability of new materials showing selectivity for different metals. Vanadyl (VO^{2+}) and uranyl (UO_2^{2+}) are the most well recognized oxometal species and of the two, vanadyl is more stable. It

is seen from the literature that the solutions of VO^{2+} in medium and strongly acidic solutions are stable for many months [1]. Vanadium is an important constituent of steel, petroleum and alloy industries and is also used as a catalyst. Its determination is, therefore, important. A number of electrodes [2–5] have been developed for the determination of vanadium which sense it as vanadate (VO_3^-). However, there is no report of an electrode developed for vanadyl ions. A survey of the literature further revealed that di-(2-ethylhexyl)phosphoric acid (DEHPA) and dibutyl butylphosphonate (DBBP) have good affinity for vanadium and have been used for its extraction from the ores containing vanadium [6,7]. These two extractants can thus be the materials of choice to be used as electroactive material for the fabrication of ion-selective electrodes for vanadyl

ions. Therefore, in continuation of our work on the development of ion sensors for oxometal species [8,9], we thought it desirable to investigate poly(vinyl chloride) (PVC) based membranes of the two extractants as vanadyl selective sensors. Our efforts have been successful and the results are reported in the present communication.

2. Experimental

2.1. Reagents

Di-(2-ethylhexyl) phosphoric acid and dibutyl-(butyl) phosphonate were obtained from Mobil, USA. High molecular weight poly(vinyl chloride), sodium tetraphenylborate (NaTB) and vanadyl sulphate were BDH, UK, products. All other reagents used were of analytical grade and the solutions were prepared in doubly distilled water.

2.2. Potential measurements

The potential measurements of the solutions, prepared in the concentration range 1.0×10^{-6} – 1.0×10^{-1} M VO²⁺ ions, were carried out at $25 \pm 0.1^\circ\text{C}$ with a PH 5662 digital pH/millivoltmeter (ECIL, India) and on a CVM 301 Century digital microvoltmeter (Century Instruments, India). Saturated calomel electrodes (SCE) were employed as reference electrodes and potentials were measured by setting up the following cell assembly:

Internal reference electrode (SCE)	Internal solution (0.1MVO ²⁺)	Membrane	Test solutions	External reference electrode (SCE)
------------------------------------	---	----------	----------------	------------------------------------

2.3. Preparation of Membranes

The method reported by Craggs et al. [10] was adopted for the fabrication of membranes. Varying amounts (20–100 mg) of the sensor material (DEHPA or DBBP) and PVC were dissolved in 20 ml tetrahydrofuran. Anion excluder, NaTB, was also added to the membranes in some compositions. The homogeneous mixture was poured into glass rings placed on smooth glass plates and the solvent was allowed to evaporate overnight, yielding a membrane of about 0.5 mm thickness and 10 mm diameter. A number of membranes of different compositions were prepared and only those which gave reproducible and stable potentials were selected for further studies. The composition of these membranes is reported in Table 1. The membranes were fixed to one end of a Pyrex glass tube with Araldite (Ciba Giegy, India) and equilibrated with 0.5 M VO²⁺ solution for three days.

2.4. Dissolution of waste V₂O₅ catalyst sample

1 g of the powdered sample of waste V₂O₅ catalyst was repeatedly digested (four times) with aqua regia. The residue was treated with 10 ml concentrated hydrochloric acid and filtered. The filtrate was boiled with HCl, cooled and made up to 100 ml. The boiling with HCl converted all vanadium(V) to vanadium(IV) [11]. A portion of this solution was further diluted 20 times keeping the overall pH at 2.0. In order to get a representa-

Fig. 1. Variation of potential with VO^{2+} activity for membranes 1 and 2.

tive value, five separate samples of the waste catalyst were dissolved and processed. The solutions were analysed on an ICP-AES (Plasma Lab-tam, Australia, model 8440).

3. Results and discussion

3.1. Working concentration range and slope

The potential response of all the four electrodes using membranes of DEHPA and DBBP of different composition was investigated by varying the concentration of the test solution from 1.0×10^{-6} – 1.0×10^{-1} M and the results obtained are given in Table 1 and shown in Figs. 1 and 2. It is seen from Fig. 1 that the electrodes nos. 1 and 2 having membranes of DEHPA and DBBP exhibit linear potential response in the concentration range 2.2×10^{-5} – 3.2×10^{-3} and 7.1×10^{-5} – 2.2×10^{-2} M with a near-Nernstian slope of 25.2

and 23.3 mV per decade of activity, respectively. Both the electrodes showed high response time of 1 min. The addition of anion excluder, NaTB, to the membranes (electrodes nos. 3 and 4) not only improved the working concentration range to 1.4×10^{-5} – 1.0×10^{-1} and 7.9×10^{-6} – 1.0×10^{-1} M but also the slope to 27.7 and 29.1 mV per decade of activity and response time to 25 and 15 s, respectively. It is important to mention that the addition of plasticizers did not improve the performance of the membranes. This observation may be ascribed to the fact that DEHPA and DBBP themselves act as plasticizers and have been used earlier for this purpose also [12,13]. As the electrodes 3 and 4 are better, they have been studied in detail. The membrane electrodes could be used over a period of six months without showing any significant change in the value of slope or working range. The membranes were stored in 0.1 M VO^{2+} solution when not in use and were re-equilibrated with 0.5 M VO^{2+} solu-

Fig. 2. Variation of potential with VO^{2+} activity for membranes 3 and 4.

tion whenever any drift in potentials was observed. Repeated monitoring of potentials (20 measurements) at 1.0×10^{-3} M VO^{2+} concentration gave a standard deviation of 0.5 mV for both the electrodes.

3.2. Effect of pH and non-aqueous medium

The pH dependence of both the membrane electrodes was investigated at 1.0×10^{-3} M VO^{2+} concentration in the pH range 1.0–4.0 by adjusting the pH of the solution with H_2SO_4 and ammonia. It was observed that the potentials remain constant in the pH range 1.8–2.5 and the same was taken as the working pH range of the electrodes. The functioning of the electrodes was also investigated in partially non-aqueous media using ethanol–water and methanol–water mixtures and the results obtained are presented in

Table 2. It is observed that in the presence of both ethanol and methanol, the slope as well as working concentration range is reduced. The effect is drastic in methanol–water mixture where the slope is considerably decreased even in 10% (v/v) methanol. Therefore, the electrodes are not suitable for estimation in methanol–water mixtures. However, in ethanol–water mixture, up to 10% (v/v) ethanolic content, there is only a small decrease in slope and working concentration range and hence both the electrodes can be satisfactorily used in presence of 10% (v/v) ethanol in water.

3.3. Potentiometric selectivity pattern

The selectivity of the electrodes in presence of various cations was evaluated by the fixed interference method as suggested by Viteri and Dia-

Table 2
Performance of DEHPA-NaTB (N0. 3) and DBBP-NaTB (No. 4) membrane sensors in partially non-aqueous medium

Non-aqueous content (% v/v)	Electrode No. 3		Electrode No. 4	
	Slope (mV/decade of activity)	Working concentration range (M)	Slope (mV/decade of activity)	Working concentration range (M)
Nil	27.7	1.4×10^{-5} – 1.0×10^{-1}	29.1	7.9×10^{-6} – 1.0×10^{-1}
Ethanol

Mg^{2+}	4.5×10^{-2}	1.0×10^{-2}
Cd^{2+}	1.0×10^{-2}	1.0×10^{-2}
UO_2^{2+}	6.3×10^{-2}	5.0×10^{-2}
Cr^{3+}	2.0×10^{-2}	3.2×10^{-2}
Al^{3+}	1.4×10^{-2}	1.0×10^{-2}
Fe^{3+}	4.5×10^{-2}	2.2×10^{-2}

NH_4^+ for electrode no. 4. This behaviour may be due to the selective uptake of vanadyl by DEHPA and DBBP in comparison to the other species listed in Table 3. It is worth mentioning that the observed selectivity coefficient values for Ni^{2+} and NH_4^+ are due to the characteristics of the membranes caused by difference in the extraction properties of DEHPA and DBBP. Hence, the electrodes can be used for the estimation of VO^{2+} in presence of equal or less concentration of these ions. However, in view of moderate selectivity of the electrodes, Ni^{2+} and NH_4^+ would cause considerable interference for electrodes 3 and 4, respectively, even if present in comparative amounts. Therefore, in order to realize the level of interference caused by these two ions in the performance of the electrodes, mixed run studies were carried out [8,15–19]. Fig. 3 shows the variation of potentials with VO^{2+} ion concentration in presence of different concentrations of Ni^{2+} . It is observed that the presence of Ni^{2+} ions up to 5.0×10^{-5} M would not cause any interference while determining VO^{2+} with this membrane sensor as no divergence from the potential versus VO^{2+} concentration plot is observed. However, higher concentrations of Ni^{2+} ions cause interference and can not be tolerated over the whole working concentration range of VO^{2+} ions. Thus, in presence of 1.0×10^{-4} and 5.0×10^{-4} M Ni^{2+} ,

Fig. 3. Effect of different concentrations of Ni^{2+} ions on the variation of potential for membrane 3.

VO^{2+} can be determined over the reduced concentration range of 7.1×10^{-5} – 1.0×10^{-1} and 3.2×10^{-4} – 1.0×10^{-1} M, respectively. Similar mixed run studies were carried out for electrode no. 4 for which NH_4^+ causes maximum interference. Plots of potential versus VO^{2+} concentration in the presence of different concentration levels of NH_4^+ are shown in Fig. 4, which indicate that 5.0×10^{-4} M NH_4^+ ions can be tolerated over the whole working concentration range of VO^{2+} ions, while in the presence of 1.0×10^{-3} and 5.0×10^{-3} M NH_4^+ ions the electrode would be effective over the reduced concentration ranges 3.2×10^{-5} – 1.0×10^{-1} and 1.4×10^{-4} – 1.0×10^{-1} M, respectively. Further, among the two electrode assemblies the DBBP–NaTB membrane (electrode no. 4) is more selective as the $K_{\text{VO}^{2+}, \text{B}}^{\text{Pot}}$ values for this electrode are lower than the DEHPA–NaTB membrane (electrode no.3).

4. Analytical applications

4.1. Analysis of waste V_2O_5 catalyst sample

The utility of the membrane electrodes was checked by using them for the quantitative determination of vanadium in a sample of waste V_2O_5 catalyst and comparing the results with those obtained with ICP-AES. The data shown in Table 4 clearly shows that both the electrodes perform exceptionally well and the results obtained are in concurrence with those obtained with ICP-AES.

4.2. Potentiometric titration

Both the membrane electrodes have also been successfully used as indicator electrodes in the potentiometric titrations of VO^{2+} (1.0×10^{-3} M, 10 ml) with EDTA (1.0×10^{-2} M) at pH 2.3. The addition of EDTA to VO^{2+} solution causes the formation of VO–EDTA complex, resulting in the reduction of VO^{2+} concentration and thereby a decrease in cell potential. The plots (Fig. 5)

Fig. 4. Effect of different concentrations of NH_4^+ ions on the variation of potential for membrane 4.

Table 4

Analytical data of V_2O_5 waste catalyst sample and vanadium content as determined with the membrane sensors 3 and 4

Element	Concentration as determined by ICP-AES (ppm)	Concentration of V as determined by electrode 3 (ppm)	Concentration of V as determined by electrode 4 (ppm)
Ti	1.00 ± 0.02	—	—
Al	7.50 ± 0.08	—	—
Fe	3.50 ± 0.05	—	—
V	14.4 ± 0.20	13.9 ± 0.4	14.0 ± 0.4

obtained are, however, not of sigmoid shape due to some interference caused by the ions being made available on the addition of the titrant. The combined effect of interference by added ions and change in concentration of VO^{2+} during the course of titration happens to yield linear change in potential as observed by us. This behaviour is commonly met with titration plots obtained by using moderately selective electrodes [15,19]. The titration may be useful if the break points of the plots corresponds to the stoichiometry of the complex. In the present case, the break point

obtained is sufficiently sharp and corresponds to the stoichiometry of $VO-EDTA$ complex. Thus the electrodes can be used to determine VO^{2+} by potentiometric titrations.

5. Conclusion

Among the four PVC-based membranes of the extractants prepared and tried as VO^{2+} sensors, the ones having anion excluder NaTB exhibited good performance with regard to the working

Fig. 5. Potentiometric titration curve of VO^{2+} (1.0×10^{-3} M, 10 ml) versus EDTA (1.0×10^{-2} M). (a) Electrode no. 3 and (b) electrode no. 4.

concentration range and selectivity. They have been successfully used for the quantification of vanadium in a sample of waste V_2O_5 catalyst. The DBBP–NaTB membrane gives the best results as it exhibits a wider working concentration range, 7.9×10^{-6} – 1.0×10^{-1} M and better selectivity. The electrodes have a fast response time and perform satisfactorily in the pH range 1.8–2.5 and in partially non-aqueous medium up to 10% (v/v) alcohol content. They give reproducible results and have a life time of more than six months.

Acknowledgements

We thank Dr A.B. Ghatag, Superintendent, Projects and Development India Ltd. (PDIL) for providing the sample of V_2O_5 waste catalyst. LPS and UK are thankful to the Council for Scientific and Industrial Research (CSIR), India, for providing financial assistance.

Abstract

A new chelating ion-exchange resin with a spacer $\text{CH}_2\text{-NH-C}_6\text{H}_4\text{-}$ based on a microreticular chloromethylated styrene-divinylbenzene copolymer containing α -nitroso- β -naphthol as a functional group has been synthesized. The sorption characteristics for manganese(II), iron(III), cobalt(II), nickel(II), copper(II), and zinc(II) have been investigated over the pH range 1.0–7.0. The resin is highly stable in acidic and alkaline medium. Iron(III) and cobalt(II); copper(II) and iron(III) are separated very effectively in a column operation by stepwise elution. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: α -Nitroso- β -naphthol; Column operation; Stepwise elution

1. Introduction

Historically, the development of complexing resins started in 1939, with the work of Erlenmeyer and Dahn [1], leading later on to the suggestion of Meinhard [2] that the complexing agents would be fixed on a supporting solid for work of this kind. α -Nitroso- β -naphthol was the first used for the separation of cobalt from nickel by Ilinski and Von knorre [3]. It was one of the first organic analytical reagents and forms chelate complexes with a number of metal ions in addition to cobalt like copper(II),

iron(III), nickel(II), palladium(II) and uranium(VI) [4–6]. The incorporation of this reagent in a matrix should be of interest in the connection with concentration and separation of heavy metal ions [7]. The preparation and properties of a chelating resin containing α -nitroso- β -naphthol as a functional group has been investigated and the exchange capacity of the resin for Cu(II), Fe(III), Co(II), Ni(II), Pd(II) and U(VI) has been examined as a function of pH [8].

The present paper describes the preparation and characterisation of a microreticular chloromethylated resin with a spacer containing α -nitroso- β -naphthol for Mn (II), Fe (III), Co (II), Ni (II), Cu (II) and Zn (II).

2. Experimental

2.1. Apparatus and reagents

IR spectra (KBr disks) were recorded with an FTIR (Perkin Elmer). The stock metal ion solutions were prepared by dissolving reagent grade chlorides in water or in buffer solutions. Buffer solutions were prepared with 0.2 M hydrochloric acid and 0.2 M sodium acetate. The chloromethylated styrene-divinylbenzene copolymer, 2 and 8% divinylbenzene was from the Ion-Exchange, India.

2.2. Preparation of resin

2.2.1. Resin II

To 50 g of resin I 200 ml dioxan was added. The pre-swollen chloromethylated polystyrene resin was refluxed with ortho-phenylenediamine in pyridine for 24 h. The product resin II was washed with cold water and then extracted in a

Soxhlet extractor with methanol for two days and dried in a vacuum oven.

2.2.2. Resin III

Resin II was diazotised according to the procedure described by Davies et al. [9]. The diazotised product was rapidly filtered off, washed with cold distilled water until free from acid and then coupled at 0–50°C with a solution of α -nitroso- β -naphthol in 5% aqueous NaOH solution, over a period of 7 days. The resin was then filtered off and thoroughly washed with distilled water until free from alkali. It was then extracted in a Soxhlet extractor with methanol for 3 days. Finally it was washed with dilute hydrochloric acid and then with demineralised water until free from acid. The product was dried under vacuum to get Resin III. The same procedure was carried out for 2 and 8% resin to obtain IIIa and IIIb resin, respectively. The particle size of the resin is 500–800 and 400–800 μm for IIIa and IIIb, respectively.

Table 2
Separation of Fe(III)–Co(II)

No.	Metal ion	Amount loaded (ppm)	Amount recovered			Eluent volume	Error (mean)	S.D.
			a	b	c			
1	Fe(III)	50	48.7	48.4	48.4	30	1.50	0.17
	Co(II)	25	23.9	23.7	23.7	15	1.24	0.14

3	Fe(III)	20	18.2	18.1	18.1	12	1.80	0.17
	Co(II)	20	18.2	18.3	18.2	12	1.77	0.07

Scheme 1.

2.3. Stability of the resin

Dry resin IIIa/IIIb 0.5 g was shaken with 25 ml acid or alkaline solutions of various concentrations for 3 days, and then filtered and washed successively with water, 0.05 M NaOH solution and water. After drying, the nitrogen content and sorption capacity for Fe(III) and Cu(II) were determined which remained unaffected in acidic and alkaline solutions indicating that resin IIIa and IIIb are stable in acidic and alkaline medium.

2.4. Water regain

A sample of 0.5 g dry resin IIIa and IIIb were immersed in water for 48 h. The resins were then filtered by suction and pressing between filter

papers to remove the surface moisture. Weighed amounts of the swollen resins were dried at 110°C for 48 h to determine water regain values. Water regain for resin IIIa and IIIb was 0.63 and 0.49 respectively.

$$\text{EWC} = \frac{\text{Wt of the wet resin} - \text{Wt of the dry resin}}{\text{Wt of the dry resin}}$$

2.5. Estimation of nitrogen and the amino group

The nitrogen content of fully dried samples of amino and the chelating resin was determined by the sodium fusion test and estimated by the Kjeldhal method. The nitrogen content of aminated polystyrene and the chelating resin was found to be 7.5 and 9.5%, respectively. Amino capacity was determined by using Crystal violet indicator [10].

Fig. 1. IR spectra of resin II and III.

2.6. Column operations

A glass column 32 cm long with a 5 mm bore was used. 5 g Air-dried resin (IIIa) was immersed in demineralised water and allowed to swell for 24 h. The column was then packed with the fully swollen beads. The bed was thoroughly washed with 0.1 M HCl acid, then with

demineralised water until free from acid. The attaining equilibrium was 7 min. for column operations. A long column is used to accommodate most of the eluent at one time so that constant flow can be maintained without disturbing the polymeric bed. This precaution was taken as some metals require large quantity of eluent.

Effect of pH on sorption of metal ions

Fig. 2. Sorption behaviour of six metal ions between pH range 1.0–7.0.

2.6.1. Separation of metal ions by using column technique

1. Cu(II)–Fe(III) separation: mixtures of Cu(II) and Fe(III) of various proportions were prepared. The column was preconditioned with 0.01 M HCl. An aliquot of 5 ml of the mixture was introduced at the top of the column. The flow rate was maintained at 0.5 ml min⁻¹. Cu(II) solution was eluted using a 3 M HCl solution while Fe(III) solution was eluted using 2 M HCl at same flow rate and analysed spectrometrically as shown in Table 1.

2. Fe(III)–Co(II) separation: mixtures of Fe(III) and Co(II) of various proportions were prepared. The column was pre-conditioned with 0.01 M HCl. An aliquot of 5 ml of the mixture

was introduced at the top of the column. The flow rate was maintained at 0.5 ml min⁻¹. The Fe(III) solution was eluted using 2 M HCl while the Co(II) solution was eluted using 1 M HCl. The fractions were collected in 5 ml fractions and the concentration of the metal ion determined spectrometrically as shown in Table 2.

2.7. Exchange-capacity determinations

The exchange-capacity of six metal ions Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and Zn(II) were determined in the pH range 1.0–7.0. The 0.25 g of air-dried resins were equilibrated with a buffer and enough metal ion solution adjusted to same pH was added to give the appropriate metal ion

Table 3
Influence of the extent of the crosslinking on metal ion intake by the resin

Crosslinking density	Metal ions (mequi g ⁻¹)					
	Fe(III)	Co(II)	Ni(II)	Cu(II)	Zn(II)	Mn(II)
2%	2.80	2.20	2.40	2.24	1.84	1.73
8%	1.92	1.52	1.95	1.76	1.12	1.05

solution. After shaking for 24 h, the mixture was filtered and the resin was thoroughly washed with buffer until free from the metal ion. The eluted metal ions were determined spectrometrically (Fig. 2).

3. Results and discussion

3.1. Synthesis and characterisation of chelating resin

The resin III presented in this study was synthesized from chloromethylated styrene-divinylbenzene beads (dvb 2 and 8%) through the reaction steps shown in Scheme 1. Fig. 1 shows the IR spectra of resin II and III. The whole characteristic feature in the IR spectrum are the bands due to the nitroso group at 1350, 1410, and 1510 cm⁻¹, a band between 1600–1700 cm⁻¹ due to the tautomeric oxime group and a band at 3150 cm⁻¹ due to O–H stretching frequency of the phenol group.

3.2. Analytical properties of the chelating resin

The high selectivity of resin III towards Cu(II) is shown in Fig. 2, which shows the sorption behaviour of six metal ions at different pH on

resin IIIa and IIIb. An absence of nitroso group shows no significant sorption of metal ions. Equilibrium studies with Cu(II) shows that the time required by the resin III for 50% uptake is 50 min. Therefore Resin III is suitable for column operations if the flow-rate is low.

3.2.1. Influence of the extent of the crosslinking on metal ion intake by resin IIIa and IIIb

The metal ion intake of the resin was studied as a function of pH to determine the optimum pH for maximum complexation. The extent of crosslinking agent in polymeric matrix influence the reactivity and therefore extent of the complexation of polymeric ligand with metal ions is shown in Table 3.

3.2.2. Influence of equilibrium pH on metal ion complexation and their percent recovery by resin III

In order to investigate the optimum pH for maximum complexation, batch studies were carried out at varying pH. The pH dependence of complexation was studied for the regions below and above the natural pH of dipositive metal–salt solutions in aqueous medium. The variation in the amount of the metal ion complexed by the resin III at different pH values are shown in Table 4.

Table 4
Influence of equilibrium pH on metal ion complexation metal ion recovery by resin IIIa

Metal ions	Fe(III) →				Co(II) →				Cu(II)			
	3.5	3.0	2.5	2.0	4.0	4.5	5.0	5.5	5.5	6.0	6.5	6.75
Equilibrium pH	3.5	3.0	2.5	2.0	4.0	4.5	5.0	5.5	5.5	6.0	6.5	6.75
Amount of metal complexed	2.39	2.64	2.78	2.69	1.82	2.01	2.16	2.24	1.93	2.08	2.21	2.03
Recovery (%) of metal ions	86	93	99	97	81	89	95	99	87	94	100	92

Table 5
Recovery of Cu(II) by batch extraction

Recovery of Copper (II)	Molar concentration (M)				
	0.01	0.1	1.0	2.0	3.0
HCl concentration	0.01	0.1	1.0	2.0	3.0
Recovery (%)	12	73	84	94	99

3.2.3. Recovery of Cu(II) by batch operation

Besides the high performance in the adsorption of metal ions, the adsorbed metal ions should be eluted rapidly and quantitatively, from a practical point of view. Various experiments on recovery of Cu(II) from resin III were carried out by batch operation. The results shown in Table 5 indicates that copper can be recovered with HCl by using different concentrations. When the acid concentration is higher than 1.0 M the adsorbed Cu(II) is eluted quantitatively.

In conclusion, the new chelating resin with $\text{CH}_2\text{-NH-C}_6\text{H}_4$ as a spacer containing α -nitroso- β -naphthol as a functional group has been found to be stable in acidic and alkaline medium. It is useful in the separation of Fe(III), Co(II) and Cu(II) and Fe(III). The stability of the chelating functional group in the resin is quite good. The exchange capacity of the resin remains unaltered after quite a number of cycles. The water regain of the resin is satisfactory. The results presented above suggests that resin III can be applied to the concentration and separation of Cu(II) effectively and repeatedly. A decrease in the metal ion capacity at higher crosslinking is due reduced accessibility of the reactive site for complexation. A highly crosslinked system restricts the diffusion of the reducing species into the matrix [11]. The variation in the amount of metal ion complexed even for a highly crosslinked system shows that polymer matrix has a definite influence in the complexation of the different metal ions. In the complexation of polymeric ligands with metal ions, the macromolecular chains coil more tightly

by crosslinking with metal ions. The reduction of EWC is higher in low crosslinked systems. In tightly crosslinked systems, the polymer chain can undergo extensive swelling from the increased diffusion of water molecules into loose networks.

Acknowledgements

The authors are thankful to the Ion-Exchange Co. Ltd. (India) for supplying us with the chloromethylated polystyrene resin and to Dr P.P. Wadgaonkar for thoughtful discussion. We are also thankful to the Polymer Division, National Chemical Laboratory, Pune, India, for determining the particle size of the resins.

Abstract

We examined the variation with ionic strength (I , adjusted with KCl, KNO₃, KBr, NaCl or NaClO₄) of the formal potential (E_{const}) for glass electrodes exhibiting a Nernstian response (i.e. $E_{\text{cell}} = E_{\text{const}} - s \log [\text{H}^+]$). For this purpose, we investigated the different factors included in the formal potential, so we obtained reported values for the liquid junction potential as a function of ionic strength and determined the logarithm of the activity coefficient for the proton in various saline media, using Pitzer equations. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Ionic strength; Formal potential; Glass electrode; Potentiometry

1. Theoretical background

Potentiometry with a commercially available H⁺ ion-sensitive glass electrode, also referred to as ‘pH-metry’, is a powerful tool for determining equilibrium constants [1]. IUPAC recommends calibrating glass electrodes in terms of the proton concentration at a constant ionic strength prior to the determination proper [2]. Glass electrodes exhibit a Nernstian response; consequently, the resulting electromotive force at constant ionic strength will be given by [3]

$$E_{\text{cell}} = E_{\text{const}}(I) + s \log [\text{H}^+] \quad (1)$$

where

$$E_{\text{const}} = E_r + E_1 + E_g^o + s \log \gamma_{\text{H}^+} \quad (2)$$

and s denotes the Nernstian slope, the value of which at 25°C is

$$s = \ln 10 \ RT/F = 59.16 \text{ mV} \quad (3)$$

In Eq. (2), E_g^o is the potential across the glass membrane at unity proton activity; E_r is the combination of the external and internal reference potentials and will thus be independent of the ionic strength of the unknown solution—unlike the liquid junction potential (E_1) and, obviously,

* Corresponding author. Tel.: +34 81 167050; fax: +34 81 167065; e-mail: eman@udc.es

the activity coefficient for the proton ($\log \gamma_{\text{H}^+}$). According to the Stockholm school [4], E_1 varies with acidity; however, several authors have shown that it can be assumed not to vary, within experimental errors, with small acidity changes (e.g. over the $-\log [\text{H}^+]$ ranges 2.3–2.9 and 10.8–11.3). In addition, fulfillment of Eq. (1) has been experimentally confirmed [3,5].

Parameter E_g^0 encompasses the asymmetry potential, resulting from differences between the inner and outer leached layers and potentially arising from composition differences introduced during the electrode's manufacturing process, a differential history for both leached layers or the adsorption of given substances by either [6].

Although formal potentials, E_{const} , are commonly used to determine equilibrium constants, virtually none of the studies involving calibration of glass electrodes in terms of the proton concentration [7–12] has reported on the variation of E_{const} with ionic strength [$E_{\text{const}} = f(I)$]. One interesting exception is the study of Pezza et al. [13], who used various ion-selective electrodes to determine the activity coefficients for the ions sensed by each electrode. In this work, we used commercially available H^+ ion-sensitive glass electrodes to compare the variation of the formal potential with ionic strength in five different electrolytes that are commonly used to adjust the latter parameter (NaCl, KCl, KBr, KNO_3 and NaClO_4).

2. Experimental

Calibrations were done in an acid medium¹ as described elsewhere [5]: variable volumes v of a strong acid of concentration c were successively added to an initial volume V_0 of inert electrolyte solution. The proton concentration was thus given by

$$[\text{H}^+] = \frac{cv}{V_0 + v} \quad (4)$$

¹ If calibration was performed by adding a base to an acid solution, then the combination of relatively small errors in the concentration of both resulted in the slope of the fitted curve deviating from the Nernstian value, as previously noted elsewhere [3,5].

where $2.3 < -\log [\text{H}^+] < 2.9$ [3]. We used an initial volume $V_0 = 40.0$ ml to which 0.04 ml aliquots of 0.1000 M HCl were successively added. Only those points included in the above-mentioned range were used to fit E_{cell} versus $\log [\text{H}^+]$ curves.

We carried out experiments at a variable ionic strength adjusted with NaCl, KBr, KNO_3 , KCl and NaClO_4 (all Merck p.a. reagents). The water used to prepare every solution was purified by passage through a Millipore Milli-Q system. All experiments were performed in a dual-wall cell through which water thermostated at $25.0 \pm 0.1^\circ\text{C}$ was circulated. Nitrogen of 99.999% purity was bubbled through the cell to remove CO_2 and stir the solution. A Crison microBU 2030 autoburette furnished with a 2.5 ml syringe for dispensing the titrant was used. The burette was controlled via a computer that afforded reading the emf of a Crison micropH 2002 pH-meter connected to a Radiometer GK2401C electrode. This last was a glass electrode combined with an Ag/AgCl reference electrode where the liquid junction was established by a salt bridge consisting of a plug of porous ceramics.

3. Results and discussion

Fig. 1 shows a typical calibration curve, of intercept $E_{\text{const}} = 378.9 \pm 0.1$ mV and slope

Fig. 1. Calibration curve of equation $E = 378.9 (\pm 0.1) - 59.1 (\pm 0.1) \text{p}[\text{H}^+]$ in 0.6 M KBr.

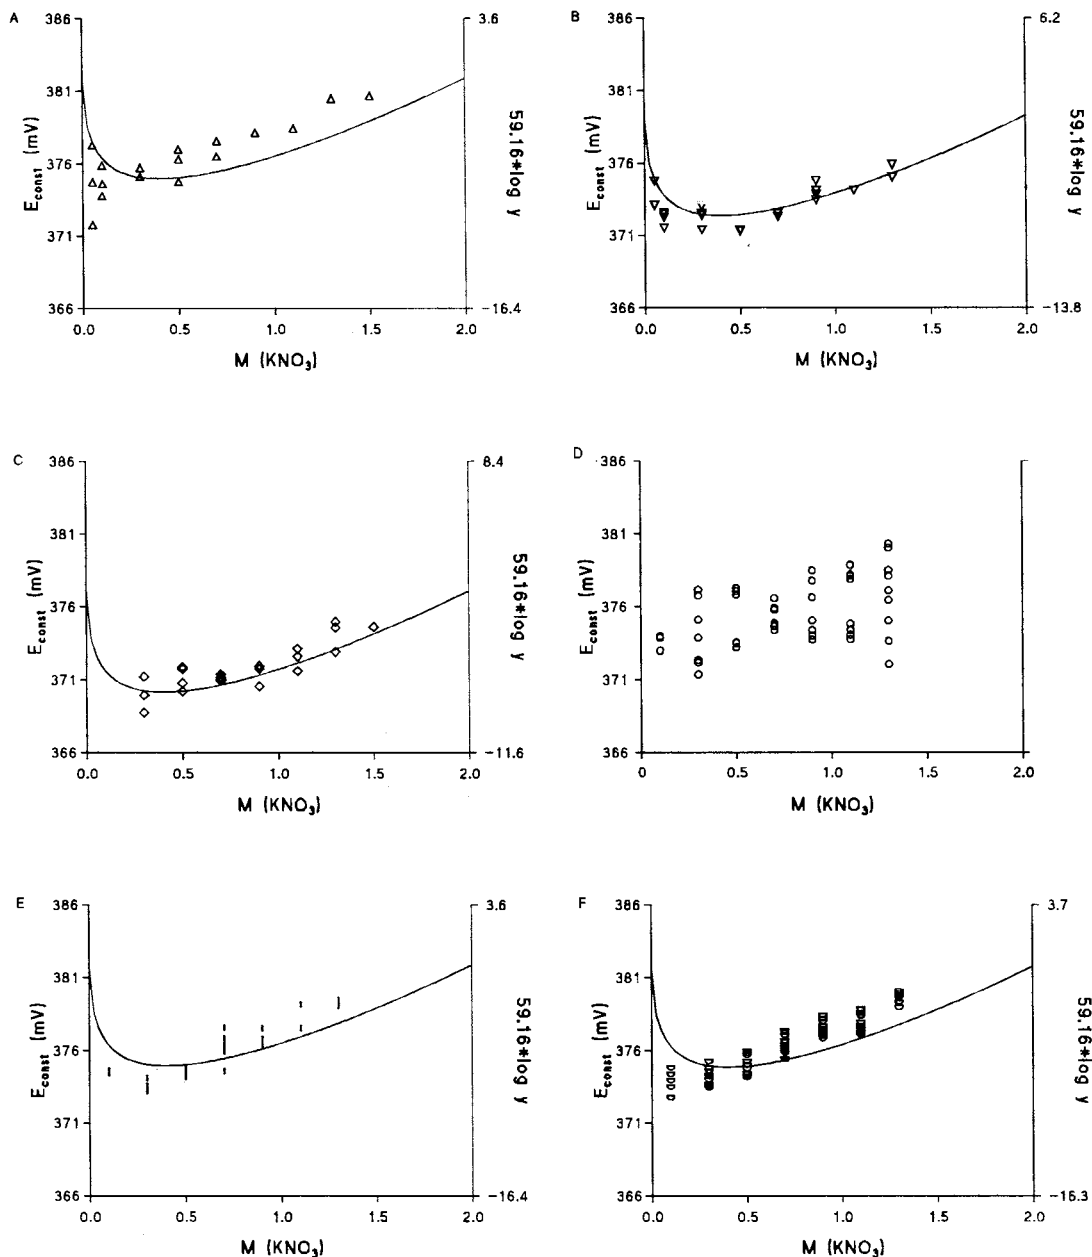

Fig. 2. Variation of E_{const} with I in KNO_3 . Data obtained with the same Radiometer GK2401C electrode on the following time frames: (A) May–June, 1992, (B) April, 1993, (C) January–April, 1994, (D) October, 1994, (E) December, 1994, and (F) February–March, 1995. The solid line represents the variation of $s \log \gamma_{\text{H}^+}$ with I according to the Pitzer equations.

59.1 ± 0.1 mV. The E_{const} values obtained from similar fitted curves for the different electrolytes are shown in Figs. 2, 4 and 5. By way of example, Fig. 3 shows the slopes of the calibration curves

obtained in KNO_3 ; as can be seen, there were no significant deviations from 59.2 mV at 25°C—the largest error was 2%—, which testifies to the Nernstian behaviour of the electrode. Similar re-

sults were obtained regarding the slopes of the fitted curves for the other electrolytes. On the other hand, careful examination of Fig. 2 reveals increased dispersion of formal potentials in graph D. The difference arose from the fact that, except in series 1D, the glass electrode was stored in a slightly acidic solution (about 0.05 M) while not in use in order to improve its response relative to storage in water or a neutral buffer [14]. During the calibrations of Fig. 2D, the electrode was kept in distilled water while not in use—an identical behaviour was observed if it was stored in a neutral buffer.

As can also be seen from Fig. 2, experimental points in the E_{const} versus I graphs followed the same pattern, albeit shifted to lower or higher potentials—note that the same scale was used in all graphs.

In order to account for the behaviour of these E_{const} versus I curves in Figs. 2, 4 and 5 one must break down E_{const} into the factors included in Eq. (2). As noted earlier, both the liquid junction potential, E_l , and the activity coefficient for the proton, vary with ionic strength.

There are few reported liquid junction potentials. By exception, Bagg [15] has reported the potentials for the junction or free diffusion between a 4 M KCl solution and NaCl or KBr solutions at a variable ionic strength (Fig. 6). The results of Bagg [15] for the liquid junction residual potential in dual-junction cells are comparable,

Fig. 3. Mean of the slopes of the calibration curves in Fig. 2.

within experimental error for this type of measurement, with those experimentally—derived in almost every system studied so far. As noted by Bagg himself, ‘this agreement is particularly satisfactory in view of (a) the probable differences of the junctions, sleeve-type and frit, used in the cells from the idealized model of junction used in the calculation, and (b) the extrapolation of some transference numbers beyond the range of concentration in which they are determined.’

The sole constraint to the use of the previous data [15] is that the ionic strength values used do not coincide with those of our experiments, so E_l must be interpolated to the desired I values. For this purpose, we used a polynomial ratio proposed elsewhere [16] as the interpolation function. We used this type of function because it fits the experimental behaviour more closely than does a simple polynomial or a cubic spline interpolation function [16].

Provided the liquid junction potential is known, Eq. (2) can be rewritten as

$$E_{\text{const}} - E_l = E_r + E_g^0 + s \log \gamma_{\text{H}^+} \quad (5)$$

If the only term that depends on ionic strength on the right-hand side of this equation is the activity coefficient for the proton, then, the plots of $(E_{\text{const}} - E_l)$ versus I and $(s \log [\text{H}^+])$ versus I should exhibit the same trend except for the shift due to the $(E_r + E_g^0)$ term. In order to confirm this assumption, we superimposed the $(s \log \gamma_{\text{H}^+})$ versus I curve and shifted it to overlap the previous one, obviously, at the same scale amplitude (20 mV) in both cases (Fig. 5B,D).

The activity coefficient for the proton was calculated in the light of Pitzer’s formalism. The pertinent equations are given in Appendix A and the curves obtained in the different electrolytes studied are shown in Fig. 7. As can be seen, every curve exhibits a minimum at a different ionic strength for each electrode, beyond which the curve is virtually linear. The similar behaviour of the $(s \log \gamma_{\text{H}^+})$ versus I curves and the $(E_{\text{const}} - E_l)$ versus I curves is apparent in Fig. 5B,D for KBr and NaCl, respectively. One quantitative way of comparing the experimental results with the curve derived from the Pitzer equations is by fitting experimental E_{const} versus I data points and

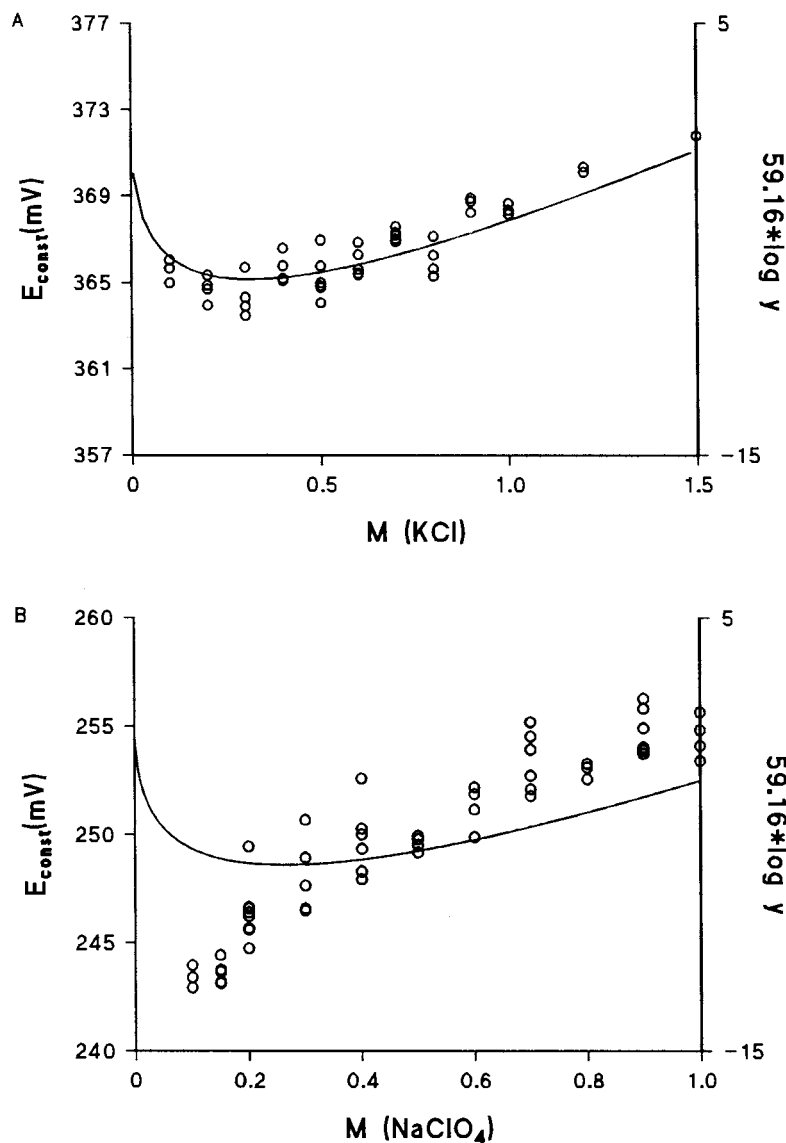

Fig. 4. Variation of E_{const} with I in the following electrolytes: (A) KCl and (B) NaClO₄. The solid line represents the variation of $s \log \gamma_{\text{H}^+}$ with I according to the Pitzer equations.

those in the $(s \log \gamma_{\text{H}^+})$ versus I curve obtained from the Pitzer equations—obviously in the virtually linear zone (Fig. 7)—to a straight line. Table 1 gives the results obtained and the ionic strength range used in each fitting. As can be seen, consistency between data is quite good for KBr (Fig. 5B) but not quite for NaCl (Fig. 5D) as the likely result of Na⁺ ion influencing the behaviour of the

glass electrode. Unfortunately, there seems to be no reported liquid junction potentials for the other systems studied, so we chose to plot E_{const} versus I and $(s \log \gamma_{\text{H}^+})$ versus I in the same graphs.

As can be seen from both Table 1 and Fig. 5A, the results in KBr were still similar, which was to be expected since E_1 remained virtually constant

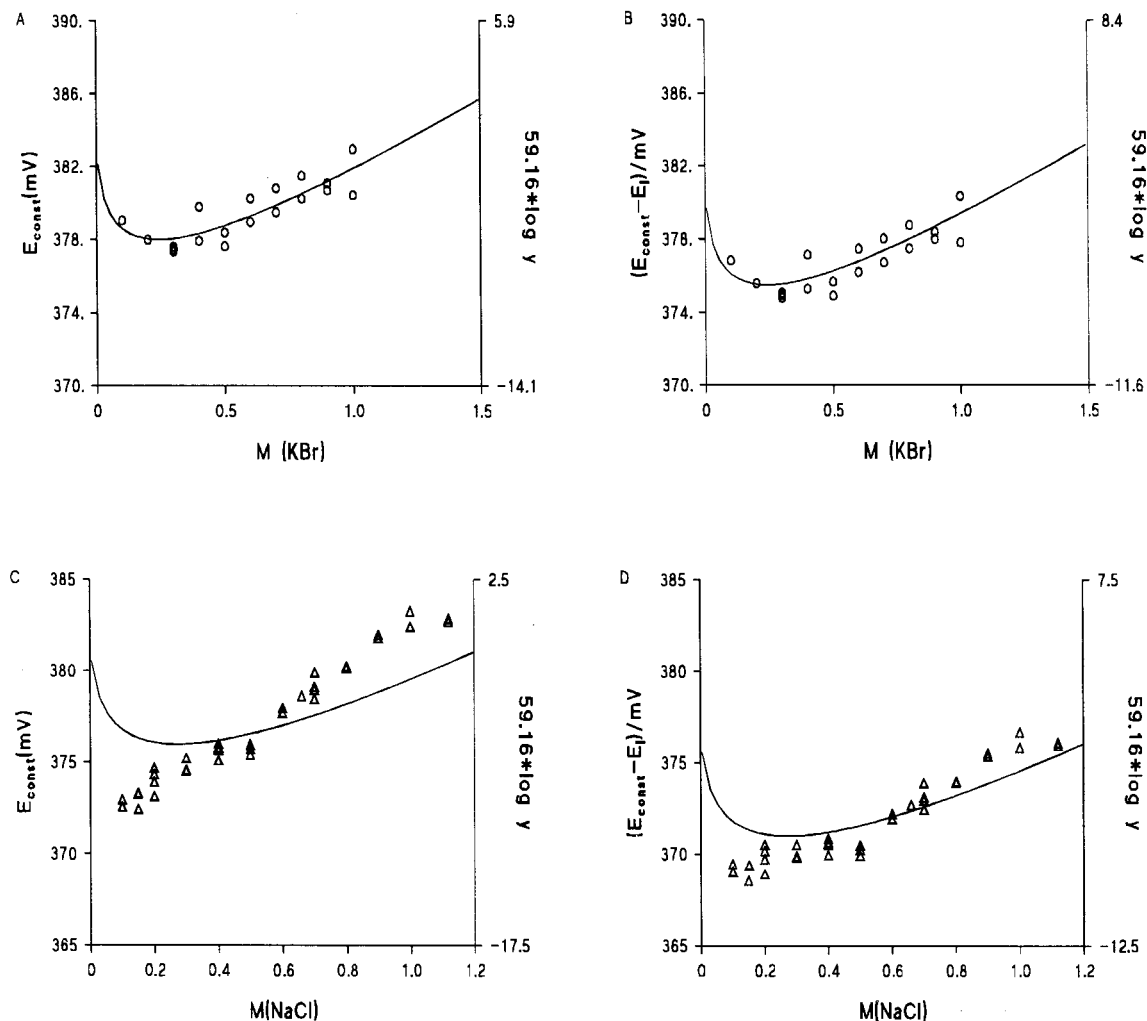

Fig. 5. Variation of (A) E_{const} with I in KBr, (B) $E_{\text{const}} - E_1$ with I in KBr, (C) E_{const} with I in NaCl, and (D) $E_{\text{const}} - E_1$ with I in NaCl. The solid line represents the variation of $s \log \gamma_{\text{H}^+}$ with I according to the Pitzer equations.

throughout the ionic strength range studied. Similar consistency was observed in KCl and KNO_3 (Table 1, Figs. 2 and 4A), which suggests that E_1 remains virtually constant over the ionic strength range where the formal potential was determined. Fig. 2 also shows six data series for the formal potential; while all exhibit a similar trend, the potential is displaced to a greater or lesser extent between one another. Based on Eq. (5), this can be ascribed to change in the $(E_r + E_g^0)$ term because, if the electrodes were theoretically im-

mersed in the same solutions, E_r should have remained constant and the change be due to a variation in the asymmetry potential with time typical of changes at the electrode surface layer.

The E_{const} versus I plot in sodium perchlorate exhibited a much greater slope than that obtained from the Pitzer fitting as the likely result of (a) the influence of sodium ion on glass membranes and/or (b) a major change in the liquid junction potential relative to potassium salts over the ionic strength range studied.

Fig. 6. Variation of E_i with I in NaCl and KBr. Triangles represent data from an earlier reference [15] and ticks the points where E_i was extrapolated.

Appendix A

The relationship of $\log \gamma_{H^+}$ to I was studied in the light of the Pitzer equations [17], which have frequently been used to describe the influence of ionic strength on the activity coefficients for strong electrolytes at moderate to high concentrations and a high electrolyte concentration. Our group has used them to interpret the variation with ionic strength of the acidity constants for some organic molecules [18–26].

Based on Pitzer's formalism, the activity coefficient for H^+ ion in the presence of excess electrolyte is given by

Fig. 7. Variation of $\log \gamma_{H^+}$ with I (on the molar scale) in $NaClO_4$, KNO_3 , KCl , $NaCl$ and KBr .

$$\ln \gamma_{H^+} = f^\gamma + 2I(B_{XH} + IC_{XH}) + I^2(B'_{XK} + C_{XK}) + I(2\theta_{HK} + I\psi_{HXK}) \quad (A.1)$$

where the ionic strength is determined from the salt concentration since the salt is in a large excess relative to the proton. f^γ , B and B' depend on I , as can be seen in the following equations:

$$f^\gamma = -A_\phi \left[\frac{\sqrt{I}}{1 + 1.2\sqrt{I}} + \frac{2}{1.2} \ln(1 + 1.2\sqrt{I}) \right] \quad (A.2)$$

$$B_{XK} = \beta_{XK}^{(0)} + \frac{\beta_{XK}^{(1)}}{2I} [1 - (1 + 1.2\sqrt{I}) \exp(-2\sqrt{I})] \quad (A.3)$$

$$\beta'_{XK} = \beta_{XK}^{(0)} + \frac{\beta_{XK}^{(1)}}{2I} [-1 + (1 + 1.2\sqrt{I} + 2I) \exp(-2\sqrt{I})] \quad (A.4)$$

Substituting B and B' in the expression for the logarithm of the activity coefficient of H^+ ion yields

$$\ln \gamma_{H^+} = f^\gamma + PI + QI^2 + RI e^{-2\sqrt{I}} + T[1 - (1 + 1.2\sqrt{I}) e^{-2\sqrt{I}}] \quad (A.5)$$

where

$$P = 2(\beta_{HX}^{(0)} + \theta_{HK})$$

$$Q = C_{HX}^\phi + \frac{C_{KX}^\phi}{2} + \psi_{HXK}$$

$$R = \beta_{KX}^{(1)}$$

$$T = \beta_{HX}^{(1)} - \frac{\beta_{KX}^{(1)}}{2} \quad (A.6)$$

P , Q , R and T are thus constants that depend on the particular inert electrolyte (see Table 2). The Pitzer parameters used to calculate them were taken from an earlier reference [17].

The activity coefficients in Eq. (A.5) are expressed on the molal scale, so they must be converted into molar units since E_{const} was determined from molar $[H^+]$ values. We used the following equation for this purpose [27]:

$$y = \gamma \frac{\rho_w}{\rho} \left(1 + \sum_i m_i M_i \right) \quad (A.7)$$

Table 1

Slopes of the linear fits of E_{const} versus I , $(E_{\text{const}} - E_1)$ versus I and $\text{slog } \gamma_{\text{H}^+}$ versus I plots in each of the electrolytes studied

Electrolyte	$59.16 \times \log y^a$ (Pitzer eq.)	Slope of E_{const} vs. I	Slope of $E_{\text{const}} - E_1$ vs. I	I range	Fig.
KNO ₃	4.0 ± 0.1	4.8 ± 0.7		0.5–1.5	2a
	4.0 ± 0.1	5.1 ± 0.6		0.5–1.5	2b

NaCl	6.0 ± 0.1	11.4 ± 0.5	9.0 ± 0.5	0.4–1.1	5c,d

^a Obtained from those points in Fig. 7 that lay within the stated ionic strength range for each electrolyte.

Table 2

Pitzer Parameters used in Eq. (A.5) for each of the electrolytes studied

Electrolyte	P	Q	R	T
KNO ₃	0.2338	0.0043	0.0494	0.2959
KCl	0.3650	−0.0062	0.2122	0.1884
KBr	0.4020	−0.01363	0.2212	0.2458
NaCl	0.4270	−0.0026	0.2664	0.1613
NaClO ₄	0.4214	−0.00899	0.2755	0.15535

where y and γ denote the activity coefficients on the molar and molal scale, respectively; ρ is the solution density; ρ_w is water density at the working temperature; i denotes any ion in solution; and M_i is the molar mass of ion i , m_i is molality and c_i its molarity.

By way of example, substituting water density at 25°C and the molecular mass of NaCl into Eq. (A.7) yields

$$y_{\text{NaCl}} = \frac{\gamma_{\text{NaCl}}}{\rho_{\text{NaCl}}} (0.997075 + 0.05827m_{\text{NaCl}}) \quad (\text{A.8})$$

Also, molality can be converted into molarity by using the following expression:

$$\frac{c}{m} = \frac{\rho_{\text{NaCl}}}{1 + \sum_i m_i M_i} \quad (\text{A.9})$$

which, for NaCl, becomes

$$c_{\text{NaCl}} = \frac{\rho_{\text{NaCl}} m_{\text{NaCl}}}{1 + 0.10110m_{\text{NaCl}}} \quad (\text{A.10})$$

The dependence of density on the ionic strength can be determined by fitting ρ versus m data pairs to a polynomial expression of m based on reported values [28,29].

Received 23 January 1997; received in revised form 02 June 1997; accepted 22 December 1997

Abstract

A method for the determination of total organic tin from marine water samples by electrothermal atomization absorption spectrometry (ETAAS) is described. Samples are previously preconcentrated with a chelating molecule (tropolone) impregnated on a macroporous polymer (Amberlite XAD-2). The graphite furnace programme and preconcentration parameters were optimized. Calibration and addition graphs were performed. Sensitivity obtained with this procedure was 13 ng l^{-1} . Relative standard deviation was always $> 10\%$ and analytical recovery were satisfactory, $\sim 100\%$. Some possible interferences were investigated, having no problems with this factor. This procedure allows the distinction between organotin compounds and inorganic tin IV, since the latter is not retained on the column. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Organic tin; Tropolone; Amberlite XAD-2; ETAAS

1. Introduction

Interest in the determination of tin and their organic compounds at trace levels in the environment has increased in recent years because of the growing use of organotin compounds over the past 30 years [1–3], due to the great number of industrial applications discovered for these compounds. Organotin toxicity is determined by its own nature and by the number of organic groups

bonded to tin. It has been found teratogenic and genotoxic effects in some organisms [4,5].

The principal use of TBT was in antifouling paints for ships because they are effective biocides against marine fouling organisms, however, they are non-specific and extremely toxic to non-target animal and plant species. Then, this use was restricted in some countries. The first actions were adopted in France in 1982 [6], followed by UK in 1985 [7,8]. France banned the use of TBT-based paints on boats $< 25 \text{ m}$ length. UK regulation restricted the sale of TBT paints containing more than 7.5% total tin in copolymers or 2.5% total tin as free tin.

* Corresponding author. Tel.: +34 981 591079; fax: +34 981 595012; e-mail: qn1956@usc.es

Due to this, marine waters can contain important levels of these compounds that increase in areas with restricted water circulation and significant recreational boating activity, a great number of techniques have been proposed for the measurement of these compounds. One of the methods widely used to determine total tin is ETAAS and although its detection power is high, it cannot be routinely used for the direct trace element analysis of many water samples. Thus, a preconcentration method is necessary to increase the detection limit, to remove interferences and to improve precision and accuracy of the results. Extraction is the most widely used preconcentration technique (liquid–liquid, liquid–solid, ion-exchange,...) over the last few years, but column preconcentration is a good option to obtain an easy, faster and reproducible method. Chelating resins (chelating molecule adsorbed on a polymeric matrix) are used in column preconcentration because of their high selectivity for transition elements, and they combine two very important analytical processes: ionic change and formation of chelates complexes [9]. These resins must contain functional groups with one or more donor atoms (N, O, P, S, As). Once a chelating molecule is adsorbed on the polymeric matrix, it must form stable complex with analytes to be separated. Polymeric matrices must have chemical stability for being no altered in the process and have spherical structure to keep forming complexes once chelating molecule have been adsorbed on it.

Nowadays, a great number of these resins are known, due to the great number of polymeric matrices and chelates available.

The use of Amberlite resins with different complexing groups has been studied by different authors. Lee et al. [10] used the Amberlite XAD-2, -4 and -7 with 8-hydroxyquinoline to separate metals in aqueous solutions. Van Berckel and Maessen [11] introduced the analyte loaded resin into the plasma through graphite furnace electrothermal vaporization. Horward and Danilova-Mirzaian [12] used the Amberlite XAD-4 with thioglycolate groups to preconcentrate Sn, Cd, Pb and Ni and Blain et al. [13] used Amberlite XAD-4 and XAD-7 with lipophilic tetraazo-

macrocycles that have high selectivity for transition metals over alkali and alkaline earth metal ions. Porta et al. [14] used the Amberlite XAD-2 and XAD-7 with ammonium pyrrolidine dithiocarbamate (APDC) and performed the preconcentration of Cd, Cu, Pb, Ni, Co and Fe of Antarctic sea water on line with atomic absorption spectroscopy with graphite furnace using the Zeeman effect background correction. The preconcentration on line also has been developed by Azeredo et al. [15] using a silica-immobilized 8-hydroxyquinoline preconcentration system, eluting trace metals (Cd, Cu, Fe, Mn, Ni, Pb and Zn in sea water) directly in graphite furnace with acid.

The polystyrene support with phosphonic acid [16], a macroreticular support and PVC polymer [17] and the resins Dowex 1X8, Lewaitit MP5080 impregnated with 8-hydroxyquinoline [18] has been also applied in this type of determinations.

The molecule tropolone has been used in previous works for the preconcentration of TBT, DBT and MBT by extraction with chloroform [19] or benzene [20] obtaining good results.

In this paper, the use of tropolone physisorbed on Amberlite XAD-2 is proposed for preconcentration of organic tin (TBT, DBT, MBT) and posterior determination by atomic absorption spectroscopy with electrothermal atomization.

2. Experimental

2.1. Apparatus

A Perkin–Elmer 1100B atomic absorption spectrometer with a deuterium-arc background corrector and a hollow-cathode lamp operating at 35 mA and with a slit width of 0.7 nm was employed to carry out the area of the absorbance peak. The wavelength was 224.6 nm. A Perkin–Elmer Model HGA-400 graphite furnace atomizer with graphite tubes coated with zirconium [21], with L’Vov platform were used. A volume of 20 μ l of sample was injected by an Auto Sampler AS-70. Glass chromatographic columns (30 \times 1.5 cm i.d.) with a glass filter and a Teflon key (Afora).

Table 1
Optimized furnace programme

Step	Temperature (°C)	Hold time(s)	Ramp time (s)	Gas Flow (ml min ⁻¹)
Dry	150	15	10	300
Pyrolysis	1000	15	5	300
Atomization	1900	3	0	0
Clean	2400	4	1	300

2.2. Reagents

Tributyltin solution in methanol, containing 1000 mg l⁻¹ of tin, prepared with tributyltin chloride at 97% of Fluka (Buchs, Switzerland). Dibutyltin solution, containing 1000 mg l⁻¹ of tin, prepared with dibutyltin dichloride at 97% of Aldrich (Milwaukee). Monobutyltin solution in methanol, with 1000 mg l⁻¹ of tin, prepared with monobutyltin trichloride at 95% of Aldrich. Tin stock standard solution, 1.000 mg l⁻¹ of BDH (Poole, UK). Tropolone (2-hydroxy-2,4,6-cycloheptatrienone) at 98% of Aldrich. Isobutylmethylketone at 99%, Analar of BDH (Poole, UK). Methanol, grade HPLC, of Scharlau (Barcelona, Spain). Nitric acid Aristar of BDH. Hydrochloric acid at 37% of Merck (Darmstadt, Germany). Amberlite XAD-2, 20–60 mesh of Aldrich Chemie (Steinheim, Germany).

2.3. Procedure

For preconcentration: 200 ml of sample with 10% HCl was passed through the column and 1 ml of MIBK in two steps (collected in the same tube) was employed to elute the retained compounds. For calibration: 20 µl of eluted sample containing 10, 20, 30, 40 µg l⁻¹ of Sn were introduced into the graphite furnace. The graphite furnace programme (Table 1) was followed and the peak absorbance noted. For the standard addition graph the same procedure than in calibration was applied but using low salinity synthetic marine water, prepared following Baxter and Frech recommendation [22].

3. Results and Discussion

3.1. Optimization of the column preconcentration

The optimum conditions to carry out preconcentration in column were determined. First, Amberlite XAD-2 was purified to avoid contamination problems in the samples. The polymer was shaken for half an hour with a magnetic stirrer with Milli-Q water, HCl 6M and NaOH 2M, respectively, and filtered off in each step, after being rinsed with Milli-Q water until neutrality of pH was obtained. Then, Amberlite XAD-2 was conditioned with 0.01% aqueous tropolone solution for an hour with a magnetic stirrer. Then the conditioned resin (1 g) was introduced in each column, to carry out the preconcentration with a preconcentration factor of 100.

Different eluents as: methanol–acetic acid (HAc) (5–30%), methanol–HCl (0.025–20%), HCl 2M, acetone and MIBK were studied. Optimum was established passing an aqueous standard solution containing 0.15 µg l⁻¹ of organic tin through the column and eluting with mentioned eluents. Then, comparing standards absorbance signals without preconcentration and eluates absorbance signals, it concludes that MIBK is the best eluent in these conditions (Fig. 1).

The addition of hydrochloric acid to eluents produce a better elution because of the good solubility of chlorides in the eluent, and the regeneration of the tropolone molecule with acid proton. Optimum concentration of hydrochloric acid in samples was determined, and it was 10% HCl, as it shows in Fig. 2.

Experiments with tin aqueous standard solution containing 0–40 µg l⁻¹ of Sn were realized and

Fig. 1. Eluent optimization.

integrated absorbance signals by ETAAS were about 0.002 Au while signals of tin aqueous solution are the same before or after elution (0.001–0.129 Au). Thus, it appears that inorganic tin is not retained.

The resin capacity was determined passing a standard solution of 0.3 mg l⁻¹ of organic Sn through the conditioned resin and eluting with 2 ml of MIBK. Then, eluates were measured by FAAS and the resin capacity was 600 µg g⁻¹.

Preconcentration factor was 100.

3.2. Optimization of the graphite furnace programme

Graphite tubes coated with zirconium were utilized [21]. Optimum temperatures and times for drying, pyrolysis and atomization were studied (Table 1). Pyrolysis and atomization graphs were

Fig. 2. Optimization of hydrochloric acid concentration for MBT (□), DBT (◇), TBT (△).

Fig. 3. Optimization of pyrolysis (left) and atomization (right) temperatures.

constructed with a column preconcentrated sample with the procedure described before, containing 40 µg l⁻¹ of tin. The optimum pyrolysis temperature found was 1000°C for 10 s with a ramp time of 5 s and internal gas flow at the maximum rate of 300 ml min⁻¹. The optimum atomization temperature was 1900°C for 3 s without ramp time and internal gas flow (Fig. 3). The tube was cleaned at 2400°C for 4 s with a ramp time of 1 s with the internal gas flow at 300 ml min⁻¹.

3.3. Calibration

Column preconcentrated samples containing 0–40 µg l⁻¹ of Sn were utilized to carry out calibration graph. For the standard addition method, the same concentrations of Sn were utilized, but dissolved in marine water.

Different calibration and addition graphs were performed for MBT, DBT and TBT and for a mixture of MBT, DBT and TBT.

The equations obtained are shown in Table 2: in all cases there are not important differences between the slopes of addition and calibration graphs, then we consider that there are not matrix effects in all cases.

3.4. Sensitivity

The limit of detection (LOD) is calculated as 3 SD m⁻¹ with SD being the within-run standard deviation of a series of blank determination, and

Table 2
Calibration and addition graphs

Compound	Calibration	Addition
MBT	$A_i = 3.2 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.998$	$A_i = 2.6 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.998$
DBT	$A_i = 4.2 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.998$	$A_i = 5.6 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.997$
TBT	$A_i = 2.2 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.997$	$A_i = 1.2 \cdot 10^{-3} + 2.9 \cdot 10^{-3}[\text{Sn}]$ $r = 0.997$
MBT + DBT + TBT	$A_i = 5.2 \cdot 10^{-3} + 2.8 \cdot 10^{-3}[\text{Sn}]$ $r = 0.991$	$A_i = 5.4 \cdot 10^{-3} + 2.9 \cdot 10^{-3}[\text{Sn}]$ $r = 0.990$

A_i means integrated absorbance and [Sn] units are in $\mu\text{g l}^{-1}$. Slope units: Au per $\mu\text{g l}^{-1}$.

m is the slope of the calibration curve (99.7% confidence level). The value obtained was 13 ng l^{-1} of tin.

The limit of quantification (LOQ) has been found to be 45 ng l^{-1} .

The characteristic mass (m_0) defined as:

$$m_0 = \frac{(\mu\text{l injected})_{\text{sample}} * (\mu\text{g l}^{-1})_{\text{sample}} * 0.0044}{\text{Abs}_{\text{sample}} - \text{Abs}_{\text{blank}}}$$

was 28.15 pg for a mixture of three studied compounds.

3.5. Precision and accuracy

The within-batch precision of the method was studied with sample spiked with 0.1, 0.2, 0.3, 0.4 $\mu\text{g l}^{-1}$ of total tin as MBT, DBT, TBT and a mixture of three compounds, five replicates each.

Table 3
Precision (five replicate analysis were performed); accuracy

[Sn] ($\mu\text{g l}^{-1}$)	RSD (%)			
	MBT	DBT	TBT	MBT + DBT + TBT
0.1	5.9	7.3	5.0	4.1
0.2	1.8	0.9	2.6	1.5
0.3	0.8	1.0	1.7	1.4
0.4	0.7	0.4	1.6	1.9
Analytical Recovery(%)	98.7	101.3	99.4	101.1

Table 4
Interferences

Metal	Maximum concentration ($\mu\text{g l}^{-1}$)	Absorbance variation (%)
Mg	$1 \cdot 10^5$	21.1
Al	5	17.3
Ca	$1 \cdot 10^5$	-18.8
Ni	$5 \cdot 10^{-3}$	-8.3
Zn	$5 \cdot 10^{-3}$	-4.1
As	$1 \cdot 10^{-2}$	1.0
Sr	$1 \cdot 10^2$	30.2
Ba	$3 \cdot 10^{-2}$	-9.1

The relative standard deviations (RSD) are shown in Table 3.

The accuracy of the method was determined by measuring the analytical recovery of samples containing 0.1, 0.2, 0.3 and 0.4 $\mu\text{g l}^{-1}$ of total tin. Results of analytical recovery are shown in Table 3.

3.6. Interferences

The behaviour of several cations typically present in natural water samples on the retention of butyltin compounds was studied because of their possible effects on the analyte metal preconcentration. A cation is considered as interferent if a variation of $\pm 10\%$ in the measurement of absorbance is observed. The cations studied and absorbance variation were showed in Table 4. The levels of cations necessary to produce an interference are bigger than the levels in the waters.

An effect of high background signal was observed with 1000 mg l^{-1} of Mg and over 300 mg l^{-1} of calcium.

Table 5
Applications

Sample	[Sn] ($\mu\text{g l}^{-1}$)	R.S.D. (%) ($n = 5$)
1	0.18	1
2	0.15	1
3	0.11	3
4	0.13	2
5	0.16	5
6	0.14	5
7	0.15	4

Calibration graph
 $A_i = -4.68 \cdot 10^{-3} + 1.41 \cdot 10^{-3}[\text{Sn}]$
 $r = 0.997$

A_i means integrated absorbance and [Sn] units are in $\mu\text{g l}^{-1}$. Slope units: Au per $\mu\text{g l}^{-1}$.

On the other hand, in the tin determination by ETAAS, principal anion interferences are sulphate and chloride because Sn can form volatile compounds with these anions [23]. These interferences are avoided by use of zirconium-coated graphite tubes [21] perhaps due to the formation of tin–zirconium compounds [24] or because zirconium competes with Sn for chlorine [23].

3.7. Applications

The proposed method was applied to different marine water samples of several ports of Galicia.

In all samples tin from the studied compounds was found. The obtained results, expressed as $\mu\text{g l}^{-1}$ of Sn and showed in Table 5, represent only the organic tin.

3.8. Conclusions

A preconcentration method of organotin compounds in column with an adsorbent resin conditioned with an aqueous solution of tropolone was optimized. In these conditions inorganic tin was not retained. A graphite furnace programme was optimized with the preconcentrated compounds. The tendency of the tin to form volatile compounds and its interaction with graphite surface was avoided by using zirconium coated graphite tubes. Optimum temperatures of pyrolysis and atomization were 1000 and 1900°C, respectively. Calibration and

standard addition graphs slopes were the same, so there are not matrix effects. It has been found that the measurement of these preconcentrated compounds is sensitive, accurate and precise and it does not exhibit important interferences.

Received 29 July 1997; received in revised form 8 December 1997; accepted 22 December 1997

Abstract

One type of lipophilic calix[4]biscrowns in the 1,3-alternate conformation which are highly selective complexant for cesium has been used to construct cesium poly(vinyl chloride) (PVC) membrane optode. The reversible sensing system has been formed by incorporating the lipophilic neutral H^+ —selective chromoionophore ETH5294 in the plasticized PVC membrane with 1,3-calix[4]bisnaphthyl-crown-6. The measuring range of cesium ions can be conditioned by buffering different pH in the cesium solutions. At pH 7.0, the measuring range of the optode membrane for cesium ions is from 1×10^{-6} to 1×10^{-2} M. The response behavior of optode membrane including response time, selectivity, reproducibility and lifetime, has been described in detail. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Optode membrane; 1,3-calix[4]bisnaphthyl-crown-6; Cesium

1. Introduction

Calixarene-based ionophores have been widely studied due to their structural and electronic features [1–3]. They have two principal advantages which make them in the use of constructing ion-selective electrodes and optodes [4–8]. The first advantage is that they allow a tridimensional control of metal ion complexation, so the electrodes and optodes usually show a high efficiency and good selectivity [9,10]. The second one is that there are alkyl group at the upper rim (aromatic nuclei) of the calix make it possible to modulate the lipophilicity of the ligands. Many studies on

the use of calixarene in ion-selective electrodes and optodes for determining lithium [11], sodium [12–15], potassium [16,17], cesium [18,19], silver [20] and amine [21,22] have been successfully carried out.

Recently, a new class of macropolycyclic crown compounds with two opposite OH groups in *p-tert*-butylcalix[4]arene bridged by a poly(oxyethylene) chains has been synthesized [23,24]. The metal cation complexation properties of so-called ‘calixcrown’ compounds has been studied in detail. Due to the presence of a glycol chain in their structure, calixcrowns have been used to complex with alkali and alkaline-earth metal cations. The selectivity of the complexation depends on the conformation (cone, partial cone, 1,2-alternate, 1,3-alternate) adopted by the rigi-

* Corresponding author. Tel.: + 33 01 69083251; fax: + 33 01 69083242.

dified calix[4]arene unit. The lipophilic calix[4]biscrowns in the 1,3-alternate conformation have been shown to be a new family of selective carriers for cesium [25].

In this paper, we report the new optical chemical sensor for the determination of cesium ion based on the use of lipophilic calix[4]biscrown, 1,3-calix[4]bisnaphthyl-crown-6. The developed optical sensing system provides a highly sensitive and selective methods for cesium determination.

2. Experimental

2.1. Reagents

The cesium selective ionophore 1,3-calix[4]bisnaphthyl-crown-6 was provided by the team of J-F. Dozol from SEP/SEATN Centre d'Etudes de Cadarache, Commissariat a l'Energie Atomique. The lipophilic pH indicator ETH5294(9-(diethylamino)-5-(octadecanoylimino)-5H-benzo[a]phenoxazine), ortho-nitrophenyl octyl ether (*o*-NPOE), dioctyl phthalate (DOP), bis(2-ethylhexyl)sebacate(DOS), sodium tetraphenylborate(NaTPB), sodium tetrakis(3,5-bis(trifluoromethyl) phenyl)borate (NaTFPB), high-molecular-weight (HMW) PVC, tetrahydrofuran (THF), tris(hydroxymethyl)aminomethane hydrochloride (Tris-HCl) were purchased from Fluka, cesium standard solution were made from cesium chloride (Fluka). All solutions were made with deionized water.

2.2. Optode membrane preparation

The optode membranes were prepared by the spin-on technique as follows: a mixture of 2.4 mg (0.004 mmol) of ETH5294, 10.2 mg (0.01 mmol) of calix[4]biscrown, 8.9 mg (0.01 mmol) of NaTFPB, 50 mg of PVC, 100 mg of *o*-NPOE was dissolved in 2 ml THF. An aliquot of 0.1 ml of this solution was pipetted onto a circular 35 mm diameter quartz plate which was fixed in a rotating (850 rpm) aluminum alloy rod under a THF-saturated atmosphere. After

about 5 s. the quartz plate with sensing membrane was removed and dried in ambient air for 10 min.

2.3. Experimental measurements

Two identical membranes both on their respective quartz plates were mounted in a flow-through measuring cell [26]. The cell was introduced into a UV-vis-NIR scanning spectrophotometer (Shimadzu UV-3101PC). Sample solutions were pipetted through the flow-through cell containing the sensing membranes by a syringe and absorbances were recorded at 665 nm. Before measurements, the new membranes should be put in pH buffer solution (used for the measurements: tris aminomethane hydrochloride buffer substance pH 7: 0.05M, Fluka Ref. 93368) for 1 h. The limiting absorbance values A_1 and A_0 were determined with the optode membranes contacting with 0.1M HCl and 0.1M NaOH solutions, respectively. For the selectivity measurements, the separate solution method (SSM) for optical sensors was used. Selectivity factors were determined by using different concentrations of cation in pH 7.0 Tris-HCl buffer solution. The selectivity coefficients were evaluated by comparing the concentration-dependent differences on the optical response functions at a common basis of $\alpha = 0.5$ [27]. The response of cesium ion was used as the standard.

3. Results and discussion

The structure of the cesium selective ionophore is shown in Fig. 1. It has been successfully applied in supported liquid membranes for the removal of cesium in the presence of sodium [24]. Its high selectivity for cesium can be explained by the preorganization of the ligand and by the fact that the less polar 1,3-alternate conformation prefers to bind the 'softer' cesium ion over the 'hard' sodium ion [28]. Moreover, the 1,3-alternate conformation allows interaction of the cesium ion with the p-electrons of two aromatic rings.

3.1. Experimental principle

In the optode membrane, there are neutral calixarene ionophore (C) as the selective host for cesium ion (M^+) and a chromo-ionophore ETH5294 (indicator (IND)) selective for the hydrogen ion. When calixarene in the membrane is complexed with cesium ions in the solution, cesium ions go into the membrane. In order to keep the electroneutrality of the membrane, the hydrogen ions of the chromo-ionophore ETH5294 go out of the membrane. Therefore, the absorption spectra of the membrane change. Fig. 2 shows the absorption spectra of the optode membrane incorporating calixarene and ETH5294, as obtained after equilibrium with pH7.0 Tris–HCl buffer solution containing different concentrations of cesium ion. It can be seen that the formation of the calixarene–cesium complex induced a reduction in the absorption band of $INDH^+$ at 615 and 665 nm. At the same time, an increase in the absorption band of IND at 545 nm was also observed.

If the complex equilibrium between calixarene in the plasticized PVC membrane phase (m) and

cesium ion in the aqueous sample solution (aq) will form an 1:1 complex [24], the over-all equilibrium can be described as follows:

The equilibrium constant K_{exch} depends on the stability constant of the calixarene–cesium complex and can be expressed as:

$$K_{\text{exch}} = \frac{[M^+C][IND][H^+]}{[M^+][INDH^+][C]} \quad (2)$$

where the concentration terms refer to the concentration of each species expressed in Eq. (1).

If α may be defined as the ratio of the concentration of unprotonated chromo-ionophore, [IND], in relation to the total amount present in the membrane, $[IND]_T$, thus,

$$\alpha = \frac{[IND]}{[IND]_T}; (1 - \alpha) = \frac{[INDH^+]}{[IND]_T} \quad (3)$$

In fact the measured absorbance A is directly related to the membrane response α , if the optode membrane obeys Beer's Law:

$$\alpha = \frac{A_1 - A}{A_1 - A_0} \quad (4)$$

where A_1 and A_0 are the limiting absorbance values for fully protonated and deprotonated chromo-ionophore, respectively.

For reasons of electroneutrality, the sum of the concentrations of the two cations must be equal to the total concentration of the accessible anionic sites $[R^-]_T$, which is the concentration of TFPB⁻ anion in the membrane,

$$[R^-]_T = [M^+C] + [INDH^+] \quad (5)$$

If $[C]_T$ and $[IND]_T$ are the respective total concentrations of calixarene and ETH5294 in the membrane, a response function for cesium ion can be derived as follows:

$$\begin{aligned} & \frac{[Cs^+]}{[H^+]} \times K_{\text{exch}} \\ &= \frac{([R^-]_T - (1 - \alpha)[IND]_T)}{[C]_T - [R^-]_T + (1 - \alpha)[IND]_T} \times \frac{\alpha}{(1 - \alpha)} \quad (6) \end{aligned}$$

Fig. 1. Structure of the cesium ionophore 1,3-calix[4]bisnaphthyl-crown-6.

Fig. 2. Absorption spectra of two optode membranes (M2) after equilibration with pH 7.0 Tris-HCl buffer solutions containing different concentrations of Cs^+ : (1) buffer solution; (2) 1.0×10^{-6} M; (3) 5×10^{-6} M; (4) 1×10^{-5} M; (5) 2.5×10^{-5} M; (6) 5.0×10^{-5} M; (7) 1.0×10^{-4} M; (8) 2.5×10^{-4} M; (9) 1.0×10^{-3} M; (10) 5.0×10^{-3} M.

For cesium-selective optode membrane, the chosen concentrations of active materials follow the relationship:

$$[R]_{\text{T}} = [C]_{\text{T}} = \frac{5}{2} [\text{IND}]_{\text{T}} \quad (7)$$

this Eq. (6) can be simplified to:

$$\frac{[\text{Cs}^+]}{[\text{H}^+]} \times K_{\text{exch}} = \frac{(1.5 + \alpha)\alpha}{(1 - \alpha)^2} \quad (8)$$

With a series of standard cesium solutions, the α values can be measured by experiments; the calibration curve can be obtained by fitting the experimental points, and also the value of K_{exch} can be obtained. For the cesium sample solution with a fixed pH, the concentration of cesium can be determined from the calibration curve by measuring the α value.

3.2. Optimization of membrane composition

The cesium-selective optode membranes containing different amounts of active materials, which is summarized in Table 1, have been subjected to response studies. The optode membranes M1–M3 contain different amounts of indicator ETH5294 in the membranes. The measuring range of optode membrane M1 for cesium ions is from 1×10^{-5} to 1×10^{-3} M, while the measuring range of optode membranes M2, M3 for cesium ions are from 1×10^{-6} to 1×10^{-2} M. It can be seen that the amount of indicator ETH5294 affects the measuring range of cesium ions. When the amount of ETH5294 in the membrane is too low, the measuring range of cesium ion is also low and narrow. Indeed, the hydrogen ions, which are

Table 1
Composition of optode membranes (in 2 ml THF)

No.	ETH5294 (mol)	NaTPB (mol)	NaTFPB (mol)	Calixarene (mol)	<i>o</i> -NPOE (mg)	DOP (mg)	DOS (mg)	PVC (mg)
M1	2×10^{-6}	1×10^{-5}	—	1×10^{-5}	100	—	—	50
M2	4×10^{-6}	1×10^{-5}	—	1×10^{-5}	100	—	—	50
M3	6×10^{-6}	1×10^{-5}	—	1×10^{-5}	100	—	—	50
M4	4×10^{-6}	1×10^{-5}	—	1×10^{-5}	—	100	—	50
M5	4×10^{-6}	1×10^{-5}	—	1×10^{-5}	—	—	100	50
M6	4×10^{-6}	—	1×10^{-5}	1×10^{-5}	100	—	—	50

used for keeping membrane electroneutrality when the cesium ions are complexed with calixarene in the membrane comes from the dissociation of ETH5294. Moreover, the initial absorbance of the membrane decreases; when the amount of ETH5294 in the membrane is larger than 1.5×10^{-5} mol, it seems the dimerization of the indicator occurs. So in this paper, 4×10^{-6} mol of indicator has been chosen in the cesium-selective optode membrane. Also, the use of different types of plasticizer has some effect on the response behavior of the optode membrane. The membranes M2, M4, M5 containing three types of plasticizer including *o*-NPOE, DOP, DOS have been studied. The sensitivity and the reversibility of the membrane M2 containing the plasticizer *o*-NPOE is also the best. This can be explained by the fact that *o*-NPOE has high dielectric constant which makes the ionic site and the indicator in the membrane more easily to be dissociated ($\epsilon_{\text{mem}} = 14$) [29]. In contrast, dissociation is hindered in the membranes containing DOS ($\epsilon_{\text{mem}} = 4.8$). So the sensitivity and reversibility of the membrane M2 are improved by the easier dissociation of the ionic site and the indicator in the membrane compared with the membrane M4, M5. As for the anionic site NaTPB and NaTFPB (M2, M6), there is no significant difference in the response behavior of membrane. According to the literature [30], the chemical stability of tetraphenylborate [TPB⁻] is limited due to the decomposition of tetraphenylborate under acidic condition, and this decomposition can be decreased by substituting the phenyl rings with electron-withdrawing groups in para or meta positions. Therefore, in this paper NaTFPB has been chosen as the anionic site in the membrane.

3.3. Measuring range

In Fig. 3, the membrane responses, α , at a wavelength of 665 nm are given as a function of $\log[\text{Cs}^+]$ for three different pH values. The curves fitting the experimental points were calculated from Eq. (8) with $K_{\text{exch}} = 3.5 \times 10^{-4}$. The good correlation of the measured data with theory confirms the validity of the assumption made in Eq. (8). It also can prove that the composition of the complex between calixarene ionophore and cesium ion is 1:1. The measuring range of cesium ion is dependent on the pH value of the solution, the detection limit is decreased with the increase of pH value of the solution. At pH 7.0, the measuring range of the optode membrane for cesium ion is from 1×10^{-6} to 1×10^{-2} M. The precision of the measurement would be poor near either end of the range. At pH 9.0, a higher sensitive optical method for the determination of cesium ion has been established, with a detection limit of 5×10^{-8} M.

3.4. Selectivity

It has been reported that calixarenes with six oxygen atoms in the glycol chain are much more selective toward cesium over sodium [24]. The selectivity data obtained with the optode membrane containing 1,3-calix[4]bisnaphthyl-crown-6 described in this paper are summarized in Table 2. Separate calibration curves has been determined for the analyte ion and the interfering ion *J* at pH 7. The selectivity coefficients has been then calcu-

Fig. 3. Membranes response of cesium-selective optode membrane M2 at: \diamond pH 7.0; \times pH 8.0; \square pH 9.0.

lated from the activity ratios for both calibration curves at identical α values as follow:

$$K_{ij}^{\text{opt}}(\text{ssm}) = \frac{a_i}{a_j}$$

Reasonably good selectivity over sodium is evident.

3.5. Response time

It takes 5 min for the membrane to reach the t_{95} value after the concentration step changes from 5×10^{-5} to 5×10^{-4} M cesium ion, as illustrated in Fig. 4. An attempt to improve the response

time by decreasing the thickness of the membrane is unsuccessful. It proves that the response time of the optode membrane is not mainly governed by a diffusion process in the bulk of the membrane. Instead, the rate of the complex formation might play a vital one.

3.6. Reproducibility and short-term stability

The reproducibility of the optical signals was evaluated by repeating changing between two samples of 5×10^{-5} and 5×10^{-4} M cesium ion in Tris-HCl buffer solution at pH 7.0. The mean absorbance values at 665 nm and their standard deviations were obtained from five measurements and were found to be reproducible to $0.122 \pm 1.80\%$ (5×10^{-5} M cesium ion) and $0.075 \pm 1.58\%$ (5×10^{-4} M cesium ion). In defining the short-term stability of the system, the membrane was immersed in a solution of 5×10^{-4} M cesium ion at pH 7.0 for 8 h and the absorbance at 665 nm was determined at hourly intervals. The short-

Table 2

Selectivity coefficients ($\log K_{ij}^{\text{opt}}$) for the optode membrane incorporating 1,3-calix[4]bisnaphthyl-crown-6

Na ⁺	Li ⁺	K ⁺	Rb ⁺	NH ₄ ⁺	Ca ²⁺	Mg ²⁺
-2.1	-3.2	-2.3	-1.8	-2.0	-2.5	-2.8

$\log K_{ij}^{\text{opt}}$, $i = \text{Cs}^+$

term stability was found to be $0.122 \pm 1.9\%$ (in average of nine measurements).

3.7. Lifetime

After several hundreds of measurements, the absorbance value of the optode membrane in contact with 0.1 M HCl solution has been measured at 665 nm. Compared with the absorbance value obtained from a freshly prepared optode membrane under the same conditions, about a 10% decrease in absorbance was observed. It can be seen that the indicator incorporating in the membrane is not seriously washed out by normal measurements.

Received 08 September 1997; received in revised form 10 December 1997; accepted 22 December 1997

Abstract

Procedures for the determination of indomethacin and acemethacin by differential pulse adsorptive stripping voltammetry with a mercury electrode have been described and optimised. The selection and optimization of the experimental parameters was done using factorial and central composite designs. Indomethacin and acemethacin in urine were determined by this method with good results and without the need for tedious prior separation. For routine calibration and calculation of the 'capacity to detect', the robust regression method least median squares (LMS) has been proposed. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Experimental design; Differential pulse adsorptive stripping voltammetry; Indomethacin determination; Acemethacin determination

1. Introduction

The acid 1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1-indole-3-acetic known familiarly as indomethacin and the acemethacin, obtained from the esterification of indomethacin by the action of hydroxyacetic acid, are two molecules that form the basis of numerous commercialised pharmaceutical products in the field of anti-inflammatory drugs. Metabolization of the drugs by the organism is an indicator of their therapeutic activity

and the determination of the drugs in body fluids may be used to follow this activity. Human urine is composed of numerous organic substances and frequently the methods described to determine drugs involve tedious separations and previous reactions [1]. A number of analytical procedures for the quantitative determination of these drugs have been proposed. High-performance liquid chromatography [1–3] and UV-visible spectroscopy [4] are commonly used. Electrochemical techniques have been used only by few authors despite the high sensitivity of some of them.

The quantities required to demonstrate the therapeutic effect of indomethacin and

* Corresponding author. Tel: +34 947 258818; fax: +34 947 258831; e-mail: jarcos@cid.cid.ubu.es

acemethacin are very small which makes it essential to optimise sensitive methods for their determination. As is known, many molecules of an organic nature tend to be adsorbed on the surfaces of many electrodes [5]. The improvement in the analytical signal obtained as a result of the preconcentration process allows stripping voltammetry to be considered one of the most accurate techniques in trace analysis. In the indomethacin and acemethacin cases the polarographic reduction of these drugs has been described [6–8] but a study of their adsorption at mercury electrodes was not.

In this work a procedure is reported for the determination of indomethacin and acemethacin by differential pulse adsorptive stripping voltammetry (DPAdSV) based on the adsorption of the molecules at mercury electrode in aqueous media and in urine, without the need for any prior separation steps. With the aim of guaranteeing the maximum analytical signal an optimization procedure using experimental design was carried out in which factors relevant to DPAdSV technique intervene.

Special importance was given to the calibration stage, where robust regression techniques were used to guarantee that outlying experimental points would not influence the calibration parameters.

2. Experimental

2.1. Reagents and equipment

Indomethacin (analytical grade) was kindly provided by Merck Sharp and Dome. Acemethacin (drug standard grade) was kindly supplied by Europharma. Britton–Robinson solutions obtained by adding NaOH 0.2 M to a mixture of boric, phosphoric and acetic acids 0.04 M each were used as buffers. Quantities between 5 and 20 ml of Britton–Robinson buffer are added to the voltammetric cell. The percentage of buffer in the cell thus varies from 25 to 100%. This solution was prepared with deionized water obtained with a Barnstead NANO pure II system and acted as a supporting electrolyte. The stock

solutions (5×10^{-3} M) of indomethacin and acemethacin were prepared in analytically pure grade acetonitrile. The solutions analysed in the procedures of optimization and calibration both in aqueous media and in urine samples were prepared by dilution of stock solutions (5×10^{-3} M) in deionized water.

Urine samples were obtained from fasting and healthy subjects in the morning and diluted 25.0-fold in water. The analysis of indomethacin and acemethacin was made by adding the suitable quantity of each drug separately to the urine sample until the required concentration was obtained.

Voltammetric measurements were carried out using a Metrohm 646 VA Processor (minimum detectable current 3.75 pA) and a 647 VA Electrode Stand with a multimode electrode (MME) operating in the HMDE mode. An Ag/AgCl/KCl (3 M) reference electrode and a platinum wire auxiliary electrode were used.

2.2. Software and hardware

Data analysis was achieved with Statgraphics [9] for the experimental design, Progress [10] for the robust regression and Detarchi [11] for determination of capacity to detect.

2.3. Experimental procedure

In the optimization stages the voltammetric measurements were taken using the following procedure: once the solution (percentage of buffer and pH suitable in each case) had been deoxygenated, the stirrer was connected and deposition began according to a time and potential determined for each experiment. When the time had elapsed, the stirrer was switched off and the solution left to settle for an equilibrium time of 10 s. The voltammogram was then recorded by making a negative sweep from the deposition potential (initial potential) to -1.6 V (final potential). The response analysed for each point of the designs made was the ratio of the intensities, $i_p/i_{p\text{blank}}$, obtained in two electrochemical sweeps: one with analyte and the other without analyte (blank). The following values were used for the rest of the

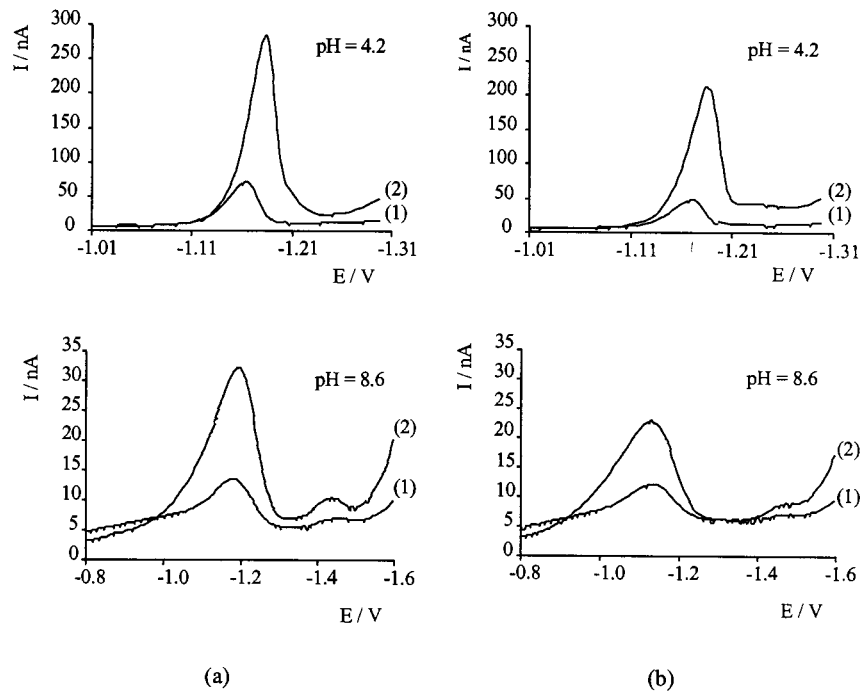

Fig. 1. Differential pulse adsorptive stripping voltammograms for (a) acemethacin 7.5×10^{-7} M and (b) indomethacin 7.5×10^{-7} M in Britton–Robinson buffer (50%) and $E_{\text{dep}} = -0.8$ V. (1) $t_{\text{dep}} = 0$ s; (2) $t_{\text{dep}} = 60$ s.

instrumental settings: mercury drop size, 0.40 mm^2 ; stirring rate in the accumulation period, $1290 \text{ rev min}^{-1}$; sweep rate, 10 mV s^{-1} ; the size and duration of the pulse -50 mV and 5 ms , respectively [12].

3. Results and discussion

3.1. Optimization of the variables in the aqueous media

A few previous electrochemical studies [6–8] on these compounds show that both substances undergo an electrochemical reduction at mercury electrode so being suited to analysis by voltammetric techniques. For acidic solutions $\text{pH} < 6$, the electrode reduction is essentially a two electron process and one voltammetric peak is obtained. For pH values > 6 , indomethacin and acemethacin exhibit two voltammetric reduction peaks. The first peak, which decreases with in-

creasing pH values, can be attributed to the reduction of protonated molecules and the second is caused by the reduction of non protonated molecules. Indomethacin and acemethacin adsorption at the HMDE was ascertained by repetitive cyclic voltammograms recorded after accumulation. A high, well-defined cathodic peak can be observed at the first scan. Later scans show a great decrease in the cathodic peak, pointing to a quick desorption from the surface. Voltammograms obtained with accumulation are always significantly higher than non accumulation ones in similar conditions. Fig. 1 shows the differential pulse adsorptive stripping voltammetric peaks for indomethacin and acemethacin, with and without accumulation, for two different pH .

The voltammetric analysis of trace elements normally involves very small current response. This explains the importance of optimising all those parameters which may have an influence on the measured current. The experimental design has been used as a tool for the optimization. In

this case, in a first step, a 2^4 factorial design was applied with replications in the central point in order to estimate the residual error. In the DPAdSV technique the peak obtained for indomethacin and acemethacin is influenced by a large number of variables. In order to optimize the response, $i_p/i_{p\text{blank}}$, the variables pH of solution, percentage of buffer in the electrochemical cell ($\%_{\text{buffer}}$), deposition potential (E_{dep}) and deposition time (t_{dep}) were chosen as experimental factors. In a first stage and by means of a factorial design the relative influence of these variables will be analysed, the most influential being selected. These factorial designs do not allow one to explore exhaustively a wide range of the experimental space, but they indicate with minimum experimental effort the possible direction that future experiments should take. In a second stage one determines by a central composite design the optimum values of the factors selected by adjustment of the corresponding response surface.

The values of the other parameters which also influence the response such as modulation amplitude, pulse repetition time, sweep rate, mercury drop size, etc. characteristics of the voltammetric technique used was made bearing in mind previous experience in the treatment of similar problems, according to which the optimum reproducibility is achieved under the experimental conditions described above [12,13]. In the first stage the 2^4 factorial design with three replications in the central point involves 19 basic experiments undertaken in random order in separate solutions of indomethacin and acemethacin concentration 5×10^{-8} M. The values corresponding to the high (+) and low (-) levels and to the central point (0) for each factor were chosen taking into account that pH values < 3 and > 9 alter the stability of the drugs, $\%_{\text{buffer}}$ values $< 25\%$ are not sufficient to adjust the solution pH, the E_{dep} values selected are very close to the experimental barriers for this variable (oxidation of mercury electrode and reduction of analyte) and t_{dep} values < 10 s are not sufficient to permit the adsorption of the analyte and values

> 120 s increase too the experimental time. The values for each factor were as follows:

$$\begin{array}{lll} \text{pH (+)} = 9.0 & \text{pH (-)} = 3.0 & \text{pH (0)} = 6.0 \\ \%_{\text{buffer (+)}} = 100.0 & \%_{\text{buffer (-)}} = 25.0 & \%_{\text{buffer (0)}} = 62.5 \\ E_{\text{dep (+)}} = -1.0 \text{ V} & E_{\text{dep (-)}} = -0.2 \text{ V} & E_{\text{dep (0)}} = -0.6 \text{ V} \\ t_{\text{dep (+)}} = 120 \text{ s} & t_{\text{dep (-)}} = 10 \text{ s} & t_{\text{dep (0)}} = 65 \text{ s} \end{array}$$

In each of the experiments carried out, five voltammetrics scans have been realised both for the blank and the analyte. The mean peak current experimental values from this design can be seen in Table 1 for indomethacin and acemethacin. Fig. 2 shows the Pareto chart done with data of Table 1 for indomethacin and acemethacin, respectively. In this figure it can be seen that the more influential experimental factors for both drugs are the pH, percentage of buffer and the deposition time, likewise the interactions $\text{pH}-\%_{\text{buffer}}$ and $\text{pH}-t_{\text{dep}}$ for indomethacin and the interactions $\text{pH}-E_{\text{dep}}$ and $\text{pH}-t_{\text{dep}}$ for acemethacin, while deposition potential and the other interactions are less influential. The directions towards which the variables move in order to maximize the response were obtained considering the vertex of the hypercube with best response.

Deposition potential is the factor that produces least variation in the response, although this increases slightly with it for indomethacin. On the other hand, the choice of this parameter is conditioned by limitations due to the reduction peak itself to potential values of -1.2 V which is why this factor was set at -1.0 V for future experiences.

In the second stage a central composite design was carried out with the variables selected above in the experimental area to which the first factorial design leads in each case. That is, the new experimental conditions of experimental design will move towards low levels of pH and $\%_{\text{buffer}}$ and slightly higher deposition times:

$$\begin{array}{lll} \text{pH (+)} = 6.0 & \text{pH (-)} = 4.0 & \text{pH (0)} = 5.0 \\ \%_{\text{buffer (+)}} = 45.0 & \%_{\text{buffer (-)}} = 25.0 & \%_{\text{buffer (0)}} = 35.0 \\ t_{\text{dep (+)}} = 200 \text{ s} & t_{\text{dep (-)}} = 90 \text{ s} & t_{\text{dep (0)}} = 145 \text{ s} \end{array}$$

The results of this design for both indomethacin and acemethacin can be seen in Table 2. The ANOVA shows that the variables that have an influence in the case of indomethacin are the pH, pH² and t_{dep}^2 ($P_{\text{level}} < 0.05$).

The ANOVA done with the data from Table 2 for acemethacin indicates that for a confidence level of 96% both pH and deposition time continue to have a marked influence while the buffer percentage exerts a smaller influence on the response.

The degree of adjustment of the response surfaces for both indomethacin and acemethacin is acceptable as can be seen from the values of R^2 , 0.92 for indomethacin and 0.90 for acemethacin, and P_{level} for the lack-of-fit 0.08 and 0.04, respectively.

The isoresponse lines (Figs. 3 and 4) for indomethacin and acemethacin allowed one to obtain the optimum values of the variables studied. The equation of the adjusted model, for each drug, appears in the legend of Figs. 3 and 4, respectively.

In accordance with these results, the following experimental conditions were chosen:

Indomethacin	Acemethacin
pH = 4.2	pH = 4.4
% _{buffer} = 35.0	% _{buffer} = 25.0
E_{dep} = -1.0 V	E_{dep} = -1.0 V
t_{dep} = 150 s	t_{dep} = 240 s

Under these conditions the peak current is improved approximately nine times for indomethacin and four times for acemethacin, in comparison with the signal obtained under the conditions of the first design.

3.2. Calibration and detection limit with specified assurance probabilities

Once the optimum parameters for the analysis have been chosen a calibration can be made. In this case three calibrations were made for each drug separately. In all cases the calibrations were carried out with successive additions of 5×10^{-7} M stock solution of indomethacin or

Fig. 2. Pareto chart with the data in Table 1. (a) indomethacin, (b) acemethacin.

acemethacin. To guarantee that erroneous experimental points would not influence the calibration parameters (sensitivity, linear range, detection limit) a robust regression method (LMS) was used [10,14]. Robust regression in LMS has already been applied successfully to calibration problems [15,16]. The experimental data together with the standardized residuals (SR) are shown in Table 3 for both drugs. When the SR was > 2.5 the point was considered as ‘outlier-leverage’ [10] and eliminated and a new regression based on the least

squares (LS) criterion was done with the rest of the experimental data. The fact that in both calibrations the last points are outliers, deviating from the linearity always in the same negative direction, raises considerations about problems of saturation of electrode surfaces (to concentrations $> 8 \times 10^{-8}$ M) since indomethacin or acemethacin are voluminous molecules.

In the evaluation of the detection limit the possibility of false negative (beta value) has been quantified according to the Clayton et al. proce-

ture [17] with the Detarchi programme [11], which provides the capacity to detect of the analytical method by evaluating the probability of false positive (α) and false negative (β) as against the probability of false positive normally employed when using the criterion of the IUPAC [18]. It should be pointed out in the rough copy of the already existing ISO norms [19] the false negative is considered in the evaluation of the detection limit. Calibrations parameters, detection limits and detection signal obtained from the different calibrations are summarized in Table 4. In all cases a probability of false positive ($\alpha = 0.05$) and a number of replications ($r = 1$) were taken for different values of probability of false negative ($\beta = 0.5$ and 0.05).

3.3. Determination of indomethacin and acemethacin in urine samples

In the voltammetric determination of indomethacin and acemethacin in urine samples, the response was affected by the same variables, percentage of buffer in the electrochemical cell

(%_{buffer}), pH of solution, deposition potential (E_{dep}) and deposition time (t_{dep}) considered before. However, their influence is not necessarily the same, since the matrix is more complicated, the background is greater and it is necessary to use higher concentrations of analyte to obtain appreciable signals. This is why a new optimization procedure was carried out for these variables by a factorial experimental design 2⁴.

Previous experiences indicate that deposition time values > 100 s favour the adsorption of the other components of the urine preventing the deposition of the drugs. Also pH values and %_{buffer} > 6 and 50%, respectively, exert a decrease of the electrochemical response. Taking into account these facts the initial experimental area is smaller and the values for the high levels (+) and low levels (-) for the variables were:

pH (+) = 5.0	pH (-) = 3.0	pH (0) = 4.0
% _{buffer} (+) = 50.0	% _{buffer} (-) = 25.0	% _{buffer} (0) = 37.5
E_{dep} (+) = -1.0 V	E_{dep} (-) = -0.6 V	E_{dep} (0) = -0.8 V
t_{dep} (+) = 30 s	t_{dep} (-) = 10 s	t_{dep} (0) = 20 s

(a) The equation of the fitted model for indomethacin is: $i_p/i_{\text{pblank}} = -7.69 + 2.38A + 0.26B - 16.95C + 0.39D - 6.68E - 2AB + 6.20AC - 9.27E - 2AD + 7.74E - 2BC - 1.11E - 3BD - 0.18CD$. A: pH; B: $\%_{\text{buffer}}$; C: E_{dep} ; D: t_{dep} . (b) The equation of the fitted model for acemethacin is: $i_p/i_{\text{pblank}} = 7.65 - 1.53A - 0.11B + 6.07E - 2C - 1.48E - 2D + 2.92E - 2AB + 0.26AC - 3.03E - 4AD - 2.73E - 2BC + 1.94E - 4BD - 1.19E - 2CD$. A: pH; B: $\%_{\text{buffer}}$; C: E_{dep} ; D: t_{dep} .

The results obtained in the 16 basic experiments carried out in random order and those of the three central points are shown in Table 5. The urine samples analysed were spiked 5×10^{-6} M in drug. From the ANOVA with the data of acemethacin it can be deduced that only the pH factor and the interaction $\text{pH} - \%_{\text{buffer}}$ are significant ($P_{\text{level}} < 0.05$). For indomethacin the standardized effects show that all the factors are significant ($P_{\text{level}} < 0.05$) with the exception of the interactions $\%_{\text{buffer}} - E_{\text{dep}}$ and $\%_{\text{buffer}} - t_{\text{dep}}$.

Under the improved conditions of the factorial design the response was improved by a factor of 7 for indomethacin (from 2.15 to 16.35 for the relation i_p/i_{pblank}). This increase in the response is satisfactory and it is not considered necessary to make another new design. For

acemethacin there was not a great increase in the response analysed (from 1.02 to 2.81 for the relation i_p/i_{pblank}) and we could make a new design moving in the direction of the influential effects. However, it has already been pointed out that in this design there are very extreme values for pH and $\%_{\text{buffer}}$. Indeed percentages of buffer $< 25\%$ in the solution are not sufficient to adjust the solution pH. Furthermore, for pH values < 2.5 one can see the precipitation of the drugs.

Fig. 5 shows the isoresponse lines of the interactions $\text{pH} - t_{\text{dep}}$ and $\%_{\text{buffer}} - E_{\text{dep}}$ for indomethacin and acemethacin. Likewise, the equation of the adjusted model for each drug with the 2^4 factorial designs done is shown in the legend of Fig. 5.

Fig. 6. Differential pulse adsorptive stripping voltammograms obtained for indomethacin and acemethacin in urine sample in Britton–Robinson buffer. — indomethacin 5×10^{-6} M. pH = 5, %_{buffer} = 50, $E_{\text{dep}} = -1.0$ V, $t_{\text{dep}} = 10$ s acemethacin 5×10^{-6} M. pH = 3, %_{buffer} = 25, $E_{\text{dep}} = -1.0$ V, $t_{\text{dep}} = 10$ s.

Thus, to provide optimum conditions for the later calibration in urine samples with DPAdSV, the following were used:

Indomethacin	Acemethacin
pH = 5.0	pH = 3.0
% _{buffer} = 50.0	% _{buffer} = 25.0
$E_{\text{dep}} = -1.0$ V	$E_{\text{dep}} = -1.0$ V
$t_{\text{dep}} = 10$ s	$t_{\text{dep}} = 10$ s

To carry out the determination of indomethacin and acemethacin in urine samples, additions of 20 μl of 5×10^{-5} M indomethacin or acemethacin were made to a urine sample diluted 25.0-fold in water. When obtaining the calibration lines, the criterion of the LMS was taken into account to detect anomalous points whether they be 'outlier or leverage'. Calibration parameters for three replicate calibrations for each drug are summarised in Table 6. The differential pulse adsorptive stripping voltammograms of urine samples from 20 healthy subjects of both sexes, aged between 16 and 60 years, were compared, the qualitative aspect being virtually constant (Fig. 6). The detection limits calculated for the 20 samples analysed, an α value 0.05, a β value 0.05 and a replication oscillate from 1.64×10^{-7} to 7.35×10^{-7} M for acemethacin and from 1.23×10^{-8} to 7.61×10^{-8} M for indomethacin.

A consideration of electrode polishing prior to application of pulsed amperometric detection

Ayano Inoue, Rosa L. Earley, Mark W. Lehmann, Lawrence E. Welch *

Department of Chemistry, Knox College, Galesburg, IL 61401 USA

Received 28 July 1997; received in revised form 24 December 1997; accepted 29 December 1997

Abstract

An examination was made of the effect of electrode polishing on the direct pulsed amperometric detection (PAD) and indirect PAD response to penicillin G. The polishing procedure produced a temporary loss of sensitivity for both types of PAD, which over time relaxed back to higher levels. A temporary increase in the electrode kinetics can be observed as well, particularly for a PAD waveform in the crossover region between direct and indirect PAD. In extreme cases, the penicillin G response can undergo a complete polarity reversal. By observing post-polish equilibration times, it was recommended that the direct and indirect PAD user observe 3 and 5 h delay times, respectively, to insure stable electrode response following an electrode polish. © 1998 Elsevier Science B.V. Keywords: Electrode polishing; PAD; Electrode response

1. Introduction

In his classic text on solid electrode electrochemistry, Adams [1] stated, 'Probably the most serious problem in solid electrode methodology is associated with understanding the true electrode surface conditions and their possible effect on the electrode process.' He went on to describe 'filming', a phenomena that led to a loss of electrode activity, hampering voltammetric studies of amines, phenols, and sulfur compounds. Many other sources have noted the importance of working electrode 'cleanness', and the deleterious ef-

fects of adsorption, electropolymerization, fouling, or poisoning of the working electrode [2–4]. Despite the broad swath of phenomena covered by these descriptions, all essentially involve an accumulation of foreign material on the surface of a working electrode, and the concomitant loss of electrode activity. Completely cleaning the foreign material from the electrode may be nearly impossible, but various techniques alone or in combination have been developed to rejuvenate working electrode activity, such as chemical treatments, potential excursions, and mechanical polishing [1].

Pulsed amperometric detection (PAD), developed by Johnson, Hughes and Polta [5,6], utilized a regular waveform incorporating potential excursions

sions to produce a fresh electrocatalytic electrode surface prior to each current measurement. This methodology allowed amperometric determinations of many organic species that had resisted prior efforts due to loss of electrode activity from fouling [7,8]. Despite adapting one rejuvenating process into the PAD waveform, the practice of polishing the working electrode, at least on an occasional basis, did not disappear. It is interesting to note that in some laboratories using PAD [9–14], the practice of electrode polishing has been incorporated as a part of a regular electrode conditioning ritual prior to experimentation, presumably to fight against fouling from sources that were not completely eliminated via potential excursions. Mechanical polishing is known to temporarily alter the response of a working electrode, often requiring 60–90 min before a stable baseline can be attained following the procedure. However, recent work in this laboratory [15] has suggested that the post-polish instability might extend for a considerably longer period. Some evidence of kinetic alteration was observed after polishing as well. Without suggesting that electrode polishing not be done, as it has proven its value, this study sought to examine the prudence of electrode polishing as a commonplace PAD

pre-experimental ritual. In particular an evaluation was to be made of the signal stability of PAD using a common electrode and a common analyte system following an abrasive polish.

2. Experimental

Penicillin G was purchased from Sigma Chemical (St. Louis, MO). Methanol and acetonitrile were reagent grade from Fisher (Pittsburgh, PA). All other solutions were made from reagent grade chemicals from Aldrich (Milwaukee, WI), Baker (Phillipsburg, NJ), Fisher, or Sigma. Water was distilled and deionized before use as a solvent.

Flow injection analysis trials were done with a Waters 625 LC system (Milford, MA) and a Waters 464 pulsed electrochemical detector. A 75- μ l sample injection loop was employed for all. Injected penicillin solutions were all solvent matched to avoid having a system peak overlapping with the analytical peak. To improve the flow stability during flow injection analysis, an Upchurch (Oak Harbor, WA) U-469 back pressure regulator was placed in-line following the pump. All solvents were vacuum filtered through an Alltech (Deerfield, IL) 0.20- μ m nylon filter. The solvent mixtures were degassed further using a 30 ml min⁻¹ helium sparge during the flow injection trials.

Flowing stream work utilized a thin-layer cell with a single gold working electrode having a diameter of 2.5 mm. The counter electrode was a stainless steel block mounted opposing the thin-layer cell, with the flow channel created by a teflon spacer between the two. The reference electrode was a Ag/AgCl. The BAS MF-2060 polishing kit was used to polish the working electrode at noted intervals. The working electrode was polished using a Buehler (Lake Bluff, IL) Microcloth and Buehler Gamma Micropolish Alumina, no. 3, having a particle size of 0.05 μ m.

Current integration was always during the final 16.7 ms of the detection step, as required by the detector. Detector signal polarity was inverted so that increased anodic response would produce peaks rather than troughs on the output plots. Output data was collected by a PC using LabCalc

software (Galactic, Salem, NH). The collection interval was synchronized with the potentiostat, such that a single data point was collected per PAD cycle.

3. Results and discussion

The analyte chosen for study was penicillin G, which was observed in acetate buffer solvent containing portions of organic modifier. This system was advantageous in that it had been well characterized by previous studies [13–18], and that it can support both direct and indirect PAD by proper waveform selection. Either of these methods could be used to monitor sensitivity to penicillin G following an electrode polish. For this study, it was decided to operate in or near the crossover region between direct and indirect PAD [13,15,18]. Direct PAD represents an anodic oxidation of the penicillin G following its adsorption

onto the working electrode. Although the adsorption causes an attenuation of electrode surface oxidation, the loss in anodic current is more than offset by electrocatalytic oxidation of the penicillin, causing a net increase in anodic signal. With indirect PAD the penicillin still adsorbs to the working electrode, but the kinetics of the electrocatalytic oxidation of the penicillin have slowed to the point that the anodic current produced from this process is minimal, failing to offset the loss of current from surface oxidation and yielding a net decrease in anodic signal. The crossover region represents the transition zone between using direct and indirect PAD. Response in this region is often bidirectional, yielding both an oxidative and suppressive component. Practical PAD procedures can use either direct or indirect PAD, although for optimum S/N response one would like to avoid the crossover region where the signal from the oxidized penicillin is nearly equal to the suppressed signal from forma-

Fig. 2. Direct PAD response to penicillin G following electrode polishing. Flow injection analysis. Solvent: 12% methanol/8% acetonitrile/80% 0.2 M acetate buffer (pH 4.7) (v/v), 1.0 ml/min. Injections: 1.00×10^{-3} M penicillin G. PAD waveform: given in Table 1B. Traces: (A) typical pre-polish response, (B) 5 min after polishing, (C) 58 min after polishing, (D) 184 min after polishing.

tion of residual oxide. For $I-E$ curves that help illustrate the crossover phenomena, direct PAD, and indirect PAD, see Ref. [13].

The crossover region for penicillin G in 12% methanol/8% acetonitrile/80% 0.2 M acetate buffer (pH 4.7) (v/v) (12/8/80), is shown in -3 M penicillin G. PAD waveform: given in Fig. 1. At the initial E_1 (detection) potential value of 1100 mV, very little of the penicillin is oxidized. By shifting the E_1 more positive one can provide additional overpotential to enhance the efficiency of the penicillin oxidation, enabling the conversion from indirect to direct PAD. While this crossover region might be a poor region to perform sensitive detection of penicillin G, it is useful for the study at hand. In particular, peak size in the crossover region is a function of both the amount of adsorbed penicillin G and the particular reaction kinetics for the penicillin oxidation. By monitoring in this region, one can observe kinetic changes in addition to gauging the stability and sensitivity of the detector.

For each different waveform, initial stable output response for repetitive penicillin G injections was obtained. The cell was then disabled, the gold working electrode removed and polished as noted in the experimental section, then the cell reassembled and response to the same penicillin G solution measured as a function of time after reassembling the cell. A plot of the response using a direct PAD waveform is shown in Fig. 2. Looking at the pre-polish trace (A), one can note the 'dip' following the peak. This is typical behavior for a direct PAD waveform that is right on the edge of the crossover region, still containing a trace of the suppressive effect prevalent with indirect PAD. The same effect can be seen in traces (H) and (I) from Fig. 1. After polishing, it can be seen that the sensitivity to penicillin is diminished, but returns gradually over time. Kinetic information can be gathered by observing the relative magnitude of the oxidative and suppressive peak components. Since the changes are subtle in Fig. 2, the ratio produced by dividing the peak height

Fig. 3. Indirect PAD response to penicillin G following electrode polishing. Flow injection analysis. Solvent: 12% methanol/8% acetonitrile/80% 0.2 M acetate buffer (pH 4.7) (v/v), 1.0 ml/min. Injections: 1.00×10^{-3} M penicillin G. PAD waveform: given in Table 1C. Traces: (A) typical pre-polish response, (B) 4 min after polishing, (C) 56 min after polishing, (D) 182 min after polishing.

of the positive peak component by that of the negative was calculated. This ratio goes from 9.76 in (A) to 13.9 in (C) to 7.76 for (D). Trace (B) has no negative component at all. This indicates that there is an increase in the rate of penicillin G oxidation following the polish, as the peaks show a shift out of the crossover region toward direct PAD, with relaxation back into the crossover region with sufficient time. The ratio typically will relax back to a similar value as that seen with the pre-polish set, or, in some cases, to a smaller value. This parallels the peak height relaxation, which also end up of similar height to the pre-polish or slightly larger. The disparity arises because of the uncertainty of the electrode surface condition while collecting the pre-polish set.

A plot of the response using an indirect PAD waveform is shown in Fig. 3. The behavior here is similar in regard to the initial loss of sensitivity followed by a gradual regeneration in the wake of the electrode polish. The indirect PAD conditions

in use are remote enough from the crossover region such that there is no positive component to the pre-polish response, nor is there any positive component produced in the aftermath of polishing. It is possible that an increase in oxidation kinetics may be occurring as seen in Fig. 2, but if so it is at most causing a small area reduction of the suppression peak, which could not be isolated from the area change due to sensitivity loss. In any case the degree of penicillin oxidation is very small under these conditions, and a rate increase might not cause an observable change. Other indirect PAD waveforms slightly closer to the crossover region show the generation of a temporary direct PAD component immediately after polishing.

The most dramatic effect takes place when a waveform in the middle of the crossover region for penicillin G was chosen, as shown in Fig. 4. Despite keeping all other experimental conditions exactly the same, one can produce an inversion in

Fig. 4. PAD response to penicillin G in the crossover region after electrode polishing. Flow injection analysis. Solvent: 12% methanol/8% acetonitrile/80% 0.2 M acetate buffer (pH 4.7) (v/v), 1.0 ml/min. Injections: 1.00×10^{-3} M penicillin G. PAD waveform: given in Table 1D. Traces: (A) typical pre-polish response, (B) 4 min after polishing, (C) 57 min after polishing, (D) 178 min after polishing.

response, albeit temporary, simply by polishing the working electrode. This figure very clearly illustrates the increase in oxidation rate, and thus the shift from indirect toward direct PAD caused by polishing. The change in sensitivity is also clear.

For all waveform types, peak heights were reduced upon polishing. This is representative of the process reducing the active surface area of the working electrode. Penicillin detection via either direct or indirect PAD relies on adsorption of the penicillin to the gold surface [13]. When viewed microscopically, the seemingly planar surface of the working electrode actually is quite rough, with active electrode surface ranging over a significant depth. Abrasive polishing will flatten this rough surface, producing something closer to planar which ultimately has much less surface area. Consequently, adsorption dependent detection of penicillins is suppressed after the abrasive proce-

dure. However, as the PAD waveform is reapplied to the electrode and it is allowed to equilibrate, the surface will begin to 'erode' back, eventually producing a rough surface approximating the one observed pre-polish. This would explain the sensitivity change observed for both direct and indirect PAD, as output current depends on the amount of adsorbed analyte for each.

Although not obvious in Fig. 3, it is likely that the oxidation rate kinetics are increased under all circumstances following a polish. The rate change can be observed throughout the crossover region. Prior work has suggested that electrode polishing causes an increase in the oxidation rate for penicillin with PAD, based on an analysis of peak symmetry characteristics [15]. The proposed electrocatalytic oxidation of the penicillins is postulated to occur via an oxygen transfer from a surface oxide site to the sulfide group on the penicillin. This can only occur when the penicillin

is adsorbed to the electrode surface at the sulfide moiety, and if there is nearby oxide to affect the transfer. The mature 'rough' electrode surface appears to have a number of sites which geometrically are hindered from completing the oxygen transfer, thus slowing the overall rate of oxidation. After polishing, the flatter, less tortuous electrode surface is less likely to provide surface geometries hindering the oxygen transfer process, thus leading to more rapid and more efficient penicillin oxidation. As the surface regains its original 'roughness', the oxidation rate reverts back to its original range.

Although waveforms in the crossover region will be a poor choice in terms of sensitivity to penicillins, the change in sensitivity upon polishing extends beyond the crossover region and throughout the PAD detection range for these molecules. This is likely the case for all PAD analytes that involve oxide-catalyzed detection. Given this finding, it would seem imperative to not collect quantitative information until the detector sensitivity has stabilized following an electrode polish. It is important to note that the time required for this stabilization is much greater than

the time required to obtain a stable baseline. Whether or not electrode polishing is done on a regular basis, it would seem a safe assumption that occasional polishing of PAD working electrodes is unavoidable. If so, and given that baseline stability is a poor indicator of the analyte sensitivity of the detector, this begs the question as to how long one should wait before collecting quantitative data following a polish. Numerous studies examining the peak stability following a polish were run for a variety of waveforms. Typical response can be seen in Fig. 5 for both direct and indirect PAD. The direct PAD stabilized somewhat faster, which seems reasonable given the higher current density and faster electrode kinetics. Three hours seemed to be a good minimum waiting period following a polish for this type of waveform, while indirect PAD requires a more lengthy wait: 5 h as a minimum would be recommended. Although they are of less practical utility, waveforms in the middle of the crossover region also required a minimum of 5 h for stabilization.

4. Conclusion

Abrasive polishing of a working electrode should be undertaken with caution as it will require 3–5 h delay before a stable peak response can be obtained. Given this, polishing as part of a regular pre-experimental ritual should not be undertaken unless a long period is available for equilibrating. It might be best to polish the day before an experiment, with overnight equilibration of the detector prior to the quantitative PAD trials.

Spectrophotometric determination of trace amounts of cobalt with 2-hydroxybenzaldehyde-5-nitro-pyridylhydrazone in presence of surfactant after separation with Amberlite IRC-718 resin

Chan-Il Park¹, Ki-Won Cha^{*}

Department of Chemistry, Inha University, Incheon 402–751, South Korea

Received 18 September 1997; received in revised form 22 December 1997; accepted 2 January 1998

Abstract

2-Hydroxybenzaldehyde-5-nitro-pyridylhydrazone (2HB-5NPH) was synthesized and its application in the spectrophotometric determination of metal ions was studied in the presence of surfactants. A separation procedure, using a short column filled with Amberlite IRC 718, is proposed for the spectrophotometric determination of traces of cobalt. The influence of several ions, as interference, was discussed. The procedure was applied to determination of cobalt in mixture sample with satisfactory results (\geq recovery 96%; relative error \leq 2%; relative standard deviation \leq 1.2% in the concentration range of 0.02–2.0 mg l⁻¹; detection limit, 0.01 mg l⁻¹ in solution). Control of the pH during the column operation is essential because the adsorption capacities are very sensitive to change in pH. Their separation was carried out in 0.005 M Malic acid, 1.5 M HCl, 2.0 M HNO₃ media. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Hydrazones (characterized by the grouping —C=N—N—, and related to Schiff's base), have been used as photometric [1–5] and fluorimetric [6–10] analytical reagents for the determination of

metal ions. In analytical chemistry, hydrazones have been used for detection, determination and isolation of compounds containing the carbonyl group [11] and hydrazones act as multidentate ligands with metal ions (usually from the transition elements), forming colored chelates [12]. These chelates are then used in selective and sensitive determination of the metal ions. And, with the addition of certain surfactant reagents can increase the stability and solubility of many organic compounds and metal complexes [13–17].

			$\nu_{\text{C=N}}$	$\nu_{\text{C-N}}$	$\nu_{\text{N-H}}$
5-N-2-PH	200	92.5	—	1420	1290
2HB-5NPH	244	71.6	1600	—	1292

The metal complexes formed in micellar media are generally more stable than those formed in the absence of micelles. These organized molecular assemblies are used in spectroscopic measurements due to their possible effects on the system of interest. In the field of metal ion complexation, at concentrations above the CMC, micelles form a ternary complex with advantageous properties, such as hyperchromic and bathochromic displacements, that can modify sensitivity and selectivity of the method by affecting the interferences and matrix effect [18,19]. The ability of micellar systems to solubilize slightly insoluble or even very insoluble complexes and/or ligands has been used to enhance the analytical merit of given methods [19,20].

In a previous work [21], the author synthesized 2-pyridinecarbaldehyde-5-nitro-pyridyl hydrazone (2PC-5NPH) and showed it to be a sensitive reagent for Fe(III). In this work, the analytical possibilities of a new reagent, 2-hydroxybenzaldehyde-5-nitropyridyl hydrazone (2HB-5NPH) are reported. This paper describes the spectrophotometric determination of Co(II) by 2HB-5NPH with separation of Co(II) using Amberlite IRC-718 resin. One of the few commercial chelating ion exchange resins available is Amberlite IRC-718 for which the chelating ability is attributed to iminodiacetic acid groups. Very little evaluation has been performed on this exchanger. The present paper gives the adsorption capacities for Co(II) and some metal ions between Amberlite IRC-718 resin and inorganic acid solutions and applies the results to quantitative separation of metal ions. The present method is highly sensitive and simple for separation and spectrophotometric determination of Co(II).

2. Experimental

2.1. Apparatus

Absorption spectra and absorbances were measured with recording spectrophotometer, Perkin-Elmer Model 555S, with 1 cm quartz cells. Shimadzu AA-670 atomic absorption spectrometer was used for metal ions determination. All pH measurements were made with a NOVA-310 pH meter. The resin used in the column was Amberlite IRC-718, 16–50 mesh. The resin was washed successively with 6 M HCl, water, 1 M NaOH, water, 1 M HCl and water in order to remove organic and inorganic contaminants.

2.2. Reagent

Analytical-reagent grade chemicals and distilled, deionized water were used throughout. Cobalt(II) stock solution (100 mg l⁻¹) was prepared by dissolving appropriate amounts of analytical grade Co(NO₃)₂·6H₂O in doubly distilled water and was standardized with EDTA. Working solutions were prepared by suitable dilutions of the stock solution with water. Surfactants were from Sigma and all were used without further purification. Surfactant solutions (1 × 10⁻³M) were prepared by dissolving suitable amounts of surfactants in water with gentle heating.

2.3. Procedure

2.3.1. Synthesis of 2-hydroxybenzaldehyde-5-nitro-pyridylhydrazone

2HB-5NPH was prepared as follows. An ethanolic solution of equimolar quantities (0.1M) of 2-hydroxybenzaldehyde and 5-nitro-2-pyridyl-

Fig. 1. Absorption spectra of 2HB-5NPH and Co(II)-2HB-5NPH. Co(II): 1.0 mg l^{-1} , 2HB-5NPH: $6.0 \times 10^{-5} \text{ M}$.

hydrazine (Aldrich) was refluxed for 3 h. The product (light yellow needles, m.p. $243.5\text{--}244.1^\circ\text{C}$) was separated after cooling and recrystallized from ethanol. A $1.0 \times 10^{-3} \text{ M}$ solution of the reagent was prepared by dissolving 0.243 g of 2HB-5NPH in 1000 ml of methanol. This solution is stable for several months when kept in an amber glass bottle.

2.3.2. Spectrophotometric determination

An aliquot of metal standard solution was transferred to a 50 ml volumetric flask, and 5.0 ml of $1 \times 10^{-3} \text{ M}$ 2HB-5NPH methanol solution, 3.0 ml of pH 6.5 hexamethylenetetramine (HTM) buffer solution and 7.5 ml of $1.5 \times 10^{-4} \text{ M}$ surfactant solution were added sequentially. The solution was made up to the mark with methanol. The absorbance of the solution was measured at 470 nm against a reagent blank as a reference.

2.3.3. Separation

2.3.3.1. Column separation. A glass column ($25 \times 150 \text{ mm}$) having a stopcock was packed with 15 g of the resin. The resin was regenerated with 6.0 M HCl and a large volume of water.

2.3.3.2. Batch procedure. Resin (1.0 g) and 50 ml solution of Co(II), Cr(III), Ni(II), Zn(II), Cu(II) and Pb(II) in a 100 ml beaker were stirred moderately for 24 h at room temperature. After equilibrium, the solution was filtered through Whatman #2 filter paper. The filtrate was diluted with water and the concentration of metal ions was determined by AAS.

2.3.3.3. Column procedure. Separation of metal ions in the column system was carried out under the following conditions. A fixed volume of aqueous solution of the metal ions was adjusted to a suitable pH and percolated through the column at a flow rate of $1.0 \pm 0.2 \text{ ml min}^{-1}$. Cr(III) and Co(II) was eluted with 0.25 M HCl, Ni(II) with 1.5 M HCl and Cu(II) and Pb(II) with 2.0 M HNO_3 . Co(II) was analysed spectrophotometrically.

3. Result and Discussion

3.1. Identification of hydrazones

2HB-5NPH is yellowish solid which is slightly solution in water but can be easily dissolved in methanol. Identification of the synthesized hydra-

zones was carried out by Infrared (IR) spectroscopy. The IR spectra of the synthesized hydrazones were measured with potassium bromide pellet in order to confirm their structures. The spectra had absorption peaks assigned to the stretching vibration of an azomethine bond ($-\text{N}=\text{C}$) around 1600 cm^{-1} . The melting point, yield and IR spectral data of the synthesized hydrazones are shown in Table 1.

3.2. Spectrophotometric determination

2HB-5NPH [I]

2HB-5NPH is a light yellow crystalline material soluble in most organic solvents. The reagent forms intensely colored complexes with a number of transition metal ions. In these complexes, 2HB-5NPH acts as a tridentate ligand. Complexation is accompanied by elimination of the labile proton of the ligand in most of the chelate systems.

The absorption spectra of the binary and ternary complexes and the reagent blanks are shown in Fig. 1. The Co(II)-2HB-5NPH complex has a strong absorbance at 470–475 nm and that of the reagent blank is at 375–385 nm; the spectra do not overlap. On addition of cetyltrimethylammonium bromide (CTMAB), the absorption band remained unchanged except for a slight increase in peak absorption. Maxima and constant absorbance is obtained for 1.0 mg l^{-1} of Co(II) with 3.0 ml of $1.0 \times 10^{-3} \text{ M}$ 2HB-5NPH solution per 50 ml, so 5.0 ml of this 2HB-5NPH solution is selected as optimal.

The effect of pH on the Co(II)-2HB-5NPH-CTMAB complex formation was studied over the

Fig. 2. Sorption capacities of metal ion on Amberlite IRC-718 chelating resin according to pH change. Metal solution: $2.5 \text{ mg } 50 \text{ ml}^{-1}$; resin taken: 1 g; shaking time: 24 h.

Fig. 3. Sorption capacities of metal ion on Amberlite IRC-718 chelating resin according to Malic acid concentration. Metal solution: $2.5 \text{ mg } 50 \text{ ml}^{-1}$; resin taken: 1 g; shaking time: 24 h, pH: 3.5.

Fig. 4. Sorption capacities of metal ion on Amberlite IRC-718 chelating resin according to HCl and HNO₃ concentration. Metal solution: 2.5 mg 50 ml⁻¹; resin taken: 1 g; shaking time: 24 h.

pH range 3–11. No absorbance was observed with any of the reagents in acidic solutions (< pH 4.5). The optimal pH range for formation of the complex is 6.6–7.2. The solution pH was adjusted with hexamine buffer solution and hydrochloric acid or sodium hydroxide was used to maintain the optimum pH. It does not affect the intensity but improves the stability of the color of the complex.

The effect of nonionic surfactants [Brij 52, Triton X-100], cationic surfactants [cetyltrimethylammonium bromide (CTMAB), dodecyltrimethylammonium bromide (DTMAB)] and anionic

surfactant [sodium dodecyl sulfate (SDS)] were studied. As shown in Table 2, the cationic surfactants had a increase of absorbance but in the anionic and nonionic surfactants showed no effect or diminished on the absorption spectra of the Co(II)-2HB-5NPH complex. The absorbance increased with a increase of CTMAB concentration until 1.5×10^{-4} M, but the absorbance diminished with further increase of CTMAB. As can be seen, CTMAB showed the best enhancement effects and so was selected for further investigations.

We measured the mole ratio of Co(II) and 2HB-5NPH in Co(II)-2HB-5NPH complex with

Fig. 5. Elution curve of Cu(II), Cr(III), Co(II), Ni(II) and Pb(II). Loading: 5 mg of Cu(II), Cr(II), Co(II), Ni(II), Pb(II) + 0.005 M Malic acid in 100 ml, pH 3.5. Elution: H₂O, 0.25 M HCl, 1.5 M HCl and 2.0 M HNO₃ solution.

and without CTMAB. The results indicate the formation of a 1:2 complex between Co(II) and 2HB-5NPH with or without CTMAB. An improvement in detection limit achieved upon the addition of CTMAB. The addition of CTMAB to the Co(II)-2HB-5NPH system results in a 1.24-fold improvement in the detection limit of the technique.

The molar absorptivities in presence of CTMAB found by least-squares analysis of 10 measurements, was $6.5 \times 10^4 \text{ mol}^{-1} \text{ cm}^{-1}$. Under the optimal conditions explained above, a

linear calibration curve obtained over the range $0.02\text{--}2.0 \text{ mg ml}^{-1}$ of Co(II) ions. The detection limit ($s/n=2$) was found to be 0.01 mg l^{-1} . The relative standard deviation for 0.5 mg l^{-1} of Co(II) was 1.2% ($n=5$).

The selectivity in the proposed method was investigated by determining 1.0 mg l^{-1} of Co(II) in the presence of various other ions. Interference was regarded as significant when it produced a difference of more than 3% in absorbance from that found with Co(II) ion alone. The results are given in Table 3. The results indicated that the

Table 4
Sensitivities of reagents for the spectrophotometric determination of Co(II)

Method	Detection limit ($\mu\text{g ml}^{-1}$)	λ_{max} (nm)	Reference
Dithizone	0.07	550	[22]
Nitroso-R-salt	0.0019	420	[23]
	0.0042	520	[23]
<i>o</i> -Nitroso-resorcinol	0.0025	430	[23]

2HB-5NPH	0.01	472	Present method

concentration range of 1.0–0.1 g ml⁻¹ for Pb²⁺, Ni²⁺, Cu²⁺ and Pd²⁺ are upper limits for interference. Therefore, it can be understood that the separation of Co(II) from the matrix is necessary prior to spectrophotometric determination. For this purpose, a column separation method was investigated.

3.3. Column separation method

The adsorption capacity to pH (Amberlite IRC-718 resin) profiles for Co(II), Zn(II), Ni(II) and Pb(II) are given in Fig. 2. Fig. 2 shows that adsorption depends apparently on the pH of the solution due to the competing protonation and complexation reactions of the functional group (iminodiacetic acid) of resin. The order for metal ion's adsorption capacity, as shown by adsorption percent at pH 3.5 (Fig. 2), is as follows: Cr(III) < Co(II) < Cd(II) < Zn(II) < Ni(II) < Pb(II) < Cu(II). The metal ions were found to be adsorbed into malic acid over the concentration range of 0.0025–0.0075 M (Fig. 3). The adsorption capacities of the resin toward metal ions were found to depend on the HCl and HNO₃ concentration of the sample solutions (Fig. 4). For Co(II) ion the capacity decreased gradually with increasing the HCl concentration from 0.1 to 0.5 M. In particular, adsorption capacity of Pb(II) ion did not change over the range 0.25–2.0 M HCl. However, the capacity for Pb(II), Zn(II) ion decreased with increasing HNO₃ concentration (Fig. 4).

The effect of flow rate of the sample loading through the column was studied over the range 0.5–2.0 ml min⁻¹. The adsorption of metal ions remains almost unchanged regardless of any change in the flow rate. In subsequent experiments a flow rate of 1.0 ± 0.2 ml min⁻¹ was maintained for both adsorption and elution. From the results presented in Figs. 3 and 4, HCl and HNO₃ solutions have been considered as an eluent for the separation of the synthetic metal solution. The column was equilibrated with acetic acid buffer of pH 3.5. 50 ml of a 0.05 M malic acid containing 5.0 mg of each metal ion was loaded onto the column (Fig. 5). Co(II) was eluted with 200 ml of 0.25 M HCl after loading

with 50 ml of sample solution. Then 200 ml of 1.5 M HCl and 300 ml of HNO₃ were used to elute Ni(II), Pb(II) and Cu(II).

The effluent of 150 ml of 0.25 M HCl was used directly for the spectrophotometric determination of Co(II) as the 2HB-5NPH complex at 473 nm and Cd(II), Cr(III), Ni(II), Pb(II) and Cu(II) concentration were analysed by atomic absorption spectrophotometry.

3.4. Comparison with some other reagent

2HB-5NPH compares well with the most sensitive and widely used reagents for the spectrophotometric determination of Co(II). The sensitivities of the various reagents are compared in Table 4.

4. Conclusion

The spectrophotometric determination method of Co(II) has been investigated after separation of Co(II) from the mixed ions using Amberlite IRC-718 resin. The complex between 2HB-5NPH and Co(II) in the presence of CTMAB is very stable and more sensitive than that in the absence of surfactant. The Co(II)-2HB-5NPH complex in CTMAB has an absorption maximum at 473 nm and obeys the Beer's law in the range of 0.02–1.5 mg l⁻¹. Molar absorptivity is 6.5 × 10⁴ mol⁻¹ cm⁻¹ l. Co(II) was separated as run 200 ml of 0.25 M HCl after loading with 50 ml of sample solution.

Abstract

A system for separation of zinc traces from large amounts of cadmium is proposed in this paper. It is based on the solid-phase extraction of the zinc in the form of thiocyanate complexes by the polyurethane foam. The following parameters were studied: effect of pH and of the thiocyanate concentration on the zinc extraction, shaking time required for quantitative extraction, amount of PU foam necessary for complete extraction, conditions for the separation of zinc from cadmium, influence of other cations and anions on the zinc sorption by PU foam, and required conditions for back extraction of zinc from the PU foam. The results show that zinc traces can be separated from large amounts of cadmium at pH 3.0 ± 0.50 , with the range of thiocyanate concentration from 0.15 to 0.20 mol l⁻¹, and the shaking time of 5 min. The back extraction of zinc can be done by shaking it with water for 10 min. Calcium, barium, strontium, magnesium, aluminum, nickel and iron(II) are efficiently separated. Iron(III), copper(II) and cobalt(II) are extracted simultaneously with zinc, but the iron reduction with ascorbic acid and the use of citrate to mask copper(II) and cobalt(II) increase the selectivity of the zinc extraction. The anions nitrate, chloride, sulfate, acetate, thiosulphate, tartarate, oxalate, fluoride, citrate, and carbonate do not affect the zinc extraction. Phosphate and EDTA must be absent. The method proposed was applied to determine zinc in cadmium salts using 4-(2-pyridylazo)-resorcinol (PAR) as a spectrophotometric reagent. The result achieved did not show significant difference in the accuracy and precision (95% confidence level) with those obtained by ICP–AES analysis. © 1998 Elsevier Science B.V. Keywords: Zinc separation; Solid-phase extraction; Polyurethane foam; Cadmium matrices

1. Introduction

Zinc is frequently present at trace level in cadmium and their compounds. However, the spec-

* Corresponding author. Tel.: +55 71 2375784; fax: +55 71 2355166; e-mail:slcf@ufba.br

trophotometric determination of this element in these matrices is troublesome because many of the chromogenic reagents proposed also react with cadmium.

Numerous methods have been published for such determination. However, they are not simple and usually require extensive and laborious steps for the separation of zinc from cadmium, using procedures which involve: liquid–liquid extraction [1–6] of zinc or cadmium, ion exchange [7,8], and precipitation [9].

This paper proposes a method for the separation and determination of zinc in cadmium matrices based on solid-phase extraction (SPE) of zinc in the form of thiocyanate complexes by the polyurethane foam (PU foam).

The PU foam has been used as a solid sorbent on a wide variety of inorganic and organic compounds from different media. It was first proposed by Bowen [10] in 1970. Braun [11–13] and Palagyi [14] have described reviews about the use of PU foam in procedures of separation and preconcentration.

The use of PU foam for zinc extraction has been proposed by several authors [15–18]. The extraction mechanism of the zinc by the PU foam in the form of thiocyanate complexes has been studied by Moody et al. [15]. Maloney et al. [16] have proposed a procedure for simultaneous extraction of zinc, cobalt(II), iron(III) and cadmium(II) from thiocyanate medium by PU foam. Nickel is not extracted. Braun and Abbas [17] have proved that zinc, mercury and indium are extracted quantitatively by PU foam in the form of thiocyanates complexes. Hamza et al. [18] have used PU foam treated with dithizone for the extraction of zinc and bismuth.

Zinc(II) reacts instantaneously with 4-(2-pyridylazo)-resorcinol (PAR) [19,20] in the range of pH from 9.0 to 10.0, forming a complex with maximum absorption at 496 nm and molar absorptivity of $8.30 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$. Cadmium(II) also reacts with PAR, forming a complex with absorption maximum at 510 nm and molar absorptivity of $8.12 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$.

2. Experimental

2.1. Apparatus

Spectrophotometric measurements were made using a Varian Cary 1E spectrophotometer with matched 1.00-cm quartz cells.

An Applied Research Laboratories model 3410 minitorch sequential inductively coupled plasma spectrometer with an IBM PC-AT computer was used for ICP-AES analysis.

A Rigaku-B3 wavelength dispersive X-ray fluorescence spectrometer, with a rhodium tube operated at 40 kV and 30 mA, a LiF crystal, and a scintillation counter was used.

A 300 Analyser pH meter was used to measure the pH values.

A VKS-100 mechanical shaker, 100 cpm was used for shaking of the solutions.

2.2. Reagents

All reagents were of analytical-reagent grade unless otherwise stated. Doubly distilled water was used to prepare the solutions. The nitric acid and hydrochloric acid were of Suprapur quality (Merck). The laboratory glassware was kept overnight in a 5% nitric acid solution. Before being used the glassware was washed with doubly distilled water and dried in a dust-free environment.

Zinc solution ($10.00 \mu\text{g ml}^{-1}$) was prepared by diluting a $1000.00 \mu\text{g ml}^{-1}$ zinc solution (atomic absorption Aldrich) using a 5% hydrochloric acid solution.

Potassium thiocyanate solution (1.0 mol l^{-1}) was prepared by dissolving the reagent (Carlo Erba) in doubly distilled water.

Masking solution containing citrate and acid ascorbic (1.6%) was prepared by dissolving its sodium salts (Merck) in doubly distilled water.

4-(2-Pyridylazo)resorcinol solution (0.05% m/v) was prepared by dissolving a monosodium reagent (Merck) in doubly distilled water.

Buffer solution (pH 10.0) was prepared by mixing 42.0 g of di-sodium hydrogen carbonate and 53.0 g of sodium carbonate in 1 l of doubly distilled water.

Polyurethane foam: a commercial, open cell, polyether-type PUF (Vulcan of Brazil, VCON 202, 42% resilience and 10–12 cells/linear cm) was broken into small particles in a blender with doubly distilled water and used as described by Carvalho [21–23].

2.3. Separation procedure

It was added into a polypropylene flask the following reagents: 10.00 ml of zinc(II) cation solution in the mass range of 1.0–60.0 μg , 5.00 ml of 1.0 mol l^{-1} thiocyanate solution and 10.00 ml buffer solution. It was mixed and added the mass of 60 mg of comminuted PU foam (previously treated with 0.20 mol l^{-1} thiocyanate solution). Then the system was stoppered and mechanically shaken for 5 min. The PU foam was collected by vacuum filtration (filter paper $\phi = 2.0$ cm), washed with 0.2 mol l^{-1} KSCN solution, transferred to another polypropylene flask where zinc was, then, back extracted with 10.00 ml of doubly distilled water, after shaking for 10 min.

2.4. Spectrophotometric determination of zinc using PAR reagent

The following reagents were added into a volumetric standard flask of 10 ml: zinc(II) solution in the mass range of 0.40–10.0 μg , 2.50 ml of carbonate buffer and, 1.00 ml of PAR solution. Then, it was filled up with doubly distilled water and its absorbancy was measure at 496 nm.

3. Results and discussion

3.1. Effect of pH on the zinc sorption

The pH effect on the zinc sorption was studied. The results show that the extraction was maximum and constant in the range of pH from 2.0 to 10.0 as it can be seen in Fig. 1. The pH control was done using acetate buffer with pH 3.75–5.75, borate buffer pH 8.0 and carbonate buffer with pH 10.0. For pH 2.0, 3.0, and 12.0, solutions of hydrochloric acid and sodium hydroxide were used, respectively. The procedure proposed rec-

Fig. 1. Effect of pH on the zinc extraction.

ommends the extraction with the pH solution at 3.0 ± 0.5 because in such pH, cadmium is not extracted by the PU foam. At pH higher than 5.0, cadmium can also be extracted by the PU foam in the form of thiocyanate complexes.

3.2. Effect of the thiocyanate concentration on the zinc extraction

In order to test the thiocyanate concentration required for a quantitative extraction, 10.00 μg of zinc was extracted by PU foam changing the thiocyanate concentration from 0.02 to 2.00 mol l^{-1} . The results in Fig. 2 show that the extraction efficiency increases when the thiocyanate concen-

Fig. 2. Effect of thiocyanate concentration on the zinc extraction.

Fig. 3. Effect of the solution volume on the zinc extraction.

tration reaches a constant value over 0.15 mol l^{-1} KSCN, in which the system has the highest distribution coefficient ($D \geq 10^4$).

3.3. Effect of the solution volume on the zinc extraction

In order to evaluate the effect of the solution volume on the efficiency of zinc extraction were prepared several solutions with variable volumes of (5, 10, 25, 50, 80, 100, and 250 ml). All of them contained a fixed mass of $10.00 \mu\text{g}$ of zinc and the thiocyanate concentration of 0.20 mol l^{-1} . Then, zinc was extracted by using 55 mg of PU foam. The system was shaken for 10 min. The results show that the extraction was constant and quantitative for solutions in the range of volume from 5 to 80 ml. It can be seen in Fig. 3.

3.4. Effect of shaking time

The effect of the shaking time on the extraction efficiency was studied. The results show that 3 min are enough for a quantitative extraction of $10.00 \mu\text{g}$ of zinc and the thiocyanate concentration of 0.20 mol l^{-1} . In the procedure proposed, 5 min is recommended to guarantee a maximal extraction.

3.5. Amount of PU foam necessary for complete extraction

The effect of the amount of PU foam on the zinc extraction was also evaluated. It was found that 55 mg of PU foam is required as the minimal mass for a quantitative extraction of $60.00 \mu\text{g}$ of zinc.

Thus, PU foam in the range of mass from 55 to 65 mg is recommended to guarantee a complete extraction. This test was done using PU foam with a sorption capacity of 0.016 mmol of zinc/g of PU foam determined by the sorption isotherm [23].

3.6. Back extraction of zinc

Several solutions were tested for zinc back extraction by PU foam. The results show that zinc can efficiently be recovered using 10 ml of doubly distilled water, or 10 ml of ethanol solution (10% v/v), or 10 ml of nitric acid solution 0.10 mol l^{-1} , or 10 ml hydrochloric acid solution 0.10 mol l^{-1} . The back extraction with water was chosen because it was more convenient for spectrophotometric measurements. The carbonate buffer showed a poor result. Cadmium complexes are not back extracted with water and, in this case, a nitric acid solution must be used.

3.7. Zinc separation from cadmium

Zinc can be separated from large amounts of cadmium. However, at pH higher than 5.0 and the thiocyanate concentration up to 0.30 mol l^{-1} , cadmium in the form of thiocyanate complexes can also be extracted by the PU foam. Thus, the pH recommended for the separation of zinc from cadmium, is at 3.0 ± 0.50 and thiocyanate must be in the range of concentration from 0.15 to 0.20 mol l^{-1} . Table 1 show the pH effect on the separation of zinc from cadmium.

In order to test the separation procedure efficiency for spectrophotometric determination of zinc with PAR reagent, several amounts of zinc (2.00, 4.00, 8.00, 12.00, and $16.00 \mu\text{g}$) were mixed with $1000.00 \mu\text{g}$ of cadmium(II) and the procedure proposed in Section 2 was applied. The

Table 1
Separation of zinc (10.00 µg) in the presence of several amounts of cadmium

Cadmium present (µg)	Zinc extracted at pH 3.00	Cadmium extracted at pH 3.00	Zinc extracted at pH 5.0	Cadmium extracted at pH 5.0 (µg)
200.00	99%	<LD	99%	45.88 (22.94%)
500.00	98%	<LD	98%	72.39 (14.48%)
1000.00	99%	<LD	98%	199.0 (19.90%)
2000.00	98%	6.66 (0.33%)	90%	315.50 (15.78%)
3000.00	94%	11.59 (0.38%)	87%	358.10 (11.94%)
5000.00	90%	31.29 (0.63%)	85%	870.00 (17.40%)

LD, detection limit. PU foam amount: 60 mg [SCN⁻]: 0.20 mol l⁻¹.

Zn and Cd were back extracted with nitric acid solution and determined by ICP–AES.

amount of zinc recovered was plotted on the *y*-axis and the amount of zinc added on the *x*-axis. The linear equation resulted in the followings data: the angular coefficient was 1.022 ± 0.033 and the linear and correlation coefficient were 0.044 ± 0.125 and 0.9997, respectively. These data show the separation efficiency of the method proposed.

3.8. Separation of zinc from other elements

Solutions containing 10.00 µg of zinc(II) and different amounts of several cations were prepared and the efficiency of the separation procedure was tested. The results show that at pH 3.0 and thiocyanate concentration of 0.20 mol l⁻¹, 10 µg of zinc can be perfectly separated from 5.0 mg of the followings ions: aluminum(III), calcium(II), magnesium(II), strontium(II), iron(II), nickel(II), and barium(II). Iron(III), copper(II), cobalt(II), and zinc(II) are extracted simultaneously. However, the iron(III) reduction with ascorbic acid and the use of citrate to mask copper(II) and cobalt(II) increase the selectivity of the zinc separation. Mercury(II), gallium(III) and lead(II) ions are also extracted by the PU foam in this medium. Nevertheless, these ions are not back extracted with water. The anions nitrate, chloride, sulfate, acetate, tartarate, thiosulphate, oxalate, fluoride, citrate, and carbonate do not affect the zinc extraction by the PU foam. Phosphate and EDTA must be absent. In this experiment all determinations of those elements were done using ICP–

AES analysis and/or X-ray fluorescence spectrometry to measure directly metal thiocyanate complexes on the PU foam.

3.9. Application

The analytical curves for the zinc(II)–PAR system was done according to the procedure described in Section 2. The system showed a calibration sensitivity [24] of 1.355 ml µg⁻¹ for a dynamic interval of application from 60 ng ml⁻¹ to 1.00 µg ml⁻¹, detection limit of 20 ng ml⁻¹ and a variation coefficient of 0.84%.

The analytical characteristics of the separation procedure are summarized in the Table 2. They were done based on the zinc extraction from 0.20 mol l⁻¹ thiocyanate solutions at pH 3.0.

The method proposed was applied to zinc determination in several cadmium salts. The accuracy and precision achieved were not significantly different from 95% confidence level those obtained by ICP–AES analysis (Table 3).

Cd(H ₃ CCOO) ₂ ·2H ₂ O	5.57 ± 0.01	5.63 ± 0.09

4. Conclusions

Zinc can be easily extracted by the PU foam in a wide range of pH and large thiocyanate concentration. However, for the separation of zinc from cadmium the pH and the thiocyanate concentration are critical.

The zinc recovered from PU foam with water is ideal for application of the analytical technique of determination used.

The pH and thiocyanate concentration control as well as the use of masking agents allowed an efficient and simple zinc separation procedure from many others elements.

The solid-phase extraction has two typical advantages over the solvent extraction: avoiding the manipulation of organic solvents, which are frequently toxic and eliminating common problem of emulsions. The PU foam is also commercially available at low price.

The separation method proposed is opportune, considering that the spectrophotometric determination of zinc traces in cadmium matrices is troublesome, could be also applied for determination of zinc by other analytical methods.

Abstract

A new method is described for the determination of antimony based on the cathodic adsorptive stripping of Sb(III) complexed with 2',3,4',5,7-pentahydroxyflavone(morin) at a static mercury drop electrode (SMDE). The reduction current of the adsorbed antimony complex was measured by 1.5th-order derivative linear-sweep adsorption voltammetry. The peak potential is at -0.51 V (vs. SCE). The effects of various parameters on the response are discussed. The optimized analytical conditions were found to be: supporting electrolyte, chloroacetic acid (0.04 mol/l, pH 2.3); concentration of morin, 5×10^{-6} mol/l; accumulation potential, -0.25 V (vs. SCE); scan rate, 100 mV/s. The limit of detection and the linear range were 7×10^{-10} mol/l and $1.0 \times 10^{-9} \sim 3.0 \times 10^{-7}$ mol/l Sb(III) for a 2-min accumulation time, respectively. This method has been applied to the determination of Sb(III) in steel and brass samples and satisfactory results were obtained. The adsorptive voltammetric characteristics and composition of the Sb(III)–morin complex were studied. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

The content of antimony in alloys has certain influences on its corrodibility, conductivity and tenacity, etc. Sensitive analytical methods to determine trace Sb(III) in alloys are needed for the study of materials sciences. Many methods for determining trace Sb are available, including spectrometry, fluorometry, etc. [1–3]. Electrochemically, antimony can be detected by polarography. In hydrochloric acid, the Sb(III) reduction wave is

located at -0.15 V, whereas in 1 mol/l sodium hydroxide it is at -1.25 V [4]. Hua and Gao [5] observed the Sb-hydrogen catalytic wave in an aqueous $\text{Na}_2\text{SO}_4\text{--CoSO}_4\text{--}(\text{C}_4\text{H}_9)_4\text{NBr}$ medium. This method may be used to determine Sb(III) in semiconductor materials at a level of 2.0×10^{-7} mol/l. In succinic acid buffer solution (pH 4), a complex polarographic wave which is formed by Sb(III) and cupferron was observed by Donoso. The detection limit of this AC polarographic method is 2.0×10^{-6} mol/l Sb(III) [6].

The development of adsorptive cathodic stripping voltammetry (ACSV) has allowed the determination of many trace metals including those

* Corresponding author.

that could not be determined by conventional anodic stripping voltammetry (ASV) [7–14]. ACSV has received increasing attention in recent years [15]. Apart from extending the scope of ASV, ACSV offers improved schemes for determination of metals which suffer from difficulties such as extreme redox potentials or poor selectivity. The first step in ACSV is the formation of the metal–ligand complex, followed by controlled interfacial accumulation of the complex onto the electrode during the depositing step and the reduction of the adsorbed metal complex by application of a negative going potential scan. The reduction current generated is a sensitive measure of the concentration of the metal. Thus, ligands that may be used for ACSV must form complexes with the metals of interest, the complexes thus formed must adsorb on the electrode and must be reducible. Several ligands including 8-hydroxyquinoline [7], *p*-dimethylaminophenyl-fluorone (*p*-DMPF) [8], gallic acid [9], and catechol [10] have been used to accumulate antimony as complexes by adsorption on the mercury electrode surface. It has been shown that antimony can be determined successfully in hair [8] and seawater [10] using one of these, but the sensitivity is not great and accurate analyses would require a deposition time of several minutes.

In our laboratory we have been investigating various preadsorptive voltammetric techniques utilizing a variety of organic complexing agents for trace and ultratrace metal determinations which both maximize sensitivity and selectivity [11,16,17]. We report here the trace determination of antimony by adsorptive cathodic stripping voltammetry (ACSV) using the complexing agent 2',3,4',5,7-pentahydroxyflavone (morin) [13]. We have found this technique to be both highly sensitive (detection limit of 7×10^{-10} mol/l with 2 min of accumulation time) and relatively unaffected by a variety of commonly interfering substances. The adsorptive voltammetric characteristics at a static mercury drop electrode (SMDE) were studied. This method has been applied to the determination of antimony in steel samples and satisfactory results were obtained.

2. Experimental

2.1. Apparatus

A model SDP-1 0.5th-order derivative polarograph (Jintan Analytical Instrument Factory) modified according to Ref. [18] (in order to add the 1.5th-order derivative technique mode) was used. It was coupled with a model LZ3-104 X–Y recorder (Shanghai Dahua Instrument Factory). The three-electrode system consisted of a model SH-84 SMDE (Department of Chemistry, Shandong University) as the working electrode, a platinum plate as the counter electrode and a SCE as the reference electrode. A model UV-3000 UV–visible spectrophotometer (Shimadzu) was used for spectrophotometry.

2.2. Reagents and solutions

A 1×10^{-2} mol/l stock solution of morin was prepared by dissolving an appropriate amount of morin (analytical-reagent grade) in ethanol (guarantee reagent). Solutions of other concentration for experiments were obtained by diluting the stock solution with ethanol. A 1×10^{-2} mol/l stock of antimony(III) was prepared by dissolving an appropriate amount of Sb_2O_3 (high purity

Fig. 1. 1.5th-order derivative plot: 0.4 mol/l chloroacetic acid–0.01 mol/l NaOH (pH = 2.3); $E_a = -0.25$ V; $t_a = 120$ s; $t_r = 30$ s; $v = 100$ mV/s; (1): 1×10^{-7} mol/l Sb(III); (2): 5×10^{-6} mol/l morin; (3): (1) + (2).

reagent) in a small amount of HCl and diluting with 1 mol/l of HCl solution. Standard solutions were obtained by diluting the stock solution with 1 mol/l HCl solution. Chloroacetic acid and NaOH were of analytical-reagent grade. All solutions were prepared using doubly distilled water.

2.3. Procedure

The supporting electrolyte was 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH. The solution containing Sb(III) and morin was deaerated for 10 min with pure nitrogen. The measurements were carried out after a preconcentration step, in which the solution was stirred during an accumulation time, t_a of 2 min at an accumulation potential E_a . After a rest period of 30 s, the response curve was recorded by scanning the potential in the negative direction with the 1.5th-order derivative technique. Each measurement was performed with a fresh drop with an area of the SMDE of 2.23 mm². All potentials were measured against the SCE.

3. Results and discussion

3.1. Adsorptive voltammetric characteristics of the Sb(III) complex with morin

In a solution of 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH (pH 2.30), no peak of 1×10^{-7} mol/l Sb(III) appears (Fig. 1(1)), but a peak (p_1) appears in the linear-sweep voltammogram of morin for $E_a = -0.25$ V at $t_a = 2$ min (Fig. 1(2)). The peak potential, E_{p1} , is -0.43 V. When a micro amount of Sb(III) is added to the solution containing morin, a new peak, p_2 , appears at a potential of -0.51 V (Fig. 1(3)). It seems reasonable to assume that the new peak results from the Sb(III) complex with morin. The peak-to-peak value of the 1.5th-order derivative plot, e'_{pp} , for p_2 is more sensitive than the peak current on the voltammogram of the reduction of the complex, i_p , so that all the measurements were performed using the 1.5th-order derivative technique. e'_{pp} of p_2 increases with the concentrations of Sb(III) and the e'_{pp} of p_1 decreases. When the concentration of

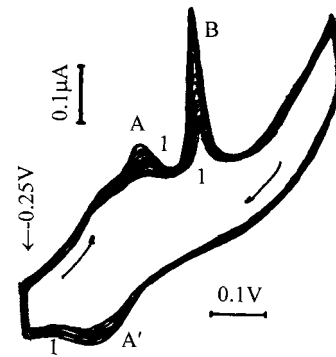

Fig. 2. Repetitive cyclic voltammograms for 8×10^{-6} mol/l morin (A,A') with 1×10^{-6} mol/l Sb(III) (B) in unstirred 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH (pH 2.3) solution. Conditions: scan rate, 100 mV/s; equilibrium, 30 s. The first scan is indicated by the number 1. Total time for the successive scans is 5 min.

Sb(III) is over 4×10^{-7} mol/l, the peak of morin, p_1 disappears. This means that the property of the free morin is not same as the morin in the Sb–morin complex; the latter is not reduced at potential of -0.43 V.

Fig. 2 shows cyclic voltammograms for 5×10^{-6} mol/l morin recorded in the presence of 1×10^{-6} mol/l Sb(III) in an unstirred 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH (pH 2.3) buffer solution. The cathodic peak current of the Sb–morin complex (peak B) at -0.51 V gradually increases with repetitive scans while the current of the free ligand morin (peak A) at -0.43 V simultaneously decreases. Since e'_{pp} values of different concentrations are not the same for long accumulation time, the complex on the surface of electrode should not reach saturation in this case. A peak is observed in the anodic branch. The peak A' which has correspondence to the ligand peak A at -0.31 V was observed to decrease with repetitive scans. The anodic peak of Sb–morin complex is not observed. This means the interfacial electrochemical reduction of the complex is an irreversible process.

The effect of e'_{pp} with accumulation time is shown in Fig. 3A for two different Sb(III) concentrations. Both curves show initially linear behaviour, with the curve of higher concentration showing saturation more rapidly. The i_p and e'_{pp}

Fig. 3. The effect of accumulation time (A) and potential (B) on the e'_{pp} of the Sb(III)–morin complex. A, 1, 5×10^{-8} mol/l Sb(III); A, 2, 1×10^{-7} mol/l Sb(III). Other conditions as in Fig. 1.

are proportional to the potential scan rate, v , and $v^{2.5}$, respectively. These results are characteristic of the reaction of adsorbed reactants on the electrode [19–21].

Fig. 4 shows the drop-time curves of the supporting electrolyte and that of solutions of morin and its complex with Sb(III). When morin is added to the supporting electrolyte, the drop-time decreases in the potential range from +0.1 to –1.1 V. In the presence of both morin and Sb(III), the shape of the drop-time curve is similar

Fig. 4. Drop-time curves. (1): 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH; (2): (1) + 1×10^{-4} mol/l morin; (3): (2) + 1×10^{-4} mol/l Sb(III).

to that of morin alone, but the curve is higher in the potential range from 0.0 to –1.1 V. These phenomena demonstrate the adsorptivity of morin and Sb(III) complex with morin.

3.2. The composition of Sb–morin complex

The absorbance maxima of morin are located at 250 and 340 nm for absorption spectra in 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH. When Sb(III) is added to the solution, a new absorbance peak at 420 nm appears and its intensity increases with concentration of Sb(III) until the maximum absorbance is reached at a ratio of 1:3 Sb(III) to morin (L). This is evidence for the formation of the complex of 1:3 composition, viz, SbL_3 . The value of e'_{pp} for the reduction of the complex adsorbed also has a maximum, when the ratio of the concentration of Sb(III) to that of morin is 1:3. This means that the complex in the bulk of the solution and the complex adsorbed on the surface of the electrode have the same composition.

3.3. Parameters affecting the adsorptive stripping behaviour

To check the applicability of the adsorption preconcentration behaviour of the Sb–morin complex at the SMDE for the determination of Sb(III) by ACSV, different parameters were investigated.

Table 1

Results of the determination of antimony in samples and recoveries of Sb(III) added to the brass samples

Sample	Antimony content ($\mu\text{g/g}$)			Relative standard deviation	Recovery (%)
	Standard	Found	Mean		
Steel-231	13.0	12.8, 13.2 14.1, 13.8 12.6, 12.9	13.3	5.8	
Steel-224B	25.0	23.8, 24.7 23.6, 24.5 24.9, 23.8	24.2	4.1	
Brass		32.5, 31.6 33.2, 31.9 31.8, 32.4	32.2	1.8	97.3

The dependence of e'_{pp} on the accumulation time, t_a , was examined for samples containing 5×10^{-8} mol/l (Fig. 3A,1) and 1×10^{-7} mol/l (Fig. 3A,2) Sb(III) in the range 0 ~ 180 s. The maximum peak height was observed at 120 s and 160 s for 1×10^{-7} mol/l and 5×10^{-8} mol/l Sb(III), respectively. Fig. 3B shows the effect of accumulation potential E_a on the e'_{pp} of the peak of the Sb–morin complex. The largest peak current was obtained in the range of $-0.2 \sim -0.27$ V and the e'_{pp} decreased at more negative potentials. The effects of pH on the e'_{pp} and E_{p2} of the Sb–morin complex were studied. Maximum peak current was reached in the pH range 2.2–2.4. The peak potential, E_{p2} , of Sb–morin complex was observed to shift linearly to more negative potential with increasing pH. The relationship of E_{p2} with pH is $E_{p2} = -0.39 - 0.05\text{pH}$. The morin concentration had a pronounced effect on the adsorptive stripping response. e'_{pp} increases linearly with the morin concentration at a concentration of less than 3×10^{-6} mol/l. The e'_{pp} tended to remain constant at a concentration of more than 3×10^{-6} mol/l.

3.4. Analytical application

It was found experimentally that the optimum composition of the supporting electrolyte is 0.04 mol/l chloroacetic acid–0.01 mol/l NaOH (pH 2.30); the optimum concentration of morin is

5×10^{-6} mol/l and the optimum accumulation potential is -0.25 V. Under these conditions, the linear range and the detection limit of 1.5th-order derivative linear-sweep adsorption voltammetry are $1.0 \times 10^{-9} \sim 3.0 \times 10^{-7}$ mol/l and 7.0×10^{-10} mol/l, respectively, when the accumulation time was 120 s. Reproducibility tests on 11 results at 1×10^{-7} mol/l Sb(III) showed a relative standard deviation of 3.2%.

Solutions containing 5×10^{-8} mol/l antimony and various amounts of foreign ions were prepared and measured according to the above procedure. The experimental results show that a 1000-fold excess of Ca^{2+} , Mg^{2+} , Co^{2+} , Ni^{2+} , Mn^{2+} , Ge^{4+} , Fe^{3+} , Fe^{2+} , Al^{3+} , a 600-fold excess of Zn^{2+} , Cd^{2+} , Cu^{2+} , a 120-fold excess of Cr^{3+} , V^{5+} , Sn^{4+} , a 30-fold excess of Bi^{3+} , a 10-fold excess of Ti^{4+} , a 2-fold excess of Pb^{2+} did not interfere with the determination of Sb(III) under the experimental conditions.

Standard steel samples (ca. 0.4 g) were dissolved with 20 ml of HCl (1 + 1) in a beaker [22,23], then 15 ml of HCl (5 + 1), 10 ml of 5% manganese sulfate solution and 150 ml of water were added. After boiling, 16 ml of 4% potassium permanganate solution was added and boiled for 2 min. The solution was allowed to settle for 5 min and filtered using quantitative filter paper. The precipitate was washed with hot water four times and dissolved with a solution of 8 ml HCl and 2 ml 30% H_2O_2 in a beaker. The solution

obtained by dissolving the precipitate was heated slowly until a large number of bubbles appeared, then the solution was boiled for 1 min. After cooling, the solution was diluted with hydrochloric acid (5 + 1) to 50 ml in a 50-ml volumetric flask and mixed thoroughly.

Samples of brass (ca. 0.4 g) were dissolved with 5 ml of nitric acid (1 + 1) in a beaker. When 10 ml of 8 mol/l sulfuric acid was added to the beaker, the solution was heated to dispossess nitrate radical and boiled to a paste. The same steps as above were followed.

A suitable volume was taken from the flask and transferred into a cell, and the pH of the solution adjusted with sodium hydroxide; the 1.5th-order derivative plot of current was recorded using the above procedure. 1.5th-order derivative plots of current were also recorded for the solution after adding a standard solution of Sb(III) to the sample solution under the same conditions. The amount of antimony in the sample solution can thus be determined from the resulting standard addition plot. Typical results obtained were summarized in Table 1.

Abstract

The goal of this study was to determine the kinetic parameters involved in the decomposition of 2-(5-methyl-4-isoxazolylamino)-*N*-(5-methyl-4-isoxazolyl)-1,4-naphthoquinone-4-imine (**1**) in aqueous solution and to identify the main degradation products. An isocratic HPLC assay was used to study the degradation rate of **1**. The products of hydrolysis were identified by comparison of their retention times with those of authentic samples. The amount of **1** and the two degradation products resulting from storage of **1** in various buffer solutions was followed in function of time by a reversed-phase HPLC stability-indicating method. The observed degradation rates followed pseudo-first-order kinetics at constant pH, temperature and ionic strength. The log *k*–pH-profile was constructed at 35°C from the first-order rate constants obtained from studies at pH values ranging from 0.88 to 10.80 ($\mu = 0.5$ M). Hydrolysis in the acidic and alkaline media resulted in the formation of two degradation products in each case. The pH-rate profile of **1** in buffer solution was adequately described using a four-term rate equation. The obtained pH-rate profile indicated specific acid–base catalysis with a region of maximum stability between pH 6.40 and 7.40 which can be adequate for formulations of **1**. © 1998 Elsevier Science B.V. Keywords: Isoxazolylnaphthoquinone; Degradation; Stability; Kinetics; pH-Profile

1. Introduction

The isoxazolylnaphthoquinones are a family of compounds that show important biological properties [1–6]. The preliminary results obtained with 4-aminoisoxazolyl-naphthoquinones against *Sta-*

phylococcus aureus [7] were so excellent that we focused our interest on 2-(5-methyl-4-isoxazolylamino)-*N*-(5-methyl-4-isoxazolyl)-1,4-naphthoquinone-4-imine (**1**), a derivative with 4-aminoisoxazol in positions 2 and 4 of the naphthoquinone ring.

Previous studies [8–10] have demonstrated that isoxazolylnaphthoquinones with the amino group in the 4-position of the isoxazole ring decompose in aqueous solution to give degradation products

with very similar structures, which required selective methods of analysis as HPLC.

Stability indicating analytical methods are of fundamental importance in stability studies. One part of the analytical method development is validation; once the method has been selected it is necessary to evaluate it under the conditions expected for real samples before being used for a specific purpose. It is essential to use well-characterized and fully validated analytical methods which yield reliable results that can be satisfactorily interpreted.

The objective of the present study was to determine the stability of **1** in aqueous solutions by HPLC. These data are necessary in the pharmaceutical field, since knowledge of solvent, pH, temperature, or a combination of these parameters under which drug substances are unstable, help to avoid degradation in drug formulation, storage, and some analytical conditions.

2. Experimental

2.1. Materials

The derivatives [2-(5-methyl-4-isoxazolylamino)-*N*-(5-methyl-4-isoxazolyl)-1,4-naphthoquinone-4-imine] (**1**), [*N*-(5-methyl-4-isoxazolyl)-4-amino-1,2-naphthoquinone] (**2**), and [2-hydroxy-*N*-(5-methyl-4-isoxazolyl)-1,4-naphthoquinone-4-imine] (**4**), were synthesized and purified according to a method previously reported [11,12]. The 9,10-anthraquinone (**5**) was purchased from E. Merck and

Fig. 1. HPLC chromatograms showing the separation of degradation products **2** and **4** from the peaks **1** and **5**.

purified by successive sublimation [13]. All the other chemicals, including buffer components, were of analytical-reagent grade. Hydrochloric acid, citric acid, sodium hydrogen phosphate, potassium dehydrogen phosphate, sodium hydroxide and sodium hydrogen carbonate buffer solution with varying pH were used in all experiments [14]. These solutions were adjusted to a total ionic strength (μ) of 0.5 M with sodium chloride [15].

Methanol of HPLC-grade was supplied by Sintorgan[®] (Buenos Aires, Argentina). Distilled-deionized water with a Milli Rho Milli-Q System was used for the preparation of all the solutions and the mobile phase.

2.2. HPLC system

The HPLC system consisted of a solvent delivery pump (Konik 500G), a 150×4 mm column packed with $5.0 \mu\text{m}$ octadecylsilane (MicroPak MCH-5-Varian), an UV detector (UVIS-200 variable-wavelength) and a Konik model SP-4290 Integrator.

A flow-rate of 0.9 ml min^{-1} was maintained and the effluent was monitored at 241 nm with a detector sensitivity of 0.02 AUFS.

The mobile phase consisted of methanol:water (75:25 v/v), and the mixture was filtered through a $0.45 \mu\text{m}$ pore nylon membrane (Schleicher and Schuell) and deaerated under reduced pressure. All the analyses were performed under isocratic conditions at room temperature.

The sample volume was $20 \mu\text{l}$ (Rheodyne Model 7125 injector fitted with a $20 \mu\text{l}$ loop).

2.3. Other instruments

All analytical weighings were performed with an Electrobalance model G with a sensitivity of 2×10^{-4} mg (Cahn Instrument, CA). A pH meter (Orion Model SA 520) fitted with combination electrodes was used for all pH measurements. The pH meter was standardized with the combination of standard buffer solutions at room temperature.

For the kinetic measurements, a constant tem-

perature bath was regulated by a Haake F₃ thermostat with $\pm 0.1^\circ\text{C}$ precision.

2.4. Kinetic method

Sample solutions were prepared by dissolving **1** in suitable amounts of methanol and adjusting to volume (25 ml) with the appropriate buffer, sonicated until completely dissolved, and then 1.8 ml aliquots of these solutions were transferred to 14 tightly closed snap test-tubes. The reaction flasks were immediately placed in a water bath maintained at $35 \pm 0.1^\circ\text{C}$ for up to 7 h. At appropriate time intervals, two flasks were removed from the water bath and 1 ml aliquots of the reaction mixture were added to the volumetric flask containing the internal standard stock solution and immediately brought to a known volume with these solutions in order that the analytical concentration were within the linear range of detection. A fixed volume ($20 \mu\text{l}$) of these samples was injected onto a reversed-phase column at room temperature. Concentration of **1** was determined in duplicate by a stability indicating HPLC method.

2.5. Ionic strength effect studies

The effect of the ionic strength on the hydrolysis of **1** was determined by keeping the pH, buffer concentration, drug concentration and temperature constant, and varying only the ionic strength by addition of different amounts of sodium chloride.

3. Results and discussion

3.1. Analytical results-chromatograms

The 9,10-anthraquinone (**5**) was used as an internal standard for quantification purposes; a stock solution ($3.70 \times 10^{-5}\text{M}$) was prepared in methanol and stored at $+4^\circ\text{C}$ for a maximum period of 24 h. The use of internal standard reduces the variability due to transient changes in the detector sensitivity as well as HPLC column

Scheme 1.

time, 4.61 min.), **2** (peak 2; retention time, 2.69 min), **4** (peak 4; retention time, 2.03 min.) and internal standard **5** (peak 5; retention time, 7.75 min). These results permitted the analysis of intact **1** in the presence of its hydrolytic degradation products.

The identity of **2** and **4** was verified by comparison of their retention time with that of authentic samples.

A total chromatographic time of 15 min, including post-run-re-equilibration time, was needed.

3.2. Method validation

The essential parameters to ensure the acceptability of the performance of an analytical method are sensitivity, repeatability, reproducibility, precision, percent recoveries, minimum detectable quantity, minimum detectable concentration, limit of detection and limit of quantitation [16–21].

The linearity of the analytical method was determined by mathematical treatment of the results obtained by analysis of eight standard solutions with varying concentrations of analyte. The regression line was calculated by the least-squares

method of peak area ratio versus analyte concentrations. The regression equations derived from the least-squares method, the correlation coefficients, limits of detection (LOD) and limits of quantification (LOQ) are shown in Table 1. The statistical data evidences the negligible scatter of the experimental points with respect to the regression line. Relative response factors were calculated from the slopes of the corresponding calibration curves. Triplicate samples were run for each concentration.

The range of the analytical method for compounds **1**, **2** and **4** was determined and expressed as 0.8–28.4 $\mu\text{g ml}^{-1}$.

The sensitivity of the method was calculated for each derivative as the slope of the calibration line; the results obtained were 8.3×10^{-2} , 5.42×10^{-2} and 7.97×10^{-2} $\mu\text{g ml}^{-1}$ for **1**, **2** and **4** respectively. These results demonstrate the suitability of the method to measure small decreases in the active ingredient.

The repeatability of the chromatographic procedure was assessed within short intervals of time at a concentration of 12.00 $\mu\text{g ml}^{-1}$. The CV using peak area concentration measurement was $\sim 1.8\%$ (nine injections). Under these condi-

Fig. 3. pH-Rate profile degradation kinetics of **1** at various pH values, 35°C. The points are experimental values, and the solid line is the theoretical curve calculated from Eq. (1).

tions the average retention time (t_R) for **1** was 4.89 min, and the deviation in t_R for each injection was < 2%.

The reproducibility of the assay method for **1** was evaluated at two different concentrations (9.04 and 12.05 $\mu\text{g ml}^{-1}$), six times within one day at time intervals of 1 h. The values obtained within day were $9.37 \pm 0.04 \mu\text{g ml}^{-1}$ ($n = 6$, CV 0.47%) and $12.68 \pm 0.08 \mu\text{g ml}^{-1}$ ($n = 6$, CV 0.61%).

The precision of the analytical procedure was determined by making five consecutive injections of derivative **1** at two different concentrations (6.21 and 11.8 $\mu\text{g ml}^{-1}$). The results indicate excellent precision with CVs < 1.2%.

The analytical recovery of the method was determined using four different concentrations for **1** and synthetic mixtures of **1** with its decomposition products. The average recovery was calculated as the percent of observed concentration divided by the known concentration. Determinations were performed in quintuplicate and by direct comparison with the internal standard sample (**5**). The concentrations of **1** were in the range 3.1–18.4 $\mu\text{g ml}^{-1}$. Table 2 shows the results obtained for intact **1**, which indicates the effectiveness of the analytical method with relative standard deviations < 1.8%. The mean recovery of **1** was found to be $103.9 \pm 1.1\%$ ($n = 20$).

Table 5
Rate constants for compound **1**

Compound	k_1 (h ⁻¹)	k_H (M ⁻¹ h ⁻¹)	k_O (h ⁻¹)	k_{OH} (M ⁻¹ h ⁻¹)	pK _a
1	0.292	0.445	6.7×10^{-3}	2500	3.70

The recovery experiments for four synthetic mixtures of **1**, and its decomposition products were performed by adding varied amounts of authentic drug **1** to a constant concentration of degradation products **2** and **4** Table 3. The percentage mean recovery for **1** in mixtures with **2** was 103.60 ± 0.83 ($n = 20$) and in combination with compound **4** was 105.7 ± 1.0 ($n = 20$). In both cases the recovery of **1** scarcely varied with concentration, in presence of the degradation products.

Minimum detectable quantity and minimum detectable concentration for derivative **1** were 94

ng and $0.12 \mu\text{g ml}^{-1}$ respectively. These results are the mean value of five determinations.

3.3. Reaction order and observed rate constants

The kinetics of the degradation of **1** was studied by following the disappearance of the unchanged compound as a function of time. The results indicated that in aqueous solutions it follows pseudo-first-order kinetics under the constant conditions of pH, temperature, and ionic strength.

Typical first-order plots are shown in Fig. 2 at different pH values. The rates of hydrolysis were determined from the slopes of logarithmic residual concentration of **1** and storage time plots by a least-squares regression analysis. For all the buffer solutions studied for the degradation of **1**, the regression lines were linear with $r > 0.99$.

The buffer systems employed, the observed rate constants and the t_{90} and $t_{1/2}$ values are given in Table 4. The results obtained show that compound **1** reacts according to Scheme 1. At acidic and neutral pH, **1** gives the products **2** and protonated 4-amino-5-methylisoxazole (**3**). In basic pH, **1** undergoes hydrolysis to generate compounds **3** and **4**.

3.4. pH-rate profile

The pH-rate profile of **1** was obtained by plotting the logarithm of k_{obs} versus the pH of solutions at constant μ of 0.5 and at 35°C. The pH dependence of the pseudo-first-order rate constant for degradation of **1** over the pH range 0.88–10.80 is illustrated in Fig. 3. The shape of the curve indicates that in pH < 2.5 solutions, the degradation of **1** is pH independent. The inflection point in the region of pH 3.00–4.00 is due to the dissociation equilibria of **1** with a pK_a of 3.70 which was obtained as the fitted parameters Table

Fig. 4. Plots of $\log k_{\text{obs}}$ vs. the square root of ionic strength for the hydrolysis of **1** at pH 3.86 and 35°C.

5. At pH values < 5.5, specific acid catalysis occurs. In the range of pH 6.00–8.00, **1** was more stable than in other pH regions and the degradation was mainly due to the effect of spontaneous or water catalysis. The optimal stability observed was at a pH of ~ 6.95. At higher values, only the specific base catalysis was significant and in consequence the pH-rate profile exhibited both specific acid and specific base catalysis with neutral pH values optimum for stability. The overall rate equation for the degradation of **1** is:

$$k_{obs} = k_1 \frac{[H^+]}{[H^+] + K_a} + k_H [H^+] + k_o + k_{OH} [OH^-] \quad (1)$$

In Eq. (1) k_1 is the rate constant for water addition to the protonated imine, $[H^+]/[H^+] + K_a$ is the fraction of the compound in the protonated form, k_H is a second-order rate constant for the hydrogen ion catalyzed degradation, k_o represents the rate constant for the uncatalyzed reaction and k_{OH} is the specific basic catalysis rate constant.

The solid curve drawn in Fig. 3 was constructed from the apparent rate constants summarized in Table 5 Eq. (1). The excellent agreement observed between the experimental results and those calculated from this figure indicates that Eq. (1) adequately describes the observed pH effect on the degradation kinetics of **1**.

3.5. Salt effect

The effect of μ on the degradation of **1** was studied at pH 3.86 (citric acid–sodium hydrogen phosphate buffer) at $35.0 \pm 0.1^\circ\text{C}$. The value of μ was varied by addition of sodium chloride. At μ values of 0.5, 1.0 and 1.5 the k_{obs} values were 0.123, 0.123 and 0.124 h^{-1} . The plot of $\log k_{obs}$ versus $\mu^{1/2}$ Fig. 4 indicates that no kinetic salt effect was observed at pH 3.86 for the degradation of **1** [22].

4. Conclusions

The HPLC method developed in this study has proved to be simple, accurate, precise and offers adequate sensitivity and selectivity for the analysis of derivative **1** in presence of its degradation

products. The validation procedure was carried out using compound **1** in a high degree of purity and synthetic mixtures of the intact drug with its degradation products.

The pH-rate profile indicated that the maximum chemical stability of **1** is in the range of 6.40–7.40. The t_{90} value calculated from the pH-rate profile in the valley region was 14.8 h.

The quality parameters here determined support the suitability of the method as a stability-indicating assay.

Abstract

A novel thin-layer amperometric detector (TLAD) based on chemically modified ring-disc electrode and its application for simultaneous measurements of nitric oxide (NO) and nitrite (NO₂⁻) in rat brain were demonstrated in this work. The ring-disc electrode was simultaneously sensitive to nitric oxide (NO) and nitrite (NO₂⁻) by modifying its inner disc with electropolymerized film of cobalt(II) tetraaminophthalocyanine (polyCoTAPc)/Nafion and its outer ring with poly(vinylpyridine) (PVP), respectively. The ring-disc electrode was used to constitute a novel TLAD in radial flow cell for simultaneous measurements of NO and NO₂⁻ in rat brain combined with techniques of high performance liquid chromatography (HPLC) and in vivo microdialysis. It was found that the basal concentration of NO in the caudate nucleus of rat brain is lower than 1.0×10^{-7} mol l⁻¹, NO₂⁻ concentration is 5.0×10^{-7} mol l⁻¹ and NO exists in brain maybe mainly in the form of its decomposed product. © 1998 Elsevier Science B.V. Keywords: Cobalt(II) tetraaminophthalocyanine; Poly(vinylpyridine); Nitric oxide; Nitrite; Thin-layer amperometric detector; In vivo microdialysis

1. Introduction

Nitric oxide has received extensive attention due to its important and mysterious physiological

roles [1–3]. It has been identified as an endothelium-derived relaxing factor [EDRF] in the vascular system [4], a neurotransmitter in the nervous systems [5] and a cytotoxic factor in the immune systems [6]. Moreover, it has been believed to be related to some tissue damage such as ischaemia/reperfusion tissue damage [7] and excitatory neuronal death [8].

There is an extensive growth in the studies of NO in the fields of life science and its related subjects [9,10]. Many techniques have been developed for the evaluation of NO levels in biological materials. These include spectroscopic and electrochemical methods [11–16]. Also, some indirect methods have been used for this purpose based on NO synthesis processes and its related physiological effects such as measurements of L-citrulline or nitrite [17] or bioassay of the relaxation of blood vessels [18], stimulation of guanylate cyclase [19] and inhibition of platelet aggregation [20]. NO, similar to some other neurotransmitters coexisting with their related metabolites [21], exists in biological systems not only in the form of itself but also its decomposed products, of which NO_2^- is the dominate [22]. Consequently, effectively simultaneous measurements of NO_2^- and NO would not only offer a better approach to evaluate NO levels in biological system but also provide an effective means to investigate NO physiological reactions and roles. However, in most cases, NO_2^- , the main decomposed product of NO, interferes with NO detection, and vice versa. Therefore, it is difficult to determine NO sensitively in presence of NO_2^- and vice versa. To our knowledge, little effort has been made to circumvent this problem up to now. The novel amperometric detector based on chemically modified ring-disc electrode in the radial flow cell is in the equivalent to series daul electrode in a thin-layer cross flow cell. However, the high collection efficiency with the ring-disc electrode makes it possible to achieve high selectivity such as the determination of an analyte in the presence of an interferent and then can meet the requirements mentioned above.

Metal phythalyocyanines (MPc) such as CoPc, NiPc and CuPc have received a great deal attention due to their catalytic behaviors based on the redox centre in the polymer [23–25]. A greatly reduced oxidation potential can be obtained for a variety of organic compounds such as cysteine, mercaptosuccinic acid, glutathione, oxalic acid and catechol at the electrode modified with MPc [26,27]. Also, they can be used as an electron transfer mediator in the enzyme-based biosensors [28]. However, little has been studied on the deter-

mination of NO with the electrode based on the electropolymeric film of CoTAPc.

This work demonstrated a novel TLAD in the radial flow cell simultaneously sensitive to NO and NO_2^- based on a chemically modified ring-disc electrode with polyCoTAPc/Nafion and PVP. The TLAD was employed for simultaneous measurements of NO and NO_2^- in rat brain combined with the techniques of in vivo microdialysis and high performance liquid chromatography (denoted microdialysis/HPLC–TLAD). This combined technique provide an effective means to assay the levels of NO and its main decomposed product, NO_2^- , in rat brain simultaneously.

2. Experimental

2.1. Chemicals

NO saturated solution was prepared by bubbling NO gas through deoxygenated distilled water for 30 min and its saturation concentration is 1.9 mmol l^{-1} [29]. NO serial standard solutions were obtained by diluting NO saturated solution. NO standard solutions could also be obtained by NO producing systems developed in our laboratory [30]. The prepared solutions were kept in a glass flask with rubber septum, stored in a light-free place and could assure to be stable for 3 h.

Cobalt(II)-4,9,16,23-tetraaminophthalocyanine monomer ($\text{C}_{32}\text{H}_{20}\text{N}_{12}\text{Co}$) was synthesized according to the procedure described by Achar et al. [31] and characterized by FT-IR. The structure of CoTAPc was given in Fig. 1. Its FT-IR spectra are (KBr, cm^{-1}): 3281, 3183, ($\gamma_{-\text{NH}_2}$), 1345, 1258, 1060, 1090, ($\gamma_{\text{C}-\text{N}}$), 826, 868 (δ_{Ar}), 735, 752, 950, 1607 ($\delta_{\text{N}-\text{H}}$). PVP was prepared by mixing vinyl pyridine and 1% dimethylbenzoyl peroxide in a little tube. After reacted for 12 h at 80°C , PVP solid was obtained, and its solution was obtained by dissolving PVP solid in methanol. Tetra-*n*-butylammonium perchlorate (TBAP) was prepared by the reaction of tetra-*n*-butylammonium bromide with sodium perchlorate. Artificial cerebrospinal fluid (ACSF) containing 140 mmol l^{-1} NaCl, 2.4 mmol l^{-1} KCl, 1.0 mmol l^{-1} MgCl_2 , 1.0 mmol l^{-1} CaCl_2 ,

5.0 mmol l⁻¹ NaHCO₃ and 0.6 mmol l⁻¹ ascorbic acid was prepared. Phosphate buffer solution consisting of 0.01 mol l⁻¹ Na₂HPO₄ and 0.02 mol l⁻¹ KH₂PO₄ was prepared and was adjusted to pH 5.0. Nafion (5% solution in ethanol) was purchased from Aldrich, Sodium nitrite was obtained from Shanghai First Chemical Factory, its solution was prepared daily. Other chemicals were of at least reagent grade quality and used as received. The aqueous solutions were prepared with doubly distilled water.

2.2. Apparatus

Electrochemical experiments were performed with an Electrochemical Analyzer (CHI832) from USA in conjunction with a computer in which data and voltammograms were recorded and stored. A platinum disc ultra microelectrode was fabricated by sealing a platinum wire (15 μm) into a glass pipe and used as a working electrode while investigating the mechanism of the responses of NO and NO₂⁻ at the modified electrodes. Prior to experiments, the fabricated ultra microelectrode was polished with diamond paste and rinsed thoroughly with acetone and water. Its electrochemical pretreatment was carried out by scanning the potential from -0.30 to +1.30 V for ten cycles

Fig. 1. Structure of CoTAPc

in a 0.5 mol l⁻¹ sulfuric acid solution. A platinum wire was used as counter electrode and potential was referenced to a Ag/AgCl (saturated KCl) electrode. A TLAD, as shown schematically in Fig. 2, was composed of a three-electrode system, Teflon cell body and Teflon pad. A ring-disc electrode from Bioanalytical Systems (BAS) in Japan consisting of dual electrodes (inner disc and outer ring) was used as dual working electrodes, stainless steel was served as counter electrode, and potentials applied with Biosensing Unit (BS-1, BAS, Japan) were referenced to a Ag/AgCl electrode. Microdialysis was accomplished using a CMA 101 microdialysis pump and a microdialysis probe (CMA12, dialysis length, 3 mm; diameter, 0.24 mm; all gifted from BAS, Japan). The collected dialysate was separated with liquid chromatograph (HP1090, USA) coupled with a Synchronpak SAX-300 column from USA.

2.3. Electrode modification

The ultramicroelectrode was allowed to air-dry and then placed into a dimethyl sulfoxide (DMSO) solution containing 5.0×10^{-3} mol l⁻¹ CoTAPc monomer and 0.1 mol l⁻¹ TBAP employed as the supporting electrolyte. Cycling potential between -0.20 and +0.90 V was applied to the working electrode at a scan rate of 100 mV s⁻¹ until a stable voltammetric response was obtained. The electrode was then rinsed with acetone and distilled water and allowed to air-dry. The polyCoTAPc modified ultramicroelectrode was further coated twice with a thin film of Nafion by depositing 1 μl of a 1% Nafion solution on the electrode surface each time and allowing ethanol to air dry.

A PVP coated ultramicroelectrode was constructed by placing 2 μl of 0.1% PVP solution on the surface of a dried ultramicroelectrode and allowing the solvent to evaporate.

2.4. Voltammetric responses of NO and NO₂⁻ at the modified ultramicroelectrodes

Prior to NO measurements, the polyCoTAPc/Nafion modified ultramicroelectrode was placed in a phosphate buffer solution (pH 5.0) and cyclic

Fig. 2. Schematic diagram of a TLAD

voltammetry was performed in the potential range 0.00 to +1.00 V until a steady-state cyclic voltammetric and differential pulse voltammetric (DPV) responses were obtained. The response of NO at the CoTAPc/Nafion modified ultramicroelectrode were carried out using DPV method, a sensitive and highly distinguished technique, in a hermetic deoxygenated phosphate buffer solution. DPV was performed at a scan rate of 5 mV s^{-1} and 5 pulses per s (pulse height 50 mV, pulse width 60 ms). The response of NO_2^- at a PVP coated ultramicroelectrode was studied by using cyclic voltammetric technique in a phosphate buffer solution.

2.5. Modification of the ring-disc electrode

The inner disc of the ring-disc electrode was modified with polyCoTAPc and Nafion in the same fashion mentioned in Section 2.3. After modified with polyCoTAPc, the inner disc was further coated with Nafion by placing $15 \mu\text{l}$ of 1% Nafion on the electrode surface and allowing the

solvent to evaporate. Prior to coating PVP on the outer ring, it was necessary to rinse it thoroughly and carefully with acetone and distilled water so that the remains such as CoTAPc monomer would be washed away. The outer ring was modified with $5 \mu\text{l}$ of 0.1% PVP solution in the mode mentioned in Section 2.3. The chemically modified ring-disc electrode was served as the dual working electrodes of the TLAD.

2.6. Responses of the system to NO and NO_2^-

Prior to injunction with HPLC, the responses of NO and NO_2^- at the TLAD were evaluated by using a technique of flow injection analysis (FIA). The operating potentials of the outer ring and inner disc were applied at +0.80 and +0.75 V, respectively. A deoxygenated phosphate buffer solution containing 0.1 mmol l^{-1} EDTA was served as a mobile phase. In order to estimate the in vivo concentrations of NO and NO_2^- , it was necessary to determine the in vitro recovery of the microdialysis probe which was performed as described in

the literature [32,33] and the linearity of the microdialysis/HPLC-TLAD. This was accomplished by placing the microdialysis probe in a known concentration of NO or NO_2^- solution and perfusing at a rate of $1.0 \mu\text{l min}^{-1}$. The collected dialysate was injected into the HPLC-TLAD system and served for analysis. The *in vitro* relative recovery could be determined by comparing the results of this experiment with those of an experiment run under similar conditions except that the standard solutions were not perfused with the microdialysis probe. The system linearity was tested in the same mode by using serial different concentrations of NO and NO_2^- .

2.7. *In vivo* brain microdialysis

Experiments were carried out in adult and male Sprague–Dawley rats (280–320 g) that were anesthetized with 125 mg g^{-1} urethane and fixed in a Koff stereotaxic frame. The microdialysis probe was stereotaxically implanted into the nucleus caudatus and then was perfused with ACSF solution at a constant flow rate of $1.0 \mu\text{l min}^{-1}$ using a microdialysis pump. Following 50 min equilibration period, the dialysate were collected every 25 min, and served for the measurements of NO_2^- and NO. At the end of this experiment the positions of the microdialysis probe and the carbon fiber microelectrode, with which *in vivo* voltammetry was carried out, were verified by standard histological procedure. The results were expressed to an average value.

3. Results and discussion

3.1. DPV responses of NO at a polyCoTAPc/Nafion modified ultramicroelectrode

Fig. 3 depicts the DPV responses of NO at a polyCoTAPc/Nafion modified and an unmodified ultramicroelectrode. As can be seen that NO could be oxidized at nearly $+0.70\text{V}$ and a higher response could be obtained at the polyCoTAPc/Nafion modified ultramicroelectrode compared with that at the unmodified ultrami-

croelectrode. This indicated that the polyCoTAPc/Nafion modified ultramicroelectrode shows a sensitive response to NO measurement.

CoPc was demonstrated to show a high catalytic activity for the oxidation of some organic compounds mentioned above based on the redox centre of $\text{Co}^{\text{III}}/\text{Co}^{\text{II}}$ in the polymer which facilitate the electron transfer between the electrode and the analyte. It has been reported that metal complexes could interact with simple diatomic molecules such as O_2 , CO and NO resulting in the formation of their adducts [10,34,35]. For example, the interaction between O_2 and ion(II) metal porphyrin has received extensive studies to elucidate the biological functions of haemoglobin and myoglobin *in vivo* [36]. Metallophthalocyanine complexes, similar to metalloporphyrin and metal salen complexes which are served to model

Fig. 3. DPV responses of NO at an unmodified (a) and a polyCoTAPc/Nafion modified ultramicroelectrode (b) in a deoxygenated phosphate buffer solution, NO concentration is $2.0 \times 10^{-6} \text{ mol l}^{-1}$.

Fig. 4. Cyclic voltammograms of $1.0 \times 10^{-4} \text{ mol l}^{-1} \text{ NO}_2^-$ at an unmodified (a) and a PVP modified ultramicroelectrode at a scan rate of 100 mV s^{-1} in a phosphate buffer solution.

enzyme sites, especially for enzymes of cytochrome P-450 families [37], could also interact with simple molecules [38]. In this work, the electrode process could be expressed as following:

NO, a highly active gas, could penetrate through Nafion film and form its adduct with CoTAPc. The formed adduct, poly[CoTAPc(NO)] could be oxidized easily resulting in a high current response at the electrode. The product of the electrochemical reaction, NO^+ can be fixed in Nafion film and not be further oxidized to produce NO_2^- .

3.2. Voltammetric response of NO_2^- at a PVP coated ultramicroelectrode

Fig. 4 shows the typical voltammetric responses of NO_2^- at a PVP modified and an unmodified ultramicroelectrode. The PVP coated ultramicroelectrode exhibits a sensitive response to NO_2^- compared with that at the unmodified ultramicroelectrode. The response of NO_2^- at a PVP coated ultramicroelectrode is about four times as that at the unmodified one.

PVP is a positively charged polymer due to protonation at its pyridine while in presence of acidic solution. The protonated PVP film attracts negatively charged ions such as NO_2^- resulting in a high response of NO_2^- at the PVP coated ultramicroelectrode. The processes of protonation and electrochemical reaction could be expressed as following:

3.3. Responses of the TLAD to NO and NO_2^-

Responses of the TLAD to NO and NO_2^- were studied by using FIA technique. Prior to the injection of the mixture of NO and NO_2^- solution, NO and NO_2^- solutions were injected separately to study the response of the TLAD to NO and NO_2^- , respectively. Fig. 5 depicts the FIA responses of the TLAD to $1.0 \times 10^{-6} \text{ mol l}^{-1} \text{ NO}_2^-$. As shown in Fig. 5, the inner disc shows no response to NO_2^- while the outer ring displays a good response, indicating that Nafion coated at the inner disc serves as an effective barrier to discriminate against NO_2^- . On injecting $1.0 \times 10^{-6} \text{ mol l}^{-1} \text{ NO}$ solution into the system, a high peak at the inner disc was observed attributed to NO oxidation while the outer ring shows no responses ($\text{S/N} > 3$). This suggests that a high response of NO could be obtained at the polyCo-TAPc/Nafion modified inner disc, and that NO oxidation product, NO^+ was effectively entrapped in Nafion film, not be further oxidized to produce NO_2^- , which can diffuse away from the inner disc and be oxidized at the PVP coated outer ring. It has been reported that NO could be oxidized at the electrodes modified with various gas-permeability films [12,13]. We also found in

this work that the PVP coated outer ring shows response to NO while NO concentration was higher than $1.0 \times 10^{-5} \text{ mol l}^{-1}$. This indicates NO can penetrate through PVP film and be oxidized at the outer ring. Therefore, in this case the response of the outer ring should be ascribed to the oxidation of NO_2^- and NO while injecting the mixture of NO and NO_2^- into the system. How-

Fig. 5. FIA responses of the TLAD to $1.0 \times 10^{-6} \text{ mol l}^{-1} \text{ NO}_2^-$. A and B are corresponding to the outer ring and inner disc of the ring-disc electrode, respectively. Phosphate buffer solution containing $0.1 \text{ mmol l}^{-1} \text{ EDTA}$ was served as a mobile phase with a flow rate of 1.0 ml min^{-1} .

Fig. 6. FIA responses of the TLAD to the mixture of $1.0 \times 10^{-6} \text{ mol l}^{-1} \text{ NO}_2^-$ and $1.0 \times 10^{-6} \text{ mol l}^{-1} \text{ NO}$. The mobile phase was deoxygenated thoroughly. Other conditions were the same as above.

ever, the sensitivity of the outer ring to NO is much lower than that to NO_2^- , and NO shows no observed response at the PVP coated outer ring when its concentration was lower than $5.0 \times 10^{-6} \text{ mol l}^{-1}$. Consequently, the current response at the outer ring could be ascribed to the oxidation of NO_2^- only in this work. Fig. 6 shows the responses of the TLAD to NO and NO_2^- mixture. In comparison with Fig. 5, we could find that NO at the concentration of $1.0 \times 10^{-6} \text{ mol l}^{-1}$ indeed shows no observed response at the PVP coated outer ring. Also, we could find that in Fig. 6, high responses at the inner disc and the outer ring were obtained due to the oxidation of NO and NO_2^- , respectively. This indicates that the TLAD based on chemically modified ring-disc electrode were simultaneously sensitive to NO and NO_2^- and could be employed for the simultaneously sensitive measurements of NO and NO_2^- .

3.4. Simultaneous measurements of NO and NO_2^- in the dialysate

The in vitro relative recovery of a microdialysis probe which is necessary to assess NO and NO_2^- real concentration in rat brain was determined by dialysis rate. Generally, the higher dialysis rate, the lower relative recovery. Also, the lower dialysis rate would cause the collected dialysate fouled

due to the longer collected time. The effect of the dialysis rate was investigated and found that the optimum dialysis rate is $1.0 \mu\text{l min}^{-1}$ in this work. The in vitro relative recovery of NO and NO_2^- , based on $1.0 \times 10^{-6} \text{ mol l}^{-1}$ NO and NO_2^- were determined to be an average of 25 and 30% ($n = 6$) at a dialysis rate of $1.0 \mu\text{l min}^{-1}$, respectively. Prior to the injection of the dialysate, standards of NO and NO_2^- were injected into the assay system for calibration and it was found that the system was linear with NO and NO_2^- concentrations ranging from 2.0×10^{-7} to $4.1 \times 10^{-6} \text{ mol l}^{-1}$ and 2.5×10^{-7} to $7.5 \times 10^{-4} \text{ mol l}^{-1}$ with correlation coefficients of 0.994 ($n = 12$) and 0.996 ($n = 10$), respectively. The calculated detection limits, at a signal-to-noise ratio of 3, of NO and NO_2^- were 1.0×10^{-7} and $1.2 \times 10^{-7} \text{ mol l}^{-1}$, respectively. Fig. 7 shows a typical chromatograms of the dialysate from the caudate nucleus. As can be seen no obvious peak attributed to NO oxidation was observed at the inner disc, indicating that the concentration of NO maybe lower than the detection limit of the system. To testify this result further, in vivo voltammetry was carried out with a carbon fiber microelectrode (CFME) which shows a high response to NO based on the polyCoTAPc and Nafion (whose detection limit is $5.0 \times 10^{-8} \text{ mol l}^{-1}$). The modified CFME also shows no obvious response to NO, indicating that NO concentration in the

Fig. 7. Typical chromatograms of the dialysate from the nucleus Caudatus of rat brain. The dialysate was separated using a Synchropak SAX-300. Other conditions were the same as above. (a): ascorbate, (b): nitrite.

nucleus caudatus is lower than its detection limit. Bedioui and other groups [39–41] have determined basal NO production by washed platelets with carbon microfibers coated with tetrakis(3-methoxy-4-hydroxyphenyl) nickel porphyrin and Nafion films as described previously [11] and they found that the basal NO level was not detectable due to its low concentration. Our present work also shows that the basal concentration of NO in the nucleus caudatus of rat brain, like in other biological tissues such as platelets and *Rhodobacter sphaeroides* [42] could not be detected either. The two peaks of the outer ring are ascribed to NO_2^- and ascorbate, respectively, and the concentration of NO_2^- is determined to be at an average of $5.0 \times 10^{-7} \text{ mol l}^{-1}$ ($n = 4$), which is in agreement with references [43,44].

4. Conclusion

TLAD, a novel detector in radial flow cell, was developed based on chemically modified a ring-disc electrode with polyCoTAPc/Nafion and PVP, which are sensitive to NO and NO_2^- , respectively. A new effective approach for simultaneous in vivo measurements of NO and NO_2^- was established by combining the TLAD with in vivo microdialysis and HPLC. This combined technique was employed for simultaneous and sensitive measurements of NO and NO_2^- in rat brain. It was found that the basal concentration of NO in the nucleus caudatus of rat brain is lower than $1.0 \times 10^{-7} \text{ mol l}^{-1}$, and NO_2^- concentration is $5.0 \times 10^{-7} \text{ mol l}^{-1}$. These results suggest that NO, a highly active free radical, exists in the region of rat brain maybe mainly in the form of NO_2^- , its main decomposed product. Although the combined technique developed in this work specifically for simultaneous measurements of NO and NO_2^- , it can potentially be applied to some other biochemicals such as neurotransmitters and their related metabolites in the biological materials. We will carry out detailed studies of NO release induced by ischaemia/reperfusion and other biochemicals determinations based on this combined technique, and these results will be reported soon.

Abstract

Polymer enhanced ultrafiltration (PEUF) is a newly developed method for the removal of heavy metals from aqueous solutions. This method was applied for the removal of mercury and cadmium with the presence of polyethyleneimine (PEI) as a water soluble polymer. After ultrafiltration experiments for metal–polymer mixtures, two separate streams, namely, retentate and permeate, former of which contains mainly metal–polymer complex and free polymer molecules while latter of which mainly contains free metal ions, were obtained. At the end of PEUF experiments, performance of operation was determined by concentration analyses which was achieved by atomic absorption spectroscopy (AAS) applied in a different way for permeate and retentate streams considering the effect of presence of polymer. For mercury analysis, cold vapor AAS was applied. It was observed that the presence of PEI did not affect the atomic absorption signal when 10% HCl was added to the sample solutions. For calcium and cadmium, flame AAS was used. It was observed that change in PEI concentration results in change in measured concentration of calcium and cadmium. Therefore, two new approaches were developed for accurate measurement of concentrations of calcium and cadmium. It was also observed that presence of other metals did not affect the accuracy of the measurement of a particular metal in the concentration range studied. © 1998 Elsevier Science B.V. Keywords: Polymer enhanced ultrafiltration; Heavy metal ions; Atomic absorption spectrometry; Data treatment

1. Introduction

During the past two decades, increasing attention has been focused on pollution of the natural environment. The threat of pollution of the environment by heavy metals is well known by now

[1]. Thus, stringent quality standards for waste water containing heavy metals have been enacted. With these more stringent standards, industries which previously discharged their effluent with minimal pretreatment are now being required to remove heavy metals down to very low concentrations. One promising method which may meet this requirement is Polymer Enhanced Ultrafiltration (PEUF) described previously in detail [2,3]. This

* Corresponding author. Tel.: +90 312 2102607; fax: +90 312 2101264; e-mail: lyilmaz@rorqual.cc.metu.edu.tr

method includes the addition of water soluble polymer which is followed by the ultrafiltration operation. The water soluble polymer are used to bind metals to form macromolecular complexes. This large molecule will be retained by the membrane in the retentate stream, while the non-complexed ions pass through the membrane to the permeate stream. In most of the previous studies, batch or semi batch ultrafiltration systems were employed to remove metals from aqueous solutions (almost all single metal solutions) using various polymers [4–14]. In our previous studies [2,3], continuous PEUF was applied for removal of mercury and cadmium, which are among the most toxic heavy metals, from single and binary metal containing solutions using polyethyleneimine (PEI) as a water soluble polymer and very high retentions of heavy metals were obtained by adjusting pH and loading ratio (i.e. metal/polymer ratio) values. In our previous study [2], it was also proved that retention is mainly dependent on metal/polymer ratio in the feed rather than their individual concentrations. The water used in industry may contain an excess amount of calcium and magnesium ions (i.e. hard water). Therefore, in many heavy metal containing waste streams, these ions may also exist in abundance. Since calcium and magnesium are Class A metals and have similar properties; one of them, calcium, was selected to investigate the possibility of complex formation with PEI, and the effect of calcium on mercury–PEI complex.

In feed and permeate streams of PEUF process, metal ions and polymeric ligand were present at varying concentrations. Accurate determination of heavy metal concentrations in these streams are very important for the evaluation of the performance of this method which was mainly determined calculating the retention of metal defined as:

$$R_i = 1 - \frac{C_{pi}}{C_{fi}}$$

where i is the metal ion, C_{pi} is the concentration of metal i in the permeate stream and C_{fi} is the concentration of metal i in the feed stream. Atomic absorption spectroscopy (AAS) has been one of the Environmental Protection Agency

Fig. 1. Results and calibration measurements.

(EPA) method of choice, for the elemental analysis of aqueous samples because of its utility, sensitivity and accuracy [15,16]. This method can rapidly determine metals in trace amounts. In the previous studies on the development of PEUF process for heavy metal removal [4–14], generally AAS was employed for the metal analyses. In these studies, effect of existence of other constituents such as polymeric ligands, surfactants and low molecular weight organics on the measured metal concentrations were hardly discussed. Various complexation enhanced ultrafiltration methods, including PEUF, were also employed as a preconcentration step for determination of trace heavy metals by AAS. In some of these studies, effect of complexation agents were mentioned. In one of these studies, it was found that no interferences due to the presence of dissolved surfactant i.e. Triton X-100 host micelles and 1-(2-pyridyl-

lazo)-2-naphthol, were observed during the analyses after applying micellar ultrafiltration method for removal of nickel, cobalt, copper, magnesium and zinc [17]. For determination of Cr(III) and total Cr, a chelating ion exchanger, polyamino phosphonic acid, was used for speciation and preconcentration of the sample and retention of Cr(III) [18]; optimization of process variables were performed to have accurate analyses results by flame atomic absorption spectroscopy and no interferences were observed during the analyses due to the existence of other metals such as calcium, cadmium, lead, zinc. In a study [19], which employs PEUF as preconcentration step, the conditions for the flame atomic absorption spectroscopy were investigated for the determination of metal ions. In this study, polyethyleneimine (PEI) and its thiourea derivatives were used as polymeric ligands. It was found that the presence of polymer affected the analyses of copper, cadmium, zinc and magnesium. As the polymer concentration increased in the range of 1–4%, decrease in absorbance was observed. To eliminate this effect, standard solutions were prepared under the same conditions with the sample solutions which contain polymer. In that study, no attempt was made to obtain true metal concentrations using data evaluation methods.

In the present work, it would be attempted to find suitable analyses conditions for determination of concentrations of mercury, calcium and cadmium using atomic absorption spectroscopy

after PEUF experiments which were performed for removal of mercury and cadmium from aqueous solutions. Effect of various sample preparation parameters were investigated. Effect of presence of polymer at various concentrations on measured metal concentrations were evaluated in detail. To compensate for the presence of polymer, modifications in application of the AAS method and in the data evaluation were attempted. Therefore, we may state that our aim is to widen applicability and accuracy of atomic absorption spectrometric techniques in determination of heavy metal ion concentrations especially for solutions which may contain water soluble complexing polymers and binary metal mixtures.

2. Experimental

2.1. Materials

In the ultrafiltration (UF) experiments and concentration analyses, polyethyleneimine with average molecular weight 50000 Da (Sigma), mercury nitrate ($\text{Hg}(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$, Merck), cadmium nitrate ($\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, Merck), calcium nitrate ($\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, Merck), sodium hydroxide (Merck), nitric acid (Merck), hydrochloric acid (Merck) and sodium tetraborohydrate (Merck) were used. Demineralized water of $18.2 \text{ M}\Omega \text{ cm}^{-1}$ obtained from water purification system (Millipore) used for dilution and preparation of feed solution. For the laboratory scale and pilot scale systems, different types of membranes were used. For the former, the membrane was Osmonics flat sheet (HG01) type having effective area of 0.0155 m^2 molecular weight cut-off (MWCO) 5000 Da; for the latter, it was Amicon spiral wound (S10Y10) type having effective area of 0.93 m^2 and MWCO 10000 Da.

2.2. Apparatus

The laboratory scale Osmonics SEPA UF cell and the pilot scale Amicon SP20 UF systems were employed for PEUF experiments which are described previously [2,3]. Philips 9200X AAS were used for analyses of metals used in PEUF experi-

Fig. 2. Effect of change in PEI concentration on determination of concentration of calcium by FAAS.

ments. Cold vapor atomic absorption spectroscopy (CVAAS) was applied for mercury analysis using Philips 9360X cold vapor system.

2.3. Methodology

Feed solutions at desired metal and PEI concentrations were prepared and stirred at 250–300 rpm for 2 h prior to UF experiments. For mercury experiments, studied PEI and mercury concentrations were in the range of 0.003–0.5% and 10–1000 mg l⁻¹, respectively, while, for cadmium and calcium experiments, those were 0.003–0.1 and 10–300 mg l⁻¹, respectively. In mercury and cadmium studies, it was observed that retention of metals was around 0.98 before the critical loading (g metal per g PEI) ratio at which decrease in retention starts [2,3]. Therefore, in permeate streams mercury and cadmium concentrations can be as low as 0.3 mg l⁻¹. On the other hand, as calcium did not form a complex with PEI, almost all calcium ions pass through the membrane [3]. Since molecular weight of polymer is much higher relative to MWCO point of membranes, it is expected that no polymer passes to the permeate

stream. Details of operation of PEUF process was given elsewhere [2,3]. Feed solutions at desired metal and polymer concentrations were prepared and stirred at 250–300 rpm for 2 h prior to ultrafiltration experiments and its pH was adjusted. During the ultrafiltration experiments; pH, temperature, feed flow rate and pressure difference was kept constant and monitored continuously. During an ultrafiltration run feed solution was circulated by means of the pump, then passed through the membrane. Separate retentate and permeate streams were returned to the feed solution tank to keep the feed concentrations constant. At certain time intervals, samples from both permeate and feed were taken to determine the metal concentration. Although feed solution was prepared for certain metal concentration, there were deviations from the prepared concentrations due to evaporation and/or taking samples from feed and permeate streams. Therefore, feed streams should also be analyzed.

Suitable concentration range detected in AAS for each metal varies and can be listed as follows according to the used systems i.e. CVAAS for mercury and air–acetylene for calcium and cad-

Fig. 3. Effect of change in PEI concentration on determination of concentration of cadmium by FAAS.

mium: mercury $0.01\text{--}50\ \mu\text{g l}^{-1}$, cadmium $0.05\text{--}3\ \text{mg l}^{-1}$ and calcium $0.2\text{--}20\ \text{mg l}^{-1}$ [20]. Exceeding these concentrations, calibration plot usually deviates from linearity. Therefore, sample solutions should be diluted before AAS analyses so that concentration of metal in the solutions is reduced to fall into these range.

For the determination of mercury concentration, CVAAS was employed as it is mentioned,

Fig. 4. Calibration curve for standard solutions of cadmium containing PEI.

since mercury is unique among the metallic elements due to its significant vapor pressure at room temperature ($0.16\ \text{kPa}$ at $293\ \text{K}$). Before employing CVAAS, various concentrations of HCl, such as 10% HCl (i.e. concentrated HCl was diluted ten times) added to sample solutions during the dilution to reduce all the forms of mercury in the solution to Hg^{2+} form. NaBH_4 solution was prepared by dissolving NaBH_4 and NaOH in demineralized water with concentrations of 1 and 0.1% w/v, respectively. The function of NaOH was to prevent the hydration reaction between NaBH_4 and water. Containing $10, 30, 40, 50\ \mu\text{g l}^{-1}$ mercury and the same amount HCl as in the diluted sample solutions, standard solutions were prepared. Then, calibration curve was determined by using these standard solutions and blank which includes demineralized water and HCl. In CVAAS method, mercuric ions in the samples can be reduced by NaBH_4 solution to elemental mercury. Mercury is swept out of the solution by N_2 (inert gas) to a long-path glass absorption cell where the atomic absorption of the mercury is measured at $253.7\ \text{nm}$.

For the cadmium and calcium analyses, acetylene–air flame AAS (FAAS) was used: For

Fig. 5. Calibration curve for standard solutions of cadmium containing PEI.

some cases, there was no need for dilution of sample solutions since the studied concentration was in the range of concentrations of standard solutions. For cadmium, concentrations of standard solutions are 1, 2, 3 mg l^{-1} , while for calcium, those are 4, 8, 15, 20 mg l^{-1} . Like mercury analyses, calibration curves were determined. Wavelengths of most sensitive absorption lines 422.7 nm and 228.8 nm for calcium and cadmium, respectively were employed.

Background correction was achieved by means of deuterium lamp.

3. Results and discussions

Since CVAAS and FAAS were employed for the metal analyses, the best analyses conditions were determined for both techniques and different metals.

3.1. Analysis of solutions without polymer

As it is mentioned, at the beginning of the analyses, calibration of spectrophotometer was performed using standard solutions and blank. Concentrations of standard solutions and their absorbance measurements are plotted in Fig. 1 for mercury. There is a linear relationship between absorbance and concentration which indicates that Beer's Law is valid within the concentration range used ($10\text{--}50 \mu\text{g l}^{-1}$). Linearity was also

proven by means of given equation which is $A = 0.00117 + 0.00388C$, where A is the absorbance, C is the concentration of mercury in terms of $\mu\text{g l}^{-1}$, with a regression coefficient 0.99976.

Similar calibrations were also carried out for calcium and cadmium and linear curves were obtained.

Therefore, it can be concluded that both CVAAS applied for mercury and FAAS applied for cadmium and calcium are suitable to analyze permeate stream which contains almost no PEI.

For each sample, three measurements were taken to see deviations in the signal taken from AAS. It was observed that variations between these measurements did not exceed 1%.

3.2. Analysis of solutions containing polymer

3.2.1. Cold vapor atomic absorption spectroscopy

Before mercury analysis in CVAAS, samples were acidified with HCl to dissociate mercury–PEI complex. However, the amount of acid added to the sample is crucial to eliminate the effect of the presence of PEI in the solution. Thus, experiments were carried out with the solutions of $30 \mu\text{g l}^{-1}$ mercury at different PEI concentrations and HCl concentrations (Table 1). In the range of 10–15% HCl, the errors were acceptable. These observations may be explained as follows: At lower HCl concentrations, the reduction of all mercury forms to Hg^{2+} form may not be achieved, whereas at higher HCl concentration, excess amount of HCl may cause sudden release of hydrogen gas which may result in the dilution of analyte plug. It may be concluded that in 10–15% HCl solutions, PEI was denatured or mercury–PEI complexes were broken completely. Based on these observations, further studies to investigate the effect of polymer presence, at varying mercury and PEI concentrations were carried out at fixed HCl concentration of 10%. Results were reported at Table 2; no significant change in atomic absorption signal was observed in the presence of PEI. There was one study [19] in literature which reports similar findings.

The effect of existence of PEI was also further eliminated by means of dilution from mg l^{-1} to $\mu\text{g l}^{-1}$ ranges after PEUF experiments which

Table 3
Corrected concentration results for solutions containing 0.01% PEI in Fig. 2

Concentration without correction (mg l ⁻¹)	Corrected concentrations (mg l ⁻¹) (with correction I)	Actual concentrations (mg l ⁻¹)
4.54	5.25	5.42
9.95	10.97	10.97
13.33	14.74	15.17

Table 4
Corrected concentration results for solutions containing nearly 0.01% PEI in Fig. 3

Concentration without correction (mg l ⁻¹)	Corrected concentrations (mg l ⁻¹) (with correction I)	Actual concentrations (mg l ⁻¹)
0.87	1.00	1.00
1.74	1.92	2.00
2.86	2.96	3.00

provides decreasing PEI concentrations in the sample solutions. In diluted samples, maximum PEI concentration was around 0.05%.

Since binary studies were carried out with mercury–calcium and mercury–cadmium pairs, the effect of one metal on analysis of other metal was also investigated. No interference was observed in the concentration range studied for all metals.

3.2.2. Flame atomic absorption spectroscopy

Since the presence of PEI in the solution may affect the some properties of the solutions, e.g. the viscosity, surface tension [19] and/or cause some interference in the absorption signals, the influence of PEI concentration on the analysis of calcium and cadmium was investigated: As it is seen in Figs. 2 and 3, increase in PEI concentration causes decrease in measured calcium, cadmium concentrations, respectively, then it gives a minimum value at certain PEI concentration and starts to increase slightly within the studied PEI concentration range. In a previous study [19], it was also found that the existence of PEI affected the analyses of cadmium, copper, nickel and zinc. However, linear decrease was observed in the metal concentrations, as polymer concentration increased. This is due to the difference in the studied PEI concentration ranges, 1–4% in that

study, while 0.005–0.1% in this study. This effect of PEI on atomic absorption signal has special importance for the feed stream in PEUF which mainly contains free PEI and/or metal–PEI complex. For permeate stream, this effect is not considerable because it was found that permeate stream contains almost no PEI from the viscosity measurements which gave that viscosity of the solution taken from permeate streams was approximately equal to that of water.

Therefore, it can be concluded that during the analysis of samples taken from the feed stream, the effect of PEI should be eliminated: at the end of the UF experiments, sample solutions were diluted to acceptable limits for detection of metals by AAS. Although their PEI concentration became smaller, PEI may still affect the analysis results. Therefore, two different approaches were applied to make a correction. First, standard solutions containing PEI the same amount as in the diluted samples and containing no PEI were prepared, separately. According to the first approach, the standard solutions containing PEI were used for the calibration, then, samples were analyzed. For the second approach, standard solutions of each metal containing no PEI were prepared and calibrated by plotting the absorbance versus concentration graphs. Concentrations of samples taken from feed streams and apparent concentra-

F3	230	1.51	1.67	1.62
F4	250	1.54	1.70	1.65
F5	275	1.54	1.70	1.65

tions of standard solutions containing PEI were determined by means of these graphs. Calibration curves were obtained plotting apparent concentrations of standard solutions containing PEI versus concentrations of standard solutions containing no PEI. Linear relationships were observed. Therefore, these relations were used for corrections for sample solutions containing PEI.

To check the accuracy of the second approach, same procedure was applied for solutions with known metal concentrations containing same amount of PEI, approximately 0.01%, as in the curves plotted in Figs. 4 and 5. As it is seen in Tables 3 and 4, actual concentration values and corrected concentration results found with second approach are nearly the same. This means that corrections made by this approach are good enough to eliminate the presence of PEI in the solution and to have accurate concentration results.

To show the applicability of these two approaches to PEUF systems, samples taken from feed stream at certain time intervals during PEUF experiments were analyzed using these methods

(Tables 5 and 6). As mentioned before, exact concentrations of metal in the feed stream were not known and may vary with time. For the second approach, same calibration curves, Figs. 4 and 5, for calcium and cadmium, respectively, were employed, since concentration of PEI in the diluted samples were the same as in the standard solutions containing PEI plotted in Figs. 4 and 5. As it is seen, concentration results obtained from two different approaches were approximately the same. This means that preparing calibration curves for different PEI concentrations like Figs. 4 and 5, analyses can be performed without using standard solutions containing PEI at each experiment. As it is seen in Tables 5 and 6, there was greater than 10% difference between corrected and uncorrected concentration results. Therefore, correction with these methods should be required to evaluate the real performance of UF system.

4. Conclusions

Recently, PEUF method has gained importance from the environmental point of view. Since per-

formance of PEUF mainly depends on the retention of metals, analysis methods are very important to determine the metal concentrations in permeate and feed streams correctly. AAS can be used successfully to determine the concentrations of mercury, calcium and cadmium at the end of PEUF experiments.

It was found that existence of one metal did not affect the analysis of other in binary metal solutions. Also, permeate streams contain almost no PEI therefore they cause no deviation from the correct atomic absorption signal. Therefore, there is no difficulty in determining the concentration in the permeate streams. However, for the samples taken from the retentate streams, the existence of PEI affects the analysis results. This effect can be eliminated by means of adding certain amount of HCl to the sample solutions for the mercury analysis in CVAAS. For cadmium and calcium analyses in FAAS, two approaches using standard solutions containing PEI and no PEI were applied to have corrected concentration results.

Abstract

The spectrofluorimetric determination of Fe^{3+} using salicylic acid as an emission reagent has been investigated by measuring the decrease of fluorescence intensity of salicylic acid due to the complexation of Fe^{3+} –salicylic acid. An emission peak of salicylic acid, which is decreased linearly by addition of Fe^{3+} , occurs at 409 nm in aqueous solution with excitation at 299 nm. The determination of the ferric ion is in the range 1×10^{-6} – 10×10^{-6} M Fe^{3+} (0.0558–0.558 $\mu\text{g}/\text{ml}$) and the detection limit is 5×10^{-8} M. The quenching effect of Fe^{3+} on the fluorescence intensity of salicylic acid may be considered on the basis of complexation between salicylic acid and Fe^{3+} . The effects of foreign ions were investigated. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Fluorescence quenching; Stern–Volmer equation; Salicylic acid; Fe^{3+}

1. Introduction

Spectrofluorimetry has been widely applied to determine many anions and cations. However, few spectrofluorimetric methods have been investigated for the determination of Fe^{3+} . This is probably due to the character of its paramagnetism or heavy atomic ion [1]. Some fluorimetric methods have been based on quenching phenomena. For example, one method reported the reduction of Fe^{3+} with hydroxylamine and the addition of fluorescent 2,2',2''-terpyridyl to form a chelate [2]. Iron, copper and cobalt ions, having unfilled d sublevels, and do not usually form

fluorescent chelates but can quench the fluorescence of chelates of aluminium, etc. and can be measured indirectly. Thus the quenching of aluminium 8-hydroxyquinoline can be used to measure clinically important ions, such as Fe^{3+} , Cu^{2+} and Co^{2+} [3].

Mori et al. proposed a sensitive and convenient fluorimetric procedure for the determination of iron using *o*-hydroxyhydroquinonephthalein as the fluorogenic reagent in the presence of Brij-58. Unfortunately, cations such as Al^{3+} , Cu^{2+} and Sn^{4+} interfered [4].

Recently, the use of 5-(4-methylphenylazo)-8-aminoquinoline for the fluorimetric determination of iron was reported [5]. Cha and Park reported spectrofluorimetric determination with 2-pyridine-carbaldehyde-5-nitro-ridyl-hydrazone in the pres-

* Corresponding author. Fax: +82 32 8722520; e-mail: kwcha@dragon.inha.ac.kr

ence of hexadecyltrimethylammonium bromide surfactant [6].

In this work, the fluorescence intensity of salicylic acid in the presence of Fe^{3+} was investigated. The change of fluorescence intensity of salicylic acid due to the interaction of Fe^{3+} –salicylic acid in an aqueous medium was measured. This phenomenon provided a sensitive and very simple determination method of Fe^{3+} in the absence of Fe^{2+} .

2. Experimental

2.1. Apparatus and reagents

All fluorescence measurements were made with a JOBIN YVON SPECTRO JY3-D spectrofluorometer using 1 cm quartz cells. The band passes were at 4 nm for both excitation and emission monochromators. The light source was a 150 W Xenon lamp.

Fe^{3+} and Fe^{2+} stock solutions (1.0×10^{-3} M Fe^{3+} and Fe^{2+}) were prepared by dissolving $\text{FeNH}_4(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$ and $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ with water. Salicylic acid solution (1.0×10^{-3} M) was prepared by dissolving salicylic acid (Sigma reagent) with 30% ethanol.

pH 8.5 buffer solution was prepared as follows: ammonium chloride (5.35 g of 0.1 M) was added to 1.2 ml of 14.8 M ammonium hydroxide solution, then diluted to 1000 ml with water. Analytical reagent grade chemicals and water obtained from a Millipore Milli-Q water purification system were used throughout.

2.2. Procedure

Salicylic acid solution (4 ml of 1.0×10^{-4} M) was added to a 100 ml volumetric flask, containing an appropriate volume of Fe^{3+} solution and 2 ml of pH 8.5 buffer solution, then diluted to the mark with water. The fluorescence intensity of the solution was measured at 409 nm, with excitation at 299 nm. The duration of each measurement is ca. 10 min. All fluorescence intensity measurements were corrected with blank solution. All experiments were performed at room temperature (22°C). The

quenching effect of oxygen was removed by passing nitrogen gas through the sample solution.

3. Results and discussion

3.1. Excitation and emission spectra of salicylic acid

The excitation and emission spectra of the sali-

Fig. 2. pH effect of solution on the fluorescence intensity of Fe^{3+} -salicylic acid. Fe^{3+} : 4.0×10^{-6} M; salicylic acid: 4.0×10^{-6} M.

Fig. 3. Calibration curves of Fe^{2+} (a) and Fe^{3+} (b); salicylic acid: 4.0×10^{-6} M.

cylic acid in the presence of Fe^{3+} and of the reagent alone were obtained with a pH 8.5 buffer solution and are shown in Fig. 1. The excitation and emission peaks of the salicylic acid appeared at 299 nm and 409 nm, respectively. As can be seen in Fig. 1, a decrease of the fluorescence intensity in the maximum emission peak (409 nm) can be observed in the presence of Fe^{3+} . Therefore, E_x 299 nm and E_m 409 nm were selected as operating wavelengths during all laboratory work.

3.2. Effect of pH

The pH effect of the test solution on the fluorescence intensity of Fe^{3+} –salicylic acid was studied in the above procedure. The result is shown in Fig. 2. The maximum fluorescence intensity occurred at pH higher than pH 8.0. Thus pH 8.5 is recommended for further studies.

3.3. Effect of salicylic acid concentration

The difference fluorescence intensity (ΔF) of Fe^{3+} solution (4×10^{-6} M) had a linear relationship with a concentration of 1×10^{-6} – 10×10^{-6} M salicylic acid.

Hence, 4×10^{-6} M salicylic acid was chosen as optimum for further studies.

3.4. Calibration curve of Fe^{3+}

Fig. 3 shows the calibration curve of Fe^{3+} in 4×10^{-6} M salicylic acid. In order to determine Fe^{3+} using the decrease of fluorescence intensity of salicylic acid according to Fe^{3+} concentration, the fluorescence decreases of salicylic acid containing various Fe^{3+} concentrations were measured at 409 nm, with excitation at 299 nm (Fig. 3b). In Fig. 3b, the fluorescence intensity of salicylic acid was decreased linearly with increasing Fe^{3+} concentration in the range of 1×10^{-6} – 10×10^{-6} M and the detection limit ($S/N=2$) is 5×10^{-8} M. Also, in order to determine Fe^{2+} , the above described procedure was applied to Fe^{2+} instead of Fe^{3+} . In Fig. 3a, the fluorescence intensities of the salicylic acid solution were approximately constant with increasing Fe^{2+} concentration (1×10^{-6} – 10×10^{-6} M).

3.5. Quenching by Fe^{3+}

The efficiency of quenching of a fluorescent species by a quenching species follows the Stern–Volmer relationship [7], if the fluorophore and quencher concentrations are in the appropriate range:

Fig. 4. Stern–Volmer plots for the quenching of salicylic acid fluorescence by Fe^{3+} . (a) 22°C (b) 40°C; salicylic acid: 4.0×10^{-6} M.

Table 1
Tolerance limits for the determination of Fe³⁺

Foreign ions	Tolerance, (M)
Cu ²⁺	4 × 10 ⁻⁵
Cr ³⁺	2 × 10 ⁻⁵
Ni ²⁺	1 × 10 ⁻⁴
Fe ²⁺	7 × 10 ⁻⁶
Mg ²⁺	1 × 10 ⁻⁴
Co ²⁺	1 × 10 ⁻⁵
Zn ²⁺	—
Ba ²⁺	7 × 10 ⁻⁵
Pb ²⁺	2 × 10 ⁻⁵
Al ²⁺	5 × 10 ⁻³
Ca ²⁺	—
Li ⁺	—
Mn ²⁺	5 × 10 ⁻³
Cd ²⁺	5 × 10 ⁻⁵

CO ₃ ⁻	—
NO ₃ ⁻	1 × 10 ⁻⁴

Concentration: Fe³⁺ = 1.0 × 10⁻⁶ M, salicylic acid = 4.0 × 10⁻⁶ M.

—, no interference.

$$I_o/I = 1 + K_{sv}[Q]$$

where I_o and I are the fluorescence intensity in the absence and presence of the quencher, respectively. K_{sv} is the Stern–Volmer quenching constant and $[Q]$ is the concentration of the quencher. If a system obeys the Stern–Volmer equation, a plot of I_o/I versus $[Q]$ will give a straight line with a slope of K_{sv} and a y -axis intercept of 1.

Fig. 4 is the Stern–Volmer plot of the Fe³⁺–salicylic acid system. In Fig. 4, I_o/I term linearly increased with increasing the Fe³⁺, $[Q]$. The effect of static quenching according to temperature is lower at higher temperature (Fig. 4b). In the case of dynamic (collisional) quenching, quenching efficiency increases with increasing temperature. Therefore it may be concluded from the consideration of Fig. 4 and Ref. [8] that the quenching mechanism is static quenching (formation of complex between salicylic acid and Fe³⁺).

3.6. Effect of foreign ions

The effect of foreign ions on the fluorescence intensity of the Fe³⁺–salicylic acid system was studied on 1.0 × 10⁻⁶ M Fe³⁺. The tolerance limit was calculated as the concentration of a species which resulted in less than 5% deviation in the fluorescence of Fe³⁺. The results are summarized in Table 1. Most anion and cation species are tolerated in relatively high concentration or did not interfere and Zn²⁺, Ca²⁺, Li⁺, Mn²⁺ and Sr²⁺ ions did not interfere in concentrations 10⁴-fold greater than Fe³⁺ concentration. Fe²⁺, Co²⁺, Sm³⁺ and Y³⁺ ions cause interference.

3.7. Application

The method was applied to the determination of iron ion in tap water and natural water samples. In order to determine the total amount of iron ion in the sample, 1–2 drops of 0.01 M KMnO₄ were added to the sample solution to oxidize Fe²⁺ to Fe³⁺. The sample solution was analyzed for iron without a preconcentration process. The results shown in Table 2 are in good agreement with those obtained by inductively coupled atomic emission spectrometry (ICP–AES) performed for comparison.

In conclusion, this method is worthy of use as an alternative spectrofluorimetric determination of Fe³⁺ at sub-ppm levels at concentrations lower than 7 × 10⁻⁶ M Fe²⁺.

Department of Chemistry, Panjab University, Chandigarh-160014, India

Received 9 October 1997; received in revised form 5 January 1998; accepted 13 January 1998

Abstract

A simple, rapid, sensitive and selective method for the microgram detection and spectrophotometric determination of EDTA in water, human urine and detergents, based on its reaction with Co(II) and phosphomolybdic acid at pH 0.5–2.0 is reported. Absorbance is measured against Co(II)–phosphomolybdic acid reference solution at 750 nm. The effect of time, temperature, pH and Co(II) or phosphomolybdic acid concentration is studied, and optimum operating conditions are established. Beer's law is applicable in the concentration range 0.3–1.9 $\mu\text{g ml}^{-1}$ of 10^{-5}M EDTA. Its detection limit is 0.14 μg in the solution phase and 0.03 μg in the resin phase. The relative standard deviation is $\pm 0.13 \mu\text{g}$. Ag(I), Zn(II), Cu(II), Ni(II), Pb(II), Cd(II), Ca(II), Mg(II), Fe(III), Cr(III), U(VI), chloride, nitrite, phosphate, oxalate, borate and amino acids do not interfere. © 1998 Elsevier Science B.V. Keywords: Spectrophotometry; EDTA; Co(II); Phosphomolybdic acid

1. Introduction

EDTA was determined using iron(III) thiocyanate [1], iron(II) complex of 2,4,6-tripyridyl *s*-triazine [2] and ferric alum solution in sulphuric acid [3] at 475 μm , 593 μm and 305 nm, respectively. Yamaguchi et al. [4] determined its traces using a cupric oxide-loaded cation exchanger. The Cu–EDTA complex formed in percolate was determined by reaction with sodium diethyldithiocarbamate in sodium borate buffer (pH

9.3)–NaCl medium. 4-Aminoantipyrine [5] was used as reagent for spectrophotometric determination of EDTA at pH 4. Nemcova et al. [6] proposed an indirect spectrophotometric method for its determination with bromopyrogallol red in the presence of tensides. EDTA has been back titrated with Pb^{2+} using a.c. oscillopolarographic detection of end point [7]. Recently, Sheppard and Henion [8] determined EDTA as nickel chelate in environmental water by solid-phase extraction and capillary electrophoresis/tandem mass spectrometry. In the present communication, a procedure is reported for the detection and spectrophotometric determination of microgram

quantities of EDTA based on its colour reaction with Co(II) and phosphomolybdic acid at pH 0.5–2. The method is extended to its determination in water, urine and commonly available Indian detergents.

2. Experimental

2.1. Reagents

Analytical-grade reagents and doubly distilled water were used throughout. Strongly basic anion-exchange resin Amberlite IRA 400 (standard grade, B.D.H.) was used in OH^- form after proper conversion and thorough washing with demineralized water. Solutions of Co(II) (10^{-1} M), EDTA (10^{-1} M) and phosphomolybdic acid (4%) were prepared in demineralized water. More dilute solutions of EDTA were prepared from the stock solution.

2.2. Apparatus

A Hitachi Model 330 double-beam recording spectrophotometer with 10-mm cells was used for absorbance measurements.

2.3. Detection

About 5 to 10 resin beads (OH^- form) are placed on a white spot plate and blotted dry with

filter paper. One drop of test solution is added, followed by one drop each of Co(II) and phosphomolybdic acid solution. A royal blue colour develops instantaneously on the bead surface if the test solution contains EDTA.

2.4. Determination

EDTA (1.0 ml containing 0.3–1.9 μg), Co(II) (2.0 ml of 10^{-1} M solution) and phosphomolybdic acid (2.0 ml of 4% solution) is shaken for a few seconds. The volume is made up to 10 ml with water. The pH is maintained in the range 0.5–2.0. The absorbance is measured at 750 nm against a blank solution at room temperature (25–30°).

Varying amounts of EDTA (3.7–13.0 μg) are added to the tap water, distilled water and human urine samples (5.0 ml), and the EDTA is then determined by the above method (Table 1).

Known amounts of metal ions Zn(II), Cu(II), Pb(II), Cd(II), Ca(II), Mg(II) or Fe(III) (1.0 μg) are added to a normal urine sample (5.0 ml) together with excess EDTA (10.0 μg). EDTA not complexed by the metal, is then determined using the above procedure.

About 500 mg of liquid or powdered detergent is dissolved in distilled water (~20 ml). Any insoluble matter persisting, even after slight warming, is discarded after centrifuging the solution. A blue colour develops on adding Co(II) and phosphomolybdic acid (2 ml each) to the solution. The absorbance is measured at 750 nm (Table 1).

3. Results and discussion

The redox reaction of Co(II)–EDTA complex with phosphomolybdic acid, which forms a royal blue colour, is used for a selective and sensitive detection and spectrophotometric determination of EDTA.

Two types of ion-exchange resin, Amberlite IR 120 (H⁺ form) and Amberlite IRA 400 (OH⁻ form) were added in two different microtest tubes containing the coloured complex formed by the recommended procedure. The negatively charged resin beads turn royal blue, indicating that the complex formed is negatively charged.

The plot of absorbance of the royal blue complex as a function of wavelengths shows a plateau with a maximum absorbance at 750 nm. Beer's law is obeyed for solutions containing 0.3–1.9 µg ml⁻¹ of 10⁻⁵ M EDTA under the optimum conditions.

The effect of time, Co(II) or phosphomolybdic acid concentration and variation in pH on the absorption of the royal blue complex was examined. The royal blue colour developed instantaneously, is stable for 48 h at room temperature (25–30°C), and is also thermally stable up to 50°C. It was revealed that 2.0 ml each of 10⁻¹ M Co(II) and 4% phosphomolybdic acid are the most suitable. The absorbance decreases if the amount of Co(II) is increased further. The absorbance remains constant if the amount of phosphomolybdic acid is more than 2.0 ml of 4% solution. The absorbance was maximum and constant in the pH range 0.5–2.0 at 750 nm. On increasing the pH, the absorbance of the royal blue complex decreases.

The identification limit of EDTA at room temperature (25–30°C) is 0.14 µg in solution phase and 0.03 µg in resin phase, with a minimum concentration of 10⁻⁶ M. Aminocarboxylic acids (NTA, CyDTA, EGTA) interfere with the test in solution phase (if present at more than 50 times excess), but not in the bead test. Ion-exchange beads, thus, act as catalyst and detection medium to improve the selectivity and sensitivity of the test.

Up to 0.3 µg of EDTA is determined quantitatively by this method in the presence of certain ions such as Ag(I), Zn(II), Cu(II), Pb(II), Cd(II), Ca(II), Mg(II), Ni(II), Fe(III), Cr(III), U(VI), chloride, nitrite, phosphate, oxalate and borate, common amino acids (alanine, aspartic acid, glutamic acid, leucine, serine, phenylalanine, lysine and valine) and some other organic compounds (iminodiacetic acid, citric acid, oxalic acid, glycine, gluconic acid), even if present at 100 times excess.

The reproducibility of results was checked by 10 replicate determinations with 9.26 µg EDTA. The accuracy of the method was checked by five unknown determinations. The average error and standard deviation were found to be 0.30 and ± 0.13 µg, respectively. Recovery of EDTA is 98%. In the absence of determination error, the true value fell within 9.17–9.35 µg with a confidence interval of 95%.

The present procedure is suitable for detection and determination of EDTA in natural water, human urine (with or without adding frequently present metal ions such as Zn(II), Cu(II), Pb(II), Cd(II), Ca(II), Mg(II) or Fe(III)) and commercially available detergent samples, without interference from organic compounds and common ions that are known to be present in these samples (Table 1). The recovery of EDTA is satisfactory in each case. For all the samples tested, the method is simple, rapid, precise, accurate and reproducible.

The present method is better than that of Bhattacharya and Kundu [3], as the Fe–EDTA complex is photosensitive [2,9] and undergoes decomposition in sunlight. That the presence of Ca²⁺ and Mg²⁺ does not interfere in the present determination is significant, because the usual titrimetric methods of employing alkali solutions for microdetermination of EDTA are frustrated in the presence of these ions in the sample. The method proposed by Sheppard and Henion [8] is tedious and time consuming.

The results obtained by this procedure agree satisfactorily with those obtained by the method reported in literature [10].

Reversed-phase HPLC method for the estimation of acetaminophen, ibuprofen and chlorzoxazone in formulations

S. Ravisankar *, M. Vasudevan, M. Gandhimathi, B. Suresh

Department of Pharmaceutical Analysis & Drugs Testing Laboratory, J.S.S. College of Pharmacy, Ootacamund, Tamilnadu, India

Received 21 October 1997; received in revised form 12 January 1998; accepted 13 January 1998

Abstract

A simple, precise and rapid reversed-phase HPLC method was developed for the simultaneous estimation of acetaminophen, ibuprofen and chlorzoxazone in formulations. The method was carried out on a Kromasil[®] C₈ column using a mixture of 0.2% triethylamine:acetonitrile (adjusted to pH 3.2 using dilute orthophosphoric acid), and detection was carried out at 215 nm using ketoprofen as internal standard. All these drugs showed linearity in the range of 2–10 µg ml⁻¹, and limits of quantification was found to be 10, 50 and 20 ng ml⁻¹ for acetaminophen, ibuprofen and chlorzoxazone, respectively. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Acetaminophen; Ibuprofen; Chlorzoxazone; Simultaneous estimation; Reversed-phase HPLC

1. Introduction

Acetaminophen, [1–3] chemically known as *N*-acetyl-*p*-aminophenol is used widely as non-steroidal antiinflammatory and antipyretic agent. Chlorzoxazone [3] is a muscle relaxant and chemically is 5-chloro-2-hydroxy benzoxazole. Ibuprofen [1–3], an aryl acetic acid derivative, chemically is (*RS*)-2-(4-isobutyl phenyl) propionic acid and is used as a non-steroidal antiinflammatory drug. A combination of 325 mg of acetaminophen, 400 mg of ibuprofen and 250 mg of chlorzoxazone is commercially available in tablet form.

A literature survey [4–10] revealed that there are a number of methods available for their individual determination, or for any two of these three drugs in combinations. However, there is no simultaneous method reported for their simultaneous estimation. Hence the present work describes a reversed-phase HPLC method for the estimation of these three drugs in combined dosage form.

2. Experimental

2.1. Reagents and chemicals

Acetonitrile, HPLC grade, orthophosphoric acid, AR grade, and triethylamine, AR grade, were supplied by SD Fine Chemicals Ltd., India,

* Corresponding author. Tel.: +91 423 43393; fax: +91 423 42937.

Water, HPLC grade, was from a Millipore system. Reference standards were obtained from Indoco Remedies, Mumbai, India.

2.2. Chromatographic conditions

A Waters® HPLC system was used for the analysis. The column used was Kromasil® C₈, (5 µm, 25 cm × 4.6 mm ID). A mixture of acetonitrile:0.2% triethylamine (adjusted to pH 3.2 using orthophosphoric acid) (50:50, v/v) was used as mobile phase at a flow rate of 1.5 ml min⁻¹ with an operating pressure of 3000 psi. A Rheodyne® 7125 injector with a 20-µl loop was used for the injection of samples. Detection was done at 215 nm, with a sensitivity of 0.05 AUFS. The mobile phase was filtered through 0.45-µm membrane filter and degassed. The separation was carried out at room temperature, 20 ± 1°C.

2.3. Preparation of standard solutions

Standard stock solutions of acetaminophen, ibuprofen and chlorzoxazone, each of 1 mg ml⁻¹ concentration, were prepared separately in the mobile phase. A stock solution of 100 µg ml⁻¹ of ketoprofen (internal standard) was prepared in the mobile phase. From the standard solutions, suitably diluted mixed standard solutions were prepared to contain 2, 4, 6, 8 and 10 µg ml⁻¹ of acetaminophen, ibuprofen, and chlorzoxazone, containing 10 µg ml⁻¹ of ketoprofen as internal standard.

2.4. Extraction of drugs from the formulations

Twenty tablets, each containing 325 mg of acetaminophen, 250 mg of chlorzoxazone and 400 mg of ibuprofen were weighed and finely powdered. A quantity of powder, equivalent to 32.5 mg of acetaminophen, 25 mg of chlorzoxazone and 40 mg of ibuprofen, was weighed accurately and transferred to a sintered glass crucible and extracted with two quantities, each of 25 ml, of acetonitrile. The combined extracts were made up to 100 ml with the mobile phase. The resulting solution (2.5 ml) was diluted with mobile phase to 25 ml in a standard flask. From this a 2-ml

aliquot was mixed with 1 ml of the internal standard solution (which contains 100 µg ml⁻¹ of ketoprofen) and made up to 10 ml in a standard flask with the mobile phase.

2.5. Procedure

Each 20 µl of mixed standard solutions, containing internal standard, were injected and the chromatograms were recorded (Fig. 1). The retention times of acetaminophen, chlorzoxazone, ketoprofen (Internal standard) and ibuprofen were found to be 1.93, 3.91, 5.65 and 12.50 min, respectively. This was followed by injecting the sample solution obtained from the formulation along with the internal standard. Acetaminophen, ibuprofen, and chlorzoxazone showed linearity in the range of 2–10 µg ml⁻¹. Calibration curves were plotted (Fig. 2) using peak ratios of the standard peak areas and internal standard peak area (response factor). The peak areas of the sample chromatograms were compared, and the amounts of acetaminophen, ibuprofen and chlorzoxazone were calculated, and are shown in Table 1.

3. Recovery studies

To study the reliability and suitability of the above method, recovery experiments were carried out. To 5-ml aliquots of the sample solution obtained from the formulation, 5 ml of the standard solution, which contained 8 µg ml⁻¹ of acetaminophen, ibuprofen and chlorzoxazone, containing 10 µg ml⁻¹ of ketoprofen as internal standard, were added. The contents of acetaminophen, ibuprofen and chlorzoxazone were once again determined by the proposed method by recording the chromatogram. From the amount of the drug present, percentage recovery was calculated using the following formula:

$$\% \text{Recovery} = \left[\frac{b - a}{c} \right] \times 100$$

where, a = amount found before addition, b = amount found after addition and c = amount of standard drug added.

Fig. 1. Chromatogram of acetaminophen, ibuprofen and chlorzoxazone, with ketoprofen as internal standard.

4. Results and discussion

Chromatograms of mixed standard solutions which contained acetaminophen, ibuprofen and chlorzoxazone along with internal standard (ketoprofen) were recorded. A computer-controlled data station with Baseline 810 software was used to plot the peak area vs. concentration in $\mu\text{g ml}^{-1}$. Calibration curves were obtained by using peak area ratios of standard and internal standard vs. concentration. All three drugs showed linearity

in the range of 2–10 $\mu\text{g ml}^{-1}$. The limits of quantification (LOQ) for acetaminophen, ibuprofen and chlorzoxazone were found to be 10, 50 and 20 ng ml^{-1} , respectively. Precision of the method was studied by making five injections of the same standard, with concentrations close to the expected concentrations in samples, and the standard deviation was determined.

From the marketed formulation, sample solutions were made and spiked with internal standard (ketoprofen), and the response factor was

Fig. 2. Calibration curve of acetaminophen, ibuprofen and chlorzoxazone.

Table 1
Analysis of formulations and recovery studies

Drug	Amount (mg tablet ⁻¹)		% label claim ^a	% recovery ^a
	Labeled	Found ^a		
Acetaminophen	325	321.48 ± 3.44	98.96 ± 1.83	99.26 ± 0.52
Chlorzoxazone	250	246.58 ± 2.78	98.63 ± 1.52	100.53 ± 0.84
Ibuprofen	400	406.37 ± 3.21	101.59 ± 0.96	98.62 ± 0.48

^a Mean ± S.D. of five determinations.

used to calculate the concentration of each drug. From the concentration, the amounts of each drug present in tablets were calculated. The reliability and suitability of the method could be seen from the recovery values. Further, there is no interference due to excipients. The proposed HPLC method for the simultaneous estimation of acetaminophen, ibuprofen and chlorzoxazone is simple, rapid and accurate. Thus, the present HPLC method is suitable for the quality control of raw materials, formulations and dissolution studies.

Abstract

Silica gel and glass beads were modified by using acid chloride of metal–tetrakis(4-carboxyphenyl)porphine (M–TCPP) through a peptide bond, and an anion-exchange resin with M–TCPP by ion-exchange reaction and physical adsorption. The carriers modified with Co³⁺–TCPP proved to accelerate the redox reaction which is catalyzed by glutathione oxidase (GSHOx), while those modified with Mn³⁺–TCPP exhibited no activity. Formation of GS-SG and hydrogen peroxide was confirmed by means of mass spectroscopy and colored reaction, respectively. The silica gel modified with Co³⁺–TCPP exhibited the strongest activity among the tested carriers, and was expected to be useful practically as a solid catalyst for the determination of glutathione. © 1998 Elsevier Science B.V. Keywords: Glutathione oxidase-like activity; Oxidation of glutathione; Hydrogen peroxide; Carriers modified with Co³⁺–tetra-(4-carboxyphenyl)porphine

1. Introduction

Previously, we studied the glutathione peroxidase (GSHPx)-like activity of ion-exchange resins modified with metalloporphyrins, which revealed that an anion-exchange resin modified with Mn³⁺–tetrakis(sulfophenyl)porphine exhibited potent

GSHPx-like activity [1]. In the previous study, we suggested that an anion-exchange resin modified with Co³⁺–tetrakis(sulfophenyl)porphine (Co-TSPP_r) and tetrakis(4-carboxyphenyl)porphine (Co-TCPP_r) catalyzed the oxidative reaction of glutathione (GSH) without requiring any peroxide, which is catalyzed by glutathione oxidase [2]. In that time, the modified anion-exchange resins were revealed to have a disadvantageous feature, i.e. adsorption of glutathione with ionic interac-

* Corresponding author. Tel.: +81 86 2517951; fax: +81 86 2517953; e-mail: saito@pheasant.pharm.okayama-u.ac.jp

tion between GSH and the anion-exchange resin. To avoid the adsorption, we had selected, as a carrier, silica gel and glass beads, specifically to aminopropyl silica gel and aminoacyl glass beads to which acid chloride derivative of Co-TCPP may be easily bound. In the present paper, we studied the glutathione oxidase (GSHOx)-like activity of the glass beads and the silica gel modified with Co-TCPP as well as the anion-exchange resin modified with Co-TCPP. Consequently, it has revealed that the carriers modified with Co-TCPP catalyzed the following redox reaction (1).

In addition, hydrogen peroxide in the reaction mixture was determined, and the resulting hydrogen peroxide was revealed to be related to a fixed rate of GSH. This result suggested that GSH can be determined spectrophotometrically based on the amount of hydrogen peroxide released from the reaction (1) catalyzed by the silica gel modified with Co-TCPP.

2. Experimental

2.1. Materials and reagents

Reagent-grade tetrakis(4-carboxyphenyl)porphine ($\text{H}_2\text{-TCPP}$) and tetrakis(4-methylpyridyl)porphine ($\text{H}_2\text{-TMPyP}$) were purchased from Wako Junyaku and used without any purification. Amberlite IRA 900 was selected as a mother anion-exchange resin and Dowex MSC-1 as a mother cation-exchange resin. They were washed with 1 mol l^{-1} HCl and NaOH solutions, and with water and acetone, successively, and dried up. Aminoacyl controlled-pore glass beads (particle size, 200–400 mesh) and aminopropyl silica gel (Licrosorb-NH₂; particle size, 10 μm) were purchased from CPG Inc. and Merck AG, respectively, as mother carriers. Aqueous solutions of glutathione were prepared in requirement from glutathione (reduced form, Sigma and

Aldrich). Peroxidase (Type I, from horseradish) for the determination of hydrogen peroxide was purchased from Sigma and Aldrich. Other reagents and chemicals were of analytical or reagent grade.

2.2. Preparation of ion-exchange resins modified with M-P

$\text{H}_2\text{-TCPP}$ was converted into Co^{3+} and Mn^{3+} complexes (Co- and Mn-TCPP) and $\text{H}_2\text{-}$

TMPyP into Fe^{3+} -TMPyP by the methods described in the literature [3,4]. The modified resins (M-P_r, M-P 25 $\mu\text{mol g}^{-1}$ dry resin) were prepared from aqueous solutions of the metal-porphyrins and ion-exchange resins (Amberlite IRA 900 and Dowex MSC-1), according to the method reported previously [5–9].

2.3. Preparation of glass beads and silica gel modified with Co-TCPP

Co^{3+} - and Mn^{3+} -tetrakis(4-chloroformylphenyl)porphine (M-TCPPCl, M = Co^{3+} and Mn^{3+} , see Fig. 1), acid chloride of M-TCPP, was prepared from M-TCPP and thionyl chloride in dioxane at 70°C by the conventional method. Excess thionyl chloride and dioxane was removed under vacuum, and solid M-TCPPCl was washed with dioxane and dried under vacuum. For linking M-TCPP to carriers, a mixture of M-TCPPCl and silica gel or glass beads in dioxane were refluxed until the mixture becomes clear. Silica gel or glass beads modified with M-TCPP (M-TCPP_s and M-TCPP_g, M-TCPP 25 $\mu\text{mol g}^{-1}$ dry carrier) were filtered, washed with water and acetone, and dried under vacuum.

2.4. Apparatus

Absorption spectra and absorbances were measured on Shimadzu UV-180 and UV-160 spec-

Fig. 1. Structures of metalloporphyrins.

trophotometers with 10-mm fused-silica cells. Mass spectra between 70 and 800 amu were obtained by the electrospray ionization method on a Micromass AutoSpec-OA-Tof mass spectrometer.

2.5. Evaluation of the GSHOx-like activity

A modified carrier (50 mg) was added to a mixture of GSH (10 mmol l⁻¹, 1.0 ml) and 0.05 mol l⁻¹ borate buffer (pH 6.0, 4.0 ml) solutions, and the mixture was incubated at 35°C for 20 min. For the determination of unchanged GSH, 0.1 ml of the supernatant was added to 5.0 ml of the Ellman's reagent solution (a 1:4 mixture of 0.5 mg ml⁻¹ 5,5'-dithiobis(2-nitrobenzoic acid) and 0.05 mol l⁻¹ phosphate buffer (pH 7.2) solutions). An absorbance of the mixture at 412 nm was measured against the reagent blank after standing for 10 min. The control was the supernatant that was obtained in the same manner using IRA 900 in the place of the M-TCPP_r, and the reagent blank for M-TCPP_g and -TCPP_s. The activity of the modified carrier was evaluated on the basis of the decrease in the absorbance against the control.

2.6. Determinations of hydrogen peroxide released from GSH

A sample solution (0.2 ml, containing less than

4 μmol of GSH) was mixed with 0.05 mol l⁻¹ borate buffer (pH 7.0, 2.0 ml) solution. After addition of carrier modified with Co-TCPP (25 mg), the mixture was incubated at 35°C for 20 min, when GSH was oxidized to GS-SG while producing hydrogen peroxide. A supernatant (0.5 ml) of the mixture was added to 4.0 ml of a 4:1:1 mixture of 0.05 mol l⁻¹ borate buffer (pH 7.5), 7.0 mg ml⁻¹ phenol, 0.5 mg ml⁻¹ 4-aminoantipyrine and 10 Unit ml⁻¹ peroxidase (from horseradish) solutions, and the absorbance of the resulting quinoid dye in the mixture was measured at 505 nm against the reagent blank.

2.7. Procedure of determination of GSH

The procedure was essentially the same as that of determination of hydrogen peroxide described in the above section. A calibration curve of GSH against the absorbance was drawn, and GSH should be indirectly determined by referring to the curve.

3. Results and discussion

3.1. Metalloporphyrins

The metalloporphyrins used in this study are shown in Fig. 1. All of them except M-TCPPCl are water soluble. They were immobilized easily and firmly on the ion-exchange resins, as described previously [5–9], by electrostatic and physical interactions. M-TCPPCl, which was an acid chloride of M-TCPP and was easily prepared from M-TCPP, was firmly linked to aminopropyl-silica gel and aminoacyl-glass beads through peptide bonds. All of the modified carriers were stable to temperature, in moisture and storage, and M-TCPP on the carriers was hardly eluted with water and organic solvents.

3.2. Reactions

The redox reaction (1) is catalyzed by glutathione oxidase (GSHOx). To confirm the pro-

gress of reaction (1), the formation of GS-SG was investigated by using Co-TCPP_r. To detect GS-SG, the mass spectrum of the supernatant of the reaction mixture was measured using electrospray ionization. As a result, two strong peaks at 307 and 613 amu, attributed to fragment and quasi-molecular ions of GS-SG, were observed. These two peaks, however, were not detectable (less than 1% of intensity) in the mass spectrum of GSH aqueous solution. These results indicated that GSH was oxidized to GS-SG by oxygen in the presence of Co-TCPP_r.

Formation of hydrogen peroxide was also confirmed by using the following color reaction (2).

Hydrogen peroxide + 4-aminoantipyrine (AAP) + phenol

As a result, a considerable amount of hydrogen peroxide was detected in the supernatant of the reaction mixture as discussed in the following section.

Since the higher the GSHOx-like activity of the modified carrier, the more the GSH decreases and the more the hydrogen peroxide generates, quantities of the unchanged GSH and the generated hydrogen peroxide should be a reliable indication of the activity.

3.3. Reaction conditions for examination of GSHOx activity

The anion-exchange resin, IRA 900, adsorbs a considerable amount of GSH. Accordingly, the control by the use of IRA 900 should be referred to in each examination. However, in the cases of M-TCPP_g and -TCPP_s, the reagent blank was used as a reference because glass beads or silica gel do not absorb GSH.

To evaluate the GSHOx-like activity of the modified carriers, unchanged GSH was determined by the Ellman's color reaction with 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) [10].

The following examinations were carried out to obtain optimum conditions.

3.4. Effect of pH and the GSHOx activity

The amounts of unchanged GSH (%) against pH are presented in Fig. 2; compared to the unchanged GSH at pH 6.0, GSH was nearly zero after treatment with the carriers modified with Co-TCPP, while most of GSH remained unchanged in the case of Mn-TCPP_g and -TCPP_r. This result indicates that the carriers modified with Co-TCPP can exhibit strong GSHOx-like activity in contrast with the no activity of Mn-TCPP_g and -TCPP_r. It is of interest that Mn-TCPP fixed on carriers, having

strong GSH peroxidase-like activity [1], did not show any GSHOx-like activity at pH 6.0. This difference in activity may be caused by the affinity of oxygen and/or GSH to metal ions.

Fig. 2. Effect of pH. Co-TCPP_g (●), Co-TCPP_s (■), Co-TCPP_r (▲), Mn-TCPP_g (○) and Mn-TCPP_r (△). Modified carrier, 50 mg; incubated for 20 min at 35°C.

Within the tested pH region, Mn-TCPP_g had no activity. Even though Mn-TCPP_r exhibited a weak activity in the higher pH region of more than 7.0, the rate of unchanged GSH was more than 40%, as can be seen in Fig. 2. On the contrary, Co-TCPP_r, -TCPP_s and -TCPP_g strongly catalyzed reaction (1) in the tested pH region. However, the activity of Co-TCPP_g was a little weaker than that of Co-TCPP_r and -TCPP_s at pH 5 or below. These results indicated that the activity depends not only on the central metal but also on the carrier.

In the present study, we decided to examine the carrier modified with Co-TCPP in the region between pH 6.0 and 7.0 in detail, as this was the region in which they showed strong activity.

3.5. Time course

Fig. 3 shows the time course of reaction (1). Initially, we presumed that Co-TCPP_r would give more rapid equilibrium of reaction (1) than other two, because a considerable quantity of GSH could be decreased by adsorption on Co-TCPP_r. Contrary to our presumption, 5-min incubation with Co-TCPP_g and -TCPP_s gave equilibrium of reaction (1), but Co-TCPP_r re-

Fig. 3. Time courses. Co-TCPP_g and Co-TCPP_s (●); and Co-TCPP_r (▲). Modified carrier, 50 mg; pH 6.0; incubated at 35°C.

Fig. 4. Effect of incubating temperature. Co-TCPP_g and Co-TCPP_s (●). Modified carrier, 50 mg; pH 6.0; incubated for 20 min.

quired about 15 min incubation before equilibrium as seen (Fig. 3). Co-TCPP_g and -TCPP_s accelerated reaction (1) to a greater extent than Co-TCPP_r, and were suggested to be superior to Co-TCPP_r as a catalyst. For the present examination, we selected Co-TCPP_g and -TCPP_s as catalysts to be used in the further examinations, and we judged incubation for 20 min to be enough for the evolution of the activity, taking time to spare into consideration.

3.6. Effect of incubating temperature

The effect of the incubating temperature on the unchanged GSH (%) was examined between 25 and 45°C by using Co-TCPP_g and -TCPP_s. Most of GSH disappeared between 30 and 45°C. Unchanged GSH was close to zero, except at 25°C, where around 10% of GSH remained unchanged (see Fig. 4). As the standard incubating temperature, we selected the region around 35°C, where, in general, most enzyme reactions take place. One of advantageous features of Co-TCPP_g and -TCPP_s is that their activity is not affected seriously by the incubating temperature, in contrast to most of enzymes.

Fig. 5. Effect of amount of the modified carriers. Co-TCPP_g (●) and Co-TCPP_s (▲). pH 6.0; incubated at 35°C for 20 min.

3.7. Effect of amount of Co-TCPP_g and -TCPP_s

Since the amount of catalyst was expected to affect the rate of reactions, we checked the relationships between the amount of the modified carriers and unchanged GSH. Reaction (1) attained equilibrium when more than 50 mg of the carriers were added (see Fig. 5). In addition to 25 mg of carriers, Co-TCPP_s gave about 10% of unchanged GSH, while Co-TCPP_g gave about 40%, indicating that Co-TCPP_s exhibited stronger activity than Co-TCPP_g when a small amount of carrier is used. This result suggested that Co-TCPP_s is more effective than Co-TCPP_g. Thus, in the present study, we concluded that Co-TCPP_s was the best catalyst among the three kinds of modified carriers tested, and that the addition of 50 mg of Co-TCPP_s was significant to examine the activity in more detail.

3.8. Repeated uses

To confirm that Co-TCPP_s acts as a catalyst in the oxidative reaction of GSH, repeated uses of

Fig. 6. Repeated uses of Co-TCPP_s. Co-TCPP_s and Fe-TMPyP_r, 50 mg; pH 6.0; incubated at 35°C for 20 min.

Co-TCPP_s were checked. In that time, Fe-TMPyP_r (50 mg), which was reported to have a strong catalase-like activity [8], was added to the reaction mixture to decompose the resulting hydrogen peroxide, which can interfere with reaction (1). After being used 10 times, Co-TCPP_s held enough GSHOx-like activity, although it had decreased by about 5% (see Fig. 6). Thus, we concluded that Co-TCPP_s serves as a catalyst in reaction (1).

3.9. Proposed reaction scheme

Previously, we studied the uricase-like activity of an anion-exchange resin modified with Mn³⁺ -

Table 1
Resulting hydrogen peroxide when GSH was oxidized

Solid catalysis	Hydrogen peroxide determined ^a (μmol)
Co-TCPP _s	1.2
Co-TCPP _g	1.2
Co-TCPP _r	0.7

^a 4.0 μmol of GSH were used.

tetrakis(sulfophenyl)porphine (Mn-TSPP_r) and demonstrated, from a resonance Raman study, that the activity was due to a redox cycle reaction of manganese ion, as described in the literature [11,12]. By analogy with the above scheme of uricase-like activity, we propose the following reaction scheme, wherein the GSHox-like activity of Co-TCPP on the carriers is involved.

3.10. Quantity of the resulting hydrogen peroxide

According to the above reaction scheme, 1 mol of hydrogen peroxide should be formed from 2 mol of GSH. To check this point, the quantity of hydrogen peroxide was determined by following

Fig. 7. Plot of amount of GSH against absorbance due to the resulting hydrogen peroxide. Co-TCPP_s, 50 mg; pH 7.0; incubated at 35°C for 20 min.

the procedures described above. The determination was carried out at pH 7.0, which is the optimum pH of peroxidase for determining hydrogen peroxide. As a result, the use of Co-TCPP_g and -TCPP_s gave only 1.2 μmol of hydrogen peroxide from 4.0 μmol of GSH, as shown in Table 1. The lower yield of hydrogen peroxide than that expected was attributed to the

fact that hydrogen peroxide was partially decomposed by Co-TCPP on the carrier, which had been previously reported to exhibit weak catalase-and/or GSHPx-like activities. We, therefore, concluded that this result supported the above scheme.

In the case of Co-TCPP_r, the resulting hydrogen peroxide was 0.7 μmol less than that observed in the case of Co-TCPP_s. Since an anion-exchange resin adsorbs considerable quantity of GSH, and the adsorbed GSH is expected not to take part in the reaction (1), this result again would not contradict the above scheme.

To confirm that hydrogen peroxide is formed from GSH with a fixed rate of the GSH, the resulting hydrogen peroxide from GSH at different concentrations, 1–4 μmol, was determined in the presence of Co-TCPP_s. A plot of GSH quantity against absorbance, that is quantity of hydrogen peroxide, gave a good straight line sufficient to be used as a calibration curve of GSH (Fig. 7). This line indicated that the resulting hydrogen peroxide was proportional to GSH quantity, which was revealed to be the fixed rate of GSH.

3.11. Analytical application

As mentioned above, since the plot of GSH against absorbance was regarded as a calibration curve of GSH where Beer's law was applicable in the range between from 1.0 to 4.0 μmol , we could determine GSH by using the curve. From this point of view, Co–TCPP_s having the strongest activity among the tested carriers, was promising for the determinations of GSH as a solid catalyst.

4. Conclusion

The carriers modified with Co–TCPP exhibited GSHOx-like activity. Particularly, Co–TCPP_s was regarded as a good mimetic of GSHOx, and is expected to be practically applicable to the determination of GSH as a solid catalyst.

Abstract

An isotope dilution method for the determination of chloride ion in aqueous samples is described. The method makes use of the isotopic shift in the rotational lines of the 1–0 band of HCl emitted in the near infrared region of the spectrum by vibrationally excited HCl molecules present in a hydrogen/entrained air flame. Chloride ion in the sample is converted to chlorine gas by electrolysis and swept into a hydrogen/entrained air flame where it is converted into HCl. Because isotope dilution is an absolute method of analysis, matrix effects are minimized, and the chlorine generation step need not be quantitative. With the system described in this paper, samples must contain at least 9 mg of chloride ion per ml, and a 2-ml sample is required. Over the range from 10 to 30 mg Cl⁻ ml⁻¹, the average error was -0.96%, and the average relative standard deviation was 3.3% for seven samples using seven of the more intense lines in the P branch. Compared with standard silver nitrate titrations, the isotope dilution procedure was not affected by such common interferences as bromide ion and iodide ion. The technique was applied to several seawater samples from different regions. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

The element chlorine occurs widely in nature, primarily as chloride ion, and is generally found combined with sodium, potassium, and magnesium. In minerals, it is found in halite (NaCl),

sylvine (KCl), and carnallite (KCl·MgCl₂·6H₂O), among others [1,2]. Dissolved in water, chloride ion is found in ground water, seawater, mineral springs, and salt brines. Salt brines, which frequently contain large amounts of dissolved chloride ion, are an important source of chemicals throughout the world [2]. While the oceans remain the largest sources of brine, brines are also found in terminal lakes such as the Dead Sea in

* Corresponding author.

Israel and Jordan and the Great Salt Lake in Utah, and in underground deposits formed after evaporation of ancient terminal lakes. In the chloro-alkali process for the production of chlorine and caustic soda (the eighth and ninth largest volume chemicals produced in the United States), solution-mined brines or solar-evaporated solid salt are used as feedstocks [3]. In oceanographic work, chloride ion is used as a reference standard, and its determination in seawater is complicated by the complex nature of the sample matrix [4]. Because of the widespread occurrence of chloride ion naturally, and its importance in many chemical processes, methods for the determination of chloride ion in aqueous samples are of general interest.

Previous work [5] has shown that chloride ion in aqueous samples can be determined by flame infrared emission (FIRE) spectrometry [6,7]. In this procedure, chloride ion was converted to molecular chlorine (Cl_2) by reaction with a saturated solution of potassium permanganate in the presence of concentrated sulfuric acid. The molecular chlorine generated by the strong oxidizing conditions was subsequently purged from solution with a stream of He, and introduced into a hydrogen/entrained-air flame, where a portion of the HCl emission intensity at $3150\text{--}2425\text{ cm}^{-1}$ was monitored with a simple radiometer, equipped with a lead selenide detector and a narrow-band optical band pass filter with a maximum transmission at $3.8\text{ }\mu\text{m}$. Calibration curves were prepared by plotting the peak height of the emission intensity profiles versus the concentration of sodium chloride standard solutions.

While the early FIRE method was generally satisfactory, it was subject to matrix interferences. For example, for a 5 mM Cl^- solution, the presence of 0.595 mM Br^- suppressed the HCl emission signal by as much as 39%, and resulted in large negative analytical errors [5]. While the depressive effect of bromide ion could be prevented by the addition of iodate ion to the sample [5], such measures are frequently inconvenient for complex samples where a number of potential interferences may be present.

To avoid matrix effects in complex samples, isotope dilution analysis is frequently used [8]. Since the technique was introduced in 1931 by Hevesy and Hobbie [9], a variety of techniques based on isotope dilution have been developed. While the method originally employed radioactive isotopes, the availability of mass spectrometry soon led to the use of stable isotopes. In direct-dilution classical isotope dilution [8], a pair of isotopes is selected from among those that make up the analyte, and the isotopic ratio in the unknown sample is determined by some means, such as mass spectrometry. A known aliquot, enriched in one of the selected isotopes of the analyte (the spike), is then added to a known amount of sample. After the isotopes have equilibrated, a portion of the analyte is separated from the sample matrix, purified to eliminate interferences, and the isotopic ratio of the spiked sample is determined. From a knowledge of the amount of sample and spike and the initial and final isotopic ratios, the concentration of the sample can be calculated.

Mass spectrometry is the most frequently used means of determining isotopic ratios with stable isotope dilution. In the case of chlorine [10], the chloride ion is first precipitated as AgCl and filtered with $0.45\text{ }\mu\text{m}$ polytetrafluoroethylene filters. Vaporization of a $1\text{--}10\text{-}\mu\text{g}$ sample of the precipitate from a rhenium double filament at $1600\text{--}1800^\circ\text{C}$ results in the formation of thermal Cl^- ions, which are analyzed by the mass spectrometer. While isotope dilution mass spectrometry is quite good, the technique requires a mass spectrometer and a relatively skilled operator.

Because it should be possible to resolve the rotational lines of H^{35}Cl and H^{37}Cl emitted from a hydrogen flame using a relatively modest Fourier-transform infrared spectrometer, it seemed worthwhile to investigate the use of Fourier-transform flame infrared emission (FT-FIRE) spectroscopy [11] as a means of determining isotopic ratios in the isotope dilution analysis of aqueous samples containing chloride ion. This paper presents the results obtained with isotope-dilution flame infrared emission (ID-FIRE) spectrometry.

2.1.1. FTIR spectrometer

A Mattson Galaxy Series 5000 spectrometer (Model GL-5020, Mattson Instruments, Madison, WI), equipped with a deuterated triglycine sulfate (DTGS) detector, was modified for flame infrared emission measurements by disconnecting the original, internal blackbody source and substituting an external blackbody source located outside the instrument. The FTIR spectrometer was interfaced to a 486/33-MHz computer, and spectral data were collected and processed with WinFirst[®], an FTIR software program from Mattson. Each spectrum was accumulated for 20 scans (2.08 min total time), and the gain of the instrument was set for the maximum of 20. Spectra were acquired with a 0.75-cm^{-1} resolution with 1×0 fill and triangular apodization. The optical axis of the spectrometer was 10 mm above the burner tip.

2.1.2. Blackbody source

The external blackbody source consisted of a coil of nichrome heating wire wound around a ceramic tube (6 mm OD \times 50 mm long) and connected to a 110-V variable transformer. This external source was used only when the spectrometer was first turned on and undergoing an automatic internal systems check. Unless the signal from the detector was above a certain level during this check, the internal software assumed that the blackbody source was not functioning, and the instrument would not initialize.

To circumvent the internal software, radiation from the hot external blackbody source was collimated by M_1 , a front-surfaced spherical mirror (Part Number 34-9845, Ealing Electro-Optics, Holliston, MA) with a 30-cm focal length. The collimated beam was subsequently directed into the emission port of the FTIR by a $5 \times 5\text{-cm}$, plane front-surfaced mirror (Part Number 23-4203, Ealing Electro-Optics) placed 57 cm from M_1 . The plane mirror (FM) was mounted on the side of a triangular aluminum block with a rod through one corner to allow it to swing out of the light path between the burner and the FTIR. Once the initial systems check had been completed, the external blackbody source was turned off, and the plane mirror was rotated out of the light path between the burner and the emission port of the FTIR.

2.1.3. Burner

In previous FIRE studies in this laboratory, different microburner designs have been evaluated [7,12,13]. The microburner used in this study was a modification of a concentric two-tube burner described previously [13]. The stainless steel tubing in the earlier burner [13] could not withstand the corrosive action of the large amount of hydrogen chloride gas present at the flame temperature for more than a few hours. As a result, other materials more inert to the burning of chlorine gas in the flame were investigated.

While burners fabricated from fused silica were satisfactory, the best material investigated to date was ceramic, composed of 99% Al_2O_3 (Omegatite 450, Omega, Stamford, CT). The inner tube had an outer diameter of 3.2 mm and an inner diameter of 1.6 mm (Cat. # ORA11618-6, Omega). The outer tube had an outer diameter of 6.4 mm and an inner diameter of 4.0 mm (Cat. # ORX1814, Omega). Glass wool was packed between the inner and outer ceramic tubes to stabilize the inner tube and diffuse the gas flow in the outer tube. Burners fabricated from these components were found to be unaffected by the corrosive gases present in the flame. A special exhaust system was constructed to prevent the release of toxic and corrosive electrolysis and flame combustion products into the laboratory environment.

Gas flow to the burner was controlled with standard laboratory rotameters (Cole-Palmer, Chicago, IL). The hydrogen flow rate was 175 ml min^{-1} .

2.1.4. Electrolysis cell

An electrolysis cell was used to generate chlorine gas from aqueous chloride solutions. Fig. 2 shows a schematic diagram of the electrolysis cell that was fabricated from Pyrex glass tubing. The body of the cell was 2 cm in diameter and 6.5 cm long. A side arm, 2 cm long with an outside diameter of 6 mm, was positioned 4 cm from the bottom of the cell. A Teflon[®] stopper was machined and fitted with an O-ring to seal the top of the electrolysis cell. Holes in the Teflon[®] stopper for the electrodes and gas dispersion tube were drilled to provide a gas-tight fit. A gas dispersion tube (Cat. # 9435-D, Ace Glass, Louisville, KY)

Fig. 2. Scheme of the electrolysis cell. PS, power supply; P, hydrogen purge gas; TS, Teflon[®] stopper; OR, O-ring; GF, glass frit; E, Pt electrodes; TF, Teflon[®] fittings; T, glass trap.

with a porosity of 10–20 μm was used to bubble hydrogen through the aqueous sample. A hydrogen flow rate of 10 ml min^{-1} was used to purge electrolytically generated chlorine gas from the cell and into the flame. The electrodes were made of Pt/20% Ir (Nobel-Met, Roanoke, VA) and were 1.6 mm in diameter and 10 cm long. A d.c. power supply (Model # 3002A, Electro Industries, Chicago, IL) provided a current of 2 A at 5 V to the electrodes.

The purge gases from the electrolysis cell were first passed through a glass trap to prevent spray collecting in the transfer line. The outlet of the spray trap was connected to the burner with Teflon[®] tubing (3.2 mm outside diameter, 1.6 mm inside diameter). All gas connections were made with Teflon[®] Swagelok[®] fittings and ferrules (Texas Valve and Fittings, Irving, TX).

2.2. Reagents and solutions

All chemicals were ACS reagent grade and used without further purification. Standard NaCl solutions were prepared by drying ACS reagent-grade NaCl at 120°C for 24 h and dissolving weighed samples in 3 M H_2SO_4 . The 3 M H_2SO_4 solution was prepared by diluting concentrated sulfuric acid with deionized water.

A stock solution of isotopically enriched NaCl was prepared by dissolving a weighed sample of Na³⁷Cl in 3 M H₂SO₄. Isotopically enriched NaCl with a known isotopic composition (Lot I-2608, 94.97% ³⁷Cl; Lot I-3009, 94.15% ³⁷Cl) was obtained from Cambridge Isotopes, Cambridge, MA, and was dried at 120°C for 24 h before use.

2.3. Procedure

A 2.000-ml aliquot of the aqueous NaCl solution to be analyzed was transferred to the electrolysis cell using a Class A glass pipet. The stopper on the electrolysis cell was replaced, and the hydrogen flow to the burner and the purge tube was turned on. Following activation of the exhaust system, the hydrogen/entrained air flame was ignited. While the flame and the sample introduction system were stabilizing, the plane mirror (FM, Fig. 1) was rotated into position so that radiation from the external blackbody source would be directed into the emission port of the FTIR spectrometer. Once the external blackbody source had been turned on, it was allowed to heat until it glowed red, whereupon the FTIR and computer were turned on. After the FTIR was initialized and ready to collect data, the external blackbody source was turned off, and the mirror (FM) was rotated out of the optical path between the burner and the FTIR. Finally, the power supply to the platinum electrodes was turned on, and the ro-vibrational infrared emission spectrum of HCl was collected between 3200 and 2400 cm⁻¹ with the FTIR spectrometer.

For each analysis, spectra from unspiked and spiked samples were collected. Spectra from unspiked samples were used to determine the ratio of ³⁷Cl/³⁵Cl in the original sample. Once the spectrum of the unspiked sample was collected, the power to the electrodes was turned off, the Teflon[®] stopper was removed from the electrolysis cell, and the waste solution was discarded. The cell was rinsed with deionized water and dried using a tissue. A second 2.000-ml aliquot of the NaCl solution to be analyzed was then added to the electrolysis cell as before, and spiked with 0.500 ml of the isotopically enriched NaCl standard using a 500- μ l Oxford P-7000 Sampler Sys-

tem pipet (Monojet Scientific, St. Louis, MO). After adding the spike, the hydrogen purge was allowed to run for several minutes so that the bubbling action would completely mix the sample and the spike. Finally, the HCl spectrum of the spiked sample was collected as described previously. The ceramic burner tube was changed each time a new sample was run to minimize problems with sample carry-over.

3. Results and discussion

3.1. Sample introduction system

ID-FIRE determination of chloride ion in aqueous media must fulfill two primary requirements: (1) it must deliver analyte to the flame in a steady, continuous manner during the time period over which the FTIR collects spectral data; and (2) the volume should be as small as possible to minimize the size of the spike needed to produce a measurable change in the ³⁷Cl/³⁵Cl intensity ratio. The electrolysis cell shown in Fig. 2 fulfills both of these requirements.

The first requirement arises from the inherent nature of Fourier-transform spectroscopy—namely, that the variations in the intensity of radiation striking the detector are assumed to arise solely from the mirror movement in the Michelson interferometer, and are not due to other external factors such as variations in source intensity and/or the rate of sample introduction. The second requirement arises from the expense associated with isotopically enriched Na³⁷Cl (\$600 per 0.5 g). For the seawater analyses reported in this paper, a 0.500-ml spike of NaCl containing 0.01270 g Cl⁻ ml⁻¹ of isotopically enriched ³⁷Cl (95%) was sufficient to alter the ³⁷Cl/³⁵Cl intensity ratio of a 2.000-ml sample of seawater so that an isotope dilution determination could be conducted. Under these conditions, approximately 50 determinations of chloride ion in seawater could be conducted with a 0.5-g sample of Na³⁷Cl, making the cost per determination approximately \$12.

When the power supply (5 V) is activated and an aqueous sample containing chloride ion is

present in the electrolysis cell, hydrogen is generated at the cathode and chlorine is generated at the anode, according to the following half cells,

If the acidity of the solution in the electrolysis cell is controlled by the addition of 3 M H_2SO_4 , the hydrolysis of Cl_2 to hypochlorous acid can be prevented by the law of mass action, since the reaction

is readily reversible. With this arrangement, the chlorine gas generated by electrolysis can be sparged from solution using a gas dispersion tube and a stream of hydrogen gas. When the mixture of H_2 and Cl_2 enters the hydrogen flame maintained on the microburner, it combusts to HCl according to the reaction,

Once in the flame, the HCl is excited and emits the ro-vibrational 1–0 band at 3.46 μm in the near infrared.

The sample introduction system shown in Fig. 2 accomplishes the following objectives in an extremely convenient manner. (1) It converts the chloride ion in aqueous samples directly into gaseous HCl in a continuous manner compatible with the requirements of the FTIR. (2) The conversion of chloride ion into gaseous HCl occurs automatically and does not require sample handling or collection on the part of the operator. (3) The electrolysis step separates the analyte from most other constituents in the aqueous sample, thereby reducing potential interferences. (4) The HCl produced in the flame is automatically excited vibrationally at the temperature of the flame and emits the ro-vibrational spectrum of HCl at 3.46 μm . (5) The sample volume is small and minimizes the size of the spike needed for seawater analysis.

Finally, it should be stressed that, because of the nature of isotope dilution analysis, it is not necessary to convert all of the chloride ion in the sample to chlorine gas by electrolysis. Nor is it

necessary to purge all of the chlorine gas from solution into the flame and convert it to HCl. It is only necessary that the sample introduction system for ID-FIRE produce sufficient HCl in the flame for the FTIR to collect a spectrum.

3.2. Spectral considerations

Fig. 3 shows a typical infrared emission spectrum from 3200 to 2400 cm^{-1} , obtained by electrolyzing a 2.000-ml aqueous sample containing naturally occurring NaCl, using the sample introduction system described previously. The spectrum in Fig. 3, which clearly shows the P- and R-branches of the 1–0 band of HCl, was obtained by co-adding 20 mirror scans over a period of 2.08 min at a spectral resolution of 0.75 cm^{-1} using triangular apodization and 1×0 filling.

Fig. 4A shows an expanded portion of the HCl spectrum over the wavenumber interval from 2800 to 2500 cm^{-1} . Each rotational line in the HCl infrared emission spectrum is clearly split into a doublet. The smaller intensity component, due to H^{37}Cl , is located on the long wavelength side of the more intense H^{35}Cl line. For the 1–0 band of HCl, the constant separation between the components of the doublets [14,15] is about 2 cm^{-1} , a value that is easily resolved with modern FTIR instruments. For the naturally occurring NaCl sample shown in Fig. 4A, the intensity ratio of the H^{35}Cl component is about three times that of the H^{37}Cl component. This is in line with the expected natural abundance ratio of the two isotopes (75.77% ^{35}Cl and 24.23% ^{37}Cl) [16].

Fig. 4B shows an expanded portion of the HCl spectrum from 2800 to 2500 cm^{-1} for a sample of NaCl that has been spiked with an aliquot of isotopically enriched Na^{37}Cl . Compared with the spectrum in Fig. 4A, the intensity of the H^{37}Cl emission (I^{37}) in Fig. 4B is clearly increased, while the intensity of the H^{35}Cl emission (I^{35}) is clearly reduced.

In contrast to mass spectrometric measurements, where only a single pair of isotopic lines is available (corresponding to the masses of $^{35}\text{Cl}^-$ and $^{37}\text{Cl}^-$) [10], a single spectrum in ID-FIRE produces a large number of rotational pairs in the 1–0 band of HCl, each of which can be used to

Fig. 3. Flame infrared emission spectrum of HCl from 3200 to 2400 cm^{-1} at 0.75 cm^{-1} resolution showing the P- and R-branches.

determine the relative isotopic abundance of the two stable isotopes of chlorine. In this paper, rotational pairs refer to emission lines from H^{37}Cl and H^{35}Cl which start from the same initial J value and end at the same final J' value. Of the possible lines available in the HCl spectrum, Table 1 lists the pairs which were found to be the most satisfactory for isotope dilution work. Not surprisingly, these lines are the more intense components of the ro-vibrational spectrum and are located in the P-branch.

3.3. Isotope dilution

The concentration of chloride ion in an unknown aqueous sample can be determined by isotope dilution from Eq. (5),

$$\text{Cl}_s = \left[\frac{\text{Cl}_{\text{sp}} V_{\text{sp}}}{V_s} \right] \left[\frac{M_{\text{nat}}}{M_{\text{sp}}} \right] \left[\frac{\phi_{\text{sp}}^{37} - R_m \phi_{\text{sp}}^{35}}{R_m \phi_s^{35} - \phi_s^{37}} \right] \quad (5)$$

where Cl_s is the concentration (g ml^{-1}) of chloride ion in the unknown sample, Cl_{sp} is the known

concentration (g ml^{-1}) of chloride ion in the spike solution, V_s is the volume of the unknown sample, V_{sp} is the volume of the spike added, M_{nat} is the molar mass (g mol^{-1}) of naturally occurring chloride ion, M_{sp} is the molar mass (g mol^{-1}) of isotopically enriched chloride ion in the spike, ϕ_s^{37} is the natural abundance fraction of ^{37}Cl in the unknown sample prior to spiking, ϕ_s^{35} is the natural abundance fraction of ^{35}Cl in the unknown sample prior to spiking, ϕ_{sp}^{37} is the fractional abundance of ^{37}Cl in the spike solution, ϕ_{sp}^{35} is the fractional abundance of ^{35}Cl in the spike solution, and R_m is the measured ratio of $^{37}\text{Cl}/^{35}\text{Cl}$ in the sample after spiking. If R_s is the measured ratio of $^{37}\text{Cl}/^{35}\text{Cl}$ in the sample before spiking, the natural abundance fractions of ^{37}Cl and ^{35}Cl in the unspiked sample are given by Eq. (6) and Eq. (7), respectively.

$$\phi_s^{37} = \frac{R_s}{1 + R_s} \quad (6)$$

$$\phi_s^{35} = (1 - \phi_s^{37}) \quad (7)$$

Fig. 4. Flame infrared emission spectrum showing a portion of the P-branch of the HCl spectrum from 2750 to 2550 cm^{-1} at 0.75 cm^{-1} resolution. (A) Sample with the natural isotopic abundance of chlorine. (B) Sample spiked with Na^{37}Cl .

In ID-FIRE spectroscopy, R_s is taken as the ratio of the intensity of the $H^{37}Cl$ line to that of the corresponding $H^{35}Cl$ line for a given rotational transition (Table 1) before the sample is spiked. Likewise, R_m is taken as the ratio of the intensity of the $H^{37}Cl$ line to that of the corresponding $H^{35}Cl$ line for a given rotational transition (Table 1) after the sample is spiked.

3.4. Analytical validation

To validate ID-FIRE as an analytical method for the determination of chloride ion in aqueous samples, a series of analytical studies was conducted using synthetically prepared solutions containing known amounts of NaCl. The first step in the validation was to determine the optimum analytical procedure.

3.4.1. Line selection

As mentioned previously, the 1–0 vibrational band of HCl provides many pairs of transitions whose intensity ratios could be used to determine R_s and R_m . The best results were obtained using the average intensity ratio obtained from the seven line pairs of the P-branch of the HCl spectrum listed in Table 1. Analytical determinations using more than these seven line pairs did not improve the results. As a result, R_s and R_m values in Eq. (5) and Eq. (6) were calculated as the average intensity ratio of the seven line pairs listed in Table 1.

Table 2 gives the measured values of R_s obtained by averaging the ratios of the seven line pairs in Table 1 for 10 trials, each trial involving the coaddition of 20 spectral scans using the FTIR. The average R_s calculated from this spectral data and presented in Table 2 is within 1.2% of the value expected from the tabulated abundances of ^{37}Cl and ^{35}Cl (24.23 and 75.77%, respectively) [16]. The relative standard deviation of the ten trials is 2.60%.

It must be noted that great care was required in performing these experiments to avoid sample carry-over. Although the ceramic material used to fabricate the burner was quite satisfactory with respect to thermal stability and corrosion, it was easily contaminated. It was observed early in the

validation process that, after a spiked sample had been run through the instrument, the R_s values obtained on subsequent samples were noticeably increased. At first, the higher value for R_s was attributed to isotope carry-over in the electrolysis cell (in particular, the fritted glass purge tube) or in other portions of the transfer line. While careful cleaning of the electrolysis cell between samples proved to be important, the major contamination problem was traced to the ceramic tubing used to fabricate the burner. Contamination problems were avoided by carefully cleaning the electrolysis cell and replacing the ceramic tubing of the burner prior to running each new sample.

3.4.2. Limit of quantitation

A precise limit of detection is somewhat difficult to define for the ID-FIRE technique, since the procedure depends more on the determination of an accurate ratio of intensities rather than on the detection of an intensity in the presence of background noise. Thus, even though a weak HCl spectrum may be obtained for a dilute sample (clearly indicating the presence of chloride ion in the sample), the quantitative results obtained from the intensity ratios may be totally inadequate from an analytical standpoint. A limit

of quantification, defined as that concentration of Cl⁻ in the sample below which the ro-vibrational spectrum of HCl is no longer intense enough to give reliable ratios, was determined to be about 9 mg Cl⁻ ml⁻¹ (18 mg of chloride ion present in the 2-ml sample in the electrolysis cell).

3.4.3. Accuracy and precision

Table 3 compares the ID-FIRE results with a standard argentometric titration procedure [17] for the determination of chloride ion in a series of five standard solutions containing only aqueous NaCl. Each standard solution was analyzed four times by argentometric titration, and the average of each of the four separate determinations is shown in Table 3. For each ID-FIRE determination, the value of R_s for the sample was measured 4 times with separate aliquots of sample using the average intensity ratio from the seven line pairs in Table 1. The values of these four R_s measurements were then averaged and used in Eq. (5) and Eq. (6). To conserve the enriched Na³⁷Cl spike solution, the value of R_m was measured only once. Each standard NaCl solution was analyzed three times by ID-FIRE spectrometry, and the average of each of the three determinations is shown in Table 3.

The data in Table 3 show an average bias of -3.46% for the ID-FIRE method. Since the analytical results should depend only on the measured values of R_s and R_m , the negative bias must arise from errors associated with the measurement of the intensity ratio for the two isotopic components. One possible correction to the measured intensity ratio could involve differences in the values for the rotational constants for H³⁵Cl and H³⁷Cl.

For H³⁵Cl, the intensity I^{35} of any given rotational line in the infrared emission spectrum will be proportional to N_J^{35} , the number density of H³⁵Cl molecules in the flame in the upper vibrational level, with the rotational quantum number J . The number density, N_J^{35} , is given by [18],

$$N_J^{35} = \frac{N^{35}hcB^{35}}{kT} (2J+1) \exp\left[\frac{-B^{35}J(J+1)hc}{kT}\right] \quad (8)$$

where h is Planck's constant, c is the speed of light, k is Boltzmann's constant, B^{35} is the rotational constant of H³⁵Cl, T is the absolute temperature, and J is the rotational quantum number for the molecule in the upper vibrational state. Since an analogous equation describes the number density of H³⁷Cl molecules in the flame in the upper vibrational level with the rotational quantum number J , it is obvious that the intensity ratio I^{37}/I^{35} for any pair of isotopic rotational lines (emission lines from H³⁷Cl and H³⁵Cl starting from the same J value and ending at the same J' value) will depend on the ratio of the concentrations of these isotopic molecules in the flame and on the ratio of two terms which contain the rotational constants for H³⁵Cl and H³⁷Cl.

Rotational constants for the first vibrational excited state were determined [19] by an analysis of nine line positions in Fig. 3 and found to be 10.09 cm⁻¹ (10.1 cm⁻¹ in Ref. [19]) and 10.08 cm⁻¹ for H³⁵Cl and H³⁷Cl, respectively. This difference is not sufficiently significant to account for the negative bias shown in Table 3.

Another possible source of error in the measured intensity ratio for the two isotopic molecules is the effect of finite mirror retardation on instrumental line shape. Because the distance

traveled by the mirror in the interferometer is finite, the instrumental line shape obtained by Fourier transformation follows a sinc function [20]. In the ID-FIRE experiments, the side lobes of the sinc function were suppressed using a triangular apodization function. However, the presence of residual negative side lobes adjacent to the large ^{35}Cl peaks is clearly evident in Fig. 4A and Fig. 4B. These side lobes, when blended into nearby peaks, affect both line intensity and peak positions. The effect is most pronounced when one peak is more intense than another and the separation between adjacent peaks is small, i.e. the instrument is being used to monitor lines which are only just resolvable.

The effect of side lobes on the measured $^{37}\text{I}/^{35}\text{I}$ ratio is difficult to predict and will vary with the separation between the pair of isotopic rotational lines. While other apodization functions might be used to reduce side lobes, there will be a corresponding increase in linewidth and reduction in peak height. Clearly the best solution to this problem is to use an instrument with the highest possible resolution so that the ^{37}Cl and ^{35}Cl lines are more widely separated.

Since an increase in resolution or change in apodization function was not possible with the instrument used in these studies, an instrument calibration procedure was employed to minimize the negative bias observed for the ID-FIRE method. When the actual chloride ion concentrations in Table 3 (column 1) were plotted against

the ID-FIRE results, a least-squared linear relationship was obtained,

$$\text{corrected Cl}_s = 1.0622\text{Cl}_s - 0.4209 \quad (9)$$

with a correlation coefficient of 0.9997 for the regression line. As this instrumental correction factor must be empirically determined, Eq. (9) applies strictly to the instrument used in these experiments with the resolution conditions, apodization function and rotational line pairs described for this analysis.

Table 4 gives the results obtained with ID-FIRE using a single measurement of R_s and R_m for each determination. Column 2 gives the values obtained directly from Eq. (5); column 3 shows the results obtained by applying the instrumental correction factor given in Eq. (9). Each value in columns 2 and 3 represents an average of three determinations. From the data in Table 4, the average error was found to be -0.96% for the seven samples, and the average relative standard deviation for the seven samples was 3.3% .

3.4.4. Matrix effects

To assess the accuracy of the ID-FIRE technique in the presence of interferences, a series of synthetic NaCl solutions was prepared containing known amounts of bromide and iodide, two important potential interferences. Table 5 gives the results obtained for the determination of these solutions using ID-FIRE and a standard argentometric titration procedure [17]. The titrations were

^d Average of four determinations.

carried out using an autotitrator (DL 70, Mettler Instrument, Hightstown, NJ) equipped with a silver/silver chloride indicator electrode. Table 5 gives the concentration of chloride ion, in g l⁻¹, calculated from the known weight of primary standard NaCl in the solution. The results for ID-FIRE are the average of three determinations, and the results for the silver nitrate titration represent the average of four determinations.

It is clear from the data in Table 5 that the accuracy of the ID-FIRE determination of chloride ion is quite good even in the presence of relatively large amounts of bromide and iodide ions, both of which can be seen to cause substantial systematic errors in the silver nitrate determination. The accuracy obtained with the ID-FIRE determination of chloride ion in the presence of bromide ion, in particular, demonstrates the ability of isotope dilution to eliminate the effects of matrix interferences. In a previous FIRE spectrometry study [5] to determine chloride ion in aqueous media, a calibration curve, based on the intensity of the 1–0 band of HCl, was prepared using calibration standards. In this earlier FIRE study, the presence of bromide ion in the sample was found to significantly reduce the intensity of HCl emission from the flame, leading to large negative systematic errors in the determination of chloride ion.

In the ID-FIRE study, the presence of matrix components that affect the intensity of the HCl emission produced by the flame does not lead to analytical errors as long as the I^{37}/I^{35} intensity ratios of the 1–0 HCl band are unaffected. For

samples containing bromide ion and iodine ion, electrolysis of the sample produces Br₂ and I₂ along with Cl₂. However, when Br₂ and I₂ are introduced into the hydrogen/entrained air flame, they do not produce measurable emission from HBr and HI. They do, however, depress the overall intensity of the HCl emission signal, perhaps by the formation of interhalogen compounds which are known to form with several stoichiometries [21].

The depression of the HCl signal was more severe for the case of iodide ion than for bromide ion. This did not affect the analytical results obtained by ID-FIRE as long as the ro-vibrational spectrum of HCl was strong enough to allow the intensity ratios of ³⁵Cl and ³⁷Cl to be measured. If too much iodide ion was present, however, the emission intensity of the HCl band became too low to measure the intensity ratios.

3.5. Determination of chloride ion in seawater

Seawater was used to demonstrate the utility of ID-FIRE with a complex, real sample. Seawater provides an almost ideal sample for the ID-FIRE chloride ion determination because the concentration of chloride ion is typically about 20 mg Cl⁻ ml⁻¹ (well above the limit of quantification), and because argentometric titrations commonly used for the determination of chlorinity [17] are potentially subject to interference by other ions present in the sample, such as bromide ion and iodide ion.

Table 6 compares the results obtained by argentometric titration [17] and ID-FIRE for four sea-

water samples collected from different regions. Each sample was analyzed four times by titration and three times by ID-FIRE using the correction factor in Eq. (9). As shown in Table 6, the values obtained by the two techniques are in good agreement.

4. Conclusion

The ID-FIRE determination of chloride ion in aqueous samples has several important advantages. (1) Because the procedure is based on isotope dilution, sample introduction need not be quantitative, and matrix effects are minimized. (2) The conversion from chloride ion to HCl is handled automatically by the sample introduction system. Consequently, no sample pretreatment and minimal sample handling are required. (3) Compared with silver nitrate titrations, only a relatively small sample size is needed (2 ml). This may be of importance in the analysis of such samples as interstitial water from sediments (i.e. pore water analysis) where sample size is limited. (4) The method is rapid. Only 2 min are required to collect the spectral data.

A small negative bias, believed to be an artifact of the instrumental line profile, could be minimized by application of an empirically determined correction factor. Finally, the accuracy and preci-

sion obtainable with the ID-FIRE procedure depend on the amount of time, effort and expense warranted by the sample. In this paper, effort and expense was reduced by limiting the number of replicate samples and the number of FTIR scans collected for a given determination. It is clear, however, that these parameters can be increased if warranted by the analytical situation.

Abstract

Donnan Dialysis of Ag^+ and Zn^{2+} was investigated through a cation exchange membrane (CMS Neosepta) when a proton concentration difference was maintained between the two sides of the membrane. Developed for the production of brine from sea water, CMS Neosepta showed a higher permeability to monovalent than to bivalent cations. Several physico-chemical parameters have been determined (electrical resistance, membrane potential, sorption of electrolytes, Zn^{2+} and Ag^+ diffusion coefficients). The flux of Ag^+ and the diffusion potential in the membrane increase with HNO_3 concentrations. Ag^+ and Zn^{2+} can be separated because of the preferential membrane transfer for Ag^+ . © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Transport; Separation; Ag^+ ; Zn^{2+} ; Donnan dialysis; Monovalent cation selective membrane

1. Introduction

Among various techniques [1–7] that have been used for separation and concentration of cations mixtures, separation by Donnan dialysis is one of the simplest and most economical process.

The purpose of this work is to study Donnan dialysis in order to separate Ag^+ monovalent from Zn^{2+} bivalent cations. A CMS cation exchange membrane separates the salt mixture solutions from the acid solutions. Salts and acid have

the same common anion. Cations and protons move in opposite directions toward a final state corresponding to the equality of the electrochemical potentials for each cation in the two compartments. Previous experiments [8,9] have shown that the permeability of this CMS membrane was greater for sodium than for bivalent cations because a layer of positive charges has been fixed on one side of the membrane. This layer will induce a stronger electrostatic repulsion to bivalent than to monovalent ions.

First, several physico-chemical parameters of the membrane were determined when it was equilibrated with the electrolyte solutions. Then the

ionic fluxes as well as the potential difference between the two aqueous sides of the membrane (membrane potential) were measured and analysed for different systems.

2. Experimental

The CMS Neosepta membrane used for the experiments was manufactured by Tokuyama Soda. Its thickness was 150 μm and its exchange capacity 2.3 meq per gram of dry membrane. The working area was 7 cm^2 . Different systems with the following compositions were investigated:

$(10^{-2} \text{ M})\text{AgNO}_3$ and/or

$(10^{-2} \text{ M})\text{Zn(NO}_3)_2$ | CEM | $(x \text{ M})\text{HNO}_3$

In the stripping solution, the HNO_3 concentra-

tions range between 0.25 and 1 M. The salt solutions were in contact with the positive charge layer of the membrane.

The electrical resistance of the membrane, the amounts of sorbed electrolyte and the exchange capacity were determined by previously described methods [10].

The volume of the solutions on both sides of the membrane was 40 ml. The solutions were thoroughly stirred and the temperature maintained at 25°C. The flux of Ag^+ and/or Zn^{2+} arriving into the acid solution was measured by titrating these ions at regular intervals of time.

The membrane potential was measured under the same conditions by introducing two electrodes. These electrodes were connected to a millivoltmeter (Tacussel MINISIS 8000). When the feed solution contained only Zn^{2+} ions, the mem-

Fig. 2. Conductance (λ) of the membrane versus (n_s), the ratio of the moles of sorbed electrolyte over the exchange capacity. (◆) AgNO_3 ; (□) $\text{Zn}(\text{NO}_3)_2$.

brane potential was directly measured using a pair of KCl saturated calomel electrodes. In the presence of Ag^+ , the membrane potential was measured using a silver or a calomel electrode in the feed solution and a calomel electrode in the acid solution. The value of the membrane potential was deduced from the measured potential, taking into consideration the silver electrode and the calomel electrode standard potentials with the silver ion activity in the feed solution.

3. Results and discussion

3.1. Determination of diffusion coefficients

Fig. 1, shows the amount of sorbed moles per fixed site in the membrane at equilibrium with each electrolyte solution for different concentrations. From these data, it is possible to calculate the cation over anion concentration ratios in the membrane phase. The high values of these ratios

in the considered concentration range show a high rejection of nitrate co-ions, allowing to neglect the amount of nitrate anions in the membrane with respect to that of cations. The error on sorbed moles is $\pm 4\%$.

Figs. 2 and 3 show the variations of the membrane conductance λ ($\Omega^{-1} \text{ cm}^{-2}$) when equilibrated with HNO_3 , AgNO_3 and $\text{Zn}(\text{NO}_3)_2$ solutions as a function of the number of moles of sorbed electrolyte (n_s) present inside the membrane. The λ values were determined with an error lower than $\pm 5\%$. The extrapolated value of λ at $n_s = 0$ gives the value of the conductance when only counter-ions Ag^+ or Zn^{2+} [11] are bound to the fixed sites.

By applying the Nernst–Einstein equation to the extrapolated values of the membrane conductance, and taking into account that the membrane phase density is 1.04, one can deduce the values of the three different diffusion coefficients: 17.8, 3.47 and $0.46 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ for H^+ , Ag^+ and Zn^{2+} respectively.

Fig. 3. Conductance (λ) of the membrane versus (n_s), the ratio of the moles of sorbed electrolyte over the exchange capacity. Electrolyte = HNO_3 .

As expected protons give the highest mobility. But these results also show a higher mobility of Ag^+ ions with respect to Zn^{2+} ions and consequently explain the higher permeability of the membrane to Ag^+ .

3.2. Dialysis of silver ions

The system AgNO_3 (10^{-2} M)–membrane– HNO_3 (x M) was investigated for several concentrations of HNO_3 .

Table 1 gives the values of the flux of Ag^+ ions (J_{Ag^+}), crossing the membrane, the measured e.m.f. (E_M) of the electrochemical cell and the calculated diffusion potential inside the membrane.

The flux of Ag^+ and the diffusion potential increase with the increasing HNO_3 concentration in compartment 2. These results show that the transfer of protons is a rate determining step.

To determine membrane potentials, the following electrochemical cell was built up:

The measured e.m.f. (E_M) is the sum of all the potentials: electrode E_{Ag} , and $E_{\text{Hg-Hg}_2\text{Cl}_2}$, junction E_j , Donnan E'_i and E''_i and diffusion potentials E_D [12]:

$$E_M = E_{\text{Ag}} + E'_i + E_D - E''_i + [E_j](\text{KCl-HNO}_3) - E_{\text{Hg-Hg}_2\text{Cl}_2} \quad (1)$$

The following equation can be used to calculate the difference of the Donnan potentials, [13–15].

$$E'_i - E''_i = \frac{RT}{F} \ln \frac{(a'_{\text{Ag}^+})_1 (a_{\text{H}^+})_2}{(a_{\text{Ag}^+})_1 (a''_{\text{H}^+})_2} \quad (2)$$

where a' and a'' are the individual ion activities in the layers of the membrane phase in contact with the aqueous solutions and a_{H^+} and a_{Ag^+} the activities in the bulk aqueous solutions, subscripts 1 and 2 refer to the two solutions.

The junction potential $[E_j](\text{KCl-HNO}_3)$ can be calculated by applying the Henderson equation [16].

Eq. (1) can then be used to determine E_D from experimental values of E_M . But several assumptions are required:

1. The continuity of the electrochemical potential of the cations at each membrane–solution interface.

Table 1

Values of J_{Ag^+} , E_{M} , E_{J} and E_{D} for different concentrations of HNO_3 : System: AgNO_3 (10^{-2} M)–membrane– HNO_3 (x M)

HNO_3 (M)	$J_{\text{Ag}^+} \times 10^{10}$ (mol cm $^{-2}$ s $^{-1}$)	E_{M} (mV)	$[E_{\text{J}}]$ (KCl– HNO_3) (mV)	E_{D} (mV)
0.25	$80 \pm 2\%$	582	7	72.5 ± 1.5
0.50	$98 \pm 2\%$	610	10	87.0 ± 1.5
1.00	$123 \pm 2\%$	635	14	95.0 ± 1.5

Table 2

Values of $J_{\text{Zn}^{2+}}$, E_{M} , E_{J} and E_{D} for different concentrations of HNO_3 system: $\text{Zn}(\text{NO}_3)_2$ (10^{-2} M)–membrane– HNO_3 (x M)

HNO_3 (M)	$J_{\text{Zn}^{2+}} \times 10^{10}$ (mol cm $^{-2}$ s $^{-1}$)	E_{M} (mV)	$[E_{\text{J}}]$ $\text{Zn}(\text{NO}_3)_2$ –KCl (mV)	$[E_{\text{J}}]$ KCl– NO_3 (mV)	E_{D} (mV)
0.25	$7.3 \pm 2\%$	120	2	7	141 ± 2
0.50	$14.2 \pm 2\%$	153	2	10	150 ± 2
1.00	$18.0 \pm 2\%$	172	2	14	203 ± 2

- The amount of H^+ in the membrane layer of the (') interface is negligible with respect to the amount of Ag^+ . In the (") interface layer, the amount of Ag^+ is negligible with respect to the amount of protons.
- The activity coefficients of the cations in the membrane are equal to unity.
- The compositions of the aqueous phases are not significantly changed by the transmembrane transport of ions.

3.3. Dialysis of zinc ions

Comparing Tables 1 and 2 shows that Zn^{2+} ions provide lower fluxes than those obtained with Ag^+ ions.

The same type of equations as with Ag^+ is used to obtain the junction potentials and the same assumptions are applied for the calculation of E_{D} using Eqs. (1) and (2). Moreover, the following approximations have been used:

$$(a'_{\text{Zn}^{2+}}) = \frac{X}{2} \quad (3)$$

and

$$(a''_{\text{H}^+}) = X \quad (4)$$

X is the concentration of the fixed sites in the membrane phase.

3.4. Dialysis of silver and zinc ions

Table 3 shows that the Zn^{2+} flux remains always much lower than that of Ag^+ . The fluxes of these two ions increase with the increasing diffusion potential. The same electrochemical cell was used and an Ag^+ electrode has been used again.

The difference between the interfacial Donnan potentials $E'_i - E''_i$ is calculated using as previously the equality of electrochemical potentials of an ion in the solution and inside the membrane. In solutions containing several ions, potential calculations can be performed from the activities of any of these ions. In the present case, it is no longer the Ag^+ ion concentration which is supposed equal to the concentration of the fixed site in the membrane layer adjoining the interface but the sum of Ag^+ and Zn^{2+} concentrations.

$$(C_{\text{Ag}^+})' + 2(C_{\text{Zn}^{2+}})' = X = 2.2 \times 10^{-3} \text{ mol cm}^{-3} \quad (5)$$

These two concentrations were determined by measuring the amount of Zn^{2+} and Ag^+ ions in a membrane sample after being equilibrated in an aqueous solution of (10^{-2} M) AgNO_3 + (10^{-2} M) $\text{Zn}(\text{NO}_3)_2$:

$$(C_{\text{Ag}^+})' = 0.48 \times 10^{-3} \text{ mol cm}^{-3}$$

$$(C_{\text{Zn}^{2+}})' = 0.86 \times 10^{-3} \text{ mol cm}^{-3}.$$

Table 3

Values of J_{Ag^+} , $J_{\text{Zn}^{2+}}$, E_{M} , and E_{D} for different concentrations of HNO_3 System: AgNO_3 (10^{-2} M) + $\text{Zn}(\text{NO}_3)_2$ (10^{-2} M)–membrane– HNO_3 (x M)

HNO_3 (M)	$J_{\text{Ag}^+} \times 10^{10}$ (mol cm $^{-2}$ s $^{-1}$)	$J_{\text{Zn}^{2+}} \times 10^{10}$ (mol cm $^{-2}$ s $^{-1}$)	E_{M} (mV)	$[E_j]$ (KCl– HNO_3) (mV)	E_{D} (mV)
0.25	$80 \pm 2\%$	$10.2 \pm 2\%$	598	7	126.5 ± 1.5
0.50	$120 \pm 2\%$	$11.5 \pm 2\%$	615	10	129.0 ± 1.5
1.00	$132 \pm 2\%$	$12.6 \pm 2\%$	634	14	134.5 ± 1.5

Table 4

Separation of silver from zinc with CMS membrane after one hour dialysis Initial concentration in compartment (1): AgNO_3 (10^{-2} M) + $\text{Zn}(\text{NO}_3)_2$ (10^{-2} M)

Initial [HNO_3] (M) compartment (2)	Compartment composition (2)		Extractions factors	
	[Ag^+] 10^3 M	[Zn^{2+}] 10^3 M	Ag^+	Zn^{2+}
0.25	5.4	0.7	1.17	0.075
1.5	7.6	0.7	3.17	0.075
1	8.4	0.7	5.25	0.075

In classical exchange membranes, cations of different charges can be separated because of the preferential transfer of low charged cations. An extraction factor K_1^2 , is defined for every cation between two solutions (Table 4):

$$K_1^2 = \frac{C_2}{C_1} \quad (6)$$

where C is the concentration of the cation after 1 h dialysis; subscripts 1 and 2 refer to the solutions in compartments (1) and (2).

If $K_1^2 > 1$ or < 1 , most of the cations will be recovered in compartment 2 or in compartment 1 respectively.

Equimolecular amounts of silver and zinc in the feed solution were separated into two fractions, one enriched in silver and the other enriched in zinc. Results show that cations can be separated from each other with this membrane (Table 4).

4. Conclusion

The CMS Neosepta membrane previously used to separate sodium from calcium in sea water can also be used to separate other cations such as

Ag^+ from Zn^{2+} . Our results show that the extraction coefficients were higher than 1 for Ag^+ and lower than 1 for Zn^{2+} (Table 4).

The efficiency of this separation, (i.e. the Ag^+ over Zn^{2+} extraction coefficients ratio) is increasing when HNO_3 concentration and diffusion potential are increasing.

The extraction equilibria of the ion associate of periodate with 1-(3,5-diamino-6-chloropyrazinecarboxyl) guanidine

S.M. Aldhaferi *

Department of Chemistry, Faculty of Science, UAE University, P.O. Box 17551, Al-Ain, United Arab Emirates

Received 7 July 1997; received in revised form 30 October 1997; accepted 13 November 1997

Abstract

The extraction equilibrium of the ion-associate of periodate with 1-(3,5-diamino-6-chloropyrazinecarboxyl) guanidine hydrochloride (DPG^+Cl^-) was investigated spectrophotometrically. The optimum conditions for the extraction of the ion associate $\text{DPG}^+ \cdot \text{IO}_4^-$ with cyclohexanone have been established. The ion association constants, β , K_D and K_{ex} and the molar absorptivity of the formed ion associate were determined. These values enable a convenient application of the investigated system for the extraction spectrophotometric determination of periodate ions in the aqueous media. The molar ratio of the ion associate was found to be 1:1 of periodate to the reagent DPG^+Cl^- at pH 4–5. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Extraction equilibrium; Periodate; DPG^+Cl^- ; Ion-associate

1. Introduction

The oxoanions are amongst the latest studies groups of species from which form liquid–liquid extractable ion associates with onium cations [1–6]. In previous articles, El-Shahawi et al. [4–6] reported the formation and extraction of perruthenate bismuthate and periodate with some onium cations.

The compound 1-(3,5-diamino-6-chloropyrazinecarboxyl) guanidine hydrochloride (DPG^+

Cl^-), also called amiloride hydrochloride (Fig. 1), has been successfully applied as analytical reagent [7–9]. A number of selective and sensitive spectrophotometric and spectrofluorometric methods were developed for the determination of perchlorate, perrhenate and periodate employing this reagent. In these articles, it was shown that the extraction systems of reagent associates formed with oxoanions proceeds rapidly with a high recovery factor. In the connection with the development of new selective analytical methods using amiloride or amiloride derivatives, a deeper understanding of the extraction mechanism is required. Thus, the present communication reports

* Permanent address: Federal Environmental Agency, P.O. Box 5951, Abu Dhabi, United Arab Emirates. Tel.: +971 2 777363; fax: +971 2 770501.

the extraction equilibrium of the reagent associate formed with periodate in aqueous solution with a view to achieve better association and complete extraction of the produced associate into organic phase.

2. Experimental

2.1. Apparatus

A Shimadzu double beam UV-visible spectrophotometer model UV-2101 PC with 1 cm stoppered quartz cells and Shimadzu FTIR 8101 Fourier transform infrared spectrophotometer were used. A Philips 9418 digital pH-meter with a glass and saturated calomel electrodes were used for the pH measurements.

2.2. Reagents and solutions

All chemicals used were of analytical reagent grade. Britton–Robinson buffer was prepared from boric, acetic and phosphoric acids and sodium (chloropyrazinecarboxyl) guanidine hydrochloride dihydrate (Merck) was used without further purification. A 0.01 M solution of the reagent DPG^+Cl^- hydrochloride was made by dissolving 0.3021 g of the reagent in 100 ml of distilled water-hydrochloric acid (1:1 v/v).

2.3. Procedure

Transfer aliquot portions (2 ml) containing various amounts of the reagent DPG^+Cl^- (1.2×10^{-5} – 40×10^{-5} M) to 50 ml of potassium periodate solution to cover the concentration range 1 – 6.5×10^{-6} M KIO_4 at pH 4. Extract twice with 10 ml (2×5) of cyclohexanone and shake the funnels on a shaking machine for 10 min. After separation of the two layers, the aqueous phase was transferred through a filter paper and the periodate in the aqueous phase was then determined iodometrically with 1×10 M sodium thiosulphate or spectrophotometry as triiodate after addition of KI. The concentration of the periodate in the parallel samples containing the same amount of the reagent DPG^+Cl^- was

measured without extraction with cyclohexanone. The amount of periodate in the organic phase was then calculated by the difference and distribution coefficient was calculated by Eq. (11) (see the text below). Collect the organic layer and filter it through a filter paper impregnated with cyclohexanone into 10 mm quartz cell. Measure the absorbance at 354 nm against a reagent blank.

3. Results and discussion

3.1. Examination of the main experimental variables

The extraction of the reaction product of periodate ions and the reagent DPG^+Cl^- was examined in a variety of solvents with a range of functional group types, e.g. ketones, esters, ethers and chlorinated and aromatic hydrocarbons. Cyclohexanone was found the most efficient extraction with a low blank in the absence of periodate ions. Similarly [7,8] with perchlorate and perrhenate, the mechanism of the extraction is presumed to be based on the formation of an ion-associate complex. In cyclohexanone the produced ion-associate gave the highest absorbance and apparent molar absorptivity at 354 nm at pH 4–6 of the aqueous phase. This behaviour is considered to be due to the weak proton-accepting properties of the periodate ion of the ion pair of the donor accepting properties of the ion pair and the solvent respectively [10]. Therefore, cyclohexanone was selected as a proper solvent for these reasons and because its lower density allows a better separation of layers. The extraction of the ion-associate in cyclohexanone was rapid and the absorbance of the extracted species was found to be

*Aqueous solution 10 ml, organic phase 10 ml and $[\text{IO}_4^-] = 6.50 \times 10^{-6}$ M.

constant up to 2 h standing time for sampling containing $1-6.5 \times 10^{-6}$ M KIO_4 .

The influence of the pH of the aqueous phase was critically investigated by mixing 2 ml of aliquot (10 ppm periodate) solution with 2 ml of 0.01 M amiloride hydrochloride and 5 ml Britton–Robinson buffer (pH 2.2–11). The organic phase was separated, shaken with anhydrous sodium sulfate (0.2 g) and filtered to remove water and the absorbance of the organic extract was measured at $\lambda = 354$ nm against the reagent blank. The absorbance was found high and almost constant in the pH range 4–6 and decreasing outside this limit. Thus, in the subsequent work, the aqueous phase was buffered at pH 4–6. The absorbance of the formed associate was found constant over 5–15 ml of buffer. Thus, 5 ml buffer solution were used in the subsequent work.

The composition of the extracted ion-associate in cyclohexanone was determined by the continuous variation method [11]. Equimolar solutions of potassium periodate and the reagent DPG^+Cl^- (0.001 M) were mixed in complementary proportions to a fixed total volume at pH 5 with 10 ml of cyclohexanone and were allowed to equilibrate for 10 min for completion of the reaction. The absorbance of the produced ion-associate was measured against a reagent blank. A plot of the absorbance of the extracted ion-associate in the organic phase versus $[\text{IO}_4^-]([\text{IO}_4^-] + [\text{DPG}^+\text{Cl}^-])$ produced a graph that indicate the formation of

an ion-associate having a periodate to a reagent ratio 1:1. The molar absorptivity of the produced ion-associate was found to be $4.0 \pm 0.3 \text{ mol l}^{-1} \text{ cm}^{-1}$.

In aqueous acid media periodate ion has complex equilibria and resembles tellurates in their stoichiometries. The main equilibria in acid solutions are as follows [12]:

Thus, the produced ion-associate was isolated in the solid state by evaporation of the organic solvent under reduced pressure and was characterized by elemental analysis (Calculated, C = 17.81, H = 2.22, Cl = 8.85, N = 24.23 found, C = 17.92, H = 2.34, Cl = 9.26 and N = 24.66) and visible spectra. The electronic spectrum of the isolated associated dissolved in cyclohexanone was found identical with that of the organic phase obtained by the extraction of the periodate with the reagent DPG^+Cl^- at pH 5 indicating that the extracted and isolated species are identical. The IR spectrum of the isolated solid ion-associate in KBr disc was also compared with those of KIO_4 and the reagent DPG^+Cl^- recorded separately in KBr discs and as a mechanical mixture of KIO_4 and the amiloride hydrochloride with some differences ascribed to the formation of the respective

ion-associate of chemical formula $C_6H_9ION_7^-$ IO_4^- . Thus, the predominant species in the aqueous phase under the used experimental conditions is the IO_4^- species.

3.2. Extraction equilibria

To calculate the equilibrium constants K_{ex} , K_D and β , the extraction equilibrium was critically investigated according to the previously reported model [13]. The following equilibria were considered:

(i) Formation of an ion-associate in the aqueous phase according to the reaction:

with an equilibrium constant (ion-association constant, β)

$$\beta = [DPG^+ \cdot IO_4^-] / [DPG^+ + IO_4^-]. \quad (6)$$

Fig. 2. The plot of $\log [DPG^+ Cl^-]$ vs. $\log D_{IO_4^-}$ ($C_{IO_4^-} = 1.9 \times 10^{-6}$ M).

Table 2

Values of K_{ex} , K_D and β for the extraction system of equilibrium constants of the produced ion-associate in cyclohexanone*

$\log K_{ex} = 4.8 \pm 0.2$	$K_{ex} = 6.3 \times 10^4 \pm 1.7$	$n = 8$
$\log K_{ex}^* = 4.2 \pm 0.3$	$K_{ex}^* = 1.6 \times 10^4 \pm 2.1$	$n = 4$
$\log K_D = 1.2 \pm 0.2$	$K_D = 15.8 \pm 1.4$	$n = 7$
$\log \beta = 3.7 \pm 0.2$	$\beta = 4.8 \times 10^3 \pm 1.61$	$n = 8$

*Values obtained by the Likussar and Boltz method [14].

**Conditions: Extraction from 50 ml of aqueous solution of KIO_4 ($1-6.5 \times 10^{-4}$ M) at pH 4 mixed with 2 ml of the reagent $DPG^+ \cdot Cl^-$ ($1.2 \times 10^{-5}-40.0 \times 10^{-5}$ M) with 10 ml (2×5) cyclohexanone.

(ii) Distribution of the ion-association complex between the aqueous and the organic phase:

with a distribution constant, K_D

$$K_D = [DPG^+ \cdot IO_{4(org)}^-] / [DPG^+ + IO_{4(aq)}^-]. \quad (8)$$

The overall extraction process is described by the equation

With the corresponding extraction constant K_{ex} .

$$K_{ex} = [DPG^+ \cdot IO_{4(org)}^-] / [DPG^+] \cdot [IO_{4(aq)}^-] = K_D \beta. \quad (10)$$

Hence, assuming one equilibrium species (IO) of periodate (Eq. (1)) is the only predominant at a given pH 4–6, the distribution ratio $D_{IO_4^-}$ was determined at a constant initial IO_4^- concentration in the aqueous phase and various concentrations of $[DPG^+ Cl^-]$ according to the formula:

$$D_{IO_4^-} = [DPG^+ \cdot IO_{4(org)}^-] / [DPG^+ \cdot IO_{4(aq)}^- + [IO_{4(aq)}^-]]. \quad (11)$$

At low concentrations of $DPG^+ Cl^-$, Eq. (11) transforms into the following [13]:

$$D_{IO_4^-} = [DPG^+ \cdot IO_{4(org)}^-] / [IO_{4(aq)}^-]. \quad (12)$$

After substituting Eq. (12) into Eq. (10) and taking the logarithms, the following equation is obtained:

$$\log D_{IO_4^-} = \log K_D \beta + \log [DPG^+]_f. \quad (13)$$

Table 3

A comparison on the values of the molar extinction coefficient ($\log \varepsilon$) of the ion-associates of some spectrophotometric procedures on the determination of periodate ions

Method	λ_{\max} (nm)	$\log \varepsilon$ (mol l ⁻¹ cm ⁻¹)	Reference
Amiloride hydrochloride-IO ₄ ⁻ *	354	4.6	Present work
Trimethylammonium iodide-IO ₄ ⁻ **	509	4.8	[5]
Amiloride hydrochloride-IO ₄ ⁻	354	4.6	[9]
Tiphenyltetrazolium chloride-IO ₄ ⁻	295	5.0	[15]

*Solvent = 4-Methyl-2-pentenone.

**Solvent = Cyclohexanone.

The results obtained at pH 4 are presented in Table 1. The mass balance equation is given by

$$[\text{IO}_4^-]_{\text{aq.}} V_{\text{aq.}} + [\text{IO}_4^-]_{\text{org.}} V_{\text{org.}} = [\text{IO}_4^-]_{\text{aq. initial}} V_{\text{aq.}} \quad (14)$$

where $V_{\text{aq.}} = 10$ ml and $V_{\text{org.}} = 10$ ml. The β , K_{ex} and K_{D} values were then determined graphically from the experimental data (Table 1) of the distribution ratio, $\log D_{\text{IO}_4^-}$ vs. $\log[\text{DPG}^+ \text{Cl}^-]$. The equilibrium concentration of $[\text{DPG}^+]_{\text{f}}$ was calculated employing the equation

$$\begin{aligned} [\text{DPG}^+ \text{Cl}^-]_{\text{initial}} &= [\text{DPG}^+ \text{IO}_4^-]_{\text{org.}} V_{\text{org.}} \\ &= [\text{DPG}^+ \text{IO}_4^-]_{\text{aq.}} V_{\text{aq.}} \end{aligned} \quad (15)$$

The results are summarized in Fig. 2. The values of K_{ex} and K_{D} are read from the plot (Fig. 1) and the β calculated from $\beta = K_{\text{ex}}/K_{\text{D}}$. Table 2 summarizes the values of equilibrium constants of the produced ion-association complex in cyclohexanone. The composition of the extracted species was also obtained from the slope of Fig. 2 and confirmed the composition of the extraction ion-associate to be $\text{DPG}^+:\text{IO}_4^- = 1:1$. The values of K_{ex} (Table 2) was also obtained employing the method of Likussar and Boltz [14] with equimolar solution of periodate and the reagent $\text{DPG}^+ \text{Cl}^-$ in a concentration ($C_{\text{DPG}^+} + C_{\text{IO}_4^-} = 1.1 \times 10^{-4}$ M) and a constant volume of solutions (or extracts) against the proper blank solution containing the $\text{DPG}^+ \text{Cl}^-$ in the same concentration. The values confirmed data obtained according to the chemical model reported by Alexandrov et al. [13].

4. Conclusion

The present article demonstrates that the liquid–liquid extraction procedure involving the formation of the ion-association complex $\text{DPG}^+ \cdot \text{IO}_4^-$ is applicable for periodate determination. The extracted ion-associate has a moderate stability, $\beta = (1.2 \pm 0.28) \times 10^{-4}$. The molar absorptivity of the produced ion-associate $\varepsilon = (4.02 \pm 0.29) \times 10^{-4}$ mol l⁻¹ cm⁻¹ competes favorably with the molar absorptivities of most ion-associates on spectrophotometric determination of periodate (Table 3).

Short communication

Some aspects of the use of heteropoly anions in elemental analysis by simple potentiometric ion-pair formation-based titration

K. Vytřas *, J. Ježková, J. Skořepa

Department of Analytical Chemistry, Faculty of Chemical Technology, University of Pardubice, CZ-532 10 Pardubice, Czech Republic

Received 15 July 1997; received in revised form 8 January 1998; accepted 9 January 1998

Abstract

The possibility of the use of heteropoly anions formed by addition of phosphate to the solutions of either molybdate or tungstate in the determination of phosphorus by the simple method of potentiometric titration was studied. The heteropoly anions are titrated on the ion-pairing principle using a titrant containing a lipophilic counter-ion, i.e. 1-(ethoxycarbonyl)pentadecyltrimethylammonium bromide (Septonex), the titration being monitored by carbon paste electrode, although other liquid membrane-based electrodes can also be used. Calibration plots of the titrant end-point consumption vs. concentration are not linear, but allow one to evaluate the content of phosphorus. Similar procedures, when optimized, should be elaborated for determination of numerous other elements forming heteropoly anions. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Potentiometric titrations; Ion-pairing reaction; Heteropoly anions; Carbon paste ion-selective electrodes

1. Introduction

Many salts are known having complex anions which contain either molybdenum or tungsten atoms, oxygen atoms, and a much smaller proportion of atoms of another acid-forming, relatively small element, such as P(V), As(V), Si(IV), etc.; the 12-heteropoly anions of general formula

$[X^{n+}M_{12}O_{40}]^{(8-n)-}$ [where X^{n+} is a central cation and M represents either Mo(VI) or W(VI)] are the most common examples [1,2]. Molybdoheteropoly anions of this type are of some importance in analytical chemistry of many elements. For example, the reaction in which the canary-coloured precipitate is obtained in the cold by adding a solution of a phosphate to a solution of ammonium molybdate containing nitric acid and the formula of which is $(NH_4)_3[PMo_{12}O_{40}] \cdot 2HNO_3 \cdot H_2O$, serves for a qual-

* Corresponding author. Tel: +420 40 6037512; fax: +420 40 6037068; e-mail: karel.vytras@hlb.upce.cz

itative detection of phosphate [3]. Spectrophotometric measurements of yellow solutions of molybdoheteropoly anions (or, after their reduction, of so-called molybdenum blue) are often used for quantitative analysis of phosphorus, arsenic and silicon [4]. Recently, a method of spectrophotometric determination of yttrium by reaction with molybdate (in which a heteropoly anion is formed) and Rhodamine B (forming an ion-pair with this heteropoly anion) was reported [5].

In potentiometry, salts of some heteropoly anions (mostly 12-tungstophosphates) can be incorporated as electroactive ion-exchangers into membranes of ion-selective electrodes used in direct potentiometric determination of various cations and, in addition, the solutions of these salts can also be used as anionic titrants in potentiometric ion-pair formation-based titrations. Applications have been described for determination of salts of various alkaloids, antibiotics, vitamins, cationic and non-ionic surfactants, etc. [6–17]. A reverse procedure in which 12-molybdophosphate was titrated with cetylpyridinium chloride and monitored using a cathodically polarized platinum indicator electrode has been described by Selig [18,19]; the method involving the conversion of the orthophosphate first to the molybdophosphate followed by precipitation of it as the tris(cetylpyridinium) 12-molybdophosphate has also been studied.

In this report, we have investigated the new possibilities of monitoring the titrations of heteropoly anions using carbon paste electrodes as potentiometric indicators.

2. Experimental

2.1. Apparatus

Potentiometric titrations were performed using an OP-208/1 pH meter (Radelkis, Budapest) in manual mode, or ATI Orion 960 Autochemistry System (Orion Research, Boston, MA) connected to an HW 486DX2 80 personal computer if auto-

mated mode was used. Sensing electrode was the carbon paste electrode [20], with paste prepared by intimate mixing of 1.0 g graphite powder (CR 5, Tesla, Lanškroun) and 0.4 cm³ of tricresylphosphate (p.a. grade, Lachema, Brno). An RCE-102 calomel electrode (Crytur, Turnov) of double-junction construction, filled with saturated potassium chloride (inner compartment) and 0.1 M sodium nitrate (outer compartment) was used as a reference half-cell.

Fig. 1. Automated potentiometric titration of phosphate (10 $\mu\text{mol}/50 \text{ cm}^3$) with 0.01 M Septonex in the presence of 0.12 mmol Na_2WO_4 and 9.6 mmol HCl. Output of the ATI Orion 960 Autochemistry System; end-point titrant consumption, 3.400 cm³.

Fig. 2. Calibration dependences for determination of phosphorus forming (A) molybdophosphates; (B) tungstophosphates.

2.2. Titrant and other solutions

1 - (Ethoxycarbonyl)pentadecyltrimethylammonium bromide (Septonex, Slovakofarma, Hlohovec) as a 0.01 M aqueous solution was used as the titrant. Stock solutions of $\text{Na}_3\text{PO}_4 \cdot 12\text{H}_2\text{O}$, Na_2WO_4 and $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$ as well as all other solutions were prepared from analytical grade chemicals; deionized and distilled water was used throughout.

3. Results and discussion

As confirmed by titrations of phosphate mixed with either molybdate or tungstate in various ratios, heteropoly anions of different composition (or mixtures of them) were obtained during such conversions. Although the shape of the potentiometric titration curves was always convenient for evaluation of the end-point (see Fig. 1), the titration stoichiometry did not remain constant, thus not allowing suggestion of a general procedure. It should be noted that the results presented in previous papers [18,19] also did not bring unequivocal conclusions and some corrections based on an empirical logarithmic relationship between the amount of phosphorus present and the optimum Mo/P ratio had to be used (perhaps this was also a reason why no similar study appeared since the papers were published). Finally, it seemed that

such an evaluation must be used which allows determination of the content of phosphorus using calibration dependences.

In the procedure using molybdate, a constant amount of $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$ (2 cm³ of 0.009 M solution) was measured into a 100-cm³ beaker, and volumes of 0.0, 0.1, 0.2, ... 1.0 cm³ of 0.01 M Na_3PO_4 were pipetted, water was added to ca. 50 cm³, pH adjusted by addition of 1 cm³ conc. hydrochloric acid, and the solution was titrated with 0.01 M Septonex. In the second procedure, a constant amount of Na_2WO_4 (1 cm³ of 0.12 M solution) was measured into a beaker, and the same portions as given above of other components were added before the titration started. The end-points were evaluated and plotted against the concentration of phosphorus. As seen in Fig. 2, the dependences, although not linear, could be used to determine the content of phosphorus up to ca. 0.1 μmol cm⁻³ concentration in the sample. For lower contents of phosphorus where the calibration curve is nearly linear, it is expected that the determination proceeded via the reaction

i.e. with the stoichiometric 1:3 P/titrant ratio. However, as quite different heteropoly anions may be formed in dependence on the P/Mo (P/W) ratios, the pH value to which solutions are adjusted, sequence of the reagents added, etc.

[23], both calibration curves follow non-linear dependences.

4. Conclusions

Although much work must be done to optimize the procedures (finding the optimum pH value, minimizing the blank when using tungstate, studies at lower concentration levels, etc.), it could be concluded that the formation of heteropoly anions of molybdate and tungstate with other species like PO_4^{3-} , AsO_4^{3-} , BO_3^{3-} , SiO_4^{4-} , IO_4^- , etc. [21,22] offers some new possibilities to determine quite a lot of elements and perhaps also to contribute to their speciation studies by simple potentiometric methods. This preliminary communication is believed to be the first of some systematic research achieved in this field.

Book reviews

Molecular Genetics and Evolution of Pesticide Resistance. T.M. Brown (editor), ACS, Washington, DC, 1996. xiii + 265pp. US\$ 97.95. ISBN 0-8412-3453-1

This volume is compiled from two dozen papers given at a special conference on Molecular Genetics and Ecology of Pesticide Resistance. Although the discussion of pesticide resistance is not new, the investigation of its genetic aspect is a currently expanding field. Papers have been carefully selected to provide coverage of the most important findings in the all relevant areas of pesticides and pests. This must have been a particularly daunting task for the committee since the pests under investigation vary greatly and include species of bacteria, fungi, plants (weeds) and insects, although it is only at the molecular level that some of the similarities in resistance mechanisms become apparent. The similarities between antibiotic and pesticide resistance are also discussed with a chapter specifically set aside to review this issue. This in fact is one of the most interesting chapters as it highlights, in a condensed form, the different molecular and subsequent biochemical modifications which result in resistance.

The text is divided into four sections. Firstly, molecular genetics, which clearly demonstrates how important it is to investigate this aspect of resistance if we are to make any progress in developing novel pesticides that do not quickly become redundant due to further resistance. Secondly, a selection of papers under the topic of evolution and population genetics includes discussion of the use of genetic monitoring to detect the incidence of resistance. The section on resistance management strategies is brief but informative,

giving excellent insight through practical experience. Finally, ecology, transgenesis and regulatory issues are discussed and demonstrate some of the really problematic issues in this field, namely the transfer of resistance throughout a population and between species. The monitoring of the movement of genetic resistance between plants is particularly important with the advent of genetically engineered crops that are resistant to herbicides or pests. This aspect is concisely reviewed in one of the chapter in this section. The book is rounded off with a chapter which considers the role of regulatory organizations (US EPA) in the control of pesticide resistance.

On the whole this is a very informative book which addresses many of the important aspects of pesticide resistance, an area that will certainly gain importance in coming years. This is a relatively specialized text that will not be immediately accessible to those outwith the field. However, I believe that readers from widely differing scientific backgrounds will find something of interest if they take the time to browse through this text.

Environmental Immunochemical Methods by J.M. Van Emon, C.L. Gerlach and J.C. Johnson (Eds.), ACS, Washington, DC, 1996. x + 342 pp. US\$109.95. ISBN 0-8412-3454-X.

This book provides an excellent cross-section of the many and often widely differing environmental applications of immunochemical detection. In recent years environmental immunochemistry has

gained increasing recognition as an inexpensive but reliable analytical technique with a number of procedures now validated for regulatory purposes. This volume presents almost 30 papers which, between them, encompass aspects of research and development, application of methods, data interpretation, and evaluation. As may be expected a number of the applications focus on the detection of pesticides in the environment, however this fact does not lead to repetition, instead it highlights the many different formats which can be used to exploit immunological interactions. This indeed is one of the real strengths of this text, illustrating, by the diversity of papers, the very many and varied ways the technique can be employed. For example, Van Emom and Lopez-Avila demonstrate how immunoaffinity can be utilised as a preliminary extraction for target analytes with subsequent detection by LC-MS. This application provides a solution to the extraction of pollutants from complex matrices and the added advantage of being adapted to on-line processing. Other methods presented adopt the more traditional methods such as ELISA, but include a number of alternative modifications which customise their application to suit specific analytes.

This publication not only provides papers covering the practical aspects of immunochemistry but also addresses the issue of accessible communication, namely through a focal Web site dedicated to this field. Discussion of this issue is clearly presented, including prototype pages and defined guidelines regarding how this project will be implemented, which once initiated will provide an excellent resource. Importantly, quality assurance and the calibration of assays are dealt with in their own right, providing useful guidelines for researchers setting out to evaluate their immunoassay.

It can be concluded that this book provides a very useful resource to anyone involved in the development, evaluation or use of environmental immunochemistry. The nature of this text is such that it is easily accessible to those new to this field, an aspect which is enhanced by the extensive use of explanatory diagrams, while also providing an exciting collection of papers that will be of interest to those with many years experience in this area.

Subject Index

Volume 46 (1998)

- Absorption spectra 1433
Acemethacin determination 1493
Acetaminophen 1577
Acid–base equilibria in montmorillonite suspensions 951
Acid dissociation constant 1285
Activated carbon 1311
Adrenaline 985
Adsorption 1387
Adsorptive cathodic stripping voltammetry 1137
Ag⁺ 1605
Ag(I) determination 1387
Al–EDTA 227
Aliquat-336 921
Alkali Blue 6B 551
Al–oxalate 227
Amberlite IRC-718 1515
Amberlite XAD-2 1479
Amines and amino acids 565
Amino acids 491
Amperometric detection 149, 711
Ampicillin 101
Analysis 815
Analysis of alloy 521
Anilino-(1,3-dioxo-2-indanylidene) acetonitrile 885
Anion coordination chemistry 1079, 1085
Anion exchange chromatography 291
Anion-exchange FPLC–ICP–AES 227
Anodic stripping voltammetry 607
Antimony 1531
Antimony screening 1265
Application studies 45
Aqueous 145
Aqueous medium 1439
Arsenic 867, 1311
Atomic absorption spectrometry 541, 615, 1557
Atomic emission spectrometry 395
Autoprotolysis constant 1285
Azo dyes 491
- Background current 129
Ba(IO₃)₂ 149
Barbiturates and phenytoin 111
- Base dissociation constant 1285
Bentazon 1131
Benzeneacetaldehyde-4-hydroxy- α -oxo-aldoxime 1425
Benzoxainone derivative 573
Berberine 679
Binary and ternary complexes 53
Biogenic amines 1079, 1085
Biological fluids 83
Biological samples 501, 1107
Biosensor 1223
2,2'-bipyridyl 1285
1,4-bis(naphth[2,1-d]oxazole-2-yl)benzene 679
Blood 1347
Borate complex 717
Bovine serum albumin 171
Brass 1531
Bromoacetone 589
5-Br-PADAP 1107
BTEX 1169
Bulk acoustic wave 171
- Cadmium 101, 301
Cadmium(II) 551
Cadmium(II)–taurine complexes 91
Cadmium matrices 1525
Calcium 1245
Calibration transfer 129
Calixarene hydroxamic acid 1041
1,3-calix[4]bisnaphthyl-crown-6 1485
Capillary electrophoresis 255, 565, 735, 743
Capillary gradient gel electrophoresis 727
Capillary zone electrophoresis 1, 291, 347
Captopril 75
Carbon fiber ultramicroelectrode 985
Carbon paste electrode 1363
Carbon paste ion-selective electrodes 1619
Carboxylic ligands 1079
Carminic acid–bromate redox reaction 1379
Carriers modified with Co³⁺–tetra-(4-carboxyphenyl)porphine 1583
Catalyse 595
Catalytic 1011

- Catalytic–photometric method 1299
Catalytic spectrophotometric method 1379
Catechins 717
C₆₀- γ -cyclodextrin 993
Cd(II), In(III), Tl(I), Pb(II) 1195
Central composite design 897
Cerium(IV) 897
Cerium (IV) 961
Certified reference materials 449
Cesium 1485
Cesium ion-selective electrodes 885
Charge-transfer complexes 111
CH-B-15-C-5 45
Chemical analysis 423
Chemical characterization 1273
Chemically modified electrode 993
Chemiluminescence 961
Chemiluminescence (CL)-emission 179
Chemiluminescent detection 565
Chiral drugs 743
Chloride 1299
Chloride analysis 1591
Chloride and iodide detection 639
Chloride–nitrite–nitrate 969
Chloroform 123, 607
5-Chloro-8-quinolinol 647
Chlorzoxazone 1577
Chromatographic resolution 907
Chromium(V) 23
Cobalt 1137, 1425
Cobalt determination 1107
Cobalt(II) 977
Cobalt(II) tetraaminophthalocyanine 1547
Coffee 1259
Co(II) 1515, 1573
Column operation 1461
Competitive ELISA 325
Complexation 999
Complexation of alkaline earth aluminum ions 875
Complexes 491, 765
Complexing reagent 485
Concentration 145, 541
Contaminated soil 423, 449
Continuous flow 969
Copper 615
Copper-base alloys 1279
Copper(II) 1187
Coprecipitation 1305
Coproporphyrin-1 977
Cough syrup 221
Coupled techniques 271
Covalent affinity chromatography 335
Cromatographic determination 485
Cross-sections 1329
Crown ethers 9
Cryogenic preconcentration 631
Cu(II) determination 1387
 β -Cyclodextrin 743
Cyclophosphamide 1395
Cytochrome *c* 993
Data treatment 1557
Degradation 1537
Density 689
Derivative spectrophotometry 933, 1107, 1433
Determination 1299, 1321
Diabetes 355
Dialysis concentrate 1305
Diazepam 951
Diazotization-coupling reaction 671
Dibutyl(butyl)phosphonate 1453
Diethylenetriamine 145
Di-(2-ethylhexyl)phosphoric acid 1453
Differential electrolytic potentiometry 639
Differential pulse adsorptive stripping voltammetry 1493
Differential pulse polarography 123, 655, 1347
Dilute acid 1019
Diphenhydramine hydrochloride 221
Direct analysis 1265
Direct detection of unlabelled polysaccharides 727
Disease 243
5,5'-Dithiobis-(2-nitrobenzoic acid) 1341
Dithizone 1205
Divalent heavy metals 573
DNA biosensor 171
DNA damage 155
DNA-modified electrode 155
DNA separation 735
Donnan dialysis 1605
Dopamine 559
Dopamine hydrochloride 39
DPG + Cl⁻ 1613
Drug analysis 1245
Drug–clay interactions 951
EDTA 1573
Electrocatalysis 993
Electrochemical 465
Electrochemical biosensor 155
Electrochemical quartz crystal microbalance 711
Electrochemical sensor 1405
Electrode polishing 1507
Electrodeposition 139
Electrode response 1507
Electron paramagnetic spectroscopy 23
Electrophoresis 197
Electrothermal atomic absorption spectrometry 139, 1321
Enantiomeric mixtures 907
Enantiomer separation 743
Environment 23
Environmental analysis 155
Enzyme immunoassay (EIA) 385
Enzyme sensors 465
Epinephrine 985

- ETAAS 1479
Europium determination 527
Experimental design 897, 1493
Explosive detection 1405
Extraction 507, 1187
Extraction equilibrium 1613
Extraction procedures 449
Extraction-spectrophotometry 9, 1073
- Fe³⁺ 1567
Fe(II III) determination 1387
Field analysis 385
Flame spectrometry 1591
Flow injection 149, 845, 897, 1011, 1245
Flow injection analysis 1137, 1293
Flow-injection analysis 961
Flow injection analysis 639
Flow-injection liposome immunoanalysis (FILIA) 851
Fluorapatite 1273
Fluorescence quenching 1567
Fluorimetry 527, 815
Fluorometry 1163
Formal potential 1469
Formation constants 1439
Fourier-transform infrared emission 1591
Free concentration taurine measurement 91
Fruit samples 671
Fulvic acid 23
- Gas chromatography 45, 221, 395, 589, 861
Gas oil 607
Gasoline 607
Gas phase molecular absorption spectrometry 631
GC-ECD 915
Gender 243
Geological materials 533
Glass electrode 1469
Glutathione oxidase-like activity 1583
GOD 595
Gold complex 583
Graphite furnace atomic absorption spectrometric (GFAAS) 1041
Graphite furnace atomic absorption spectrometry 1311
Graphite-furnace atomic absorption spectrometry 1265
Gravimetric determination 1237
- 2HB-5NPH 1515
Heavy metal 335
Heavy metal ions 1557
Heavy metal removal 551
Heavy metal removal, cadmium, mercury, chromium and lead 1205
Heavy metals 423, 439, 449
Heparin 757
2-heptanone 861
Herbicide 851
Herbicides 1131
- Heteropoly anions 1619
Hexachlorobenzene 915
Hexacyanomanganate(IV) 63
High-performance capillary electrophoresis 757
High-performance liquid chromatography 717
High resolution separation technique 271
HPLC-DAD 1329
Human erythrocyte ghosts 1433
Human urine 697
Hydrides 631
Hydrochlorothiazide 961
Hydrogen peroxide 63, 1583
Hydroxylamine hydrochloride 39
Hypertension 325
- I⁻ 711
Ibuprofen 1577
ICP 1115
ICP/AES 1279
ICP-MS 407
Ifosphamide coated wire sensor 1395
Imazethapyr 851
Iminodiacetate adsorbent 1051
Immobilization 171
Immunoassay 851
IMS 1169
Indicators 1065
Indirected UV detection 1
Indomethacin determination 1493
Inductively coupled plasma atomic emission spectrometry 533, 1095
Inductively coupled plasma mass spectrometry 1155
Inhibitor determination 465
Inorganic ligands 1085
