Abstract

This paper reports an investigation on optimal separation and detection for animal prostaglandins, i.e. prostaglandin E₂(PGE₂) and thromboxane B₂(TXB₂) by capillary zone electrophoresis with indirect detection at 254 nm. It was found that the addition of 3 mmol l⁻¹ phosphomolybdic acid in 5 mmol l⁻¹ chromate buffer can lower the detection limits of PGE₂ and TXB₂, i.e. the calculated detection limits ($k = 3$) with phosphomolybdic acid is 0.05 μg ml⁻¹, only a 1/5-fold improvement compared to that without phosphomolybdic acid. Also adding phosphomolybdic acid, the mechanism for improving detection limits was explained properly. The separation and detection of PGE₂ and TXB₂ can be completed in 4 min. The linear ranges for PGE₂ and TXB₂ were the same, i.e. 5 ~ 80 μg ml⁻¹, analytical precision ($n = 8$) was 1.2 ~ 1.4% and 3.5% for the measurement of migration times and determination of peak height, respectively. The approach was demonstrated in the lung tissue of SD rats, the measurement results were in good agreement with previous investigations. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Capillary zone electrophoresis; Indirect UV detection; Prostaglandins

1. Introduction

Prostaglandins (PGs) are one type of important bioactive material in human and animal

bodies. Their synthesis from arachidonic acid is mediated through the cyclooxygenase pathway in vivo. Prostaglandins E₂(PGE₂) and thromboxane B₂(TXB₂) are two of the more important kinds of metabolic products in the body. Their physiological effects are different, but their molecular structure is similar. Their molecular formula is as follows:

* Corresponding author.

Capillary zone electrophoresis (CZE) is a type of separation technique characterized by high efficiency and small sample volume, great progress has been made in instrumentation and application in the last several years. In principle, CZE has been considered particularly suitable for bioseparation. Most capillary electrophoretic separations are performed using UV detection. However, many biomolecules such as the platelet activating factor (PAF), TXB_2 and PGE_2 , lack chromophores at useful wavelengths and cannot be detected with UV methods.

Indirect detection can be used as a universal detection scheme, without the need for time-consuming precolumn derivatization or experimentally complicated postcolumn derivatization procedures. Indirect UV detection in capillary electrophoresis (CE) has been applied to the detection of various compounds such as organic acids [1,2] inorganic ions [3,4] and the biomolecules PAF [5].

The goal of this work was to investigate the separation of PGE_2 and TXB_2 in animal bodies by CZE with indirect UV detection at 254 nm. Modification of the indirect detection sensitivity and separation selectivity of CZE as a relation of components in the background electrolyte was investigated. As a result of this work, we found that the presence of phosphomolybdic acid in chromate system can improve the detection and separation of PGE_2 and TXB_2 .

2. Experimental

2.1. Apparatus

All electropherograms were generated using a Mode 1229 capillary electrophoresis system with

254 nm UV detector (New Technology Application institute of Beijing). The uncoated fused-silica capillary (Hebei Yongnian Light Fiber Factory) was 50 μm i.d. \times 374 μm o.d. with an effective length of 50 cm long and the total length was 65 cm. The signals were transmitted to a X-Y recorder (Sichuan Meter Factory). All experiments were carried out at ambient temperature (ca. 24–26°C). UV spectra were measured with a Shimadzu UV-2100 scanning spectrophotometer, using quartz cuvettes with an optical path 0.5 cm.

2.2. Chemicals

PGE_2 and TXB_2 were obtained from Sigma. All other reagent came from China and were analytical-reagent grade. All the solutions were prepared by subboiling distilled water.

2.3. Disposal of SD rat lung samples

Fifteen rats were divided into three groups, five in the normal group, five in the hypoxic group and five in the drug group, 15 ml of methanol was added to 0.50 g of broken SD rat lung and mixed immediately on a vortex vibrator, then centrifuged (4000 rpm \times 15 min). The supernatant was drawn out, the protein and other impurities were removed, 7 ml of water and 7 ml chloroform were added into the supernatant and mixed until two layers were seen clearly. The chloroform phase was taken out and dried with N_2 , then stored at -4°C waiting for measurement.

2.4. Procedures

The capillary was initially washed with 1 M KOH for 10 min, then with water for 10 min and

running buffer for 30 min. When the buffer solution in the capillary was changed, the capillary was purged for 3 min with the new buffer solution. In order to make sure the precision of migration time, the capillary was purged for 1 min with the running buffer before each injection.

Stock solutions of potassium chromate, potassium hydrogen phthalate and sodium benzoate (0.1 mol l^{-1} each) and 0.15 mol l^{-1} phosphomolybdic acid were prepared by dissolving the chemicals in subboiling water. Lower concentration solutions were obtained by dilution and filtered through a $0.3 \mu\text{m}$ membrane before going into the capillary separating column.

PGE₂ and TXB₂ standard solutions in methanol (1 mg ml^{-1} each) were adjusted to the required pH value by 0.1 mol l^{-1} KOH or 0.1 mol l^{-1} HCl solution in order to keep the sample pH close to the test buffer pH value, then diluted to the desired concentration with buffer and the indicated concentration was that after dilution with buffer.

3. Results and discussion

3.1. Selection of the indirect absorption probe ions

Because PGE₂ and TXB₂ lack chromophores at 254 nm, indirect absorption detection must be employed. In indirect detection, a detectable ion is chosen as one of the components of the background electrolyte, thus creating a large background signal. When a non-detectable sample ion passes the detection window, there will be a decrease in the background signal. The detectable ion has UV absorption properties and is called an indirect absorption probe ion. The technique results in a negative peak as a sample component displaces a chromophoric ion. Because indirect UV detection relies on the displacement of a chromophore, the probe ion should have a large molar absorption to maximize the decrease in signal resulting from its displacement. Additionally, the matching of electrophoretic mobility of a

probe ion with a sample ion would give a high-resolution separation.

At pH 8.0, 10 mmol l^{-1} potassium chromate, 20 mmol l^{-1} potassium hydrogen phthalate and 20 mmol l^{-1} sodium benzoate were chosen respectively and each of these act both as a kind of probe ion and as a running buffer system. Fig. 1 shows the results of separation and detection of PGE₂ and TXB₂ ($40 \mu\text{g ml}^{-1}$ on buffer solution each). From Fig. 1 we can see, from sensitivity, peak shapes, background noise and resolution, that the chromate system is superior to potassium hydrogen phthalate and sodium benzoate system. However, the resolving power is not enough for separating PGE₂ and TXB₂, and the detected sensitivity is very poor.

3.2. Effect of phosphomolybdic acid

3.2.1. Improving detection limits

Phosphomolybdic acid is always used as a visualizing agent for the analysis of PGE₂ and TXB₂ in chromatography [6]. The investigators found that when 3 mmol l^{-1} of phosphomolybdic acid was added to the chromate buffer system, the absorption of chromate at 254 nm increased rapidly, and the optimized concentration of chromate was decreased from 10 mmol l^{-1} to 5 mmol l^{-1} , in the case of hydrogen phthalate and benzoate buffer system, there was no promotive effect. As can be seen in Fig. 1(a) and Fig. 3, the detected signals of PGE₂ and TXB₂ are much larger with phosphomolybdic acid than without.

In indirect UV detection, the key factors determining the detection limit have been reported to be the concentration of the visualization agent, C_p ; the dynamic reserve, D_r (i.e. the ratio of the background absorbance to the noise) and the displacement ratio, R , (i.e., the number of visualization agent molecules transferred by one sample molecule). The detectable concentration C_D can be estimated as follows [7,8].

$$C_D = C_p / R \cdot D_r$$

It can be seen that, decreasing C_p or increasing D_r will reduce the detection limit.

Phosphomolybdic acid is a visualization agent which has a stronger complex capability, and was

used to complex with PGE₂ and TXB₂ at 80 ~ 90°C [6]. Here, perhaps there is some complex effect between chromate and phosphomolybdic acid. Mixing them can form a kind of complex compound which has stronger molar absorption at 254 nm. The UV-absorption spectrogram (Fig. 2) confirmed our speculation. Fig. 2 presents three UV-absorption spectrograms, Fig. 2(a) obtained from 3 mmol l⁻¹ phosphomolybdic acid (pH 8.0), Fig. 2(b) from 10 mmol l⁻¹ phosphomolybdic acid (pH 8.0) and Fig. 2(c) from the mixed solution of 5 mmol l⁻¹ chromate and 3 mmol l⁻¹ phosphomolybdic acid (pH 8.0). Obviously, the complex compound between chromate and phosphomolybdic acid has been formed and it has stronger molar absorption at 254 nm.

The indirect absorption detection limits of PGE₂ and TXB₂ were decreased from 0.25 µg ml⁻¹ to 0.05 µg ml⁻¹ ($k = 3$) by adding 3 mmol l⁻¹ phosphomolybdic acid in 5 mmol l⁻¹ chro-

mate buffer system at pH 8.0. The experiments confirmed that the detection limit would be improved by lowering C_p or increasing the molar absorption of the visualization agent in the presence of phosphomolybdic acid. A phenomenon observed in Fig. 3 is that the noise was obviously increased. This degradation of signal-to-noise ratio is amplified by the increase of noise at high absorbency values occurring in most photometers [2].

3.2.2. Effect on the separation

In order to further investigate the effect of phosphomolybdic acid on the separation of PGE₂ from TXB₂, the migration times of electroosmotic flow (methanol), PGE₂ and TXB₂ were measured under different phosphomolybdic acid concentrations in the 5 mmol l⁻¹ K₂CrO₄ system (pH 8.0) (Fig. 4). Fig. 4 suggests that the migration times

Fig. 1. The detected sensitivity and separation for PGE₂ and TXB₂ in different probe ion systems. Peak 1, methanol; Peak 2, PGE₂; Peak 3, TXB₂. Running buffer (pH 8.0 each): (a) 10 mmol l⁻¹ potassium chromate (28 kV, 18 µA), (b) 20 mmol l⁻¹ sodium benzoate (28 kV, 15 µA), (c) 20 mmol l⁻¹ potassium hydrogen phthalate (28 kV, 28 µA).

Fig. 2. The UV-absorption spectrogram, (a) 3 mmol l⁻¹ phosphomolybdic acid (pH 8.0), (b) 10 mmol l⁻¹ chromate (pH 8.0), (c) 3 mmol l⁻¹ phosphomolybdic acid and 5 mmol l⁻¹ chromate (pH 8.0).

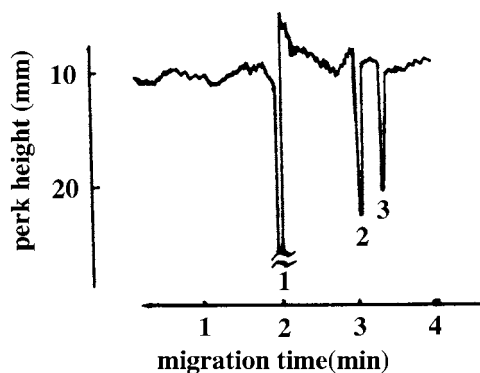

Fig. 3. Effect of phosphomolybdic acid on the detection sensitivity and the separation of PGE₂ and TXB₂. Buffer, 5 mmol l⁻¹ potassium chromate and 3 mmol l⁻¹ phosphomolybdic acid (pH 8.0). Applied voltage, 25 kV. Sample concentration, 40 μg ml⁻¹ each. Peak 1, methanol; Peak 2, PGE₂; Peak 3, TXB₂.

of methanol PGE₂ and TXB₂ will be shortened by increasing the concentration of phosphomolybdic acid. A main cause was that the ion strength in the buffer solution was increased, thus leading to a higher separation current and larger electroosmotic flow. However, the migration time of PGE₂ was reduced dramatically. So the concentration of phosphomolybdic acid did not exceed 5 mmol l⁻¹, otherwise, the PGE₂ peak would be eluted with electroosmotic flow. The separation efficiencies for PGE₂ and TXB₂ are the highest when the concentration of phosphomolybdic acid is between 3 and 4 mmol l⁻¹. If the concentration of phosphomolybdic acid was below 3 mmol l⁻¹, the retention times of components are increased, resulting in badly tailing peaks and poor resolution. So, in this work, a 3 mmol l⁻¹ concentration of phosphomolybdic acid was chosen, and the highest plate numbers, between 5×10^5 and 6.2×10^5 , were obtained. The improvement of resolution further confirmed that the effective mobility of PGE₂ and TXB₂ would be closely matched to those probe ions, due to the complex formed between phosphomolybdic acid and chromate, resulting in sharper peak shape and leading to higher separation efficiency.

3.2.3. Effect of pH

The pH of the running buffer solution controls the mobility of weak acids. The PGE₂ and TXB₂ are all typical weak acids. The pH of the electrolyte solution used in our work can have a large effect on the separation of PGE₂ and TXB₂. The changes in electroosmotic flow and the retention time of the components as the pH changes in the buffer system were described in Fig. 5. Fig. 5 showed that as the pH value increased, the electroosmotic flow enlarged, i.e. the retention time of methanol was shorter. The dramatic change occurred at pH 5~8. The tendency of the retention times to change for PGE₂ and TXB₂ were the same with methanol. At lower pH, both PGE₂ and TXB₂ will become easily protonated and a decrease in their electrophoretic mobility is observed, resulting in a tailing peak. As the pH is increased, the electroosmotic flow is increased, which leads to an increase in the effective mobility and sharpens the separation peak of PGE₂ and TXB₂. But, if the pH is over 9, the separation current is increased dramatically. The experiments show that the highest efficiency separation of PGE₂ from TXB₂ is at pH 7~8.

3.2.4. Correction curve and sample analysis

The optimum buffer solution for the separation of PGE₂ and TXB₂ contained 5 mmol l⁻¹ potassium chromate and 3 mmol l⁻¹ phosphomolybdic acid at pH 8.0, which combines complete resolution with a shear analyses. When

Fig. 4. Effect of phosphomolybdic acid concentration on the migration time of electroosmotic flow (×). PGE₂ (○), TXB₂ (●). Other conditions as in Fig. 3.

Table 1

The characteristic parameters of the correction curve for PGE₂ and TXB₂ in CZE

Component	Detection limit ($\mu\text{g ml}^{-1}$) ($k = 3$)	Linear range ($\mu\text{g ml}^{-1}$)	Linear regression coefficient	R.S.D.% ($n = 8$)	
				tr. ^a	h ^b
PGE ₂	0.05	5~80	0.9971	1.2	3.5
TXB ₂	0.05	5~80	0.9956	1.4	3.5

^a tr., retention time.^b h, peak height.

the applied voltage was 25 kV, the retention times for PGE₂ and TXB₂ were 3 min 5 s and 3 min 32 s, respectively (Fig. 3). The correction curve was described by the separation peak height against component concentration. The characteristic parameters of correction curve were shown on Table 1.

The standard curve method was used for analysis of PGE₂ and TXB₂ in the lung samples of SD rats. First, the lung sample diluted with 25 μl methanol was used for the determination of PGE₂, then 75 μl of methanol was added for the determination of TXB₂. In order to measure the recovery, five normal lung samples were taken, then every sample was divided described by the

separation peak height against component concentration. The characteristic parameters of correction curve were shown on Table 1.

The standard curve method was used for analysis of PGE₂ and TXB₂ in the lung samples of SD rats. First, the lung sample diluted with 25 μl methanol was used for the determination of PGE₂, then 75 μl of methanol was added for the determination of TXB₂. In order to measure the recovery, five normal lung samples were taken, then every sample was divided into two aequators and 2 μg standards of PGE₂ and 8 μg TXB₂ were added into one of the aequators. The disposal process of the sample recovery test was the same as mentioned previously in Section 2. The analysis results for PGE₂ and TXB₂ of rat lung in each group and recovery in this work were shown in Table 2.

Fig. 5. Effect of pH on the electroosmotic flow time (\times) and the migration times of PGE₂ (\circ) and TXB₂ (\bullet). Other conditions as in Fig. 3.

4. Conclusions

In this work, the analysis of components in an organism by CZE was studied. The following conclusions have been drawn:

1. Capillary electrophoresis is an efficient method for analysis of trace components in a complicated matrix because the matrix influence can be easily removed.
2. For the separation of trace components, the optimum buffer system should insure that the separating time is as short as possible, which would decrease peak broadening due to diffusion of molecule.

Table 2
The analysis results for PGE₂ and TXB₂ in various SD rat lungs ($\mu\text{g ml}^{-1}$)

Group	<i>n</i>	PGE ₂		TXB ₂		Recovery (%)
		Mean value	Range	Mean value	Range	
Normal	5	0.62	0.38~0.82	11.7	9.6~14.5	85
Hypoxia	5	0.71	0.58~1.02	12.5	9.6~16.3	—
Drug	5	0.57	0.28~0.83	9.54	8.2~12.7	—

- Since many biological compounds lack chromophores at useful wavelengths, the indirect absorption detection is a kind of universal and simple detection method. We found that the probe ion, which has high molar absorption and mobility matched to the sample ion, must be selected so as to obtain high detection sensitivity and resolution.
- A complex formed between chromate and phosphomolybdic acid has high molar absorption, which could improve the detection sensitivity for PGE₂ and TXB₂. So, the complex should be used for the detection of the other compounds.

Received 25 October 1996; received in revised form 8 July 1997; accepted 25 July 1997

Abstract

An extraction-spectrophotometric method for the determination of phenytoin in capsules and plasma is presented. The method is based upon oxidation of phenytoin using alkaline potassium permanganate solubilized in chloroform/cyclohexane (1:1) after crowning with dicyclohexano-24-crown-8 (DC-24-C-8). The formed benzophenone being soluble in the oxidation reaction medium was directly measured at 238 nm. The optimum conditions for the reaction were studied and the detection limit was found to equal 1.2 mg/100 ml. The developed method was applied to the determination of the drug in capsules and plasma. The method is simple, accurate and avoids laborious multistep extraction procedures. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Phenytoin; Extraction-spectrophotometry; Potassium permanganate; Crown ethers

1. Introduction

Phenytoin, 5,5-diphenylimidazolidine-2,4-dione, is one of the most frequently prescribed anticonvulsants. It is considered as the drug of choice in treating all forms of epilepsy except absence seizures. It is also used to treat various psychoses, trigeminal and related neuralgias and various cardiac arrhythmias [1]. Phenytoin is extensively metabolized in the liver to 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (PHPPH) and between 60 and 70% of the administered dose is excreted as free or as a glucuronide conjugate of PHPPH.

Minor metabolites include 5-(3-hydroxyphenyl)-5-phenylhydantoin, 3,4-dihydro-3,4-dihydroxyphenytoin, catechol and 3-*O*-methylcatechol. The plasma half-life varies considerably within the approximate range of 7–60 h and is dose-dependent [2].

Phenytoin is a weakly absorbing compound ($A_1^{1\%} = 27$ at 258 nm), moreover, the lack of a well defined UV absorption spectrum makes its determination in low concentrations by direct UV spectrophotometry difficult, and this problem is more aggravated if it is needed to be estimated in biological fluids.

Phenytoin has been determined spectrophotometrically by a variety of methods ranging from a

* Corresponding author.

simple procedure based on measuring the absorbance at 235 nm [3] to more complicated ones that involve chemical derivatization. Wallace et al. [4] described a method for determining phenytoin in blood based on hydrolysis of the hydantoin ring in strong alkali followed by a Hofmann degradation of the resulting amide with bromine to yield benzophenone which was steam-distilled and measured at 257 nm. At a later stage, Wallace [5] published a method for the assay of phenytoin in biological specimens consisting of hydrolysis of the hydantoin ring in strong alkali, then permanganate oxidation to benzophenone which was extracted into n-heptane after reflux for 30 min and measured at 247 nm. A more recent method [6,7] for the determination of phenytoin in plasma was based on extracting the sample with 1,2-dichloroethane, followed by back extraction from the organic layer into alkali and oxidation by potassium permanganate with heating on a steam bath. The oxidation product was extracted into 2,2,4-trimethylpentane and measured at 247 nm. Other methods for the estimation of phenytoin in pharmaceutical preparations and/or biological fluids include: colorimetry [8], spectrophotometry using orthogonal functions [9], titrimetry [10], fluorimetry [11], thin layer chromatography (TLC) [12], gas liquid chromatography (GLC) [13] and high performance liquid chromatography (HPLC) [14].

The previously published spectrophotometric methods used for the assay of phenytoin are time consuming, laborious (they need multistep extractions and reflux) and require fairly large plasma samples. GLC methods are often complicated for routine clinical situations and usually demand a time interval exceeding that required for a spectrophotometric scan. Additionally, hydantoins may be liable to thermal degradation at the injection temperature [15]. HPLC methods, although sensitive, are expensive and require sophisticated instrumentation which might not be available in many modest quality control laboratories.

Extraction analysis has been practiced for more than a century, but the use of macrocyclic compounds for this purpose is of recent date. Frensdorff and Pedersen [16,17] carried out pioneer work on extraction with crown ethers, however

their use in chemical analysis is still limited because the stability constants between metal ions and crown ethers are low. Potassium permanganate dissolved in benzene by dicyclohexyl-18-crown-6 was used for oxidising alkenes under mild conditions [18]. Also, quantitative oxidations of stilbene to adipate and of benzyl alcohol to benzoate have been demonstrated. The scope of these oxidations is still being developed since this reagent could be particularly useful where water solubility is a major limitation and where mild conditions are necessary.

In the present work, dicyclohexano-24-crown-8 (DC-24-C-8) has been used to solubilize potassium permanganate in cyclohexane/chloroform mixture (1:1). The metal complex anion formed could be used efficiently for the quantitative oxidation of phenytoin to benzophenone which, being soluble in the reaction medium, could be measured spectrophotometrically.

2. Experimental

2.1. Apparatus

A Perkin Elmer spectrophotometer Model 550 S and a laboratory centrifuge with maximum speed (4000 rpm) were used.

2.2. Materials

Phenytoin and phenytoin sodium (pharmaceutical grade) were kindly provided by Alex for pharmaceutical and chemical industries, Alexandria, Egypt. 'Epanutin' capsules containing 100 mg phenytoin sodium per capsule (Parke-Davis), DC-24-C-8, 97% containing <2% dibenzo-24 crown-8 (Aldrich), potassium permanganate AR, formalin solution 40% w/v (BDH), chloroform AR and cyclohexane AR were used.

2.3. Reagents

2.3.1. Potassium permanganate/DC-24-C-8

Weigh and transfer 0.06 g of DC-24-C-8 to a 50 ml volumetric flask using a chloroform/cyclohexane mixture (1:1). Add 600 mg of potassium

permanganate and shake the flask mechanically for 10 min. Complete the volume to the mark with the same solvent mixture. This solution was always freshly prepared.

2.3.2. Sodium hydroxide/DC-24-C-8

Weigh and transfer 0.03 g of DC-24-C-8 to a 25 ml volumetric flask by means of chloroform/cyclohexane mixture (1:1). Add 2 g of NaOH and shake the flask mechanically for 30 min. Complete to the mark with the same solvent mixture and filter the solution.

2.4. Standard phenytoin sodium solution

Accurately weigh 25 mg of phenytoin sodium and transfer it to a 120 ml separatory funnel. Add 10 ml of 1 M sulphuric acid followed by two 25 ml portions of chloroform and shake to extract phenytoin. Combine the extract in a 100 ml volumetric flask and adjust the volume.

2.5. Sample preparation

Accurately weigh and transfer an amount of the mixed contents of 20 capsules corresponding to 25 mg of phenytoin sodium to a 120 ml separatory funnel. Add 10 ml of 1 M sulphuric acid followed by 50 ml of chloroform. Shake vigorously to extract phenytoin. Combine the extract in a 100 ml volumetric flask and adjust the volume.

2.6. Procedure

2.6.1. Calibration graph

Accurately transfer volumes of 0.3–1.3 ml (in 0.2 ml steps) of standard phenytoin sodium solution to 10 ml volumetric flasks. Continue as described under assay procedure.

2.6.2. Assay

Transfer 1 ml of each of the test and standard solutions to 10 ml volumetric flasks. Add to each flask 4 ml of the prepared $\text{KMnO}_4/\text{DC-24-C-8}$ reagent and 1 ml of NaOH/DC-24-C-8 solution. Leave the flasks for 10 min for reaction time, add 1 drop of formalin solution and shake for 1 min. Complete the volume to the mark using chloro-

form and cyclohexane so that their final concentration is 50% v/v. Centrifuge the solutions at 4000 rpm for 15 min filter (to ensure the complete elimination of the formed MnO_2) and finally measure the absorbance at 238 nm against a reagent blank similarly prepared side by side using the same reagents but without drug solutions.

2.7. In vitro assay of phenytoin sodium in plasma

To 10 ml plasma contained in a 60 ml separatory funnel add 1 ml of phenytoin sodium standard solution prepared in distilled water (0.2 mg ml^{-1}) and 5 ml of 1 M sulphuric acid. Extract with three 10 ml portions of chloroform. After separation, collect the chloroformic extracts into a graduated measuring cylinder and evaporate in a water bath until the volume is reduced to 2 ml. Continue as described under assay procedure starting from 'add to each flask 4 ml of the prepared $\text{KMnO}_4/\text{DC-24-C-8}$...'. Calculate the concentration of recovered drug from a calibration graph.

3. Results and discussion

Fig. 1(a) shows the UV absorption spectrum of phenytoin in chloroform. It is obvious that the lack of well defined peaks with reasonable specific intensity renders its direct determination by UV spectrophotometry a fairly hard task especially when good sensitivity is a prerequisite. In the present study, alkaline potassium permanganate oxidation was conducted in organic solvent (cyclohexane/chloroform 1:1) where both the drug and its oxidation product are soluble. Solubilization of KMnO_4 and NaOH in this organic mixture was made possible through the use of a macrocyclic polyether 'DC-24-C-8' which has the useful property of solubilizing inorganic compounds in aprotic solvents including aromatic hydrocarbons. The formed benzophenone (Scheme 1) was consequently measured directly at 238 nm against a blank (Fig. 1(b)). The shift of λ_{max} towards a shorter wavelength (238 nm) may be due to the high polarity of the medium contributed by chloroform and the crown ether [19].

DC-24-C-8 does not absorb significantly above 220 nm. The absorption spectrum of KMnO_4 /DC-24-C-8 in chloroform/cyclohexane (1:1) is very similar to that of aqueous permanganate ion in 0.1 M sulphuric acid (Fig. 2(a) and (b)), thus proving its solubilization in organic solvents by using the crown ether as ligand.

3.1. Optimization of the reaction conditions

3.1.1. Choice of the cyclic polyether

The cyclic polyether was chosen in such a way to give a stable complex with potassium. Thus, DC-24-C-8 was used in the present study for the following reasons.

1. Having a hole diameter of approximately 4 Å, it can accommodate potassium ions with ionic diameter of 2.66 Å which provides a comfortable fitting condition for them.

Fig. 1. (a) Absorption spectra of 18.4 mg/100 ml of phenytoin in chloroform and (b) benzophenone in 10 ml of cyclohexane/chloroform mixture 1:1 corresponding to 3 mg/100 ml of phenytoin sodium after oxidation with potassium permanganate/DC-24-C-8 reagent.

Scheme 1.

2. It possesses eight oxygen atoms which can form ion dipoles with potassium ion. Moreover, these oxygen atoms are arranged in a cylindrical symmetrical configuration which permits the formation of stable salt complexes [20].

Fig. 2. (a) Absorption spectra of 3.045 mg potassium permanganate in 50 ml of 0.1 M sulphuric acid and (b) 47.90 mg of potassium permanganate in 10 ml of cyclohexane/chloroform mixture 1:1 containing 0.0049 of DC-24-C-8.

- It has two cyclohexyl groups rather than two benzo groups which firstly increases the basicity of oxygens leading to higher stability of the formed complex, secondly, the transparency in the UV region and thirdly, the flexibility of the macrocyclic ligand to wrap itself around the cation (i.e. steric hindrance produced by the benzo groups results in a weaker cation–ligand interaction).

3.1.2. Choice of the solvent

The solvent or reaction medium was chosen on the basis of three factors: (1) the solubility of phenytoin and benzophenone; (2) the UV cutoff of the solvent; and (3) the extractability of $\text{KMnO}_4/\text{DC-24-C-8}$. In general, the common solvents in extraction with crown ethers are chloroform, 1,2-dichloroethane, benzene and nitrobenzene. In order to fulfill all the above requirements, a 1:1 mixture of chloroform and cyclohexane was found to be the most suitable.

3.1.3. Effect of $\text{KMnO}_4/\text{DC-24-C-8}$ and $\text{NaOH}/\text{DC-24-C-8}$ concentrations

The effect of changes in $\text{KMnO}_4/\text{DC-24-C-8}$ concentration was studied by measuring the absorbance of benzophenone at 238 nm, for solutions containing a fixed concentration of phenytoin and different volumes of $\text{KMnO}_4/\text{DC-24-C-8}$ reagent. It was found that 4–6 ml of the reagent gave maximum absorption. On the other hand, it was previously demonstrated that within wide limits the molarity of NaOH is not critical for the oxidation of phenytoin [15].

3.1.4. Effect of oxidation time

The effect of oxidation time was studied by using a fixed concentration of phenytoin and the optimum reagent concentration. The optimum time was selected as 10 min.

3.1.5. Elimination of excess potassium permanganate

An excess of KMnO_4 was used to oxidise phenytoin. The remaining unconsumed oxidant was eliminated. Several reducing agents were tried where formalin solution was found to be the most convenient.

3.2. Calibration graph construction

Using the previously described optimum experimental conditions, it was found that the graph obtained by plotting the absorbance at 238 nm versus concentration of phenytoin sodium showed a linear relationship over the range of 0.87–3 mg/100 ml. The linear regression equation was found to be: $A = 0.008 + 0.126C$, where C is the concentration in mg/100 ml. The correlation coefficient was 0.9994 and the detection limit was found to equal 1.2 mg/100 ml.

4. Applications

The proposed method was applied to the determination of phenytoin sodium in capsules and the results obtained are presented in Table 1. The presence of interferences in commercial capsules can not be overlooked, therefore the results obtained using the proposed method were compared to those of an HPLC method [21] (Table 1) using t - and F -tests. The calculated values did not exceed the corresponding theoretical ones, thus indicating the insignificant difference between the compared methods.

Monitoring of phenytoin plasma level is of great importance in clinical studies because of its non-linear elimination pharmacokinetics [21] and the possibility of toxicity or inadequacy of the dosage after long treatment. The ability of the proposed method to determine phenytoin in plasma has been appraised through spiking plasma samples with the drug at different concentration levels. It was found that phenytoin sodium could be estimated with good recoveries (Table 2) at the levels of 16–22 $\mu\text{m l}^{-1}$ in plasma (provided that 6–10 ml specimens are used), thus indicating that there is no interference from endogenous constituents. Also, the primary metabolite (PHPPH) does not interfere [5]. The alkaline nature of the permanganate solution and the polarity of the hydroxyl group make the phenolic metabolites insoluble in the organic phase.

Table 1

Assay results of phenytoin sodium in capsules by the proposed spectrophotometric method and the comparative HPLC method

Received 7 April 1997; received in revised form 24 July 1997; accepted 28 July 1997

Abstract

A novel iodide ion-selective electrode has been produced based on a molecular deposition technique in which water-soluble porphyrin was alternatively deposited with water-soluble polypyrrole on a 2-aminoethanethiol modified silver electrode. The potentiometric response is independent of pH of the solution between pH 1 and 7, while it is dependent on the nature of the medium. The electrode has a linear dynamic range between 1.6×10^{-6} and 0.1 M with a Nernstian slope of 59 mV/decade and a detection limit of 1.0×10^{-6} M in acetate buffer (0.1 M, pH 4.6). The electrode has the advantages of low resistance, short conditioning time and fast response. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Multilayer films; Sensor; Potentiometry; Iodide ion; Porphyrin

1. Introduction

The fabrication of an electrode surface with functional multilayer films has been attracting much interest because of its potential application [1,2]. Recently, Decher and coworkers developed the preparation of multilayer ultrathin films by alternating deposition of bipolar cationic and anionic compounds (or polyelectrolytes) [3–5]. This new technique is an extension of self-assembly developed by Sagiv [6] and is a rapid and experimentally very simple way to produce complex layered structures with precise control of layer

composition and thickness. We developed this concept further and achieved molecular deposition (MD) films containing polyelectrolytes [7], porphyrin, phthalocyanine [8], enzyme [9], superfine particles [10] and so on. In addition, assembling alternate dye-polyion molecular films by electrostatic layer-by-layer adsorption was reported by Ariga et al. [11].

In this paper, this new technique was applied to fabricate a new kind of chemically-modified electrode (CME) by alternating deposition of water-soluble porphyrin and polypyrrole on the surface of a 2-aminoethanethiol-modified silver electrode. The CME was shown to exhibit excellent potentiometric response toward iodide ion. In this

* Corresponding author. Fax: +86 431 9823907.

work, our primary interest was focused on devising a new kind of CME which could be used as a potentiometric sensor for iodide ion and would also possess quite a few features, such as simple fabrication, fast response, independence of electrode size and topology, good mechanical and chemical stability, and so on.

2. Experimental

2.1. Reagents

The molecular structures of the porphyrin and polypyrrole used to fabricate the multilayer film electrode are shown in Fig. 1. 2-Aminoethanethiol and tetraphenylporphinetetrasulfonic acid (tppS₄) were obtained from Aldrich. Pyrrole obtained from Aldrich was distilled and stored under a nitrogen atmosphere before use. Water-soluble polypyrrole solutions were prepared following the literature [12]. In short, pyrrole monomer was

Fig. 1. Molecular structures of the porphyrin and polypyrrole used to fabricate the multilayer film electrode.

added to an aqueous ferric chloride solution whose pH had been adjusted to the desired level using concentrated HCl (typically pH 1.0). The solution was aged for 15 min and filtered prior to use. Typical solutions were composed of 0.02 M pyrrole monomer and 0.006 M FeCl₃. To ensure controlled deposition, the solutions were typically used for only 2–3 h. All other chemicals were of analytical grade and all the solutions were prepared with doubly distilled water.

2.2. Apparatus

UV–Vis spectra were obtained using a Shimadzu 3100 UV-Vis-near-IR recording spectrophotometer. Potential measurements were made with a Model pHx-215 Ionalyzer (Shanghai Second Analytical Instrument Plant, China). The electrochemical cell used can be represented by: Ag|MD film | acetate buffer (0.1 M, pH 4.6)|| KCl(sat.), Hg₂Cl₂|Hg

The electrode potential was measured in 50 ml of a 0.1 M acetate buffer solution (pH 4.6) with stirring at 25°C. The electrodes were preconditioned in stirred water for 5–10 min until a steady potential was obtained before use. Cyclic voltammetric experiments were performed on a Model DH-2 potentiostat/galvanostat (Jilin Longjing Analytical Instrument Plant, China). A three-electrode cell was used with silver electrode modified with MD film or bare silver electrode as the working electrode, saturated calomel as the reference electrode and platinum wire as the auxiliary electrode. 2:1(v/v) phosphate buffer solution (0.1 M, pH 5.0)/acetonitrile were used as cyclic voltammetric experiments and deoxygenated for 10 min before use.

2.3. Fabrication of multilayer film electrode

Fabrication of multilayer films on quartz slides is similar to that of tppS₄/PyC₆BPC₆Py system [8] by substituting PyC₆BPC₆Py with water-soluble polypyrrole. Fabrication of multilayer films on a silver electrode was as follows: a silver electrode (1.5 mm diameter) was polished with emery paper followed by alumina (1.0, 0.5 and 0.3 μm). The

resulting electrode was thoroughly washed with water, sonicated in ethanol, washed again with water and ethanol and finally dried in air. A clean silver electrode was first immersed for 24 h at room temperature in an ethanolic solution that consisted of 0.01 M 2-aminoethanethiol to give one monolayer of self-assembled film. After rinsing with ethanol, the electrode was transferred into 0.1 M HCl to obtain a positively charged surface followed by immersion in a solution containing 1 mg tppS₄ in 10 ml H₂O for 30 min. In this way the surface of the electrode was covered with one layer and its surface charge was reversed. After rinsing with water, the electrode was transferred into the in situ polymerized polypyrrole solution for 10 min, thus adding a second layer and restoring the original surface charge. A multilayer tppS₄ film can be obtained by repeating these two steps in a cyclic fashion. In the present experiments, a silver electrode deposited with six layers of tppS₄ was used throughout. Between measurements, the electrode was stored in a dry state at room temperature.

3. Results and discussion

3.1. Fabrication of the multilayer film electrode

Self-assembly of a monolayer of alkanethiols on a silver surface has been reported [13–15]. In this study, a clean silver electrode was first incubated in an ethanolic solution of aminoethanethiol to get a self-assembled monolayer film. Afterwards, the modified substrate was dipped into 0.1 M HCl solution to obtain a positively charged surface. The multilayer tppS₄ anions can be obtained by alternating deposition of tppS₄ with water-soluble polypyrrole based on electrostatic interaction. The deposition process was followed by UV–Vis absorption spectra using a quartz slide as substrate (Fig. 2). An obvious absorption peak was found at 422 nm, which corresponds to the Soret band of the porphyrin. The linear increase in the optical density of the films with number of layers indicates a process of uniform deposition. The broad visible

absorption confirms the existence of highly conductive polypyrrole. Fig. 3 shows cyclic voltammograms of a bare silver electrode and a silver electrode modified with six layers of porphyrin in 2:1(v/v) phosphate buffer (0.1 M, pH 5.0)/acetonitrile, respectively. It can be seen that no response was obtained with the bare silver electrode; however on the modified silver electrode, one coupled redox peak appeared which is assigned to the contribution of the porphyrin. These results show that multilayer films containing porphyrin can be fabricated on the surface of the silver electrode by means of the molecular deposition technique.

3.2. The pH dependence of the multilayer film electrode response to iodide ion

Fig. 4 shows the pH dependence of the observed potentials of the electrode in different pH values of H₃PO₄ and NaH₂PO₄ buffer solutions in the presence of 1×10^{-3} M iodide ion. From Fig. 4 it can be seen that stable response potentials were obtained in a pH range of 1–7. This result shows that in the pH range of 1–7, the pH value of the solutions had no effect on the response behavior of the electrode.

3.3. Effects of media on the multilayer film electrode response

Fig. 5 shows the effects of different buffer media at the same concentration [0.1 M] and different pH on the response behavior of the electrode. As indicated in Fig. 5, the electrode had the largest dynamic range in acetate buffer (pH 4.6) and phosphate buffer (pH 4.0). The response slopes were 59 and 55 mV/decade, respectively. The linear ranges were between 1.6×10^{-6} and 0.1 M and 2.0×10^{-6} and 0.1 M, respectively. In pH 2.0 and 6.0 phosphate buffer, the responses of the electrode were good, but their linear ranges were narrow (6.3×10^{-6} and 0.1 M for pH 2.0 and 4.0×10^{-6} and 0.1 M for pH 6.0). Because the acetate buffer solution is the buffer system usually used, it was chosen for the following experiments.

Fig. 2. UV-Vis absorption spectra of alternating film deposition of tppS₄ and water-soluble polypyrrole. From the lower to upper curves, the number of tppS₄ layers is 2, 4, 6, 8. The insert shows the absorption at 422 nm as a function of the number of layers deposited.

3.4. Performance of the multilayer film electrode

A typical calibration graph for the electrode is shown in Fig. 6. The electrode has a linear response over the range of 1.6×10^{-6} to 0.1 M with a Nernstian response slope of 59 mV/decade and a detection limit (extrapolation of linear graph) of 1.0×10^{-6} M. The typical dynamic response time of the electrode (t_{95}) was less than 15 s under stirred conditions for 1×10^{-5} to 1×10^{-4} M iodide ion. The steady state potential response after addition of iodide ion remained constant for 30–60 s, then slowly increased in the negative direction and reached a final steady potential value.

The potential response of the electrode towards iodide ion has good repeatability. The relative standard deviation (R.S.D.) is 1.7% for ten determinations of 1×10^{-3} M iodide ion at pH 4.6, 0.1 M acetate buffer.

3.5. Studies of interference

The selective coefficients of the electrode were determined by the method involving a fixed interfering ion concentration of 0.1 M, in 0.1 M acetate buffer (pH 4.6) [16]. In the calculations, activities were replaced by the corresponding concentrations. Table 1 lists the selectivity coefficients (average of three determinations). From Table 1 it

Fig. 3. Cyclic voltammograms of the bare silver electrode (a) and silver electrode modified with six layers of porphyrin (b) in 2:1(v/v) phosphate buffer (0.1 M, pH 5.0)/acetonitrile. Scan rate, 50 mV.

can be seen that for the common anions the electrode has good selectivity compared with poly[tetrakis(*p*-aminophenyl)porphyrin] film-modified electrode [17].

Fig. 4. pH dependence profile of the multilayer film electrode containing tppS₄. The solutions contain H₃PO₄-NaH₂PO₄ and 1×10^{-3} M iodide ion.

Fig. 5. Effects of different buffer media on the response of the electrode to iodide ion.

1. (a): 0.1 M H₃PO₄-NaH₂PO₄ (pH 2.0)
2. (b): 0.1 M Na₂HPO₄-NaH₂PO₄ (pH 4.0)
3. (c): 0.1 M Na₂HPO₄-NaH₂PO₄ (pH 6.0)
4. (d): 0.1 M HAC-NaAC (pH 4.6).

3.6. Stability of the multilayer film electrode

In the experiments, we found that the number of tppS₄ layers deposited has a marked influence on the response and stability of the multilayer film electrode, an optimum number of layer existing for the best response and stability. When the electrode consisted of six layers of tppS₄ in our case, the best response and stability were obtained. For example, for 60 days after the sensor has been fabricated, a calibration graph was obtained every 2 days, and its slope did not change.

3.7. Analytical application

A suitable amount of dry edible seaweed was weighed into a china crucible, 2 ml no-iodine water and 2 ml 2 M KOH solution added and

Fig. 6. A typical calibration graph for the electrode (acetate buffer: 0.1 M, pH 4.6).

stirred until a paste formed. Then it was transferred into an oven for 1–2 h at 80–100°C, then into a high temperature oven for 4–6 h at 550–600°C. After charcoal formed, it was washed with hot no-iodine water, filtered into a 50-ml calibrated flask and adjusted to pH 7 with concentrated H_2SO_4 solution then diluted to the mark with no-iodine water. An appropriate volume of the solution was added to the cell and tested according to the above procedure. The results obtained were compared with a spectrophotometric method [18] and were shown to be in agreement: for sample 1, 10.0 mg/kg for the proposed method and 9.8 mg/kg for the spectrophotometric

Table 1
Selectivity coefficients for the electrode

Anion	Log K_{ij}^{pot}
Cl^-	-4.9
Br^-	-3.9
NO_3^-	-5.0
SO_4^{2-}	-5.5
SCN^-	-3.7
SO_3^{2-}	-4.5

ClO_4^-	-3.7

method; for sample 2, values are 12.5 and 12.0; for sample 3, 11.5 and 11.7 mg/kg, respectively.

4. Conclusion

An iodide ion-selective electrode fabricated by the molecular deposition technique has a stable and selective potential response toward iodide ion in 0.1 M acetate buffer solution with a detection limit of 1.0×10^{-6} M and a slope of 59 mV/decade. The electrode has a fast response, low resistance and good reproducibility.

Quantitative analysis of chromium(V) by EPR spectroscopy

John Chappell, Barry Chiswell *, Arran Canning

Department of Chemistry, The University of Queensland, Brisbane QLD 4072, Australia

Received 13 May 1997; received in revised form 24 July 1997; accepted 28 July 1997

Abstract

A procedure to accurately quantitate chromium(V) in environmental and medicinal chemistry samples was developed using electron paramagnetic resonance spectroscopy (EPRS) as the method of detection. It was found to have an error in the order of $\pm 10\%$ and a detection limit of 0.010 mM (0.5 mg l^{-1}) chromium(V). The method has been used to quantitate the formation of chromium(V) in the interaction of chromium(VI) with fulvic acid and a simple model of this acid, viz, 1,2-dihydroxybenzene. Analysis of solutions obtained from the reaction of 1,2-dihydroxybenzene with chromium(VI) demonstrated that even when the organic substrate was present in a 182-fold excess, the maximum chromium(V) concentration attained represented just 1.44% of the initial chromium(VI). Reactions between chromium(VI) and fulvic acid yielded similar results. It was therefore concluded that at background environmental concentrations of chromium and fulvic acid, the production of chromium(V) is insignificant, however, its possible importance in contaminated systems cannot be disregarded on this basis alone. The method for quantitative analysis reported in this paper should be an invaluable tool for investigations into the significance of chromium(V) in the toxicological mechanism of chromium(VI) and its role as a mutagenic agent. © 1998 Elsevier Science B.V. 1. Introduction

Speciation of chromium in environmental samples has generally been a 2-fold process. Typically, the total chromium concentration is determined by techniques such as atomic absorption spectroscopy, while the hexavalent chromium is analysed by a variety of procedures including the diphenyl carbazide method [1–3] and ion chromatography [4]. The underlying assumption in this methodology is that all chromium present will

be inorganic and in either the hexavalent or the trivalent form [5–8]. Therefore, by obtaining the concentration of one species [Cr(VI)] and knowing the total chromium concentration, the concentration of the other species [Cr(III)] can be obtained by difference. Some researchers have suggested that such assumptions are simplistic and result in mis-leading conclusions because they do not take into consideration the possibility of organically or colloiddally bound chromium being present in the system. In an effort to overcome such problems, these researchers have developed methods using ion chromatography and high per-

formance liquid chromatography to account for these other forms of chromium [9–12].

Most previous work has ignored the possible presence of chromium compounds in oxidation states other than (VI) and (III), and until the advent of EPRS studies, the formation of chromium(V) was an unproven hypothesis in the chromium(VI) reduction cycle due to its high reactivity and low kinetic stability [13]. Detection of both inorganically [14] and organically bound chromium(V) with ligands containing both oxygen and sulfur donor atoms such as diols and glycols [15–17], phenols [18] and thiols [19–21] has been achieved, although quantitation has been unsuccessful. Chromium(V) production has also been reported with compounds of biological and biochemical interest, including D-glucose, D-fructose and other saccharides and their derivatives [22,23], ascorbate [24], L-rhamnose and D-mannose [25] and adenosine [26].

Although chromium(III) is probably the ultimate form of the metal bound in the cell, there is evidence accumulating that the oxidation states +4 and +5 maybe important in the reaction sequence leading to the adverse biological behaviour of chromium [27]. For instance, chromium(IV) and chromium(V), both exchange ligands more readily than chromium(III), leading to these species being proposed to be the active genotoxic forms of chromium [28]. In 1982, Wetterhahn [29] was the first to report a stable intermediate chromium(V) compound formed from the metabolism of inorganic chromate by rat liver microsomes in the presence of NADH. The chromium(V) was detected by EPRS and persisted for approximately 80 min after initiation of the reaction. The suggested formation of the chromium(V) was by a one-

electron transfer by the microsomal electron transport P-450 system to chromate [29]. Since then there has been a vast amount of work undertaken in determining what leads to the production of chromium(V) in the cells, and relatively long-lived chromium(V) species have been produced by the following methods: the action of glutathione on chromate [21,27]; the reaction of riboflavin (vitamin B₂) with chromium(VI) [30]; and chromate reactions with ribonucleotides. These reactions have all been studied in vitro due to the limitations of EPRS, but recently the detection of chromium(V), from chromium(VI) reduction, has been found to be possible using low frequency EPRS [31]. Recent studies have shown also that chromium(V) intermediates are definitely capable of producing damage to DNA [29].

It has been suggested from the results of EPRS studies that stable, water-soluble chromium(V) compounds can form from the reaction of humic substances with hexavalent chromium [32–34]. While the evidence for these reactions is sound, the concentrations of reactants used in the relevant studies were unrealistically high with respect to likely concentrations of chromium to be found environmentally. It was the aim of this research to verify the production of stable, water-soluble chromium(V) complexes with fulvic acid and to quantify the amounts of chromium(V) formed using electron paramagnetic resonance (EPR) spectroscopy as a detection method. The method of analysis developed was also applied to the determination of chromium(V) produced from the interaction of chromium(VI) with 1,2-dihydroxybenzene, which can be considered to be a very simple model molecule of fulvic acid.

Fig. 1. EPR spectrum of the chromium(V) formed from the reaction of equal volumes of 0.14% (w/v) fulvic-L and 0.020 M potassium chromate in aqueous solution at pH 4.2. EPR parameters: microwave power = 126 mW; receiver gain = 3.20×10^5 ; modulation amplitude = 1.6 G.

2. Experimental

2.1. Reagents and glassware

A stock solution of 0.020 M chromium(VI) was prepared from potassium chromate (K_2CrO_4 , 99.5%, BDH Chemicals Ltd.). Fulvic acid solutions were prepared on the day of use from solid fulvic acid extracted from lucerne compost by a method outlined previously [35]. Solutions of 1,2-dihydroxybenzene ($\text{C}_6\text{H}_6\text{O}_2$, 99.0%, Riedel-deHaen) were prepared on the day of use and stored away from light to minimise decay. Commercially available 2-ethyl-2-hydroxybutyric acid ($\text{C}_6\text{H}_{12}\text{O}_3$, Aldrich Chemical Company Inc., 99%) was used without further purification. Anhydrous sodium dichromate was obtained from the dihydrate ($\text{Na}_2\text{Cr}_2\text{O}_7$, 99.5%, BDH Chemicals Ltd.) by drying in vacuo at 100°C for at least 10 h to constant weight. Ace-

tone and doubly distilled hexane were dried over molecular sieves (Ajax Chemicals, type 4A). All other chemicals were of analytical grade and dilutions were performed with distilled water.

All glassware was soaked for at least 12 h in 4 M nitric acid after cleaning with distilled water. Final rinsing was performed with milli-Q water.

2.2. Preparation of phosphate buffers

A phosphate buffer was prepared from potassium dihydrogen orthophosphate (KH_2PO_4 , 99.5%, BDH Chemicals Ltd.) and disodium hydrogen orthophosphate (Na_2HPO_4 , 99.0%, BDH Chemicals Ltd.). A pH of 7.4 was attained by mixing 6.54 ml of 0.02 M KH_2PO_4 with 28.97 ml of 0.02 M Na_2HPO_4 and adjusting the final volume to 100 ml with distilled water.

Fig. 2. Formation and decay of chromium(V) formed from the interaction of equal volumes of 0.14% (w/v) fulvic-L and 0.020 M potassium chromate at pH 4.2.

2.3. Electron paramagnetic resonance spectroscopy

Electron paramagnetic resonance analysis was performed in the X-band region with a Bruker ESP300E spectrometer using a 1 mm i.d. quartz flow-through cell. The instrument was programmed to record and store spectra at pre-determined time intervals. Analysis of the spectra was performed using WinEPR and X-EPR, computer software packages developed by Bruker.

Simulations of experimental spectra were obtained using SOPHE, a computer program developed by the Centre for Magnetic Resonance, The University of Queensland, Australia.

2.4. Synthesis of

sodium(2-ethyl-2-hydroxybutyrate)

oxochromate(V) monohydrate

The synthesis and characterisation of sodium(2-ethyl-2-hydroxybutyrate)oxochromate(V) monohydrate was performed according to the method reported by Krumpolc and Rocek in 1979 [36].

2.5. Preparation of standard solutions for EPR analysis

Solutions of sodium(2-ethyl-2-hydroxybutyrate)oxochromate(V) monohydrate were prepared in 0.01 M 2-ethyl-2-hydroxybutyric acid.

Solutions of 2,2,6,6-tetramethylpiperidine-1-oxyl ($C_9H_{18}NO$, 98.0%, Aldrich Chemical Company, Inc.), otherwise known as TEMPO, were prepared by dissolution in distilled water.

2.6. Fulvic acid/chromium(VI) reactions

Equal volumes of 0.020 M potassium chromate and 0.14% (w/v) fulvic acid were mixed and the pH adjusted to between 4 and 5 with 5 M hydrochloric acid.

outlined in Table 1. The initial pH for each reaction mixture was adjusted to 7.36 ± 0.03 by addition of small amounts of 1 M hydrochloric acid.

To achieve a molar ratio of 182:1, equal volumes of 1.82 M 1,2-dihydroxybenzene and 0.010 M potassium chromate were mixed. The initial pH of the reaction mixture was adjusted to 7.36 ± 0.03 with 5 M hydrochloric acid.

3. Results and discussion

Reaction of chromium(VI) with fulvic acid produced a chromium(V) complex whose EPR spectrum had $g = 1.9784$ and a line width of 1.80 G (Fig. 1). The reaction occurred in the pH range of 4–8 with increased rates of formation and decay at lower pH values. The concentration of chromium(V) increased to a maximum before slowly decreasing. When conducted at pH 4.2, the maximum chromium(V) concentration was attained approximately 8 h after the reaction was com-

Fig. 4. EPR spectrum of 0.002 M sodium bis(2-ethyl-2-hydroxybutyrate) oxochromate(V) monohydrate in 0.010 M 2-ethyl-2-hydroxybutyric acid. EPR parameters: microwave power = 2 mW; receiver gain = 1.25×10^4 ; modulation amplitude = 0.184 G.

menced (Fig. 2) and the signal was still detectable 1 week later. At pH values below 3.5, a precipitate was formed, and EPR analysis of the supernatant yielded a broad signal in the $g = 2$ region, which is indicative of the presence of chromium(III). Chromium(V) was not observed at $\text{pH} > 8$. These results are consistent with the findings reported by Boyko and Goodgame [32], although the chromium(V) production was reported over a greater pH range in their work.

As with any instrumental method of analysis, quantitative determination by EPR spectroscopy requires the use of a reference material for calibration purposes. As a matter of convenience, it is useful if the reference material has the same electron spin multiplicity as the unknown. Two such materials are sodium(2-ethyl-2-hydroxybutyrate) oxochromate(V) monohydrate and 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO).

The synthesis of sodium(2-ethyl-2-hydroxybutyrate)oxochromate(V) monohydrate, a chromium(V) compound that is relatively stable in

aqueous solution was first reported by Krumpolc and Rocek in 1979 [36]. It was later found that dissolution of the complex in an excess of the hydroxy acid ligand, resulted in the chromium(V) being highly stable in solution for periods of about 1 h [37].

After synthesis, the chromate(V) complex was tested for impurities by microanalysis, iodometric analysis and infrared spectroscopy. The experimental results for carbon and hydrogen microanalysis agree well with both the calculated results and those reported by Krumpolc and Rocek (Table 2). The infrared spectrum of $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ obtained in this work is shown in Fig. 3, together with previously reported values (Table 3). The agreement between the experimental and literature values is excellent.

The possible presence of chromium(VI) in the chromium(V) complex was determined spectrophotometrically using an iodometric method of analysis [36]; no chromium(VI) was detected. In addition, the iodometric procedure allowed the

Fig. 5. Decay of 0.002 M sodium bis(2-ethyl-2-hydroxybutyrate) oxochromate(V) monohydrate in 0.010 M 2-ethyl-2-hydroxybutyric acid with time.

calculation of the chromium concentration in solution; this was 14.05%, and compared very well with the calculated value of 14.08%. EPR spectroscopy of a portion of $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ solid did not yield any indication of the presence of chromium(III). Likewise, UV/Vis spectroscopy of an aqueous solution of the chromium(V) complex indicated that the tri- and hexavalent chromium species are not present.

On the basis of the microanalysis and the iodometric method, the sodium bis(2-ethyl-2-hydroxybutyrate)oxochromate(V) monohydrate is approximately 99% pure and is suitable for use as a standard chromium(V) material. However, the material does not fulfil the requirements of a primary standard and requires standardisation before use.

The EPR spectrum of an aqueous solution of 0.002 M $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ prepared in 0.01 M 2-ethyl-2-hydroxybutyric acid contains a signal with $g = 1.9786$. The hyperfine coupling constant and line width are 17.06 and 1.30 G respectively (Fig. 4).

The stability of the chromium(V) solution was established by recording the EPR spectrum every

5 min for approximately 5 h (Fig. 5). At the conclusion of the experiment, the chromium(V) had decreased 8.15% relative to the initial concentration. However, no significant decrease in concentration was observed for the first 30 min of the experiment; after 40 min, the concentration had decreased by 0.40% and at 1 h, 1.20%. Therefore, it was concluded that if the standard solution could be prepared and analysed within 30 min, it would be stable enough to be used as a standard for quantitative EPR spectroscopy.

2,2,6,6-Tetramethylpiperidine-1-oxyl, otherwise known as TEMPO, is a commercially available organic radical. Its stability is well known and it has been used extensively as a radical scavenger and as a standard material for quantitative EPR analysis [38–40]. Solid TEMPO is unstable at room temperature and must be stored in a refrigerator; therefore, it is only useful as a reference material if it can be standardised. Fortunately, the extinction molar coefficients for the compound in various organic solvents are well known, allowing the determination of TEMPO concentration in those solvents by UV/Vis spectroscopy [41]. However, a thorough search of the literature failed to

Fig. 6. EPR spectrum of 0.002 M 2,2,6,6-tetramethylpiperidine-1-oxyl. EPR parameters: microwave power = 2 mW; receiver gain = 1.25×10^4 ; modulation amplitude = 0.184 G.

find any molar extinction coefficient values for TEMPO in aqueous solution. Therefore, TEMPO was standardised by weighing two 0.03127 ± 0.00002 -g samples; these are identical weights within experimental error. One sample was dissolved in water and used for EPR experiments, the other was dissolved in methanol and the concentration of solution determined using its quoted molar extinction coefficient and UV/Vis spectroscopy ($\epsilon_{\lambda=450 \text{ nm, methanol}} = 10.4 \text{ M}^{-1} \text{ cm}^{-1}$) [41].

The methanol solution with a calculated concentration of 2.0013 mM was determined by visible spectroscopy to have an actual concentration of 1.9471 mM. Therefore, the TEMPO solid can be taken to be 97.3% pure; the main source of impurity is most likely to be absorbed water. The concentration of aqueous solutions of TEMPO used in EPR experiments was adjusted accordingly.

The EPR spectrum of an aqueous solution of 0.002 M TEMPO is centred about $g = 2.0051$ and exhibits a hyperfine coupling between the electron

and ^{14}N ($I = 1$, 99.63% abundant) of 15.85 G (Fig. 6). Weak signals can also be observed for the hyperfine coupling between the electron and ^{15}N ($I = 1/2$, 0.37% abundant), and to a lesser extent, with ^{17}O ($I = 5/2$, 0.037% abundant).

The double integral of an EPR spectrum yields the number of electron spins within the sample cavity. By comparison of an unknown sample with a reference material, the number of spins can be converted to a sample concentration. It is often the case that the reference material will have quite a different paramagnetic centre from the unknown material, and in order to determine the concentration of the unknown compound, one must consider the difference in transition probabilities for the materials [42].

The difference in transition probabilities was first considered by Aasa and Vanngard with respect to anisotropic powder spectra [43]. It was demonstrated that the difference could be corrected for if the double integral of the first derivative EPR signal was divided by the average g value (g^{av}) given by the formula,

Fig. 7. Comparison of EPR spectrum of 0.002 M Na[CrO(HEBA)₂]·H₂O with its simulation. EPR parameters: microwave power = 2 mW; receiver gain = 1.25 × 10⁴; modulation amplitude = 0.184 G.

$$g^{av} \cong \frac{2}{3} \sqrt{\frac{g_x^2 + g_y^2 + g_z^2}{3}} + \frac{1}{3}(g_x + g_y + g_z). \quad (1)$$

In the isotropic system g_x , g_y , and g_z are equal and by Eq. (1), g^{av} equals the experimental value of g . Therefore, in the isotropic system, the differences in transition probabilities are accounted for by dividing the double integral by the relevant experimental g value.

Another method for correction of differences in transition probabilities relies on simulations of the experimental spectra and the following formulae¹ [44]:

$$N_{Ou} = N_{Or} \frac{I(\text{Exp})_u}{C'_u I(\text{Sim})_u} \times \frac{C'_r I(\text{Sim})_r}{I(\text{Exp})_r} \quad (2)$$

¹ The normalisation constant, C' , reported in the literature is the inverse of that described here. During the course of this research, it was found that the formulae in the literature contained an error. The finding was confirmed by one of the authors of the original work, G.R. Hanson. The formulae presented in this research paper are correct.

where

$$C' = \frac{S(S+1)(RG)(MA)P^{1/2}}{T}$$

and $I(\text{Exp})$ = double integral of the experimental spectrum; $I(\text{Sim})$ = double integral of the simulated spectrum; C' = normalisation constant; (RG) = receiver gain; (MA) = modulation amplitude; P = microwave power; T = temperature; S = electron spin, and the subscripts u and r refer to the unknown and reference samples, respectively.

An EPR spectrum of an aqueous solution of 0.002 M Na[CrO(HEBA)₂]·H₂O and its simulation are presented in Fig. 7. It is evident that the simulated and experimental spectra have different intensities. However, the intensity difference is even more significant for the EPR spectrum of aqueous TEMPO and its simulation (Figs. 8 and 9).

Simulations of spectra obtained from low concentrations of chromium(V) are more difficult to achieve. For instance, a 4 × 10⁻⁵ M Na[CrO(HEBA)₂]·H₂O solution requires the use of high microwave power and receiver gain. To increase

Fig. 8. Comparison of EPR spectrum of 0.002 M TEMPO with its simulation. EPR parameters: microwave power = 2 mW; receiver gain = 1.25×10^4 ; modulation amplitude = 0.184 G.

the signal to noise ratio, the modulation amplitude is increased, leading to changes in the line shape of the EPR signal. The resulting spectrum cannot be accurately simulated with either Gaussian or Lorentzian line shape models (Fig. 10). A similar problem, although not as significant, exists for the simulation of spectra obtained from solutions of low TEMPO concentration. One of the limitations of the software used for simulations was the inability to use line shape models other than Gaussian or Lorentzian. It is expected that poor simulations of experimental spectra will introduce significant error into the procedure.

Experimental data for standard solutions of chromium(V) and TEMPO are presented in Table 4. The intensity of the experimental spectrum, $I(\text{Exp})$, is recorded as the mean of at least five experimental results. Parameters which effect the spectral intensity are also presented.

Using a TEMPO solution with a standardised concentration of 1.9968 mM, a $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ solution with a calculated concentration of 1.7825 mM was determined to be

1.7616 mM by substitution of the relevant data (Table 4) into Eq. (2). This corresponds to a purity of greater than 98.8% for the $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ standard.

Because the simulated spectra did not fit the experimental spectra very well for solutions with low concentrations of $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$, the spectral simulation method was tested by calculating concentrations of dilute TEMPO solutions from dilute $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ solutions. The examples presented (Table 5) clearly demonstrate that poor simulation of an experimental spectrum will lead to erroneous results.

For this particular application, the spectral simulation procedure is useful for the standardisation of $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$, but not for the routine analysis of low concentration solutions. For this task, the average g method must be employed.

The determination of unknowns is performed using the $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ standard solutions. Similar results could also be obtained from the TEMPO solutions, but an additional calculation step is necessary. The hyperfine coupling of

Fig. 9. Simulated EPR spectrum for TEMPO.

the electron with ^{53}Cr ($I = 3/2$, natural abundance = 9.55%) was generally not observed for low concentration chromium(V) solutions. Therefore, the experiments were focused on the centre signal, attributed to the one unpaired electron. However, the double integral of that signal represents only 90.45% of the total number of spins within the spectrometer's cavity. The hyperfine coupling for TEMPO is observed in all cases. If comparing the area of the centre signal of a chromium(V) spectrum with the area of a TEMPO spectrum, the resulting chromium(V) concentration will only account for 90.45% of the actual concentration. It is more convenient to use $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ as the reference material and compare the centre signals for both reference and unknown.

A calibration curve is constructed by plotting the double integrals of the EPR spectra against concentration. However, to compensate for differences in transition probability between the reference and unknown, the areas of the spectra must be divided by the g value. Before a concentration can be determined from the calibration curve, the

double integral of the unknown must also be divided by the corresponding g value.

The calibration data for chromium(V) standards within the concentration range of the unknown materials is shown in Table 6. The blank value was obtained from 0.01 M 2-ethyl-2-hydroxybutyric acid. The resulting correlation coefficient is 0.9998, indicating excellent linearity.

If spectra have been recorded using different instrument parameters, the data must be normalised. EPR spectra of the chromium(V) product of the reaction between 1,2-dihydroxybenzene and chromium(VI) were recorded with modulation amplitude = 10.11 G, microwave power = 126 mW, and receiver gain = 1.250×10^4 . These parameters differ from those of the $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ standard solutions. Therefore, the double integrals must be normalised to the parameters used to record the reference solutions (Table 7).

It was found that when the 1,2-dihydroxybenzene and chromium(VI) were reacted at a ratio of 182:1, the maximum concentration of chromium(V) produced was 0.144 mM (Table 7). Since

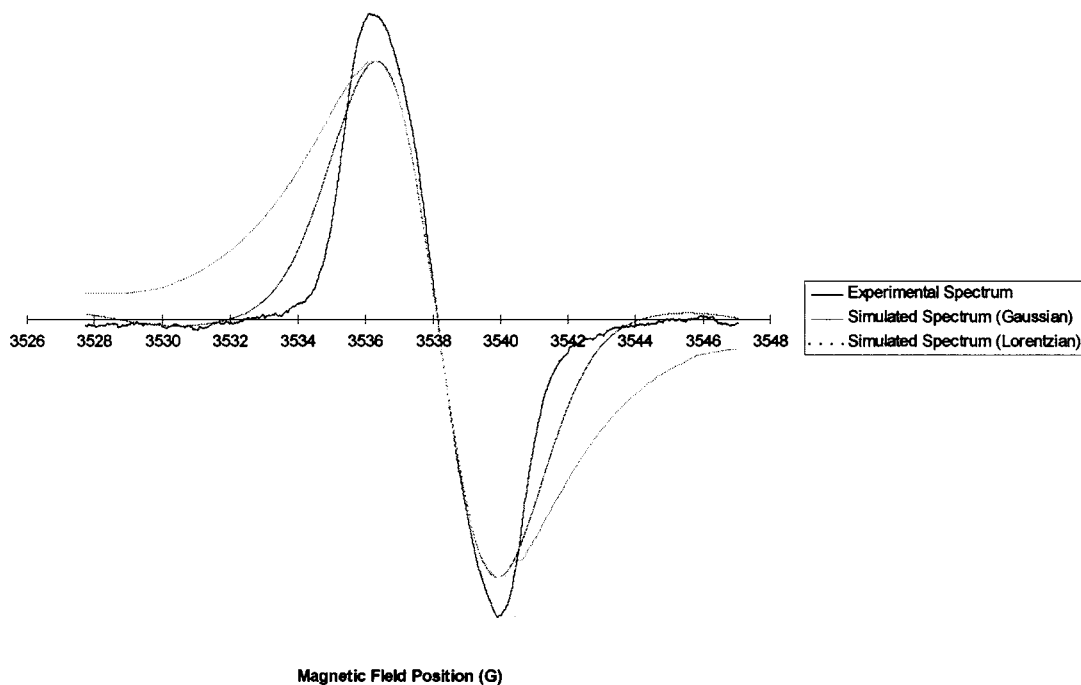

Fig. 10. Comparison of the EPR spectrum of 4×10^{-5} M $\text{Na}[\text{CrO}(\text{HEBA})_2] \cdot \text{H}_2\text{O}$ with simulations based on Gaussian and Lorentzian line shapes. The intensities of the simulated spectra are multiplied by 60 to aid comparison. EPR parameters: microwave power = 126 mW; receiver gain = 1.25×10^4 ; modulation amplitude = 5.15 G.

the initial concentration of chromium(VI) was 0.020 M, or 20 mM, the maximum chromium(V) concentration represents only 0.71% of the total amount of chromium in the system. The reactions conducted at lower molar ratios produced less chromium(V) (Table 7). A relationship was not found between the molar ratio and the maximum concentration of chromium(V).

The interaction between chromium(VI) and fulvic acid was studied with modulation amplitude = 10.11 G, microwave power = 126 mW and receiver gain = 1.250×10^5 . Again, these parameters differ from those used for the chromium(V) reference solutions, necessitating a normalisation process (Table 8). The maximum chromium(V) concentration was found to be only 0.014 mM.

The main source of error associated with analysis by the spectral simulation procedure is due to the EPR spectrometer. Based on the standard deviation of 10 spectral intensities of 0.2 mM TEMPO, the error associated with the EPR spec-

trometer may be taken as $\pm 9.3\%$ (assuming that the error is equivalent to two standard deviations). Consideration of the other errors associated with the procedure (analytical balance and volumetric glassware) lead one to propose an overall error of $\pm 10\%$.

Determination of error and detection limit for analyses performed by division of spectral intensities by the relevant g value is achieved from the linear regression analysis. If the detection limit is taken as 0.010 mM chromium(V) (0.5 mg l^{-1}), the error does not exceed $\pm 10\%$.

Normally the development of a new analytical procedure is accompanied by a validation of the results. This is usually achieved by either analysing some internationally recognised standard reference material (SRM) and comparing the experimental and accepted results, or by employing a standard additions procedure. In the standard additions procedure, samples of the unknown are spiked with known amounts of ana-

no SRMs available for chromium(V) in aqueous solution. The latter procedure is not possible since, with the exception of sodium bis(2-ethyl-2-hydroxybutyrate) oxochromate(V) monohydrate prepared in excess 2-ethyl-2-hydroxybutyric acid, aqueous chromium(V) exhibits poor stability. In the reaction mixtures studied, the chromium(V) concentration increases to a maximum value before slowly decreasing. The literature suggests that the concentration of chromium(V) is dependant on the ratio of concentrations of chromium(VI), the organic substrate and other reaction products [46]. Addition of a known excess of chromium(V) would almost definitely alter the quasi-equilibrium state, thereby changing the expected concentration of chromium(V).

The calibration curve for the standards proved to have an excellent linear fit and the standardisation of Na[CrO(HEBA)₂]·H₂O with TEMPO, a recognised reference material for quantitative EPR analysis, gave good results. However, in the

absence of a suitable validation technique for this particular method, it must be conceded that any results obtained should be treated with caution.

The detection limit of the developed procedure is 0.01 mM, or 0.5 mg l⁻¹. While this is comparable with techniques such as atomic absorption spectroscopy (AAS), it is not low enough for determination of chromium(V) at background environmental concentrations. In non-contaminated conditions the concentration of chromium(VI) in the natural water rarely exceeds 1 µg l⁻¹ [47]. Therefore, without a pre-concentration step, EPR analysis is not a useful technique for the determination of background chromium(V) concentrations in the natural environment, particularly with respect to aqueous samples. However, the technique still has great potential for use within the laboratory situation for in vitro investigations of the interactions of chromium(VI) with biologically significant compounds such as glutathione and ascorbate.

The development of a pre-concentration step for the analysis of chromium(V) would be

Table 8

difficult. Because of the instability of the species in aqueous solution, there is high risk that the usage of common pre-concentration techniques, such as column chromatography and solvent extractions, might alter the oxidation state of the metal. Furthermore, chromium(V) often exists in a quasi-equilibrium state, dependant on the ratio of reactants. A pre-concentration step might alter the concentrations of reactants, and hence the amount of chromium(V) produced, thus leading to results that are not consistent with the original sample.

If using 'real' samples such as dam water or cell tissue, it is possible that the presence of other paramagnetic species might obscure the chromium(V) signal, making quantitative analysis impossible. For instance, a dam water sample might contain manganese(II), copper(II) or iron(III), all of which give EPR signals in the *g* = 1.9–2.0 region. It should be possible to overcome this problem by subtracting a background spectrum from the analytical spectrum. If, for example, manganese(II) and copper(II) were interfering with a chromium(V) signal, then the unknown sample could be analysed by AAS to determine the concentrations of manganese and copper. A background solution containing the interfering metals at the determined concentrations could then be prepared. Subtraction of the background EPR spectrum from that of the unknown sample would result in an unobscured chromium(V) signal. It would also be necessary to know the relevant salt or chelating agent for any interfering metal, since these can have an effect on the EPR spectrum [48].

In the reaction between chromium(VI) and 1,2-dihydroxybenzene, where the organic compound is present in a 182-fold excess, the amount of chromium(V) produced represents only 1.44% of the total chromium in the system. Because all chromium(VI) must proceed through the chromium(V) intermediate, it is most likely that the reduction of chromium(V) to chromium(III) occurs at a rapid rate, yet slowly enough to allow detection.

The amount of chromium(V) produced from the interaction of chromium(VI) with fulvic acid is also quite small in relation to the total chromium in the system. The maximum concentration of chromium(V) produced from the reaction of equal volumes of 0.020 M chromium(VI) and 0.14% (w/v) fulvic acid was 0.014 mM. This value is about half that obtained for the interaction of 1,2-dihydroxybenzene with chromium(VI) at a molar ratio of 1.8: 1 (Table 7). However, the results do not indicate that all interactions between chromium(VI) and suitable organic compounds will produce only a small percentage of chromium(V).

The analytical procedure reported in this paper can now be used to obtain quantitative data for the chromium(V) producing reactions between the chromium(VI) and various organic compounds of biological and environmental significance.

Received 28 April 1997; received in revised form 24 July 1997; accepted 29 July 1997

Abstract

Two simple, rapid and sensitive spectrophotometric methods for the determination of catecholamine derivatives (pyrocatechol, dopamine, levodopa and methyl dopa) are developed. The first method involves the oxidation of *o*-dihydroxybenzene derivatives by *N*-bromosuccinimide followed by oxidative coupling with isoniazid leading to the formation of a red-coloured products of maximum absorbance ($\lambda_{\max} = 480\text{--}490\text{ nm}$). The second method is based on the formation of green to blue complex ($\lambda_{\max} = 635\text{--}660\text{ nm}$) between *o*-dihydroxybenzene derivatives and sodium nitroprusside in the presence of hydroxylamine hydrochloride. All measurements of the two procedures are carried out in an alkaline medium at room temperature. The two methods are successfully applied for the determination of dopamine hydrochloride, levodopa and methyl dopa in injections and tablets of pharmaceutical preparation. The common excipients used as additives in pharmaceuticals do not interfere in the proposed methods. The reliability of these methods are established by parallel determination with the reported and official methods. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Pyrocatechol; Dopamine hydrochloride; Levodopa; Methyl dopa; Isoniazid; Hydroxylamine hydrochloride; Sodium nitroprusside; *N*-Bromosuccinimide; Spectrophotometry; Pharmaceuticals

1. Introduction

Catecholamine drugs are aromatic vic-diols in which either the 3- or 4-position is unsubstituted and these positions are not sterically blocked. These drugs are now widely used in the treatment of bronchial asthma, hypertension, Parkinson's disease, myocardial infarction and cardiac

surgery. Dopamine, a neurotransmitter, is one of the naturally occurring catecholamines, and its hydrochloride salt is being used in the treatment of acute congestive failure and renal failure [1]. This has stimulated many investigators to work out compendial methods for the determination of catecholamine in authentic and dosage forms. Various methods like spectrofluorimetry [2,3], spectrophotometry [4], ion-exchange column chromatography [5], gas chromatography [6,7]

and radioimmunoassay [8,9] have been described in the literature for the determination of dopamine and dopa from the various biological samples and pharmaceutical preparation. The present work describes the two simple sensitive and accurate spectrophotometric methods for the determination of catecholamine derivatives (pyrocatechol, levodopa, methyl dopa and dopamine hydrochloride) using isoniazid (INH) in the presence of *N*-bromosuccinimide (NBS). The other method determines the pyrocatechol and dopamine hydrochloride using sodium nitroprusside (SNP) in the presence of hydroxylamine hydrochloride (HAH). The methods are adopted for the assay of three catecholamine drugs in pure and pharmaceutical formulations. These three drugs are officially listed in USP [10] which describes a nonaqueous titration for the assay of dopamine hydrochloride in raw material and an

HPLC technique for injection solutions. A visual titration and UV spectrophotometric methods at 280 nm are prescribed for levodopa and methyl dopa, respectively.

2. Experimental

2.1. Apparatus

A Jasco Model UVIDEDEC-610 UV-VIS spectrophotometer with 1.0-cm matched cells was used for the electronic spectral measurements.

2.2. Reagents

Dopamine hydrochloride (Sigma, USA), levodopa (SD Fine, India), methyl dopa (SD Fine, India), Pyrocatechol (CDH, India), Isoniazid

Fig. 1. Absorption spectra of: (1) PCL ($3 \mu\text{g ml}^{-1}$) + NBS + INH product; (2) LDP ($6 \mu\text{g ml}^{-1}$) + NBS + INH product; (3) DPH ($7 \mu\text{g ml}^{-1}$) + NBS + INH product; (4) MDP ($8 \mu\text{g ml}^{-1}$) + NBS + INH product; (5) NBS + INH reagent blank.

Fig. 2. Absorption spectra of: (1) PCL ($5 \mu\text{g ml}^{-1}$) + HAH + SNP product; (2) DPH ($8.5 \mu\text{g ml}^{-1}$) + HAH + SNP product; (3) HAH + SNP reagent blank.

(BDH, Poole, UK), sodium nitroprusside (E-Merck, Germany) were used.

All other chemicals used were of analytical reagent grade. Deionised water was used to prepare all solutions and in all experiments.

2.3. Solutions

Freshly prepared aqueous solutions of the pure drugs and pyrocatechol (PCL) (protected from sun light) ($50 \mu\text{g ml}^{-1}$) were used as the standard

solution for analytical purposes. Dopamine hydrochloride (DPH), levodopa (LDP), and methyl-dopa (MDP) were standardised by the reported method [11]. Solutions of 0.2% aqueous isoniazid, 0.07% aqueous hydroxylamine hydrochloride, 0.3% aqueous sodium nitroprusside, 0.05% *N*-bromosuccinimide, 5% sodium carbonate and 0.01 M sodium hydroxide were used.

2.4. General procedure

2.4.1. Method A

Aliquots of standard solutions of PCL (20–146 μg), DPH (70–350 μg), LDP (60–300 μg) or MDP (125–400 μg) were transferred to a 25-ml calibrated flask, to which 0.05% NBS, 0.02% INH and 0.01 M sodium hydroxide were added to the catecholamine solution, and the mixture was set aside for 5 min. The contents were diluted to the mark and mixed well. The absorbance at λ_{max} was measured against a reagent blank.

2.4.2. Method B

Aliquots of standard solutions of PCL (37–250 μg) or DPH (60–425 μg) were transferred to a 25-ml calibrated flask, to which 0.3% SNP, 0.07% HAH and 5% sodium carbonate solution were added, and the mixture was set aside for 5 min. The contents were diluted to the mark and mixed well. The absorbance at λ_{max} was measured against a reagent blank.

Details of the experimental conditions of the two methods are given in Tables 1 and 2.

2.5. Procedure for the assay of catecholamines in pharmaceutical preparation

2.5.1. Tablets

Twenty tablets were weighed and finely powdered. A weighed amount of the powder containing 50 mg of LDP or MDP was dissolved in water and filtered. The filtrate was made up to 100 ml and an aliquot of this solution was treated as described above for the determination of LDP or MDP.

2.5.2. Injection

DPH injection solutions were appropriately diluted with water to get the required concentration of the drug, and then the general procedure was followed. The amount of DPH was calculated from a calibration graph.

3. Results and discussion

3.1. Absorption spectra

A red-coloured oxidating coupling product with an absorption maximum at 480–490 nm is formed when PCL, DPH, LDP or MDP were allowed to react with NBS in the presence of INH in a sodium hydroxide medium. Green to blue products with absorption maxima at 635–660 nm were formed, when PCL or DPH are allowed to react with SNP in the presence of HAH in a sodium carbonate medium. The absorption spectra of

both red, green and blue products and the reagent blanks are shown in Figs. 1 and 2.

The details of optical characteristics are summarised in Table 2.

3.2. Reaction sequence

Vicinal dihydroxybenzene derivatives were readily oxidised to *o*-benzoquinone by NBS. INH, by virtue of its strong electron-donating group, couples with *o*-benzoquinone in alkaline medium leading to the formation of oxidative coupled products as given in the reaction in Scheme 1 [12,13]. Other oxidising agents such as $\text{Cr}_2\text{O}_7^{2-}$, H_2O_2 , chloramine-T and MnO_4^- were tried instead of NBS and found to be less effective. However, in acidic medium dichromate and MnO_4^- oxidising agents does not form any colour under the experimental conditions.

A characteristic green to blue-coloured product is formed when DPH or PCL is allowed to react with SNP in the presence of HAH in an alkaline medium. Use of this method was unsuccessful for the identification of the product in solid form. However, Gupta and co-workers [14] and Nagaraja et al. [15] have proposed the formation of

indophenol blue or a coordination complex with a charge transfer absorption using SNP as a reagent for the analysis of phenol. This indicates that the formation of the green to blue colour by the proposed method B may be due to either the formation of indophenol blue or a coordination complex of CT type.

3.3. Stability

The resultant products of the proposed methods were studied at different temperatures. The results indicate that the absorbance values remain constant in the temperature range 5–70°C. At higher temperatures the absorbance values decrease, indicating the dissociation of the products on prolonged heating. The coloured products were stable for 3–48 h at room temperature.

3.4. Interference

An antioxidant, sodium metabisulphate, and sodium chloride that is commonly present in the DPH injection, and also commonly used excipients such as starch, talc, glucose, lactose, dextrose

and magnesium stearate, did not interfere, while vitamin C, adrenaline and noradrenaline were found to have interfered. In method B, the results of interference shows that a 2-fold excess of LDP and MDP do not interfere.

3.5. Application

The applicability of the method to assay of pharmaceutical preparations was examined. The results obtained (Table 3) compared favourably to those reported by El-Kommos et al. [13] and the official method [11].

4. Conclusions

The proposed methods are simple, rapid, precise, sensitive and economical. The two methods can be successfully applied as an alternative to the existing methods.

Abstract

In this paper, separations of organic compounds, such as, *n*-alkanes, alcohols, ethyl esters of C₁–C₈ carboxylic acid, halogen derivatives, position-isomers of the replacement aromatic hydrocarbon, optical isomers of ethyl lactate and isoamyl alcohol, etc. were studied using 4'-cholestenoxycarbonyl-benzo-15-crown-5 liquid crystal crown ether (CH-B-15-C-5) as stationary phase in gas-solid chromatography (GSC), general gas-liquid chromatography (GLC) and crown ether liquid crystal gas-liquid chromatography (CL-GLC). Also, the chromatographic characteristics, such as the chemical stability, thermal stability, selectivity, polarity and operating temperature range, of the CH-B-15-C-5 as stationary phase for GSC, GLC and CL-GLC systems were studied. The results showed that the polarity of this chromatographic column is mean-weak; the chemical and thermal stabilities and the selectivity are good and the operating temperature range is wide. The results of separations of organic compounds are satisfactory. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Gas chromatography; Application studies; Stationary phase; CH-B-15-C-5

1. Introduction

Recently, much attention has been paid to chromatographic characteristics and applications of crown ether stationary phase [1–5]. Cholesteric liquid crystal crown ether CH-B-15-C-5 has different phase states under a range of different temperatures, and a large variety of physical properties under different operating conditions in the same temperature range. The constitutional

formula and phase transition temperatures of CH-B-15-C-5 are described in the following.

When the temperature is decreased from 182 to 165°C, the compound forms cholesteric liquid crystal. If it is decreased to 125°C, it remains anisotropic liquid crystal; then if the temperature

* Corresponding author.

decreases below 125°C it forms anisotropic solid crystal. But, in the course of heating from below 125 to 182°C it cannot form cholesteric liquid crystal. Therefore, the stationary phases of CH-B-15-C-5 have three gas chromatographic functions: gas-solid chromatography (GSC), general gas-liquid chromatography (GLC) and crown ether liquid crystal gas-liquid chromatography (CL-GLC). We separated organic compounds, such as, *n*-alkanes, alcohols, ethyl esters of C_1 – C_8 carboxylic acid, halogen derivatives, etc., and position-isomers of the replacement aromatic hydrocarbons, such as the *o,m,p*-xylenes, -dichlorobenzenes, -nitrochlorobenzenes, and 1,3,5- and 1,2,4-trimethylbenzene, etc. Good separation results were achieved using crown ether liquid crystal stationary phase under the different chromatographic conditions. We have explored the chiral resolutions of optical isomers of ethyl lactate and isoamyl alcohol in gas chromatography (GC) with a new cholesteric liquid crystal crown ether (CH-B-15-C-5) stationary phase.

We have not seen any other reports on this type of study up to now.

2. Experimental

2.1. Apparatus and reagents

An SC-6 Gas Chromatograph, with a hydrogen flame ionization detector, was used. Chromatographic column: stainless steel column, 2 m \times 3 mm I.D.; stationary phase, Chromosorb W (60–80 mesh) on the column packed with 10% CH-B-15-C-5.

CH-B-15-C-5 liquid crystal crown ether was prepared by Prof. Xie Mingguo, and was determined by IR, NMR, MS and elemental analysis [6,7]. Ethyl lactate and isoamyl alcohol were chromatographic pure reagents. *R*(–)-Ethyl lactate and *S*(–)-2-methyl-1-butanol were optically pure (Fluka, USA). Other reagents were analytically pure.

2.2. Procedure

In the GSC method, column temperature was raised from room temperature to 182°C at a rate of 10°C min⁻¹, kept there for 30 min, then lowered to 165°C at a rate of 2°C min⁻¹ and kept there for 30 min, then lowered to below 125°C to the necessary temperature and separation of organic compounds was carried out.

In the GLC method, the temperature was raised to 130–190°C and organic compounds were separated.

In the CL-GLC method, the column temperature was raised to 182°C at a rate of 10°C min⁻¹, kept there for 30 min, then lowered to 165°C at a rate of 2°C min⁻¹, and kept there for 30 min, then lowered at a rate of 2°C min⁻¹ to the necessary temperature and organic compounds were separated.

3. Results and discussion

3.1. Separations of ethyl esters of C_1 – C_8 carboxylic acid, C_5 – C_{12} *n*-alkanes, C_1 – C_8 alcohols and some organic mixtures

In the GSC method, ethyl esters of C_1 – C_8 carboxylic acid, C_5 – C_{12} *n*-alkanes, C_1 – C_8 alcohols and some organic compounds mixtures were separated, at a column temperature of 120°C. Carrier gas was nitrogen. Hydrogen and air flow-rates were 30 and 60 cm³ min⁻¹, respectively (for results see Fig. 1).

The results show that the homologues of alkane and ethyl esters of carboxylic acid abide by carbon number law (see Fig. 1A Fig. 1B), but in the *n*-alcohol homologous series, methanol deviates considerably from carbon number law. A comparison of the size of the methanol molecule and CH-B-15-C-5 demonstrates the cause: methanol molecules enter the crown ether cavity, but higher alcohols can not.

It is evident from Fig. 1D that aromatics are retained for a larger time in the GSC method than with cyclohexane and cyclohexene. The most likely cause of this behaviour is the similarity of aromatics to the aromatic nucleus in the CH-B-15-C-5 cavity [8].

Fig. 1. GSC of homologous series of ethyl esters of carboxylic acids, *n*-alkanes, alcohols, and organic mixtures at a column temperature of 120°C. (A) The GSC of ethyl esters of C₁–C₈ carboxylic acid (carrier gas flow-rate was 20 cm³ min⁻¹). (1) Ethyl ester of formic acid; (2) ethyl ester of acetic acid; (3) ethyl ester of *n*-propionic acid; (4) ethyl ester of *n*-butyric acid; (5) ethyl ester of *n*-valeric acid; (6) ethyl ester of *n*-caproic acid; (7) ethyl ester of *n*-enanthic acid; and (8) ethyl ester of *n*-caprylic acid. (B) The GSC of C₅–C₁₂ *n*-alkanes (carrier gas flow-rate was 15 cm³ min⁻¹). (1) *n*-Pentane; (2) *n*-hexane; (3) *n*-heptane; (4) *n*-octane; (5) *n*-nonane; (6) *n*-decane; (7) *n*-undecane; and (8) dodecane. (C) The GSC of alcohols (carrier gas flow-rate was 20 cm³ min⁻¹). (1) Methanol; (2) ethanol; (3) *n*-propanol; (4) *n*-butanol; (5) *n*-pentanol; (6) *n*-hexanol; (7) *n*-enanthol; and (8) *n*-octanol. (D) The GSC of aromatics and other organic mixtures (carrier gas flow-rate was 30 cm³ min⁻¹). (1) Cyclohexane; (2) methylcyclohexane; (3) cyclohexene; (4) benzene; (5) toluene; (6) *m*-xylene; (7) isopropylbenzene; (8) butylbenzene; (9) *o*-ethyltoluene; (10) 1,3,5-trimethylbenzene; and (11) *p*-cymene.

3.2. Separations of position-isomers for replacement aromatic hydrocarbons

Carrier gas flow-rate was 20 cm³ min⁻¹. Hydrogen and air flow-rates were 25 and 50 cm³ min⁻¹, respectively. *o,m,p*-Xylenes, -dichlorobenzenes, -nitrochlorobenzenes, and 1,3,5- and 1,2,4-trimethylbenzene were separated at a column temperature of 110°C by the GSC method (for results see Fig. 2).

Carrier gas flow-rate was 20 cm³ min⁻¹. Hydrogen and air flow-rates were 25 and 50 cm³ min⁻¹, respectively. *o,m,p*-Xylenes, -dichlorobenzenes, -nitrochlorobenzenes, and 1,3,5- and 1,2,4-

trimethylbenzene were separated at a column temperature of 130°C by the GLC method (for results see Fig. 3).

Carrier gas flow-rate was 20 cm³ min⁻¹. Hydrogen and air flow-rates were 25 and 50 cm³ min⁻¹, respectively. *o,m,p*-Dichlorobenzenes, -nitrochlorobenzenes, and 1,3,5- and 1,2,4-trimethylbenzene were separated at a column temperature of 130°C by the CL-GLC method (for results see Fig. 4).

In the GSC and GLC methods, retention behaviour of the position-isomers on the CH-B-15-C-5 column accorded with the retention law of the crown ether stationary phase [9]. That is, on the

Fig. 2. GSC of position-isomers of replacement aromatic hydrocarbons at a column temperature of 110°C. (a) Xylenes; (b) dichlorobenzenes; (c) nitrochlorobenzenes; (d) 1,3,5-trimethylbenzene (peak 1) and 1,2,4-trimethylbenzene (peak 2).

crown ether column, retention times of substances depended on polarity, hydrogen bond and crown ether cavity, etc. In the separation of xylenes, dichlorobenzenes and nitrochlorobenzenes, molecular polarity order was $o \rightarrow m \rightarrow p$ -, but peak order was $m \rightarrow p \rightarrow o$ - (see Figs. 2 and 3) because the p -isomer molecular shape was columnar, which could accord with the cavity of crown ether [10].

In the CL-GLC method, because of the orderly arrangement of crown ether liquid crystal molecules and the increase of orientation effect of these molecule and the columnar molecule of p -isomer, the order of chromatographic peaks was $m \rightarrow o \rightarrow p$ - (see Fig. 4).

3.3. Separations of optical isomers of ethyl lactate and isoamyl alcohol

Carrier gas flow-rate was $25 \text{ cm}^3 \text{ min}^{-1}$. Hydrogen and air flow-rates were 25 and $60 \text{ cm}^3 \text{ min}^{-1}$, respectively. In a column temperature operating range of 75–125°C, ethyl lactate and isoamyl alcohol were separated using the CH-B-15-C-5 GSC stationary phase (for results see Table 1).

Carrier gas flow-rate was $30 \text{ cm}^3 \text{ min}^{-1}$. Hydrogen and air flow-rates were 25 and $50 \text{ cm}^3 \text{ min}^{-1}$, respectively. In a column temperature operating range of 130–190°C ethyl lactate and isoamyl alcohol were separated with the CH-B-15-C-5 GLC stationary phase (for results see Table 2).

Carrier gas flow-rate was $30 \text{ cm}^3 \text{ min}^{-1}$, hydrogen and air flow-rates were 25 and $50 \text{ cm}^3 \text{ min}^{-1}$, respectively. In a column temperature operating range of 130–175°C, ethyl lactate and isoamyl alcohol were separated with the CH-B-15-C-5 CL-GLC stationary phase (for results see Table 3).

From experiments of chiral resolution for optical isomers in the GSC, GLC and CL-GLC systems we found that the separations of ethyl lactate and isoamyl alcohol could be obtained by this stationary phase, and the resolutions were almost as good as those on the GSC, GLC [11] and CL-GLC systems. But, relatively, with the GLC method chiral resolution able was lower than that with the GSC and CL-GLC methods, especially in the high-temperature column, resolution R values were evidently lower than in the GSC and CL-GLC systems.

3.4. Polarities and stabilities of the columns

Polarities of CH-B-15-C-5 were determined by the determination of the McReynolds phase constants. The results showed that the polarity of the column in the GSC system was stronger than that of SE-30 column, but weaker than that of the PEG-20M and B-15-C-5 columns [12], and in the GLC and the CL-GLC systems the polarities of this crown ether liquid crystal column were weaker than that in the GSC system. Thus, the polarity of the CH-B-15-C-5 column was mean-weak (see Table 4).

Fig. 3. GLC of position-isomers of replacement aromatic hydrocarbons at a column temperature 130°C. (a) Xylenes; (b) dichlorobenzenes; (c) nitrochlorobenzenes; (d) 1,3,5-trimethylbenzene (peak 1) and 1,2,4-trimethylbenzene (peak 2).

Fig. 4. CL-GLC of position-isomers of replacement aromatic hydrocarbons at a column temperature of 130°C. (a) Xylenes; (b) dichlorobenzenes; (c) nitrochlorobenzenes; (d) 1,3,5-trimethylbenzene (peak 1) and 1,2,4-trimethylbenzene (peak 2).

The chemical stability and thermal stability of CH-B-15-C-5 were very good as results determined by this column were satisfactory. Also, the chemical properties of this liquid crystal crown ether compound were stable for a long time at a temperature of 200°C [13] and the possible operating temperature range was wide.

3.5. Shape of chromatographic peaks

The chromatographic peak shapes were good. Basic GLC theory could explain the symmetrical chromatographic peaks in the GLC [14] and the CL-GLC systems (e.g. Figs. 3 and 4), but basic GSC theory could not explain the symmetrical

chromatographic peak in the GSC system of this crown ether column (e.g. Figs. 1 and 2). We presume that, besides adsorption theory, in the GSC stationary phase the molecular steric arrangement is of great importance for the retention behaviour of organic compounds.

In the CH-B-15-C-5 GSC stationary phase, after the crown ether compound was kept at a temperature of 182°C for 30 min, solid crystal was orderly arranged at temperatures lower than 125°C. Under the above conditions of GSC, it is beneficial to obtain symmetrical chromatographic peaks, in the GSC system, of organic homologous series compounds, position-isomers of replacement aromatic hydrocarbons [15], and optical isomers of ethyl lactate and isoamyl alcohol.

Table 1

Retention times t_R (min) and resolutions (R) of chiral separations for optical isomers of ethyl lactate and isoamyl alcohol using CH-B-15-C-5 stationary phase in the GSC system

	$t_{S(+)}$	$t_{R(-)}$	R	$t_{R(+)}$	$t_{S(-)}$	R
75	11.5	12.7	3.41	23.5	25.0	3.80
85	10.6	11.7	3.10	16.5	18.4	3.60
95	9.6	10.6	2.90	6.5	8.1	3.46
105	8.5	9.6	2.61	3.1	4.2	3.05
115	7.0	8.2	2.30	2.1	3.0	2.50
125	6.6	7.5	1.85	1.8	2.5	2.12

3.6. Selectivity of the column

CH-B-15-C-5 is a low-molecular crown ether liquid crystal compound that has non-polar carbon-carbon bonds, polar carbon-oxygen bonds and aromatic rings, etc., therefore, it can act with many organic compounds, for example, alkane and alkene homologues, alcohols, ethers, aromatics, position-isomers, etc. This crown ether compound also has chiral carbon atoms which possess chiral recognition for the optical isomers, for example, ethyl lactate, isoamyl alcohol, etc.

The resolving power of the GSC, GLC and CL-GLC systems was compared using resolution R values.

CH-B-15-C-5 are orderly arranged solid crystals in the GSC and crown ether liquid crystals have an orderly arrangement in the CL-GLC system. Compound molecular chiral carbon atoms were orderly arranged because the crown

175	2.4	2.7	0.95	0.6	0.8	1.00
190	1.5	1.5	—	0.4	0.4	—

Table 3

Retention times t_R (min) and resolutions (R) of chiral separations for optical isomers of ethyl lactate and isoamyl alcohol using CH-B-15-C-5 stationary phase in the CL-GLC system

Temp. (°C)	Ethyl lactate			Isoamyl alcohol		
	$t_{S(+)}$	$t_{R(-)}$	R	$t_{R(+)}$	$t_{S(-)}$	R
130	6.0	7.4	2.00	1.9	2.6	1.95
145	4.5	5.6	1.85	1.5	2.0	1.86
160	3.1	3.9	1.50	1.2	1.7	1.60
175	2.0	2.7	0.60	1.0	1.4	1.51

ether molecules were orderly arranged. But, in the GLC system, CH-B-15-C-5 could not form liquid crystal, thus the compound molecular chiral carbon atomic arrangement was disorderly.

The orderly arrangement state was useful for chiral molecular orientation [16]. The chiral resolving power of orderly arranged CH-B-15-C-5 molecules was stronger than that of the disordered orientation state. Therefore, the R value of the CL-GLC system was higher than that of the GLC system under the same experimental conditions, e.g., carrier gas flow-rates, hydrogen and air flow-rates, and column temperature, etc. (see Tables 2 and 3). On the other hand, chiral carbon atomic disordering effect increased with increase of molecular thermal motion. As the CH-B-15-C-5 molecular chiral resolving power was lower, the resolution R value decreased with the increase of temperature in the GLC system (see Table 2).

To sum up, separations can be obtained of organic homologues, organic mixtures, position-isomers of replacement aromatic hydrocarbon, optical isomers of ethyl lactate and isoamyl alcohol, etc., using CH-B-15-C-5 as a stationary phase in GC. Satisfactory results can be obtained in the column temperature range of 75–140°C, and

Table 4

Comparison of polarities of chromatographic columns

120	43	548	275	167
130	41	539	268	148

column temperature can be increased if using the CL-GLC method to separate substances of high boiling point.

Binary and ternary complexes of inosine

M.M. Khalil *, A.M. Radalla

Department of Chemistry, Faculty of Science, Cairo University, Beni-Suef Branch, Beni-Suef, Egypt

Received 14 May 1997; received in revised form 29 July 1997; accepted 30 July 1997

Abstract

Formation of binary and ternary complexes of Cu(II) and Ni(II) metal ions with inosine as a primary ligand and some biologically important aliphatic and aromatic carboxylic acids (succinic, oxalic, malic, maleic, malonic, tartaric, 5-sulfosalicylic, salicylic and phthalic acids) as secondary ligands was studied by the potentiometric technique at 25°C and 0.10 M (NaNO₃) ionic strength. The ternary complex formation was found to take place in a stepwise manner. The stability constants of these binary and ternary systems were calculated. The lower stability of 1:2 complexes of inosine compared to the corresponding 1:1 systems is in accord with statistical considerations. The values of $\Delta \log K$ for the ternary complexes studied have been evaluated and discussed. The mode of chelation of ternary complexes was ascertained by conductivity measurements. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Binary and ternary complexes; Inosine; Potentiometric and conductometric studies

1. Introduction

Interaction of nucleosides and nucleotides with metal ions has been a subject of much recent interest. Because of the role of bivalent metal ions in many biochemical processes [1–7], considerable research is being undertaken to understand the nature of metal ion interaction with vital molecules like DNA and RNA. Ternary complexes of nucleosides and nucleotides have attracted the attention of many workers [8–21]. This is mainly because they provide models for metalloenzyme reactions in biological systems [22–24]. They also explain to some extent the specific and selective interactions that take place

in many biological systems. As a continuation of our research program to study the binary and ternary complexes of biological importance [25–28], the present work traces the formation and characterization of binary and ternary complexes involving Cu(II) and Ni(II) metal ions, inosine and some biologically important aliphatic and aromatic carboxylic acids.

2. Experimental

2.1. Materials and solutions

Chromatographically pure inosine was purchased from Sigma. A fresh sample was weighed and a solution was prepared for each titration to

* Corresponding author. Fax +20 823 14606.

exclude loss by hydrolysis or photochemical decomposition. The metal salts were provided by BDH as nitrates. All solutions of Cu(II) and Ni(II) metal ions were prepared and standardized complexometrically by EDTA using suitable indicators [29]. Carbonate-free sodium hydroxide (titrant, prepared in 0.1 M NaNO₃ solution) was standardized potentiometrically with KH-phthalate solution (Merck AG). Aliphatic and aromatic carboxylic acids, nitric acid and sodium hydroxide were from Merck p.a.

2.2. Apparatus

Potentiometric pH measurements were carried out on solutions in a double-walled glass vessel at 25 ± 0.1°C using a Griffin pH J-300-101G digital pH meter. The temperature was controlled by circulating water through the jacket, from a constant temperature bath. The cell was equipped with a magnetic stirrer and a tightly fitting rubber stopper, through which an Amel 882 delivery dispenser, readable to 1 µl, and electrode system were inserted. The electrode system was calibrated in terms of hydrogen-ion concentrations instead of activities. Thus, all constants determined in this work are concentration constants.

Conductance of solutions was measured with a SUNTEX, conductivity meter SC-170.

2.3. Procedure and measuring techniques

The following solutions were prepared and titrated potentiometrically against standard carbonate-free NaOH (0.10 M) solution:

1. (a) 0.032 M HNO₃ (5 cm³) + 0.50 M NaNO₃ (10 cm³)
2. (b) (a) + 0.01 M carboxylic acid (5 cm³)
3. (c) (b) + 0.01 M metal ion (2 cm³)
4. (d) (a) + 0.01 M inosine (5 cm³)
5. (e) (d) + 0.01 M metal ion (2 cm³)
6. (f) (a) + 0.01 M metal ion (5 cm³) + 0.01 M carboxylic acid (5 cm³) + 0.01 M inosine (5 cm³)

The total volume was adjusted to 50 cm³ by adding double-distilled water in each case. All pH-metric titrations were performed at 25°C and µ = 0.1 M (NaNO₃). An Irving and Rossotti pH

Table 1

Stability constants of 1:1 and 1:2 metal–inosine complexes and Δ log K values for these systems at 25 ± 0.1°C, µ = 0.1 M (NaNO₃)^a

Metal ion	log K _{ML} ^M	log K _{ML₂} ^{ML}	Δ log K
Cu(II)	5.00 ± 0.06	3.64 ± 0.05	−1.36
Ni(II)	4.40 ± 0.08	3.92 ± 0.05	−0.48

^aFor inosine: pK_a = 8.65 ± 0.09.

titration technique [30] with modifications [31,32] was used to determine the protonation constants of the ligands and formation constants of the metal complexes. Multiple titrations have been performed for each system. All our calculations of stability constants have been determined successfully in the low pH region. Therefore, the formation of hydroxy complexes or mixed ligand complexes with hydroxy groups could be neglected.

The mixture (g) was titrated conductometrically against 0.10 M NaOH solution: g, 0.01 M Cu^{II} (10 cm³) + 0.01 M salicylic acid (10 cm³) + 0.01 M inosine (10 cm³).

3. Results and discussion

The dissociation constant of cationic inosine, H₃L⁺, could not be calculated potentiometrically, because of the highly acidic nature of the associated proton (pK_a = 1.2) [33]. The first proton association constant of neutral inosine, H₂L, was determined potentiometrically in aqueous solutions, under the experimental conditions (t = 25°C, µ = 0.1 M NaNO₃). Proton ionization was assigned to the N₁H group with the oxygen at the 6 position assuming the negative charge. The value obtained (8.65) agreed quite well with that previously reported by Simpson using the spectrophotometric technique [33]. The second dissociation of the proton from the ribose OH group of inosine takes place at higher buffer region (pH > 12) and hence the corresponding dissociation constant could not be calculated by this method.

The proton-dissociation step involved in the titration of inosine can be represented as follows:

R = Ribose

The equilibria involved in the formation of 1:1 and 1:2 metal–inosine binary complexes may be represented as follows:

The stability constants of 1:1 and 1:2 binary complexes of inosine with Cu(II) and Ni(II) metal ions have been determined (Table 1). The constant determined by us for Cu (inosine) 1:1 complex agrees well with that given previously by Albert [34]. However, our stability constant for the Ni (inosine) 1:1 complex is somewhat higher than the value given by the same author. It was also found that the stability constants determined in this work for normal 1:1 metal complexes of inosine are higher than those determined recently by Reddy and Reddy

[21]. The disagreement found may be attributed to the different methods, temperature and ionic strength used for determination.

It is of great interest to compare the stability constants of 1:1 metal–inosine complexes with those of hypoxanthine species [34]. Both hypoxanthine and inosine (purine and its corresponding nucleoside, respectively) form metal complexes with the same binding site (N₇ of the imidazole moiety). The weak basicity of inosine is reflected in the lower stability of its metal complexes than that of hypoxanthine.

The stability constants of the 1:2 metal–inosine complexes are lower than those of the corresponding 1:1 systems, as expected from statistical considerations. The $\Delta \log K$ ($\log K_{ML_2}^{ML} - \log K_{ML}^M$) values for the inosine complexes are negative (Table 1). This is the

Table 2

Acidity constants of carboxylic acids and stability constants of their 1:1 and 1:2 binary complexes at $25 \pm 0.1^\circ\text{C}$, $\mu = 0.1 \text{ M}$ (NaNO_3)

Fig. 1. Potentiometric titration curves for the Cu^{II} -5-sulfosalicylic acid-inosine system.

normal trend in neutral ligands where the enthalpy is more favourable for a 1:1 species (exothermic) as compared to a 1:2 species.

The acidity constants of carboxylic acids and the stability constants of their $\text{Cu}(\text{II})$ and $\text{Ni}(\text{II})$ complexes have been determined (Table 2) under the same experimental conditions.

The stability constants of binary $\text{Cu}(\text{II})$ complexes with the ligands studied are found to be higher than those of $\text{Ni}(\text{II})$ complexes (Tables 1 and 2), which is in accordance with Irving-William's order [36].

In Figs. 1–6, representative sets of experimental titration curves obtained according to the sequence described in the experimental part for the

different mixed-ligand systems are displaced. The formation of a ternary complex is ascertained by comparison of the mixed-ligand titration curve with the composite curve obtained by graphical addition of the inosine titration data to that of the (1:1) M^{II} -carboxylic acid titration curve. The Ni^{II} -salicylic acid-inosine system is taken as representative, as shown in Fig. 7. The mixed-ligand system was found to deviate considerably from the resultant composite curve indicating the formation of a ternary complex.

Therefore, it is assumed that in the presence of both ligands, the carboxylic acid is ligated to the metal ion, then followed by ligation of inosine, i.e. the ternary complex formation could be considered in stepwise equilibria (Eqs. (3) and (4)):

Fig. 2. Potentiometric titration curves for the Cu^{II} -succinic acid-inosine system.

Fig. 3. Potentiometric titration curves for the Cu^{II} -oxalic acid-inosine system.

$$K_{\text{MAL}}^{\text{MA}} = \frac{[\text{MAL}]}{[\text{MA}][\text{L}]} \quad (5)$$

The overall stability constant $\beta_{\text{MAL}}^{\text{M}}$ may be represented by Eq. (6):

$$\begin{aligned} \beta_{\text{MAL}}^{\text{M}} &= \frac{[\text{MAL}]}{[\text{M}][\text{A}][\text{L}]} \\ &= K_{\text{MAL}}^{\text{MA}} \times K_{\text{MA}}^{\text{M}} \end{aligned} \quad (7)$$

where A = carboxylic acid and L = neutral ligand inosine.

The relative stability of the ternary complexes,

as compared to that of the corresponding binary complexes, can be quantitatively expressed in different ways. A review of those methods [37] has shown that, for a variety of reasons, the most suitable comparison is in terms of $\Delta \log K$. Table 3 demonstrates the difference in stabilities of the binary and ternary complexes in terms of $\Delta \log K$ as defined by Eq. (8)

$$\Delta \log K = \log K_{\text{MAL}}^{\text{MA}} - \log K_{\text{ML}}^{\text{M}} \quad (8)$$

In the ternary systems studied, the values of $K_{\text{MAL}}^{\text{MA}}$ were found to lie in the sequence: phthalic > salicylic > 5-sulfosalicylic > succinic > malic > malonic > maleic > tartaric > oxalic acid.

Fig. 4. Potentiometric titration curves for the Ni^{II} -salicylic acid-inosine system.

Fig. 5. Potentiometric titration curves for the Ni^{II} -malic acid-inosine system.

The higher stability of phthalic acid complex than salicylic acid may be explained [38] as follows: since the carboxylate oxygen is not directly bound to the benzene nucleus, it therefore adjusts stereochemically more easily than the phenolate oxygen which is directly attached to the benzene nucleus. The coulombic repulsion between the end oxygens will be more when both O,O donor atoms are phenolic oxygens than when they are carboxylic oxygens. Thus the $\Delta \log K$ should be higher when the ligand coordinates through the two carboxylate oxygens (phthalic acid) than when it is salicylic acid, which contains one carboxylate and one phenolate oxygen.

The relative stabilities of the ternary complexes of salicylic acid and 5-sulfosalicylic acid follow their relative basicities.

With respect to aliphatic acids, the order of stabilities of their mixed-ligand complexes is in accord with the basicities ($\text{p}K_{\text{a}} + \text{p}K_{2\text{a}}$) of the ligands. It is well known that the increase in basicity of a ligand increases the stability of its metal complexes.

The higher values of $\Delta \log K$ with aromatic acids than aliphatic acids may be attributed to the presence of an aromatic ring [39,40] which alters the bonding properties of these carboxylic acids.

Fig. 6. Potentiometric titration curves for the Ni^{II} -phthalic acid-inosine system.

Fig. 7. Ni^{II}-salicylic acid-inosine system. (1) HNO₃; (2) Inosine; (3) Ni^{II}-salicylic acid (1:1); (4) Ni^{II}-salicylic acid-inosine; (5) Composite curve.

Another parameter, percent Relative Stabilisation (% R.S.) to quantify the stability of a ternary complex may be defined [41] as

$$\% \text{ R.S.} = [(\log K_{\text{MAL}}^{\text{MA}} - \log K_{\text{ML}}^{\text{M}}) / \log K_{\text{ML}}^{\text{M}}] \times 100$$

The values of % R.S. have been calculated (Table 3).

For some systems, the parameter % R.S. is negative. This may be attributed to the higher stability of binary M^{II}-inosine complexes than those corresponding to the ternary systems involving carboxylic acids. Negative values of % R.S. agree with the $\Delta \log K_{\text{M}}$ values, as shown in columns 6 and 7 in Table 3.

In Fig. 8, a representative conductometric titration curve for the ternary complex of copper(II) with salicylic acid and inosine is displaced. The titration curve shows an initial decrease and an inflection at $a = 2$. This probably corresponds to the neutralization of H⁺ ions resulting from the formation of the Cu(II)-salicylic acid binary complex.

Between $2 < a < 3$, the conductance increases slightly due to the formation of the ternary complex and is associated with the release of a proton from inosine. Beyond $a = 3$, the conductance increases more uniformly due to the presence of an excess of NaOH.

Evidence for the structure of isolated solid ternary complexes needs further study (e.g. X-ray crystal structure determination), which must be considered in the future.

Abstract

The reaction between hexacyanomanganate(IV) and hydrogen peroxide in acidic medium is strongly catalysed by vanadium. The stoichiometry has been proved to be $\Delta[\text{Mn(IV)}]/\Delta[\text{H}_2\text{O}_2] = 1$. S-shaped absorbance–time curves are obtained for a wide range of conditions, which seems to be due to the transient formation of hydroperoxyl radicals, $\text{HO}_2\cdot$; therefore, the reaction is autoinduced. The reaction kinetics is first order on the hexacyanomanganate(IV) concentration. Complex dependence of the initial rate on the H_2O_2 as well as H^+ concentrations are observed both for the uncatalysed and for the catalysed reactions, but the rate laws are given and reaction mechanisms are proposed. The catalytic effect of vanadium has been used to determine traces of vanadium (the (IV) and (V) oxidation states are determined together). By applying the initial rate method a detection limit of 0.9 ng ml^{-1} (18 nM), and a linear range up to 50 ng ml^{-1} were found. The relative standard deviations for the 4 and 25.5 ng ml^{-1} levels were 5.2 and 2.5% respectively. Positive kinetic interferences from Cr(VI), Hg(I) and Ag(I) have been observed; other interferences are less severe and Cr(III), Fe(II) and Fe(III), among many others, do not interfere. The Mn(IV) solution must be prepared daily and its conservation needs some care (0°C) but the proposed method has been applied to the determination of vanadium in a phosphate rock (reference material, BCR No. 32) without previous separations. Recovery experiments have also been performed; excellent results were obtained in both cases. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Hexacyanomanganate(IV); Hydrogen peroxide; Vanadium catalytic determination; Kinetics

1. Introduction

Hexacyanomanganate(IV), Mn(CN)_6^{2-} , is a relatively strong oxidizing agent. From the halfwave potential of its reversible voltammetric reduction at a rotating platinum-disk electrode, a formal

potential of about 0.85 V (vs. SCE) in acidic medium can be estimated [1]. Hexacyanomanganate(IV) cannot be easily isolated [2] but it can be yielded in acidic solution by fast disproportionation of hexacyanomanganate(III) [1,3] (Mn(II) and $(\text{CN})_2$ are also produced). The hexacyanomanganate(IV) solution is not stable and it slowly decomposes to yield Mn(II) , $(\text{CN})_2$ and HCN [3], but the reaction is fairly slow at room

* Corresponding author. Fax: +34 43 212236; e-mail: qa-pubsec@sq.ehu.es

temperature and it can be used for oxidizing purposes for a period of time. For instance, hexacyanomanganate(IV) has been used, in the reaction $\text{Mn}(\text{CN})_6^{2-}$ –As(III) [4], as the indicator reagent for the kinetic determination of iodide [5]. We observed that the hydrogen peroxide oxidation by hexacyanomanganate(IV) is slow and it is strongly catalysed by vanadium. This could well be the basis of a catalytic method for the determination of vanadium.

Vanadium has a well-known industrial relevance (steels, pigments, inks, paints, etc.) [6] or; it is also important in biochemistry as it seems to be an essential element [7]. It can also be considered a path finder for original type of crude oil [8], for uranium deposits [9] or for human industrial activities (in waters, air, soils, etc.). Methods for the determination of vanadium were reviewed some years ago [10]. In the following years the number of publications dealing with the determination of vanadium has continually grown and a new review has appeared [11]. Catalytic methods for vanadium are among those with high sensitivities and low detection limits (the counterpart is the need for time measurements) and they usually include reactions in which vanadium catalyses organic substrate oxidations by bromate, chlorate or peroxydisulphate [12]. In the last few years more papers dealing with the catalytic determination of vanadium have appeared [13,14] and most of them have been applied to the determination of vanadium in steels [15–18], petroleum products [18–20], water [16,21–26], aerosols [27,28] and atmospheric particulate matter and human serum [29]. These methods usually have limits of detection at the parts per billion (ppb) level. The initial rate method is frequently used.

On the other hand, the reactions between manganese in high oxidation states and species such as O_2 , O_2^- and H_2O_2 seem to have a great importance in biological processes, though not much is known about them [30]. These kinds of reactions have a number of interesting features. For instance the Mn(III)– H_2O_2 reaction has been found to be autocatalytic [31] and the MnO_4^- – H_2O_2 reaction has been found to be oscillatory [32]. This behaviour is not strange in oxidations by permanganate ion. The MnO_4^- –mandelic acid re-

action [33] and the MnO_4^- – N_2H_4 reaction [34] are autocatalytic and the MnO_4^- – $\text{C}_2\text{O}_4^{2-}$ reaction is autocatalytic in closed (batch) conditions [35] and bistable in open (flow) conditions [36]. Owing to these characteristics all these reactions could serve, at least theoretically, as the basis of chemical oscillators [37], but this would need detailed kinetics and mechanistic information. We thought that the title reaction might have common aspects with some of the aforementioned reactions. Hence we decided to study the kinetics of the $\text{Mn}(\text{CN})_6^{2-}$ – H_2O_2 reaction.

Modern approaches to kinetic determinations include the use of multivariate calibration methods. The most used algorithm is probably partial least squares calibration (PLSR) [38,39] but some others such as principal components regression (PCR) and artificial neural networks (ANN) [40,41] have also been used. These methods are finding increasing use in analytical work because they do not need previous knowledge of the kinetic model, rate constants, etc. Some of them can be applied not only to linear but also to non-linear systems. They have been applied specially in the simultaneous determination of multiple components of interest and a review on the subject has recently appeared [42]. Though PLSR has begun to be used for individual kinetic determinations [43], the interest for the study of the reaction kinetics has driven us to use the classical approach.

The present work has clearly two different aims: to study some interesting kinetic aspects of the indicator reaction hexacyanomanganate(IV)–hydrogen peroxide and to develop a method for the catalytic determination of vanadium.

2. Experimental

2.1. Reagents

All chemicals were of analytical-reagent grade and doubly-distilled water was used throughout. Potassium hexacyanomanganate(III) was prepared according to the method of Lower and Fernelius [44]. Spectrophotometric assays by the methods previously reported [45] indicated a con-

tent of at least 95%. The solid is indefinitely stable if kept in the dark.

Hexacyanomanganate(IV) solution (2.7×10^{-3} M) was prepared by dissolving 0.0443 g of $\text{K}_3\text{Mn}(\text{CN})_6$ (whenever $\text{K}_3\text{Mn}(\text{CN})_6$ is taken into acidic solution HCN is produced, so care should be taken) in a dark 25 ml standard flask containing 1 g of sodium perchlorate and some 0.1 M perchloric acid previously cooled to 0°C (probably owing to kinetic effects the sodium perchlorate prevents precipitation of manganese(IV) oxide by hydrolysis and lowers the freezing point of the solution). The solution is diluted to volume with 0.1 M perchloric acid. Before use the solution must be kept at $\approx 0^\circ\text{C}$ for about 1 h to allow the Mn(III) disproportionation to proceed to completion. The Mn(IV) solution thus obtained can be used for a period of 6–8 h if kept at $\approx 0^\circ\text{C}$. Other solutions with different Mn(IV) concentrations were obtained by the same procedure if required.

Hydrogen peroxide (30%), perchloric acid (70%) and solid sodium perchlorate (Fluka all of them) were used as received. Hydrogen peroxide was assayed from time to time with permanganate [46] and its content was always according to specifications. Perchloric acid was standardized with Na_2CO_3 (methyl red as indicator). A 10^{-2} M vanadium(V) solution was prepared by dissolving 0.610 g of NaVO_3 (Merck) in 500 ml of water; it was standardized with ferrous sulphate solution [47] and stored in a polyethylene bottle in the refrigerator.

2.2. Apparatus

A Shimadzu UV-260 spectrophotometer with 1 cm path-length fused-silica cells, and constant-temperature cell-holders was used. The temperature in the cells was continuously monitored by means of a small Pt 100 temperature probe, installed just before the water entrance in the cell-holder, and kept constant ($\pm 0.2^\circ\text{C}$) by circulating water from a Haake F3 K thermostat controlled by the probe. A microcomputer HP Vectra ES/12, coupled to the spectrophotometer, controlled it, acquired the data and allowed to process them through laboratory written programs.

Volumes less than 1 ml were added with micropipettes (Eppendorf or Brand).

2.3. Procedures

2.3.1. Stoichiometry measurements

When $\text{Mn}(\text{CN})_6^{2-}$ was in excess the following spectrophotometric procedure was used. In a 10 ml standard flask, 2.76 g of $\text{NaClO}_4 \cdot \text{H}_2\text{O}$ (ionic strength control), 0.4 ml of 2.5 M HClO_4 and a measured amount of H_2O_2 were added; the volume was finally adjusted to 10 ml with water. A 2.5 ml portion was accurately measured into a thermostated cuvette of the spectrophotometer and the thermal equilibrium was allowed to be reached (5–10 min). Then $100 \mu\text{l}$ of 2.7×10^{-4} M V(V) as catalyst and $100 \mu\text{l}$ of $\text{Mn}(\text{CN})_6^{2-}$ of the required concentration were added. The cell was shaken (zero time) and the reaction was followed at 387 nm (where the $\text{Mn}(\text{CN})_6^{2-}$ species shows an absorption maximum [45]), with water as reference. The remaining Mn(IV) was determined by extrapolating to zero time the final straight line of the $\ln A$ vs. time plot ($A_\infty = 0$) (a linear regression program was used). The method is similar to the logarithmic extrapolation method for the resolution of mixtures by differential reaction rate methods [48]. Each run was repeated once and the final result was the mean of the two runs.

Under conditions where an excess of H_2O_2 was present the stoichiometry was determined by the following titrimetric procedure. In a 50 ml standard flask, 19 g of $\text{NaClO}_4 \cdot \text{H}_2\text{O}$ (ionic strength control), 2 ml of 2.5 M HClO_4 and a measured amount of H_2O_2 were added; the volume was adjusted to 50 ml with water. To a 10 ml aliquot, 0.15 ml of 10^{-3} M V(V), as catalyst, and 5 ml of $\text{Mn}(\text{CN})_6^{2-}$ of the required concentration were added. After the reaction had proceeded to completion (and no colour was detected) 5 ml of 2.5 M H_2SO_4 were added and the remaining peroxide was determined by titration with 0.02 M KMnO_4 standard solution. In all cases the result was the mean of three replicates.

2.3.2. Kinetic measurements

A 2.5 ml volume of a solution containing the required amounts of H_2O_2 , $\text{NaClO}_4 \cdot \text{H}_2\text{O}$ (ionic

strength control) and HClO_4 were placed in a 1 cm cuvette. After the thermal equilibrium was reached 100 μl of a vanadium solution and, finally, 100 μl of a $\text{Mn}(\text{CN})_6^{2-}$ solution were added. The cell was shaken (zero time) and the absorbance–time data (387 nm) were obtained at least for three half-lives. The initial rate was determined by using the first straight part of the run (usually the 3–5% of the reaction) and linear regression analysis was applied. The temperature was varied between 15 and 45°C, the ionic strength between 0.1 and 3, the acidity between 0.001 and 2 M, the added Mn(II) concentration between 0 and 0.05 M, the H_2O_2 concentration between 0 and 0.2 M, the initial $\text{Mn}(\text{CN})_6^{2-}$ concentration between 0.25×10^{-4} and 2.25×10^{-4} M and the vanadium concentration between 0 and 10^{-6} M. With the exception of the variable studied the initial conditions were: $\text{Mn}(\text{CN})_6^{2-}$, 2×10^{-4} M; H_2O_2 , 0.1 M; H^+ , 0.1 M; T, 25°C; μ , 2 and V(V), 5×10^{-7} M (only for the catalysed reaction). Each kinetic run was usually repeated once, with the replicate measurement agreeing to within $\pm 5\%$ for 95% of the cases, and the initial rate was taken as the mean of the two runs.

2.3.3. Vanadium determination

In a 25 ml standard flask, 11.5 g of $\text{NaClO}_4 \cdot \text{H}_2\text{O}$, 1.7 ml of 2.5 M HClO_4 and 1 ml of 30% H_2O_2 are added. The solution is taken to volume with water. A 1.5 ml portion is accurately measured into the cuvette and left to stand for 10 min in the controlled temperature cell-holder of the spectrophotometer. One millilitre of the sample solution ($\leq 0.13 \mu\text{g V}$) and 100 μl of 2.7×10^{-3} M $\text{Mn}(\text{CN})_6^{2-}$ are added carefully to avoid mixing, the lid is put on and the cell inverted two or three times (this point was taken as zero time). The absorbance is followed just enough time to determine the initial rate (less than a 5% decrease in absorbance is sufficient, and this is attained in a 10–30 s time, depending on the vanadium content). The measured initial rate is used to read the vanadium concentration from a calibration plot prepared in the same way. Each determination was repeated once and the final result was taken as the mean of the two determinations.

2.3.4. Vanadium determination in phosphate rock samples

Homogeneous and dried (2 h at 105°C) phosphate rock are accurately weighted (0.1 g), dissolved in some few ml of a HCl and HNO_3 mixture (3:1) and taken practically to dryness on a sand bath. The residue is dissolved in water and diluted to volume in a 250 ml standard flask with some more water. A 1 ml portion is treated as for determination of vanadium.

3. Results and discussion

3.1. Stoichiometry

A reaction time short enough to allow reliable data was attained with 10^{-5} M vanadium(V) as catalyst. When $\text{Mn}(\text{CN})_6^{2-}$ was in excess, a mean of 1.04 ($s = 0.04$, $n = 9$) was found for the $\Delta[\text{Mn}(\text{IV})]/\Delta[\text{H}_2\text{O}_2]$ ratio, this value being significantly higher than 1 (t -test, $P = 0.05$), probably owing to the $\text{Mn}(\text{CN})_6^{2-}$ decomposition (Fig. 1). On the other hand, when H_2O_2 was in excess this value does not differ significantly from unity. Taking into account all the results ($[\text{Mn}(\text{IV})]_0/[\text{H}_2\text{O}_2]_0$ ranging from 0.1 to 5), the stoichiometry will be 1:1; that is, $\text{Mn}(\text{CN})_6^{2-}$ acts as a two-electron oxidizing species, in the same way of some precedence [4], its reaction product being some colour-

less Mn(II) species because a flat visible spectrum is obtained in the final solution. A high evolution of bubbles indicates that oxygen is another reaction product. Therefore, the reaction can most probably be represented by the equation:

3.2. General aspects of the overall reaction kinetics

Ultraviolet light decomposes hexacyanomanganate(IV) [49] but the rate of the reaction $\text{Mn(CN)}_6^{2-} - \text{H}_2\text{O}_2$ was photochemically insensitive at light levels present in the spectrophotometer, since the reaction proceeded to the same extent both in the spectrophotometric cell and in the dark.

The $\text{Mn(CN)}_6^{2-} - \text{H}_2\text{O}_2$ reaction displays kinetic curves that under certain conditions exhibit S-shaped profiles (Fig. 2A). Consequently, tests on the kinetic behaviour show that first-order plots are not linear, but they show in all cases a (negative) continuously increasing slope (Fig. 2B). However, the initial slope of these plots seems to be independent of the Mn(CN)_6^{2-} concentration. This kind of behaviour seems to indicate that, after first-order kinetics in the early stages of the reaction, an autoacceleration effect takes place, perhaps due to an autocatalytic or chain process. The well-known permanganate–hydrogen peroxide and permanganate–oxalate reactions [35,50] are autocatalytic, the Mn(II) species produced being responsible for the catalysis. It could be thought that the $\text{Mn(CN)}_6^{2-} - \text{H}_2\text{O}_2$ reaction behaves in a similar way. In order to test this possibility a series of five runs was made by adding successively new amounts of Mn(CN)_6^{2-} to the reaction mixture once the reaction had gone to completion. The successive curves obtained practically reproduced the first kinetic run. This indicates that the accumulated Mn(II) does not exert any significant effect on the kinetics, at least at the concentration levels produced in the reaction mixture. Nevertheless, when a Mn(II) salt is initially added in a great excess (10^{-3} M or higher) the reaction is faster but the shape of the

Fig. 2. (A), typical kinetic runs and (B), pseudo-first order plots. $[\text{Mn(IV)}]_0$, 2×10^{-4} M; $[\text{H}^+]$, 0.1 M; T, 25°C; μ , 2; λ , 387 nm; $[\text{H}_2\text{O}_2]$, (1) 0, (2)–(5) 0.1 M; $[\text{Mn(II)}]_{\text{added}}$, (1) (2) (4) (5) 0, (3) 10^{-3} M; $[\text{V(V)}]$, (1)–(3) 0, (4) 2×10^{-7} M, (5) 5×10^{-7} M.

reaction profile does not change (Fig. 2A, curve 3). That is to say, Mn(II) added at high concentrations actually catalyses but some other species, instead of Mn(II), must be responsible for the autoacceleration effect, most probably some highly reactive intermediate. In the oxidation of H_2O_2 by either Mn(III), Ce(IV) or Co(III) compounds the hydroperoxyl radical, $\text{HO}_2\cdot$, has been proposed as an intermediate [31]. This radical is highly reactive and usually leads to chain mechanisms which are responsible for autoacceleration kinetics. The presence of the radical $\text{HO}_2\cdot$ can be detected by adding Cu^{2+} that acts as scavenger for it [51]. In the presence of Cu^{2+} the following reaction takes place at close to diffusion-controlled rates:

the Cu^+ produced will be rapidly oxidized to Cu^{2+} in the reaction mixture. The effect of Cu^{2+}

on the $\text{Mn}(\text{CN})_6^{2-} - \text{H}_2\text{O}_2$ reaction was tested and the results are illustrated in Fig. 3. In the presence of Cu^{2+} at concentrations higher than 10^{-4} M the autoaccelerating effect significantly diminishes and the reaction kinetics approaches to the kinetic curve in the absence of H_2O_2 (Fig. 3, curve 1) (concentrations of Cu^{2+} higher than 5×10^{-3} M could not be used since it precipitates with $\text{Mn}(\text{CN})_6^{2-}$). Therefore, it can be concluded that the hydroperoxyl radical, $\text{HO}_2\cdot$, is an intermediate in the H_2O_2 oxidation by $\text{Mn}(\text{CN})_6^{2-}$ and it is the responsible species for the autoacceleration. Since $\text{HO}_2\cdot$ does not remain as a reaction product but it has a transient nature, the autoacceleration process should not be properly termed autocatalysis. A chain mechanism (autoinduction) could probably explain the observed results better. It should be here emphasized that the initial rate is not affected by Cu^{2+} because it only influences the propagation steps (Fig. 3).

Attempts to fit the entire absorbance–time curves to the usual kinetic models for autocatalytic reactions [52,53] were unsuccessful. The methods of Guggenheim and Kezdy-Swinbourne [54], for cases in which a slow secondary reaction sets in, were also unsatisfactory. Therefore, only the kinetics of the early stages of the reaction (before the autoacceleration effect becomes appreciable) has been quantitatively studied. Initial rate measurements were made.

3.3. Effect of variables on the initial rate

Plots of the initial rate vs. the $\text{Mn}(\text{CN})_6^{2-}$ initial concentration are linear both in the absence and in the presence of vanadium(V) as catalyst. This means that the reaction shows a first order dependence on the hexacyanomanganate(IV) concentration in the initial stages; afterwards, the pseudo-first order is disrupted by the autoinduced process.

The initial rate increases with the vanadium(V) concentration (Fig. 2, curves 2,4,5) according to a linear dependence. When vanadium(IV) was added instead, exactly the same results were obtained. This could be due to the oxidation of V(IV) by Mn(IV); in fact a standard potential of about 1.09 V (vs. HNE) can be estimated for the $\text{Mn}(\text{CN})_6^{2-}/\text{Mn}(\text{CN})_6^{3-}$ couple from the reversible halfwave potential in acidic medium [1]; this is a somewhat higher value than 1 V, the standard potential of the $\text{VO}_2^+/\text{VO}^{2+}$ couple in acidic medium [55], so that the $\text{Mn}(\text{CN})_6^{2-} - \text{V}(\text{IV})$ reaction is thermodynamically favourable in this medium. The responsibility for the catalytic path should actually be some V(V)/V(IV) cycle through which the electron transfer from H_2O_2 to $\text{Mn}(\text{CN})_6^{2-}$ takes place in an easier way. On the other hand, the catalytic activity of vanadium has been found to be lowered through time if it is previously mixed with the hydrogen peroxide solution, so some vanadium–hydrogen peroxide interaction appears to be produced. Most probably slow formation of vanadium(V) peroxocomplexes with a lower, if any, catalytic activity is involved [56]. This is the reason why hydrogen peroxide and vanadium must be mixed just before starting the reaction (see Section 2).

As it was mentioned above, aquomanganese(II) acts also as a catalyst. A plot of the initial rate vs. $[\text{Mn}(\text{II})]_{\text{added}}$ (in the absence of vanadium) gives a straight line with positive intercept, at least in the range $10^{-3} - 10^{-1}$ M. In the presence of vanadium a parallel straight line with a higher intercept is obtained. This indicates that the catalytic effects of vanadium and manganese are independent, which suggests the existence of two parallel catalytic pathways in addition to the non-catalytic one. The non-catalytic pathway actually consists

of two reactions, the $\text{Mn}(\text{CN})_6^{2-}$ decomposition [3] and the uncatalysed reaction. According to these results, the observed initial rate, v_0 , can be satisfactorily described by the following equation

$$v_0 = -\frac{d[\text{Mn}(\text{IV})]}{dt} = k_{\text{obs}}[\text{Mn}(\text{IV})] \\ = (k_d + k_u + k_{c,\text{Mn}}[\text{Mn}(\text{II})]_{\text{added}} + k_{c,\text{V}}[\text{V}(\text{V})]) \\ [\text{Mn}(\text{IV})] \quad (3)$$

where k_{obs} , the pseudo-first-order constant, includes the decomposition reaction of $\text{Mn}(\text{IV})$ (k_d) [3], the uncatalysed reaction (k_u) and the reactions catalysed by manganese ($k_{c,\text{Mn}}[\text{Mn}(\text{II})]_{\text{added}}$) and vanadium ($k_{c,\text{V}}[\text{V}(\text{V})]$) respectively.

The value of k_d is known from previous work [3], and so k_u can be evaluated from the slope of the plot v_0 vs. $[\text{Mn}(\text{IV})]$ in the absence of catalysts. For $[\text{H}_2\text{O}_2]$, 0.1 M; $[\text{H}^+]$, 0.1 M; μ , 2 and T, 25°C; $k_{\text{obs}} = (7.6 \pm 0.4) \times 10^{-4} \text{ s}^{-1}$ ($n = 8$). In these conditions $k_d = 4.6 \times 10^{-5} \text{ s}^{-1}$, and from here:

$$k_u = (7.1 \pm 0.4) \times 10^{-4} \text{ s}^{-1} \quad (n = 8)$$

For the same conditions the value of $k_{c,\text{V}}$ can be evaluated from a plot of v_0 vs. $[\text{V}(\text{V})]$, and it was found to be:

$$k_{c,\text{V}} = (2.3 \pm 0.1) \times 10^3 \text{ s}^{-1} \text{ M}^{-1} \quad (n = 5)$$

Finally, the value of $k_{c,\text{Mn}}$ can be calculated both in the presence and in the absence of vanadium from a plot of v_0 vs. $[\text{Mn}(\text{II})]$ provided all other constants are known. In the above conditions:

$$k_{c,\text{Mn}} = (0.24 \pm 0.02) \text{ s}^{-1} \text{ M}^{-1} \quad (n = 12)$$

(all the errors are given as standard errors estimated from the regression analysis).

An increase in the concentration of H_2O_2 increases the initial rate, in the absence as well as in the presence of vanadium as shown in Fig. 4. This behaviour suggests an inner-sphere mechanism in which the charge transfer step is preceded by some $\text{Mn}(\text{IV})\text{-H}_2\text{O}_2$ interaction. A similar $\text{Mn}(\text{IV})\text{-substrate}$ interaction was proposed for the reaction $\text{Mn}(\text{CN})_6^{2-}\text{-As}(\text{III})$ [4]. Taking into account such a precedent, a similar mechanism can be proposed for the uncatalysed reaction

Fig. 4. Effect of H_2O_2 concentration. $[\text{Mn}(\text{IV})]_0$, $2 \times 10^{-4} \text{ M}$; $[\text{H}^+]$, 0.1 M; μ , 2; T, 25°C, λ , 387 nm; $[\text{V}(\text{V})]$, (1) 0, (2) $5 \times 10^{-7} \text{ M}$. The solid line curve represents the simulated dependence profile for the uncatalysed reaction.

The kinetics depends on reactions (4) and (5) because reaction (6) is fast and does not exert influence on the rate law. In the same way than for the $\text{Mn}(\text{CN})_6^{2-}\text{-As}(\text{III})$ reaction [4] the species $\text{Mn}(\text{IV})^*$ would be a very reactive intermediate and the species $\text{Mn}(\text{IV})\text{-H}_2\text{O}_2$ an adduct in which the charge transfer from H_2O_2 to $\text{Mn}(\text{IV})$ would not have completely taken place.

From the proposed mechanism, and by applying the steady-state assumption to the $\text{Mn}(\text{IV})^*$ species, the following rate law for the reaction in the absence of vanadium is derived:

$$v_0 = \left(k_d + \frac{k_1 k_2 [\text{H}_2\text{O}_2]}{k_{-1} + k_2 [\text{H}_2\text{O}_2]} \right) [\text{Mn}(\text{IV})] \quad (7)$$

Eq. (7) can take two limiting forms depending on the H_2O_2 concentration:

(i) At high $[\text{H}_2\text{O}_2]$

$$v_0 = (k_d + k_1) [\text{Mn}(\text{IV})] \quad (8)$$

(ii) At low $[\text{H}_2\text{O}_2]$

$$v_0 = \left(k_d + \frac{k_1 k_2}{k_{-1}} [\text{H}_2\text{O}_2] \right) [\text{Mn}(\text{IV})] \quad (9)$$

That is to say, a plot of $v_0/[\text{Mn(IV)}]$ vs. $[\text{H}_2\text{O}_2]$ should be straight for low $[\text{H}_2\text{O}_2]$ approaching a constant value for high $[\text{H}_2\text{O}_2]$. Fig. 4 shows such a plot; from it a value of $8 \times 10^{-4} \text{ s}^{-1}$ and $0.29 \text{ s}^{-1} \text{ M}^{-1}$ can be estimated for the limiting value of $v_0/[\text{Mn(IV)}]$ and for the initial slope respectively. Taking into account the value of k_d it results:

$$k_1 = 7 \times 10^{-4} \text{ s}^{-1}$$

and

$$k_2/k_{-1} = 3.9 \times 10^2 \text{ M}^{-1}$$

Using these values the effect of $[\text{H}_2\text{O}_2]$ can be simulated and compared with the experimental results (Fig. 4). The result obtained can be considered satisfactory. The reaction in the presence of vanadium shows a similar behaviour (Fig. 4), but the limiting value of $v_0/[\text{Mn(IV)}]$ (if it exists) has not been attained experimentally and so the rate constant values can not be calculated and the simulation is not possible.

The effect of the acidity is quite complex. When the acidity effects for the uncatalysed and the catalysed reactions are compared (Fig. 5) three pH regions can be distinguished. Only in the central region (pH from 0 to 2 approximately) the reaction rate is clearly increased by the presence of vanadium. This can be explained by considering three Mn(IV) species with different protonation grades (probably Mn(CN)_6^{2-} ,

Fig. 5. Effect of acidity. $[\text{Mn(IV)}]_0$, $2 \times 10^{-4} \text{ M}$; $[\text{H}_2\text{O}_2]$, 0.1 M ; μ , 2; T, 25°C , λ , 387 nm ; $[\text{V(V)}]$, (1) 0, (2) $5 \times 10^{-7} \text{ M}$. Solid line curves represent simulated dependence profiles.

$\text{Mn(CN)}_5(\text{CNH})^-$ and $\text{Mn(CN)}_4(\text{CNH})_2$ agreeing with previous evidence [1]). If all the three species react, three parallel pathways should be expected. However, only the reaction of the monoprotonated complex (the predominant species at pH 0–2 [1]) seems to be catalyzed by vanadium.

Considering the uncatalysed reaction, the effect of acidity was studied for $0.1 \text{ M H}_2\text{O}_2$ and so Eq. (8) can be applied; if $k_{1(0)}$, $k_{1(1)}$ and $k_{1(2)}$ are the rate constants for the three Mn(IV) species with different protonation degrees, the rate law will depend on $[\text{H}^+]$ in the following way:

$$v_0 = \left(k_d + \frac{k_{1(0)}[\text{H}^+]^2 + k_{1(1)}K_1[\text{H}^+] + k_{1(2)}K_1K_2}{[\text{H}^+]^2 + K_1[\text{H}^+] + K_1K_2} \right) [\text{Mn(IV)}] \quad (10)$$

where K_1 and K_2 are the successive dissociation constants of the diprotonated species $\text{Mn(CN)}_4(\text{CNH})_2$. A plot of $v_0/[\text{Mn(IV)}]$ vs. $-\log[\text{H}^+]$ can be seen in Fig. 5. From such a plot the following values can be roughly estimated [57]:

$k_{1(0)} = 1 \times 10^{-3} \text{ s}^{-1}$ (the value of the ordinate for $-\log[\text{H}^+]$ values low enough).

$k_{1(1)} < 6 \times 10^{-4} \text{ s}^{-1}$ (the value of the ordinate for $-\log[\text{H}^+]$ values neither too low nor too high. Because K_1 and K_2 are not distant enough, the value of this constant can only be tentative).

$k_{1(2)} = 5 \times 10^{-3} \text{ s}^{-1}$ (the value of the ordinate for $-\log[\text{H}^+]$ values high enough).

$K_1 = 0.4$ (the inflection point for $-\log[\text{H}^+]$ low values).

$K_2 = 3 \times 10^{-2}$ (the inflection point for $-\log[\text{H}^+]$ high values) and from these values Eq. (10) has been calculated and plotted in Fig. 5 (for simulation purposes a value of $k_{1(1)} = 5 \times 10^{-4} \text{ s}^{-1}$ has been tentatively used).

The rate constants for the catalysed reaction can be obtained by difference between the overall and the uncatalysed reactions. If, as it has been stated above, only the reaction of the monoprotonated species is catalysed by vanadium, the Eq. (3) will take the form:

$$v_0 = \left(k_d + k_u + \frac{k_{1(1),v}K_1[\text{H}^+]}{[\text{H}^+]^2 + K_1[\text{H}^+] + K_1K_2} [\text{V(V)}] \right) [\text{Mn(IV)}] \quad (11)$$

By using the K_1 and K_2 values previously obtained and the concentration of vanadium added (5×10^{-7} M), a value of

$$k_{1(1),V} = 3 \times 10^3 \text{ s}^{-1} \text{ M}^{-1}$$

can be estimated. The constant $k_{1(1),V}$ is similar to $k_{1(1)}$ but for the catalysed reaction. Eq. (11) has been plotted in Fig. 5. Both for the catalysed and uncatalysed reactions the agreement between experimental points and simulated dependences can be considered satisfactory, even if sometimes the simulated curves do not perfectly fit the experimental data points, pointing out the possibility of some extra complexity.

Ionic strength exerts opposite effects on the reaction kinetics in the presence and in the absence of vanadium. Thus, when ionic strength increases from 0.1 to 3 a slight increase in the initial reaction rate is produced when vanadium is present, whereas a slight decrease is produced when it is absent.

From the effect of temperature (15–45°C), on the initial reaction rates, apparent activation energies of 78 ± 2 and 62 ± 7 kJ mol⁻¹ were found for the uncatalysed and the catalysed reactions respectively ($n = 7$ in both cases).

3.4. Optimization

In any instrumental method the conditions selected should achieve the maximum signal/background ratio. In a catalytic method the signal and background values are obtained from the overall and uncatalysed reactions respectively. In our case the parameter to be optimized was the ratio of reaction rates overall/uncatalysed [58]. The effect of the variables affecting the initial rate was studied by the univariate method.

Taking into account the effect of each variable on the initial reaction rate, the following optimum conditions were chosen:

- The Mn(IV) concentration does not seem to affect the initial rates ratio. A value of 10^{-4} M [Mn(IV)] was chosen in order to get suitable initial absorbance values.
- Low Mn(II) concentrations increase the reaction rates ratio and so, no Mn(II) was initially added for vanadium determination.

- The effect of H₂O₂ on the reaction rates ratio is similar to the effect on the kinetics: for low [H₂O₂] values the rates ratio rapidly increases with [H₂O₂] and it tends to level off for values of [H₂O₂] higher than 0.2 M. A value of 0.2 M [H₂O₂] was selected.
- The reaction rates ratio has a very sharp maximum value for 0.1 M [H⁺] and so it was selected as optimum for vanadium determination.
- High ionic strengths and low temperatures increase the reaction rates ratio; because of it, values of 3 for ionic strength and 25°C were chosen as optimum.

3.5. Calibration

Owing to the reaction kinetics (autoinduction) the rate constant method (integral) cannot be used. The fixed time and the fixed concentration methods were tried but unsatisfactory (non-linear) plots resulted regardless of the time and concentration chosen. It was previously stated that the title reaction is first order on the V(V) concentration; so plots of the initial rate, v_0 , vs. [vanadium] were straight and they can be used as calibration plots.

Under the optimum conditions the calibration plot was linear up to 50 ng ml⁻¹ vanadium and the equation of the regression line was found to be:

$$\begin{aligned} v_0(\text{A.U.} \times \text{s}^{-1}) \\ = (2.4 \pm 0.1)10^{-4} + (2.80 \pm 0.05)10^{-5} \\ \times C_V(\text{ng ml}^{-1}) \quad (r = 0.9989; n = 10) \end{aligned}$$

where the errors in both the intercept and the slope are given as standard errors estimated from the regression analysis.

From the standard deviation of the background signal, the detection limit [59] was estimated to be 0.9 ng ml⁻¹ (18 nM). The relative standard deviation calculated at the 4 and 25.5 ng ml⁻¹ levels were 5.2 and 2.5% respectively (10 replicates).

Table 1
Interferences in the determination of 25 ng ml⁻¹ vanadium (5.0 × 10⁻⁷ M)

Tolerated concentrations of interferent species (M)	Mole ratio, [ion]/[V(V)]	Species
10 ⁻¹ ^a	200 000	NO ₃ ⁻ , SO ₄ ²⁻ , PO ₄ ³⁻ , acetate

3.6. Effect of foreign ions

The study of interferent ions is summarized in Table 1. A species was considered to interfere when the vanadium concentration found differed from the expected one more than twice the standard deviation at that level of concentration. Some comments may be made on the data in Table 1. The metal ions which most seriously interfere are Ag(I), Hg(I) and Cr(VI), which also seem to exert some catalytic effect. The presence of Hg(II), Ti(IV) and Mg(II) is tolerated up to 20-fold the molar concentration of vanadium. No significant effect has been observed from any other metal ions. Although Fe(II), Sn(II) and As(III) reduce hexacyanomanganate(IV) they do not interfere, even at concentrations higher than those specified, because they are previously oxidized by hydrogen peroxide in the recommended procedure. Among anions, iodate interferes at concentrations higher than 10⁻⁷ M, and at a concentration of 10⁻⁴ M it completely changes the shape of the kinetic curves; this behaviour cannot be easily explained but it could be related to the very complex iodate–hydrogen peroxide reaction, which has been studied previously [60] and can be oscillatory [61]. Other anionic species such as iodide, thiosulphate, thiocyanate, oxalate and bromide slowly reduce hexacyanomanganate(IV), whereas sulphite does it faster. Less important effects are produced by nitrite, tartrate and bromate. Chloride, fluoride, silicate and citrate only interfere at levels higher

than 10⁻² M. The presence of EDTA (> 10⁻⁴ M) significantly modifies the reaction kinetics.

3.7. Application

The proposed method has been applied to the determination of vanadium in a natural Moroccan phosphate rock (phosphorite) (certified reference material, BCR No 32) without previous separations and with excellent results. The results of the vanadium determination and the data from some recovery studies are summarized in Table 2. The mean per cent of vanadium found in the reference material was 99.7% ($s = 2\%$; $n = 10$) and the mean per cent found in the recovery studies was 101.2% ($s = 3.2\%$; $n = 12$). In both cases the mean values do not differ significantly from 100% (t -test, $P = 0.05$) and the standard deviations do not differ significantly from each other (F -test, $P = 0.05$).

4. Conclusions

The catalytic effect of vanadium on the reaction Mn(CN)₆²⁻–H₂O₂ can be used for the determination of vanadium at the ppb level. The indicator reaction seems to be a chain reaction induced by the HO₂· radical. Though the integral methods are precluded, tentative mechanisms for the effects of H₂O₂ and acidity are proposed. The initial rate

method has been used. This allows us to take the data along a short period of time if compared with other catalytic methods. Though some other catalytic methods have been reported to have lower detection limits, the proposed method is among those with low detection limits, good reproducibility and wide dynamic range. All this, together with a relatively low number of interferences has allowed the determination of vanadium in phosphate rocks without needing previous separation.

Received 3 February 1997; received in revised form 8 July 1997; accepted 1 August 1997

Abstract

As shown in this paper, multivariate calibration in general and principal component regression (PCR) in particular allow the determination of Captopril by differential pulse polarography (DPP) in the presence of oxygen despite the overlap between their polarographic bands. Electrochemical parameters (pulse amplitude, pulse delay and drop time) are optimized from response surfaces using PCR to determine the relationship between the variables to be optimized and the relative square error of prediction (RSEP), which was adopted as the parameter to be minimized. The proposed method is quite fast and inexpensive as a result of the decreased analysis times and sparing use of the inert gas. It was applied to the determination of Captopril in synthetic samples and a commercially available pharmaceutical preparation, with relative errors and confidence intervals < 2.5% and 2.0%, respectively. It should be noted that the sample can be analysed directly following dissolution in water without the need to remove the excipients. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Captopril; Polarography; Principal component regression

1. Introduction

One of the main reasons for the relatively scant use of polarography in routine analyses is the need to remove oxygen from the sample before any polarograms are recorded in order to avoid side reactions and/or overlap between the analytical signal and that for oxygen. If oxygen removal could be dispensed with, then analytical costs

would be substantially reduced and the throughput increased.

Oxygen is easily reduced at a dropping mercury electrode (DME) in two steps. In the first wave hydrogen peroxide is formed and in the second, more negative wave, the peroxide is reduced to water. In acid and neutral media, the reduction of oxygen to hydrogen peroxide is an irreversible electrode process, above pH 10, it becomes reversible. On the other hand, hydrogen peroxide is oxidized with a high overvoltage in both acid and alkaline media.

Dissolved air must usually be removed from the analytical solution in order to avoid interactions of oxygen with the target analyte or side reactions between the analyte and oxygen (or the hydrogen peroxide resulting from its reduction). Usually, air is removed by bubbling an inert gas through the solution, after which the gas stream is passed over the solution surface while the polarogram is being recorded. The time required for effective removal of the oxygen varies with the gas flow-rate, solution volume and geometry of the polarographic cell, but is usually 10–15 min. Avoiding the need to remove oxygen and hence decrease analysis times and use of inert gas is therefore a desirable objective.

This paper shows that multivariate calibration and, specifically, principal component regression (PCR), enables the differential pulse polarographic (DPP) determination of analytes whose bands are fully overlapped with that of oxygen, even if this is not removed from the solution. In order to check the method developed, Captopril, a potent antihypertensive agent used in the treatment of both renovascular and essential hypertension, was determined. This drug has so far been determined in both biological samples and pharmaceutical preparations by use of chromatographic [1], spectrofluorometric [2] and radioassay methods [3], in addition to various electrochemical techniques including cyclic voltammetry [4] and DPP [5], where Captopril gives a wave that is fully overlapped with the first wave for oxygen at the maximum sensitivity.

Developing an effective analytical method entails optimizing every single variable that influences its performance. Electrochemical methods are usually optimized by altering each variable in turn while keeping all others constant. This involves time-consuming preliminary experiments and, frequently, the obtainment of inappropriate optimal parameter values that can lead to spurious results through disregard of potential interactions between variables.

In this work, surface response methodology was used to optimize the experimental model for the determination of Captopril by DPP in the presence of oxygen.

2. Experimental

2.1. Apparatus and software

The measurements were performed with an IN-ELECSA Electrochemical System consisting of a PDC1212 Potentiostat and a CTG drop time controller, interfaced to an ACER 550 computer. A DME was used as the working electrode, an Ag/AgCl saturated electrode and a Pt electrode as reference and auxiliary electrodes, respectively.

Calculations were made at a 486DX4/AT personal computer.

PCR and optimization process were carried out with the program UNSCAMBLER, version 5.00 [6].

2.2. Solutions and reagents

200 $\mu\text{g ml}^{-1}$ solutions of Captopril was prepared from the corresponding hydrochloride (Sigma).

Analytical grade reagents were used throughout and all solutions were prepared from double-distilled water.

2.3. Procedure

Several 25-ml flasks were filled with 10 ml of 0.25 M HCl, an appropriate volume of Captopril solution and double-distilled water to the mark. The solutions were then used to record differential pulse polarograms. The Captopril concentrations in these synthetic samples were obtained from polarograms recorded at 3 mV intervals over the range -73 to -130 mV, using a pulse amplitude of -50 mV, a pulse delay of 20 ms and a drop time of 3 s. The drug concentration was calculated by applying PCR to the data obtained from -82 to -121 mV, using a single principal component (PC).

For the determination of Captopril in pharmaceutical formulations, 10 tablets were placed in a 250-ml flask, made to volume with double-distilled water and ultrasonicated for 3 min. An aliquot of 0.2 ml of the resulting solution was transferred into a 25-ml flask that was then filled with 10 ml of 0.25 M HCl and made to the mark

with double-distilled water. This solution was used to record a differential pulse polarogram under the same conditions as for the synthetic samples and the polarogram was processed as described in the previous paragraph.

3. Results and discussion

Below pH 3, Captopril [(2S)-1-(3-Mercapto-2-methyl-propionyl)-L-proline] exhibits a single, anodic polarographic peak resulting from the reaction of its thiol group with the mercury electrode according to the following, well-known scheme for the thiol function:

The peak is diffusion-controlled and its current is linearly dependent on the concentration over a wide range of the latter. Above pH 3, a new peak (specifically, an adsorption pre-peak) appears that is related to the COOH group of Captopril (pK_a 3.52 and 2.86 for the *trans* and *cis* forms, respectively).

Fig. 1 shows the DPP obtained for a solution containing $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl, with bubbling of argon for a variable time. As can be seen, in the absence of bubbling, a peak at -25 mV

due to dissolved oxygen and a small shoulder due to Captopril and fully overlapped with the previous one were obtained. As bubbling was extended and oxygen gradually removed as a result, the Captopril wave became increasingly more defined.

The reduction of oxygen at -25 mV involves the formation of hydrogen peroxide, which can also react with Captopril, thereby reducing its concentration and diminishing its wave. In order to confirm this assumption, two solutions containing the same Captopril concentration in 0.1 M HCl but H_2O_2 concentrations differing by a factor of 10 were prepared. After 10 min, both solutions were deoxygenated by bubbling argon through them and their polarograms recorded. A comparison of the waves obtained confirmed that the presence of hydrogen peroxide had no effect on the Captopril wave.

3.1. Influence of electrochemical variables

The effect of the different electrochemical variables potentially affecting the DPP for Captopril (viz. pulse amplitude, pulse delay and drop time) was studied. For this purpose, a non-deoxygenated $10 \mu\text{g ml}^{-1}$ solution of Captopril was used to record polarograms at variable values of one parameter and constant values of the other two. Fig. 2a illustrates the influence of pulse amplitude between -90 and -10 mV . As can be seen, the less negative pulse amplitude produce a decrease of the background current and the peak is shifted to more negative potentials and noise increased. In addition, the less negative pulse amplitudes increased the definition of the Captopril shoulder as a result of the distance between the maxima for oxygen and the drug being increased. This is more clearly reflected in the contour map (Fig. 2b): line B (Captopril maximum) departs from line A (oxygen maximum) as the pulse amplitude becomes less negative. Therefore, the condition of maximum signal (-90 mV) coincide with maximum overlap between the oxygen and Captopril peaks and minimum overlap (-10 mV) coincides with maximum noise and band broadening and minimum signal. A compromise must thus be made for optimal performance.

Fig. 1. Influence of the gas bubbling time on the DPP for a solution containing $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl. Pulse amplitude, -40 mV ; pulse delay, 40 ms; drop time, 3 s.

Fig. 2. (a) Effect of pulse amplitude on the DPP for a solution containing $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl (pulse delay, 20 ms; drop time, 3 s). (b) Contour map.

On the other hand, changes in pulse delay only affected the peak height, as can be expected and decreasing the delay (Fig. 3) increased the signal, with no change in the background current. Finally, increasing the drop time increased the signal as a result of the increased electrode area (Fig. 4).

3.2. Response surface

Faced with the difficulty of choosing the most appropriate pulse amplitude, pulse delay and drop time, we used response surface methodology, which comprises various mathematical and statistical techniques of assistance in modelling and analysing problems where the response of interest is influenced by several variables simultaneously.

Fig. 3. Effect of pulse delay on the DPP for a solution containing $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl (pulse amplitude, -50 mV ; drop time, 3 s).

Fig. 4. Effect of drop time on the DPP for a solution containing $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl (pulse amplitude, -50 mV ; pulse delay, 20 ms).

The relation between the response and the independent variables is unknown in most cases, so the first step in the process involves an approximation to the actual relation between the response and the set of independent variables. As a rule, such a relation is approximated via polynomial functions. In this work, we used PCR to construct the surface response.

The first problem encountered was determining which variable or quantity should be used as the response. While most available methods for this purpose seek to maximize the signal, these conditions (a large pulse amplitude) were previously found to result in maximum overlap between the oxygen and Captopril bands and because the final goal was the quantitative determination of Captopril, the most appropriate response variable was thought to be that allowing the calibration and prediction errors to be quantified. To this end, the relative standard error (RSE) [7] defined as

$$\text{RSE} = 100 \times \sqrt{\frac{\sum (c_{\text{found}} - c_{\text{added}})^2}{\sum (c_{\text{added}})^2}}$$

was chosen, which is known as RSEC or relative square error of prediction (RSEP) according to that the concentration values are referred to the calibration or prediction process.

Variables were optimized by using the programme Unscrambler [6,9] and a Box Behnen factor design [8] at three levels (using middle points instead of corner points), with the following high and low values: pulse amplitude, -30 to -60 mV; pulse delay, 20–50 ms; drop time, 2–4 s.

The program constructs an optimization matrix from 15 experiments where, in addition to the variables to be optimized (A pulse amplitude, B pulse delay and C drop time), interaction effects (AA , BB , CC , AB , AC and BC) are included. In order to obtain RSEC and RSEP, a calibration set consisting of four solutions containing 3, 7, 12 and $16 \mu\text{g ml}^{-1}$ Captopril in 0.1 M HCl and a prediction set comprising three solutions containing 5, 9.5 and $14 \mu\text{g ml}^{-1}$ Captopril, also in 0.1 M HCl, were prepared and their differential pulse polarograms recorded from -65 to -145 mV

under each of the 15 different conditions. The calibration set was subjected to PCR [9] under each condition considered, using a single PC because the variance of the concentration matrix accounted for in the validation (cross-validation) process always exceeded 97%. As the Captopril peak changed with pulse amplitude, various intervals (-95 to -135 , -85 to -125 and -75 to -115 mV) were used at the pulse amplitudes -30 , -45 and -60 mV, respectively. After the models were constructed, the calibration and prediction sets were predicted and RSEC and RSEP, respectively, calculated.

The next step involved finding the models that relate the obtained values of RSE and the variables (A , B , C , AA , BB , CC , AB , AC and BC) using PCR. The established models were checked in order to find the possible existence of non-significant effects. So, for this purpose, a normal probability plot of effect and values of the estimated effects was made. Finally, the models were recalculated by giving a zero weight to those variables subject to no significant effects. In this way, models with normally distributed residuals (and hence correct fitting between the variables to be optimized and RSEC or RSEP) were obtained.

Fig. 5a shows the response surface (RSEC) obtained at the intermediate drop time tested (3 s), which was that resulting in the lowest RSEC. As can be seen, RSEC decreased with decreasing delay pulse (i.e. the peak height increased). On the other hand, increasing the pulse amplitude decreased RSEC through decreased overlap between the Captopril and oxygen peaks. The maximum RSEC was obtained at long pulse delays and more negative pulse amplitudes, whereas the minimum RSEC corresponded to short pulse delays (maximum signal). These optimum conditions, while broad, were restricted as a result of the study of the response surface for RSEP (Fig. 5b). As can be seen, in the zones of minimum RSEC values (short pulse delays) for the calibration process, RSEP values depended on pulse amplitude. At less negative pulse amplitude, RSEP decreased as a result of the decreased overlap and reached a minimum at -50 mV, beyond which it increased as a result of the increased noise in the polarograms. Under these conditions of pulse am-

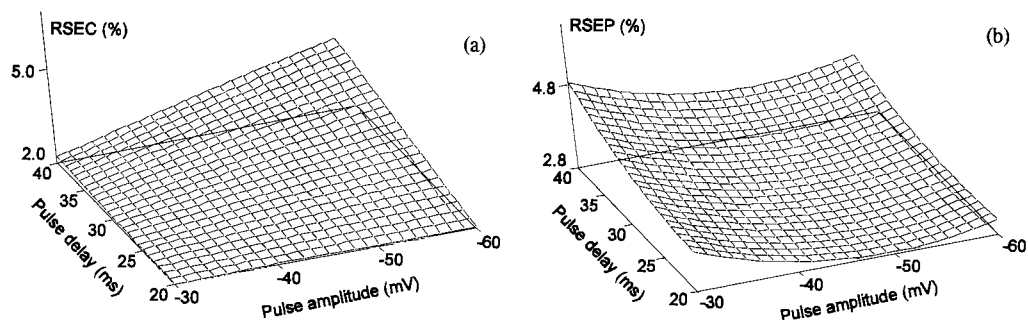

Fig. 5. Response surface for (a) RSEC and (b) RSEP.

plitude, noise associated was more important than the decreased overlap (relative maximum at about -50 mV in Fig. 2b). As regards pulse delay, the effect was the same as for RSEC: a decrease in the delay decreased RSEP through decreased height peak.

The conditions that minimized RSEP and hence those used to determine Captopril in the presence of oxygen were thus a pulse amplitude of -50 mV, a pulse delay of 20 ms and a drop time of 3 s.

3.3. Calibration

After the optimum conditions for the determination of Captopril were established, a new calibration was performed by using a larger number of solutions. Thus, nine solutions containing Captopril concentrations between 3.2 and $16.0 \mu\text{g ml}^{-1}$ at $1.6 \mu\text{g ml}^{-1}$ intervals were used to record differential pulse polarograms under the same optimum conditions, in duplicate (in order to ensure that the calibration matrix included noise as a source of variability). The data obtained from the 18 polarograms recorded from -79 to -139 mV (the maximum for Captopril lay at -109 mV, the mid-point of the range), at 3 mV intervals, were used for PCR calibration using the program Unscrambler [6–9] and the cross-validation method with as many segments as objects existed. The model thus obtained, Model 1 (from -79 to -139 mV), accounted for 99.6% of the variance of the concentration matrix with a single PC, as well as for 97.4% of the variance of the current matrix—both in the validation process.

More exhaustive selection of the variables used to construct the model increased both variance values. Fig. 6 shows the initial variance of the current matrix as a function of the different variables, as well as the residual variance obtained with a single PC. As can be seen, the last corresponded largely to variables above -121 mV. On the other hand, the variation of the current residuals against the leverage for each variable (Fig. 7) reveals that some variables had high residuals and/or low leverages and might thus be distorting the model. Such variables corresponded to the range from -124 to -139 mV.

For both reasons, variables below -121 mV were excluded and the system was recalibrated

Fig. 6. Plot of variance vs. potential: (○) Initial variance; Residual variance obtained with a single PC. [(□) Model 1, (△) Model 2].

Fig. 7. Plot of residual variance vs. leverage. (●) Model 1, (○) Model 2.

using the same validation procedure. The new model, Model 2 (from -79 to -121 mV), accounted for 99.8 and 98.5% of the variance of the concentration and current matrix, respec-

tively, reduced the variance not explained by a single PC (Fig. 6) and, as a rule, decreased residuals and increased variable leverages (Fig. 7). RSEC was 2.03% for Model 1 and this value was reduced to 1.45% for Model 2.

The variance of the current matrix not accounted for by the model using the first factor was ascribed to noise in the polarograms, as reflected in most of the figures shown in this work. The decrease in the signal increased noise and hence led to noisier variables. Consequently, excluding the currents at more negative potentials from Model 2 increased the variance it accounted for. The noise cannot be attributed to the presence of oxygen because it was also observed in its absence, rather, it originated from the potentiostat itself. The difference between the concentrations found for each measurement made on each calibration solution was $<1.5\%$ in every case but one, where the variation was 3.1%.

Table 1

Results obtained in the determination of Captopril in synthetic samples, each one was measured twice

Added amount (mg ml ⁻¹)	Found amount \pm confidence interval (mg ml ⁻¹)	Relative error (%)	Found amount ^a \pm S.D. (μ g ml ⁻¹)	Relative error (%)

Table 2

Results obtained in the determination of Captopril in a pharmaceutical preparation (Cesplón)

Declared amount (mg)	Found amount \pm confidence interval (mg)	Recovery (%)	Found amount ^a \pm S.D. (mg)	Recovery (%)
25.00	25.41 \pm 0.33	101.64	—	—
25.00	24.88 \pm 0.38	99.52	25.19 \pm 0.28	100.76
25.00	25.28 \pm 0.44	101.12	—	—

^a Average of three determinations.

3.4. Determination of Captopril in synthetic samples

The predictive capacity of the proposed model was checked by quantifying the amount of Captopril present in solutions of known concentration. Recordings were obtained under the same conditions as those for the calibration solutions and predictions were calculated by the programme Unscrambler.

Table 1 shows the results. The relative S.D. of the predicted values for a given solution was always $\pm 1.0\%$. Also, there was close agreement between the amounts added and found: relative errors were all $< 2.5\%$ and the confidence intervals $< 2\%$ of the amounts predicted.

3.5. Determination of Captopril in a commercially available pharmaceutical preparation

The proposed method was used to quantify the analyte in a commercially available formulation: Cesplón. As can be seen from Table 2, the percent recoveries and confidence intervals obtained were quite good.

4. Conclusions

The use of PCR for calibration allows Captopril to be determined in the presence of oxygen, where the differential pulse polarograms for the two are fully overlapped. Use of response surface methodology allows the optimum values for the

electrochemical variables (pulse amplitude, pulse delay and drop time) to be established in order to minimize errors.

The proposed method expedites analyses as it avoids the need to bubble an inert gas to remove oxygen and allows the determination of Captopril in real samples (pharmaceutical preparations) with no excipient separation pretreatment.

Differential pulse polarographic determination of ofloxacin in pharmaceuticals and biological fluids

M. Rizk, F. Belal *, F.A. Aly, N.M. El-Enany

Department of Analytical Chemistry, Faculty of Pharmacy, University of Mansoura, Mansoura 35516, Egypt

Received 8 October 1996; received in revised form 23 July 1997; accepted 4 August 1997

Abstract

A sensitive method is described for the determination of ofloxacin in its pure form, dosage forms and biological fluids. The proposed method depends upon the polarographic activity of ofloxacin in Britton Robinson buffers, whereby a well-defined cathodic wave is produced over the pH range 4.1–10.3. The wave was characterized as being irreversible, diffusion-controlled with limited adsorption properties. The current-concentration relationship was found to be rectilinear over the range 5×10^{-5} – 5×10^{-4} M and 1×10^{-5} – 5×10^{-4} M using the DC_t and DPP modes respectively, with a minimum detectability (S/N = 3) of 3×10^{-7} M. The proposed method was successfully applied to the determination of ofloxacin in tablets and biological fluids. The results obtained were found to be in agreement with those obtained by a reference method. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Ofloxacin; Polarography; Pharmaceutical analysis; Biological fluids

1. Introduction

Ofloxacin is a synthetic fluorinated quinolone

derivative having activity against both gram negative and gram positive bacteria through inhibition of their DNA gyrase [1]. It is widely used in the treatment of respiratory tract and urinary tract infections [2]. Various techniques have been utilized for the determination of ofloxacin either per SE or in dosage forms. These techniques include: potentiometric titration [3], spectrophotometry [4–7], spectrofluorometry [5,6], HPLC [8–17], microbiology [18] and adsorptive stripping voltammetry [19].

During the preparation of this manuscript, a paper dealing with the polarographic determination of ofloxacin appeared [20]. Astonishingly, the authors used BRb of pH 4 for their determination, at that medium, the wave was very poorly

* Corresponding author.

defined. The wave was found to be substantially improved as the pH value of the medium was increased up to pH 8.36 (the one we used) whereby well-defined wave was obtained. Meanwhile the authors [20] had limited their method to the use of DC_T mode, therefore we attempted the Differential Pulse Polarography (DPP) mode which allowed better working range and lower detection limit.

2. Experimental

2.1. Materials

Ofloxacin was kindly provided by Hoechst Oriented Pharmaceutical Company (Cairo, Egypt) and was used as received. Tablets (each containing 200 mg of ofloxacin) were obtained from commercial sources.

Reagents

- Britton Robinson buffers (0.08 M) [21], covering the pH range 2.7–10.3.
- Methanol: AR grade (Aldrich).
- A stock solution (2.5×10^{-3} M) of ofloxacin was prepared in methanol, and was further diluted with the same solvent to give the appropriate concentrations.

The methanol concentration in the polarographic cell was kept always at 20%. The solutions were purged with pure nitrogen for 5 min, then polarographed at ambient temperature.

2.2. Apparatus

The polarographic study and DPP measurements were carried out using the Polarecord E 506 Metrohm (Herisau, Switzerland). The drop time (1 s) was electronically controlled using a 663 VA Stand from the same company. The polarograms were recorded using a potential scan of 10 mV s^{-1} . A three-electrode system composed of a Dropping Mercury Electrode (DME), $Ag^0/AgCl$ reference electrode, and a graphite rod as the auxiliary electrode, was used. Phase-selective AC_T polarograms were recorded using the same instrument; the superimposed alternating voltage being 15 mV at a frequency of 75 Hz and a phase angle of 90° .

The effect of mercury height was studied using Sargent-Welch Polarograph Voltametric Analyzer equipped with $Ag^0/AgCl$ reference electrode and a platinum wire as the auxiliary electrode.

The cyclic voltametry apparatus consisted of a Wenking LB 75 potentiostat, a Wenking VSG 72 function generator, a Goldstar DM 6135 digital multimeter and a Philips PM 8271 xyt recorder, a three-electrode system composed of a graphite working electrode, $Ag^0/AgCl$ reference electrode, and a platinum auxiliary electrode was used.

Fig. 1. Typical polarogram of ofloxacin (1×10^{-4} M) in BRb pH 8.36 containing 20% methanol.

Fig. 2. Effect of pH on the development of the polarographic waves of ofloxacin (5×10^{-4} M).

The voltammogram of 5×10^{-4} M solution were recorded at different scan rates of 20, 50, 100, 200 and 500 mV s^{-1} .

2.3. Procedure for tablets

Weigh and pulverize 10 tablets. Transfer a weighed quantity of the powder equivalent to 20 mg of ofloxacin. Dissolve in 100 ml of methanol then filter. Transfer 2 ml of the filtrate into 25 ml volumetric flask and complete to the mark with BRb of pH 8.36. Pour the contents of the flask into the polarographic cell. Record the DC_t and DPP polarograms. Calculate the nominal content of the tablet using previously plotted calibration graph or the corresponding regression equation.

2.4. Procedure for spiked urine

Add a quantity of ofloxacin to the urine to obtain a final concentration of $0.5 \text{ mg} \cdot \text{ml}^{-1}$ then add 2 ml of phosphate buffer (pH = 7.0). Stir the mixture, extract with 3×10 ml of dichloromethane–isopropyl alcohol mixture

(90:10 V/V). Allow the extract to dry under nitrogen gas at room temperature. Dissolve the residue in methanol and filter into 50 ml volumetric flask. Complete to the mark with methanol, proceed as described above.

3. Results and discussion

Fig. 1 shows a typical (DC_t and DPP) polarogram of ofloxacin in BRb of pH 8.36 containing 20% methanol. Methanol was added as a solubilizer for ofloxacin, meanwhile it decreased adsorption interferences. Reduction of ofloxacin at the DME was found to be pH dependent. The $E_{1/2}$ was shifted to more negative values upon increasing the pH as shown in Fig. 2. A plot of $E_{1/2}$ versus pH gave two straight lines with a break at pH 6.1 (Fig. 3) which corresponds to the second pK_a value of ofloxacin (the first one at 0.9 did not appear on the curve because the pH range over which reduction occurs began from 4.1) by analogy to the second pK_a value of nalidixic acid which has almost the same function group [26].

Fig. 3. Effect of pH on the $E_{1/2}$ (mV) values of ofloxacin (5×10^{-4} M) in BRb containing 20% methanol.

The relation between $E_{1/2}$ and pH for the wave is expressed by the following equations:

$$E_{1/2} = -0.9622 - 0.0577 \text{ pH} \quad (R = 0.99560) \quad (1)$$

Over the pH range of 2.6–7.0 and

Table 1
Effect of pH on the development of the polarographic waves of ofloxacin

pH $E_{1/2}$ (V)	$E_{1/2}/\text{pH}$ (mV)	Half-peak width ($W_{1/2}$) (mV)	Number of protons (Z)	αn_a
4.10--1.250	-28	13	0.34	0.9
5.00--1.270	-36	12	0.63	1.03
6.10--1.310	-51	12	1.01	1.08
7.00--1.360	-60	12	1.12	1.10
7.50--1.390	-68	14	1.27	1.10
8.36--1.450	-57	11	1.13	1.17
9.10--1.490	-106	14	1.94	1.08
9.90--1.575	-112	—	1.99	1.05
10.30--1.620	—	—	—	0.93

$$E_{1/2} = -0.4994 - 0.1089 \text{ pH} \quad (R = 0.99959) \quad (2)$$

Over the pH range of 7.5–10.3.

Logarithmic analysis of the reduction waves obtained in BRb of different pH values resulted in straight lines. Assuming that the rate determining step involves the transfer of two electrons (a free radical, one electron-transfer is not likely to occur), the values of the slopes suggest that the reduction process is irreversible in nature. The αn_a values were calculated using the treatment of Meites and Israel [22] and were listed in Table 1.

It is noticed that, the degree of reversibility increased as the pH is raised up to pH 8.36 then it began to decrease. This character was further confirmed by CV measurements. The cyclic voltammograms of ofloxacin (5×10^{-4} M solution) in BRb of pH values 4.0, 7.0 and 10.0 show one cathodic peak using different scan rates (10 – 500 mV s^{-1}). The peak potentials of the wave display a cathodic shift on increasing the scan rate, thus revealing the irreversible nature of the reduction process [23].

The number of protons, Z , consumed in the electrode reaction is given by the following equation [24]:

$$E_{1/2}/\text{pH} = -\frac{0.059Z}{\alpha n_a}$$

where is the transfer coefficient. The value of αn_a was calculated from the following equation:

$$E = E_{1/2} - (0.0559/n_a)\log[(i/i_d) - i]$$

Fig. 4. Alternating current behavior of ofloxacin (5×10^{-4} M) in BRb of different pH values. Superimposed alternating voltage: 15 mV; frequency: 75 Hz; phase angle: 90° (SE: supporting electrolyte).

Where i_d is the limiting current. At pH 8.36 Z was found to be 1.13, i.e. two protons are probably consumed in the electrode reaction.

3.1. Study of the wave characteristics

Increasing the mercury height (h) resulted in a corresponding increase in the waveheight (w); a plot of \sqrt{h} vs. the waveheight gave a straight line. A plot of $\log w$ gave a straight line, the slope of which was 0.49. Changing the buffer concentration over the range 0.006 to 0.06 M resulted in a negligible decrease in the waveheight. These two characters point out to the diffusion-controlled nature of the wave.

The alternating current behavior (AC_t) of ofloxacin was studied using a phase-selective angle of 90° . In BRb of pH 5.0, 7.0 and 8.36, the summit potentials (Es) were shifted to more negative values of 119, 99.27 and 90.625 mV respectively. Fig. 4 demonstrates that a pH values of 7.0 and 8.36, adsorption of the reduction product of the depolarizer may occur.

The diffusion coefficient (D) was calculated using the Ilkovic equation [25] and was found to be 2.72×10^{-7} cm². S⁻¹ in BRb of pH 8.36 (Table 2).

Solutions of ofloxacin in BRb of pH 8.36 containing 20% methanol were found to be stable for about 2 h, after which the waveheight began to decrease slowly.

The relation between the limiting current i_d (μ A) and the concentration, C (mM), was found to be rectilinear over the concentration range 5×10^{-5} – 5×10^{-4} M and 1×10^{-5} – 5×10^{-4} M in the DC_t and DPP modes, respectively.

$$C = 0.0002 + 0.838i_d \quad (r = 0.99998)$$

using DC_t mode, and

$$C = -0.0002 + 0.774i_d \quad (r = 0.99999)$$

using DPP mode respectively, with a minimum detectability of 3×10^{-7} M (S/N = 3).

The diffusion current constant [$I_d = i_d/C$ m^{2/3} t^{1/6}] was calculated at 25° and found to be 0.63 ± 0.01 .

3.2. Number of electrons involved in the electrode reaction

The number of electrons consumed during the reduction was accomplished through comparison of the waveheight of ofloxacin with that obtained from an equimolar solution of a closely related compound, i.e. nalidixic acid [26]. In BRb of pH

NB: The results are the average of 18 separate determinations.

8.36 both compounds gave one peak of the same height pointing out to a two electron transfer process.

Based on these facts, the following mechanism is proposed.

3.3. Analytical application

Polarogram of ofloxacin in BRb of pH 8.36 exhibits cathodic wave. The current is diffusion-controlled and proportional to the concentration over a convenient range of concentration. Both DC_t and DPP modes were successfully applied to the assay of ofloxacin in commercial tablets (200 mg-tablet) and the results obtained are shown in Table 3. The percentage recoveries based on the average of nine separate determinations were 98.5 ± 0.4 and 99.01 ± 0.3 , respectively. The results obtained were favourably compared with a

reference [5] was 98 ± 0.5 based on measuring the native fluorescence of ofloxacin in 1 M sulphuric acid at 512 nm after excitation at 298 nm. Statistical analysis [27] of the results obtained by both methods using the Student *t*-test and Variance Ratio *F*-test, shows no significant difference between the performance of the two methods regards the accuracy and precision, respectively (Table 3).

Ofloxacin is given by mouth in doses of 200–400 mg daily. It is metabolized to desmethyl and *N*-oxide metabolites. It is eliminated mainly by the kidneys. Excretion is affected by tubular secretion and glomerular filtration, and 75–80% of the dose is excreted unchanged in the urine over 24–48 h, resulting in high urinary concentration [28] (Table 4).

The DPP mode could be successfully applied to the determination of ofloxacin in urine over the concentration range of 4–180 μg ml⁻¹. Thus the proposed study could be applied to the determination of ofloxacin in spiked urine. The results are

Table 3

abridged in Table 5. It can also be adopted for the pharmacokinetic studies of ofloxacin.

The within-day precision was evaluated through replicate analysis of urine samples spiked with ofloxacin at certain concentration level. The percentage recoveries based on the average of four separate determinations were 97.36 ± 0.73 , the corresponding RSD% was 0.75 indicating high precision of the method. The between-day precision was also evaluated as proceeding above. The percentage recoveries based on the average of four separate determinations were 96.25 ± 1.62 , the corresponding RSD% was 1.68 indicating also the high precision of the method.

Abstract

The behaviour of taurine as a ligand (L) towards silver(I) and cadmium(II) was studied at 25°C and in 1 mol dm⁻³ NaClO₄, as a constant ionic medium. Experimental data, obtained for both cations from electromotive force measurements performed by using silver and cadmium amalgam and glass electrodes, were explained by assuming the formation of the AgL, AgL₂, CdL, and CdL₂ complexes. The taurine protonation constant and stability constants of the above complexes were determined. The cadmium(II)–taurine system was investigated by determining the free concentration of taurine from the Ag electrode potential and the knowledge of equilibria existing between silver(I) and taurine. Experimental data obtained from this approach were explained by assuming the presence of the above species with very close stability constant values. The success of this method supports the possibility of using the Ag/Ag–taurine, taurine electrode to measure the free concentration of taurine in its solutions. © 1998 Elsevier Science B.V. Keywords: Silver electrode; Silver(I)–taurine complexes; Cadmium(II)–taurine complexes; Free concentration taurine measurement

1. Introduction

Generally, aminoacids develop their basic and acid function through the –NH₂ and carboxylic groups, respectively. On the contrary, taurine contains an aminic and a –SO₃⁻ group. However, its ligand properties depend on the presence of the

aminic nitrogen atom so that it acts as a monodentate ligand.

In the human body taurine is conjugated with bile cholic acids and forms taurodeoxycholic and taurocholic acids with deoxycholic and cholic acids, respectively. Micellar aggregates of the former bile cholic salts have been previously investigated [1,2].

Although taurine is a simple compound, only few studies can be found in the literature on its

behaviour as a ligand towards cations. This is probably due to the poor stability of its complexes. Only five papers deal with stability constants of taurine complexes [3,4].

Albert [5] studied the complex formation of taurine with cobalt(II) and copper(II) at 20°C. In 1959, Datta et al. [6] investigated the complex formation between silver(I) and taurine at 25°C. Both groups performed electromotive force (e.m.f.) measurements in solutions at low ionic strength (about 0.01 mol dm⁻³) in order to determine the taurine protonation and complex formation constants. In 1972, van Poucke et al. [7] studied equilibria occurring between silver(I) and taurine at 25°C and in 0.5 mol dm⁻³ KNO₃. They explained their glass electrode e.m.f. measurements assuming the presence of two complexes, 1:1 and 1:2, with logarithm of stability constants 2.97 and 6.15, respectively.

More recently, equilibria between taurine (L) and both calcium(II) and nickel(II) were investigated. For calcium(II), the formation of CaL (log β = 0.217) and CaHL (log β = 8.426) was assumed to explain nuclear magnetic resonance (NMR) and electron spin resonance (ESR) data [8]. In the case of nickel(II) [9], e.m.f. measurements carried out with a glass electrode at 25°C in 0.1 mol dm⁻³ NaClO₄ or LiClO₄, were explained by assuming the existence of the only species, NiL, with stability constant log β = 3.62.

The aim of this research is to investigate the properties of taurine as a ligand with several cations in a wide range of concentration of the reagents. To this purpose, we decided to adopt the constant ionic medium method proposed by Biedermann and Sillén [10] to minimise the activity coefficient variations due to the change of the concentrations of the reagents. The conditions are 25°C and 1 mol dm⁻³ NaClO₄, as an ionic medium.

Complex formation between silver(I) and taurine was studied for several purposes. Only two reports are present in the literature and they do not agree with each other. Moreover, they were not performed at 25°C and 1 M NaClO₄, one was carried out at a very dilute ionic strength. Furthermore, the high redox potential of the Ag⁺/Ag couple allows the use of this electrode to investi-

gate the behaviour of taurine as a ligand towards other cations. This can be very useful when the free concentration of the cation cannot be measured at equilibrium, using an amalgam electrode.

The protonation of taurine (L⁻ = C₂H₆NO₃S⁻) and equilibria taking place between silver(I) and taurine were characterized together with the relative stability constants. From the knowledge of the silver(I)–taurine system, a silver electrode in a silver(I)–taurine solution provides the free concentration of taurine, *c_L*. The possibility of such an electrode to work as an indicator of taurine was verified. To this purpose the cadmium(II)–taurine system was studied following two independent procedures. First, cadmium amalgam and glass electrodes were employed. The same system was then investigated by using glass and Ag/Ag–taurine, taurine electrodes. Comparison of the results obtained with both procedures supports the reliability of the response of the taurine electrode.

2. Experimental

2.1. Method

The behaviour of taurine as a ligand was studied using different approaches. The first step of the analysis involved the determination of the taurine protonation and of the silver(I)–taurine complex constants. The second step was the characterization of the cadmium(II)–taurine system using both a direct (cadmium amalgam) and competitive (silver–taurine electrode) technique.

2.1.1. Protonation of taurine (L⁻)

Knowledge of the taurine protonation is necessary to study the complex formation of taurine with silver(I) and cadmium(II). The protonation of taurine was studied at 25°C by measuring the e.m.f. of the following cell:

where Pt, H₂ is a H₂ electrode, R.E. is the reference electrode previously described [11], and the e.m.f. is measured as a function of $0 \leq C_L \leq 0.05$ mol dm⁻³, $0.00 \leq C_H \leq 0.1$ mol dm⁻³ and $12 \geq -\log c_H \geq 2$.

Solution P has the following general composition: C_H M in H^+ , C_L M in taurine, $(1.00 - C_H)$ M in Na^+ and 1 M in ClO_4^- .

The analytical excess of hydrogen ions is indicated with C_H . Capital and small C_x indicate the total and free concentration of the x species, respectively.

2.1.2. The silver(I)–taurine system

In order to investigate equilibria taking place between silver(I) and taurine, the e.m.f. of the following galvanic cells was measured:

where Ag E. and G.E. are silver and glass electrodes, respectively and R.E. is the reference electrode. Solutions S were prepared in a constant ionic medium, 1 mol dm^{-3} $NaClO_4$, with the following general composition: C_{Ag} M in Ag^+ , C_H M in H^+ , C_L M in taurine, $(1 - C_{Ag} - C_H)$ M in Na^+ , 1 M in ClO_4^- .

According to Biedermann and Sillén [10], in a constant ionic medium, it is possible to substitute concentrations per activities, so that the e.m.f. of cell (II) and (III) at 25°C and in mV units, can be written as follows:

$$E_{II} = E_{II}^{\circ} + 59.16 \log c_{Ag} + E_j; \quad (1)$$

$$E_{III} = E_{III}^{\circ} + 59.16 \log c_H + E_j. \quad (2)$$

C_{Ag} , C_H and c_{Ag} and c_H indicate the total and free silver and hydrogen ion concentrations, respectively. In Eqs. 1 and 2, E_{II}° and E_{III}° are related to the activity coefficients γ through the relations:

$$E_{II}^{\circ} = E'_{II} + 59.16 \log \gamma \text{ and}$$

$$E_{III}^{\circ} = E'_{III} + 59.16 \log \gamma.$$

The activity coefficients are held constant by the presence of an ionic medium. E_{II}° and E_{III}° which are constant and E_j , which represents the liquid junction potential, were first determined in the absence of the ligand, when $C_{Ag} = c_{Ag}$ and $C_H = c_H$. E_j depends only on c_H in acid solutions. In the investigated experimental conditions, $E_j = -60 c_H$. Then C_{Ag} and C_H were kept constant while the total concentration of the ligand, C_L ,

was gradually increased and E_{II} and E_{III} were measured for each point.

The experimental data obtained from this approach were the analytical concentration of silver(I), hydrogen ions, and taurine, C_{Ag} , C_H and C_L respectively, and the free concentration of silver(I) and hydrogen ions, c_{Ag} and c_H , obtained directly by measuring the e.m.f.

2.1.3. The cadmium(II)–taurine system (cadmium amalgam)

Equilibria taking place between cadmium(II) and taurine were studied at 25°C in 1 mol dm^{-3} $NaClO_4$ by measuring the e.m.f. of the following galvanic cells:

where Cd(Hg) is a cadmium amalgam electrode and the other symbols have the same meaning as above. Solutions S_1 has the following general composition: C_{Cd} M in Cd^{2+} , C_H M in H^+ , C_L M in taurine, $(1 - 2C_{Cd} - C_H)$ M in Na^+ , 1 M in ClO_4^- .

According to Biedermann and Sillén [10] the e.m.f. of cell (IV) and (V), at 25°C and in mV units, can be written as follows:

$$E_{IV} = E_{IV}^{\circ} - 29.58 \log c_{Cd} - E_j;$$

$$E_V = E_V^{\circ} + 59.16 \log c_H + E_j.$$

The procedure followed to obtain E_{IV}° , E_V° , c_{Cd} and c_H was similar to that described in Section 2.1.2.

The experimental data obtained through this approach were the analytical concentrations of cadmium and hydrogen ions, C_{Cd} and C_H , respectively, and the free concentrations of cadmium(II) and hydrogen ions, c_{Cd} and c_H , respectively.

2.1.4. The cadmium(II)–taurine system (silver–taurine electrode)

The hypothesis was formulated that a silver electrode dipped in a taurine solution can work as a taurine electrode. From the knowledge of the silver(I)–taurine system, studied above, and from the potential of the silver electrode it should be possible to obtain the free concentration of taurine.

To verify this hypothesis the cadmium(II)–taurine system previously studied using glass and cadmium amalgam electrodes, was further investigated with the glass and the silver(I)–taurine electrodes. Comparison of the results obtained by these two procedures supported the validity of the hypothesis. To this purpose the e.m.f. of the following cells was measured:

The symbols indicate the same electrodes as above, but solution S_2 had the following general composition: C_{Ag} M in Ag^+ , C_{Cd} M in Cd^{2+} , C_{H} M in H^+ , C_{L} M in taurine, $(1 - C_{\text{Ag}} - 2C_{\text{Cd}} - C_{\text{H}})$ M in Na^+ , 1 M in ClO_4^- .

The e.m.f. can be expressed at 25°C and in mV units, by equations similar to (Eq. (1)) and (Eq. (2)). E_{VI}° , E_{VII}° and E_j were determined in the first part of each measurement in the absence of taurine, but in the presence of cadmium(II). From several preliminary e.m.f. measurements it was deduced that appreciable concentrations of other cations such as cadmium(II), copper(II), nickel(II), cobalt(II) (cation/silver concentration ratio up to 10), did not interfere with the response of the silver electrode. E_{VI}° and E_{VII}° values did not change in the presence of the above cations.

Table 1 shows an example of the trend of E_{VI}° of the silver electrode, in the presence of increasing concentrations of copper(II). Even increasing the $C_{\text{Cu}}/C_{\text{Ag}}$ ratio up to 10, the E_{VI}° values are constant within ± 0.03 mV.

After the determination of E_{VI}° , E_{VII}° and E_j , an

alkaline solution containing taurine was added to reach the selected values of C_{L} and $-\log c_{\text{H}}$, by keeping constant C_{Ag} . The e.m.f. of the cells was measured by keeping C_{L} , C_{Ag} and $-\log c_{\text{H}}$ constant and by increasing gradually C_{Cd} until a slight cloudiness was observed. The values of C_{H} were calculated for each point.

The experimental data obtained from this procedure were the C_{L} , C_{Ag} , C_{Cd} and C_{H} analytical values, and the c_{H} , and c_{Ag} measured directly by means of cell (VI) and (VII).

2.2. Materials and analysis

Silver(I) perchlorate was prepared by dissolving Ag_2O in a slight excess of dilute HClO_4 . Silver oxide was prepared by adding a slight excess of carbonate free NaOH to a dilute solution of AgNO_3 , BDH p.a., recrystallized from water. The oxide obtained was washed with bidistilled water at least 25 times, until neutrality.

The standard solution was filtered through a gooch (G3) and kept in dark glass, away from the light.

The total silver(I) concentration, C_{Ag} , was determined volumetrically and potentiometrically against NaCl . The results of several determinations agreed better than $\pm 0.1\%$. The analytical excess of hydrogen ions, C_{H} , was determined potentiometrically, according to Gran [12].

NaClO_4 , HClO_4 , NaOH and $\text{Cd}(\text{ClO}_4)_2$ were prepared and analysed as described before [13,14].

2.3. Details on the e.m.f. measurements

Cadmium amalgam (0.01%) was prepared as previously described [14]. Silver electrodes were prepared coulometrically by covering a Pt wire used as a cathode, with electrolytic silver, flowing a 0.1 mA current for about 10 h through a 1% $\text{KAg}(\text{CN})_2$ solution. Electrodes of different lengths (between 1.0 and 2.5 cm), gave responses in good agreement. Potential values measured from two different silver electrodes dipped in the same solution agreed within ± 0.05 mV.

The other experimental apparatus included an electronic voltmeter Keithley mod. 199, pHM 65 Radiometer and mod. 654 Metrohm equipped with hydrogen and glass electrodes, respectively. Salt bridge, reference electrode and all the other details of the e.m.f. measurements are similar to those described earlier [11].

All measurements were performed at 25°C. All solutions containing silver ions were kept away from the light. Their analysis was carried out in red light to avoid the photochemical decomposition of silver ions. In these conditions, the e.m.f. values of the cell containing silver ions were constant within 30 min after each new addition and remained stable (within ± 0.10 mV) for several hours, even at low C_{Ag} concentration ($\geq 0.1 \times 10^{-3}$ M). In white light, the e.m.f. values never reached stable values, but a slow drift of 0.02 mV per 1–2 min was observed. After each series of e.m.f. measurements, the Ag electrodes were thoroughly washed with NH_3 and kept in bidistilled water overnight. Electrodes prepared as previously described gave correct responses even after a few months from their preparation, if washed and kept correctly.

A stream of nitrogen (99.999%) was bubbled through the solutions throughout the measurements to prevent the absorption of CO_2 .

The response of the glass electrodes was checked against that of a H_2 electrode, assumed to be correct. Both measured values agreed within ± 0.1 mV up to $-\log c_{\text{H}} \leq 9$, while beyond this c_{H} , the glass electrode showed remarkable deviations. In order to study the protonation of taurine a H_2 electrode was used. H_2 (99.999%) was supplied by cylinders.

3. Results

The results of the present investigation will be given after the style of Section 2.1

3.1. Protonation of taurine

Taurine shows two possible protonation steps, the first corresponding to the $-\text{NH}_2$ and the second to the $-\text{SO}_3^-$ group. In the range of concentrations studied we were able to appreciate only the protonation of the aminic group.

As the protonation function is independent of the total taurine concentration, no appreciable evidence of polynuclear species was found, as expected. The experimental data were explained by assuming the presence of HL with protonation constant $\log K_1 = 9.01 \pm 0.02$, where $K_1 = c_{\text{HL}} / (c_{\text{H}} c_{\text{L}})^{-1}$.

No reliable values were obtained for K_2 , as solutions with a sufficient fraction of H_2L^+ , can be obtained only at very high C_{H} values. At such C_{H} it was hard to assume that the activity coefficients were constant, as the composition of the ionic medium changed markedly. This did not involve any loss of accuracy, because only $\log K_1$ was used in further calculations.

3.2. The silver(I)–taurine system

Several series of measurements were carried out at $C_{\text{H}} = 0.01, 0.025, 0.05, 0.1$ and 0.15 mol dm^{-3} and $C_{\text{Ag}} = 0.5, 1, 2, 4 \times 10^{-3} \text{ mol dm}^{-3}$. Without a preliminary hypothesis, it can be assumed that the reagents participate to the general equilibrium:

with the stability constant $\beta_{q,p,r}$, where $q \geq 1, p \leq 0, \geq 0, r \geq 1$.

Experimental data were elaborated to determine the q, p, r prevailing values and the relative equilibrium constants. From the mass balance of silver ion, taking into account the mass action law, the following equation can be written:

Table 2
Species formed by taurine with silver(I) and cadmium(II)

Cation		Species ML		Species ML ₂	
Ag ⁺		3.53 ± 0.07	Graphic	6.47 ± 0.05	Graphic
		3.53 ± 0.05	BSTAC	6.48 ± 0.01	BSTAC
		3.53 ± 0.05	Proposed value	6.48 ± 0.05	Proposed value
Cd ²⁺	Cd amalgam	2.05 ± 0.10	Graphic	3.74 ± 0.08	Graphic
		2.01 ± 0.08	BSTAC	3.78 ± 0.03	BSTAC
		2.01 ± 0.08	Proposed value	3.78 ± 0.05	Proposed value
Cd ²⁺	Ag/Ag(I)–taurine	2.00 ± 0.10	Graphic	3.78 ± 0.10	Graphic
		2.1 ± 0.12	BSTAC	3.8 ± 0.1	BSTAC

The stability constant values are expressed as $\log \beta_{1,0,r}$. Protonation constant $\log K_1 = 9.01 \pm 0.02$

The error limits relative to the constants obtained by the graphic method correspond to the maximum difference possible with a still acceptable agreement between experimental and calculated data. The SD is reported in the other cases.

$$\eta = \log(C_{Ag}/c_{Ag})$$

$$= \log(1 + \sum \sum \sum q\beta_{q,p,r} c_{Ag}^{q-1} c_H^p c_L^r) \quad (3)$$

For the analysis of the experimental data it was necessary to calculate the ligand free concentration c_L , which was obtained from the mass balance of C_H , taking into account the mass action law:

$$C_H = c_H + K_1 c_H c_L + \sum \sum \sum p\beta_{q,p,r} c_{Ag}^q c_H^p c_L^r \quad (4)$$

In Eqs. 3 and 4 hydrolytic species of silver were considered negligible on the basis of the previous results [15,16]. As a first approximation the hypothesis was formulated that the presence of complexes involving protons was negligible. As a consequence, the last term of Eq. (4) could be neglected for the calculation of c_L . The validity of this hypothesis was demonstrated a posteriori.

The function η versus $-\log c_L$ is plotted for each experimental point in Fig. 1. Note that independently of C_{Ag} and C_H , all the points fall on the same curve. Therefore, the presence of polynuclear and mixed complexes involving protons can be discarded, i.e. $q = 1$ and $p = 0$. The trend of the experimental points can be explained by assuming the presence of the AgL and AgL_2 species, and the above formulated hypothesis can be assumed to be true.

By applying the normalized curve method [17] the values of the relative constants $\beta_{1,0,1}$ and $\beta_{1,0,2}$ were obtained. The equilibrium constant values were also obtained by analysing the experimental data with the BSTAC program [18]. In Table 2 the values obtained by graphical methods and those calculated by computer are collected and they are in good agreement. The constants of Table 2 were used to calculate the theoretical curve of Fig. 1. The agreement between experimental points and calculated curve is satisfactory.

Fig. 2. Complex formation between cadmium(II) and taurine. The curve is calculated with the constants of Table 2. The points were obtained by using the cadmium amalgam electrode.

Fig. 3. Most of the points obtained by using Ag/Ag(I)–taurine, taurine electrode to study the cadmium(II)–taurine system. The curve is calculated by using the constants of Table 2.

3.3. The cadmium(II)–taurine system (cadmium amalgam)

Similarly to the above section, several series of experimental data were obtained at different $C_H = 0.025, 0.05, 0.1 \text{ mol dm}^{-3}$ and $C_{Cd} = 0.25, 0.5, 1$ and $2 \times 10^{-3} \text{ mol dm}^{-3}$.

Experimental data were elaborated by applying a treatment similar to the one explained before, but in this case mass balances of cadmium, C_{Cd} and hydrogen ion, C_H were considered.

In Fig. 2 the η' function ($\eta' = \log C_{Cd}/c_{Cd}$) is plotted as a function of $-\log c_L$. Also in this case, all the experimental points fall on the same curve independently of C_{Cd} and C_H . Polynuclear and mixed complexes involving protons are not present in appreciable concentrations.

Equilibria taking place between cadmium(II) and taurine can be accounted for by assuming the presence of the CdL and CdL_2 species.

In Table 2 the values of stability constants obtained by graphical and computer methods are reported. Also in this case the values are in good agreement. The curve in Fig. 2 was calculated

with the constant values of Table 2. The calculated curve and the experimental points are in satisfactory agreement, supporting the validity of the procedure adopted.

3.4. The cadmium(II)–taurine system (silver–taurine electrode)

Several series of e.m.f. measurements of cell (VI) and (VII) were carried out at $-\log c_H = 8, 8.5, 9$ and 9.5 and $C_L = 0.1, 0.15, 0.2 \text{ mol dm}^{-3}$. C_{Ag} was kept constant for each series and the cadmium(II) concentration was gradually increased until a slight colloidal precipitate was observed by the Tyndall effect.

These results were used to obtain prevailing species and relative constants to verify if the silver electrode dipped in a taurine solution works reversibly to give the free concentration of taurine, c_L .

From the C_{Ag} and c_{Ag} experimental data and from the knowledge of the silver(I)–taurine system, it was possible to calculate c_L , by using the mass balance equations relative to silver ions:

$$C_{Ag} = c_{Ag} + \beta_{1,0,1} c_{Ag} c_L + \beta_{1,0,2} c_{Ag} c_L^2 \quad (5)$$

On the other hand, by taking into account the range of C_H and c_H investigated, Eq. (4) could be written for all the points measured, as follows:

$$C_H = c_H + K_1 c_H c_L \sim K_1 c_H c_L \quad (6)$$

From the analytical concentrations of taurine and cadmium(II), the mass balance equation of taurine could be written, by taking into account the mass action law:

$$C_L = c_L + \beta_{1,0,1} c_{Ag} c_L + 2\beta_{1,0,2} c_{Ag} c_L^2 + C_H + ZC_{Cd} \quad (7)$$

In Eq. (7) all symbols are already explained. Z indicates the formation function, defined as the average number of ligands per central group, in this case cadmium(II). In the same equation, hydrolytic species of cadmium(II) were neglected on the basis of the results obtained by Biedermann and Ciavatta [19].

The experimental data in the form $Z(-\log c_L)$ plotted in Fig. 3 show that all the points fall on

Table 3

Stability constants ($\log \beta_{1,p,r}$) of complexes formed by cadmium(II) with taurine, ammonia [23] and glycine [22] at 25°C and in 1 mol dm⁻³ ClO₄⁻

		CdHL	CdL	CdL ₂	CdL ₃	CdL ₄
Taurine	(This work)	—	2.01	3.78	—	—
NH ₃	[23]	—	2.54	4.78	6.08	7.26
Glycine	[22]	10.52	4.36	7.99	10.13	—

the same curve independently of C_L , C_H , C_{Cd} and the ratio C_{Cd}/C_{Ag} . Polynuclear, mixed silver(I)–cadmium(II)–taurine complexes and complexes involving hydrogen ions can be excluded. Points at low Z could not be obtained as at $C_{Cd} \geq 3.5 \times 10^{-3}$ mol dm⁻³ a colloidal precipitate was detected. As $Z_{max} = 2$, two taurine molecules can be bound per cadmium(II), as expected from the approach carried out using the cadmium amalgam electrode. As only two species CdL and CdL₂ were formed, the formation function can be written as follows:

$$Z = (c_{CdL} + 2c_{CdL_2})/C_{Cd}$$

or

$$Z = (\beta_{1,0,1} c_L + 2\beta_{1,0,2} c_L^2)/(1 + \beta_{1,0,1} c_L + \beta_{1,0,2} c_L^2) \quad (10)$$

By applying the graphical method of normalized curves proposed by Sillén [17] the stability constants for the CdL and CdL₂ species could be obtained. On the other hand, experimental data introduced in the BSTAC [18] computer program, gave very close values. Both graphical and computed results are collected in Table 2. The values agree well with each other and the calculated curve obtained by using the constants of Table 2 fits well with the experimental data (Fig. 3).

4. Discussion

Different considerations can be formulated on the basis of the results of this paper. The first one refers to the behaviour of taurine as a ligand towards silver(I) and cadmium(II). No data were available from the literature at 25°C and in 1 mol dm⁻³ NaClO₄ as an ionic medium.

As taurine is a monodentate ligand, it cannot form chelate complexes, hence species with poor stability

are expected. The study of the complex formation of taurine and cations performed using only the glass electrode causes many difficulties, as it involves the competition between proton and cation for taurine. This competition takes place in the range $8 \leq -\log c_H \leq 10$, where taurine is partially deprotonated, but every cation can easily hydrolyse or even precipitate as hydroxide. For example, Leden [20] and Froneaus [21] used the ratio between total and free metal as a function of the ligand concentration to study complex formation by measuring the free concentration of the cation.

This paper shows that it is advantageous to measure directly the free concentration of the cation (with silver or cadmium amalgam electrodes, respectively) or that of the ligand (with the silver electrode).

Table 2 of this paper gives the stability constants of the AgL, AgL₂, CdL, and CdL₂ species.

The values of the stability constants for the CdL and CdL₂ species, obtained with cadmium amalgam and silver electrodes agree very well together. This result supports the validity of our procedure and allows the silver, silver(I)–taurine, taurine electrode to be used to perform direct measurements of the ligand free concentration. The high potential value of the Ag/Ag⁺ couple suggests that this procedure can be applied to many other cases. The presence of several cations, such as copper(II), cadmium(II), lead(II), nickel(II), and cobalt(II), does not interfere with the response of the silver electrode (see Table 1). This is advantageous if cations like calcium(II) and magnesium(II) are to be studied. We are applying this method to the investigation of the behaviour of taurine as a ligand towards such cations and this will be the subject of a next study.

A difficulty of this method is the low stability of silver(I) solutions when exposed to light. Otherwise, silver electrodes can be prepared very easily and can be used for a long time.

We were not able to find quantitative data in the literature on the complex formation between cadmium(II) and taurine.

Protonation constant of taurine was determined at very low ionic strength [5]. Our value, by taking into account the different experimental conditions, agrees with that of the literature (9.01 and 9.08, respectively). Also for silver(I), literature values were determined at ionic strengths 0.01 and 0.5 mol dm⁻³ KNO₃. The values proposed in this study are higher than those of the literature [6,7], but the latter disagree with each other. Only the value of log $\beta_{1,0,2}$ proposed for AgL₂ agrees with that proposed by Datta et al. [6], if the different experimental conditions are considered.

The behaviour of taurine can be compared with glycine and ammonia.

In Table 3 the values of this work and those of the constants of the complexes of cadmium(II) with glycine [22] and ammonia [23] obtained in the same experimental conditions, are collected and compared.

Only glycine is able to form complexes involving protons. There is no evidence of polynuclear complexes.

Ammonia forms four complexes, glycine three, and taurine only two. The values of $\beta_{1,0,1}$ and $\beta_{1,0,2}$ of taurine and NH₃ are of the same order of magnitude, while the complexes formed by glycine are far more stable. NH₃ can never be able to form chelates because it is an unidentate ligand. From values of the constants of species formed by taurine, it is confirmed that taurine is also not able to form chelates. This is in agreement with Ahrlund et al. [24] who asserted that the -SO₃⁻ group has few possibilities to be an electron donor and therefore the formation of chelate because of its presence it is very improbable.

The high capability of NH₃ to form complexes with respect to taurine can be explained by a probable bigger steric hindrance of the latter molecule.

5. Conclusion

This paper contributes to the knowledge of the behaviour of taurine as a ligand towards proton, silver(I), and cadmium(II).

Two independent procedures were used to study the cadmium(II)–taurine system and the agreement between these two approaches has proved the reliability of this method. For this reason it can be used to obtain the free concentration of taurine when it is not possible to measure the free concentration of the cation or when difficulties arise using the glass electrode.

Abstract

Cadmium (II) ion-catalyzed degradation of ampicillin in methanol at 20°C has been studied. It has been observed that the rate values tend to saturate when the concentration of ampicillin or the metal ion is increased. The results obtained in the present study suggest that ampicillin degradation occurs through the formation of a 1:1 (SM) and 2:1 (S₂M) ampicillin–metal complexes. These complexes decompose giving a single product (absorption maximum at 285 nm; $\epsilon_p = 1.82 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$) that has been isolated and identified $(\text{Cd}^{\text{II}} (\text{L}^{2-})_2 (\text{H}_2\text{O})_4 \text{ Na}_2)$. The appearance of this product reflects a first order reaction with respect to the 1:1 complex, with a rate constant of $3.87 \times 10^{-2} \text{ min}^{-1}$ and the existence of an equilibrium between the 1:1 and 2:1 initial complexes. The equilibrium constant value, calculated from kinetic data, is $1.7 \times 10^3 \text{ l mol}^{-1}$. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: β -lactam; Ampicillin; Kinetics; Cadmium

1. Introduction

The opening of the β -lactam ring by a serine hydroxy group is thought to be the first chemical step in the reaction of penicillins and cephalosporins with transpeptidase and β -lactamase enzymes [1]. The first of these bacterial enzymes is the primary killing site for the lethal action of β -lactam antibiotics [2]. The second is the primary method of defence used by bacteria to resist these bactericides [3]. Both reactions are interpreted as hydroxylic addition across the β -lactamic bond to give a penicilloyl enzyme intermediate, an ester of penicilloic acid. The

β -lactamic bond is broken and the hydroxylic hydrogen atom migrates to the nitrogen atom of β -lactam amide. Because of the importance of the alcoholysis reaction with β -lactamic antibiotics quite a lot of theoretical and experimental research has been reported [4–6].

In the present study we describe the decomposition of ampicillin [I] in methanol medium catalyzed by Cd^{2+} , the latter, having a large ionic radius, is presumed to have a great catalytic effect. In order to obtain a kinetic scheme for the reaction, degradation kinetic data were used. The reaction occurs initially with the formation of two complexes of intact ampicillin and cadmium with stoichiometric values of 1:1 and 2:1 (ampicillin/cadmium), respectively. The complexes decompose due to the nucleophilic attack of the

methanol molecule so that at the end of the reaction a single final product is obtained. The analytical results show that this compound is a complex formed by the binding of two molecules of penamaldate derivative of ampicillin (which precedes from antibiotic degradation) to a Cd^{2+} ion.

2. Experimental

Sodium ampicillin [I] (99% pure) was obtained from Aldrich. Methanol, CdCl_2 and $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ were from Merck. All other reagents used were of analytical grade.

2.1. Stoichiometric determination

The stoichiometry of the single reaction product of ampicillin degradation catalyzed by Cd^{2+} ions was determined using the continuous variation method on a long-term basis (24 h).

2.2. Long-term agreement with Beer's law and application of Coleman's test

Compliance with Beer's law was verified at 285 nm in two series of solutions in which the mole ratio between ampicillin and metal was kept constant at 2:1 and 2.3:1, respectively, while reagent concentration was varied. Absorbance measurements at 285 nm were carried out on a Spectronic 2000 spectrophotometer equipped with a Selecta thermostat ($\pm 0.1^\circ\text{C}$) 24 h after the preparation of these solutions, sufficient time for the kinetic reaction to end. Coleman's matrix method [7] was applied in graphic form to the absorbance data (A_{ij}) measured using a wide range of wavelengths. In this way, we determined the number of absorbent species at the end of the reaction. A_{ij} denotes the absorbance value of a particular solution j at a specific wavelength i . The entire set of absorbance data for each series of spectra was displayed as the matrix A_{ij} .

2.3. Kinetic measurements

The kinetic measurements were made by monitoring the appearance of a reaction product of ampicillin degradation at 285 nm on a Perkin Elmer Lambda 5 spectrophotometer equipped with a thermostatic cell holder.

The reaction was carried out using a series of methanolic solutions containing different excesses of ampicillin (ranging from 10 to 500×10^{-4} M), constant metal concentration (1×10^{-4} M), and also in ampicillin solutions of constant concentration (1×10^{-4} M) and different metal ion concentration (ranging from 2×10^{-5} to 2×10^{-3} M). The measurements were taken vs. methanol in 1 cm path length spectrophotometric cells.

In each kinetic experiment the reaction rate was calculated from the slope of the straight line obtained when the initial absorbance values were plotted vs. time, dA/dt , and from the molar absorptivity of degradation product, which is equal to $1.82 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$. In the kinetic mixture which contained excess antibiotic (2000:1), a zero order rate constant was obtained from the 285 nm absorbance increase.

2.4. Isolation and analysis of the degradation product

A solution with 0.7427 g of sodium ampicillin and 0.3084 g of $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ in 50 ml of methanol (mole ratio 2:1) was kept at room temperature for 24 h. After the completion of the reaction, the solution was then evaporated in vacuum at room temperature and cooled to around 4°C obtaining a yellowish white precipitate. The solid was filtered, washed with methanol, ether and acetone, air-dried, and finally, dried in a vacuum desiccator with P_2O_5 .

Infrared spectra were recorded between 4000 and 400 cm^{-1} on a Nicolet 20SXB using potassium bromide pellets. $^1\text{H-NMR}$ and $^{13}\text{C-NMR}$ spectra were recorded at 300 MHz on a Bruker AM-300 spectrometer. The powdered sample was dissolved in DMSO-d_6 using TMS as reference. Chemical analysis was performed on Perkin Elmer 2380 atomic absorption equipment. An electron impact mass spectrum was carried out on

a Hewlett Packard HP-5988-A, with DIP: ramp of 25°C until 280°C (The electronic ionization was at 70 eV) and a LSIMS/FAB⁻ spectrum by bombardment with Cs⁺ ions in glycerol was carried on a mass spectrometer Micromass model AutoSpecEQ.

The results obtained were: C, 41.12; H, 4.95; N, 8.47; S, 6.49; Na, 4.60 and Cd, 11.40. δ_{H} , 1.35(6H, CH₃) 3.4(3H, OCH₃) 7.25 (5H, C₆H₅); δ_{C}^{13} : 30.58, 56.55, 57.41, 127.63, 127.97, 170.01, 203.50; ν_{max} (KBr/cm⁻¹) 1672, 1603 and 1385.

3. Results and discussion

Fig. 1 shows the spectra, of a methanol solution of ampicillin with Cd(II) ion at equimolar concentrations at different periods of time. The spectrum presents a steady rise in absorption, reaching a peak at 285 nm. The changes observed in the spectrum could be attributed either to the decomposition reaction kinetics of ampicillin or to a kinetic process in which a complex 1:1 was transformed with time to another complex 2:1, both formed by intact ampicillin coordinated with the

Fig. 1. Absorption spectra of sodium ampicillin (1.25×10^{-4} M) and cadmium chloride (1.25×10^{-4} M) in methanol (20°C). The curves are labelled at times 0, 5, 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60 and 70 min of reaction.

Fig. 2. Absorbance change vs. reaction time in the Cd²⁺ promoted methanolysis of ampicillin (1×10^{-4} mol dm⁻³) at 20°C: Cd²⁺ concentration (mol dm⁻³) 2×10^{-3} , 3×10^{-4} , 1×10^{-4} , 4×10^{-4} , 2×10^{-5} . Infinity time = 24 h.

Cd(II) ion. However, the second possibility can be ruled out, since it is known that metal ions catalyze the degradation of β -lactam compounds [6], in both methanolic and aqueous media.

The absorbance at 285 nm tends towards a constant value with time as can be seen in Fig. 2 where the spectrum at infinity was recorded. These absorbance values obtained at the end of the reaction are related to the initial concentrations of ampicillin and metal ion. Fig. 3 shows the absorbance values at infinity of kinetic mixtures with different mole ratio. We can see that the break point appears at a mole fraction value of ampicillin equal to 0.67. This value corresponds to a theoretical value for a 2:1 mole ratio. It suggests that at the end of the reaction a product, P with peak absorption at 285 nm, was formed by the binding of two molecules of an assumed ligand, produced as a result of ampicillin decomposition, to the Cd(II) ion(2:1). The shape of the plot in Fig. 3 also demonstrates that the forma-

Fig. 3. Job's plot using absorbance values measured at the end of the reaction (24 h) at 20°C. The sum of the reactants was 2.5×10^{-4} M.

tion of the product occurs in a complete reaction, showing that the absorbance values are proportional to the reagent which is not present in excess.

At the end of the reaction, under the experimental conditions used, only the above mentioned 2:1 compound was formed. This fact was confirmed by Coleman's graphic test which was positive for a single absorbent species (Fig. 4). Thus, we applied the test to the spectrophotometric data

Fig. 4. Computer-assisted test for one species in the cadmium-ampicillin system, based on the absorbance data taken after 24 h of reaction, infinity time. (A_{ij} is the absorbance value of a solution j at a wavelength i).

corresponding to two series of methanolic solutions with varied concentration of reagents and constant mole ratios (ampicillin: Cd) at 2:1 and 2.3:1, respectively. We obtained a family of lines radiating from the origin when A_{ij} values were plotted vs. A_{285j} , as can be seen in Fig. 4. This group of lines agrees with Beer's law throughout the entire range of ultraviolet wavelengths, and gives evidence that at the end of the reaction a single reaction product is formed. Taking this fact into account and that absorbance due to excess ampicillin is negligible at the wavelength used. We can suppose that absorbance at infinity time is produced exclusively by the reaction product, P. Thus, the molar absorption coefficient, ϵ_p , was determined from the absorbance values at infinity time of kinetic solutions in the presence of excess ampicillin (from 4:1 to 16:1). The concentration of the product, P, was assumed to be equal to that of the Cd(II) ion, i.e. the reagent available in lower amounts in all kinetics experiments. The average value obtained for ϵ_p was $18\,162 \pm 276$ l mol⁻¹ cm⁻¹. The wavelength of maximum absorption (at 285 nm) and the value of the molar absorption coefficient can be associated with the formation of the penamaldate derivative of ampicillin [9–11] (formula 1 in Scheme 1).

This result is according to stoichiometry, L₂Cd(II), obtained by analyzing the isolated solid. The elemental analysis results of the compound obtained are consistent with the empirical formula: Cd^{II} (L²⁻)₂ (H₂O)₄, 989.30 g mol⁻¹. The two atoms of sodium probably form a salt through the carboxylate group. In addition, the spectrum UV as well as the molar absorption coefficient at 285 nm (1.9×10^4 l mol⁻¹ cm⁻¹) were the expected values according to the study made in solution.

The IR bands are consistent with the proposed structure. The characteristic band of the carboxylic group is observed at 1603 cm⁻¹ (ν_{as} COO⁻) and at 1385 cm⁻¹ (ν_s COO⁻). Moreover, the distance between the two bands, 218 cm⁻¹, is similar to that observed in the IR spectrum of the sodium salt of ampicillin. This fact justifies the presence of the sodium ion in the molecule of reaction product. The C=O (β -lactam) absorption is not observed near 1780 cm⁻¹.

Scheme 1. Fragmentation of the degradation product.

Nonetheless, a band appears at 1672 cm^{-1} , which can be attributed to an ester group. It indicates that the $\text{C}=\text{O}$ β -lactam is esterified in the ampicillin degradation product. The presence of the ester group is also confirmed from the $^1\text{H-NMR}$ spectrum, in which absorption at 3.4 ppm can be assigned to the protons of the methoxyl group [8]. In the $^{13}\text{C-NMR}$ spectrum a signal at 170.1 ppm can be observed. This signal relates to the carbon from the β -lactamic carbonyl group, which appears in ampicillin at 175.5 ppm [14]. This implies the breaking of the ampicillin molecule.

Fig. 5a shows the electron impact mass spectrum of the isolated solid at the end of the reaction. The proposed fragmentation mechanism for the forma-

tion of ion fragments with higher stability (m/z 233, 201 and 101) is depicted in Scheme 1. Aside from the above fragments, it is possible that the peak at m/z ratio 465 is probably due to the binding of two fragments (m/z 233) with the loss of a proton. This is not surprising if we take into account the high stability of fragment m/z 233. Ion fragments of m/z 261 would result from the loss of a $\text{R}-\text{C}=\text{O}$ group by the ligand molecule. Finally, the peak at m/z 344 can be attributed to a fragment of m/z 261 which remains linked to Cd(II) ion, losing a methoxyl group. The m/z values of the ion fragments are in agreement with the proposed formula for both the reaction product, P, and the ligand, L, the latter arising from ampicillin methanolysis.

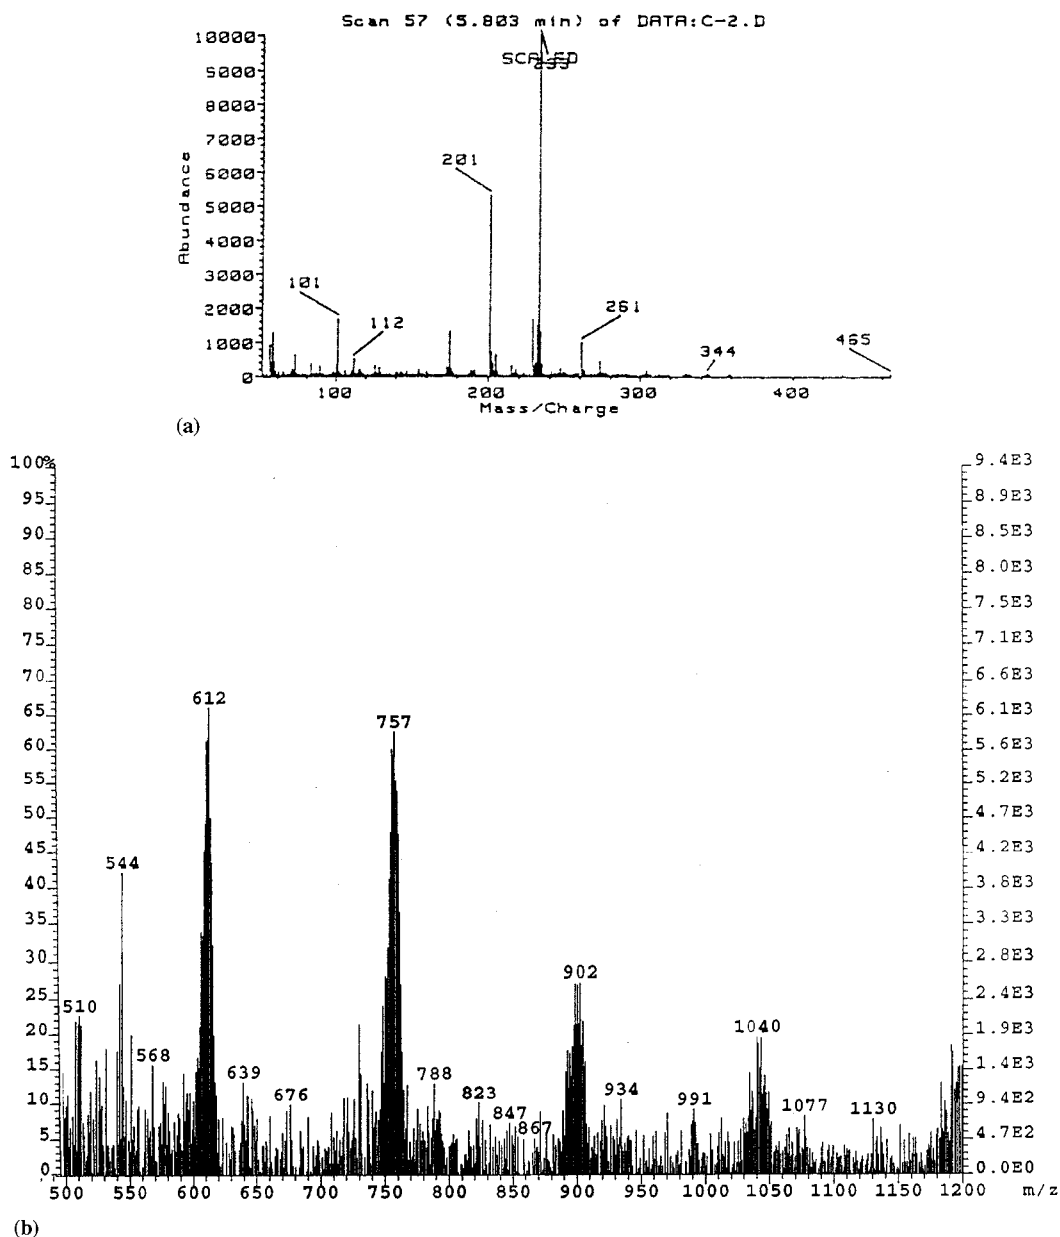

Fig. 5. (a) Mass spectrum (electron impact) of degradation product of ampicillin. (b) Mass spectrum (LSIMS) of the solid in glycerol.

Spectrum FAB⁻ (Fig. 5b) presents a series of signals with a distribution of isotopic peaks which are the expected for the proposed formula. Cd isotopes contribute in an essential way to such distribution. If we take into account that the most

abundant Cd isotope has a mass of 114, the peak at a value m/z 991 can be related to a molecular ion from the isolated compound with a molecular weight of 989.3 g/mol, as mentioned previously. The highest spectrum peak at m/z 612 could

Initial Cd(II) concentration: 1 · 10⁻⁴ M.

correspond to the ion fragment resulting from the loss of a ligand molecule (with a mass of 379.4) by the molecular ion. The peak at 757 can be related to a complex molecule which has lost a fragment of m/z 233 (formula II in Scheme 1) plus a proton. The fragment of m/z 233 is the most stable when the molecule is ionized by electron bombardment. Therefore, the LSIMS spectrum provides additional information to that obtained from the electron impact spectrum, both are in accordance with the proposed formula for product P.

Once the empirical formula and the molar absorption coefficient at maximum absorption (285 nm) for the single reaction product of ampicillin in presence of cadmium ions was determined, we studied the kinetic formation of the product P. In order to do so, we measured the absorbance (285 nm) of methanolic mixtures of ampicillin and metal at different times. The initial rate values (v_{obs}) of the kinetic process were calculated for each experiment giving the following equation:

$$v_{\text{obs}} = \frac{dA}{dt} \frac{1}{\epsilon_p} \quad (1)$$

where dA/dt is the slope of the linear plot of the initial absorbance data vs. time, and ε_p, as noted above, equals 1.82 × 10⁴ l mol⁻¹ cm⁻¹. The values of v_{obs}, dA/dt, and the linear determination coefficient, r², were calculated by fitting the absorbance–time plots, (Table 1).

The v_{obs} values were related to the initial concentration of ampicillin, as shown in Fig. 6a. It indicates that the initial rate of the process decreases when antibiotic concentration increases, at high concentrations of ampicillin, the rate tends to become constant. This saturation effect is also observed with respect to the metal ion as shown in Fig. 6b. Under conditions of excess ampicillin (> 1000 times), a constant rate was observed. Thus, in this case a linear plot of absorbance vs. time is obtained for all the reaction time. This plot has not been included due to its simplicity.

To explain the saturation curves (Fig. 6) we propose a scheme for the reaction where it is assumed that the formation of two complexes of ampicillin, S, and cadmium ion, M. The proposed scheme is described in Eq. 2:

where P is the reaction product. The appearance rate of this product can be written as:

$$\frac{d[P]}{dt} = k_0 + k[SM] \quad (3)$$

The values of k (the first order constant with respect to SM) and of K_c (the formation constant for the 2:1 complex (S₂M) from the 1:1 complex (SM)) were calculated following the kinetic scheme given above, where k₀ is the lower rate for

Fig. 6. (a) Plot of v_{obs} vs. substrate concentration. $[M] = 1 \times 10^{-4} \text{ mol dm}^{-3}$. (b) Plots of v_{obs} vs. metal ion concentration: $[\text{Ampicillin}] = 1 \times 10^{-4} \text{ mol dm}^{-3}$. Temperature = 20°C .

ampicillin degradation and can be associated to the non-catalyzed reaction rate and/or to antibiotic degradation coordinated to metal complex 2:1 (S_2M). Its value, which corresponds to the rate asymptotic value of the curve in Fig. 6a, has been obtained in a separated kinetic experiment with a large excess of ampicillin (2000 times). Under these conditions, the rate was constant $1.41 \times 10^{-7} \text{ mol l}^{-1} \text{ min}^{-1}$.

Formation of compounds SM was assumed to be faster than their decomposition; ampicillin concentration, which was much higher than cadmium ion concentration, remained virtually constant. The equilibrium constant was therefore written as:

$$K_c = \frac{[\text{S}_2\text{M}]}{[\text{SM}][\text{S}]_T} \quad (4)$$

The concentration of SM was expressed as:

$$[\text{SM}] = \frac{[\text{M}]_T - [\text{P}]}{1 + K_c[\text{S}]_T + \frac{1}{K_1[\text{S}]_T}} \quad (5)$$

where $[\text{M}]_T$ is the initial cadmium concentration.

In practice, the concentration of the product $[\text{P}]$ and the concentration of free cadmium ion were very small at the beginning of the reaction, and, as such, could be neglected in the calculations. Thus, the initial rate of appearance of the product, v_{obs} , could be expressed as:

$$\frac{1}{v_{\text{obs}} - k_o} = \frac{1}{k[\text{M}]_T} + \frac{K_c}{k[\text{M}]_T} [\text{S}]_T \quad (6)$$

Taking these equations into account, the first order rate constant for formation of product k , and the association constant K_c , were obtained from the kinetic data of solutions in which the concentration of Cd(II), $[\text{M}]_T$, was kept constant as the concentration of ampicillin was varied (provided that $[\text{S}]_T$ was much greater than $[\text{M}]_T$).

Fig. 7 shows the kinetic data plotted according to Eq. (6). The curve was fitted using the least squares method. The value of the linear determination coefficient (r^2) was equal to 0.994. The first order rate constant (k), calculated from the intercept (2.583×10^5) in Fig. 7, was 3.87×10^{-2}

Fig. 7. Plot of $1/v_{\text{obs}} - k_o$ vs. antibiotic concentration, $[S]_T$.

min^{-1} at 20°C . Considering the first order rate constant and the slope, we calculated the association constant (K_o), which was $10^{3.23} \text{ l mol}^{-1}$.

On the other hand, the methanol in the medium may be involved in nucleophilic attack on the ampicillin molecule by the β -lactam carbonyl group. Such a step would be favored considering the arrangement of the cadmium ion to the ampicillin molecule. The methanol, due to its marked basicity ($\text{p}K_a > 9$), would act as a nucleophilic catalyzer, leading to the formation of the corresponding unstable penicilloic ester [13]. The breakdown of this intermediate ester would be expected to be slower than the rate of formation, since the $\text{p}K_a$ of methanol is higher than 14 [12].

In addition, this ester (intermediate derivative) appears to disrupt the thiol ring, an event that would lead to the formation of the α -methyl penamaldic derivative [12], a compound compatible with peak absorption at around 280 nm.

Much remains to be clarified as to the chemical mechanism of metal ion catalysis in the reaction of ampicillin degradation. Nevertheless, we can submit that the catalytic effect in methanolysis of β -lactam catalysed by the metal ion appears to be closely related to the different arrangement of the metal ion.

Abstract

Simple and sensitive spectrophotometric methods are described, for the first time, for the determination of sodium salts of phenobarbital (1), thiopental (2), methohexital (3) and phenytoin (4). The methods are based on the reaction of these drugs as n -electron donors with the σ -acceptor iodine and various π -acceptors: 7,7,8,8-tetracyanoquinodimethane; 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; 2,3,5,6-tetrachloro-1,4-benzoquinone; 2,3,5,6-tetrafluoro-1,4-benzoquinone; 2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone; tetracyanoethylene and 2,4,7-trinitro-9-fluorenon. Depending on the solvent polarity, different coloured charge-transfer complexes and radicals were developed. Different variables and parameters affecting the reactions were studied and optimized. The formed complexes were examined by UV/VIS, infrared and $^1\text{H-NMR}$. Due to the rapid development of colours at ambient temperature, the obtained results were used on thin layer chromatograms for the detection of the investigated compounds. Beer's plots were obeyed in a general concentration range of 1–400 $\mu\text{g ml}^{-1}$ for the investigated compounds with different acceptors. Interference from some co-formulated drugs was also studied. No interference was observed due to additives commonly present in the pharmaceutical preparations. The proposed methods could be applied successfully to the determination of the investigated compounds in pure and pharmaceutical dosage forms with good accuracy and precision, the recoveries ranged from 98.7 ± 0.5 to $101.1 \pm 0.5\%$. The results were compared favourably with the official methods. © 1997 Elsevier Science B.V.

Keywords: Spectrophotometry; Charge-transfer complexes; Barbiturates and phenytoin; Pharmaceutical analysis

1. Introduction

Barbiturates are widely used as sedative hypnotic drugs in a wide variety of conditions and are also employed to produce anesthesia [1]. Phenytoin is one of the cyclic ureides which related in structure to the barbiturates. It was reported to be the least hypnotic, most strongly anticonvulsant and most effective against grand mal [1].

Different methods for the determination of the sodium salts of barbiturates and phenytoin have been reviewed [2–5]. Few direct spectropho-

metric methods have been reported for the determination of the investigated compounds [6–9]. Other reported methods involve, titrimetry [10–13], gravimetry [13,14], stripping voltametry [15] and chromatography [9,16–18]. Quantification of phenytoin sodium in combination with either phenobarbital free acid or phenobarbital free acid, caffeine citrate and atropine sulphate (anti-sacer compositum tablets) cannot be achieved by adopting the B P 1993 method as these substances will interfere through co-extraction. In addition, the analysis of phenytoin sodium tablets is not specified by USP 23 NF 18.

With the exception of HPLC methods, most procedures suffer from some drawbacks. The British Pharmacopeia titrimetric and gravimetric methods are time consuming and depend upon measuring fairly concentrated solutions. They lack simplicity, sensitivity and selectivity. In addition, they could not be used for the determination of the dosage forms containing barbiturate free acids in conjunction with those of sodium salts. Therefore, it was considered worthwhile to develop rapid and selective procedures suitable for their routine quality control analysis. Moreover, the existing spectrophotometric methods cannot be used to distinguish between the sodium salts and the corresponding free acid derivatives. There is a need for selective spectrophotometric methods which could be utilized in detecting and distinguishing between the sodium salts and the free acids without the need for any pretreatment or prior separation.

The molecular interactions between electron donors and acceptors are generally associated with

the formation of intensely coloured charge-transfer complexes [19], which absorb radiation in the visible region. A variety of electron donors [19–22] were reported to yield charge-transfer complexes with various acceptors. Rapid formation of the complexes makes their utility in photometric analysis simple and convenient. Barbiturates and phenytoin sodium salts have not yet been investigated as n -electron donors to form charge-transfer complexes and radical ions with iodine and different π -acceptors.

This paper describes, for the first time, the application of iodine, tetracyanoquinodimethane, tetracyanoethylene and dichlorodicyanobenzoquinone, which were selected according to their high electron affinities, to the spectrophotometric determination of the sodium salts of phenobarbital, thiopental, methohexital and phenytoin in pure samples and in dosage forms. Interference from commonly encountered substances was also studied. The structures of the compounds studied are given in scheme 1.

Phenobarbital Sodium (1)

Scheme 1.

2. Experimental

2.1. Apparatus

A Perkin-Elmer 3B UV/VIS, Norwalk, CT and a Uvidec-320, Tokyo, Japan. Spectrophotometers with 1-cm matched quartz cuvettes. Infrared Spectrometer IR-470, Shimadzu, Japan. $^1\text{H-NMR}$ Spectrometer, EM-360, 60 M Hz NMR Spectrometer, Varian Instrument Division, Palo Alto, CA. The geometries of phenobarbital anion, TCNE and both together in all possible spatial positions were fully optimized at the full self-consistent field (SCF) level by using MNDO/3, a general molecular orbital package implemented with molecular mechanics software MMX-PC [23].

2.2. Materials and reagents

All solvents used were of analytical reagent-grade. Phenobarbital sodium: El-Nasr for Pharmaceutical Chemicals, Cairo, Egypt; thiopental sodium: Egyptian International Pharmaceutical Industries, Cairo, Egypt; methohexital sodium: Lilly Research Center, Windlesham, Germany; phenytoin sodium: The Nile Company for Pharmaceuticals and Chemical Industries, Cairo, Egypt. Iodine: resublimed, Riedel De-Haen AG, Germany, 8.5 mg ml^{-1} in 1,2-dichloroethane, the solution was found to be stable for at least one week at 4°C . 7,7,8,8-Tetracyanoquinodimethane (TCNQ): Aldrich Chemical, Milwaukee, WI, 1 mg ml^{-1} in acetonitrile, the solution was found to be stable for at least one week at 4°C . Tetracyanoethylene (TCNE): Nacalai Tesque, Kyoto, Japan, 1 mg ml^{-1} in acetonitrile, prepared fresh daily. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (DDQ): Merck-Schuchardt, Munich, Germany, 2 mg ml^{-1} in methanol, the solution was prepared fresh daily. 2,3,5,6-Tetrachloro-1,4-benzoquinone (Chloranil), Prolabo, Rhone-Poulenc, France. 2,3,5,6-Tetrafluoro-1,4-benzoquinone (Fluoranil): Aldrich-Europe (Beerse, Belgium). 2,5-Dichloro-3,6-dihydroxy-1,4-benzoquinone (Chloranilic acid), BDH Chemicals, Poole, UK. 2,4,7-Trinitro-9-fluorenon (TNF), Fluka, Switzerland. Fluoranil,

chloranil, chloranilic acid and TNF, each 5 mg ml^{-1} in acetonitrile, were prepared fresh daily.

2.3. Pharmaceutical formulations

The following commercial dosage forms were subjected to the analytical procedures: (1) sominaletta ampoules (The Alexandria Company for Pharmaceuticals and Chemical Industries, Alexandria, Egypt), labelled to contain phenobarbital sodium 40 mg per 1 ml ampoule; (2) thiopental sodium vials (Egyptian International Pharmaceutical Industries, Cairo, Egypt), labelled to contain 500 mg thiopental sodium per vial; (3) brietal vials (Lilly Research Center, Windlesham, Germany), labelled to contain 500 mg methohexital sodium per vial; (4) epanutin capsules (The Nile Company for Pharmaceuticals and Chemical Industries, Cairo, Egypt), under license from Parke-Davis, Detroit, MI), labelled to contain phenytoin sodium 100 mg per capsule; (5) epanutin with phenobarbital capsules (The Nile Company for Pharmaceuticals and Chemical Industries, Cairo, Egypt, under license from Parke-Davis, Detroit, MI), labelled to contain phenytoin sodium 100 mg and phenobarbital free acid 50 mg per capsule; and (6) antisacer compositum children tablets (Swiss Pharma, Cairo, Egypt, under license from Wander, S.A., Berne, Switzerland), labelled to contain phenytoin sodium 50 mg , phenobarbital free acid 25 mg , potassium bromide 200 mg , caffeine citrate 10 mg and atropine sulphate 0.2 mg per tablet.

2.4. Procedures

2.4.1. Preparation of standard stock solutions

Into a 50-ml calibrated flask, $100\text{--}200 \text{ mg}$ of the drug was weighed accurately and dissolved in 2 ml methanol, completed to volume with the same solvent (in case of DDQ), with 1,2-dichloroethane (in case of iodine) and with acetonitrile (in case of other acceptors) and diluted quantitatively to obtain the suitable final concentration listed in Table 1.

Table 1

Linear calibration limits and molar absorptivity values for the reaction of the investigated compounds with various acceptors

Acceptor/donor	Linear limits $\mu\text{g ml}^{-1}$, $\epsilon/10^3 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$			
	Phenobarbital	Thiopental	Methohexital	Phenytoin
Iodine	25–150, 1.32	25–100, 1.63	25–150, 1.36	25–200, 0.73
TCNQ	5–20, 11.40	1–10, 25.20	5–250, 14.10	5–20, 14.00
TCNE	10–75, 2.72	5–50, 4.80	10–75, 2.66	10–75, 3.76
DDQ	10–100, 1.76	10–100, 2.21	10–100, 1.85	10–100, 2.09
TNF	10–150, 1.07	10–150, 1.34	10–150, 1.12	10–150, 1.27
Chloranil	50–400, 0.44	50–400, 0.55	50–400, 0.45	50–400, 0.32
Fluoranil	25–300, 0.71	50–400, 0.37	10–100, 2.15	25–200, 3.21
Chloranilic acid	25–150, 0.98	25–150, 1.19	25–150, 1.03	25–150, 1.17

The solvents used were 1,2-dichloroethane for iodine, methanol for DDQ and acetonitrile for other acceptors and the drugs were as their sodium salts.

2.4.2. General procedure

Aliquot volumes of standard stock solutions, containing 10–4000 μg drug was transferred to 10-ml calibrated flasks. One millilitre of the reagent was added and diluted to volume with the same solvent (in case of DDQ), with 1,2-dichloroethane (in case of iodine) and with acetonitrile (in case of other acceptors). The absorbances of the resulting solutions were measured at the wavelength of maximum absorption after the appropriate times, listed in Table 2, at $25 \pm 5^\circ\text{C}$ against reagent blanks treated similarly.

2.4.3. Analysis of tablets and capsules

The contents of 20 tablets or capsules of each drug were weighed and powdered or evacuated and a quantity of the powder $\equiv 100 \text{ mg}$ was transferred into a 50-ml calibrated flask, dissolved in 2 ml of methanol, swirled and sonicated for 2 min, completed to volume with the corresponding solvent (as in standard solution), shaken well for 15 min and filtered, rejecting the first portion of the filtrate and then proceeded as in Section 2.4.2.

2.4.4. Analysis of ampoules

A volume of the mixed 10 ampoules containing about 50 mg drug was transferred into a 50-ml calibrated flask and proceeded as directed in Section 2.4.3.

2.4.5. Analysis of vials

Into a 50-ml calibrated flask, 50 mg of the drug was accurately weighed and then proceeded as in Section 2.4.3.

2.4.6. Preparation of the complexes for infrared measurements

To 2 ml of 0.05 M drug in methanol, 2 ml of 0.05 M of each acceptor in the appropriate solvent (methanol for DDQ, 1,2-dichloroethane for iodine and acetonitrile for other acceptors), was added in a round bottom flask containing $\approx 30 \text{ ml}$ of the appropriate solvent and stirred for 30 min. The solvent evaporated under reduced pressure and the resulting oily residues were dried over calcium chloride.

2.4.7. Solutions for $^1\text{H-NMR}$ measurements

30 mg of each drug, scheme 1, were dissolved in 1 ml $\text{d}_6\text{-DMSO}$ and 1 ml containing an equimolar amount of the acceptors in the same solvent was added and used directly for $^1\text{H-NMR}$ measurements.

3. Results and discussion

3.1. Reaction with iodine

1,2-Dichloroethane was found to be an ideal solvent for the formation of tri-iodide ion pair (inner complex). Methylene chloride, chloroform

^a Using phenobarbital sodium as donor.

^b High blank readings.

^c The same readings were obtained with methanol.

and carbon tetrachloride produced lower absorbance readings. Polar solvents were found to be unsuitable as their blanks with iodine gave high absorbances.

The violet colour of iodine in 1,2-dichloroethane (λ_{\max} at 240 and 515 nm) immediately changed into lemon yellow (λ_{\max} at 293 and 363 nm) upon the addition of any of the investigated compounds typical for charge-transfer complexes (Fig. 1). The consistency of these two bands, in spite of the structural variations among the different studied compounds, is probably due to the common origin of the transition in n-electron transfer from the sodium salts of barbiturates and phenytoin to the σ -acceptor iodine. The high intensity of the charge-transfer bands are common to complexes of n-donors with iodine [19]. The appearance of absorption peaks at 293 and 363 nm was attributed to the formation of a charge transfer complex between the investigated drugs and iodine having an ionized structure $DI^+ \dots I_3^-$, taking into account that the spectrum of I_3^- in 1,2-dichloroethane shows two absorption maxima at 293 and 363 nm ($\epsilon = 45\,800$ and $25\,000 \text{ dm}^3 \text{ mol}^{-1} \text{ cm}^{-1}$, respectively). This complex should originate from an early intermediate outer complex $D \dots I_2$. From the investigated compounds and iodine, only thiopental sodium absorbs at 293 nm, other compounds have no absorption at 293 and 363 nm. Therefore, measurements are carried out at 363 nm for thiopental sodium due to interfer-

ence from its native uv absorption and at 293 nm for other compounds.

3.2. Reaction with π -acceptors

The interaction of the investigated compounds with certain polyhalo and polycyanoquinones π -acceptors in non-polar solvents (such as 1,2-dichloroethane), Table 2 was found to produce coloured charge-transfer complexes with low molar absorptivity values. In polar solvents, such as acetonitrile, (Table 2 and Fig. 2), complete electron transfer from the donor to the acceptor moiety takes place with the formation of intensely coloured radical ions with high molar absorptivity values, according to the following scheme:

Fig. 1. Absorption spectra of: phenobarbital sodium (1); thiopental sodium (2) and their reaction products with iodine (3,4), using 25, 10, 175 and 70 $\mu\text{g ml}^{-1}$ respectively, all in 1,2-dichloroethane.

The dissociation of the (D–A) complex is promoted by the high ionizing power of the solvent acetonitrile [24].

The resulting bands of the named compounds with π -acceptors are similar to the maxima of radical anions of the acceptors obtained by iodide reduction method and coincide with the values reported in the literature [24].

The predominant chromogen with TCNQ in acetonitrile is the bluish-green coloured radical anion which exhibits strong absorption maxima at 842, 825, 762, and 742 nm. These bands may be attributed to the formation of the radical anion $\text{TCNQ}^{\cdot-}$, which was probably formed by the dissociation of an original donor–acceptor (D–A) complex with the investigated compounds in acetonitrile. With TCNE, the characteristic shaped absorption band of TCNE radical anion with reported maximum in acetonitrile at 432 nm was not formed. Instead, droplet at 394 and 414 nm was formed which corresponds to 1,1,2,3,3-pentacyano propenide (PCNP) anion. From the quantitative point of view, PCNP anion is preferable to TCNE anion in having high molar absorptivity [24].

The formation of radical anions were possible in methanol, ethanol, propan-1-ol, propan-2-ol or dimethylsulphoxide. However, non-linear response compared with acetonitrile was observed. The latter was considered as an ideal solvent as it also afforded maximum sensitivity due to its high dielectric constant which promotes maximum yield of radical anions in addition to its high solvating power of the reagents. Methanol gave maximum sensitivity in case of DDQ, inspite chloroform and carbon tetrachloride could also be used.

The relative sensitivity of the seven acceptors in analytical work may be compared by their ϵ -values. TCNQ, TCNE, DDQ and iodine, exhibiting the highest ϵ -values related to their high electron affinities were selected for further quantitative work. The weak and small values in cases of TNF, chloranil and fluoranil may be explained on the basis of insufficient ionization of these relatively weak π -acceptors which possess lower electron affinities [19].

The application of the Job's method [25] of continuous variation indicated 1:1 ratio for all the investigated compounds with all acceptors stud-

Fig. 2. Absorption spectra of the reaction products of phenobarbital sodium (15 , 83 and $67 \mu\text{g ml}^{-1}$) with each of TCNQ (1), DDQ (2), TCNE (3) respectively, (2) in methanol, (1 and 3) in acetonitrile.

ied. This indicates that only one center is responsible for the complex formation. These findings are supported by the reaction of the sodium salts with hydrochloric acid where they were found to be titrated as monobases.

3.3. Reagent concentration

The results for variation of reagent concentration indicated that 1 ml of either 0.05% iodine, 0.1% TCNQ or TCNE, 0.2% chloranilic acid, 0.4% DDQ 0.5% chloranil or fluoranil, 1% TNF are suitable. The higher concentrations used of the reagents may be useful for rapidly reaching equilibrium, thus minimizing the time required to attain maximum absorbance readings at the corresponding maxima.

3.4. Reaction time

The optimum reaction time was determined by following the colour development at ambient temperature ($25 \pm 5^\circ\text{C}$). Complete colour development was attained instantaneously or after 5 – 30

min with all compounds investigated (Table 2). The colours remain stable for at least a further 30 min.

3.5. Infrared and $^1\text{H-NMR}$ studies

The formation of donor–acceptor complexes was confirmed by both IR and $^1\text{H-NMR}$ techniques.

The majority of infrared measurements on such complexes have been concerned with shifts in the vibrational frequencies in donor or acceptor (or both). Decreases in the vibration frequency of a particular band have been used as evidence for a particular site of a charge-transfer interaction [19]. The infrared spectra of the complexes show some differences compared with the sum of the spectra of the two components. This was used to distinguish between weak charge-transfer complexes and the products of electron transfer or proton-transfer reactions [19].

The IR bands of the C–O or the C–S in the complexed molecules are shifted $\approx 20 \text{ cm}^{-1}$ lower than the absorption of the free compounds.

This indicates a decrease in the stretching force constant and favours coordination to the oxygen or sulphur atom. Moreover, the absorption frequencies assigned to the C–N stretches are shifted $\approx 20 \text{ cm}^{-1}$ to higher frequencies. These shifts are expected if the oxygen or sulphur atoms are the donor centers. Similar changes in the IR spectra of the donor upon complexation have been reported for several carbonyl compounds [26]. Dimethylacetamide and thioamides were reported to bind the iodine by oxygen or sulphur respectively [27].

In $^1\text{H-NMR}$, generally, the protons of the donor are shifted to a lower field (paramagnetic shift). The $^1\text{H-NMR}$ spectra of the complexes of the investigated compounds, with different acceptors were recorded in d_6 -DMSO together with the spectra of the free compounds.

The aromatic protons of the complexed phenobarbital sodium are shifted to a lower field ($\Delta\delta = 0.15 \text{ ppm}$) and the methyl and methylene protons are shifted (from 0.1 to 0.2 ppm). In the complexed thiopental sodium, 4- CH_3 , 1- CH_2 and 3- CH are shifted to a lower field ($\Delta\delta = 0.15 \text{ ppm}$). In the complexed methohexital sodium, 8- CH_2 and 11- CH are shifted to a lower field ($\Delta\delta = 0.2 \text{ ppm}$), while the other protons remain unchanged. In the complexed phenytoin sodium, the aromatic protons are shifted ($\Delta\delta = 0.07 \text{ ppm}$). Hence, as stated in similar reports [21,22], it could be deduced that the charge-transfer may proceed from the anion formed from the dissociation of ONa or SNa of barbiturates or phenytoin.

3.6. Molecular modelling, molecular mechanics and proposed interaction mechanism

To study the sites of interactions between the donor and the acceptor, the donor and the acceptor were minimized alone and together by computation. In this work, molecular modelling and mechanics for phenobarbital sodium and TCNE as examples for donors and acceptors respectively led to the following:

(1) In the case of electroneutral fully optimized molecules, phenobarbital sodium attacks TCNE at the area of C=C. Phenobarbital sodium has two

possible donating entities (O^- and the N–1 by its lone pair of electrons). It is acceptable that the electrostatic surface area of two molecules, such as phenobarbital sodium and TCNE, can be the mathematical sum of their individual total surface areas (S_T). By this calculation, the hypothetical sum will be 231 \AA^2 (S_T of phenobarbital anion) + 145 \AA^2 (S_T of TCNE) = 376 \AA^2 . Strong electrostatic attraction at the mentioned centers between the two molecules when minimized together was found to result in an actual total surface area of 351 \AA^2 , i.e. 25 \AA^2 less than the hypothetical sum.

(2) The distance between the O^- of phenobarbital anion and each of the two carbons of TCNE (C=C) equals 2.83 and 3.14 Å.

(3) The distance between the N–1 of phenobarbital anion and each of the two carbons of TCNE (C=C) equals 2.92 and 3.26 Å.

From these studies it could be concluded that there is a strong interaction between phenobarbital anion, the donor with TCNE and the acceptor, guided by the reduced electrostatic surface (25 \AA^2). Again, the source of electron donation can be better from the O^- than the N–1 of phenobarbital anion mediated by the distance between each of these atoms and the acceptor.

3.7. Quantification

Under the specified reaction conditions, the molar absorptivity at the λ_{max} was found to be a function of concentration of the investigated drugs. In all cases studied, Beer's law plots ($n = 10$) were linear with very small intercepts (-0.0276 to $+0.0257$), slopes ranged from 0.009 to 0.097 in the concentration ranges given in Table 1. The correlation coefficients ranged from 0.9950 to 0.9998. The confidence intervals for slopes and intercepts were calculated. The intervals for intercepts were tested at 95% confidence limits and 8 df and the results show that there were no significant difference between zero and intercepts.

The mean of eight replicate analyses of solutions of the studied compounds at the concentration limits listed in Table 1 gave relative S.D. values up to 1.8%. This level of precision of the

method is adequate for the quality control analysis of the studied drugs.

3.8. Specificity and interference

The proposed procedures have the advantage that most of the assays are performed in the visible region away from uv-absorbing interferents that might be co-extracted from dosage forms. Owing to the basic character of the investigated compounds, they can act as strong n-electron donors ($pK_a = 11-12$), the reactions were found to be specific for the sodium salts derivatives in the presence of the structurally related barbituric, thiobarbituric, phenobarbital and methylphenobarbital free acids ($pK_a = 6-8$).

Interference studies were carried out in order to investigate the effect of commonly encountered compounds that present in barbiturate dosage forms. No interference was observed from phenobarbital, methylphenobarbital free acids, paracetamol, atropine sulphate, thiocol, potassium bromide, ergotamine tartarate, meprobamate and caffeine citrate. On the other hand, chlorpheniramine maleate being basic enough ($pK_a = 9.2$) was found to interfere with the assay procedures, Table 3.

3.9. Analysis of pharmaceutical formulations

The obtained high intensity absorption bands and the very low reagent backgrounds make these procedures suitable for the routine quality control analysis of the investigated compounds with minimum interference. The proposed and official methods were applied to the determination of tablets, capsules, ampoules and vials. The obtained mean values (\pm S.D.) of the labelled amounts ranged from 98.7 ± 0.5 to 101.1 ± 0.5 , Table 4. In the 't' and 'F' tests, no significant differences were found between the calculated and theoretical values (95% confidence) of both the proposed and official methods. This indicates similar precision and accuracy.

3.10. Identification on thin-layer chromatograms

The different colours developed from the interaction of the investigated compounds with the different acceptors could be used on thin layer chromatograms for detection and differentiation of these compounds (from their R_f values), Table 5. So spraying with iodine solution colours all the spots yellow while with TCNQ spray reagent, bluish-green radical anions spots are observed. The colours obtained for other spray reagents are given in Table 5. In general, the order of de-creas-

ing sensitivity is: TCNQ, TCNE, DDQ, iodine, fluoranil, chloranil chloranilic acid, bromanil and TNF. The detection limits with TCNQ (the most sensitive reagent) ranged from 0.5 to 5 μg per 50 mm^2 for the studied compounds. The rapid development of colours at room temperature with non-corrosive reagents, the variation of colour shades, the sensitivity and stability of colours suggest obvious use of these acceptor reagents to supplement existing methods for the detection of the sodium salts of barbiturates and phenytoin on chromatograms.

4. Conclusions

The proposed spectrophotometric methods are simpler, time saving and more sensitive than the

British Pharmacopeia gravimetric and titrimetric methods. In addition, they can be applied to the quality control analysis of the sodium salts of phenobarbital, thiopental, methohexital and phenytoin pure or in combination with other drugs. TCNQ exhibiting the highest ϵ values with all the studied compounds could be considered the most suitable one for further work.

Moreover, the proposed methods could be considered superior to the British Pharmacopeia 1993 as they could be used successfully for the analysis of phenytoin sodium in the presence of phenobarbital free acid (epanutin with phenobarbital capsules and antisacer compositum tablets). In addition to ultraviolet-visible spectrophotometry, infrared and ¹H-NMR spectroscopy could also be used to study the possible site of interaction between the donor and acceptor.

Received 7 April 1997; received in revised form 30 July 1997; accepted 5 August 1997

Abstract

In the present study, an effective method is presented for the separation and preconcentration of uranium (VI) by solid phase extraction (SPE). For this purpose, U(VI) oxinate is formed by the reaction of U(VI) with 8-hydroxyquinoline and adsorbed onto the octylsilane (C-8) SPE cartridge. The analyte is completely eluted with chloroform and determined by differential pulse polarography. The SPE conditions were optimized by evaluating the effective factors such as pH, oxine concentration, type and concentration of buffer and masking agent. By the proposed method a preconcentration factor more than 100 was achieved. The average recovery of uranium (VI) oxinate (0.1 mg l^{-1}) was 99.8%. The relative standard deviation was 1.6% for seven replicate determinations of uranyl ion in the solution with a concentration $20 \text{ } \mu\text{g l}^{-1}$. Some concomitant ions such as Ca^{+2} , Mg^{+2} and Fe^{+3} which interfere in extraction or determination process of uranium were masked with EDTA in aqueous phase during the extraction process. The proposed method was successfully used for the determination of uranium in Caspian Sea and Persian Gulf water samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Uranium; Seawater; Solid phase extraction; Oxine; Chloroform; Trace analysis; Differential pulse polarography

1. Introduction

Considerable interest has developed in the determination of trace uranium in environmental sites as well as in facilities of the nuclear industry. Electroanalytical techniques have frequently been used for this purpose. In particular, adsorptive stripping voltammetry (ADSV) is becoming a widely accepted tool for ultra-trace measurement

of uranium [1–9]. While characterized by detection limit in the subnanomolar range, such procedure often suffer from interferences due to overlapping stripping peaks (from some co-existing metals). However, recently a direct and selective ADSV has been described [10,11]. A chemical separation of the trace uranium prior to analysis serves the dual purpose of:

- increasing its concentration to levels at which it can be reliably determined by differential pulse polarography.

* Corresponding author.

- removing it from the seawater matrices to enhance the polarographic selectivity.

One of the most popular separation and preconcentration methods in trace metal analysis involves the liquid–liquid extraction of the analytes. We have successfully used this technique followed by adsorptive differential pulse polarography for the determination of uranium in mineral ores [12]. Concentration factors of this technique are insufficient for ultra-trace analysis even using sensitive methods as well as differential pulse polarography. In an attempt to overcome these limitations a method which involves complexation of the metal ions with chelating agents followed by adsorption on octadecylsilane chemically bonded silica gel (ODS) [13] or activated carbon have been reported [14]. Although ODS has been used for the preconcentration of some trace metals from seawater [15,16]. This technique has never been used for the separation and preconcentration of uranium from seawater. The application of ODS solid phase cartridge to the separation and concentration of U(VI) from seawater and its differential pulse polarographic determination after elution from the solid phase with chloroform is reported here.

2. Experimental

2.1. Chemicals and reagents

Chloroform, tri-butylamine, perchloric acid, and 8-hydroxyquinoline (oxine) were from E. Merck p.a. grade. The supporting electrolytes used were tri-butylammonium perchlorate (tri-BAP) and tetrabutylammonium perchlorate (TBAP). Tri-BAP was prepared by gradual neutralization of tri-butylamine with perchloric acid while cooling the solution in iced water. Tri-BAP formed in slightly acid solution was filtered, then washed several times with double distilled water and dried in vacuum. The dried crystals were washed by normal hexane and evaporated the solvent. 400 mg solid phase extraction cartridges were from E. Merck.

Standard uranium solutions: A 10^{-3} M aqueous solution of $\text{UO}_2(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ from E. Merck was prepared as a stock solution. The standard solutions were prepared by successive dilution of this stock solution.

2.2. Apparatus

All voltammograms were recorded with a three electrode system. A polarograph E506 was used with an E505 VA Stand including a dropping mercury electrode from Metrohm (Switzerland) to plot the DP polarograms. Solid phase extractions were performed using vacuum waste collect adsorbex, SPU, E. Merck (Germany).

2.3. Electrodes

The reference electrode Ag/AgCl (sat.), TBACl (sat.) and TBAP 0.5 M in chloroform in separated compartment was directly immersed in the reaction cell. The working electrode were DME and the auxiliary electrode was a platinum wire.

2.4. Preconcentration procedure

(1) Evaluation of alkaline earth cations concentration in seawater: To a 25 ml portion of seawater were added 10 ml ammonia buffer, pH 10, and a few amounts of Erio chrom black T and titrated by a standard solution of $\text{Na}_2\text{H}_2\text{Y}$.

(2) Sample pre-treatment: Seawater samples were filtered through 25–50 and 4–5.5 μm sintered glass respectively. To 100–500 ml filtered seawater or standard solution of uranium (0.4 mg l^{-1}), were added 0.025 M plus a required excess amount (depending on the alkaline earth cations concentration) of $\text{Na}_2\text{H}_2\text{Y}$ and oxine up to 2×10^{-3} M. After 1 min stirring the pH was adjusted to 5.5 with HCl or NaOH (solution A).

(3) Solid phase extraction step: SPE cartridges were first conditioned by successive washing by 1 ml acetonitrile and 1 ml water. A 10 ml portion of oxine solution passed through over conditioned cartridges, hence the columns were saturated with oxine. The solution A was passed from SPE cartridge at about $2.5\text{--}3 \text{ ml min}^{-1}$. The cartridges were washed with 2 ml of the solution containing $\text{Na}_2\text{H}_2\text{Y}$, pH 5.5. The analyte was then eluted with 5 ml of chloroform and the eluate was collected in a 5 ml volumetric flask containing 2×10^{-4} M supporting electrolyte and 0.1 M oxine. The resulting solution was transferred into a polarographic cell for recording of the polarograms.

2.5. Polarography of uranium (VI) oxinate in chloroform

Polarographic characteristics of U(VI) in chloroform were described with detail in our previous work [12]. On the basis of the results obtained (calibration graph was linear over the range 0.5–80 μM with correlation coefficient of 0.998 and L.O.D. of 0.4 μM), the differential pulse polarographic measurement of U(VI)-oxinate in chloroform eluate may be done as follows:

Add 0.25 g of tri-BAP as supporting electrolyte to 5 ml chloroform eluate, bubble nitrogen presaturated with chloroform through the solution for 20 min, record the DP polarogram by sweeping the potential from 0.200 to -0.500 vs. reference electrode with scan rate of 5 mV s^{-1} , construct the standard addition calibration graph to determine uranium.

3. Results and discussion

3.1. Optimization of experimental conditions

Using 100 ml aqueous solution of 0.1 mg l^{-1} UO_2^{+2} , several experimental variables involve: type and quantity of solid phase, loading rate, concentration of oxine (HOX) in liquid phase as well as on SPE cartridge, pH of sample, type and concentration of buffer, type and volume of conditioning, washing and elution solutions were optimized.

Fig. 1. Effect of aqueous oxine concentration on the extraction efficiency from 100 ml of 0.1 mg l^{-1} of uranium.

3.2. Choice of solid phase cartridge

One of the reasonable ways for quantitative adsorption of the metal ions on the solid phase is the complexation of the metal ions with chelating agents and retention of the produced hydrophobic compounds on the non-polar solid phase. For this purpose we have chosen oxine as chelating agent and we have examined the efficiency of various columns such as octylsilane (C-8), octadecylsilane (C-18), phenyl bonded silica, and unmodified silica. The results obtained showed that C-8 (100–400 mg) cartridge has the most satisfactory behavior. Therefore in further experiments, we have used this type of solid phase cartridge.

3.3. Conditioning of solid phase

For this purpose, the cartridges were usually washed by methanol and water successively. The preliminary experiments in this work showed that successive washing by 1 ml acetonitrile and 1 ml water represent better results.

3.4. Choice of chelating agent

For solid phase extraction of U(VI), the use of a chelating agent is required. For this purpose we have chosen oxine and reasons are as follows.

(1) The uranium (VI) oxinate can be eluted from solid phase with organic solvents such as chloroform and dichloromethane.

(2) The uranium (VI) oxinate eluted, can be determined directly in chloroform by differential pulse polarographic method which has been previously developed by present authors [12].

3.5. Loading step

The preliminary experiment showed also that for quantitative extraction of uranium oxinate on a single column C-8 (400 mg), the concentration of the analyte must not be exceeded from 3 mg l^{-1} . In the light of extremely minute amount of uranium in seawater, and relatively great adsorptive capacity of the C-8 (400) column, no overloading problem is made, even for the processing of several liters of sample. The optimum loading rate was found 2.5–

Fig. 2. Effect of pH on uranium extraction efficiency from 100 ml of 0.1 mg l^{-1} of model solution. Oxine (HOX), $1.96 \times 10^{-3} \text{ M}$ and EDTA 0.025 M .

3 ml min^{-1} and had a little influence on the results. On the other hand we have investigated the optimum conditions for quantitative adsorption of the uranium oxinate on the solid phase.

Influence of oxine concentration: The presence of oxine on the solid and liquid phase and its abundance is an effective parameter on the extraction efficiency of U(VI). From the results obtained the most satisfactory and reproducible results were obtained when the solid phase was presaturated with oxine and over $2 \times 10^{-3} \text{ M}$ oxine was dissolved in sample solution (Fig. 1).

Influence of pH and type of buffer: Since the solid phase used in SPE may be distracted at high and low pH, therefore the pH range 2–8 often offered as operation conditions. We have investigated the effect of pH on the efficiency of $\text{UO}_2(\text{OX})_2$ extraction. The results obtained showed that the pH 5.5 was suitable (Fig. 2). Since EDTA was used as an effective masking agent for the selective extraction of analyte in the presence of some concomitant elements, we have examined the suitability of $\text{Na}_2\text{H}_2\text{Y}$ for buffering of sample solution at 5.5. We have demonstrated that a 0.025 M disodium salt of EDTA for the present SPE was convenient. Note that in the absence of EDTA, uranium oxinate precipitated on the solid phase at the same pH. It seems that the presence of EDTA in the solution is desirable, probably due to the formation of some soluble aggregates between $\text{UO}_2(\text{OX})_2$ and EDTA.

Washing step: For the elimination of any concomitant ions or compounds, the cartridge washed

with 2 ml of solution containing $\text{Na}_2\text{H}_2\text{Y}$, pH 5.5. The waste solution was analysed and no significant uranium content was observed.

Elution: Due to excellent solubility of uranium oxinate in chloroform and good electrochemical behaviors of this compound in chloroform [12], we have chosen this solvent as the eluant to benefit from very sensitive electrochemical method as well as differential pulse polarography for the previous analysis. The adsorbed uranium oxinate was eluted by three successive 5 ml portions of chloroform. The analysis of the elutes showed that in the optimum conditions, the average recovery of uranium oxinate in the first eluate was over than 99.8% and is sufficient for quantitative analysis.

3.6. Extraction efficiency and concentration factor

The results obtained for the various portions of 0.1 mg l^{-1} model solution of uranium showed that, the recovery of uranium from 100 to 500 ml of the solutions was 98–101% and concentration factor exceeded than 100-fold. A typical pulse polarogram recorded for chloroform eluate, corresponding to 100 and 500 ml of uranium model solution is shown in Fig. 3.

3.7. Interference study

Interfering ions in seawater may be divided into two groups:

(a) The elements with major amounts such as Ca and Mg which their oxinates formed in the extraction conditions of $\text{UO}_2(\text{OX})_2$, fixed on the SPE column and prevent the complete extraction of analyte. However, their presence in the chloroform eluate do not interfere with the pulse polarographic determination of $\text{UO}_2(\text{OX})_2$.

(b) The ions with minor amounts such as Cu and Fe which are extractable by SPE and their presence in chloroform eluate, may interfere with the pulse polarography of uranium. Each of the two groups may be masked by EDTA in aqueous media. We have demonstrated that in the presence of suitable EDTA concentration (0.02 M , plus a required excess, depending on the alkaline earth cations concentration) there was no interference from concomitant ions mentioned above.

Table 1
Results of recoveries from model uranium solutions

Volume of solution (ml)	Recovery (R%)			$\bar{R}\%$	RSD%
	1	2	3		
100 (0.1 $\mu\text{g ml}^{-1}$)	101.9	98.7	98.8	99.2	1.9
500 (0.2 $\mu\text{g ml}^{-1}$)	98.2	98.5	102.5	99.7	2.4

3.8. Recovery and precision

Before attending analysis of seawater, a series of experiments were performed to assess the recovery of uranium at the concentration ten times higher than normal concentration in seawater in the experimental conditions optimized. Uranium spiked bidistilled water (0.1 mg l^{-1}) was analysed by proposed methods, using standard addition procedures in polarographic cells.

The results obtained are given in Table 1. As seen from this table, the recovery of uranium was 99.8% and the relative standard deviation for five replicate determinations was 1.9–2.4%. On the other hand, the relative standard deviation for seven replicate determinations of 500 ml model water sample containing 20 $\mu\text{g l}^{-1}$ uranyl ion, was about 1.6%.

3.9. Seawater analysis

Results for the analysis of two seawater samples (Caspian Sea and Persian Gulf) are given in Table 2. All samples were analysed in triplicate.

Table 2
Uranium contents of seawater samples

No. of samples	Uranium Contents ($\mu\text{g l}^{-1}$)	
	Persian Gulf	Caspian Sea
1	2.25	2.85
2	2.30	2.75
3	2.28	2.80
	C = 2.28	C = 2.80
	RSD% = 1.2	RSD% = 1.8

Since a standard method for the determination of uranium in seawater has not been reported in literatures and inductively coupled plasma mass spectrometry (ICP-MS) as accepted independent method is not available, the accuracy of the method was examined by recovery study of the spiked samples. The recovery of the spikes added to seawater samples is given in Table 3. The quantitative recovery of the uranium spikes and relative standard deviation of 2.5% confirm the good precision and accuracy of the proposed method for the determination of uranium which can be converted to U(VI) oxinate at SPE conditions.

4. Conclusions

Solid phase extraction of $\text{UO}_2(\text{OX})_2$ combined with its pulse polarographic determination in chloroform eluate, provide an accurate, precise and reliable technique for the separation, concentration and determination of trace uranium from 500 ml of sea-water. Due to the accessible high concentration factor (100-fold), this method is very sensitive.

Table 3
Recovery of 2.5 μg of uranium spiked in 500 ml of seawater

No. of sample	Persian Gulf (%)	Caspian Sea (%)
1	99.2	99.7
2	99.5	98.6
3	98.1	99.3
	RSD% = 1.8	RSD% = 2.1

Abstract

With the aim of carrying out a calibration transfer for routine analysis, partial least squares (PLS) regression was successfully applied to simultaneously determine thallium and lead by stripping voltammetry when an interfering background current is present. The presence of a significant blank signal that overlaps the thallium peak, together with the overlapping thallium and lead signals were both suitably modelled by this multivariate regression technique. Moreover, once the PLS models are built, the piecewise direct standardization (PDS) method can be used to transfer these models over time in such a way that the number of calibration samples that will be needed in future determinations is reduced from 25 to 9, without a loss of quality in the analyses. The mean of the relative errors (in absolute values) obtained for thallium and lead is below 4.94% and 3.19%, respectively. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Calibration transfer; Partial least squares regression; Background current; Overlapping signals; Multianalyte determination; Stripping voltammetry

1. Introduction

The simultaneous determination of thallium and lead is commonly performed by stripping voltammetry, where the current recorded during the stripping step is given by the sum of both the current corresponding to the metal of interest and the background current, unrelated to the reaction of interest. The latter can also be divided into the

charging current and the background component related to redox reactions of impurities, supporting electrolytes, solvents or reactions of the electrode itself.

The accuracy of the stripping voltammetric determinations depends on the discrimination that can be achieved against the different contributions to the total current, i.e. on the uncertainty in measuring the current of the reaction of interest. Effective approaches for compensating the charging current have been developed, perhaps the

* Corresponding author.

most widely used being the differential pulse stripping voltammetry [1] which in addition, gives a gain in the overall signal-to-background ratio.

However, it should be noted that the differential pulse mode discriminates only against the nonfaradaic charging current whereas it does not correct the various faradaic components of the background current. To also discriminate this latter contribution some subtractive procedures have been developed with the aim of measuring the background current and subtracting it from the recorded current. Among these, the subtractive stripping voltammetry [1] presents the disadvantage of needing two identical electrodes (with the same surface area, morphology, etc.), which implies that, since two electrode surfaces are not perfectly matched, the background current is not always completely compensated.

The present-day electrochemical instrumentation and Chemometrics [2] provide wide information about a system under study and useful mathematical tools respectively, that allows one to approach the background current problem from a different point of view. The use of multivariate regression techniques [3], such as the partial least squares (PLS) regression [4,5], implies the extraction of the most relevant information related to the analyte of interest and possibly a way to discriminate the background current, from the whole voltammetric signal (not only from the peak current).

In this paper, PLS regression has been used to simultaneously determine thallium and lead by differential pulse anodic stripping voltammetry (DPASV) when the experimental blank also gives a voltammetric peak that seriously interferes with the thallium peak. The determination of these two metals in most electrolytes is difficult because of the similar potentials at which both are oxidized, which results in the overlapping of their voltammetric peaks and, hence, in an analytical error. In fact, several chemical and mathematical approaches have been proposed to solve these two overlapping peaks that include the use of extraction techniques [6], suitable electrolytes [7,8] or surfactants [9], medium-exchange [10,11], and others such as: derived voltammetry [12], Kalman filter [13,14], PLS [15] or continuum regressions [16], etc.

Once the PLS models had been built, a calibration transfer procedure was carried out to reduce the experimental effort that would be needed in similar analyses in the future carried out in a routine way. Among the several standardization procedures [17–20] that have been developed, the piecewise direct standardization (PDS) method [17,21] has provided very successful results when it has been used with NIR spectroscopic data, but it can also be applied to polarographic [22] and voltammetric data [23]. This method is based on calculating a matrix, the transformation matrix F , which relates a subset of signals measured for instance on a specific instrument or a set day to other signals measured on another instrument or a different day. Then, the PLS model built with the whole primary calibration set can be applied to the signals of the new situation corrected by means of the transformation matrix, in such a way that only a small subset of calibration samples has been measured in the new situation.

In this way, the number of samples needed for simultaneously determining thallium and lead in future analyses by means of the PLS regression has been reduced from 25 to 9, without a loss of quality in the determinations.

2. Experimental

2.1. Apparatus

The voltammetric measurements were carried out using a Metrohm 646 VA processor with a 647 VA stand in conjunction with a Metrohm multimode electrode (MME) used in the hanging mercury drop electrode (HMDE) mode. The three-electrode system was completed by means of a platinum auxiliary electrode and an $\text{Ag}|\text{AgCl}|\text{KCl}$ (3 mol dm^{-3}) reference electrode. A Crison micro pH-2002 pH-meter was used for pH measurements. The analysis of data was done with PARVUS [24] and MATLAB [25].

2.2. Reagents

Analytical-reagent grade (Merck) chemicals were used without further purification. All the

solutions were prepared with deionised water obtained in a Barnstead NANO Pure II system. The voltammetric measurements were carried out in an oxalic acid (0.1 mol dm^{-3}) and hydrochloric acid (0.1 mol dm^{-3}) supporting electrolyte medium ($\text{pH} = 1.037$). Nitrogen (99.997%) was used to remove dissolved oxygen.

2.3. Procedure

The solution was placed in the voltammetric cell and purged with nitrogen for 10 min. Once the solution had been deoxygenated, a deposition potential of -0.600 V was applied to the

mercury electrode during 30 s. Next, the stirrer was switched off and, after 30 s of rest period, an anodic potential scan was initiated from -0.558 V to -0.282 V in the differential pulse mode. Other instrumental parameters were: modulation amplitude, 50 mV ; pulse repetition time, 0.6 s ; nominal area, 0.40 mm^2 ; scan rate, 10 mV s^{-1} ; stirring rate, $1290 \text{ rev. min}^{-1}$. The solution was stirred and deoxygenated for 15 s after each addition.

3. Results and discussion

The major overlap of thallium and lead peaks is the most significant obstacle found in the

Fig. 2. Stripping voltammograms corresponding to the experimental blank (dotted line) and to sample 33 of calibrate A with (dash-dot line) and without (solid line) subtracting the blank signal.

simultaneous determination of both metals by stripping voltammetry. Previous analyses demonstrate that this interference is so important that if an insufficient experimental design is used (eight training samples distributed in a central composite design), then the information provided to the PLS model is too limited and, consequently, the regression model built becomes useless (explained variance below 96%). Therefore, the experimental design showed in Table 1 has been used, which exhaustively covers the considered concentration ranges; the training set is formed of 25 calibration samples whereas the test set is composed of four samples.

A whole calibration set was recorded by applying the experimental procedure to the samples of the experimental design, the corresponding voltammograms being shown in Fig. 1a, that henceforth will be denoted as calibrate A. As expected, the presence of two overlapping voltammetric peaks, that can be analysed by means of multivariate techniques [15,16], is observed; the first (left) assigned to thallium and the second (right) to lead.

However, the supporting electrolyte used in this paper also gives a voltammetric peak which, as can be seen in Fig. 2, overlaps the thallium peak. This signal, considered background current, leads to a significant increase in the recorded signal (solid line) with regard to the net signal (dash-dot line) obtained when the blank signal is subtracted. Likewise, a shifting of the thallium peak (the left peak) is observed since the blank signal and the thallium peak potential do not coincide exactly, which is more evident by comparing the voltammograms in Fig. 2. In Fig. 1a the thallium peak is being shifted to more positive potentials when the concentration of thallium is increased, i.e. when the thallium contribution to the peak is greater. Whereas in Fig. 2, when the blank signal has been subtracted, the peak potential is about -0.435 V in all the voltammograms recorded for the different levels of thallium considered.

Usually, if a blank gives a voltammetric signal in the potential range where the peaks of the metals to be determined appear, this signal is

subtracted from the calibration and test set voltammograms alike to avoid undesirable analytical errors. But, it is not always possible to have the experimental blank signal and so, a method able to model this interference would be of great interest. So, to evaluate the ability of the PLS regression to model this kind of interference, which in this case is added to the above indicated strong overlap of thallium and lead peaks, the original signal has been used in the analysis, i.e. the voltammograms showed in Fig. 1 where the blank signal has not been subtracted.

3.1. Multivariate regression models

A PLS model has been built independently for both thallium and lead, taking the current

recorded at 47 potential values as predictor variables for each sample, the concentration of metal being the response variable in each case. The data have not been autoscaled. The full cross-validation method [26,27] has been used with the aim of evaluating the stability and prediction ability of the PLS models built.

The high explained and cross-validated variance values, showed in Table 2, indicate that the interference due to the blank signal has been suitably modelled by the PLS regression, despite the significance of the phenomenon, principally on the thallium calibration. The models built for both metals consist of four latent variables, whose

Fig. 4. Scores for the 1st–2nd (a) and 1st–3rd (b) latent variables corresponding to the PLS model built for thallium (calibrate A). The first digit indicates the concentration level of thallium, the second is the level of lead.

Fig. 5. Standardization subsets (samples signalled with a circle) used in the calibration transfer procedures. On ordinates the level of thallium and on abscissae that of lead.

chemical interpretation has been analysed through the corresponding loadings and scores, Fig. 3 and Fig. 4, respectively.

The shape of the loadings calculated for the first latent variable, showed in Fig. 3a for thallium, corresponds to a 'mean voltammogram', which indicates that it is a size factor, as was expected. However, the loadings corresponding to the second latent variable, Fig. 3b, establish a difference between the two 'evident' overlapping peaks of the signal, extracting that information related to the metal of interest in each case and adequately correcting the interference due to the other overlapping peak. Thus, those potentials related to the metal of interest have positive val-

ues, whereas the contribution of the rest to the signal is subtracted through the negative sign of the corresponding loadings. In fact, the distribution of the scores in the plane formed by these first two latent variables reproduces the experimental design used (Fig. 4a) where the samples are arranged along the abscissae axis in increasing concentration order (from sample 11 to 55). The models built with both latent variables have high explained and cross-validated variance (Table 2) but the need for more variables in the PLS models is evident, especially for thallium since the interference of the blank signal is critical in this case.

On the other hand, the loadings obtained for the third latent variable in the model built for

Sample	Concentration ($M \times 10^7$) calculated with the two latent variables PLS models (without modelling interferences)		Concentration ($M \times 10^7$) calculated with the four latent variables in PLS model (modelling interferences)	
	Thallium	Lead	Thallium	Lead
<i>t1</i>	5.3312	3.3714	3.2613	3.5082
<i>t2</i>	13.1027	5.8917	13.3710	5.7825
<i>t3</i>	8.5162	10.0103	8.0696	9.4880
<i>t4</i>	12.9128	11.6537	14.0989	11.0425

thallium (Fig. 3c) are related principally to the left side of the voltammogram, establishing the difference between those potentials related to the thal-

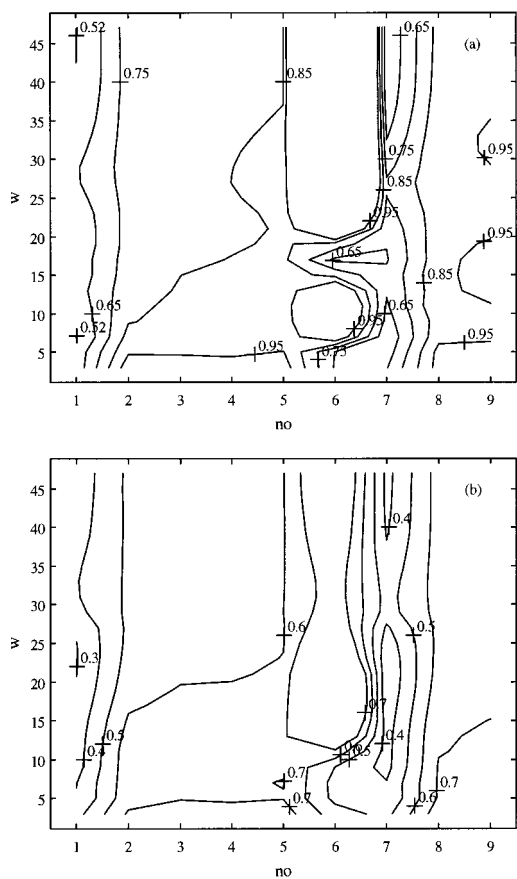

Fig. 6. SEP contour lines of the response surfaces corresponding to thallium (a) and lead (b).

lium peak and those corresponding to the blank signal, which is subtracted. Moreover, the linear relation that exists between the scores of the first (size factor) and third latent variables (Fig. 5b) indicates that the phenomenon modelled by the third latent variable is intimately related to the predictor variables themselves, i.e. to something referred to the global signal and not to the concentration of the metals. This was confirmed since another two PLS models built by subtracting the blank signal to the training set voltammograms had similar explained and cross-validated variance values, but no latent variable presented this characteristic structure (the scores in Fig. 4b seem to 'put in order' the samples in the plane of the 1st and 3rd latent variables taking into account the sum of the concentrations or levels of both analytes).

With regard to the fourth latent variable, which is included in the models of both metals, it seems to be related rather to specific samples or objects than to more general phenomena.

Table 4

Relative errors (%) for the test set samples of calibrate B calculated without and with calibration transfer

Sample	With the full calibration matrix B		Using calibration transfer	
	Thallium	Lead	Thallium	Lead
<i>t1</i>	7.01	7.17	5.07	0.71
<i>t2</i>	-2.39	-2.79	-3.13	-2.95
<i>t3</i>	-2.20	-4.47	-4.72	-5.24
<i>t4</i>	-2.85	-3.40	-6.77	-3.38

The parameters used in the calibration transfer were: $no = 7$ and $w = 47$ for thallium and $no = 7$ and $w = 21$ for lead.

The third and four latent variables are then related to the interference and some irregularities so, if one does not consider these two latent variables, it is possible to evaluate the error due to the interference. In the training set, considering only two latent variables, the mean relative error (in absolute value) is 3.11% versus 2.24% when the concentration of lead is calculated with four latent variables. In the case of thallium the effect is much more important, 14.48% versus 1.51% with two and four latent variables, respectively. This high discrepancy is due to the fact that the interference shows an overlapping signal in the range of potentials where the thallium peak appears. Detailed errors for test samples are shown in Table 3. Mean errors obtained are 5.59% versus 2.80% for lead and 20.34% versus 1.51% for thallium.

The loadings and scores shown in Fig. 3 and Fig. 4 for thallium were similar to those obtained in the PLS model built for lead, so a parallel analysis was made.

3.2. Calibration transfer

As the PLS regression technique has proved to be useful in the determination carried out, a calibration transfer procedure, the PDS method, has been applied for minimizing the experimental effort that would be necessary in later routine analyses. For this purpose, a new calibration set, henceforth named calibrate B, was recorded some days later following the above experimental design. This new training set (Fig. 1b) is very similar to the former, corresponding to the calibrate A showed in Fig. 1a, but they are not identical.

The PDS method [17,21] consists of relating the voltammograms measured in two different situations, in this case on different days, through a transformation matrix \mathbf{F} which is calculated from a small subset (standardization subset) of voltammograms recorded in both situations ($\bar{\mathbf{X}}_A$ and $\bar{\mathbf{X}}_B$ for calibrates A and B, respectively).

$$\bar{\mathbf{X}}_A = \bar{\mathbf{X}}_B \mathbf{F}$$

The standardization subset should be large enough in such a way that predictor variables sufficiently cover the whole experimental range. In

this way, each predictor variable (x_i) from the first day is related to a moving window (\mathbf{Z}_i) of variables measured on the second day by means of a local multivariate regression, the corresponding regression vectors being arranged along the main diagonal of the transformation matrix and the rest of the elements being zero, so the size of \mathbf{F} is $p \times p$, p being the number of predictor variables measured.

$$\mathbf{Z}_i = [x_{B,i-j}, x_{B,i-j+1}, \dots, x_{B,i+k-1}, x_{B,i+k}]$$

$$x_{A,i} = \mathbf{Z}_i \mathbf{b}_i$$

Then, \mathbf{F} can be used to correct any voltammogram measured on the second day to the format which would have been obtained if it had been measured on the first day. In this way, the previously built and analysed PLS models can be applied, through their corresponding closed forms [28], to the corrected signals for determining the concentration of thallium and lead in the samples measured on the second day.

The m-function *pdsgen*, implemented in the PLS Toolbox by Wise [29], has been used to calculate the transformation matrix \mathbf{F} . The input parameters for this function are the two training sets (\mathbf{X}_A and \mathbf{X}_B), the window size and the standardization subset. With the aim of optimizing the standardization procedure, several values have been used for the last two parameters. The window size (w) has taken the following values: 3, 5, 7, ..., 47; i.e. 23 different values in all, whereas the different standardization subsets (no) used are those shown in Fig. 5.

The standard error of prediction (SEP), calculated from the test set samples, has been used to evaluate the quality of the calibration transfer procedures carried out, although those errors related to the training set samples have also been taken into account. SEP is given by the square root of

$$s^2 = \frac{\sum_j (y_j - \hat{y}_{B,j})^2}{J}$$

where y_j and $\hat{y}_{B,j}$ are the true concentrations and those computed by the PLS model built for calibrate B respectively, and J is the number of

objects in the test set. Fig. 6 shows, through the contour lines of the response surfaces, the values of SEP obtained for both metals as a function of the different values of w and no used in the calibration transfer (a total of 207 independent calibration transfers have been done). As can be seen, the best results are related to the standardization subsets 1 and 7; whereas the worst were obtained with the standardization subset 6, whose samples correspond to one of the diagonals of the design (Fig. 6) and for this reason, this subset provides highly correlated voltammograms that lead to a significant structural defect in this standardization subset [30].

Since $no = 1$ implies all the training set samples in the standardization procedure, i.e. it corresponds to a full recalibration (25 training set samples), and $no = 7$ requires only the measurement of nine standardization samples in the new situation, it is evident that the latter is the optimum standardization subset for simultaneously determining thallium and lead by DPASV through the calibration transfer procedure proposed. The use of only one standardization subset for both metals is a desirable feature of the calibration transfer because, in this way, no additional experimental effort is necessary to determine one of the metals.

The influence of the different window sizes used on the SEP values is less than that of the standardization subsets. For $no = 7$, the minimum SEP corresponds to $w = 47$ for thallium and $w = 21$ for lead. The larger window size for thallium is due to the fact that the blank signal seriously interferes with the thallium peak, which makes necessary the use of some potentials where this interference does not exist to adequately carry out the calibration transfer. So, the interference of the background current is also detected in the calibration transfer step.

The relative errors corresponding to test set samples of calibrate B calculated by means of the calibration transfer and the PLS models built with the full recalibration are shown in Table 4. The errors obtained with the calibration transfer for both test and training sets are similar to those corresponding to the full recalibration, i.e. to those calculated by the PLS models built with all

the calibration samples of calibrate B, which indicates the success of the standardization approach. To confirm the ability of the instrumental standardization to predict the concentrations of thallium and lead, the procedure has been applied to the 16 samples of calibrate B which do not belong to transfer set $no = 7$; these samples are independent of the standardization procedure and their concentrations are known. The mean of the relative errors (in absolute values) obtained for thallium and lead is 4.94% and 3.19% respectively. These errors are in the range expected when this stripping technique is used, but the number of standard calibration samples that will be needed in later routine determinations of both metals has been reduced to 64%.

Received 28 May 1997; received in revised form 4 August 1997; accepted 5 August 1997

Abstract

A new concentration method of rhodium using Mg–W cell-electrodeposition has been developed. The method was combined with electrothermal atomic absorption spectrometry (ETAAS) with a tungsten tube atomizer. The optimal immersing time was 120 s. The most suitable pH for rhodium electrodeposition was 1.0. Under optimal conditions, the detection limit of rhodium by the ETAAS with the preconcentration was 13 ng ml^{-1} (3S/N). The severe interferences on the AAS signal of rhodium by large amounts of Ca, Cu, Fe, K, Na, Pb and Zn were eliminated by the Mg–W cell-electrodeposition method. The method was applied to the determination of rhodium in river and sea water. The recovery of rhodium spiked environmental samples was in the range of 95.6–109%. The present Mg–W cell-electrodeposition method can be utilized in in-situ sampling of trace elements in environmental samples (water). Furthermore, after sampling, it is easy to carry and store the W-sheet without contamination for a long time. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Until now, ion-exchange chromatography, liquid chromatography, plane, chromatography, gel-filtration chromatography, liquid–liquid extraction, coprecipitation ($\text{Fe}(\text{OH})_3$, $\text{La}(\text{OH})_3$, $\text{Zr}(\text{OH})_4$, etc.), electrolytic deposition (electrodeposition, stripping voltammetry), electrophoretic

separation, evaporation, flotation, freezing (cold-trap), sorption and adsorption (activated carbon, alumina, glass beads, silica gel, tungsten wire, etc.) and ultrafiltration have been reported as preconcentration (collection) and separation methods of trace metals in various samples [1–13]. These preconcentration methods combined with instrumental analysis have frequently been used for the determination of ultra-trace analytes in complex matrix samples. Most of them are complicated and time-consuming, except for ad-

sorption methods, which are simple and convenient. The electrolytic deposition method needs a power supply (electric source) like a potentiostat but metal ions are collected efficiently. A preconcentration method having the advantage of both is the new electrodeposition method, reported here.

Recently, rhodium has been widely used as a catalytic converter for the control of automotive emission and as a raw material of plating in electronic instruments [14]. As a result, rhodium has been widely spread in the environment. ETAAS with a metal tube, a conventional method for the determination of trace elements [15–17], is useful for the determination of rhodium in biological samples [18].

In this work, a novel, simple and convenient electrodeposition method is presented and applied to the determination of trace rhodium in environmental samples such as seawater and river water by ETAAS with a tungsten tube atomizer.

2. Experimental

2.1. Apparatus

The galvanic electrodeposition cell (Mg–W cell), used here for the preconcentration of rhodium, was reported in previous papers [19,20]. As cathode, a tungsten sheet (2.5 × 2.5 mm, 0.05 mm thick, 99.95% purity, Rembar) and, as anode, a magnesium sheet (8 × 8 mm, 0.10 mm thick, 99.9% purity, Niraco), were used. Both were connected with a copper lead wire having clips at both ends.

The ETAAS optical system employed for the rhodium determination was described in detail elsewhere [18]. A tungsten tube atomizer (20 mm long × 2.0 mm i.d.) made of tungsten foil (0.05 mm thick, 99.95% purity, Rembar) was used for the ETAAS measurements. The atomizer had a slit (0.08 × 2.7 mm) at the mid-point of the tube to insert the W-sheet. The analytical line was 343.5 nm Rh (hollow cathode lamp, Hamamatsu Photonics).

2.2. Reagents

Solutions of the matrix elements for the interference study were prepared as chlorides in 0.1–6 M

hydrochloric acid. A standard stock solution (1 mg ml⁻¹, 1 M HCl solution) of rhodium was obtained from Kishida Chemistry, Osaka, Japan. All of the chemicals used here were of analytical grade purity.

2.3. Procedures

Mg and W sheets used as electrodes were de-fatted with acetone and washed with 0.1 M HCl prior to electrodeposition. Sample solution (3 ml) was put into the cell and the pH adjusted to 1.0 with HNO₃. Mg–W sheets with a copper wire dipped into the solution and the solution was stirred for 120 s. The W-sheet put out was washed with demineralized-water and then perpendicularly inserted from a slit on the tungsten tube atomizer into the atomizer. An upper part of the W-sheet was exposed from the atomizer. The W-sheet was dried at 80°C for 10 s, pyrolyzed at 590°C for 10 s and atomized at 2230°C (using a heating rate of 5.5°C ms⁻¹) for 3 s in Ar 480 ml min⁻¹ + H₂ 20 ml min⁻¹ purge gas.

3. Results and discussion

When two metals (magnesium and tungsten) are combined and then dipped in acidified solution, a spontaneous redox reaction begins in the solution. Since this is a galvanic cell, the cell can provide a voltage and an electron flow through an electrical circuit. The voltage and the electrons can be used for the deposition of metal ions in the solution. Thus, a Mg–W cell was proposed for the preconcentration of rhodium in sample solutions. Since tungsten metal is relatively inert in dilute acids, the redox half-reactions [21] in the cell are as follows:

Therefore, the reaction proceeds from left to right. Based on the Nernst equation it could be calculated that when the Mg^{2+} concentration becomes 0.01 M, then Rh^{3+} is completely electrodeposited because its theoretical concentration becomes 7.0×10^{-163} M. Thus the Mg–W cell is suitable for the preconcentration of rhodium on a W-sheet.

It has been reported in a previous paper [18] that the optimal purge gas on ETAAS with a tungsten tube atomizer was $\text{Ar } 480 \text{ ml min}^{-1} + \text{H}_2 \text{ } 20 \text{ ml min}^{-1}$, the optimal atomization temperature was 2230°C and the pyrolysis temperature 590°C , to obtain the maximum absorbance of rhodium and protect the metal atomizer from oxidation by residual traces of oxygen in the atomizer chamber. Therefore, the subsequent experiments with the preconcentration of the electrodeposition were performed under these experimental conditions.

3.1. Effects of pH and immersing time on the electrodeposition of rhodium

It has been found that electrolytic deposition, sorption and adsorption methods are frequently affected by pH and immersing time [1–4]. Therefore, the effects of pH and immersing time on the electrodeposition of rhodium in a Mg–W cell were investigated. The results are illustrated in Figs. 1 and 2. The effect of pH was evaluated at immersing times of 120 s. Above pH 2, the amount of electrodeposition of rhodium decreased with pH. In 1.5 M of HNO_3 , it was observed that the consumption of the Mg-sheet was very high. Consequently, 1.0 was recommended as optimum pH for the Rh electrodeposition.

The absorbance of rhodium increased with immersing time up to 120 s and then reached a plateau. Subsequently, an immersing time of 120 s was selected.

3.2. Effect of electrodeposition on interferences

Chemical interferences by some matrix elements in the determination of rhodium by ETAAS have been observed [18]. Therefore, the electrodeposi-

tion of rhodium on the W sheet in the presence of matrix elements such as Ca, Cu, Fe, K, Na, Pb and Zn (1000–10 000 folds) was investigated. The rhodium AA signal was measured in terms of both peak height and peak area. The results are summarized in Table 1. Most of the matrix elements did not interfere with the rhodium

Table 1
Effect of Mg–W cell electrodeposition on the interferences

Interfering element (amount)	Peak height	Peak area
	Abs.	Abs. *t
Rh (250 ng ml ⁻¹)	0.298 ± 0.073	0.309 ± 0.055
Ca (250 µg ml ⁻¹)	0.294 ± 0.026	0.283 ± 0.043
(2.5 mg ml ⁻¹)	0.296 ± 0.026	0.293 ± 0.051
Cu (250 µg ml ⁻¹)	0.319 ± 0.053	0.303 ± 0.028
Fe (250 µg ml ⁻¹)	0.305 ± 0.072	0.296 ± 0.048
K (250 µg ml ⁻¹)	0.300 ± 0.021	0.292 ± 0.060
(2.5 mg ml ⁻¹)	0.292 ± 0.026	0.283 ± 0.063
Na (250 µg ml ⁻¹)	0.316 ± 0.060	0.306 ± 0.015
(2.5 mg ml ⁻¹)	0.313 ± 0.024	0.300 ± 0.024
Pb (250 µg ml ⁻¹)	0.296 ± 0.001	0.291 ± 0.070
Zn (250 µg ml ⁻¹)	0.312 ± 0.025	0.301 ± 0.053

The number of measurement > 3.

absorbance. The standard potentials of major co-existing ions [21] are as following.

$$E^\circ = 0.342 \text{ V (Cu}^{2+}\text{)}$$

$$E^\circ = -0.037 \text{ V (Fe}^{3+}\text{)}$$

$$E^\circ = -0.126 \text{ V (Pb}^{2+}\text{)}$$

$$E^\circ = -0.762 \text{ V (Zn}^{2+}\text{)}$$

From these values, it can be understood that, except for copper, rhodium is preferentially electrodeposited in the Mg–W cell. Therefore, it is reasonable that the coexisting metals investigated did not interfere with the rhodium signal, by considering this interference study.

Since this electrodeposition method seems relatively interference-free, the Mg–W cell electrodeposition method was used to determine rhodium in environmental samples.

3.3. Detection limit and reproducibility

The detection limit of rhodium by the ETAAS combined with the electrodeposition method was 13 ng ml⁻¹ (3S/N). The value was approximately the same as the detection limit obtained with graphite atomizers [22] and better than those obtained with ICP-AES (30 ng ml⁻¹ [23]). The reproducibility for the ETAAS with preconcentra-

tion of the electrodeposition was investigated. The relative S.D. for 500 ng ml⁻¹ of rhodium was 4.1% for 10 measurements.

3.4. Determination of rhodium in river and sea waters

Environmental samples spiked with 100–250 ng Rh ml⁻¹ were analyzed by ETAAS with the tungsten tube atomizer after the Mg–W cell-electrodeposition method under optimal conditions. The calibration curve constructed from standard solutions of rhodium was lined up to 350 ng ml⁻¹. Table 2 shows the results obtained for the environmental samples. The recovery from rhodium-spiked river and sea water was in the range of 95.6–109%. The relative S.D. for the determination of rhodium in the environmental samples by the proposed method were better than 10% at > 3 replicate analyses.

The preconcentration method developed is simple, rapid and relatively free from interferences caused by matrix elements. By the combination of ETAAS using a tungsten tube atomizer and the Mg–W cell electrodeposition method, many ultra trace metals in heavily contaminated samples can be determined rapidly and accurately, immediately after the dip of the Mg–W electrodes into

Table 2

nd, not detected.

acidified sample solutions. The preconcentration method can be most suitable to in-site sampling of environmental samples like seawater. Furthermore, after sampling, it is easy to carry and store the W-sheet without contamination for a long time.

Abstract

An alternative method for the determination of the concentration of diethylenetriamine (DETA) in aqueous mineral flotation solutions is described. This method is based on the formation of a DETA-Ni(II)-sulphite complex, which shows a UV absorption maximum at 285 nm that varies linearly with the concentration of DETA throughout the 0–50 mg l⁻¹ DETA range. A high concentration of Ni(II) is used to offset the effect of any Cu(II) or Ni(II) ions that may already be present in the industrial plant solutions under analysis. The intensity of the absorbance maximum is dependent on the sulphite ion concentration, but this problem is overcome by measuring the absorbances when the test solutions are spiked with different concentrations of DETA and then extrapolating the absorbance versus DETA concentration plot to zero absorbance to obtain the original concentration of DETA in the test solutions. © 1998 Elsevier Science B.V. Keywords: Diethylenetriamine; Concentration; Aqueous

1. Introduction

Diethylenetriamine [*N*-(2-aminoethyl)-1,2-diaminoethane, HN(CH₂CH₂NH₂)₂, DETA] has been suggested as a reagent for the depression of pyrrhotite (FeS) in industrial flotation circuits [1,2]. It can be analyzed by means of a UV spectroscopic method in which the absorption maximum at 386 nm for the complex formed

between DETA and fluram (4-phenylspiro[furan-2(3H),1'-phthalan]3,3'-dione) is monitored [3]. The absorbance of the DETA-fluram complex at this wavelength varies linearly as a function of the concentration of DETA. The method is only accurate and reliable provided the plant solutions being tested do not contain any interfering species. In our experience, however, the results obtained by this method are subject to significant variations if the plant solutions contain any ionic species that can interact with DETA. In the presence of Ni(II) ions, we have found that the absorbances recorded are significantly lower than

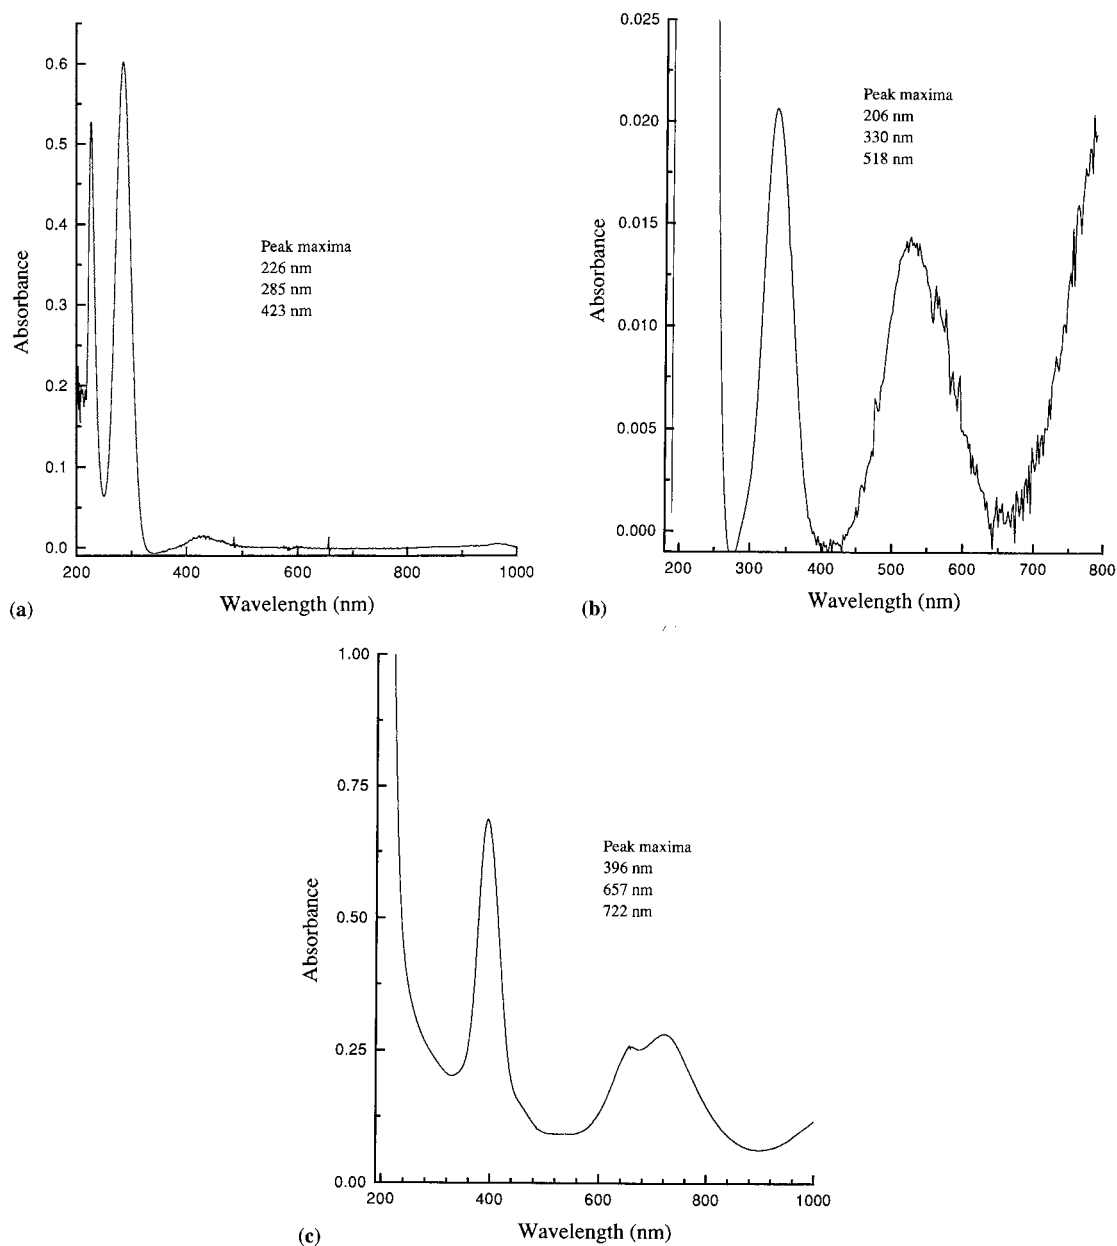

Fig. 1. UV absorbance spectra of: (a) Ni/DETA/Metabisulfite; (b) [Ni(DETA)₂]Br₂; (c) [Ni(H₂O)₆]SO₄.

those in the absence of Ni(II) ions. These absorbance differences are attributable to the formation of Ni(II)-DETA coordination complexes and can be compensated for by using reference blanks having the same Ni(II) concentrations as the test

solutions. In routine industrial operations, however, this is not an easy procedure. While it is relatively simple to determine the concentration of Ni(II) by atomic absorption spectroscopy, the chemical state of the Ni(II) ions depends on which

Fig. 2. Variation of absorbance (285 nm) with added DETA concentration mg l^{-1} (all correlations have r values of 0.933 or better). Laboratory test trials use an artificial unknown DETA sample, plant test trials are the simulated flotation circuit samples.

other ionic species are present in the solution. For example, in the presence of sulphite or metabisulphite ions, Ni(II) forms a Ni(II)-DETA-sulphite complex, which shows significantly different absorbances in its UV spectrum (Fig. 1a) than those for Ni(II)-DETA mixtures in the absence of sulphite or metabisulphite ions, e.g. $[\text{Ni}(\text{DETA})_2] \cdot \text{Br}_2 \cdot \text{H}_2\text{O}$ (Fig. 1b) or from $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$ itself (Fig. 1c).

We have now developed an alternative method for the quantitative determination of DETA in aqueous mineral flotation solutions by UV spectroscopy. The analysis is based on monitoring the variation of the absorbance of the UV maximum at 285 nm of the complex formed when DETA interacts with Ni(II) in the presence of sulphite ion at alkaline pH 8.5–9.5. The presence of varying amounts of Ni(II) ions in solution is overcome by having a large excess of Ni(II) (by addition a soluble nickel salt) in the test solutions. This alternative procedure has also been designed to offset the effect of sulphite ions on the measured

absorbance values. As with any standard addition procedure, it is best that the additions be comparable to those expected in the test solutions. If the range is too large, the relationship is no longer linear, too small and the results are not relevant.

2. Experimental

The following stock solutions were prepared: $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, 5 g $\text{Ni}(\text{II}) \text{ l}^{-1}$; simulated industrial plant DETA solutions containing 1 g l^{-1} sodium metabisulphite and set to pH 9.0–9.5 by adding lime; reference blank solution containing 1 g l^{-1} sodium metabisulphite and set to pH 9.0–9.5 by adding lime; standard DETA solution, 0.955 g l^{-1} DETA.

2.1. Procedure

Nickel sulphate solution (10 ml) and the reference blank solution (85 ml) were mixed together in a 100-ml volumetric flask. The volume was then made up to the 100-ml mark with distilled water. The mixture was centrifuged on an International Micro-Centrifuge for 6 min and a sample of the resulting green solution was decanted into a 1.00-cm quartz cuvette and the background UV absorbance at 285 nm was determined. The time between mixing the solutions and recording the UV spectrum was set at 10 min in each case, as the absorbance does decrease with time. The same procedure was repeated for 85 ml samples of the industrial plant test solutions by adding known quantities of the standard DETA solution to the mixtures before making up to the 100-ml mark with distilled water. The concentration of the DETA added was in the 0–50 mg l^{-1} range. The absorbances measured at 285 nm for the different solutions were plotted as a function of the concentration. The concentration of the DETA in the plant test solutions was determined by extrapolating the graph to zero absorbance and dividing the

¹ This concentration is about ten-fold in excess of that required in order to minimize the effect of any Cu(II) or Ni(II) ions already present in the industrial solutions under analysis.

Table 1
Concentrations of DETA from the Ni(II)-DETA-sulphite absorbance measurements

Actual DETA concentration (mg l ⁻¹)	DETA concentration from our method (mg l ⁻¹)	Range of added DETA used in trial (mg l ⁻¹)
10.0	10.1 ^a	0–48.0
1.20	1.14 ^a	0–48.0
3.87	4.18	0–10.0
1.22 ^b	1.02	0–40.0

^a Average of three replicate trials.

^b Value determined by fluram method.

value of the *x*-axis intercept by 0.85 (to account for the volume dilution from 85 to 100 ml).

3. Results and discussion

The UV spectrum of the Ni(II)-DETA-sulphite complex is shown in Fig. 1a. The 285-nm absorption band is clearly characteristic of the complex and increases proportionately with increasing concentration of DETA. Fig. 2 is a typical plot of the results obtained for an initially unknown concentration of DETA. The concentration of DETA measured by this method compares well with that determined by the fluram method. The results given in Table 1 show that our alternative UV spectroscopic procedure is reliable over the tested

range of 1–50 mg l⁻¹ DETA, which is the range normally expected in flotation plant solutions and effluents. Moreover, it will probably prove to be the method of choice for industrial situations where varying concentrations of Ni(II) ions are already known to be present in the pulp solutions.

Determination of the solubility product of $\text{Ba}(\text{IO}_3)_2$ by flow injection with amperometric detection

Bianca Mendes Martins, Mauro Bertotti *

Instituto de Química, Universidade de São Paulo, São Paulo, 05508-900, Brazil

Received 1 July 1997; accepted 6 August 1997

Abstract

The solubility of $\text{Ba}(\text{IO}_3)_2$ has been determined in solutions containing a supporting electrolyte (KCl) to maintain the ionic strength in the 0–0.5 M range. The approach envisaged was based in the amperometric determination of iodine (or triiodide) generated in the reaction involving iodate in equilibrium in the saturated solutions and iodide contained in the solution carrier using a flow injection procedure, the electrode potential being maintained at +0.2 V in a wall-jet cell. The effect of the supporting electrolyte on the solubility of barium iodate was demonstrated and a good approximation of the value for the thermodynamic solubility constant of the precipitate was found by an appropriate correction of the solubility data using mean activity coefficients of barium iodate. The mean activity coefficients were estimated at each ionic strength by using the Debye–Hückel equation and the corrected solubility constant determined at 27°C was found to be $2.7 \times 10^{-9} \text{ mol}^3 \text{ l}^{-3}$. © 1998 Elsevier Science B.V. Keywords: Solubility product; $\text{Ba}(\text{IO}_3)_2$; Flow injection; Amperometric detection

1. Introduction

The determination of the solubility of a slightly soluble compound in a specific solvent requires measurements of the equilibrium concentration of one or both species in a saturated solution at a fixed temperature. Owing to the influence of the ionic strength in the solubility of ionic precipitates, it is very important to take into account that the measurements can be influenced by the ions of the compound itself (when the solubility is not negligible) or by ions of an inert electrolyte deliberately added to the solution. If side reac-

tions (hydrolysis of metal ions or protonation of anions derived from weak acids) are not of importance, thermodynamic solubility products can be achieved after consideration of the activity coefficients of the ions, which are dependent on the ionic strength of the solution. Hence, the relationship between the concentration solubility product (K_s) and the thermodynamic solubility product (K_s^0) for an A^+B^- compound is expressed by the following equation [1]:

$$K_s^0 = K_s f_{\text{A}^+} f_{\text{B}^-} \quad (1)$$

where f_{A^+} and f_{B^-} are defined as the activity coefficients for both ions, which can be theoretically calculated by using the Debye–Hückel equation [2].

* Corresponding author. Fax: +55 11 8155579.

In this paper we have carried out some studies on the determination of the solubility of barium iodate at various values of ionic strength maintained with KCl. A very common procedure to determine the solubility of iodate compounds consists of a titration of the iodine generated after addition of iodide to the filtered saturated solutions [3]. In a similar way, the iodine quantitatively formed can also be quantified spectrophotometrically at a fixed wavelength [4] and this procedure is best suitable for iodate precipitates which have solubility values low enough to restrict titrimetric methods. In this end, we have developed an alternative method based on the generation of iodine (or triiodide) with further amperometric detection at a suitable potential. This indirect amperometric determination with chemically generated iodine has already been reported in the development of analytical methods for nitrite [5,6]. Methods for determination of sulphite have also been used with this principle in mind, but in these cases the quantification of the analyte was based on the decrease of the amperometric signal for iodine [7,8]. In order to avoid time consuming procedures and to achieve a higher sample throughput, we have proposed a flow injection analysis method with amperometric detection for the determination of the equilibrium iodate concentration in the saturated solutions, the analytical signal being compared with those ones of standard iodate solutions. We will show that this approach (electrochemical detection associated with flow injection analysis) allows the determination of the equilibrium iodate concentration to be performed with excellent sensitivity, high reproducibility, high sampling rates and low volume of samples.

2. Experimental

2.1. Materials

All solutions were prepared from reagents of analytical grade. Iodate stock solutions were prepared from the primary standard potassium salt dissolving 0.1070 g in to a 50 ml calibrated volumetric flask to give a 10 mM solution. Iodide

solutions were prepared just after each experiment in order to avoid the formation of iodine in sulphuric medium. Saturated barium iodate solutions were prepared by addition of a sufficient quantity of the compound to each of a series of 25 ml volumetric flasks containing potassium chloride solutions, ranging in the concentration from zero (i.e. pure water) to 0.5 M. The barium iodate solutions were shaken vigorously during 1 h and laid down for a week in order to achieve a complete saturation. The excess solid barium iodate was removed by a filtering process, so that the solutions could be analyzed without interference from any suspended solid particle. Experiments were carried out at 27°C.

2.2. Apparatus

Voltammetric experiments were performed with an EG and G Model 273A potentiostat interfaced to an IBM 486 PC, the electrodes being a glassy carbon electrode (area = 3 mm²), Ag/AgCl as reference (3 M NaCl) and a platinum wire as auxiliary. Before experiments, the bare glassy carbon electrode was polished with alumina (1 μm). Voltammetric experiments involving the use of microelectrodes were carried out in a two electrode cell, the reference electrode being a Ag/AgCl electrode. Platinum microelectrodes were fabricated by sealing microwires ($r = 12.5 \mu\text{m}$)

Fig. 1. Steady state voltammograms for a platinum microelectrode ($r = 12.5 \mu\text{m}$) in a solution containing 0.1 M H_2SO_4 (A), 0.1 M H_2SO_4 + 0.4 mM iodine (B) and 0.1 M H_2SO_4 + 1 mM iodide (C). Potential scan rate = 20 mV s^{-1} .

into glass pipettes and polishing the resulting microdiscs with moist alumina powder (0.05 μm) on a polishing cloth. The flow cell was a wall-jet type, where the stream flows from a nozzle perpendicularly onto the working electrode surface. The body of the cell was made of glass, the reference electrode being a silver wire covered by silver chloride immersed in a plastic tube containing KCl. The auxiliary electrode was a steel wire. The diagrams were recorded in an HP 7090 A plotting and measurement system connected to the 273A potentiostat output. The carrier flow was delivered by gravity, the characteristic parameters being as follow: flow rate = 2 ml min^{-1} , injection loop = 100 μl and tube dimension = 1 mm inner diameter (polyethylene).

3. Results and discussion

3.1. Analytical determination of iodate

The proposed method for monitoring the equilibrium concentration of iodate in the series of solutions containing different amounts of supporting electrolyte involved the measurement of iodine (or triiodide) resulting from the reaction between the analyte and iodide in excess in acidic medium, according to the following equation:

The measurement of the current for the reduction of iodine provides a convenient and reproducible way to monitor the concentration of iodate assuming that reaction Eq. (2) is carried out quantitatively to the formation of products. This can be accomplished working with excess of iodide and protons, so all experiments were performed in a 0.1 M sulphuric acid + 40 mM iodide solution, taking in account that the expected value for the solubility of barium iodate is around a few mM. The potential for monitoring the iodine concentration was selected with base in steady state voltammetric curves recorded for iodine and iodide using a 12.5 μm platinum microelectrode. As it is shown in Fig. 1, iodide is oxidized at potentials more positive than +0.4 V. Fig. 1 also shows that at less positive potentials iodine can be

Fig. 2. Amperometric signals recorded at a glassy carbon electrode (area = 3 mm^2 , $E = +0.2$ V) after sequential injections of 100 μl of 2.0 mM potassium iodate to a carrier solution containing 40 mM iodide + 0.1 M H_2SO_4 .

detected at the microdisc due to an electrochemical reaction that involves its reduction to iodide according to the following equation:

Therefore, the cathodic current at +0.2 V was used to monitor the concentration of iodine and hence the iodate level in the solutions without interference from the components of the carrier solution or even from dissolved oxygen, since the signal for its reduction at +0.2 V is negligible if a comparison is made with the iodine signal after injection of saturated iodate solutions. Limiting currents data for the anodic and cathodic processes shown in Fig. 1 are in excellent agreement with the steady state currents calculated using the equation that describes the limiting current for a disc microelectrode [9], which is a function of the concentration of the electroactive species, radius of the microelectrode, number of electrons involved in the electrochemical reaction and the diffusion coefficient ($1.6 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ and $0.83 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for iodide and iodine respectively [6,10]).

Fig. 2 shows some consecutive diagrams recorded after injection of aliquots of 2.0 mM potassium iodate to the carrier solution (sodium iodide in sulphuric medium). As the reaction involving iodate and iodide takes place in the flowing solution, electroactive iodine is generated giving rise to a peak when it reaches the electrode surface maintained at +0.2 V. The reproducibility of the peaks shown in Fig. 2 was very good

(standard deviation = 0.9% for $n = 5$) and after all injections the current dropped to its background value. For a 0–3 mM iodate range the peak currents were plotted as a function of the analyte concentration, a very nice straight line being obtained which can be represented by the equation

$$I(\mu\text{A}) = 107.0C_{\text{iodate}}(\text{mM}) + 3.0 \quad (4)$$

with a regression coefficient, $r^2 = 0.9992$.

3.2. Determination of iodate in the barium iodate solutions

The effect of both barium ions and the supporting electrolyte on the recorded current at +0.2 V was checked by addition of solutions of barium chloride (3 mM) and potassium chloride (0.5 M) to the flowing solution (iodide + sulphuric acid). No signal was observed after addition of these species, what means that the response obtained after injection of barium iodate samples to the carrier solution is exclusively dependent on the amount of iodate. A test was also carried out to verify the eventual influence of the ionic strength on the measured signal but the peak current had

Fig. 3. Plot of the solubility product for barium iodate as a function of the ionic strength maintained with potassium chloride (triangles). Circles represent the same values after correction using the appropriate activity coefficients for barium iodate.

Table 1
Corrected solubility product of barium iodate at various ionic strength values calculated by using Eq. (6)

Ionic strength (M)	Ba(IO ₃) ₂ activity coefficient	Corrected solubility product ($10^{-9} \text{ mol}^3 \text{ l}^{-3}$)
0.003	0.890	2.7
0.104	0.602	2.5
0.205	0.531	2.5
0.305	0.491	2.5
0.405	0.463	2.3
0.505	0.443	2.0

The activity coefficients for barium iodate were determined according to Eq. (7).

the same value whatever a solution containing 1 mM potassium iodate or 1 mM potassium iodate + 0.5 M KCl was injected. Hence, the iodate quantification in the solutions containing potassium chloride was performed by comparing the resulting peaks with an analytical curve ranging from 0 to 5 mM potassium iodate dissolved in pure water. Three injections were made for each one of the set of barium iodate solutions containing KCl and the average value was used to calculate the equilibrium concentration of iodate, standard deviations of the peak currents not being larger than 1%. The concentration equilibrium constant, i.e. the equilibrium constant using molar concentrations (K_s), was calculated for which one of the six barium iodate solutions containing potassium chloride (0–0.5 M) by multiplying the ionic concentrations of both ions and taking in consideration that $[\text{Ba}^{2+}]$ was half of $[\text{IO}_3^-]$ in the saturated solutions. Fig. 3 shows a plot of K_s as a function of the ionic strength (μ) of the solutions calculated according to the following equation [1]:

$$\mu = \frac{1}{2} \sum C_i z_i^2 \quad (5)$$

which can be rearranged taking in account that the barium iodate is a 2:1 electrolyte to give

$$\mu = C_{\text{KCl}} + 3C_{\text{Ba}(\text{IO}_3)_2} \quad (6)$$

where C means the molar concentration of potassium chloride and the solubility of the barium iodate solutions respectively.

The increase in K_s values and in solubility as shown in Fig. 3 is due in part to the electrostatic attraction between the inert electrolyte ions and the ions in the crystal lattice of the solid. This effect can be corrected taking into account the mean activity coefficients of barium iodate at each of the solutions to convert the K_s values to a set of corrected solubility constants using the relationship expressed by Eq. (1). The activity coefficients for $\text{Ba}(\text{IO}_3)_2$ in the solutions containing potassium chloride at different concentrations were calculated by using the Debye–Hückel equation [2], which follows:

$$\log f_{\pm} = -\frac{0.511|Z_A+Z_B+\sqrt{\mu}}{1+0.329a\sqrt{\mu}} \quad (7)$$

where f_{\pm} is defined as the geometric mean of the single-ion activity coefficients and it is preferable to be used since it is inherently impossible to measure activity coefficients for individual ions. Values for barium iodate mean activity coefficients were calculated according to Eq. (7) using Kielland's values of \bar{a} [11]. For barium iodate $\bar{a} = 4.5 \text{ \AA}$, which resulted in the set of f_{\pm} values for each ionic strength shown in Table 1. Corrected solubility products for barium iodate were then calculated by using Eq. (1) taking into account the relationship between single-ion activity coefficients and mean activity coefficient expressed by Eq. (8):

$$f_{\pm} = (f_{\text{Ba}^{2+}} \cdot f_{\text{IO}_3^{-2}})^{1/3} \quad (8)$$

Solubility products data for the compound after the correction using the mean activity coefficients would all be the same if the Debye–Hückel equation were perfect and the slight deviation is likely to be related with the increasing error in the equation as the ionic strength increases. Therefore, the value obtained from the solution containing no KCl (ionic strength = 0.003 M) was adopted as a more reliable determination of the $\text{Ba}(\text{IO}_3)_2$ solubility product and this result is in a good agreement with other value reported in the literature ($1.6 \times 10^{-9} \text{ mol}^3 \text{ l}^{-3}$ at 25°C [12]).

4. Conclusions

The proposed flow injection procedure was found to be a very reliable way to determine the equilibrium concentration of iodate in solutions saturated with barium iodate. The indirect amperometric detection with iodine allows very low concentrations of iodate to be quantified, so even more insoluble iodate precipitates like $\text{Hg}(\text{IO}_3)_2$ ($K_s = 2.0 \times 10^{-19} \text{ mol}^3 \text{ l}^{-3}$) would have its solubility successfully determined. The simplicity, reproducibility of the results and low volume of saturated solutions (typically a few hundred microliters) are also of importance and make the method very advantageous for solubility studies involving other iodate compounds.

The solubility product of barium iodate was determined after the needed corrections using the activity coefficients in the potassium chloride medium were performed. The Debye–Hückel equation was used for this end and the determined solubility constant is to be found as a good approximation of the thermodynamic solubility product of barium iodate since this system is immune to problems associated with side reactions involving Ba^{2+} or iodate at the working pH (~ 6) [13,14]. On the other hand, some errors may be expected owing to the dependence of activity coefficients upon the specific chemical properties of the ions instead of upon just the charge and radius. Another aspect to concern refers to the formation of soluble ion pairs which would involve both ions in a side equilibrium. This is particularly likely to occur for a 1:2 electrolyte and many examples are to be seen like AgSO_4^+ or $\text{HgCl}_2(\text{aq})$ [15].

Abstract

DNA-damaging agents in the environment represent a serious danger to human health. We use a supercoiled DNA-modified mercury electrode as a fast-response biosensor for the detection of DNA strand cleaving agents. The sensor is based on a strong difference between the a.c. voltammetric responses of covalently closed circular (supercoiled) and of open circular (nicked) plasmid DNA. We show that the sensor can detect hydroxyl radicals in laboratory-prepared solutions and in various natural and industrial water samples. The sensor is also capable of detecting unknown DNA-damaging agents in industrial waters. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Supercoiled DNA; DNA-modified electrode; Electrochemical biosensor; ·OH radicals; DNA damage; Environmental analysis

1. Introduction

In recent years, a number of nucleic acid-based electrochemical biosensors were developed. Most of these biosensors [1–6] were constructed for DNA sequence-specific recognition based on nucleic acid [1–3,6,7] or peptide nucleic acid [4] probe immobilization at the electrode surface followed by hybridization with the target DNA and an electrochemical [1–5,7] or electrogenerated chemiluminescence [6] signal transduction. Several papers have dealt with electrochemical DNA

biosensors for the detection of substances, such as drugs and pollutants, that selectively interact with the probe DNA (e.g. by intercalation [8]) or that damage the DNA by chemical modification of base residues (e.g. hydrazines [9] or dimethyl sulfate [10]).

Damage to DNA usually results in serious disturbances in the life of the cell (e.g. mutations, malignant transformation, apoptosis [11]) and may endanger human health. Thus, monitoring of DNA-damaging agents in the environment is very significant. Many kinds of DNA damage result in the formation of DNA strand breaks (i.e. cleavage of the DNA sugar-phosphate backbone). Recently, we have found that transition of covalently

Fig. 1. (A) Scheme of supercoiled DNA (a) and the formation of open circular (b) or linear (c) DNAs as the result of interruption of one DNA strand (1, single-strand break (ssb); e.g. by ionizing radiation) or both strand in the same site (2, double-strand break (dsb); e.g. by a restriction endonuclease or by high doses of radiation); in the latter case, the molecule of linDNA contains a number of single strand breaks. (B) Scheme of the sensor for DNA strand cleavage based on scDNA-modified HMDE. The sensor electrode is prepared by immersing of HMDE into solution containing scDNA which is adsorbed at the electrode surface (a). After washing (W), the scDNA-modified electrode is transferred (T) into the sample tested (b). If the sample contains hydroxyl radical for example, surface-attached scDNA is nicked, thus producing oc (or linear) DNA. After washing, the sensor electrode is transferred into blank background electrolyte (c) followed by voltammetric signal transduction.

closed circular, supercoiled (sc) DNA to open circular (oc) DNA (by introduction of a single-strand break into the scDNA molecule) or to linear DNA (by scission of both DNA strands at the same site) (Fig. 1) results in the appearance of an a.c. voltammetric peak 3 [12] (Fig. 2). It has been shown that the latter peak (a non-faradaic peak observed in weakly alkaline solutions), characteristic of single-stranded DNA [13,14], is also produced by oc and linear double-stranded DNAs. These DNA molecules have free strand ends of one or both DNA strands and they can be partially unwound at the electrode. Supercoiled DNA, both strands of which are covalently closed circles, cannot be unwound and consequently, scDNA does not yield peak 3 [12,14]. Under certain conditions, one DNA strand break can be detected using a.c. voltammetry among several hundred thousand phos-

phodiesteric bonds [12]. Compared to gel electrophoresis (currently applied for this purpose), the voltammetric assay is substantially faster (it takes a few minutes, in contrast to the hours necessary to run gel electrophoresis) and offers easier quantitation of data.

Intact scDNA can be anchored at the mercury electrode surface by adsorption forces [12,14–16]. If the scDNA-modified electrode is dipped into a solution containing DNA cleaving agent (e.g. chemical [12] or natural nucleases), strand breaks are introduced into the probe DNA immobilized at the electrode surface (Fig. 1), which are subsequently detected by means of a.c. voltammetry [12]. In this paper, we demonstrate the possible use of this sensor for detection of DNA strand cleaving agents in several natural samples, including mine and technological water obtained from the uranium industry.

Fig. 2. The dependence of peak 3 height on time for which the sensor was exposed to 50 μM Fe/EDTA reagent (see Section 2) in 50 mM sodium phosphate, pH 8.5. The reaction was started by addition of hydrogen peroxide into a stirred solution of other components with dipped sensor electrode. Inset (a), blank sensor response for scDNA (solid) and for ocDNA control (oc DNA was prepared by DNase I-treatment of scDNA in solution and subsequently adsorbed at HMDE, dashed); (b) sensor response for 60 s incubation of scDNA-modified electrode in 50 μM Fe/EDTA reagent in 50 mM sodium phosphate pH 8.5 (solid) and for 120 s incubation in the same mixture with an addition of fresh hydrogen peroxide and ascorbate after the first 60 s. For other conditions, see Section 2.

2. Experimental

2.1. Material

Supercoiled plasmid pUC19 DNA was isolated by lysozyme/SDS/EDTA lysis followed by CsCl-gradient centrifugation as described [12]. Control oc DNA was prepared by treatment of scDNA with 0.02 U of deoxyribonuclease I (Sigma) in 6

mM MgCl_2 , 2 mM CaCl_2 and 40 mM Tris-HCl pH 7.4 at 0°C for 90 min followed by extraction with phenol and chloroform, then ethanol precipitation [17].

2.2. Fenton reaction

The reaction mixture contained FeSO_4 , EDTA and sodium ascorbate at the ratio 1:2:20; the starting H_2O_2 concentration was always 0.03% (about 9 mM) [18] (for example, '50 μM Fe/EDTA reagent' contained 50 μM FeSO_4 , 0.1 mM EDTA, 1 mM sodium ascorbate and 9 mM H_2O_2). The sensor electrode was immersed in a solution containing the reaction components except H_2O_2 followed by hydrogen peroxide addition (with intensive stirring).

2.3. Mine and technological water samples

Water samples obtained from the uranium industry (from a flooded mine, from a water purification plant and a sample of free circulating technological water from a chemical uranium ore-dressing plant) were used for testing the usability of the sensor in water (environmental) analysis. The content of some substances in the samples is displayed in Table 1.

2.4. Sensor procedure

DNA was adsorbed at the electrode surface from 5 μl drops of solution containing 100 $\mu\text{g ml}^{-1}$ scDNA (or 50 $\mu\text{g ml}^{-1}$ ocDNA for control measurements), 0.2 M NaCl and 10 mM Tris-HCl (pH 7.4) for 60 s. The DNA-modified elec-

trode was washed with distilled water and transferred into the solution of the tested sample for 60 s, if not stated otherwise. The electrode was then washed with water, followed by a background electrolyte solution and transferred into deaerated blank background electrolyte, which was then bubbled with argon for 60 s. The initial potential $E_i = -0.6$ V was applied at the electrode for 15 s (quiescent period) prior to the voltage scan.

2.5. Voltammetric signal transduction

Alternating current voltammetric measurements were performed with an EG and G PAR 174A Polarographic Analyzer connected to a 174/50 AC Polarographic Interface, a 5208 Two Phase Lock-in Amplifier and a Philips PM 8134 $X_t Y_1 Y_2$ Recorder. The following parameters were chosen: frequency 230 Hz, amplitude 10 mV, scan rate 20 mV s^{-1} . The phase-in component was measured due to better resolution of the DNA signals as compared to the out of phase component. Linear sweep and square wave voltammetry were performed with an AUTOLAB (EcoChemie, Utrecht, The Netherlands; for settings, see legend to Fig. 3). A Metrohm 647 VA-Stand electrode in HMDE mode controlled by a 646 VA-Processor was used. All measurements were performed with a saturated calomel reference electrode (SCE) and a platinum wire counter electrode. 0.3 M NaCl , $50 \text{ mM sodium phosphate}$, pH 8.5 was used as a background electrolyte.

3. Results and discussion

3.1. Nicking of scDNA at the mercury electrode surface by hydroxyl radicals or by deoxyribonuclease I

We showed previously [12] that peak 3 appears (Fig. 2, inset) as a result of submerging the scDNA-modified HMDE in a solution containing free radicals prior to the a.c. voltammetric measurement (Fig. 1B). In this study, we use this system for testing natural and industrial samples.

Fig. 3. Linear sweep (A) and square-wave (B) response of the sensor. (---), control ocDNA (see Fig. 2); (-·-·-), blank scDNA response; (—), sensor response for $50 \mu\text{M} [\text{Fe}(\text{EDTA})]^{2-}$, $1 \text{ mM sodium ascorbate}$, $0.03\% \text{ H}_2\text{O}_2$ in $50 \text{ mM sodium phosphate}$ pH 8.5. LSV, scan rate 1 V s^{-1} ; SWV, frequency 2 kHz , step potential 3.05 mV , amplitude 100 mV . For other details, see Fig. 2.

We tested the influence of individual components of the Fenton reaction mixture (in which hydrogen peroxide is reduced to hydroxide anion and hydroxyl radical by $[\text{Fe}(\text{EDTA})]^{2-}$; the ferrous ion is then regenerated by reaction with ascorbate [18]) on the immobilized scDNA. No cleavage was observed in the absence of H_2O_2 (in a solution of $50 \mu\text{M Fe}^{2+}$). However, in solutions free of the ferrous complex or ascorbate (but containing hydrogen peroxide), a small peak 3 was obtained (Table 2). For this reason, in all further experiments the reaction was started by addition of hydrogen peroxide into stirred solution with an immersed sensor electrode. Fig. 2 displays the temporal increase of peak 3 in a stirred solution of $50 \mu\text{M Fe/EDTA}$ reagent; under these conditions, the peak 3 height rapidly increased up to about 1 min and then leveled off, probably due to decomposition of a substantial portion of the H_2O_2 and/or ascorbate added. Deeper DNA cleavage (resulting in a further increase of peak 3 as more strand breaks occur) can be achieved by increasing the starting concentra-

tion of hydrogen peroxide and ascorbate or by a second addition of these compounds after the first minute (see inset in Fig. 2). Similar results were obtained when the ferrous/ferric redox pair was replaced by the cuprous/cupric pair (Table 2). In another experiment, the sensor was immersed in a solution containing 20 U ml⁻¹ deoxyribonuclease I, an enzyme that introduces single-strand breaks in DNA. Again, an incubation time-dependent increase of peak 3 was observed (Table 2). More details about the enzyme interaction with immobilized DNA will be published elsewhere.

3.2. Testing of natural and industrial samples

The possibility of detecting damage to immobilized scDNA by hydroxyl radicals generated through the Fenton reaction in various media was investigated. In addition, the influence of the sample by itself (with no additions) on the sensor response was tested. Results are shown in Table 3. In natural ground water samples, as well as in technological waters, the additions of the reagents yielded qualitatively similar results as the laboratory-prepared solutions, suggesting that the sensor is applicable in environmental analysis. Satisfactory results were obtained with beverages such as

^f Juice squeezed from fresh tangerine, centrifuged, 10-fold diluted with distilled water and heated in a boiling water bath for 5 min.

wine or tangerine juice (especially if diluted 10-fold, Table 3). With tangerine juice, significant DNA nicking activity was detected in the pure (centrifuged and diluted) natural sample; however, after 5 min of boiling, no DNA damage was observed. When the complete Fenton reaction mixture was added to the boiled sample, nicking of the probe DNA was observed again, suggesting that the original nicking was due to the activity of a thermolabile nuclease.

Strong damage to the immobilized scDNA was observed in the water sample obtained from a flooded uranium mine (sample VK3 with no additions, Tables 1 and 3). In contrast, the water sample taken at the output of the water purification plant (HVP) and from the open catchpit (VCA II) provided no sensor response unless the Fenton reaction mixture was added. This result demonstrates the capability of the sensor to monitor the contamination of technological waters and to detect unknown DNA damaging agents. (As shown in Table 1, the 'input' sample displays a higher content of iron, uranium and insoluble substances as compared to the 'output' sample.

Redox active metal-induced damage to DNA by non-Fenton mechanisms under aerobic conditions has been published by others [19–21]). The low (or zero) sensor responses for the HVP and VCA II samples (without addition of the Fe/EDTA reagent, Table 3), not exceeding the response of, for example water from a puddle, also suggest the good efficiency of the decontamination process and relative safety of the uranium technology.

It may be expected that biological samples with high protein contents (blood) will require deproteination to prevent protein interferences [12,22,23].

3.3. Linear sweep (LS) and square-wave (SW) voltammetry

The best resolution of DNA peak 3 is reached using phase-sensitive alternating current voltammetry (phase-in component). This technique, however, is not included in most moderately priced instruments and will hardly be widely applied in biochemical and molecular–biological laboratories. For this reason, we tested more common fast-scan voltammetric techniques (included in the software of many modern voltammetric analyzers) for their ability to differentiate between sc and oc DNA-modified mercury electrodes and to give the sensor response for 50 μM Fe/EDTA reagent after 1 min. Fig. 3 shows, in LSV, only a poorly developed peak (inflex) 3 was obtained as a result of the cleavage reaction (although the control ocDNA-modified electrode yielded a quite well-developed peak). On the other hand, square wave voltammetry provided much better sensitivity, yielding a well-developed peak 3 under the same conditions. In SWV, peak 3 is even relatively higher (as compared to the less negative peak 1, yielded by both sc and ocDNA) than in a.c. voltammetry. However, the peak resolution is somewhat worse. In any case, SWV seems to be a valuable technique for electrochemical transduction of the sensor response. Our preliminary results further suggest that damage to scDNA can also be sensitively detected using constant current derivative chronopotentiometry in neutral ammonium formate [24,25]. HMDE may represent a relative disadvantage of this biosensor. Our at-

tempts to utilize carbon electrodes for the same purpose were however, not successful, as the response of lin (oc) DNA and scDNA did not substantially differ [26]. Further experiments will be performed to find and to optimize the electrochemical technique that provides the best sensitivity and selectivity.

In conclusion, our results show that a scDNA-modified HMDE that sensitively reflects DNA strand breaks can be applied as an electrochemical biosensor for the analysis of DNA damage-inducing agents in natural and industrial waters. This biosensor is capable not only to detect the presence of an unspecified DNA-nicking agent, as shown in this paper, but also to provide information about the nature of this agent. Our preliminary results show that by combining electrochemical and biochemical approaches, information about the nature of the metal involved in Fenton chemistry as well as about the base damage preceding the strand interruption can be obtained. More details will be published elsewhere.

Abstract

N-n-Octylaniline in xylene is used for the extractive separation of palladium(II) from hydrochloric acid medium. Palladium(II) was extracted quantitatively with 10 ml of 2% reagent in xylene from 0.5–2 M hydrochloric acid medium. It was stripped from the organic phase with 1:1 ammonia and estimated spectrophotometrically with pyrimidine-2-thiol at 420 nm. The effects of metal ion, acids, reagent concentration and of various foreign ions have been investigated. The method affords binary separation of palladium(II) from iron(III), cobalt(II), nickel(II) and copper(II) and is applicable to the analysis of synthetic mixtures and alloys. The method is fast, accurate and precise. © 1997 Elsevier Science B.V.

Keywords: Palladium; *N-n*-Octylaniline; Solvent extraction

1. Introduction

The abundance of palladium in the earth's crust is $8.5 \times 10^{-13}\%$. Palladium and its alloys have a wide range of applications both in the chemical industry and in instrument making. As a catalyst it is principally used in various organic reactions.

Solvent extraction has been widely used for separation of the platinum metals [1–3]. This technique of separation uses the differences in their kinetic behaviour for the formation of extractable species as well as the strength of electrostatic interaction of their chloro-complexes with liquid anion exchangers. The inertness of the chloro-complex of palladium(II) towards aqua-

tion plays an important role in its extraction from acidic solution by an anion exchange mechanism with organic bases such as amines [4–7].

High molecular weight amines (HMWA) popularly known as liquid anion exchangers, uniquely combine some of the advantages of liquid–liquid extraction and ion exchange. Further, Smith and Page [8] observed that the acid binding property of HMWA depends on the fact that the acid salts of these bases are essentially insoluble in water but readily soluble in hydrocarbon solvent.

The use of *n*-octylaniline in the extraction of the noble metals has been described [7,9–12]. Palladium(II) was extracted with 1 M *n*-octylaniline in chloroform from 3 M hydrochloric acid but this method requires several extraction stages for quantitative recovery of metal ion (2×15

* Corresponding author. Fax: +91 231 656133.

min) [7] and the effectiveness of *n*-octylaniline in these extractions depends on its method of preparation [13]. Tri-iso-octylamine [14] has been used as a group extractant for the noble metals from 1 M hydrochloric acid medium with 2 min shaking. Palladium(II) was completely extracted from 11.5 M hydrochloric acid as a chloro-complex in the presence of tin(II) chloride by tri-*n*-octylamine (TOA) [15] in benzene and measured at 410 nm. Other extractants reported for palladium(II) are triphenylphosphine [16], di-octyl sulphoxide [17], tri-isobutyl phosphine sulphide [18] and sulphide podand 1,12-di-2-thienyl-2,5,8,11-tetra-thiadodecane (TTD) [19].

N-n-Octylaniline has been employed successfully in this laboratory for extractive separation of In(III), Tl(III), Zn(II), Bi(III) and Ga(III) [20–22]. Owing to generally greater solubility, primary amines are used less frequently than secondary amines. In addition, in *N-n*-octylaniline, the presence of an octyl group attached to the amino group in aniline renders this amine less soluble in water. Here, the use of *N-n*-octylaniline as an extractant for palladium(II) from hydrochloric acid is reported.

Because the determination of small amounts of noble metals in minerals containing large amounts of base metals is difficult, the effectiveness of *N-n*-octylaniline was evaluated as an extractant

Pd(II) = 100 μ g; Aq/Org = 25:10.

for palladium(II) from a variety of palladium-bearing materials and process solutions. The method proposed here offers extraction separation and determination of palladium(II) from associated elements as a function of hydrochloric acid media.

2. Experimental

2.1. Apparatus

An Elico digital spectrophotometer model CL-27 with 1-cm quartz cells was used for absorbance measurements.

2.2. Reagents

A stock solution of palladium(II) was prepared by dissolving 1 g of palladium chloride hydrate (Johnson Matthey, UK) in dilute analar hydrochloric acid (1 M) and diluting to 100 ml with distilled water and standardised [23]. A working solution of 100 µg/ml was made from it by diluting the stock solution with distilled water.

Other standard solutions of different metals used to study the effect of diverse ions were prepared by dissolving weighed quantities of their salts in distilled water or dilute hydrochloric acid. Solutions of anions were prepared by dissolving the respective alkali metal salts in water. All the chemicals used were of AR grade. Distilled water was used throughout. *N-n*-Octylaniline was prepared by the method of Gardlund et al. [24] and its solutions (% v/v) were prepared in xylene.

2.3. Procedure

To an aliquot of solution containing 100 µg palladium(II) in a 125-ml separatory funnel, enough hydrochloric acid and water were added to give a final concentration of 1 M with respect to hydrochloric acid in a total volume of 25 ml. The aqueous phase was equilibrated once with 10 ml of 2% *N-n*-octylaniline solution in xylene for 1 min. The phases were allowed to separate and the metal from the organic phase was back-stripped with two 5-ml portions of 1:1 ammonia solution. The extracts were evaporated to moist

where R = $-C_6H_5$, R' = $-CH_2(CH_2)_6CH_3$.

The extraction mechanism can be explained as follows:

dryness and leached with dilute hydrochloric acid to form the solution. Palladium(II) was estimated spectrophotometrically with pyrimidine-2-thiol [25,26].

3. Results and discussion

3.1. Effect of acidity

The extraction of 100 µg of palladium(II) was carried out from different acid media with 2% *N-n*-octylaniline in xylene keeping the aqueous to organic volume ratio 2.5:1. The extraction was found to be quantitative from hydrochloric, sulphuric, perchloric and hydrobromic acid (Fig. 1) but was incomplete in nitric acid due to emulsion formation. Although the extraction is quantitative in sulphuric acid media over a wide range, it needs a higher concentration while in perchloric acid and hydrobromic acid media, a narrow range of acidity is required and the equilibration time is greater. Hence the use of hydrochloric acid is recommended for further studies.

3.2. Effect of reagent concentration and nature of the extracted species

The concentration of *N-n*-octylaniline in xylene was varied from 0.2 to 7% over the acid range 0.2–10 M hydrochloric acid. It was found that 2% reagent in xylene was needed for quantitative extraction of metal ion from 1 M hydrochloric acid (Table 1).

Log–log plots of the distribution ratio versus *N-n*-octylaniline concentration (Fig. 2) at 4.0 and 5.0 M hydrochloric acid yield slopes of 1.8 and 1.5, respectively indicating that the metal to amine ratio in the extracted species is 1:2. The probable extracted species is,

Variation of equilibration period from 5 s to 30 min showed that shaking for 30 s each for hydrochloric and sulphuric acid, 10 min for perchloric acid, 5 min for hydrobromic acid is

Fig. 2. Log–log plot of distribution ratio (D_{Pd}) versus N - n -octylaniline concentration at 4 M and 5 M HCl.

needed for complete extraction of palladium(II). Prolonged shaking up to 30 min had no adverse effect on the extraction.

The extraction of palladium(II) was quantitative when aqueous to organic volume ratio was 100:10. The aqueous to organic volume ratio in the recommended procedure was 2.5:1.

The loading capacity of 10 ml of 2% N - n -octylaniline was found to be 7.5 mg of palladium(II).

3.3. Effect of diluents

The extractions were performed from 1 M hydrochloric acid medium using 2% N - n -octylaniline in various solvents as diluents. The extraction was incomplete with n -butyl alcohol, 4-methyl-2-pentanol, chloroform and amyl alcohol as diluents for amine. The extraction becomes quantitative with amine solution in benzene, toluene, xylene, isobutyl methyl ketone, carbon tetrachloride and amyl acetate. Xylene is recommended for further extraction procedures.

Table 2

Effect of diverse ions on the extractive determination of Pd(II)

Pd, 200; Cu(II), 5000	99.6	0.11	99.5	0.16

^a Average of six determinations.

3.4. Effect of diverse ions

Palladium(II) was extracted in the presence of a large number of diverse ions. The tolerance limit was set at the amount of foreign ions caus-

ing an error of less than $\pm 2\%$ in the recovery of palladium(II) (Table 2). It is observed that the method is free from interference from a large number of transition, non-transition metal ions and anions.

3.5. Binary separation of palladium(II) from iron(III), cobalt(II), nickel(II) and copper(II)

The method permits separation and determination of palladium(II) from a binary mixture containing either iron(III), cobalt(II), nickel(II) and copper(II).

Palladium is separated from iron(III), cobalt(II), nickel(II) and copper(II) by its extraction with 2% *N-n*-octylaniline in xylene from 1 M hydrochloric acid. Under these conditions all the base metals remain quantitatively in the aqueous phase where these are determined spectrophotometrically with thiocyanate [23], 1-nitroso-2-naphthol [23], DMG [23] and pyrimidine-2-thiol [27], respectively. Palladium is stripped from the organic phase with two 5-ml portions of 1:1 ammonia solution. The extracts were evaporated to moist dryness and leached with 1 M hydrochloric acid to form the solution. Palladium(II) was estimated spectrophotometrically with pyrimidine-2-thiol. The recovery of palladium(II) and that of the added ions was 99.4% and the results are reported in Table 3.

3.6. Separation and determination of palladium(II) in a synthetic mixture

Naturally occurring palladium(II) is always associated with the other platinum group and base metals, hence its separation from these metals is of great importance. Under the optimum extraction conditions for palladium(II), there is a quantitative extraction of Au(III), Pt(IV), Os(VIII) and incomplete extraction of Ru(III), Rh(III) and Ir(III). But the coextracted metal ions cannot be backstripped by 1:1 ammonia solution. Thus the reagent (*N-n*-octylaniline) is made selective towards palladium(II) by taking advantage of the stripant used. The proposed method allows the separation and determination of palladium(II) from many metal ions and the results of analyses are shown in Table 4.

3.7. Analysis of alloys

The proposed method is applicable for the analysis of various alloys for palladium content. If the sample is available, the dissolution is carried out

according to the earlier procedures [25,26,28]. This brings the elements present into the proper oxidation states for extraction of palladium(II) with *N-n*-octylaniline. However, the samples were not available at the working place, which forced us to use synthetic mixtures. These were prepared corresponding to the composition of the alloys. The results of the analysis are reported in Table 5. The average recovery of palladium(II) was 99.6%.

4. Conclusion

The important features of the method described here are that: (i) it permits selective separation of Palladium(II) from other platinum group and base metals which are generally associated with it; (ii) it is free from interference from a large number of diverse ions which are associated with palladium(II) in its natural occurrence; (iii) low reagent concentration is required; (iv) time required for equilibration is very short (30 s); (v) the method is applicable to the analysis of palladium(II) in synthetic mixtures with composition corresponding to alloys; (vi) the method appears to enable a higher ratio of sample to reagent solution to be used which can be of advantage when dealing with trace amounts of palladium(II), as in refinery process streams; and (vii) it is very simple, selective, reproducible and rapid requiring only half an hour for separation and determination.

Abstract

A simple, inexpensive, on-line bulk acoustic wave (BAW) DNA biosensor is proposed by using an Ag-plated surface rather than the conventional Au surface. Bovine serum albumin (BSA) is used as an active coating for DNA immobilization. Impedance analysis reveals that the film composed of didodecyl dithiono-oxamide (DDDTO) and BSA can dramatically enhance the amount of immobilized DNA. Detection of dissociation and hybridization of immobilized DNA is demonstrated as an example of the potential application of this type of acoustic wave DNA biosensor in clinical practice. © 1998 Elsevier Science B.V. Keywords: Bovine serum albumin; DNA biosensor; Silver surface; Bulk acoustic wave; Immobilization

1. Introduction

For many years, researchers have made great efforts to develop a good method for DNA sensing, and DNA hybridization is most often used. Radioactive probe (usually labeled with ^{32}P) techniques dominated the field of hybridization assay for more than two decades and provided extremely high sensitivities. However, the short shelf life, the health hazard, the cost and the long exposure times (many hours to days) have limited its development in the clinical laboratory. Therefore, new methods, which eliminate the time-consuming labeling procedures and the problem of

fluctuations, are necessary to make it safer and more convenient for DNA molecular diagnostics.

Among those methods tried, an optical sensor with a detection limit of 86 ng/ml was reported [1]. As another approach, nano or subnanogram quantities of the complementary DNA were detected by using electrochemical techniques, such as voltammetric DNA sensors [2,3], carbon-paste/PSA method [4], and FIA [5]. Hashimoto et al. [6] even reported a 0.1 pg/ml detection limit for a 4.4-kb target sequence. These sensors have the ability to respond to the structure/formation changes of DNA duplex. But they have the limitation of requiring the use of redox-active DNA intercalators or groove-binders as label, which are often sequence-dependent. A similar situation is also faced by optical DNA sensors. Strictly, these

* Corresponding author. Fax: +86 731 8824525; e-mail: szyao@hunu.edu.cn

two kinds of DNA sensor cannot provide real response signals, i.e. they measure other substances rather than the DNA molecule itself.

On the other hand, the bulk acoustic wave (BAW) DNA biosensor, because of its simplicity, capability of offering in-situ information and possibility for miniaturization and incorporation in a microchip array, has attracted much attention. This so-called DNA biosensor is a bulk acoustic wave device with single stranded (ss-)DNA immobilized on the sensing areas of the device. The ss-DNA complementary to target DNA are then hybridized with a sample solution containing the target DNA, and the bulk acoustic wave signals are recorded. Compared with the existing techniques, it does not need an extra indicator and reflects the real reaction responses. It has the advantages of low sensitivity to nonspecific DNA and high sensitivity to the target molecule. Moreover, it has the ability to record a real-time plot of each step of the DNA reaction and thus provides an approach to the dynamic and mechanism study. A key step in developing such sensors is to immobilize probe DNA molecules effectively onto the surface of the bulk acoustic wave devices.

Most bulk acoustic wave DNA biosensors are made with gold-plated quartz crystals. Fawcett et al. [7] first reported such a sensor in 1988. They took an AT-cut gold-plated quartz crystal and had the single-stranded nucleic acid immobilized onto it through covalent binding to a styrene-acrylic acid copolymer. The real in-situ liquid-phase measurement was carried out by Okahata et al. [8] who bound the modified ss-DNA having an -SH group at the 5'-phosphate end onto a BAW device with Au electrodes on both sides through self-assembled chemisorption, which was developed by Ito et al. [9]. They also developed a cast film of a DNA-lipid complex deposited on a quartz-crystal microbalance to study intercalation behavior of dyes in DNAs [10]. Su et al. [11] undertook a study to elucidate the immobilization of nucleic acids on PdO deposited on Au-plated quartz crystals with a view to study the DNA biosensor through the network analysis method. In addition to these, LB-membrane and other

methods have also been developed [12,13].

However, to our knowledge, few investigations have been undertaken to evaluate the immobilization behavior of DNA on the surface of Ag-electrode quartz crystals of the bulk acoustic wave (BAW) sensor — these are more easily available and have the advantages of much lower cost than the Au-plated ones. In this paper, we proposed a BAW biosensor with probe DNA covalently immobilized on the didodecyl dithiono-oxamide (DDDTO)-bovine serum albumin (BSA) modified Ag surface.

Bovine serum albumin, as an important modifying material in clinical laboratories, has attracted much interest. Due to the presence of amino groups in its structure, it has been widely used in enzyme sensors to assist the immobilization of enzyme molecules [14,15]. Results have shown that BSA can hardly be desorbed from the surface of the self-assembly thiol monolayer [16]. Thus, the BSA method combined with the self-assembly technique in more recent years has improved its stability and widened its application in the study of biological phenomena. The reports from those early researchers have confirmed that sulfide and/or disulfide compounds can be strongly adsorbed on Ag surfaces, as well as Au and Cu surfaces, forming a very stable monolayer [17]. Hence, the combination of BSA method and self-assembly technique can be used for immobilizing DNA on Ag-plated BAW sensors.

In our preliminary work, the possibility of immobilizing DNA on an Ag-plated BAW device is investigated. Impedance analysis has been used to study the surface modification procedures and the DNA immobilization processes. The experiment results show that DNA can be successfully immobilized on the less costly BAW sensor with an Ag surface which gives a good result in terms of immobilizing capacity and stability. The dissociation and hybridization experiments reveal that the proposed Ag-plated BAW DNA biosensor can be reused and can give as good results as those from Au-plated ones.

2. Experimental

2.1. Apparatus

The experimental setup was the same as that described previously [18]. An AT-cut 9 MHz quartz crystal (Model JA-5, Peking Factory No. 707) with silver electrodes on both sides (area: $0.28 \text{ cm}^2 \times 2$) was used as the BAW resonator. A home-made oscillator [19] was used to drive the crystal at its resonant frequency in aqueous solutions. The frequency output from the oscillator was measured by a universal counter (Model SC-7201, Iwatsu Co., Tokyo) and was recorded by an IBM compatible personal computer via an HPIB bus and an HP-IB interface plugged in the computer (Hewlett-Packard). An HP 4192A-LF impedance analyzer was employed to perform admittance measurements of the BAW crystal. The temperature was controlled by a water jacket and a model WMZK-1 Temperature Controller (Medical Equipment Co. Shanghai) at $15 \pm 0.1^\circ\text{C}$ except where otherwise stated.

2.2. Materials

Double-stranded salmon sperm DNA (ds-DNA, Shanghai Biochemical Products Institute) and bovine serum albumin (MW 66 000, $A_{415 \text{ nm}}^{0.1\%} < 0.06$, Shanghai Bo'ao Biotechnical Co.) were used as received. Denatured single-stranded DNA was obtained by heating the native dsDNA in a water bath at 100°C for ca. 5 min followed by rapid cooling in an ice bath. $2 \times \text{SSC}$ buffer solution was prepared by mixing 300 mmol l^{-1} sodium chloride with 30 mmol l^{-1} sodium citrate, and its pH value was adjusted to pH 7.4. Didodecyl dithiono-oxamide (DDDTO) of chemical-reagent grade was used. HOAc–NaOAc buffer solution (pH 5.0) was deoxygenated before each experiment. All chemicals used were of analytical-reagent grade. Double distilled water was used for the reagent preparation and throughout the procedure.

2.3. Surface modification

The surface modification processes were monitored through impedance measurements. The measurements were made in-situ with one surface of the BAW resonator in contact with solutions, except where otherwise stated. Before the experiments, 30 min were needed to stabilize the whole setup including the impedance analyzer, the frequency counter and the power supply.

1. *Cleaning procedure.* The BAW resonator was mechanically polished to a mirror finish using 50-nm alumina to avoid the effects of surface roughness on frequency response. After being rinsed with distilled water, the resonator was dipped for 30 min in 1.0 mol l^{-1} NaOH and rinsed again with distilled water. Then 1.0 mol l^{-1} HCl was applied to the surface for another 30 min, followed by rinsing with water, alcohol, water and air-dried. With this cleaning, a clean crystal surface was formed on each sensor to give better repetition.
2. *DDDTO–BSA modification.* The cleaned BAW resonator was dipped in a ca. 1.2% solution of DDDTO in acetone for 1.5 h, then air-dried and washed with acetone and water three times. After this, the sensing surface was treated with $20 \mu\text{l}$ 4.5% (wt.) of BSA solution for 2 h.
3. *DNA immobilization.* After rinsing thoroughly with water and then HOAc–NaOAc buffer solution, $20 \mu\text{l}$ ds-DNA solution ($0.5 \mu\text{g } \mu\text{l}^{-1}$) was added into the detector cell and left for 1.5 h. Then the crystal was washed with HOAc–NaOAc buffer and water.

3. Results and discussion

3.1. Modified Ag-plated BAW sensor with DDDTO and BSA

It is well known that a bulk acoustic wave sensor is an electromechanical transducer which converts electrical energy to mechanical energy, and vice versa. Its electrical equivalent circuit was shown previously [20]. For this equivalent circuit, the admittance Y (reciprocal of impedance Z) is:

$$Y = 1/Z = G + jB$$

where G is conductance and B , susceptance, which are the real part and the imaginary part of admittance Y , respectively. From the impedance analysis, the four circuit elements, i.e. R_m , the motional resistance, L_m , the motional inductance, C_m , the motional capacitance and C_0 , the static capacitance, can be related to the loss of mechanical energy dissipated to the surrounding medium, the mass and the mechanical elasticity of the vibrating body, and the geometry of the quartz crystal electrode [20], respectively. They can be extracted from G and B frequency spectra obtained through impedance measurements (Fig. 1) by fitting admittance data using a nonlinear least square technique, the Levenberg–Marquardt method [21,22], to minimize the sum of the squares of the differences between measured and computed admittance data.

The modification of DDDTO and BSA onto the Ag surface was monitored by the BAW device through impedance measurements. Fig. 2(a) shows a typical profile of the frequency of maximum conductance (f_o , $f_o = 1/2\pi(L_m C_m)^{1/2}$) responses of the sensor upon the introduction of DDDTO solution onto the Ag surface. As can be seen from Fig. 2(a), f_o decreases rapidly during the first 10 min for up to 33 Hz, and then slows down. As DDDTO is self-assembled onto the Ag

Fig. 1. Typical plots of the conductance (G) and susceptance (B) spectra of a 9-MHz BAW resonator.

Fig. 2. Responses of the resonant frequency (Δf_o , a) and static capacitance (C_0 , b) of the 9-MHz BAW device with silver-plated electrodes upon DDDTO loading.

surface, we can assume that initially the binding sites on the surface were sufficient enough to let DDDTO molecules be easily adsorbed onto the Ag surface when its solution was applied to the bare Ag electrode and caused a rapid decrease in f_o . With time, the adsorbed monolayer began the procedure of assembling towards a highly ordered structure [17,23–25], as well as the procedure of adsorbing onto the Ag surface. Accordingly, the rearrangement of the DDDTO molecules made the mass loading not so significant as during the first 10 min.

Additional information, such as the static capacitance C_0 , can be obtained from the equivalent circuit parameters measurements. C_0 is predominantly determined by the dielectric properties of the quartz crystal. Yet, in a conductive solution, it is directly affected by the structure of the electrified interface, i.e. the capacity of the electrical double layer at the charged interface [26]. As shown in Fig. 2(b), the initial adsorption results in

an increase in C_0 and further adsorption leads to a significant decrease. The DDDTO molecules approach the surface in its native state with most of the polarizable groups located on the outer surface, which causes an increase in the polarity and hence the charge density at the inner Helmholtz plane and thus a rise in the double-layer capacitance. As the adsorbed monolayer forms a self-assembly structure, the declination in surface polarity due to the redistribution of those groups occurs, leading to a decrease in the double-layer capacitance and thus in C_0 [27].

The BSA modification step was subsequently carried out. From the experiment, we noted that the DDDTO-coated BAW sensor exhibited a rather hydrophobic surface, which gave a good background for BSA adsorption because BSA molecules tend to be adsorbed strongly to a hydrophobic surface [28]. The pH was pH 5.0 which was around the isoelectric point of the BSA molecule and thus enhanced its hydrophobicity by loss of its net electric charge.

In impedance analysis, L_m is the quantity reflecting the mass of the vibrating body. Yet, because L_m and C_m are always correlated, the corrected L' is used [29]. The real-time plots of changes in L' during the procedure of BSA adsorption are given in Fig. 3. The overall L' shift is 60.44 μH corresponding to a frequency shift of 120 Hz.

It is known that the width of the half-height of the conductance maximum of the crystal should broaden if the viscoelastic properties of the film affect the resonant frequency. In this stage, no significant difference was found between the bare crystal and the DDDTO–BSA coated one. Therefore the film behaved as a quasi-rigid layer under the experimental conditions. Assuming that BSA is an ellipsoidal molecule with rough dimension of $4 \times 4 \times 14$ nm [30], monolayer coverage of BSA should be approximately 550 ng cm^{-2} for head-on type adsorption and 140 ng cm^{-2} for side-on type arrangement calculated from the molecular mass of 66 000 as two extreme cases. These correspond to frequency changes of ca. 140 Hz and 36 Hz for our 9-MHz AT-cut quartz crystal, respectively, based on the Sauerbrey's equation [31]. The frequency shift obtained in our experiment shows

BSA loading is between the two extreme cases, suggesting that the arrangement of BSA molecules under the experiment conditions was not exactly like the two extreme cases. The above discussion does not take into account the possible denaturing and unfolding of BSA on the electrode surface. It should be emphasized that this discussion is not strictly enough, however this theoretical calculation can provide a rough estimate of the upper and lower limits of the amount of adsorption.

3.2. Immobilization of DNA

Covalent immobilization of DNA on the DDDTO–BSA modified Ag surface was observed (Fig. 4). The in-situ frequency responses of the control experiments are also shown in Fig. 4.

The frequency shift Δf_0 of the first curve (bare electrode surface) is -140 Hz, while the third curve (DDDTO–BSA modified crystal) gives Δf_0 of -482 Hz, confirming the successful immobilization of DNA on the Ag-plated BAW device.

Owing to the presence of amino groups in the BSA structure, the BSA-coated quartz crystal becomes protonated and attracts the negative charge of the nucleic acid's 5'-phosphate groups, forming a phosphoramidate bond.

Fig. 3. Inductance changes of the silver-plated BAW sensor with time upon BSA adsorption.

Fig. 4. Comparison of frequency changes of the silver-plated BAW DNA biosensor with time after addition of DNA solution (at point B) under different surface modification conditions: (1) Bare electrode; (2) Single DDDTO modified electrode; (3) DDDTO-BSA modified electrode.

It is known that the isoelectric point of the DNA molecule is in the range of pH 4.0 ~ 4.5. When pH > 4.0, the DNA molecule exhibits a highly polycationic state. On the other hand, as the stability of hydrogen bond formed between the base pairs depends on the pH value, the pH of the solution is often kept at less than 11 for the sake of stability [32]. Thus, the medium pH in this experiment is chosen to be within the range of 5.0 ~ 7.4, which makes the DNA molecule more readily bind the amino groups of the BSA molecule.

Conductance spectra of the BAW resonator in solutions are shown in Fig. 5, the G_{\max} decreases during the DNA immobilization and the width of the half-height of the conductance maximum broadens, suggesting that the adsorbed DNA film is more viscous than that of the sublayers and hence the amount of the adsorbed DNA cannot be determined exactly using the Sauerbrey's equation. Further study on the relationship between the frequency response of the proposed BAW DNA biosensor and the mass of adsorbed DNA is being undertaken. The initial DNA contact (curve b) causes the decrease in G_{\max} (or an

increase in R_m) while the f_o remains unchanged (which implies no significant mass loading or elasticity change takes place), suggesting an increase in loss of mechanical energy dissipated to the surroundings, i.e. addition of DNA causes an increase in $\rho\eta$ of the solution. On the other hand, the final f_o of the DNA solution shifts towards a lower frequency (curve c), reflecting an increase in L_m . The above observation reflects the adsorption of DNA onto the surface of the silver-plated electrode.

3.3. Comparison of immobilizing capacity

Because of its amido groups, DDDTO can attract the nucleic acid's 5'-phosphate groups, too. However, due to the steric hindrance effect caused by the two long alkyl chains in its structure, it might not provide many active binding sites for immobilizing DNA which itself is a huge molecule. To compare the value of the frequency shift corresponding to DNA immobilization on different surfaces, a series of experiments were carried out (Fig. 4). The frequency changes of the BAW device were monitored under the same conditions.

Fig. 5. Conductance spectra of the silver-plated BAW DNA biosensor in solution observed in the course of DNA immobilization. (a) DDDTO-BSA coated crystal; (b) Initial contact of the crystal with DNA; (c) The sensor with immobilized DNA.

Compared with the bare crystal and the single DDDTO coated one, the film consisting of DDDTO and BSA layers dramatically enhanced the amount of immobilized DNA. Thus we may deduce that the BSA coated on the DDDTO sublayer possesses a large surface area and provides a rich active site for immobilizing DNA.

In order to test the stability of the modified DNA layer, the unreacted BSA was blocked with 0.1 M glycine solution (pH 7.4). Then, the crystal was immersed in HOAc–NaOAc buffer, and the frequency was monitored. Results showed that the frequency of the BAW DNA biosensor slightly increased (perhaps resulting from the removal of nonspecific adsorption), only in the initial 10 min, and then stabilized with a frequency variation of ± 8 Hz for an observation interval of 1 h.

3.4. Dissociation and hybridization of DNA on the BAW DNA biosensor

The dissociation and hybridization processes of the immobilized DNA were monitored as an example of the potential application of this BAW DNA biosensor. An HOAc–NaOAc solution containing 1 mg ml⁻¹ DNA was applied to the DDDTO–BSA treated Ag surface. It was then allowed to incubate overnight. Immobilized DNA was dissociated by treating with 95 ~ 90°C 2 × SSC buffer solution (pH 7.4) for 5 min to get single-stranded (ss-)DNA. Then it was hybridized again with ss-DNA. In order to get a highest ratio of hybridization, the condition was controlled at 65°C in a 2 × SSC hybridization buffer solution (pH 7.4) [33]. The series resonate frequency was measured before and after each step and the results are listed in Table 1. Apparently, the longer the incubation time, the more the amount of immobilized DNA, provided that the saturation point was not reached.

The overall Δf_0 corresponding to DNA immobilization is 658 Hz, confirming the successful immobilization of DNA on the Ag-plated BAW sensor. The dissociation step caused an increase in f_0 for about 335 Hz. Somehow it is a bit higher than that expected for the loss of all complementary single strands (329 Hz). Partial removal of nonspecific adsorption during the washing step

Table 1
Frequency responses of the BAW DNA sensor under different conditions

BAW DNA sensor	Δf_0 , Hz
Coated with DDDTO–BSA ^a	0
Modified with ds-DNA (1 h)	-119 ± 2
Modified with ds-DNA (overnight)	-658 ± 2
Dissociated	-323 ± 2
Hybridized	-651 ± 2

The values are the average of five experiments.

^aThe frequency responses to DDDTO and BSA coatings are controlled at about 160 Hz and 120 Hz, respectively.

might account for this observation. However, the difference is not very significant and is around the range of experimental error. In the hybridization procedure, the 328-Hz decrease is in accordance with the expected value, suggesting a possible way to make the sensor reusable. Compared with the results given by the Au-plated DNA sensors [13], it can be said that our Ag-plated BAW DNA biosensor can provide as good results as those from Au-plated ones.

4. Conclusions

The possibility of immobilizing DNA on Ag rather than an Au-plated BAW device has been investigated. The results demonstrated that on the basis of DDDTO–BSA coating, DNA can be immobilized on the Ag surfaces. Successful DNA immobilization in our experiment makes the proposed silver-plated BAW DNA biosensor a promising tool in clinical applications. The standard deviation of background signals during the measurement of series resonant frequency is in the region of ± 2 Hz. Accordingly, the limit of detection for on-surface DNA under the currently unoptimized experimental conditions is about 2 ng. Since this method is uncomplicated, rapid, conceptually simple, and economically feasible, it will become a competitive method over presently existing techniques. Further exciting possibilities for the future lie in the development of a rapid response method combined with this BAW DNA biosensor. The specificity could be raised by im-

mobilizing a highly specific genetic fragment as the probe.

Abstract

An investigation of chemiluminescence (CL)-emission generated by the oxidation of pyrogallol using various inorganic oxidant compounds is reported in this F.I.A.-merging zone application. The oxidant compounds that showed measurable CL-emission were permanganate, periodate, hypochlorite anions, cerium(IV) and hydrogen peroxide. The different oxidant compounds showed CL-emissions at different pH-ranges. The CL-emission was limited by the inner filter effect and this was more intense for oxidants of selective oxidation. Kinetic effects were also found in the case of oxidation by permanganate. Plots of CL-emission against pH give evidence of speciation and or deactivation mechanism effects. The analytical parameters for the determination of the oxidants are given. Sensitivities of 895 600, 19 500, 33 723, 10 680 and 56 703 mV M⁻¹ were found for the determination of permanganate, cerium(IV), periodate, hypochlorite and hydrogen peroxide, respectively. The calibration curves of the oxidant determination were generally S-shaped; the S-shaped calibration curve of periodate was closer to a straight line relationship while that of hypochlorite was almost a straight line; detection limits in the range of 10⁻⁴ M oxidant concentration were found for nearly all oxidants. The analytical parameters for determination of pyrogallol by the CL-emission generated through oxidation by the different oxidants at optimum conditions were 1.16 × 10⁶ mV M⁻¹ for permanganate; 0.086 × 10⁶ mV M⁻¹ for cerium(IV); 0.91 × 10⁶ mV M⁻¹ for periodate; 0.012 × 10⁶ mV M⁻¹ for hypochlorite; and 0.25 × 10⁶ mV M⁻¹ for hydrogen peroxide. The detection limit was 1.0 × 10⁻⁴ M. The nearly straight-line relationship (initial part of the plot) for CL-emission with oxidant concentration gives an indication that the CL-reaction of pyrogallol oxidation by hypochlorite proceeds through a process that involves energy transfer while the pronounced S-shaped curve produced by permanganate gives the indication that the reaction proceeds through a process that does not involve energy transfer according to the mathematical model of CL-emission that controls the F.I.A.-merging zone technique of the flow apparatus used in this work. The sequence of completeness of the oxidation process by each oxidant was MnO₄⁻ > H₂O₂ > IO₄⁻ > OCl⁻; the stoichiometric quantity of the oxidant per pyrogallol molecule for the rapid part of the overall oxidation by each different oxidant was attempted; this is an index-value of the oxidation state of the fluorescent excited molecule. Finally, the impact of the above findings for further analytical applications is discussed. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Chemiluminescence (CL)-reactions are becoming increasingly popular for trace analysis, because of their high sensitivity, rapidity, simplicity and low cost of instrumentation [1–3]. Some CL-reactions are extremely sensitive to concentration changes while recent developments in increasing sensitivity and reliability of photomultipliers have given extra interest in CL-reactions. In addition the implementation of the CL-reaction analytical system with a F.I.A. manifold gives an extra element of simplicity, reproducibility, rapidity, convenience and above all provides a degree of automation to the analytical procedure.

The CL-emission generated during pyrogallol oxidation by H_2O_2 has not met the proper attention by researchers because other CL-systems were far more sensitive. However, the CL-emission that accompanies the oxidation of pyrogallol by H_2O_2 [4] is also observed with oxidation by other oxidants i.e. by permanganate [5,22], by periodate [6–8], and is observed with other pyrogallol substituted compounds (i.e. gallic acid, tannins, etc.). The CL-emission intensity can be enhanced by catalytic or sensitizing effects [4,6,22]. Finally, and more important the CL-emission is pH-range selective to the oxidants and the pyrogallol-compounds.

The above properties of the pyrogallol CL-system are very important in analytical chemistry and further investigation of the system may lead to useful applications in the determination of organic compounds in samples like drugs, pharmaceuticals, food products, biological fluids, etc. The generation of CL-emission by a number of oxidant reagents that show pH-range specificity may become a tool for the determination of such oxidants in different fields of science, i.e. in environmental chemistry (determination of OCl^-), clinical chemistry (determination of H_2O_2) and in organic analytical chemistry (determination of IO_4^-). The selective determination of oxidative anions may also be of benefit to ion-chromatography with post column detection of these anions. Finally, the phenomenon is important in instrumental analysis using enzyme immobilization on particles of high specific surface area and packing

them in the optical cell. Many such applications are being investigated in our laboratory.

The present study reports the investigation of the CL-emission generated during pyrogallol oxidation by different oxidant compounds. Each pyrogallol-oxidant system is investigated for the effects of the pH, and of concentrations of pyrogallol and oxidant.

2. Experimental

2.1. Reagents

All chemicals were of analytical reagent grade unless otherwise specified and distilled water was used throughout.

Buffer solutions of $\text{HClO}_4/\text{NaClO}_4$, $\text{H}_3\text{PO}_4/\text{H}_2\text{PO}_4^-$, $\text{CH}_3\text{COOH}/\text{CH}_3\text{COO}^-$, $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$, $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ and $\text{HCO}_3^-/\text{CO}_3^{2-}$ were prepared by dissolving a tenth of the formula weight of the corresponding salt in water and diluting to 900 ml, adjusting to the desired pH by the addition of 70–72% w/w HClO_4 (Merck) or 1 M NaOH titrisol solution (Fluka) and making up to 1 l with distilled water.

Oxidant stock solutions (0.01 M) of potassium permanganate (Baker), cerium sulfate tetrahydrate (Merck), and potassium periodate (Fluka), were prepared by dissolving one hundredth of the specific formula weight of the oxidant compound in the desired buffer solution and further diluting with the buffer solution to 1 l. The oxidant solutions were stored in reagent bottles or when necessary in dark brown glass bottles to avoid photochemical decomposition.

Oxidant 0.01 M stock solution of hydrogen peroxide was prepared by diluting the proper volume of 30% w/v H_2O_2 (Merck) to 1 l with the proper buffer solution.

Oxidant 0.1 N standard solution of hypochlorite was prepared by standardising a commercial sodium hypochlorite solution by iodometric titration and then diluting a certain volume of the commercial solution to the appropriate volume with the proper buffer solution.

Pyrogallol working solutions were freshly prepared by dissolving the appropriate weight of

pyrogallol (Merck) in the desired buffer solution and making up to the proper volume of the volumetric flask with the same buffer solution. Volumes of 100.0 ml were prepared each time and special care was taken to avoid long exposure to light and air.

2.2. Apparatus

An F.I.A. manifold equipped with flow-cell CL-detector was used (Fig. 1). The red sensitive photomultiplier (EMI 9865 B) combined with power supply at 1600 V was used for detecting the emission of light. A pH-meter (Crison Micro pH 2000) equipped with pH-electrode (Ingold) and temperature measuring element was used for adjusting the pH of buffer solutions.

2.3. F.I.A. method

The method of merging zone was used to mix the stream of oxidant with the stream of pyrogallol (Pg) solution just before entering the flow cell of the detector.

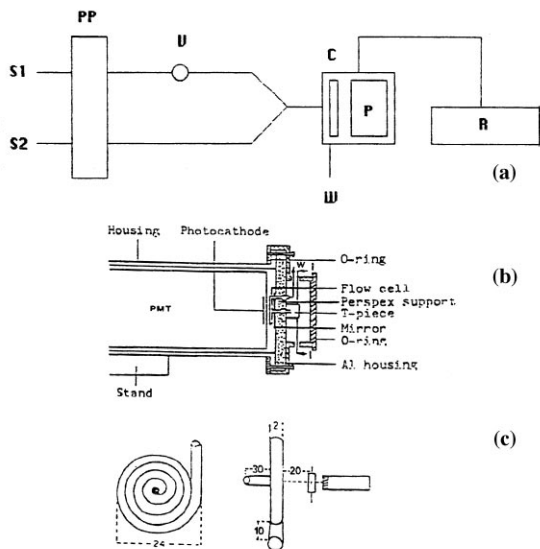

Fig. 1. (a) F.I.A. manifold: (PP) peristaltic pump; (C) optical cell; (P) photomultiplier; (R) recorder; (V) injection valve; (W) waste bottle; (S1, S2) flow streams for the buffered solution of pyrogallol and oxidant, respectively. (b) Details of the cell compartment. (c) Details of the design of the optical cell (dimensions in mm).

2.4. Mathematical expression of CL-emission under the operating conditions of this apparatus

For a CL-reaction (Scheme A)

$$+ \\ *h\nu$$

in a batch-type reactor, the general equation for CL-emission is given by Eq. (1)

$$I(t) = f \cdot h\nu \cdot n_{P^*}(t) \quad (1)$$

where $h\nu$ = quantum of light emitted from the electronic transition of a single P^* -species; $n_{P^*}(t)$ = the number of P^* -species that are present at time, t , in the CL-solution; f = the quantum efficiency of P^* -species to relax through the emission of light.

Because the P^* -species formed are transient species of negligibly short life, the $n_{P^*}(t)$ will be given by the rate of formation of P^* -species at time t and therefore Eq. (1) is modified to

$$I(t) = C \cdot f'(t) \quad (2)$$

where $f'(t) = d(n_{P^*}(t))/dt$, and $C = f \cdot h\nu$

Under the regime of integral reactor, the operational mode of F.I.A./merging zone, and the design of the tubular snail-shaped optical-cell, the CL-emission intensity, $I(\text{CL})$, observed is given by Eq. (3)

$$I(\text{CL}) = \int_0^{t_{\text{eq}}} I(t) dt \quad (3)$$

where t_{eq} is the time needed for the reaction to reach equilibrium (i.e. $P_i^* = 0$).

However, dealing with a flow system, the time variable is given by

$$t = s/F \quad (4)$$

where s = the distance of the position of the front of the CL-solution from the start of the optical-cell; and F = the flow rate of the pumped CL-solution.

Therefore, from Eqs. (2) and (3)

$$I(\text{CL}) = C \cdot \int_0^{t_{\text{eq}}} f'(t) dt \quad (5)$$

and if we modify for the independent variable of s

$$I(\text{CL}) = C' \cdot \int_0^{S_{\text{eq}}} f'(s) ds = C' \cdot [f(s)]_0^{S_{\text{eq}}} = C' \cdot (n_{\text{P}^*})_{\text{eq}} \quad (6)$$

where $(n_{\text{P}^*})_{\text{eq}}$ is the total number of P_i^* -species formed until the reaction has reached equilibrium.

For CL-reaction with energy transfer i.e. (Scheme B);

For reasons similar to those mentioned above, the CL-emission in a batch type reactor is given by Eq. (7)

$$I(t) = f \cdot h\nu \cdot n_{\text{P}^*_{oi}}(t) \cdot n_{\text{P}_F}(t) = C' \cdot f'(t) \cdot g(t) \quad (7)$$

where $f'(t) = d(n_{\text{P}^*_{oi}})/dt$ i.e. the rate of formation of P^*_{oi} species at time t ; and $g(t) = \int_0^t (d(n_{\text{P}_F})/dt) dt = \int_0^t g'(t) dt$ (i.e. the number of P_{Fj} -species formed from $t = 0$ to time t) and for the integral reactor regime

$$I(\text{CL}) = C'' \cdot \int_0^{S_n} f'(s) \cdot g(s) ds \quad (8)$$

where at each infinitesimally small CL-solution volume ds_s , the $f'(s)$ is the rate of formation of P^*_{oi} and $g(s)$ the number of P_{Fj} species present, and S_n is the length of the cell-reactor where the front of the CL-solution stops to emit CL-light.

2.5. Investigation of the mathematical expression of the CL-emission

Eq. (8) suggests that the CL-emission is proportional to the common area defined by the $f'(s)$ and $g(s)$ curves in their plot against the independent variable s from $s = 0$ to $s = S_n$ as shown in Fig. 2.

The total length of CL-solution, S_n , emits CL-light from every infinitesimally small volume, $\pi r^2 ds$ in the tubular cell which is proportional to the height of the shaded area at each s_i in Fig. 2.

The light-dark shaded area corresponds to the CL-light that comes from the range of s where the P^*_{oi} -species are dominant while the heavy-dark shaded area corresponds to the CL-light that comes from the range where the P_{Fj} -species are dominant. The shaded area is the integral

$$\int_0^{S_{\text{max}}} g(s) ds + \int_{S_{\text{max}}}^{S_n} f'(s) ds$$

and the CL-emission measured is proportional to this area. Therefore the CL-light that is generated is given by the summation of the two definite integrals

$$I(\text{CL}) = \kappa \cdot \left(\int_0^{S_{\text{max}}} g(s) ds + \int_{S_{\text{max}}}^{S_n} f'(s) ds \right) \quad (9)$$

According to Eq. (9), if there is no energy transfer, the two integrals combine into one and we end up with Eq. (6) since in this particular case $g(s) \equiv f'(s)$ and $S_n = S_{\text{eq}}$.

Fig. 2. The ideal number of fluorescent excited molecules (under energy transfer CL-reaction scheme) at each distance s from the start of the cell, and the total length of the solution that emits light in reference to Eq. (9).

Further investigation of Eq. (9) is made by suggesting limiting cases of equilibrium and kinetic parameters of Scheme B CL-processes. The assumptions lead to the derivation of the limiting equations in Table 1.

3. Results and discussion

3.1. Determination of oxidants by CL-emission generated by oxidation of pyrogallol

In this investigation we scanned a large number of inorganic oxidants. The most effective ones are given below.

3.1.1. Optimization of the pumping tubes diameter

For the investigation of the CL-emission generated during oxidation of pyrogallol, the flow-through manifold was optimized for best performance. The grey/grey tubes were chosen because they gave a reproducible signal although the larger diameter ones gave relatively higher CL-signals.

3.1.2. Effect and optimization of pH and the concentrations of pyrogallol and the oxidant

The different oxidants showed a different behavior in the CL-emission generated by the oxida-

tion of pyrogallol as shown by the different effects of factors like the pH and concentrations on CL-emission described below:

3.1.2.1. $KMnO_4$ oxidant. The CL-emission produced with this oxidant is relatively high (range of 10 V) and generates CL-emissions in the pH range of 0–5.

CL-emission versus pH. There is a profound effect of pH on CL-emission (Fig. 3a). Initially, the CL-emission increases and goes through a maximum in the pH-range of 0.6–0.8, then drops steeply and at pH = 5 it is almost zero. The oxidation of permanganate at low pH values proceeds via the reaction

However, the oxidation reaction at higher pH values proceeds with the following reaction

The increase of pH increases the extent of the oxidation reaction (Eq. (R2)) and produces more MnO_2 which coats the glass walls of the optical cell. Therefore the measurements at relatively high pH were made after previously cleaning the cell with a solution of hot oxalate at pH = 0. Apart from this fouling effect which was taken care of by cleaning the optical cell after each CL-measurement, the drop in CL-emission with pH increase is justified by the slow-down of the Eq. (R1) in favor of Eq. (R2).

CL-emission versus concentration of pyrogallol, [Pg]. The effect of [Pg] on the CL-emission at pH = 0.65 and $[MnO_4^-] = 1 \times 10^{-2}$ M is shown in Fig. 3b. The CL-emission increases gradually at low concentrations but increases more rapidly at higher concentrations until it reaches $[Pg] = 5 \times 10^{-3}$ M and then starts falling again. The appearance of the maximum reveals the competition of two processes. The cause of the CL-emission increase is due to the increase of the CL-species in the reacting mixture; the drop of CL-emission with [Pg] increase is related to the inner filter effect which is quite common in all luminescence processes.

CL-emission versus concentration of permanganate, $[MnO_4^-]$. The effect of $[MnO_4^-]$ on the

Fig. 3. CL-emission vs (a) pH at $[Pg] = 5 \times 10^{-4}$ M and $[MnO_4^-] = 1 \times 10^{-2}$ M; (b) $[Pg]$ at pH = 0.65 and $[MnO_4^-] = 1 \times 10^{-2}$ M; and (c) $[MnO_4^-]$ at pH = 0.65 and $[Pg] = 5 \times 10^{-3}$ M, for permanganate oxidant.

CL-emission at pH = 0.65 and $[Pg] = 5 \times 10^{-3}$ M is shown in Fig. 3c. The profile of the curve obtained is S-shaped. The plateau of the CL-emission increase with $[MnO_4^-]$ is reached at the value of $[MnO_4^-] = 8.0 \times 10^{-3}$ M which gives a ratio of $[MnO_4^-]/[Pg]$ around 1.6. The effect of $[MnO_4^-]$ on the CL-emission at pH = 0.65 and at various different pyrogallol concentrations was also investigated. The maximum CL-emission was very close to $[MnO_4^-]/[Pg] = 2$; but with the increase of $[Pg]$ this ratio drops gradually. The change of the maximum with $[Pg]$ -level is related to the inner filter effect. However, the maximum observed in the CL-emission vs $[MnO_4^-]$ at relatively low $[Pg]$ -range is due to the kinetic effect on the overall oxidation process. The value of 2 for the ratio suggests that the number of electrons used to oxidize completely each pyrogallol molecule is approximately 10, if the K -value of the oxidation process is large enough to guarantee complete conversion.

3.1.2.2. Ce(IV) oxidant. The CL-emission generated by the use of this oxidant is relatively low

(range of 100 mV) and generates CL-emission in the pH-range of 2–6.

CL-emission versus pH. There is a profound effect of pH on CL-emission (Fig. 4a). There is an abrupt increase of CL-emission from 2.5 to 3.2 and then a sudden drop until pH = 6 where it reaches the value of zero. The drop of the CL-emission goes along with the solubility of the hydrolysis Ce-species formed at different pH values. Therefore we justify this drop on the formation of insoluble Ce-hydroxide species. The precipitation is pronounced at high concentrations of Ce^{4+} -solutions at these pH-values.

CL-emission versus concentration of pyrogallol, $[Pg]$. The effect of $[Pg]$ on the CL-emission at pH = 3.5 and $[Ce(IV)] = 1 \times 10^{-2}$ M is shown in Fig. 4b. The profile of the curve shows a maximum at $[Pg] = 5 \times 10^{-4}$ M. The maximum here is related to the inner filter effect of pyrogallol species formed during the oxidation process.

CL-emission versus concentration of ceric(IV), $[Ce^{4+}]$. The profile curve of the effect of ceric(IV) on the CL-emission at pH = 3.5 and $[Pg] = 5 \times 10^{-4}$ M is shown in Fig. 4c. The curve shows a

Fig. 4. CL-emission vs (a) pH at $[Pg] = 5 \times 10^{-4}$ M and $[Ce(IV)] = 1 \times 10^{-2}$ M; (b) $[Pg]$ at pH = 3.5 and $[Ce(IV)] = 1 \times 10^{-2}$ M; and (c) $[Ce(IV)]$ at pH = 3.5 and $[Pg] = 5 \times 10^{-4}$ M, for Ce(IV) oxidant.

maximum at 4×10^{-3} M; this value is almost ten times higher than the $[Pg]$. The maximum is, at least, partly justified from the increasing amount of precipitate with increasing concentration of the oxidant thus producing larger amounts of precipitate that gives denser turbidity to the solution in the optical cell.

3.1.2.3. KIO_4 oxidant. The CL-emission generated by the use of this oxidant is moderately high (range of 1000 mV) and generates CL-emission in the pH range of 4–13.

CL-emission versus pH. There is a continuous increase of CL-emission by the increase of pH from the value of 4 to the value of 7.2 which stays approximately the same up to pH = 7.8 and then drops to a relatively low value at pH = 9 and stays almost constant up to pH = 12 and then drops to zero at pH > 13 (Fig. 5a). The CL-emission in the optimum pH-range of 7.2–7.8 is assigned to the pyrogallol species that are liable to fluorescence with relatively high quantum efficiency. However, the pH-range of lower CL-emission intensity may be related to

species of lower quantum efficiencies perhaps products of pyrogallol condensation. It is already known that pyrogallic compounds of different substitution show the maximum at higher pH values with significantly lower CL-intensities.

CL-emission versus concentration of pyrogallol, $[Pg]$. The effect of $[Pg]$ on the CL-emission at pH = 8 is shown in Fig. 5b. The profile curve shows a maximum at $[Pg] = 7.0 \times 10^{-4}$ M. The maximum is related to the inner filter effect due to pyrogallol or pyrogallol-species formed during the oxidation process; these species show an intense inner filter effect evidenced by the steep drop of CL-emission with increase of $[Pg]$.

CL-emission versus concentration of periodate, $[IO_4^-]$. The effect of $[IO_4^-]$ on the CL-emission at pH = 8 and $[Pg] = 7.0 \times 10^{-4}$ M is shown in Fig. 5c. The profile curve shows a gradual increase with an S-shaped appearance. Unfortunately, it is not possible to increase the concentration of periodate beyond the value of 10^{-2} M since the potassium periodate has limited solubility in water.

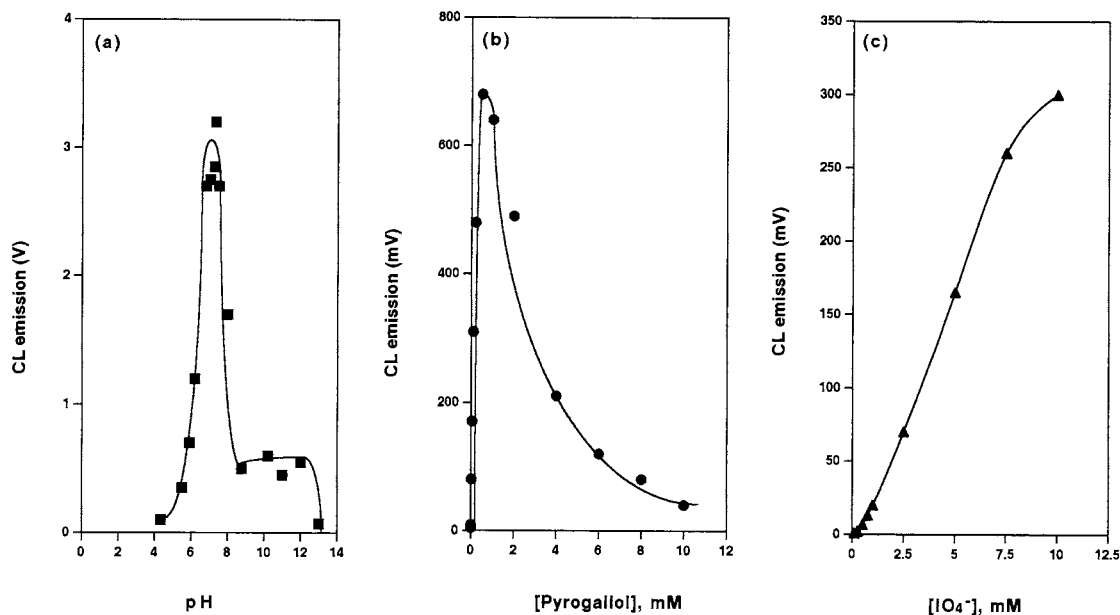

Fig. 5. CL-emission vs (a) pH at $[Pg] = 5 \times 10^{-4}$ M and $[IO_4^-] = 1 \times 10^{-2}$ M; (b) $[Pg]$ at pH = 8.0 and $[IO_4^-] = 1 \times 10^{-2}$ M; and (c) $[IO_4^-]$ at pH = 8.0 and $[Pg] = 7 \times 10^{-4}$ M for periodate oxidant.

3.1.2.4. NaOCl oxidant. The CL-emission generated by the use of this oxidant is relatively low (limited to a maximum of 250 mV) and generates CL-emission in the pH-range of 6–13.

CL-emission versus pH. There is a curve of CL-emission with increasing pH which shows two maxima, one at pH = 8.0 and the other at pH-range between 10.7 and 11.5; the CL-emission in the pH-range of 8.0–10.7 shows a shallow valley; there is an increase of CL-emission at the pH-range of 6.0–8.0 and a gradual decrease beyond pH = 11.5 up to 13 (Fig. 6a). The range of pH in which chemiluminescence is observed is definitely related to the particular oxidant since this oxidant is well known that works in alkaline media. However, the two maxima may be due to the different CL-species involved. A further investigation was held to examine the CL-emission vs pH at different levels of $[Pg]$; the results show that the two maxima increase in CL-emission with the increase of $[Pg]$; however the increase of the maximum at pH-range of 10.7–11.5 is rather pronounced while that around pH = 8 only slight with the $[Pg]$ in-

crease; finally when the $[Pg]$ is further increased, a peak at pH = 9.7 appears that is much larger while the other two start dropping. The two maxima at low $[Pg]$ indicate two kinds of pyrogallolic CL-species with different inner filter effects; the high pH maximum shows a less pronounced inner filter effect; the more intense maximum at pH = 9.7 generated at relatively high pyrogallol concentration is probably due to the chemical interaction of the two CL-species and the formation of a more efficient one.

CL-emission versus concentration of pyrogallol, $[Pg]$. The effect of $[Pg]$ on CL-emission at pH = 9 and $[OCl^-] = 1 \times 10^{-2}$ M is shown in Fig. 6b. The profile of the curve shows an abrupt increase with $[Pg]$ and then a gradual decrease. The maximum is found around $[Pg] = 5 \times 10^{-3}$ M ($[OCl^-]/[Pg] = 2$). The maximum is due to the antagonism between the inner filter effect and the net formation of CL-species. Since the CL-emission at pH = 9 is influenced largely by the CL-species of intense inner filter effect, the curve shows the characteristics of a relatively intense inner filter effect.

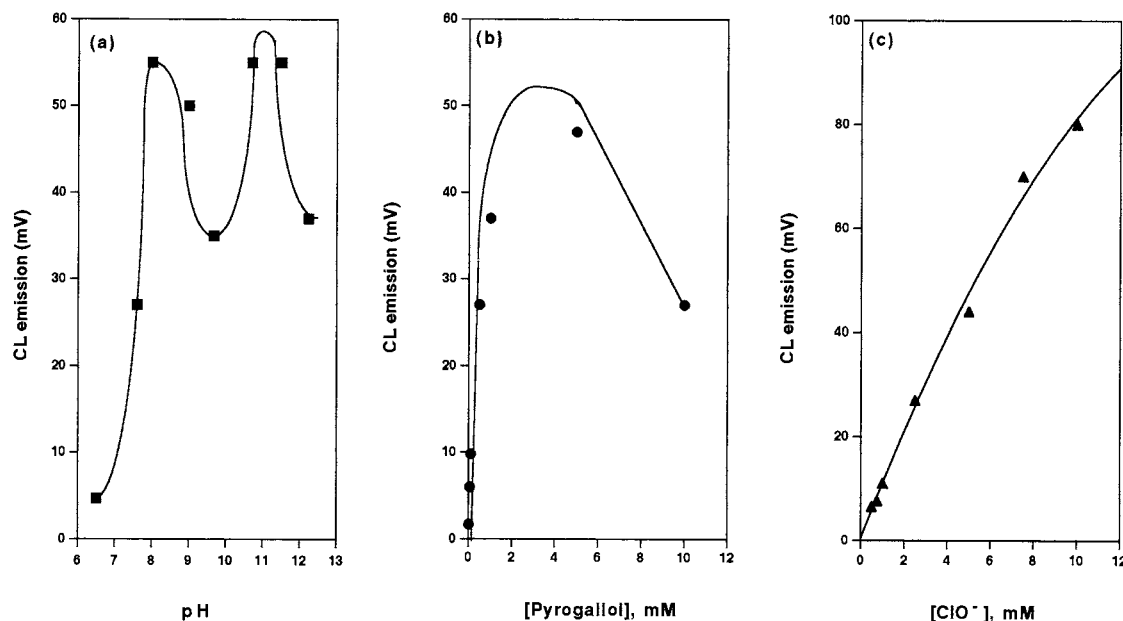

Fig. 6. CL-emission vs (a) pH at $[Pg] = 5 \times 10^{-4}$ M and $[OCl^-] = 1 \times 10^{-2}$ M; (b) $[Pg]$ at pH = 9.0 and $[OCl^-] = 1 \times 10^{-2}$ M; and (c) $[OCl^-]$ at pH = 9.0 and $[Pg] = 5 \times 10^{-3}$ M for hypochlorite oxidant.

CL-emission versus concentration of hypochlorite, $[ClO^-]$. The effect of the $[ClO^-]$ on the CL-emission at pH = 9 and $[Pg] = 5 \times 10^{-3}$ M is shown in Fig. 6c. The profile curve is obtained of almost straight-line form or slightly convex at the initial part of the smooth profile curve.

3.1.2.5. H_2O_2 oxidant. The CL-emission generated by the use of this oxidant is relatively low (limited to maximum 350 mV) and generates CL-emission in the pH-range of 8–13. The hydrogen peroxide is, however, decomposed in alkaline solutions and the decomposition becomes more intense as the pH is increased. The decomposition of H_2O_2 at pH = 11 is quite rapid at relatively high concentrations. Therefore, to avoid bubble formation in the FIA Teflon-tubing, the tubing was kept short and the concentration low ($\leq 1.0 \times 10^{-2}$ M).

CL-emission versus pH. There is a continuous increase of CL-emission with the increase of pH from the value of 8 up to 11 and then a continuous drop up to 13 (Fig. 7a). This is probably a combined contribution of the oxidant and the

pyrogallol originated CL-species in the oxidation process. It is already known that quinonoic compounds are chemiluminescent at pH = 11.

CL-emission versus concentration of pyrogallol, $[Pg]$. The effect of $[Pg]$ on the CL-emission at pH = 11 and $[H_2O_2] = 1.0 \times 10^{-2}$ M is given in Fig. 7b. The profile of the curve shows an initial steep increase and then a steep decrease; the maximum is obtained at $[Pg] = 1 \times 10^{-3}$ M. The maximum here is due to the competition between the increase of CL-emission by the increase of CL-pyrogallol derived species and the inner filter effect of increased number of fluorescent pyrogallol derived species; these species show an intense inner filter effect as indicated from the steep drop of the CL-emission with $[Pg]$ at the relatively high $[Pg]$ -range.

CL-emission versus concentration of hydrogen peroxide, $[H_2O_2]$. The effect of $[H_2O_2]$ on the CL-emission at pH = 11 and $[Pg] = 1 \times 10^{-3}$ M is shown in Fig. 7c. The profile curve shows a gradual increase with increasing concentration of oxidant and is S-shaped in the range of the obtained measurements.

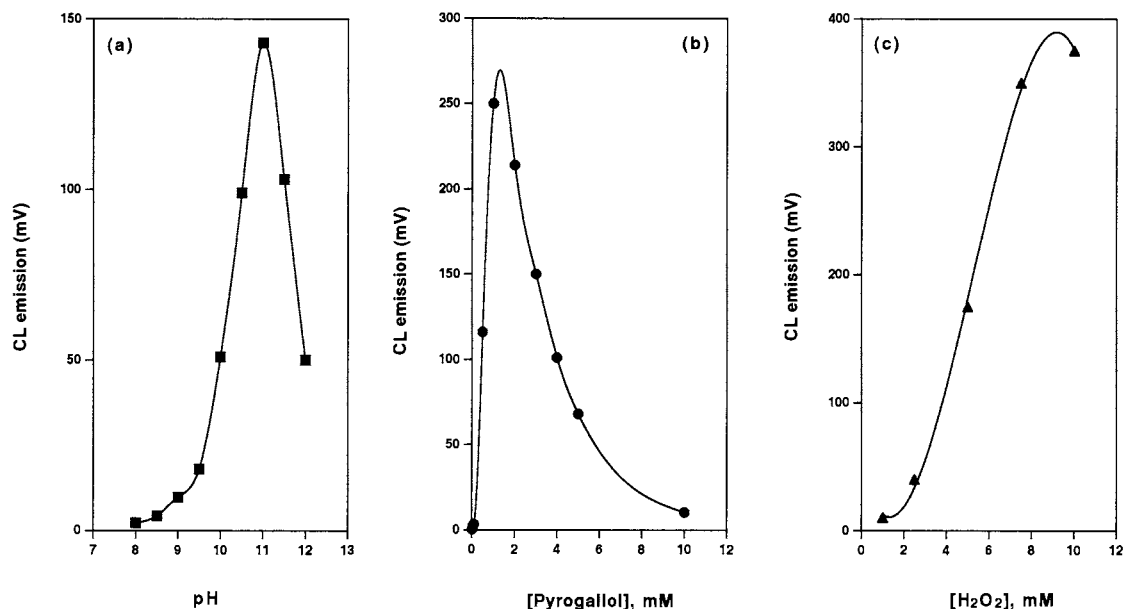

Fig. 7. CL-emission vs (a) pH at $[Pg] = 5 \times 10^{-4}$ M and $[H_2O_2] = 1 \times 10^{-2}$ M; (b) $[Pg]$ at pH = 11.0 and $[H_2O_2] = 1 \times 10^{-2}$ M; and (c) $[H_2O_2]$ at pH = 11.0 and $[Pg] = 1 \times 10^{-3}$ M, for hydrogen peroxide oxidant.

3.1.2.6. *Oxidant calibration curves and analytical parameters.* The data obtained and shown in Figs. 3c, 4c, 5c, 6c and 7c are simulated with an S-shaped model equation (Hill equation)

$$y = \frac{a \cdot x^n}{K + x^n} \quad (13)$$

where y is the CL-emission in volts or millivolts, x is the [oxidant] in M and a and K are constants. These plots give non-straight line calibration curves which are shown in Fig. 8a together with the first-differential plots for the different oxidants Fig. 8b.

However, a linear transform of Hill Eq. (13) is the logarithmic Eq. (14)

$$\log(aY - 1) = n \log X + \log K \quad (14)$$

where $Y = 1/y$ and $X = 1/x$ and the remaining parameters are as above.

The linear regression procedure provides n and K values of the linear transformation equation; these values are different from the optimum parameters calculated by the non-linear simulation and this is reasonable because the weighting

is different for the two procedures. Using the n and K parameter estimates from the linear regression of Eq. (14) and keeping a parameter estimate from the simulation of the data by the Hill equation, the equation traces a curve that shows poor fit for the high x -values while it fits better at the low x -values; this is useful to calculate the detection limits by the a/K standard error. In the present report, the limit of detection is taken from the noise of the photomultiplier/recorder introduced by the pulses of the peristaltic pump which reaches the value of 0.1 mV; this choice was made on simplistic, realistic grounds. The noise value, however, can be improved by using a more expensive pumping system. The sensitivity is determined by the slope of the non-linear calibration curve at each x -value. To obtain a mean value at some range interval of x , the easiest way is to simulate the S-shaped curve by three straight-line parts and quote the average sensitivity at the concentration-range of the steepest straight-line part for each oxidant. This is done with the aid of the first-differential plot of each calibration curve by the following method:

Fig. 8. (a) Calibration curves of oxidant based on fitting Hill model equation to the data points for (a) permanganate, (b) Ce(IV), (c) periodate, (d) hypochlorite, and (e) hydrogen peroxide.

The line at the half-height of each peak in the differential plot is drawn parallel to the x -axis and the points where this line crosses the bell-shaped curve define the concentrations of the oxidant on the steepest part of the calibration curve that the straight line passes through; the slope of this straight line is an approximation of the sensitivity of the determination of the oxidants.

The optimum parameters of the Hill equation and its linear transform for the data of the calibration curve of each oxidant are given in Table 2 together with their standard errors. The analytical parameters of sensitivity, valid range and detection limits are estimated as mentioned above and are given in Table 3.

Model equations for the calibration curves with a better fit to experimental data are necessary for

Fig. 8(b). The first-differential plots of the calibration curves of Fig. 8a.

the determination of oxidants which are sigmoidal. However, there is software available [19,21] and a design for experiments to obtain the sigmoidal curve from just three experimental points [20] and this is very convenient for routine analysis.

3.1.2.7. Analytical parameters of pyrogallol determination. The optimized conditions for obtaining the highest CL-emission signal are shown in Table 4 together with the CL-emission in millivolts. The data show a sensitivity for pyrogallol determination of: 1.16×10^6 mV M⁻¹ for permanganate; 0.086×10^6 mV M⁻¹ for Ce(IV); 0.91×10^6 mV M⁻¹ for periodate; 0.012×10^6 mV M⁻¹ for hypochlorite; and 0.25×10^6 mV M⁻¹ for hydrogen peroxide. These values correspond at optimum conditions and it can be seen that maximum sensitivity is obtained for oxidation by periodate and by permanganate. But in the case of oxidation by periodate, the sensitivity is very high for low concentrations while that by permanganate for relatively large concentrations. Detection lim-

its for pyrogallol of the range of 10^{-4} M have been obtained with most oxidants and in some cases even lower. Furthermore, there is always the possibility to increase the sensitivity by using sensitizers or catalysts and enable trace analysis for pyrogallol compounds. The reproducibility of the signal is less than 5% for pyrogallol concentrations in the middle of the valid range for oxidation with most of the oxidants. However, special care should be taken with permanganate because MnO₂ may be accumulated in the optical cell if the pH is not carefully controlled either during the analytical procedure or during the washings. Also, there is always a possibility to have precipitation of cerium hydroxide when the cerium concentration is increased or the pH is increased above the optimum.

3.2. Effect of chemistry and oxidation mechanism on pyrogallol CL-emission

It is generally accepted today that the CL-emission during oxidation of pyrogallol by H₂O₂ is

Table 2

Optimum parameters and standard errors for the Hill equation and its linear transformation for each oxidant

due to the formation of (O₂^{*})₂ excimers which then transfer their energy to species coming from the oxidation of pyrogallol according to the following reaction equations [9–11]

The excimer is formed through the collision of two peroxide species and is released from the transition state collision complex. The energy transfer may be intramolecular from the peroxide collision locus of the transition state complex to a distant part or may be intermolecular energy transfer. Eq. (R4) suggests an intermolecular transfer. For the intermolecular energy transfer, the overall oxidation mechanism will involve the two major reaction steps which are necessary for CL-emission i.e. the step of excimer formation and the step of formation of pyrogallol-oxidation species with high quantum efficiency that will enable, through energy transfer, the CL-emission of the excimer oxygen-species. The oxidation process of phenolic compounds proceeds through an autoxidation mechanism [15] and forms a sequence of oxidation products [16–18] in a number of steps as follows,

where QH₂ = phenolic compound, Q = quinonoid compound, P_i = oxidation products. In addition, it is well known that the oxidation path of pyro-

gallol by H₂O₂ goes through an oxidative condensation with purpurogallin as intermediate product (a highly fluorescent compound).

However, the different oxidants may act as reagents either of 'soft' oxidation in the sense that proceed through relatively stable intermediates, like the periodate and the hydrogen peroxide, or of 'deep' oxidation in the sense that convert the compound completely to the final product like permanganate. In the latter, the intermediate products are transient products of very short life, but significantly greater than the life of the excited species. But, it is not known, yet, clearly whether the CL-reaction is of Scheme A or B for all the oxidants or the choice depends on the oxidant. However, it was shown that the CL-emission under Scheme A is given by Eq. (6) while under Scheme B for the various limiting conditions by Eqs. (10)–(12). Eq. (10) is the most likely in this system because the CL-emission duration under stopped flow regime is extremely short. Therefore, by Eq. (6), the CL-emission is controlled by the equilibrium status of the overall reaction while by Eq. (10), it is controlled by the initial rate of pyrogallol oxidation. Furthermore, it is possible to discriminate the two processes by following the CL-emission versus the concentration of the oxidant. To check the choice we must examine the relationship of CL-emission with the oxidant concentration. Therefore, we plot the CL-emission versus [Ox]/[Pg] in Fig. 9.

From Fig. 9, it is seen that the CL-emission increases with the concentration of the oxidant. The shape of the curve for this relationship is not the same for all oxidants but it is generally an ascending curve that reaches a plateau. The start of the plateau is an important point because if the

Table 3
Analytical parameters for the determination of each oxidant

Oxidant	Non-linear range ^a (M)	Linear range ^b (M)	Sensitivity (mV M ⁻¹)	Detection limit (M)
KMnO ₄	$1.5 \times 10^{-3} - 1 \times 10^{-2}$	$2.0 \times 10^{-3} - 7.0 \times 10^{-3}$	895 600	3.0×10^{-4}
Ce(IV)	$1.75 \times 10^{-3} - 1 \times 10^{-2}$	$6.6 \times 10^{-4} - 4.5 \times 10^{-3}$	19 471	3.5×10^{-4}
KIO ₄	$1.15 \times 10^{-3} - 1 \times 10^{-2}$	$6.3 \times 10^{-4} - 1 \times 10^{-2}$	33 723	2.3×10^{-4}
NaOCl	$3.5 \times 10^{-3} - 1 \times 10^{-2}$	$8.1 \times 10^{-5} - 6.5 \times 10^{-3}$	10 680	6.1×10^{-4}
H ₂ O ₂	$2.25 \times 10^{-3} - 1 \times 10^{-2}$	$2.1 \times 10^{-3} - 7.0 \times 10^{-3}$	56 703	4.5×10^{-4}

^a The lower value is determined by multiplying the detection limit by 10; the maximum value is the maximum concentration of the oxidant in these experiments; for most oxidants (KMnO₄, Ce(IV), KIO₄, H₂O₂) this is the real maximum because of restrictions; for the oxidant NaOCl the real maximum is higher, about 0.1 M.

^b The linear range is defined from terminal values of the line-width of the first-differential plot.

reaction is complete (*K*-value high), it designates the stoichiometric quantity of the specific oxidant for the initial pyrogallol concentration in the CL-solution. The start of the plateau is not evident in some of the curves. The most evident point is the point of highest slope of the smooth curve and it is found by plotting the first differential of the curves in Fig. 9. This point gives the value of half of the oxidant molecules that are necessary to reduce one pyrogallol molecule. However, from the plots of Fig. 9b this is not so simple because the bell-shaped curves are not always symmetric to guarantee that the maximum is a contribution from measurements at equilibrium of the overall process (there may be contributions from measurements of kinetic regime of later steps of the overall reaction involved in total value). The symmetric bell-shaped curves give the indication that the measurements are made at the equilibrium region of the total reaction profile; a tailing of the symmetric bell-shaped curve may indicate measurements at the equilibrium region for the major part of the reaction system plus measurements at the kinetic region for a residual part that reacts slowly in a multi-equilibrium system. On the other hand, asymmetric bell-shaped curves may suggest measurements of multi-equilibria systems made at the equilibrium region for some steps and a significant contribution from measurements at the kinetic regime for some other steps of the whole process. But the height of the bell-shaped curve gives an indication of the size of the *K*-value of the relatively rapid part of the oxidation process. Furthermore the line-width of the bell-shaped

curve gives an indication of the number of the equilibrium-steps involved in the overall oxidation when the measurements are made at the equilibrium region of the overall process; however, the line-width largely increases if the measurements made involve reaction steps that are relatively slow. Table 5 gives the shape of the first-differential plots in Fig. 9b and their characteristics as described above.

From Table 5 and the conclusions that are implied by the shape parameters therein for the rapid part of pyrogallol oxidation process it is found that the oxidation process is relatively complete (highest *K*-value) for permanganate; less complete for hydrogen peroxide, periodate and cerium(IV); and much less-complete for hypochlorite oxidant. From the height of the bell-shaped curves shown in Table 5, a sequence for the size of the equilibrium constant is obtained as follows:

In addition, the size of line-width in combination with the symmetry and the height indicates that: (a) a slow step of oxidation accompanies the rapid oxidation process by periodate in accordance with the findings of Feifer et al. [17]; (b) another reaction is involved in the rapid oxidation process by Ce(IV) which infers an increase of precipitation that occurs with the increase of [Ce(IV)] at optimum pH; [3] another relatively slower reaction accompanies the oxidation by hydrogen peroxide which is in agreement with reported oxidation mechanism [12–14].

Table 4
Optimized conditions and maximum CL-emission for different oxidant compounds

Oxidant compound	Optimized pH	Pyrogallol conc. ($\times 10^4$ mol l ⁻¹)	CL-emission (mV)	Rel. CL-emission (%)
Permanganate	0.8	50	5800	100
Cerium(IV)	3.5	7	60	1
Periodate	7.8	7	640	11
Hypochlorite	9.0	50	60	1
Hydrogen peroxide	11.0	10	248	4

The number of electrons moved during the oxidation of the pyrogallol gives the extent of oxidation that this molecule suffers by different oxidants; this is possible if the measurements are done at equilibrium for all concentrations of the oxidant and the oxidation reaction is complete. This is approximately true for the oxidation of pyrogallol by KMnO_4 . The consumption of nearly 10 electrons per pyrogallol molecule suggests the rupture of the aromatic ring and the formation of one oxalate ion. In the case of periodate there is a large degree of uncertainty since part of the CL-emission is a contribution from CL-emission measurements of variable size in the kinetic regime. In the case of Ce(IV), it is possible that the oxidant acts like permanganate but this is not clearly seen from the results since the CL-emission is definitely affected by the extent of precipitation of Ce(IV) hydrolysis-species. Finally in the case of NaOCl, the CL-emission is of the kinetic regime and there is no guarantee that the start point of the plateau reveals the stoichiometric quantity of oxidant required to oxidize one molecule of pyrogallol.

The linear initial part of the CL-emission vs $[\text{NaOCl}]/[\text{Pg}]$ is in agreement with Eq. (10) and demonstrates a CL-process that proceeds via energy transfer (Scheme B). On the other hand, the bell-shaped symmetric first-differential plot of the corresponding curve for permanganate in Fig. 9a suggests a CL-emission that proceeds without energy transfer (Scheme A). The data for hydrogen peroxide, however, are somewhat misleading. They give a symmetric bell-shaped first-differential plot of the curve in Fig. 9a which is similar to permanganate and suggest a CL-emission without energy transfer which is

contrary to the literature; however, the degradation of hydrogen peroxide in alkaline solutions (pH = 11) forms bubbles in the tube manifold of the FIA system which increase as the concentration is increased producing less accurate measurements; the lower accuracy of the data may, partly, contribute to the disagreement. In the remaining cases i.e. periodate and Ce(IV), the curves of CL-emission vs $[\text{Ox}]/[\text{Pg}]$ seem to move towards a straight-line relationship as shown by the parameter n of fitting the experimental data to Hill equation which in the different oxidants takes the values: around 3.1 (S.E. 0.2) for permanganate; around 1.9 (S.E. 0.2) for Ce(IV); around 1.7 (S.E. 0.15) for periodate; around 1.1 (S.E. 0.17) for hypochlorite; and around 3.25 (S.E. 0.88) for hydrogen peroxide. The standard error for the case of hydrogen peroxide reveals the poor fit to the Hill equation. Furthermore, the disagreement between the data in this work and the reported literature for the hydrogen peroxide case may, also, suggest that this particular case is definitely not a limiting case for Scheme B and therefore the limiting condition Eqs. (10)–(12) are not valid.

Based on the estimates of the equivalents found for the case of permanganate which provides the stoichiometry of the relatively rapid oxidation part, the maximum in Fig. 3b should appear at a corresponding value of pyrogallol concentration that is in agreement with the stoichiometry obtained. However, the maximum found in Fig. 3b does not match the stoichiometry value obtained, in fact this is 20% lower, suggesting the existence of an inner filter effect from the pyrogallol or pyrogallol oxidation products. The inner filter effect is found for oxidations by other oxidants as

Fig. 9. (a) CL-emission vs $[Ox]/[Pg]$ simulated by Hill equation curves for (a) permanganate; (b) Ce(IV), (c) periodate, (d) hypochlorite and (e) hydrogen peroxide.

well and the size of the effect can be estimated roughly from the steepness of the drop of CL-emission in Figs. 4b, 5b, 6b and 7b. The trend is that oxidation by periodate shows the most intense inner filter effect followed by hydrogen peroxide; this trend suggests that the size of inner

filter effect is related to the mechanism that each oxidant follows i.e. in the oxidation by permanganate that attacks the double bonds, it is low while in selective oxidation by periodate that breaks polyhydroxy compounds, it is relatively high. This implies that either the consecutive

Fig. 9(b). The first-differential plots of curves of Fig. 9a.

products of selective oxidation of pyrogallol are capable of a more effective inner filter effect, or that the concentration of the highly fluorescent product is much lower in a non-selective oxidation process; the latter is more reasonable in cases where the fluorescent product is not the final product of the rapid oxidation part (Scheme A), since the concentration of the transient intermediate products in a consecutive reaction is very much lower.

Since under both schemes of CL-reactions, the CL-emission is related to the number of excited molecules with high quantum efficiency, it is

clear that the pH dependence of CL-emission suggests that either the number of such species varies with pH or that the quantum efficiency of these species is altered by changes in pH; the latter is a well known phenomenon in the field of fluorescent compounds. However, changes of the number of such fluorescent species with pH is of great importance since it is well known that the kinetics of many reactions are affected by pH changes. In addition, we have to point out that independent of the change of CL-emission with pH, we also observed a distinct pH-range where the CL-emission is observed and

Table 5
Characteristics of first-differential curves of the CL-emission vs $[Ox]/[Pg]$

Oxidant	Shape	Symmetry	Maximum	Height (mV)	Line-width
KMnO ₄	Bell	Symmetric	0.8	1 113 000	0.9
Ce(IV)	Bell	Asymmetric	4.3	24 422	9.8
KIO ₄	Bell	Asymmetric	4.4	42 012	11.8
NaOCl	Linear concave	Dropping	0.1	12 090	—
H ₂ O ₂	Bell	Tail-symmetric	3.1	70 980	3.6

this range coincides with the pH-range where the specific oxidant has its maximum oxidation rate.

3.3. Analytical impact to other applications

The system is ideal for being implemented with F.I.A. manifold and a photomultiplier or a fiber optic CCD detector to provide a convenient, rapid and inexpensive analytical set up which can be further automated and linked to an instrument for various determinations based on the oxidation of organic molecules or for the detection of anions in a post column ion chromatography analysis. In cases where lower sensitivity of the CL-signal is necessary, it can be adjusted appropriately by changing the pyrogallol concentration or by changing the power supply voltage to the photomultiplier. The property of pH-selectivity among the oxidative anions enables the detection and determination of permanganate in the presence of periodate and hypochlorite anions or the reverse. Such an application may be interesting in biological or medical fields when more than one oxidant is involved in the same system. The intensity variations with pH for a specific oxidant may lead to a pH-meter based on CL-emission. The CL-emission can also be used as an external indicator for indirect titrations where the oxidant is in excess if the titration apparatus is implemented with an F.I.A. manifold.

Received 22 May 1997; received in revised form 7 August 1997; accepted 12 August 1997

Abstract

The stability constants of Fe(II), Co(II) and Cu(II)–NTA–penicillamine were determined by paper electrophoresis. The values of these constants were found to be 5.06, 5.16 and 5.28 (log *K* values), respectively at $\mu = 0.1$ and 35°C. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Electrophoresis; Stability constants; Penicillamine

1. Introduction

Penicillamine has been known as a degradation product of penicillin since 1943 [1]. However, its use in recent years as a drug [2] in treating Wilson's diseases (hepatolenticular degradation), as a protective agent against radiation [3] and as an antidote in metal ion poisoning [4–7] warrant the examination of its metal chelate properties. The properties and most important chemical reactions of naturally occurring penicillamine have already been widely studied [8–11]. The main biochemical aspects have been reviewed by Jocelyn [8]. The biological importance is attributed to the capabilities of the mercapto group to undergo various complex formation processes, primarily in

non-haem iron protein [9] and blue copper protein [10]. Sorensen [11] has demonstrated the anti-inflammatory activity of the copper–penicillamine complex. The complexes of Fe(II), Co(II) and Cu(II) with penicillamine and other sulphur containing amino acids are of great importance because of the interesting biological role of Fe(II), Co(II) and Cu(II) metal ions. The significance of investigations relating to these complexes is further enhanced by the recognition that penicillamine can be used for the treatment of metal ion poisoning [4–7] and for the resolution of racemic mixtures of penicillamine itself and other amino acids [12,13]. A search of literature [14–17] indicates that a few reports are available on Co(II) and Cu(II) binary complexes with penicillamine and no information on ternary (mixed complexes) system is available. It is also reported in literature

* Corresponding author. Fax: +91 1332 73560.

that the modes of coordination in penicillamine are amino, thio and carboxylic groups [18] and in NTA are carboxylic groups [19]. In view of this, attempts were made to determine the stability constants of the metal (M)–penicillamine, M–nitrioltriacetate (NTA) and M–NTA–penicillamine mixed complexes. The present paper describes the electrophoretic determination of the stability constants of these complexes.

2. Experimental

2.1. Apparatus

A Systronic (Naroda, India) Model 604 electrophoresis system was used. It has a built in power supply (a.c.–d.c.) that is fed directly to a paper electrophoresis tank. In order to maintain the temperature constant, two hollow metallic plates coated with thin plastic paper on the outer surface were used for sandwiching paper strips and thermostated water (35°C) was circulated through these plates. pH measurements were made with an Elico (Hyderabad, India) Model L_{1–10} pH meter using a glass electrode.

2.2. Chemicals

Fe(II), Co(II) and Cu(II) perchlorate solutions were prepared by precipitating the corresponding carbonates from solutions of nitrates (A.R. grade) with sodium hydrogencarbonate, washing the precipitates thoroughly with boiling water and treating them with a suitable amount of 1% perchloric acid. The resulting mixtures were heated to boiling on a water bath and then filtered. The solutions were standardized and diluted as required. Metal spots were detected, as violet to red in color, on the paper by spraying a saturated solution of alizarin in ethanol followed by 25% ammonium hydroxide and glacial acetic acid. A saturated aqueous solution (0.9 ml) of silver nitrate was diluted with acetone to 20 ml. Glucose, as a black spot, was detected by spraying with this solution and then with 2% ethanolic sodium hydroxide.

2.3. Background electrolyte

The background electrolytes used in the study of binary complexes were 0.1 M perchloric acid and 0.01 M penicillamine. For the study of ternary system the background electrolytes used were 0.1 M perchloric acid, 0.01 M NTA and various amounts of 0.01 M penicillamine. The ternary system was maintained at pH 8.5 by the addition of sodium hydroxide.

Stock solutions of 9.0 M perchloric acid, 2.0 M sodium hydroxide and 0.5 M penicillamine were prepared from A.R. grade reagents (BDH). A 0.01 M NTA solution was prepared from the compound obtained from Merck.

2.4. Procedure

The hollow base plate in the instrument was levelled and a 150-ml volume of background electrolyte was placed in each tank of the electrophoretic apparatus. Paper strips (Whatman No. 1, 30 × 1 cm) in triplicate were then spotted with metal ion solutions and glucose in the centre with a micropipette and were subsequently placed on the base plate and sandwiched under the upper hollow metallic plate with the end of strips lying in the two sides of the tank solution. A 200-V potential difference was then applied between the tank solution and electrophoresis was carried out for 60 min. The strips were then removed and the spots were detected. The average of the triplicate strips was noted for calculation and the movement of the glucose spot was used as a correction factor. It was found that the variation in the movement was about $\pm 5\%$. The mobilities were calculated by dividing the distance by the potential gradient and are expressed in $\text{cm}^{-2} \text{V}^{-1} \text{min}^{-1}$.

3. Result and discussion

3.1. M(II)–penicillamine binary system

The plot between ionophoretic mobility and pH is given in Fig. 1 which clearly indicates three plateaux. The first corresponds to a region in

Fig. 1. Mobility curve for M–penicillamine systems.

which metal ions are uncomplexed. The second plateau with zero mobility indicates the formation of 1:1 neutral complexes while the third plateau with negative mobility shows the anionic nature of the metal complexes. The predominant chelating properties of unprotonated anionic species of penicillamine have also been reported ruling out any such property of a zwitterion [20]. In view of these observations, the complexation of the metal ions with the penicillamine anion (L^{2-}) can be represented as

The metal spot on the paper is thus a combination of uncomplexed metal ions, a 1:1 complex and a 1:2 complex. The overall mobility of these is given by

$$U = \frac{u_0 + u_1 K_1 [L^{2-}] + u_2 K_1 K_2 [L^{2-}]^2}{1 + K_1 [L^{2-}] + K_1 K_2 [L^{2-}]^2} \quad (3)$$

where u_0 , u_1 and u_2 are the mobilities of the uncomplexed metal ions, the 1:1 metal complexes and the 1:2 metal complexes, respectively.

The first stability constant (K_1) was calculated by considering the region between the first and second plateaux. The overall mobility (U) will be equal to the arithmetic mean of the mobility of uncomplexed metal ion, u_0 , and that of the first complex, u_1 , at a pH where $K_1 = 1/[L^{2-}]$. The concentration $[L^{2-}]$ of the chelated penicillamine was calculated by the equation

$$[L^{2-}] = \frac{L_T}{1 + [H]/k_3 + [H]^2/k_2 k_3 + [H]^3/k_1 k_2 k_3} \quad (4)$$

where, L_T is the total concentration of the penicillamine and k_1 , k_2 and k_3 are the dissociation constants of penicillamine with $10^{1.90}$, $10^{7.85}$ and $10^{10.55}$ values, respectively.

The second stability constant (K_2) of the second complexes can be calculated by the region between the second and the third plateaux of the

curve. The calculated values of K_1 and K_2 are given in Table 1.

3.2. M(II)-NTA binary system

The overall mobilities of the metal spots in the presence of NTA at different pH are given in Fig. 2. There are two plateaux out of which the second plateau is negative indicating the anionic nature of all three metal ion complexes. The stability constants (K_3) of these complexes were calculated using the same method as described for the M(II)-penicillamine binary system and are given in Table 1. The dissociation constants for NTA are k_1 , k_2 and k_3 with $10^{1.66}$, $10^{2.67}$ and $10^{9.49}$ values respectively. The complexation may be represented as

3.3. M-NTA-penicillamine ternary system

It is observed from the binary systems of penicillamine and NTA that the binary complexes are formed at $pH < 8.5$ and the metals do not form hydroxo complexes up to this pH. Therefore, to avoid any side interaction, the conversion of the $[M-NTA]^-$ binary complex into the $[M-NTA-penicillamine]^{3-}$ ternary complex was studied at pH 8.5. The plot of mobility against the logarithm of the concentration of penicillamine added gives

a curve with two plateaux (Fig. 3). It is concluded that the moiety in the last plateau is due to the coordination of penicillamine anion to the $[M-NTA]^-$ moiety (1:1), resulting in the formation of a 1:1:1 $[M-NTA-penicillamine]^{3-}$ mixed complex which can be shown as

where L is the penicillamine.

In this study, the transformation of a simple complex into a mixed complex takes place and hence the overall mobility (U) of this complex is given by

$$U = u_0 \phi_{[M - NTA]} + u_1 \phi_{[M - NTA - L]} \quad (7)$$

where u_0 , u_1 and $\phi_{[M-NTA]}$, $\phi_{[M-NTA-L]}$ are the mobilities and mole fractions of $[M-NTA]^-$ and $[M-NTA-L]^{3-}$ complexes, respectively.

By the addition of the values of the mole fractions, the above equation becomes

$$U = (u_0 + u_1 K_4 [L^{2-}]) / (1 + K_4 [L^{2-}]) \quad (8)$$

where u_0 and u_1 are the mobilities in the region of the two plateaux of the curve.

The concentration of penicillamine anion at pH 8.5 was calculated. K_4 is obviously equal to $1/[L^{2-}]$. The values of K_4 are given in Table 1.

It may be concluded from these studies that penicillamine and NTA may be used to reduce the level of Fe(II), Co(II) and Cu(II) in biological

Fig. 3. Mobility curve for M-NTA-penicillamine systems.

systems. In addition, these results may be used for the resolution of racemic mixtures of penicillamine and other amino acids.

Abstract

1,4,10,13-Tetrathia-7,16-diazacyclooctadecane (ATCO) and its binary extraction system containing lauric acid were studied extensively as extractants of lanthanide ($M^{3+} = La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, Eu^{3+}$ and Gd^{3+}) in 1,2-dichloroethane solution. The percentage extraction of Ce^{3+} and Eu^{3+} by ATCO were only measured to be less than 5% during a pH range 5.5–7.0 in NCS^- , ClO_4^- and PF_6^- mediums respectively, which indicates that ATCO alone has very low extractability to lanthanide, due to the bad fit of metal ions in its cavity. However, when lauric acid was added to the ATCO organic phase, because of forming rare earth adduct, the percentage extraction for lanthanide until Gd^{3+} was enhanced in the binary system in comparison with that did not adopt the lauric acid within the pH range 6–7. The extraction species and extraction equilibrium constants $\log K_{ex}$ were found to be $CeLA_3 \cdot 3HA$, -8.5 , $EuLA_3 \cdot HA$, -6.7 , and $GdLA_2NO_3 \cdot 2HA$, -1.8 , respectively. The separation factor between Eu^{3+} and Ce^{3+} was found to be 2.5, however, poor selectivity for lanthanide was observed. From Gd^{3+} to Er^{3+} and Lu^{3+} , the synergistic effect of the binary extraction system decreases with increasing atomic number. For gadolinium, the synergistic effect becomes much weaker than that of Ce^{3+} and Eu^{3+} , no synergistic effect existed for erbium and lutetium. Thermodynamic data for synergistic solvent extraction are also reported in this paper. The order of organic phase stability constants of the extraction species is $Sm (5.8) > Pr (5.7) > Eu (5.6) > Ce (5.3) > La (5.2) > Gd (2.8)$. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Separation chemistry and technology of rare earth elements has always been of interest, especially in the latest decades, because of rare earths

* Corresponding author. Fax: +81 78 8030722; e-mail: ymasuda@kobe-u.ac.jp

wide and important applications in the fields of catalysts, glasses, ceramics, magnets, optics and electronics etc. The rapid development of lanthanides applications requires continuous improvement in the separation process for obtaining lanthanide products of high quality and in large amounts. The chemical and physical properties of lanthanides are too similar to be easily separated, to develop fine extractants with high selectivity to rare earths has become a challenging research area. Macrocyclic ligands as host-guest compounds has become a meaningful choice for research on rare earth separation, owing to its metal ion recognition and cavity size-effect fitting ability. Recently, as one branch of lanthanide coordination chemistry—the design and synthesis of macrocyclic ligands and their lanthanides complexation has been the most active and fascinating research area in inorganic and analytical chemistry and many exciting developments, which were reviewed by Alexander [1], have been found. With the expansion of this area, more and more macrocyclic ligands have been used as rare earths extractants. In this class of ligands, the size of the cavity usually determines metal-ion selectivity and specificity. According to this principle, generally, the configuration of 1,4,7,10,13,16-hexaoxocyclooctadecane (18-Crown-6, Scheme 1) is considered to hold the optimum cavity size for lanthanides, so research work has still been focusing on the extraction and separation of lanthanide with it [2,3], using its ternary extraction system with β -diketones [4], and its ionizable derivatives.

In comparison with studies of 18-crown-6 and its derivatives, thia-aza crown ethers, e.g. 1,4,10,13-tetrathia-7,16-diaza-cyclooctadecane (ATCO, Scheme 2), has never been adopted and explored for lanthanide separation, but has only been studied for transition metal element separation until now [5,6], perhaps because of its higher binding affinity and selectivity for transition metal elements rather than rare earth elements. In spite of its lower affinity to rare earth metals, what extent of extractability and selectivity to the metals has it? Can it form synergistic extraction systems combined with other extractant for lanthanide? Furthermore, can it serve as an applicable extractant in lanthanide separation? In order

Scheme 1. Configuration of 18-crown-6

to answer these questions—as a representative thia-aza crown ether ligand, ATCO has become our interest, because it holds similar configuration with 18-Crown-6, which is thought to be best fitting for rare earth ions. Thus, this work has a certain meaning and significance in analytical chemistry and separation chemistry of rare earth metals.

2. Experimental

2.1. Apparatus

Extraction procedure was carried out in a TAITEC ML-10 cool bath shaker at $25.0 \pm 0.1^\circ\text{C}$. Ultra-violet and visible absorption spectra of Arsenazo-III method for lanthanide determination were obtained from a Shimadzu self recording spectrophotometer (model 240-UV-Vis) with 10 mm optical path quartz cells. The pH of an aqueous solution was measured with a ORION RESEARCH (Model 701A/digital IONANALYZER). A Kokusan H-200 centrifuge was used

Scheme 2. Configuration of ATCO

for rapid and complete separation of two phases. The FT-IR spectra were taken down by a JASCO FT-IR spectrometer using KBr pellet under the region 400–4000 cm^{-1} .

2.2. Materials

1,4,10,13-Tetrathia-7,16-diazacyclooctadecane (98%) was purchased from Lancaster, and used without any further purification. The other reagents such as lauric acid (99%), 2-(N-Morpholino)ethanesulfonic acid (MES) (G.R.) and 1,2-dichloroethane (G.R.) etc. were bought from Nacalai Tesque. The lanthanide nitrate solutions were prepared according to the method in reference [7].

2.3. Procedures

The organic phase stock solutions of ATCO and lauric acid were prepared by dissolving appropriate amounts of them in 1,2-dichloroethane up to the concentrations 0.001 and 0.025 M, respectively. An aqueous phase solution was prepared by mixing a certain amount of a lanthanide nitrate solution and a required counter-anion solution, under a certain pH 5.0–7.0 adjusted by 0.01 M MES–NaOH buffer solution. The ionic strength was maintained by 0.2 M NaNO_3 . The organic phase containing an appropriate amount of extractant and the aqueous phase containing 5×10^{-5} M or 1×10^{-4} M lanthanide metal ion, were placed in a stoppered 50 ml glass tube at a volume ratio 10:10 ml (organic phase to aqueous phase). Before shaking, the samples were left standing in the water bath for 15 min, in order that the extraction solutions were kept at the same temperature as the water bath. Then, the two phases were mixed by a shaker at 200 strokes min^{-1} at $25.0 \pm 0.1^\circ\text{C}$, the shaking time of 3 h was enough for finishing the extraction equilibrium. After shaking, the two phases were centrifuged for 10 min, which is sufficient for complete separation. Finally, the equilibrium pH was determined using a pH meter, and the concentration of rare earth metal ions in aqueous phase by the means of Arsenazo III photometric method [8]. In all the employed experimental con-

ditions, organic and ionic interference were not found, and the lanthanide could be nearly completely recovered. It seemed that very little hydrolysis of lanthanide developed during the experimental process within the pH region 5.5–7.0 and under the working concentration of metals. Finally, the rare earth concentrations of organic phase could be calculated from the equation $[\text{M}^{3+}]_{(o)} = (C_M - [\text{M}^{3+}]_{(a)})/R$ (R: phase solution volume ratio). By using the slope analysis method, the composition of extraction species and extraction mechanism could be determined.

3. Results and discussions

3.1. ATCO's extractability of Ce^{3+} and Eu^{3+} in aqueous solution containing NCS^- , ClO_4^- and PF_6^- anion

The experimental results of extraction equilibrium depending on shaking time at pH 6.5 showed that no obvious change of extraction percentage occurred within 6 h of shaking, so 3 h was selected as the shaking time, which was considered as adequate for reaching extraction equilibrium. From the percentage extraction variations for Ce^{3+} and Eu^{3+} as a function of pH in NCS^- , ClO_4^- , PF_6^- mediums, it can be seen that the percentage extraction of ATCO for Ce^{3+} and Eu^{3+} are less than 5%, during the pH range 5.7–6.8 in the above extraction system, and the percentage extraction of Ce^{3+} is a little larger than that of Eu^{3+} . As far as we know, ATCO is a weak basic macrocyclic crown ether extractant, which contains two strong donor nitrogen atoms and four soft donor sulfur atoms within its ring linkage. Why does it have poor extractability for Ce^{3+} and Eu^{3+} ? In answering this question, two factors should be considered. Obviously, rare earth ions are hard acid ones, but ATCO is a soft base ligand, according to the theory of hard and soft acids and bases (HSAB), it should be a little difficult for them to combine with each other. On the other hand, because the atomic radii of the sulfur atom in its ring is larger than that of oxygen, the macrocyclic cavity size of 18-crown ether decreases from 2.6 Å of 18-crown-6 [9] to

Fig. 1. Percentage extraction of Eu^{3+} as a function of shaking time in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Eu^{3+} , 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution. Organic phase: 1×10^{-4} M ATCO and 1.25×10^{-3} M lauric acid (HA)₂ pH 6.5.

2.2 Å of ATCO (C.P.K. model), which is too small to hold rare earth ions. Therefore, its rare earth extractability must be much smaller than that of 18-crown-6, and it is very effective to soft basic metal ions (Pb^{2+} , Cd^{2+} and Cu^{2+}) rather than lanthanide. However, because Ce^{3+} is a bit softer than Eu^{3+} , the extractability of ATCO for Ce^{3+} ($\approx 4\%$) is a little larger than that for Eu^{3+} ($< 3\%$).

3.2. Synergistic extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} combined with ATCO and lauric acid

Because ATCO is very poor at extracting Ce^{3+} and Eu^{3+} in aqueous solutions containing inorganic counter-ions, many studies have taken on the use of organic counter-ions. In past studies on rare earth extraction using crown ethers, the picrate ion is often taken on as a lipophilic counter anion because of the large solubility of oxacrown ethers in the aqueous phase [10]. However, ATCO

is nearly insoluble in the aqueous phase of the neutral region, so the laurate ion was used in this work instead of picrate ion in order to estimate ATCO's metal-ion selectivity and specificity. Because lauric acid is a weak carboxylic acid, which is very sensitive to pH variation, with a $\text{p}K_a$ 5.3, it should have a certain extractability for lanthanide. Thus, before studying solvent extractability of lanthanide with laurate ion and ATCO, the lanthanide extraction behavior with lauric acid alone should be firstly examined.

3.3. Dependence of extractability on shaking time

The dependence of extractants' extractability of Eu^{3+} on shaking time was studied at pH 6.5. In the absence of ATCO, the percentage extraction of lauric acid for Eu^{3+} does not change after been shaken for 30 min. It means that the extraction can reach equilibrium in less than 30 min. In the presence of ATCO, the percentage extraction plotted in Fig. 1 is unchangeable after shaking for 2 h. It seems that the extraction can reach equilibrium in less than 2 h. In the experiments, 3 h was chosen as the shaking time, which was ample for completely finishing the extraction reaction. With the coexistence of ATCO and lauric acid in the organic phase, the extraction equilibrium time becomes much longer than that of using lauric acid alone as Eu^{3+} extractant. This result suggests that ATCO plays a certain role in the extraction process and the extraction reaction was slowed down.

3.4. Effect of lauric acid on the solvent extraction of Ce^{3+} , Eu^{3+} and Gd^{3+}

3.4.1. Effect of pH on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} under constant concentration of lauric acid

Under constant concentration of lauric acid, the effect of pH on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} were studied. When $\log D_0$ (the logarithmic distribution ratio for Ce^{3+} , Eu^{3+} and Gd^{3+} extracted by lauric acid alone) vs. pH is plotted three straight lines with slopes about 3.4, 2.6 and 2.0 for Ce^{3+} , Eu^{3+} and Gd^{3+} respectively are obtained in Fig. 2. These slopes indicate

that about three protons for Ce^{3+} and Eu^{3+} , two protons for Gd^{3+} can be released during the extraction process, respectively. On the other hand, lauric acid can only extract lanthanide at $\text{pH} > 6$, which is in agreement with [10], because it is a weak carboxylic acidic extractant.

3.4.2. Effect of lauric acid concentration on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} at constant pH

At constant pH, the effect of lauric acid concentration on the extraction for Ce^{3+} , Eu^{3+} and Gd^{3+} was examined. The carboxylic acid extractant in the dilution used is present as a dimer [10]. Thus, in data treatment, lauric acid is considered to be present in 1,2-dichloroethane as a dimer, which can be seen from the FT-IR spectra, due to no vibration frequency for free OH^- at the wave number for about 3500 cm^{-1} . When $\log D_0$

Fig. 2. Plots of logarithmic of distribution ratio for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of pH in lauric acid medium. Aqueous phase: 1×10^{-4} M Ce^{3+} (or Eu^{3+} , or Gd^{3+}), 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution. Organic phase: 1.25×10^{-3} M lauric acid (HA)₂ for Ce^{3+} , 6.25×10^{-4} M (HA)₂ for Eu^{3+} and Gd^{3+} , respectively.

Fig. 3. Plots of logarithmic of distribution ratio for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of dimer concentration of lauric acid. Aqueous phase: 1×10^{-4} M Ce^{3+} (or Eu^{3+} , or Gd^{3+}), 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution, pH 6.5 for Ce^{3+} , and pH 6.3 for Eu^{3+} and Gd^{3+} , respectively. Organic phase: 5×10^{-4} – 1.8×10^{-3} M lauric acid (HA)₂.

vs. $\log[(\text{HA})_2]$ (logarithmic concentration of free lauric acid) is plotted three straight lines with slopes 2.8, 1.9 and 2.2, respectively, are obtained Fig. 3. These slopes indicate that three (HA)₂ molecules for Ce^{3+} , two (HA)₂ molecules for Eu^{3+} , and two (HA)₂ molecules for Gd^{3+} are involved in the extraction reaction, respectively. The effects of pH and concentration of lauric acid on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} suggests that lauric acid can extract lanthanide by the cation exchange mechanism. The extraction species of Ce^{3+} and Eu^{3+} should be $\text{CeA}_3 \cdot 3\text{HA}$ and $\text{EuA}_3 \cdot \text{HA}$, respectively. However, the extraction species of Gd^{3+} is different from the former, it may be combined with one NO_3^- or OH^- . Based on the stability constants of Gd^{3+} with NO_3^- and OH^- respectively, the concentrations of different species of Gd^{3+} in aqueous solution within pH range 6–7 can be calculated. Consequently, the

concentration sequence is $[Gd^{3+}] > [Gd(NO_3)_2^{2+}] \gg [Gd(OH)^{2+}]$. Therefore, the extraction species of Gd^{3+} should be suggested as $GdA_2NO_3 \cdot 2HA$ instead of $GdA_2OH \cdot 2HA$. Accordingly, the extraction equilibrium equations can be written as follows:

for Ce^{3+}

for Eu^{3+}

for Gd^{3+}

Therefore, the general extraction equilibrium equation can be described as

The extraction equilibrium constant K_{ex}^0 when only using lauric acid as extractant, can be expressed as:

$$\log K_{ex}^0 = \log D_0 - n \log [NO_3^-] - m \log [(HA)_2] \\ - (3 - n)pH \quad (5)$$

where, m and n are the number of moles of $(HA)_2$ and NO_3^- , respectively. $[NO_3^-]$ is the equilibrium concentration of NO_3^- . Based on Eq. (5), the extraction equilibrium constants of Ce^{3+} , Eu^{3+} and Gd^{3+} can be calculated, respectively, and the average values of $\log K_{ex}^0$ for

Table 1
Extraction constants $\log K_{ex}^0$, $\log K_{ex}$, thermodynamic data ΔH^0 and ΔS^0 for extraction of Ce^{3+} , Eu^{3+} and Gd^{3+}

	Ce^{3+}	Eu^{3+}	Gd^{3+}
$\log K_{ex}^0$	-13.8	-12.3	-4.6
$\log K_{ex}$	-8.5	-6.7	-1.8
ΔH^0 (kJ mol ⁻¹)	-72.3	-106.1	-51.8

Fig. 4. Plots of percentage extraction for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of mole fraction of ATCO in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Ce^{3+} (or Eu^{3+} , or Gd^{3+}), 0.2 M $NaNO_3$, and 0.01 M MES–NaOH buffer solution, pH 6.5. Organic phase: total concentration of ATCO and lauric acid $(HA)_2$ being 0.001 M.

Ce^{3+} , Eu^{3+} and Gd^{3+} are shown in Table 1.
3.5. Metal-ion selectivity of ATCO's extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} in organic solution containing laurate ion

3.5.1. Synergistic extraction effect towards Ce^{3+} and Eu^{3+} and Gd^{3+}

Under constant pH and the total concentration of ATCO and lauric acid, the extractability for Ce^{3+} , Eu^{3+} and Gd^{3+} was studied with continuous variation of the mole fractions of the two ligands. The plots of percentage extraction (%E) vs. molar fraction X_L of ATCO is shown in Fig. 4. It can be found that %E values for Ce^{3+} , Eu^{3+} and Gd^{3+} reach maximum percentage extraction by the molar ratio of about ATCO:A⁻ = 1:3–1:2. It was definitely found that synergistic extraction effect occurred in the extraction process.

3.5.2. Effect of pH on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} under constant concentration of lauric acid and ATCO

Under constant concentration of lauric acid and ATCO, the effect of pH on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} were studied. When $\log D$ (the logarithmic distribution ratio for Ce^{3+} , Eu^{3+} and Gd^{3+} extracted by ATCO and lauric acid) vs. pH is plotted three straight lines with slopes 3.3, 2.8 and 1.9 for Ce^{3+} , Eu^{3+} and Gd^{3+} , respectively, were obtained (Fig. 5). These slopes indicate that about three protons for Ce^{3+} and Eu^{3+} , and two protons for Gd^{3+} can be released during the extraction process, respectively. Meanwhile, the extraction system can extract Ce^{3+} , Eu^{3+} and Gd^{3+} only at pH > 6, which is the same as the extraction using lauric acid alone.

Fig. 5. Plots of logarithmic distribution ratio for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of pH in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Ce^{3+} (or Eu^{3+} , or Gd^{3+}), 0.2 M $NaNO_3$, and 0.01 M MES–NaOH buffer solution. Organic phase: 1×10^{-4} M ATCO and 0.00125 M lauric acid $(HA)_2$ for Ce^{3+} , 3×10^{-4} M ATCO and 6.25×10^{-4} M $(HA)_2$ for Eu^{3+} and Gd^{3+} .

Fig. 6. Plots of logarithmic distribution ratio for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of dimer concentration of lauric acid in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Ce^{3+} (Eu^{3+} , or Gd^{3+}), 0.2 M $NaNO_3$, and 0.01 M MES–NaOH buffer solution, pH 6.5 for Ce^{3+} , and pH 6.3 for Eu^{3+} and Gd^{3+} respectively. Organic phase: 3×10^{-4} M ATCO and 5×10^{-4} – 1.8×10^{-3} M lauric acid $(HA)_2$.

3.5.3. Effect of lauric acid concentration on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} under constant pH and concentration of ATCO

Under constant pH and concentration of ATCO, the effect of lauric acid concentration on the extraction for Ce^{3+} , Eu^{3+} and Gd^{3+} was studied. When $\log D$ vs. $\log[(HA)_2]$ is plotted three straight lines with slopes of 3.2, 2.0 and 2.3 for Ce^{3+} , Eu^{3+} and Gd^{3+} , respectively, see Fig. 6. These slopes indicate that about three $(HA)_2$ molecules for Ce^{3+} , two $(HA)_2$ molecules for Eu^{3+} and for Gd^{3+} are involved in the extraction reaction, respectively.

3.5.4. Effect of ATCO concentration on the extraction of lanthanide (La^{3+} – Gd^{3+}) under constant pH and concentration of lauric acid

Under constant pH and concentration of lauric acid, the effect of ATCO concentration on the

extraction of La^{3+} , Ce^{3+} , Pr^{3+} , Nd^{3+} , Sm^{3+} , Eu^{3+} , Gd^{3+} , Er^{3+} and Lu^{3+} was examined. According to experimental data in Figs. 7–9, the extraction behavior for the elements studied is classified into three different types: (1) when $\log D/D_0$ vs. $\log [L]$ (logarithmic equilibrium concentration of ATCO) is plotted for La^{3+} , Ce^{3+} , Pr^{3+} , Nd^{3+} , Sm^{3+} , Eu^{3+} , six straight lines with slopes 1.2, 1.2, 1.4, 1.2, 1.4, and 1.4 respectively, are achieved (Fig. 7). However, (2) $\log D/D_0$ values for Gd^{3+} increase with increasing concentration of ATCO from 2×10^{-4} to 5×10^{-4} M, while, at ATCO concentrations larger than 5×10^{-4} M, $\log D/D_0$ begins to decrease with increasing ATCO concentration, having negatively keened slope (Fig. 8), (3) for Er^{3+} and Lu^{3+} , $\log D/D_0$ values are unchanging when the concentration of ATCO is increased from 2×10^{-4} to 7×10^{-4} M (Fig. 9). This means that no synergistic effect takes part in the extraction process for erbium(III) and lutetium(III). The result of slope analysis suggests that ATCO countered by laurate ions can extract Ce^{3+} and Eu^{3+} and Gd^{3+} by the cation exchange

Fig. 7. Plots of $\log D/D_0$ for La^{3+} , Ce^{3+} , Pr^{3+} , Nd^{3+} , Sm^{3+} , and Eu^{3+} as a function of ATCO concentration in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Ln^{3+} , 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution, pH 6.5. Organic phase: 2×10^{-4} – 7×10^{-4} M ATCO and 6.25×10^{-4} M lauric acid $(\text{HA})_2$.

Fig. 8. Plot of $\log D/D_0$ for Gd^{3+} as a function of ATCO concentration in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Gd^{3+} , 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution, pH 6.5. Organic phase: 2×10^{-4} – 7×10^{-4} M ATCO and 6.25×10^{-4} M lauric acid $(\text{HA})_2$.

mechanism with the formation of extraction adducts, respectively. The proposed extraction species should be $\text{CeLA}_3 \cdot 3\text{HA}$, $\text{EuLA}_3 \cdot \text{HA}$ and $\text{GdLNO}_3\text{A}_2 \cdot 2\text{HA}$, respectively. And the extraction equilibrium equations can be written as follows: for Ce^{3+}

for Eu^{3+}

for Gd^{3+}

Therefore, the general extraction equilibrium equation can be described as

$$\begin{aligned}
 & M_{(a)}^{3+} + pL_{(o)} + m(HA)_{2(o)} + nNO_{3(a)}^- \\
 & K_{ex} \\
 & = M L_p NO_{3(n)} A_{(3-n)} \cdot (2m + n - 3) HA_{(o)} \\
 & \quad + (3 - n)H^+ \quad (9)
 \end{aligned}$$

The synergistic extraction equilibrium constant K_{ex} can be expressed as:

$$\begin{aligned}
 \log K_{ex} = \log D - m \log [(HA)_2] - n \log [NO_3^-] \\
 - (3 - n)pH - p \log [L] \quad (10)
 \end{aligned}$$

where, $\log D$ is the distribution ratio of the synergistic extraction, when using ATCO and lauric acid as extractants; m , n and p are the number of moles of $(HA)_2$ and NO_3^- and ATCO, respectively. Through Eqs. (5)–(10), we obtain

$$\log D/D_0 = \log K_{ex} - \log K_{ex}^0 + p \log [L] \quad (11)$$

Based on the Eq. (10) and Eq. (11), the synergistic extraction equilibrium constants of Ce^{3+} , Eu^{3+} and

Fig. 9. Plot of $\log D/D_0$ for Er^{3+} (■) and Lu^{3+} (▲) as a function of ATCO concentration in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Er^{3+} (or Lu^{3+}), 0.2 M $NaNO_3$, and 0.01 M MES–NaOH buffer solution, pH 6.5. Organic phase: 2×10^{-4} – 7×10^{-4} M ATCO and 6.25×10^{-4} M lauric acid.

Gd^{3+} can be estimated by determination of the slope and intercept. $\log K_{ex}^0$, and $\log K_{ex}$ values of Ce^{3+} , Eu^{3+} and Gd^{3+} are summarized in Table 1.

From Table 1, it can be seen that the extractability of Ce^{3+} , Eu^{3+} and Gd^{3+} are enhanced by forming the adductive extraction species with laurate ions. The K_{ex} values of Ce^{3+} , Eu^{3+} and Gd^{3+} are improved by the magnitude of $10^{5.3}$, $10^{5.6}$ and $10^{2.8}$, respectively, in the existence of ATCO. Therefore, the synergistic extraction effect played a very important role during the extraction process, which is in complete agreement with the composition of extraction species deduced from the results of the mole fraction variations of ATCO. Moreover, $\log \beta_0$ for Gd^{3+} is so much smaller than that of Ce^{3+} and Eu^{3+} , it seems that both the extraction with lauric acid alone and the extraction with ATCO and lauric acid spontaneously exist in the extraction process of Gd^{3+} . During the low concentration region of ATCO (2×10^{-4} – 5×10^{-4} M), the percentage extraction for Gd^{3+} with lauric acid is larger than that with ATCO and lauric acid, but, within the high concentration region ($> 5 \times 10^{-4}$ M), the percentage extraction with ATCO and lauric acid is larger than that with lauric acid alone. Therefore, increasing the concentration of ATCO, causes the extraction to reach a maximum because of the decrease in free lauric acid concentration $[(HA)_2]$ with the concentration increment of association species between ATCO and lauric acid, which was confirmed by IR spectra of the extractants in CCl_4 . With the existence of ATCO, the frequency of C=O vibration lies in 1710 cm^{-1} , and the frequency of $\nu_{C-O}(\nu_{O-H})$ vibration shifts from 1253 cm^{-1} of $(HA)_2$ to 1255 cm^{-1} of $(HA)_2$ -ATCO, with the frequency difference equal to 2 cm^{-1} . It shows that there is a weak association interaction between ATCO and lauric acid. Due to the coexistence of $GdA_2NO_3 \cdot 2HA$ and $GdLA_2NO_3 \cdot 2HA$ in the extraction procedure, there is a deviation existing in the above deduction for determining the extraction constant of Gd^{3+} .

3.6. Thermodynamic data in the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} using ATCO and lauric acid

Under constant pH and concentrations of ATCO and lauric acid, the effect of temperature

Fig. 10. Plots of logarithmic of extraction constants for Ce^{3+} (■) and Eu^{3+} (▲) and Gd^{3+} (●) as a function of $1/T$ in ATCO–lauric acid medium. Aqueous phase: 1×10^{-4} M Ce^{3+} (Eu^{3+} , or Gd^{3+}), 0.2 M NaNO_3 , and 0.01 M MES–NaOH buffer solution, pH 6.3. Organic phase: 2×10^{-4} M ATCO and 6×10^{-4} M lauric acid (HA_2)

on the extraction of Ce^{3+} , Eu^{3+} and Gd^{3+} was studied. According to the deduced extraction mechanism, $\log K_{\text{ex}}$ at different temperatures can be calculated. Then, based on Vant Hoff's equation $\log K_{\text{ex}} = -\Delta G^0/2.303RT$ and Gibbs–Helmholtz equation $\Delta G^0 = \Delta H^0 - T\Delta S^0$, the equation $\log K_{\text{ex}} = -\Delta H^0/2.303RT + \Delta S^0/2.303R$ can be obtained. Thus, when $\log K_{\text{ex}}$ is plotted against $1/T$, three straight lines are represented in Fig. 10. ΔH^0 and ΔS^0 , which are also given in Table 1, can be determined from the slope and intercept, respectively.

Comparing ΔH^0 of Ce^{3+} , Eu^{3+} and Gd^{3+} with each other in Table 1, it can be seen that the absolute stability sequence of extraction species is $\text{Eu}^{3+} > \text{Ce}^{3+} > \text{Gd}^{3+}$. Ensor et al. [11] reported a synergistic extraction of trivalent actinides and lanthanide using HTTA and 4,13-didecyl-1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (K22DD), which showed no extraction for Ce^{3+}

and Eu^{3+} in this study. The $\log K_{\text{ex}}^0$ of HTTA for Ce^{3+} and Eu^{3+} were -9.95 and -8.58 respectively, and $\log K_{\text{ex}}$ of the synergistic agents K22DD and HTTA for Ce^{3+} and Eu^{3+} were -4.70 and -3.87 respectively, and $\log \beta_0$ for Ce^{3+} and Eu^{3+} were 5.25 and 4.71 respectively. In comparison with results of this work, it appeared very similar on the extraction properties for Ce^{3+} and Eu^{3+} . As to the formation of the extraction species, Ensor et al. also indicated that it correlated with the coordination interaction between the lanthanide and nitrogen atoms in the macrocyclic linkage. Therefore, the synergistic effect of this work is probably mainly related to the interactions between the lanthanide ions and nitrogen atoms of ATCO and oxygen atoms of lauric acid, and to the lowest extent, the interaction between the lanthanide ions and sulfur atoms of ATCO.

3.7. Organic phase stability constants of the extraction species and separation factors

According to the above suggested extraction mechanisms, the formation of synergistic complex can be described as an organic phase reaction represented by the organic phase stability constant β_0 , which can be defined from the following equation and deduction.

$$\begin{aligned} & \text{M NO}_{3(m)}\text{A}_{(3-n)} \cdot (2m+n-3)\text{HA}_{(o)} + p\text{L}_{(o)} \\ & \beta_0 = \frac{\text{M L}_p \text{NO}_{3(m)}\text{A}_{(3-n)} \cdot (2m+n-3)\text{HA}_{(o)}}{[\text{M NO}_{3(m)}\text{A}_{(3-n)}] \cdot (2m+n-3)\text{HA}_{(o)} [\text{L}]^p} \\ & \beta_0 = \frac{[\text{M L}_p \text{NO}_{3(m)}\text{A}_{(3-n)}] \cdot (2m+n-3)\text{HA}_{(o)}}{[\text{M}]_{(a)}} \\ & \beta_0 = \frac{[\text{MNO}_{3(m)}\text{A}_{(3-n)}] \cdot (2m+n-3)\text{HA}_{(o)}}{[\text{M}]} \\ & [\text{L}]^p = D/D_0[\text{L}]^{-p} \end{aligned} \quad (12)$$

Table 2
Organic phase stability constants of the extraction species

	La^{3+}	Ce^{3+}	Pr^{3+}	Nd^{3+}	Sm^{3+}	Eu^{3+}	Gd^{3+}
$\log \beta_0$	5.2	5.3	5.7	5.3	5.8	5.6	2.8

After mathematical treatment of Eq. (12), Eq. (13) can be obtained as:

$$\log D/D_0 = \log \beta_0 + p \log [L] \quad (13)$$

Comparing Eq. (13) with Eq. (11), it can be found $\log \beta_0 = \log K_{\text{ex}} - \log K_{\text{ex}}^0 = \Delta \log K_{\text{ex}}$, $\log \beta_0$ values of La^{3+} , Ce^{3+} , Pr^{3+} , Nd^{3+} , Sm^{3+} , Eu^{3+} , and Gd^{3+} are listed in Table 2.

From Table 2, it can be found that the organic phase stability constants of the extraction species of La^{3+} , Ce^{3+} , Pr^{3+} , Nd^{3+} , Sm^{3+} and Eu^{3+} are nearly the same, but much larger than that of Gd^{3+} . Therefore, the tendency of synergistic extraction reaction for light rare earths La^{3+} , Ce^{3+} , Pr^{3+} and Nd^{3+} , and medium rare earths Sm^{3+} and Eu^{3+} are much similar, but for gadolinium which becomes much more weaker than that of the former ones, and decreases quickly from Gd^{3+} to Er^{3+} and Lu^{3+} with increasing atomic number. For heavier rare earth elements, no synergistic effect can be produced, perhaps owing to the bad fitting between lanthanide and the extraction system. The separation factors (S.F.) between Gd^{3+} and Eu^{3+} (C_L : 2×10^{-4} – 5×10^{-4} M), Eu^{3+} and Ce^{3+} (C_L : 2×10^{-4} – 7×10^{-4} M) were obtained to be 1.4 and 2.5, respectively, where C_L is the initial concentration of ATCO. It is estimated that the best separation between Eu^{3+} and Ce^{3+} can be obtained in this condition.

4. Conclusion

Due to ATCO containing soft donor sulfur atoms within its macrocyclic linkage, its binding capability and smaller cavity size can not be fitted into lanthanide ion. Of course, it alone has very low extractability and selectivity for lanthanide than oxa-crown ethers and aza-crown ethers, thus is unavailable for applicable purpose. However, because it can form a synergistic extraction system in the presence of lauric acid, which tends to

extract light and medium rare earths such as Ce^{3+} and Eu^{3+} by forming rare earth adductant with lauric acid in the neutral range, it can help us to deeply understand its binding and extraction behavior for rare earths from the viewpoint of fundamental chemistry. Unfortunately, in speaking of the real structure of extraction species, it could not be determined exactly from the experiment employed, and is worthy of further study.

Determination of chromium in waste-water and cast iron samples by fluorescence quenching of rhodamine 6G

Nianqin Jie *, Qiang Zhang, Jinghe Yang, Xirong Huang

Department of Chemistry, Shandong University, Jinan, People's Republic of China

Received 20 May 1997; received in revised form 16 August 1997; accepted 16 August 1997

Abstract

A new simple, selective and sensitive fluorescence quenching method was developed to determine chromium with rhodamine 6G. The method is based on the oxidation of rhodamine 6G by chromium(VI) in sulfuric acid solution. The linear calibration graph was obtained in the range 8–80 ng ml⁻¹ chromium(VI). The detection limit is 0.8 ng ml⁻¹. The method was applied successfully to the determination of chromium in waste water and cast iron samples. © 1998 Elsevier Science B.V. All rights reserved.

The chromium content of water is probably increasing steadily as a result of industrial activity in populated areas. Chromium appears frequently as a pollutant in our environment [1]. The hexavalent form is of prime concern because of its high toxicity. Cr(VI) poisoning causes skin disorders and liver damage, and there are some reasons to believe that chromates are carcinogenic. For these reasons, its maximum allowable level in drinking water has been limited to 0.05 mg l⁻¹ hexavalent Cr(VI). On the other hand, the chemistry of chromium is very important in the field of metallurgical industry. The addition of small amounts of chromium to cast iron significantly modified its wear and heat resistance. Therefore, the accurate determination of Cr at trace level is important in the field of environmental science and industry.

Many spectrophotometric methods for the determination of chromium have been developed [2–4]. Electrometric methods are also available [5,6], as well as AAS methods [7,8] and iron chromatography methods [9,10]. These methods have their advantages and their disadvantages respectively. Some of these methods suffer from interferences of other substances, and some require separation or complicated instrumentation.

Fluorometric methods have been reported for the determination of Cr(VI) in water and cast iron samples [11–13], but these methods also suffer from the interferences of Fe(II), Pb(II) and Hg(II), and they have low sensitivity. Fluorescence quenching method for the determination of chromium(VI) is rarely reported [14,15], and these methods are of low sensitivity. So far, there has been no report on the determination of chromium(VI) using rhodamine 6G. In this paper, a fluorescence quenching method for the determina-

* Corresponding author.

tion of Cr(VI) using rhodamine 6G has been described. The method is based on the measurement of decrease in fluorescence intensity at 545 nm of rhodamine 6G in sulfuric acid medium. The method offers several distinct advantages over other fluorometric methods [11–15] for chromium(VI): higher sensitivity, good selectivity and ease of operation. The method has been used to determine trace chromium in waste water and cast iron samples. The results are satisfactory.

1. Experimental

1.1. Apparatus

An RF-540 spectrofluorimeter (Shimadzu, Kyoto) with a plotter unit and a 1 cm quartz cell was used for recording the spectra and making fluorescence measurements.

1.2. Reagents

All chemicals were of analytical–reagent grade. Deionized, distilled water was used throughout.

Chromium(VI) stock solution: 1 mg ml^{-1} . Dissolve 0.2827 g of potassium dichromate in water and dilute to volume in a 100 ml standard flask. The stock solution was diluted to μg of chromium(VI)/ml as working solution.

Rhodamine 6G stock solution: 1.5 mg ml^{-1} . It was diluted to $1 \mu\text{g ml}^{-1}$ as working solution. Sulfuric acid solution: 12.5 mol l^{-1} .

1.3. Analytical procedure

As aliquot of working solution of chromium(VI), 1.5 ml of rhodamine 6G working solution, and 1.0 ml sulfuric acid solution (12.5 mol l^{-1}) were added sequentially to 25 ml standard volumetric flask. The contents of the flask were mixed, then it was placed in a boiling water bath for 5 min, after which it was cooling under tap water and diluted to the mark with water and mixed. The fluorescence intensity was measured at 545 nm (with excitation at 525 nm) against a reagent blank, prepared concurrently.

2. Results and discussion

2.1. Spectra characteristics

As shown in Fig. 1, the excitation and emission spectra of the rhodamine 6G and rhodamine 6G chromium systems are similar. The excitation and emission wavelength were at 525 and 545 nm, respectively. But the fluorescence intensity of rhodamine 6G decreased when the chromium(VI) was added.

2.2. Optimum conditions for fluorescence quenching

The results indicated that a maximum and constant fluorescence quenching was reached in the range 1.0–2.0 ml of rhodamine 6G ($12.5 \mu\text{g ml}^{-1}$) (Fig. 2). In this work, 1.5 ml of rhodamine 6G ($12 \mu\text{g ml}^{-1}$) was chosen. The effect of sulfuric acid concentration on the fluorescence quenching of the system was examined. The maximum fluorescence quenching occurred in the range 0.25–0.75 mol l^{-1} of sulfuric acid. The fluorescence quenching decreased for values outside this range (Fig.

Fig. 1. Fluorescence spectra. (a) Excitation and (b) emission spectra of rhodamine 6G system(1,2) and rhodamine 6G-Cr(VI) system(1',2') condition: 40 ng ml^{-1} Cr; 0.5 mol l^{-1} H_2SO_4 ; and $0.72 \mu\text{g ml}^{-1}$ rhodamine 6G.

Fig. 2. Effect of rhodamine 6G concentration. Conditions: 40 ng ml⁻¹ Cr, and 0.5 mol l⁻¹ H₂SO₄.

3). A 0.5 mol l⁻¹ of sulfuric acid was selected. The temperature and time on the fluorescence quenching of the system was also investigated. The optimum fluorescence quenching was reached at 100°C for 5 min and remained unaltered for up to 10 h.

Fig. 3. Effect of sulfuric acid concentration. Condition: 40 ng ml⁻¹ Cr, and 0.72 μg ml⁻¹ rhodamine 6G.

Table 1
Tolerance of foreign ions in the determination of 1 μg Cr(VI)

Ions added	Tolerance ratio (W/W)
As(V)	5000
PO ₄ ³⁻	4000
Co(II)	3000
NO ₃ ⁻ , NH ₄ ⁺	2500
Ni(II), Ca(II)	2000
Mg(II), Zn(II), Be(II)	1500
Al(III), Cd(II), F ⁻	1000
Mn(II), Br ⁻ , Cl ⁻	800
Bi(III), Mo(VI)	500
Ba(II)	200
Hg(II)	80
Pb(II)	40
Fe(III)	20
Cu(II)	4
V(V)	1
Ce(IV)	0.4
NO ₂ ⁻	0.2

2.3. Interferences

The tolerance limits of some ions for the determination of 1 μg Cr by the procedure described were studied, and the results are given in Table 1. The relative error is less than ± 5%. It can be seen that most of ions examined do not interfere, even when present in large excess. However, only Ce(IV), nitrite ions seriously interfere with the determination of Cr(VI). Therefore, the method is of good selectivity.

2.4. Calibration

The calibration graph for the determination of chromium(VI) was constructed under the optimum conditions. The linear calibration graph was obtained in the range 8–80 ng ml⁻¹ Cr(VI). The detection limit, based on three times the standard deviation of the blank, was 0.8 ng ml⁻¹ of chromium(VI). The linear regression equation and the coefficient are: $\Delta F = 19.07C + 1.13$, $r = 0.998$ (the unit of C is μg–25 ml), where ΔF is the fluorescence quenching and C is the Cr(VI) concentration.

Table 2
Determination of chromium in waste water

2.5. Practical application

Determination of Cr(VI) in industrial waste-water samples. The water samples were collected from different sources and were filtered before analysis. The results compare favorable to the spectrophotometric method and are shown in Table 2.

Determination of chromium in cast iron samples. Dissolve the weighed cast iron samples in a minimum volume of hydrochloric acid (12 mol l⁻¹) and heat gently on a hot plate to complete dissolution, then add 10% NaOH until pH is 10. Then add 2 ml of 30% H₂O₂ solution and heat gently to remove the excess of H₂O₂. Filter the solution into a flask and wash the residue on the filter paper repeatedly with hot water. Collect the filtrate and washing into the same flask, add 2.5 mol l⁻¹ of sulfuric acid until the pH is 6. Transfer the solution to a 100 ml calibrated flask, and dilute to the mark with water. Take appropriate amounts of this solution for the determination of Cr(VI) according to the procedure described above. The results are summarized in Table 3 and were compared with the certified value of Cr(VI). The contents of elements in cast iron standard samples are shown in Table 4.

Table 3

Sb	0.004	0.001
Ti	0.094	0.059
As	—	0.008

2.6. Nature of the reaction between Cr(VI) and rhodamine 6G

Rhodamine 6G is a triphenylmethane dye and emits very strong yellow–green fluorescent light. When oxidized by such strong oxidizers as potassium periodate and potassium bromate, its molecular structure is destroyed and the fluorescence disappears [16,17]. In this system, Cr(VI) is strong oxidizer, and rhodamine 6G could be oxidized by Cr(VI). Therefore, the fluorescence intensity of rhodamine 6G decreases after adding Cr(VI) to this system. It is clear that the reaction between Cr(VI) and rhodamine 6G in acidic solution is redox reaction.

3. Conclusion

A fluorometric determination of Cr(VI) with rhodamine 6G was developed in this paper. The nature of the reaction was discussed. The current method was compared with other methods and found to be more sensitive and selective. The procedure can be satisfactorily applied to the determination of Cr(VI) in waste-water and cast iron samples.

Simultaneous determination of pseudoephedrine hydrochloride and diphenhydramine hydrochloride in cough syrup by gas chromatography (GC)

S.V. Raj, S.U. Kapadia, A.P. Argekar *

Analytical Laboratory, Department Of Chemistry, The Institute of Science, 15, Madam Cama Road, Mumbai, 400 032, India

Received 30 April 1997; received in revised form 12 August 1997; accepted 18 August 1997

Abstract

A simple, rapid and precise gas chromatographic method has been developed for the simultaneous determination of pseudoephedrine hydrochloride and diphenhydramine hydrochloride in cough syrup, using a SS column of 10% OV 1 on chromosorb W-HP (80–100 mesh) and nitrogen as a carrier gas at a flow rate of 30 ml min⁻¹. The oven temperature was programmed at 135°C for 1 min, with a rise of 10°C min⁻¹ up to 250°C (held for 5 min). The injector and detector port temperatures were maintained at 280°C. Detection was carried out using Flame ionization detector. Guaphenesin was used as an internal standard. Results of assay and recovery studies were statistically evaluated for its accuracy and precision. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Simultaneous determination; Pseudoephedrine hydrochloride; Diphenhydramine hydrochloride; Cough syrup; Gas chromatography

1. Introduction

Pseudoephedrine Hydrochloride (PSE), is a sympathomimetic agent. It is used for the symptomatic relief of nasal congestion. Diphenhydramine Hydrochloride (DPH), is an antihistamine with antimuscarinic and pronounced sedative properties. It is also used as an antiemetic [1].

Literature survey reveals that both PSE and

DPH are official in U.S.P. [2], B.P. [3] and I.P. [4]. Various Spectrophotometric [5,6] and HPLC [7] methods are reported for the individual determination of PSE and Spectrophotometric [8] and GC [9] methods are reported for the individual determination of DPH from its formulations. HPLC determination of DPH and Ephedrine Hydrochloride in biachuanpeng tablets [10] and HPLC determination of DPH and Ondansetron mixture in 0.9% NaCl injection [11] are also reported. A HPTLC [12] method has been reported for the simultaneous determination of PSE and DPH in combined dosage form. However instru-

mental facility of HPTLC being rare as compared to GC and HPLC and there is no method for the simultaneous determination of PSE and DPH by GC. So a new method for the simultaneous determination of PSE and DPH from cough syrup by GC technique is developed.

2. Experimental

2.1. Instrument

CHEMITO 5210 gas chromatograph equipped with an Oracle 2 integrator and a flame ionization detector was used.

2.2. Carrier gas

Nitrogen was used as a carrier gas at a flow rate of 30 ml min⁻¹.

2.3. Stationary phase

An S.S. column (2.50 m in length and 2 mm id) of 10% OV 1 on Chromosorb W-HP (80–100 Mesh), manufactured by Sky Lab, Thane, Mumbai, was used as a stationary phase.

2.4. Solvents and chemicals

Chromatography grade Chloroform and A.R. Grade Sodium Hydroxide were used.

2.5. Standard stock solution

A combined standard solution of PSE (5 mg ml⁻¹) and DPH (5 mg ml⁻¹) were prepared in water. These Standards were procured from Merind, Mumbai, India and their purities were found to be 98.95 and 99.28% respectively.

2.6. Internal standard

Guaphenesin standard of 98.89% purity, was procured from TATA Pharma, Patalganga, India. A solution of 5 mg ml⁻¹ was prepared in water.

2.7. Procedure for calibration

In a series of separating funnels aliquots of standard drug solution equivalent to 1–10 mg ml⁻¹ for PSE and 1–5.0 mg ml⁻¹ for DPH were taken. 1 ml of internal standard and 20 ml of 1 N NaOH were added and extracted with three quantities, each of 20 ml of chloroform. The chloroform layer was collected in a conical flask and

Fig. 1. Typical chromatogram of PSE and DPH.

evaporated till 5 ml solution was left. Further evaporation was done using nitrogen up to dryness. The residue was reconstituted in 2 ml of chloroform. All the operating chromatographic conditions were set and the instrument was stabilized for steady baseline. 2 μ l of the solution were injected into the chromatographic system. The chromatograms were recorded and peak area ratios were computed.

2.8. Procedure for assay

Ten grams of cough syrup was accurately weighed and then transferred into a separating funnel. To this 1 ml of internal standard solution and 20 ml of 1 N NaOH solution were added and proceed as described in the procedure for calibration. The amount of drug present in mg per 5 ml was calculated using the formula:

Amount of drug (mg per 5 ml)

$$= \frac{RA/RI \times C \times D}{RB/RI \times W}$$

where RA = area of sample, RB = area of standard, RI = area of internal standard, C = Concentration of standard in mg ml⁻¹, D = dilution factor, W = weight of sample in mg.

2.9. Procedure for recovery studies

To study the accuracy, reproducibility and precision of the above method, recovery of the added standard was studied at three different levels. Each level was repeated three times. A plot of the amount of the drug found by the proposed method (Y-axis) against the amount of the standard added (X-axis) was drawn. The intercept on the Y-axis indicates the amount of drug present per five ml of cough syrup. From the amount of drug found. Percentage recovery was calculated using the formula:

$$\% \text{Recovery} = \frac{N(\sum XY) - (\sum Y)(\sum X)}{N(\sum X^2) - (\sum X)^2} \times 100$$

where X = amount of standard drug added, Y = amount of drug found by the proposed method, N = number of observations.

3. Results and discussion

3.1. System suitability

To ascertain the resolution and reproducibility of the chromatographic method, system suitability tests were carried out on freshly prepared standard stock solution of PSE and DPH. The Parameters obtained are as shown in Table 1. These results are in concurrence with U.S.P. 23 requirements.

3.2. Chromatography

10% OV1 column gave a good separation of the drugs and the internal standard. Sharp and sym-

Table 2

metrical peaks were achieved by programming the oven temperature at 135°C for 1 min, with a rise of 10°C min⁻¹ up to 250°C (held for 5 min). The retention times of PSE and DPH were about 4.69 and 10.50 min respectively. Retention time of the internal standard was 8.00 min (Fig. 1).

3.3. Linearity, limit of detection and limit of quantification

A linear relationship was obtained in the concentration range of 1–10 mg ml⁻¹ for PSE and 1–5 mg ml⁻¹ for DPH respectively. The calibration curves could be represented by the linear regression equations:

$$Y_{\text{PSE}} = 8.1980X + 3.9850 \quad (r = 0.999)$$

$$Y_{\text{DPH}} = 5.4006X + 5.2358 \quad (r = 0.998)$$

where Y = area and X = concentration of the drug in mg.

The Limit of Detection (LOD) and the Limit of Quantification (LOQ) of PSE and DPH were calculated on the peak area using the following equations:

$\text{LOD} = 3 \times N/B$ and $\text{LOQ} = 10 \times N/B$ where N , the noise estimate, is the standard deviation of the peak areas ($n = 5$) of the respective drugs and B is the slope of the corresponding calibration curve. LOD and LOQ were 0.5 and 2.0 mg ml⁻¹ for PSE and 0.4 and 1.5 mg ml⁻¹ for DPH respectively.

3.4. Assay

In a replicate analysis ($n = 5$) for the cough syrup (LUPIHIST, Batch No. 6001, date of manufacturing: Feb. 1996, manufactured by Lupin, Chikalthana, Aurangabad, India.), the amounts of PSE and DPH per 5 ml of the cough syrup found by the proposed method were 29.34 mg (R.S.D. = 1.85%) and 14.76 mg (R.S.D. = 1.73%) respectively, as shown in Table 2. The low values of R.S.D. indicate that the method is precise and accurate.

A blank run of the excipients present per 5 ml of cough syrup, such as Sodium Citrate (150 mg), ammonium chloride (150 mg) and menthol (0.01 ml) did not show any interference.

3.5. Accuracy and precision

The percentage recoveries obtained for PSE and DPH were 98.32 and 98.19% respectively, which indicates that the method is precise, accurate and there is no interference due to excipients present in the cough syrup (Table 3).

4. Conclusion

The proposed GC method is accurate, precise and rapid for the simultaneous determination of PSE and DPH from cough syrup. Hence it can be easily and conveniently adopted for the routine quality control analysis.

Abstract

An anion-exchange fast protein liquid chromatographic–inductively coupled plasma atomic emission spectrometric procedure (FPLC–ICP–AES) was developed for speciation of Al–citrate and other negatively charged Al complexes. FPLC separations were carried out on a Mono Q HR 5/5 strong anion-exchange FPLC column over a pH range from 3.5 to 11.0. An aqueous—NaNO₃ (4 mol dm⁻³) linear gradient elution was applied over 10 min for separation of a particular Al species. The separated Al species were determined in 0.5 cm³ eluate fractions ‘off line’ by ICP–AES. Under optimal analytical procedures Al–citrate was separated from Al–oxalate and Al–EDTA in a neutral pH range. Good reproducibility of the FPLC–ICP–AES procedure was obtained for determination of a particular Al species at optimal measurement conditions (RSD ± 2%). Al³⁺ and neutral Al–citrate species were strongly adsorbed on the column resin and did not interfere with the separation of negatively charged Al complexes. Al(OH)₄⁻ species were separated from Al–citrate in an alkaline pH region, but quantitatively determined only at a pH of 11.0. The distribution of Al species over a pH range from 3.5 to 11.0 agreed with the reported calculated data. The limit of detection (3σ basis) for separated Al species was 0.1 μg cm⁻³. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Interest in Al bioavailability and toxicity resulted in the development of numerous analytical techniques for speciation of Al. These techniques identified and quantified particular groups of Al species. The most frequently used techniques include spectrophotometry [1–6], ion-exchange

chromatography [6,7] and chelating ion-exchange chromatography [8–12] which enable the determination of the sum of positively charged monomeric Al species. In recent years investigations were directed at the development of an analytical method using a single procedure for the simultaneous determination of various Al species in environmental samples [13–18]. For this purpose ion chromatography in combination with post-column derivatization using UV–VIS [13,14] or fluorescence [15,16] detection was employed,

* Corresponding author. Tel.: +386 61 177 3900; fax: +386 61 219 385; e-mail: radmila.milacic@ijs.si

and HPLC cation-exchange chromatography with fluorescence detection [17] or cation-exchange FPLC–ICP–AES [18]. Speciation of Al using capillary zone electrophoresis was employed for simultaneous determination of Al^{3+} , Al–fluoro and Al–oxalato positively charged complexes in synthetic aqueous solutions [19].

Protein complexes and low molecular weight organic complexes of Al play an important role in biological systems. Human serum was the most widely investigated biological fluid [20–23]. Ultrafiltration and microultrafiltration [20] indicated that the majority of Al in serum is bound to serum proteins. Employing a polymeric methacrylate based anion-exchange column with ETAAS detection and gel electrophoresis [21] it was verified that approximately 90% of Al in spiked serum is bound to transferrin. Another peak appeared after separation of Al–transferrin representing the remaining 10% of Al which was presumed to be Al–citrate. Analogous observations were reported by D’Haese et al. [22] who used a similar polymer-based weak anion-exchange column with ETAAS detection for speciation of Al in the serum of dialysis patient. FPLC gel chromatography with ETAAS detection was also employed in speciation studies of Al in serum from a patient with chronic renal failure [23]. The addition of excess citric acid to serum resulted in a chromatographic peak which was assumed to correspond to Al–citrate—significantly increased. Speciation of Al–citrate was also investigated employing the HPLC–ETAAS technique [24]. Various normal, reversed phase and mixed phase (ODS/– NH_2) columns and different mobile phase conditions were used. Promising results for synthetic standard solutions of Al–citrate using a mobile phase containing MeOH:H₂O (1:1; v/v) with 0.1 M TEA and glacial acetic acid (pH 4.0) were obtained when cyclobond and cyanobonded phase columns were employed. Al–citrate recovery were moderate and did not exceed 65%. Investigation of equilibrium reactions of the citrate ion with Al by potentiometry and ¹³C NMR [25] were also reported. Al speciation in serum [26,27], blood plasma and the gastrointestinal tract [28] were investigated by a computer simulation through calculations using known thermodynamic

equilibrium constants. There is no doubt that Al–citrate is a very important low molecular weight species in biological fluids [21–23,26–28]. It is also presumed that it exists in plant leaves and is synthesized in acid forest soils, as well as other aliphatic organic acids, by organic acid-producing microorganisms [29]. Studies on the oral consumption of Al–citrate in rats indicated that it may play a key role in the delivery of Al to tissues by crossing the tissue membranes [30]. Although there are many analytical techniques available for determination of monomeric positively charged Al species [1–19], there is still a lack of reliable and quantitative analytical procedures for determination of low molecular weight Al species which are the most active in terms of Al bioavailability. In addition to computer simulation there is a need to incorporate more detailed speciation data into studies on Al bioavailability and toxicity in biological systems [31,32]. For these purposes reliable analytical procedures for determination of low molecular weight Al complexes should be developed.

The aim of our work was to perform a systematic study of the possibilities for quantitative determination of Al–citrate and other negatively charged low molecular weight Al complexes using FPLC separation on a Mono Q HR 5/5 strong anion-exchange column with ICP–AES detection.

2. Experimental

2.1. Apparatus

A strong anion-exchange FPLC column (Pharmacia, Sweden) of Mono Q HR 5/5 (column dimensions 5 × 50 mm, 10 μm beaded hydrophilic polyether resin substituted with quaternary amine groups, pH stability 2–12) was employed for the separation of Al species. The column was connected to a Varian Star gradient high pressure pump, equipped with a Rheodyne Model 7161 injector (0.5 cm³ loop). Separated Al species were determined on a Perkin–Elmer Plasma 40 emission spectrometer, adjusted to a wavelength of 396.152 nm. The plasma was operated at a power of 1.0 kW and a frequency of 40 MHz, with argon

as the coolant gas at a flow rate of $15 \text{ dm}^3 \text{ min}^{-1}$, and a nebulization flow rate of $1 \text{ dm}^3 \text{ min}^{-1}$. An Iskra MA 5740 pH meter with combined glass electrode was employed to determine the pH of the samples.

2.2. Reagents

Merck suprapur acids and water doubly distilled in quartz were used for the preparation of samples and standard solutions. All other chemicals were of analytical-reagent grade.

2.2.1. Aluminium standards

A standard Al stock solution ($500 \mu\text{g Al cm}^{-3}$) was prepared in a 0.5 dm^3 calibration flask by dissolving 3.4760 g of $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ (Riedel-de Haën) in water. Al–citrate, Al–oxalate and Al–EDTA complexes were made by mixing a solution of $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ salt with an appropriate amount of ligand (3:1 ligand to Al ratio) [33]. Stock Al–citrate, Al–oxalate and Al–EDTA solutions ($500 \mu\text{g Al cm}^{-3}$) were prepared weekly in 0.5 dm^3 calibration flasks by dissolving 3.4760 g of $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ (Riedel-de Haën) in water followed by addition of either 5.8 g of citric acid (Merck), 5.2 g of oxalic acid (Merck) or 10.2 g of EDTA. The Al–EDTA was heated for 24 h at 80°C to assure quantitative formation of the complex [33]. Fresh working standards were prepared each day. The same stock solutions were used either for the preparation of standards for calibration in ICP-AES determinations (dilution with a yttrium solution), or for the preparation of synthetic standard solutions (dilution with buffer) which were used in the investigation of Al speciation on the FPLC column.

2.2.2. Internal standard

A Merck standard yttrium stock solution ($1000 \mu\text{g cm}^{-3}$) was used as the internal standard in inductively coupled plasma-atomic emission (ICP-AES) measurements.

2.2.3. Buffer solutions

Potassium hydrogenphthalate (0.05 mol dm^{-3}) buffer solution (Merck) with the addition of an appropriate amount of nitric acid (0.5 mol dm^{-3})

(Merck) or potassium hydroxide (0.5 mol dm^{-3}) (Merck) was used to adjust pH in the range 3.5–4.5. Imidazole ($\text{C}_3\text{H}_4\text{N}_2$) (0.2 mol dm^{-3}) (Merck) buffer solution with the addition of an appropriate amount of hydrochloric acid (0.1 mol dm^{-3}) (Merck) was used to adjust the pH of samples in the range 5.0–8.0. pH values higher than 8.0 were obtained by the addition of an appropriate amount of potassium hydroxide (0.5 mol dm^{-3}).

2.2.4. Reagents in FPLC separations

Merck sodium nitrate (5 mol dm^{-3}) was prepared by dissolving 424.95 g of NaNO_3 in water and diluting to 1 dm^3 . The reagent was purified before use by a batch procedure. Five grams of chelating ion-exchange resin Chelex 100 (Na^+ form, 100–200 mesh) was added to the reagent, stirred for 24 h and filtered through a $0.45 \mu\text{m}$ filter. Lower concentrations of sodium nitrate were prepared by dilution with water.

2.3. Synthetic solutions of Al complexes

To study the distribution of Al species over a wide pH range the following procedure was applied for preparation of synthetic solutions. Buffer solution was first adjusted to the required pH. Buffer solution (45 cm^3) was then transferred to a 50 cm^3 volumetric flask. An appropriate amount of Al stock solution was added and the flask filled to the mark with buffer solution.

2.4. Recommended procedure

Separations of negatively charged low molecular weight organic complexes of Al were carried out on a Mono Q HR 5/5 strong anion-exchange column. The sample (0.5 cm^3) was injected onto the column. An aqueous—(0–100% 4 mol dm^{-3} NaNO_3) linear gradient elution was applied over 10 min at a flow rate of $1.0 \text{ cm}^3 \text{ min}^{-1}$. After separation, the column was left to regenerate for 5 min with 4 mol dm^{-3} NaNO_3 at a flow rate of $1.0 \text{ cm}^3 \text{ min}^{-1}$ and then equilibrated with water firstly for 20 min at a flow rate of $2.0 \text{ cm}^3 \text{ min}^{-1}$ and in the following 5 min at a flow rate of $1.0 \text{ cm}^3 \text{ min}^{-1}$. The separated Al species were deter-

mined in 0.5 cm³ eluate fractions 'off line' by ICP-AES. Fractions were diluted prior to analysis with 0.5 cm³ of Y standard solution, such that the internal standard concentration was 10.0 µg cm⁻³. The sequential mode of the instrument did not allow measurement of the transient emission signal for Al and Y simultaneously. Therefore, the chromatographic column was not connected 'on line' to the ICP-emission spectrometer.

3. Results and discussion

3.1. Development of the FPLC—ICP-AES procedure

At a neutral pH range Al–citrate exists as a mixture of negatively charged complexes [26–28,34]. Therefore, as a negatively charged species it should be quantitatively separated on an anion-exchange column. Gradient elution with NaCl (4 mol dm⁻³) was efficient in separating negatively charged Al–citrate but disadvantageous owing to corrosion problems with the stainless steel components of the HPLC system. In order to avoid corrosion, NaNO₃ (2–5 mol dm⁻³) was examined. Quantitative separation of Al–citrate and a narrow range of separated Al–citrate peak was obtained when gradient elution with 4 mol dm⁻³ NaNO₃ at a flow rate of 1 cm³ min⁻¹ was applied. The increasing ionic strength of the eluent during the chromatographic run (gradient elution) allowed the separation of negatively charged Al species. After separation the column resin was regenerated with 4 mol dm⁻³ NaNO₃. Washing with water followed to equilibrate the column resin before the next separation. Experimentally, it was found that to obtain reproducible retention times it was very important to ensure quantitative washing of NO₃⁻ (a large ion) from the column resin. Therefore, initial equilibration with water was applied for 20 min at a flow rate of 2.0 cm³ min⁻¹ and for the next 5 min at a flow rate of 1.0 cm³ min⁻¹. To determine the separated Al species, 0.5 cm³ fractions were collected. The high salt content of the eluent af-

fects the nebulization efficiency in ICP-AES measurements. To eliminate this influence, fractions were diluted with 0.5 cm³ of Y solution which acts as an internal standard. The concentration of Y in the diluted fractions and in the standards and blank solution which were used in the calibration procedure was 10 µg cm⁻³. During the chromatographic run the pH of the water–NaNO₃ eluent ranged from 7.0 to 6.0. It was found experimentally that the pH of the eluent did not influence the separation of Al–citrate, nor that of other Al negatively charged complexes investigated. The same retention times and efficiency of separation was obtained when either water–NaNO₃ was employed in gradient elution or when the column was equilibrated with buffer at the pH of the sample analyzed and a buffer solution in combination with buffered NaNO₃ was applied in the separation of the Al species. On the basis of these considerations the procedure was developed as described under Section 2 and was employed in further investigations of Al speciation by anion-exchange FPLC—ICP-AES.

A typical chromatogram for Al–citrate at pH of 7.0, separated on an anion-exchange FPLC Mono Q HR 5/5 column with ICP-AES detection, is presented in Fig. 1. It is evident that

Fig. 1. Typical chromatogram of Al–citrate (3.0 µg Al cm⁻³, 3 M excess of citric acid) at pH 7.0, separated on an anion-exchange FPLC Mono Q HR 5/5 column with ICP-AES detection. Sample volume 0.5 cm³, aqueous-NaNO₃ (4 mol dm⁻³) linear gradient elution, flow rate 1 cm³ min⁻¹, fraction collection 0.5 cm³, *n* = 3.

RSD = ± 2%.

negatively charged Al–citrate species are quantitatively eluted as a single chromatographic peak at the retention time of 5.5 min.

3.2. Reproducibility of the FPLC—ICP-AES procedure, linearity of measurement, limit of detection

In order to study the reproducibility of the procedure developed, six consecutive determinations of synthetic Al–citrate sample (3.0 $\mu\text{g Al cm}^{-3}$) were performed at pH 7.0. The results are summarized in Table 1. It is evident from the data of Table 1 that Al–citrate elutes reproducibly and quantitatively, between 5 and 6 min with a maximum at the retention time of 5.5 min. The recoveries range from 98 to 102%. It is also evident that good reproducibility of measurement (± 2.0%) is obtained. On the basis of these observations it can be concluded that the analytical procedure developed enables quantitative and reproducible determinations of Al–citrate in the neutral pH range. The calibration graph was found to be linear up to 4.0 $\mu\text{g cm}^{-3}$ of total Al species. The limit of detection (LOD), calculated on a 3σ basis (a value of three times the standard deviation of the blank), for separated Al species was 0.1 $\mu\text{g cm}^{-3}$.

3.3. Influence of pH on the distribution of Al species in synthetic samples of Al–citrate

To investigate the speciation of Al–citrate in the pH range 3.5–11.0, synthetic solutions of Al–citrate (2.5 $\mu\text{g Al cm}^{-3}$) were prepared at various pH values and injected onto the column. The results are presented in Fig. 2. It can be seen from this figure that the retention time for negatively charged Al–citrate complexes is 5.5 min and that the separation is quantitative in the pH range of 6.5–7.4. At pH values lower than 6.0 the percentage of negatively charged species is decreased presumably due to neutral Al–citrate complexes appearing in the solution. At a pH of 3.5 a broad peak is observed for the positively charged Al–citrate complex at an elution time of 1.0–3.0 min, and a small peak occurs indicating a negatively charged Al–citrate complex at 5.5 min. Al species which were not eluted at pH values lower than 6.0 (neutral Al–citrate, Al^{3+}) were strongly adsorbed on the column resin and did not influence the following separations. These species were removed from the column resin at the solvent front (1.0–1.5 min) by washing the column with NaOH (2 mol dm^{-3}), which is recommended by the producer as the cleaning agent.

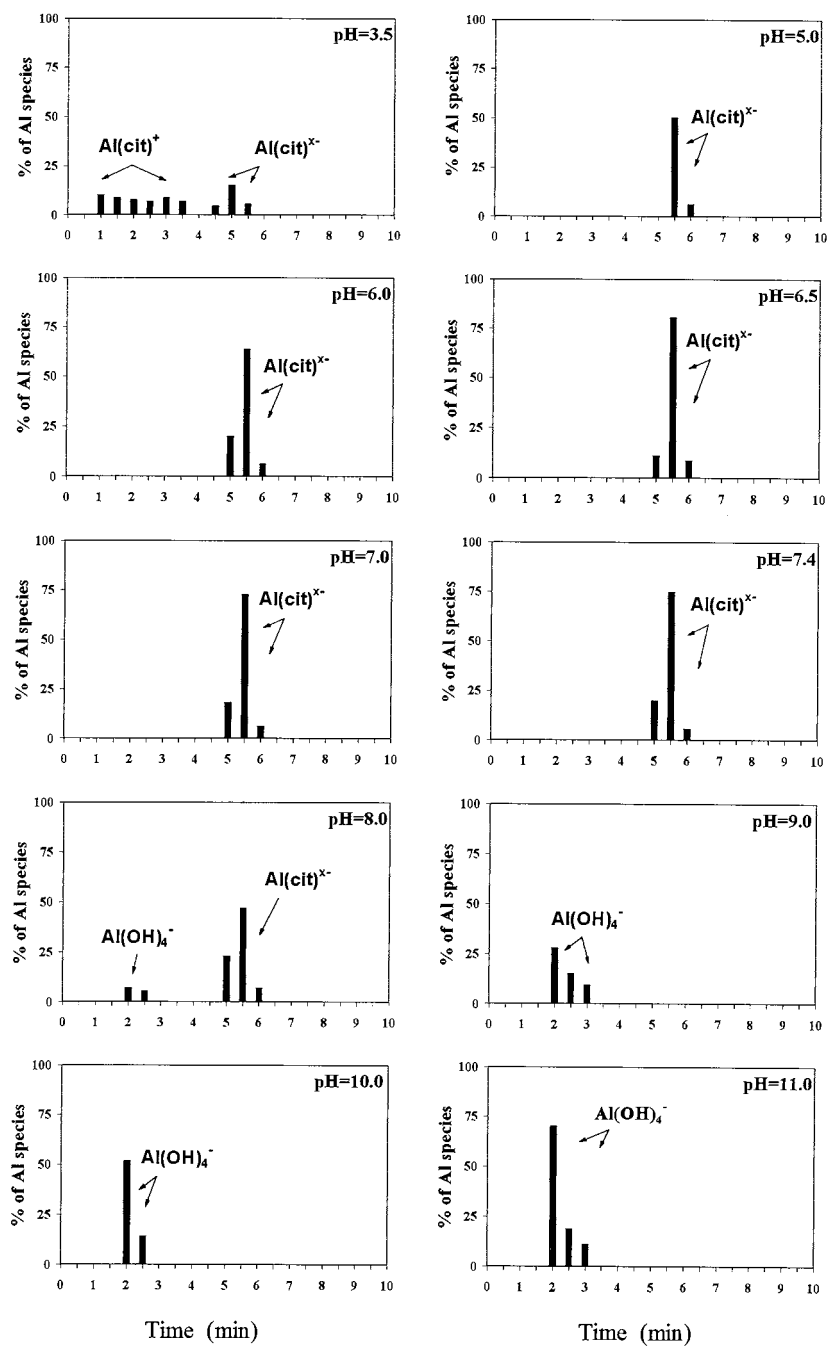

Fig. 2. Influence of pH on the distribution of Al species ($2.5 \mu\text{g Al cm}^{-3}$, 3 M excess of citric acid) employing anion-exchange FPLC with ICP-AES detection (fraction collection 0.5 cm^3). The percentage of monomeric Al species in synthetic samples of Al-citrate. Mono Q HR 5/5 column, sample volume 0.5 cm^3 , aqueous- NaNO_3 (4 mol dm^{-3}) linear gradient elution, flow rate $1 \text{ cm}^3 \text{ min}^{-1}$, $n = 3$.

With increasing pH values, above 7.4 the percentage of negatively charged Al–citrate decreases since the predominant species becomes $\text{Al}(\text{OH})_4^-$. Although $\text{Al}(\text{OH})_4^-$ species separates from negatively charged Al–citrate at the retention time of 2.0 min, its 100% recovery is only achieved at a pH of 11.0. This indicates that with increasing pH Al–citrate complexes are transformed to $\text{Al}(\text{OH})_4^-$ species. In the pH range of 8.0–10.0 the elution of Al is not quantitative due to the presence of an intermediate the hydroxo–citrate species which are strongly adsorbed on the column resin. An additional experiment was initiated by applying 8 mol dm^{-3} NaNO_3 in gradient elution, but the recoveries for $\text{Al}(\text{OH})_4^-$ were not higher. Species which were adsorbed on the column resin at pH values higher than 7.4 did not influence the following separations. These species were removed only when the column was washed with NaOH (2 mol dm^{-3}). The distribution of Al species (Fig. 2) versus pH in the presence of a 3 M excess of citric acid, in general agreed with the calculated data reported by Martin [26,27] Venturini and Berthon [28], although their calculations, based on thermodynamic equilibrium constants, were performed for different Al concentrations and, Al to citrate molar ratios.

3.4. Behaviour of $\text{Al}(\text{NO}_3)_3$ on a mono Q HR 5/5 FPLC column

Synthetic solutions of $\text{Al}(\text{NO}_3)_3$ ($2.5 \mu\text{g Al cm}^{-3}$) were prepared in buffers adjusted to pH values of 3.5, 7.0, 9.0 and 11.0. In aqueous solutions at a pH 3.5 positively charged Al^{3+} prevails, while at alkaline pH values the prevailing species is $\text{Al}(\text{OH})_4^-$ [26,18]. It could be assumed that positively charged Al^{3+} species would elute on an anion-exchange column with the solvent front, while negatively charged $\text{Al}(\text{OH})_4^-$ species should be separated on the column resin. Our experiments indicated that free Al^{3+} at a pH of 3.5 and other complexes (mixed hydroxo species) at pH of 7.0 were strongly adsorbed on the column resin. These adsorbed species did not influence the following separations and were removed only by washing with NaOH (2 mol

dm^{-3}). At pH 9.0 and 11.0 the fraction of $\text{Al}(\text{OH})_4^-$ increased and identical $\text{Al}(\text{OH})_4^-$ behaviour was observed on the column resin as in Fig. 2, where Al–citrate was prepared from $\text{Al}(\text{NO}_3)_3$ in the presence of a 3 M excess of citric acid. From these observations and from the observations in Fig. 2 it can be inferred that positively charged aqua–Al species and negatively charged $\text{Al}(\text{OH})_4^-$ do not influence the separation of negatively charged Al–citrate complexes.

3.5. Separation of Al–EDTA and Al–oxalate on a Mono Q HR 5/5 FPLC column

In order to investigate the possibility of determining other negatively charged Al complexes, Al–EDTA and Al–oxalate were prepared at pH 7.2 and injected separately onto the column. At this pH Al–EDTA exists as a negatively charged complex [34], while Al–oxalate exists partially as a negatively charged complex. This complex is in equilibrium with an intermediate, hydroxo–oxalate Al species since at higher pH the predominant species is $\text{Al}(\text{OH})_4^-$ [35]. Typical chromatograms of these separations in comparison with Al–citrate are presented in Fig. 3.

Fig. 3. Typical chromatograms of Al–EDTA, Al–citrate and Al–oxalate ($2.5 \mu\text{g Al cm}^{-3}$, 3 M excess of ligand) at pH 7.2, separated on an anion-exchange FPLC Mono Q HR 5/5 column with ICP-AES detection. Sample volume 0.5 cm^3 , aqueous- NaNO_3 (4 mol dm^{-3}) linear gradient elution, flow rate $1 \text{ cm}^3 \text{ min}^{-1}$, fraction collection 0.5 cm^3 , $n = 3$.

It can be seen that Al–EDTA is quantitatively eluted at a retention time of 2.0 min and therefore completely separated from Al–citrate. Although the retention time of Al–oxalate is 6.0 min and is close to Al–citrate (5.5 min), the peaks are still separate. The recovery of Al–oxalate at this pH is only about 30%. At this pH hydroxo–oxalate Al are the prevailing species in the presence of oxalate [35], and knowing that at pH 7.2 hydroxo–Al species are strongly adsorbed on the column resin, these observations agree with theoretical predictions [35].

3.6. Applicability of the developed FPLC—ICP-AES procedure to real samples

The developed procedure for quantitative determination of Al–citrate in the physiological pH range and the ability to understand the behaviour of other Al complexes on the column resin provides a promising basis for speciation of Al in biological samples. On the basis of the developed speciation procedure the project will start on the study of Al species uptake in plants. Plants will be grown in hydroponics nutrient solutions. Before the experiment they will be transferred to solutions of various pH, containing different concentrations of various Al species. The accumulation of Al in plant xylem and leaves will be followed using various time spans and total Al and Al species determined.

The developed speciation procedure also provides a good facility for Al bioavailability investigations in the gastrointestinal tract. The experiments will be carried out on rats, fed with high concentrations of Al–citrate. The fluid from different compartments of the gastrointestinal tract will be analysed for total Al content and particular Al–citrate species will be examined in order to understand the transport mechanisms of Al from gastrointestinal fluid to body fluids and tissues.

Before applying the developed speciation procedure to biological systems, additional steps must be investigated prior to analysis of Al–citrate, pertaining to sample preparation and the design of the experiments.

4. Conclusions

A technique was developed for speciation of Al–citrate and other negatively charged Al complexes—by separation on a Mono Q HR 5/5 strong anion-exchange FPLC column with ICP-AES detection. Linear aqueous- NaNO_3 (4 mol dm^{-3}) gradient elution enabled quantitative and reproducible determinations of Al–citrate in synthetic solutions at a retention time of 5.5 min. In a neutral pH range the recovery of Al–citrate is 100%, since it is eluted as a negatively charged species. Al^{3+} and neutral Al–citrate species do not interfere with determinations of negatively charged Al–citrate, since they are strongly adsorbed on the column resin. $\text{Al}(\text{OH})_4^-$ species are separated from Al–citrate but quantitatively determined only at a pH of 11.0. The distribution of Al species in the presence of the 3 M excess of citric acid is closely matched with theoretical calculations on the basis of thermodynamic equilibrium constants over a pH range from 3.5 to 11.0.

The completeness and the reproducibility of the developed procedure are its main advantages in comparison with other previously reported analytical procedures.

In a neutral pH range Al–EDTA is quantitatively determined as a negatively charged complex and completely separate from Al–citrate, while Al–oxalate elutes close to the retention time of Al–citrate. The recovery of negatively charged Al–oxalate species (30%) at neutral pH agrees with theoretical predictions.

The developed analytical procedure for quantitative determination of Al–citrate in the physiological pH range provides a promising basis for speciation of Al in biological samples. It will be applied to the complex interdisciplinary studies of Al species uptake in plants and in the investigation of Al bioavailability in the gastrointestinal tract—as a reliable analytical tool for the interpretation of experimental data.

Book reviews

Trends in Analytical Chemistry, Reference Edition, volume 14, 1995. Edited by Y. Goshi, J.F.K. Huber and A. Townshend, Elsevier, Amsterdam, 1995. ix + 534 pp. Dfl. 889.00. ISBN 0-444-82388-3.

Most scientists with an interest in analytical chemistry will know this series to be of immense value, both as a teaching aid and as a means of keeping-up-to-date on new developments and applications. The book is in fact a compilation of articles reprinted from regular monthly editions of TrAC, but excludes meeting reports, book reviews and news items. For those who subscribe to the journal this volume is available 'free of charge'. The cost of journal subscription is a good buy being only a little more than the Dfl. 889 for the compilation volume.

This edition has 10 sections (one for each edition) which are sub-divided into 'trends', regional trends, computer corner, internet column and features. There are some fascinating reads in this volume and the editors have done a splendid job in making sure that the articles are readable, relevant and authoritative. The regional trends articles are a recent and welcome development and concentrate (in this volume) on methodology that is useful to third world nations. There are four such articles in this volume which focus on the measurement of environmental pollutants in Malaysia, Bangladesh, Vietnam and the Philippines.

The 'trends' articles concentrate on new developments and applications and include articles on such diverse topics as mobile mass spectrometers, membrane introduction mass spectrometry, optical biosensors, capillary electrophoresis, supercritical fluid extraction, enzyme-based amperometric

biosensors, biosensors for environmental monitoring, laboratory robotics, etc.

In short, this is a superb publication and is a valuable resource for anyone with an interest in analytical chemistry.

Capillary Electrophoresis Procedures Manual edited by E. Jackson and L.W. Jackim, Elsevier, Amsterdam, 1996. 295 pp. Loose-leaf binder. US\$ 187.50. ISBN 0-444-82535-5. Distributed in the Americas by Applied Science Communications, Peace Dale, RI, USA.

This well designed, well researched, easy to read, loose-leaf manual represents a fund of practical information for the CE or would be CE experimenter. There is no doubt that reference to this manual could obviate the necessity for that time-consuming search for appropriate literature method for your particular analytical problem.

The three pages of 'quick tips' given at the beginning offer both an excellent check-list and comment on commonly encountered practical problems. This is followed by 266 pages of one page abstracts. The abstracts (taken from mainly recent literature and manufacturers' archives) cover in a concise, consistent way the procedural and equipment requirements of a very wide range of CE applications involving a large number of different classes of compound. Most importantly, as an essential guide to the expected results, each abstract includes a reprint of the expected electropherogram. In general, the quality of these reprints is good but a few are too faint or too blurred to be easily readable.

This well designed, well researched, easy to read, loose-leaf manual represents a fund of practical information for the CE or would be CE experimenter. There is no doubt that reference to this manual could obviate the necessity for that time-consuming search for appropriate literature method for your particular analytical problem.

The three pages of 'quick tips' given at the beginning offer both an excellent check-list and comment on commonly encountered practical problems. This is followed by 266 pages of one page abstracts. The abstracts (taken from mainly recent literature and manufacturers' archives) cover in a concise, consistent way the procedural and equipment requirements of a very wide range of CE applications involving a large number of different classes of compound. Most importantly, as an essential guide to the expected results, each abstract includes a reprint of the expected electropherogram. In general, the quality of these reprints is good but a few are too faint or too blurred to be easily readable.

The section containing information on equipment and materials is very USA orientated. This section also contains, for reference, a decent selection of recent (1992–95) books—this would have been better in a separate literature section.

The manual has a comprehensive index—about 1000 compounds are included. From it the reader can look up the compound of interest then the relevant abstract(s). The authors are to be commended for the amount of effort which has gone into the production of this unique practically orientated CE manual. It is a value for money text which I would have no hesitation in recommending to any CE user.

Capillary Electrophoretic Separations of Drugs edited by A.S. Cohen, S. Terabe and Z. Deyl, Elsevier, Amsterdam, 1996. ix + 450 pp., NLG 450.00, US\$ 281.25. ISBN 0-444-82519-3.

This book represents a collection of review articles (nine) and original research papers (21) reprinted from *Journal of Chromatography A*, volume 735.

The reviews (208 pages) and the research papers (240 pages) bring together many, if not all, of the leading experts in this field from a large number of countries.

The seven reviews represent well-referenced overviews of the important aspects of the development, theory, methodology and applications of CE techniques to, for example, drug assays, analysis of drugs in body fluids, chiral drug separations and the separation of macromolecules. All are consistent in format and of high standard of presentation. The figures are clear, illustrative and free from error. The many comparative tables are informative and well referenced. The extensive reference lists (complete up to 1995) given at the end of each review ensures that the reader can readily gain access to further appropriate reading material.

A range of good quality research papers is given in the research paper section. Advances in techniques, optimization and comparison with chromatography (seven papers), chiral separations

(eight papers) and the analysis of macromolecular drugs (three papers) amply illustrate the main areas of current activity. The last group of six miscellaneous papers collectively serve to illustrate the potential that CE techniques have to solve difficult analytical problems, e.g. the screening for drugs of abuse in biological fluids.

A handy author index to the articles and papers is included at the end of the book. For those with limited library facilities this hard backed edition represents a quality reference source to CE separations of drugs well worth having.

Practical HPLC Method Development, 2nd edition by L.R. Snyder, J.J. Kirkland and J.L. Glajch, Wiley, Chichester, 1997, xxvi + 765 pp. £70.00. ISBN 0-471-00703-X.

This book aims to provide a comprehensive treatment of all aspects of HPLC method development. To accomplish this, its size and scope has been increased considerably since the first edition. The original chapters covering aspects of separation theory, column characteristics, systematic method development, difficult separations, gradient elution, special samples, and computer-assisted method development have essentially been retained and brought up to date to include the large body of literature on HPLC which has appeared in the last 10 years. New chapters are included on detection, sample preparation, biochemical samples, chiral separations, preparative HPLC, quantification, an validation.

The material is mostly dealt with in commendable detail, or the reader is pointed elsewhere by way of extensive lists of references that appear at the end of each chapter. Notes on how to use the book most effectively are given in a helpful preface. This guide is certainly necessary and the authors acknowledge the challenge presented to the reader looking for information relevant to a particular separation or problem. One feels that some of these difficulties could have been avoided if the framework imposed on the book from the first edition had been rejected for a more logical and concise format. This would minimise repeti-

PII S0039-9140(97)00265-8

Practical HPLC Method Development, 2nd edition by L.R. Snyder, J.J. Kirkland and J.L. Glajch, Wiley, Chichester, 1997, xxvi + 765 pp. £70.00. ISBN 0-471-00703-X.

This book aims to provide a comprehensive treatment of all aspects of HPLC method development. To accomplish this, its size and scope has been increased considerably since the first edition. The original chapters covering aspects of separation theory, column characteristics, systematic method development, difficult separations, gradient elution, special samples, and computer-assisted method development have essentially been retained and brought up to date to include the large body of literature on HPLC which has appeared in the last 10 years. New chapters are included on detection, sample preparation, biochemical samples, chiral separations, preparative HPLC, quantification, an validation.

The material is mostly dealt with in commendable detail, or the reader is pointed elsewhere by way of extensive lists of references that appear at the end of each chapter. Notes on how to use the book most effectively are given in a helpful preface. This guide is certainly necessary and the authors acknowledge the challenge presented to the reader looking for information relevant to a particular separation or problem. One feels that some of these difficulties could have been avoided if the framework imposed on the book from the first edition had been rejected for a more logical and concise format. This would minimise repeti-

tion and reduce the need to cross-reference other parts of the book.

The 'enlightened trial-and-error' approach to method optimisation described in the first edition is restated in updated form. It can be recommended as being applicable to a range of sample types without the need for detailed theoretical knowledge of the starting material. The guidelines are illustrated throughout with examples from the literature, although much use is also made of computer-generated simulations. The authors provide a wealth of useful technical information that is often presented in tables alongside the text. It would have been better to collect much of this together in the appendices for easier reference.

As is to be expected from such distinguished HPLC experts, this work is authoritative, contains few errors and is generally well written. Having said that, the authors make a common mistake among analysts by their repeated use of 'quantitation' instead of 'quantification'. This becomes irritating in Chapter 14, a particularly bad example being the expression 'minimum quantifiable amount' (p. 645) which should of course be 'minimum quantifiable amount'. Elsewhere in this

chapter (p. 675) it states that one litre or more of an aqueous sample can be injected into an analytical reversed-phase column to obtain vastly increased sensitivity for trace analysis. Such a procedure can hardly be recommended as being practicable. Chapter 10, on computer-assisted method development, promotes the authors' method-development software, DryLab (LC Resources), and no attempt has been made to research currently available alternatives, for example HPLC Optimization (Alltech) and the Hipac range of software (Phase Separations). The information given on Enhancer, a package previously supplied by ATI Unicam, Cambridge, UK, but withdrawn at least 5 years ago, is long since out of data.

This is undoubtedly valuable work in an already well published field, but one cannot help feeling that an opportunity has been missed to produce a definitive reference source for chromatographers.

Metallothioneins: historical review and state of knowledge

M. Nordberg *

Institute of Environmental Medicine, Karolinska Institutet, S-171 77 Stockholm, Sweden

Received 21 November 1996; received in revised form 3 March 1997; accepted 4 March 1997

Abstract

The history of metallothionein (MT) research is reviewed. Various methods for isolation, characterisation and quantification are evaluated. The role of MT in metal metabolism and toxicity is explained. Gender differences and polymorphisms are brought to the attention of the reader and the possible relationship with disease is discussed. The review is an evaluation based on data from literature and from own original experimental data. Future aspects on research within the MT field is stressed. © 1998 Elsevier Science B.V. Keywords: Metallothionein; Protein; Quantification; Metals; Metabolism; Polymorphism; Gender; Disease

1. Introduction

Scientific research history of metallothionein begins in the 1950s almost 40 years ago. This review of metallothionein (MT) research displays the progress in knowledge as well as a review of biochemical and experimental methods used in such research during the last four decades. Development of MT research include contributions from scientists in the fields of biochemistry, environmental hygiene/medicine, medicine, toxicology, pathology and nutrition and is best illustrated by the number of articles that have been published. A search on medline with 'metallothionein' as the entry revealed that for the interval 1966–1975 there were 34 articles, for 1976–1979: 156 articles, 1980–1985: 691 articles, 1986–1991: 1499 articles and for 1992–April

1996, 1100 articles had been published (Fig. 1).

This means that to date approximately 4000 articles have contributed to the available information about MT. There has been a considerable development of methods in protein research, including isolation and analytical methods for iden-

tification during this time. Interest in MT was in the beginning focused mainly on two topics. The main interests were the strict protein chemistry and the toxicological, i.e. the metabolic pathways for metal toxicology particularly with regard to cadmium kinetics. Later on other interests and aspects on MT have expanded the field. In recent years important contributions have been brought in from molecular biology. Consensus and conclusions reached at several scientific meetings on metallothionein based on published data have been published as depicted in Table 1.

2. History of metallothionein

In 1957 data on a cadmium binding protein in equine tissue was published [12]. However this study was initiated by a report in the form of an abstract [13] dealing with cadmium in human organs. Small amounts of cadmium had been shown to be present in tissues and body fluids in several animal species. Hypotheses were postulated to explain this unexpected finding. Either cadmium could be present as bound to a macromolecule and therefore have a natural function in

biological system or cadmium could also be just a contaminant. In 1960 the first report on metallothionein was published [1,2]. This was the first time that the cadmium containing protein, isolated from equine renal tissue, was named 'metalothionein' based on an extremely high content of sulphur of 4.1% g^{-1} dry weight and 2.9% of Cd and 0.6% Zn. Isolation was performed from five frozen horse kidneys with for that time conventional methods. Later studies reported data on physical properties, molecular weight was estimated to be 10000 ± 260 . Specific absorption at 250 nm was explained by cadmium mercaptide bonds. Metallothionein was assumed to lack aromatic amino acids as indicated by absence of absorption at 280 nm. This was later verified by aminoacid analyses [5,14]. The high concentration of sulphur of 8.5% is explained by aminoacid analyses that revealed high content of cysteine. At this time reactive protein mercapto groups were determined by titration with silver ions, CMB and *N*-ethylmaleimide. Aminoacids were determined by two dimensional paper chromatography and ion exchange chromatography. Cysteine residues were determined as cysteic acid after oxidation of metallothionein with performic acid and as derivatives of *N*-ethylmaleimide. Sedimentation constant was determined via Schlierendiagram by use of sedimentation by ultracentrifugation to 1.75 ($S_{0,20w}$). Diffusion constant, partial specific volume and friction ratio was reported. The estimated molecular weight of the protein was still varying from 9790–10500. This was partly explained by various artefacts during preparation. Metal analyses for cadmium and zinc reported 5.2 g atoms mol^{-1} and 5.9% of MT weight for cadmium and for zinc 3.3 g atoms mol^{-1} and 2.2% by weight. Some exchange between zinc and cadmium was obviously taking place. It was suggested that bonding with three SH-groups together with one atom of either cadmium or zinc was formed.

As part of the research on health effects caused by cadmium in the Swedish group a study on rabbits [3] showed that cadmium–metalothionein could be induced by repeated injections of small doses of cadmium. A single high dose of cadmium [4] was found to be more toxic to the organism giving rise to lethality and liver damage, while the

same dose administered as several small doses during a prolonged exposure time gave no similar effects. As a matter of fact, animals with induced metallothionein synthesis by pretreatment with smaller doses of cadmium, developed resistance to the acute toxicity to the liver [4] and the testes [15]. Isolation of cadmium binding protein from the livers of cadmium exposed rabbits showed an increase of MT in relation to administered dose or amount of cadmium [5]. It was demonstrated that in animals protected by pretreatment, cadmium in the target tissues liver and testis, respectively was bound to a low molecular weight protein similar to MT.

New techniques for isolation of the protein was used. After homogenization of the tissues rivanol was used to precipitate high molecular weight proteins and cell fragments. Several steps of precipitation, dialyses and various gel chromatography steps were used. Sephadex gel had recently been introduced into protein chemistry. The first assumptions by Piscator in 1964 [3] were later confirmed in these animal experiments which demonstrated that exposure to cadmium increased concentration of MT in livers. These findings gave further support to the initial ideas of metallothionein induction as a mechanism of making tissue cadmium less toxic. For this group working with toxicity and kinetics of cadmium, it was known that cadmium gave raise to adverse health effects increasing upon exposure particular renal damage. MT research now continued or developed into two tracks—one in protein chemistry and the other one concerning its importance for kinetics and toxicity of cadmium. All studies demanded however pure and well characterized MT and this was prepared with modern techniques. Tissue was homogenized in buffer system mostly Tris–HCl buffer in sodium chloride with a pH of 8.1. This step is followed by ultracentrifugation at 105 000 g and the supernatant is taken for gelchromatography-Sephadex gel G-75. If the absorption ratio of 250 and 280 was low, improvement could be achieved in one step by G-50 for the preparative purpose that showed a protein with high absorption of 280 but no metal content was eluted from e.g mouse livers at the same fractions as MT [16]. For further separation into isoforms, frac-

tions containing MT are either taken for isoelectric focusing or ion exchange chromatography after concentration and desalting by ultrafiltration on UM-2 filters with cut off level for molecular weight of 1000 [5]. Further separation by isoelectric focusing revealed at least three isoforms in rabbit liver with pI 3.9, 4.5 and 6.0. Two of these were identified by aminoacid analyses [5]. In order to be successful with the preparation of MT from tissue it was obvious quite early on that avoidance of oxidation of the protein by a rapid preparation and in cool conditions was crucial. Mercaptoethanol could however restore oxidized MT [17,18] as shown by gelchromatography on Sephadex G-75 where MT showed up in the ordinary place after treatment of mercaptoethanol. An important contribution to tertiary structure was made when [19] two metal clusters, i.e. α and β domains with four and three metals respectively, as part of the structure was described. The α domain constitutes the C-terminal and the β domain the N-terminal of the protein.

The other track expanded into several metals and importance of MT for many metals and in particular for copper [20] and mercury [21–23]. Several pioneer works [15] showed that MT could protect against testicular damage caused by cadmium. Knowledge on MT and its involvement in transport of cadmium and that cadmium partly is present in blood [24] as MT lead to a metabolic model for cadmium toxicity. Further work focused on speciation of cadmium and it was found that cadmium as MT is taken up in the renal tubules and causes renal damage at as low concentrations as 10 ug g^{-1} of cadmium [25].

In the 1970s and early 1980s, there was only a limited number of research groups performing research related to MT. An increasing number of publications in which different nomenclature for MT was used made it clear that an evaluation of the knowledge available at that time would be of importance. A workshop with approximately 25 invited participants who had submitted background manuscripts was arranged and a tentative report [26] was prepared and distributed in advance to each participant. A consensus report was agreed during the meeting held in 1978 [7].

During this first international meeting on MT, held in Zurich consensus was reached about, e.g. nomenclature and methods for preparing the protein. This first meeting has been followed by one more meeting in Zurich 1985 which was more open but still with a workshop consensus. In-between, a meeting was arranged in Aberdeen in 1981. Other meetings have introduced a more limited focus on various areas of interests, e.g. cadmium binding proteins in non-mammalian species was brought to attention in an international meeting [27] and pharmaceutical interests as was the case at the third international meeting held in Japan in 1992 [11].

3. Protein chemistry

Important features of MT are depicted in Table 2 which is compiled from data according to Nordberg and Kojima [26] from the first international meeting on MT and with some important additional findings [28–30].

The structure of MT has two domains consisting of one cluster with three and one with four metal atoms and was first described by Winge and Miklossy [19]. The MT gene is located on chromosomes varying with species. For humans and other primates it is on chromosome 16 [31]. The protein consists of a number of isoforms coded by various alleles. The ratio of mRNA for MT-I and MT-II genes remains constant during induction

Table 2
Characteristics of metallothionein

1.	Molecular weight 6000–7000, 61 amino acids
2.	20 Cysteine (30%), N-acetylmethionine, C-alanine, no aromatics, no histidine
3.	Unique amino acid sequence [6]
4.	Tertiary structure/metal clusters [19]
5.	Metal content; Cd, Zn, Cu, Hg; 5–10% w/w
6.	Absorption 250 nm (Cd), 225 nm (Zn), 275 nm (Cu), 300 nm (Hg)
7.	Induced synthesis by Cd, Zn
8.	No disulfide bonds
9.	Heat stability
10.	Cytoplasmic localization
11.	Isoforms
12.	Localization on chromosome [31]

by metals, e.g. Cd, Cu, and Zn. It was found that there is 1.4 times more MT-I RNA than MT-II RNA indicating that transcription rate is slightly higher for MT-I gene compared to MT-II gene [31]. MT-IA and MT-IIA genes seems to be differentially regulated by metals. Lack of MT gene expression makes the organism sensitive to toxic effects. The MT gene becomes transcriptionally inactive as a consequence of DNA-methylation. Cells with extra copies of MT-genes can be selected by exposure to toxic concentration of cadmium. In metal exposed mammals zinc is the dominating metal ion in MT. One zinc seems always to be present in MT. Various biological factors influence metal ion composition such as tissue of origin, age and stage of development. This means that renal MT is higher in Cd and Cu in exposed animals than liver MT from same organism. For purification of MT various gels have been used during the years. However, Sephadex G-75 and G-50 has been proven, in an evaluation of several gels, to at present still be the most efficient technique. However, sometimes it is necessary to add mercaptoethanol to the samples in order to reduce MT back to non polymerized MT as has been discussed previously [18].

Transgenic mice [32] have been introduced in order to gain new insights on MT and metal toxicity. Experimental laboratory animals, mainly mice, have shown that species differences with regard to sensitivity and resistance to metal toxicity exists [33]. By introduction of transgenic animals the mechanism behind this would be elucidated.

4. Methods for the quantification of MT

Several methods for measuring and quantifying MT are available [33,34] as displayed in Table 3. A review of various methods has also been edited [35]. In addition to the information in Table 3 it should be mentioned that metal binding assays based on binding of metals such as cadmium [36,37], mercury [22] and silver-pulse polarography [38], immunoassay such as radio immunoassay and ELISA based on use of antibody [39] are used. Each of these methods have advan-

Table 3

ELISA	Garvey, 1984 [39]

tages and disadvantages. Methods that are dependant on the use of atomic absorption spectrophotometry and especially those dependant on Ag-binding should avoid sodium chloride in samples as this may cause interference with the analyses. The radio immunoassay needs specific antibodies that do not cross react. The immunoassay-ELISA is still under development.

4.1. Immunohistochemical

Most cadmium in the urine of humans occurs bound to MT. Urinary cadmium and MT concentrations correlate well as shown in elderly women exposed to cadmium in the general environment [41,42] and in occupationally exposed male cadmium workers [43,44], who reported values of 2–155 ng MT/g urine and for plasma 2–11 ng g⁻¹ in cadmium exposed workers. The detection limit for MT by RIA in humans is reported in plasma or serum to be 1–16 ug l⁻¹ and in urine to be 5–3000 ug g⁻¹ creatinine [41,42]. In cadmium exposed persons MT in urine is a good indicator of urine concentration of cadmium and can also be assumed to be an index of the burden of cadmium.

Immunohistochemical staining of MT in placental tissue indicated that metallothionein reflects the concentration of copper in this tissue.

The method could be used for pre-and postnatal diagnosis of Menke's disease [45].

A gender difference is observed. Women have higher MT concentration in urine compared to men even at similar cadmium levels [46] as shown with RIA [46,47]. As shown in Table 4 [39], the range of normal concentrations of MT is defined.

Levels of MT reported in various tissues are given in Table 5.

Determination of MT concentration in urine and blood have been found to be related to problems which have not been observed in tissue analyses. This is likely due to techniques for sampling and storage of samples which is most crucial for the results of analyses. Usually urine samples are treated with bactericides in order to prevent bacterial contamination with a reduced pH as result. Since metallothionein loses the metals and free thionein is obtained a change in configuration and instability of the protein follows. This is likely to influence the whole analyses and with fault of the result as has been observed in samples from humans (personal communication) that cadmium concentration in urine and MT concentration sometimes do not follow each other. In experimental studies [50] excretion of MT, cadmium, calcium, and various enzyme markers in urine were followed in male rats exposed to cadmium. MT was determined by ELISA method. Interference with luminal and basolateral membranes and handling of calcium was demonstrated [51,52]. This is in accordance with suggested model that Cd is released from CdMT after it is catabolized in lysosomes and appears in the cytoplasm of renal tubule cells where it may change the electrochemical gradient across the luminal membrane with decreased calcium absorption.

Table 4
Range of normal concentrations of MT

Method	Media	Concentration (ng ml ⁻¹)	Status
RIA	Sera	0.01–1	Normal
RIA	Sera	>2	Abnormal
RIA	Urine	1–10	Normal
RIA	Urine	>10	Abnormal

Table 5
Normal concentration of metallothionein related to method in various tissues and media

18 ug g ⁻¹	Liver	Rat	ELISA	Chan et al., 1993 [48]
30 ug g ⁻¹	Kidney	Rat	ELISA	Chan et al., 1993 [48]
35 ug g ⁻¹	Kidney cortex	Rat	ELISA	Liu et al., 1994 [49]

Detection limit ELISA 100 pg MT [48].

Thus, it is necessary to evaluate and standardize the method for urine and blood. As the body fluids are used for biological monitoring of many metals it would be most valuable to manage to measure as well metallothionein and relate concentration of metals to concentration of MT.

During the COMTOX conference in Vancouver in 1995 which was arranged by IUPAC, methods for estimation and quantification of MT were discussed. It is interesting too see that problems in MT research similar to those identified in the early phase of such research still cause confusion among scientists.

One problem with the estimation of MT in tissues and body fluids is how to manage to express true concentration and relate it to biological events. For long time this has been in the form of ug MT/g wet weight tissue. Due to the fact that the concentration of MT varies with many factors this has to be further expressed in relation to something that is stable, normal or a controlled change in the cell, e.g. MT mRNA or something else. Concentration of MT apart from being age dependent is also dependant on exposure to numerous agents [10]. Several methods for and pitfalls concerning the various methods for MT determination have been summarized recently by contributions from many scientists in MT research [35]. It is urgent to develop a method for MT quantification with high precision, accuracy and specificity. To test specificity a known amount of MT may be added to the samples. To spike the samples, several questions are raised: How should various forms of MT be quantitated? The various forms of MT might reflect various biological functions that are related to both age and to exposure as suggested previously [18]. Isoelectric focusing is a rapid, quick and good method for preparation of the various isoforms of MT. Commercially available MT has to be

checked with regard to purity even if a well recognized method has been used for preparation. It has been noticed that metal concentration in some shippings has been extremely low, indicating a lower purity of the protein.

Commercial antibodies were reported to be available for MT I, II and III. Monoclonal antibodies were believed not to be specific enough to be taken for ELISA. For in vivo measuring of MT concentration in biological samples radioimmunoassay methods with ¹⁰⁹Cd binding seems not to be useful. Dosage of ¹⁰⁹Cd is important as it has to reflect concentration of MT but cadmium might already be present.

Recently methods from molecular biology have developed the possibility to quantitate MT in eucaryotes and procaryotes that are taken for PCR. MT-gene transcription and RT-PCR to measure MT mRNA is possible. It is mentioned that to use a DNA probe for RNA-synthesis and expressed DNA is possible. MT-2 expression in lymphocytes can be performed by PCR techniques.

A question to be answered is how determination and estimation of MT in body fluids and tissues should be performed and how to relate the concentration of MT to effects? A RT-PCR method for MT-mRNA primers and oligoprobes were mentioned to be commercial available.

5. Role in metal metabolism and toxicology

MT plays an important role in the metabolism and kinetics of metals as shown in Table 6.

This has been shown for cadmium [53,54] and later for copper as summarized [55]. Cadmium is known to cause toxicity to the kidney after long-term exposure to inorganic cadmium compounds, i.e. the chemical species Cd²⁺. In animal experi-

ments it has been shown that Cd administered as MT may cause similar renal damage at tissue concentrations of Cd at 10 ug g^{-1} wet weight [25] compared to 200 ug g^{-1} wet weight when administered as Cd-ions.

In addition to the early findings of modifications of cadmium toxicity by metallothionein induction [3,4] mentioned in Section 2, data have been provided concerning the binding of Cd to MT in blood [8,18,25]. The identification of binding forms of Cd in blood-plasma and studies by autoradiography showing that Cd is distributed selectively to the kidney after administration of CdMT, while it is predominantly taken up by the liver after injection of Cd^{2+} or as Cd-albumin, provided a background for a mechanistic model for kinetics of cadmium [25,53,54]. Immediately after uptake in blood, cadmium is bound to albumin in blood plasma and distributed and taken up in the liver. It is speculated that an albumin receptor is present on the surface of liver cells. Once in the liver cadmium binds to already present MT by an exchange of zinc in the MT molecule. Cadmium induces synthesis of metallothionein and the newly synthesized MT is sequestering cadmium from other binding sites, thus protecting liver cells from toxicity. Cadmium as MT is released to the blood stream and is transported to the kidney where it is filtered through the glomerulus and is as well taken up by pinocytosis. MT is catabolized in the lysosomes of the tubules and free cadmium ions induce new synthesis of MT in the cell and cadmium is free to react with sensitive sites. Salts, calcium and low molecular weight proteins are excreted in the urine. Cadmium has a biological half-time of 10–15 years which is regarded as very long. It might be

explained by the possibility to induce synthesis of MT. This model has been further developed by contributing data from [56,57]. CdMT induced kidney damage was shown to decrease uptake and binding of calcium in membrane vesicles isolated from animals injected with CdMT [56]. Rats given combined exposure by injection of CdMT (0.25 mg kg^{-1}) Zn (12.5 mg kg^{-1}) and Cu (6.25 mg kg^{-1}) had considerably increased levels of MT in the renal cortex, i.e. up to 746 ug g^{-1} wet weight. These high concentrations of MT were considered to be of major importance explaining the protection against renal damage from Cd in these animals [49]. Repeated injections of CdMT given within a short time interval gave rise to a considerably prolonged and possibly irreversible calciuria in rats [57]. Increased excretion of magnesium has been found in rats with CdMT induced nephrotoxicity [58]. Possible contribution of endogenous intestinal metallothionein to renal accumulation of cadmium was studied in rats fed with cadmium [59]. To distinguish between exogenous and endogenous MT isoforms from the rat and pig, differences in chromatographic behaviour was used [60]. A similar pathway in the biological system was shown for copper [55].

Another important function for MT is cellular defense mechanism against free radicals where methionin might serve as a free radical scavenger as discussed in many publications, e.g. [53,55]. MT may protect DNA by sequestering copper and preventing its participation in redox reactions and may thus prevent the formation of free radicals and prohibit the reaction as further pointed out by [61].

MT regulates toxicity of various metals and trace elements. The kinetics of cadmium copper and zinc are examples of this. With regard to high-tech metals, e.g. gallium (Ga), germanium (Ge), indium (In), antimony (Sb), Tellurium (Te), Yttrium (Y), Niobium (Nb), Thallium (Tl) and Bismuth (Bi) and some more recently introduced high-tech compounds used in superconductors for instance yttrium–barium–copper–oxide (YBCO) and $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10}$ (BSCCO), their content of Bi and Cu may induce MT and exist as BiMT and CuMT. It can not be excluded that among exposed people MT levels might increase and evalu-

ation in relation to MT is warranted in the electronics industry when handling some semiconductor and superconductor materials [62].

Another aspect of toxicity of MT is exposure via food. MT and MT-like proteins have been described in various foodstuff. This question were recently asked in toxicity and intakes of various forms of metals [63] and as well discussed in a previous review [47].

6. Metallothionein and DNA, genetic polymorphism, gender perspectives

In literature data on MT, genetic polymorphism and gender perspectives are limited. Table 7 summarizes aspects on this matter. MT is regarded as an adduct for cadmium and various metals. There are 14 different genes in the human being. All are located in a gene cluster on chromosome 16 of about 82 kb [64]. Six of these have been identified to be functional and two are not. The remaining six have not been characterized [65]. The genes have been identified on the basis of nucleotide sequence and are more than expressed identified metallothioneins. As several genes coding for MT are present on the same chromosome, this might code for a specific purpose—biological function as was suggested during the first international meeting on metallothionein [7]. An age dependent correlation with metallothionein and metal indicates a specific function. In the fetus no cadmium is found but the concentration of metallothionein is high. Dur-

ing gestation and in the newborn a high concentration of intracellular MT rich in copper and zinc is mainly present in the liver [47,66]. Such copper probably serves as an important function in providing Cu for functions during the first period of life when tissue copper concentration declines to the concentration characteristic of adult life time if no metabolic disorders are present. A similar situation occurs for zinc-metallothionein. Immunohistochemical localization of MT shows MT in nucleus of hepatocytes in neonates for several days and later MT is present as a cytoplasmic protein during postnatal development as studied in rats [67]. That DNA synthesis and cell growth is stimulated by very low concentration of cadmium [68] was shown in cultured mammalian cells. Human brain tissue has been found to be rich in MT-III [69]. A growth inhibitory factor (GIF) from this tissue was identified to be a metallothionein. MT-III shows a tissue specificity and a structure that differs by having six glutamic acid insert near the C-terminal and one additional insert in the N-terminal. Expression of MT-III is not regulated by metals. MT-III is down regulated in Alzheimer's disease. So far this is the only metallothionein that has a function in relation to growth. The GIF gene and MT genes are both located on chromosome 16 in humans. MT in growing tissue and its possible relation to tumors is reported [70]. MT concentration measured by the Cd-saturation method displays a clear age dependence. A decline of MT in kidneys after age 60 is in accordance with findings for cadmium kinetics. It has been postulated [71] that the capacity of renal tissues to produce MT is age dependant and protein synthesis may be less efficient at older biological ages. Epidemiological and experimental studies in laboratory animals show that females are more vulnerable to cadmium toxicity than males [46,48]. Women have higher cadmium concentration in blood, e.g. [72], compared to men even if differences in general for cadmium levels in blood is overwhelmed by smoking habits [72]. Women have higher concentration in liver. Iron status is of importance for cadmium and MT concentration. Low iron status increases the absorption of cadmium [33]. Iron deficiency also increase the concentration of MT-I in the

bone marrow of rats exposed to cadmium, revealing an effect on the bone marrow as also suggested by Piscator [3] in rabbits with hemolytic anemia. Concentration of MT in liver is unchanged but renal concentration was reduced in animals with iron deficiency [73]. However as cadmium concentration seems to be higher in aged women compared to men it is contradictory to that observation that men have higher MT levels than women. A gender perspective is present in MT. Involvement in signal transduction has not been found in the literature. MT-III or IV might however be involved in this. MT-IV is expressed in stratified squamous epithelia differentiating cells.

MT apart from transport of metals such as cadmium and copper in the cell also functions as a free radical scavenger.

7. MT and disease

There are diseases that are linked to metabolic disorders of handling metals genetically transferred from generation to generation and metals that cause adverse health effects upon exposure. This presentation discusses conditions that MT to some extent is related to. As depicted in Table 8, examples of such diseases are Menke's and Wilson's disease. Menke's disease, an inherited X-linked recessive disturbed copper metabolism results in accumulated copper concentration in the liver and also in the placenta. Another inherited disorder with regard to copper accumulation is Wilson's disease. Patients suffering from Wilson's disease fail to excrete excess copper in bile from the liver leading to, e.g. neurological disease.

Table 8
Metallothionein and disease

Agent/metal	Organ	Illness
Cadmium	Kidney	Proteinuria, calciuria, Itai-itai-disease
Copper	Liver	Wilson's disease
Copper	Placenta	Menke's disease
GIF	Brain	Alzheimer's disease
Copper	Liver	Indian liver cirrhosis

Treatment with zinc has been suggested [74] to improve conditions by a mechanism whereby zinc induces synthesis of intestinal and hepatic metallothionein that sequester copper for the structure. To study metabolic disorders related to copper animal models have been introduced. Recently LEC-rats have been introduced and a model for involvement of MT and copper in Wilson's disease. It is proposed that non-MT bound copper is transferred to ceruloplasmin and coppertrithiomolybdate binds specifically to albumin. The toxicity is explained by participation of MT and active oxygen species that are produced upon reactions involving copper [75]. Livers of patients with diabetes mellitus have high concentrations of MT. In humans approximately 600 $\mu\text{g MT g}^{-1}$ and 60 $\mu\text{g Zn g}^{-1}$ have been reported in livers. The susceptibility of spontaneously diabetic mice to CdMT nephrotoxicity was studied [76]. In mice with spontaneous diabetes, CdMT injections gave rise to renal damage at considerably lower doses than in normal mice [76].

8. Discussion—future aspects on MT

At the first meeting on MT in Zurich it was discussed to set up a bank or producer of MT in order to have pure and standardized MT. Discussions dealt with whether interlaboratory exchange and a quality control (QC) programme would solve some difficulties that might occur due to reports on various purity of MT. To gain more information on MT it is necessary to harmonise methods for the quantification of MT. Several methods for estimating and measuring MT concentration in tissues and body fluids have been developed. At present several methods which have proved more or less successful are in use. It is necessary to bear in mind factors that influence MT concentration in tissues and fluids. To use metallothionein as a biomarker would be an advantage. As for all biomarkers MT also has to be related to some other factor. As exposure to many agents of which metals are inducers with high potency and cadmium being the strongest known inducer, it is necessary to be aware of factors influencing the concentration of metallothionein.

Little is known about the biological ageing of the synthesis of metallothionein. Studies on cadmium concentration in renal tissue have shown a decrease after the age of 50–60 years in human beings. It is most controversial to estimate the normal concentration of metallothionein. A method to measure the concentration of metallothionein should be protein specific and should manage to measure changes such as increase or decrease of normal or more precisely basic concentration. Cadmium concentration increases with exposure and particularly with age as the newborn has a low concentration of cadmium since this metal does not pass the placenta barrier. Concentration of metallothionein in the cell is influenced by so many parameters and factors that a method to quantitate concentration of metallothionein has to be standardized with respect to many factors. Just to measure the concentration in relation to exposure to some inducing agent many of the previously mentioned methods are quite acceptable. However in order to tell some ‘normal’ values and to compare obtained concentration requires an in relation factor. Cadmium has been shown to be the strongest inducer that means that lowest present concentration increases mRNA. Thus, future aspects of MT should deal with the same topics as usual. This is depicted in Table 9.

MT is a protein that demands further research and attracts scientists from many fields. A number of aspects have been brought to attention. The state of the present knowledge and seen from the historical point of view indicate that results of future research on MT will contribute to explain many biological effects.

Strategies for the qualitative and quantitative analysis of metallothionein isoforms by capillary electrophoresis

John H. Beattie *

Trace Element and Gene Expression Group, Rowett Research Institute, Greenburn Road, Bucksburn, Aberdeen AB21 9SB, Scotland

Received 11 December 1996; accepted 14 March 1997

Abstract

Metallothioneins (MT) are a heterogeneous family of proteins coded from multiple linked genes whose individual expression can be readily determined at the transcriptional level by assay of mRNA using specific DNA probes targeted against the untranslated regions. Analysis of translated protein products is more challenging since sequence variation between MT isoforms can be as little as one in 61 amino acids. Separation of these isoforms therefore requires a high resolution technique which can exploit minor differences in charge or hydrophobicity. The use of capillary electrophoresis (CE) for MT isoform separation is reviewed, including practical information on capillaries and electrolyte conditions which are most suitable for qualitative evaluation of purified MT and also for quantification of isoforms from biological tissues. Methods of sample preparation are discussed, as are methods of characterising the separated components and enhancing sensitivity of their detection. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Metallothionein; Isoform separation; Capillary electrophoresis; MECC; SPE-CE; MALDI-TOFMS

1. Introduction

Following the initial discovery of a Cd-binding protein in equine renal cortex by Margoshes and Vallee [1], subsequent characterisation of the protein [2,3] suggested the presence of a single polypeptide form with an apparent M_r of about 10 000 by velocity sedimentation and diffusion techniques and the protein was named metallothionein (MT) due to its high metal and cysteine content. Further analysis of horse MT indicated a

true apoprotein M_r of 6000 [4,5] and additional studies on rabbit MT by gel filtration, ion exchange chromatography, polyacrylamide gel electrophoresis and isoelectric focusing, demonstrated its inducibility by metals and the presence of two isoforms [4,6] which were expressed in a coordinate way in response to injection with Zn or Cd. The isoforms were named MT-1 and MT-2 according to their order of elution from an anion exchange column and their difference in charge at neutral or alkaline pH, this was related to the presence or absence of an acidic amino acid at residue 10 or 11 from the N-terminus. Since the location of cysteine residues in MT-1 and MT-2 is

* Tel.: +44 1224 716631; fax: +44 1224 716622; e-mail: J.Beattie@rri.sari.ac.uk

highly conserved and their metal binding complement in a 2-domain structure is identical, early opinion favoured a similar role for both isoforms.

However, when separation techniques based on differences in hydrophobicity, such as reversed phase HPLC, were applied to purified samples of MT, it quickly became apparent that the charge types MT-1 and MT-2 from many, particularly mammalian, species often contain two or more proteins [7–9]. These isoforms code from distinct MT genes [10,11] and screening of DNA libraries with subsequent cloning and sequencing of candidate genes suggested that there was considerable heterogeneity in many mammalian MTs. Nevertheless, little effort has been devoted to the separation and identification of the proteins coding from these genes and, as yet, there is no rational basis for assuming that a charge difference between MT-1 and MT-2 forms, due to substitution of a single acidic amino acid, is any more biologically significant than the influence of substituting other residues. Indeed, this point is illustrated by the discovery of MT-3, the expression of which has been identified in brain [12] and maternal deciduum [13], and whose activity in an *in vitro* culture system [14], can be distinguished from that of MT-1 and MT-2 due to the presence of two proline residues substituting for at least one hydroxyamino acid and an alanine [15] and not due to the insertion and substitution of acidic or basic amino acids. Aside from resolving the historical problems of MT nomenclature, it is important that the potential biological significance of each charge-similar isoform is not neglected simply because the analytical techniques available cannot easily separate them.

In order to monitor the expression of individual MT genes with regard to their function, we believe it is necessary to measure isoform protein in addition to mRNA, since there is growing evidence that MT translation can be regulated independently of transcription [16]. The separation of closely related isoforms requires a high resolution technique which can be optimised without restrictive limitations on the use of separation conditions. CE is ideal for this purpose and many types of capillary can withstand a wide

range of electrolyte composition, including extremes of pH, detergents and solvents. In addition, analysis time is rapid (usually < 15 min.), sample consumed is very small (lower nl) and commercial instruments offer automation of analysis. As a consequence of these distinct advantages and the successful application of CE to the analysis of other metalloproteins and peptides [17], we selected this technique for MT isoform analysis. Excellent introductory booklets on CE are supplied by several CE instrument manufacturers and more detailed information is available in the literature [18].

Suggestions concerning the strategies for successful qualitative evaluation and quantitative measurement of MT isoforms are outlined in this review, along with examples of separations and practical information to help select conditions best suited to a particular application. While the conditions described have worked well in our laboratory for the specified MT species, they may not be optimal for other MTs and should be regarded as a starting point for further optimisation.

2. Qualitative evaluation

Purified MT samples should be analysed for isoform heterogeneity and contamination and CE is a good technique for making this evaluation. Many methods of MT induction and purification have been published and the reader is referred to a comprehensive book describing a variety of techniques [19]. Assuming that sufficient purified material is available (at least 20 μl of a 1–5 mg MT ml^{-1} solution), there are several possible approaches to making a qualitative evaluation of MT isoform composition. The aim is to achieve as high a resolution as possible while taking advantage of electrolyte and capillary conditions which best discriminate between small differences in isoform charge and/or hydrophobicity. This may necessarily involve some compromise in sensitivity or separation time. The choice of electrolyte involves selection of a suitable buffer and, perhaps, a modifying agent such as a solvent or detergent.

2.1. Uncoated capillaries

In uncoated capillaries, highest resolution is achieved by using high ionic strength (IS) electrolytes, which improve resolution and inhibit interaction of proteins with the capillary wall. However, the currents generated by high IS electrolytes can cause excessive Joule heating and consequential loss of resolution. The capillary cooling efficiency of the CE instrument can therefore be critical to maintaining good resolution at high IS. Optimisation is therefore required, although if a higher IS buffer is particularly advantageous, an alternative strategy is to increase the capillary length or reduce the diameter, which increases electrical resistance and heat dissipation efficiency, thereby reducing current flow and Joule heating effects. This results in longer separations and/or reduced sensitivity. On some commercial instrumentation, the maximum capillary cooling capacity is around 0.05 W cm^{-1} which equates to a current of about $100 \mu\text{A}$ at 30 kV in a 57 cm capillary. Heating the capillary externally increases electro-osmotic flow (EOF), shortening MT isoform migration times [20] and modifying their separation [21].

The potential choice of buffers and modifiers is diverse and some form of separation of MT charge-distinct isoforms can be obtained using a wide variety of electrolyte conditions and chemistry. Nevertheless, selection of suitable electrolytes should be influenced by three main factors, namely their UV absorbance, conductivity and buffering pH range. In addition, a few particular conditions offer distinct advantages for MT isoform separation. Sodium phosphate is an appropriate choice because it has very low absorbance at UV wavelengths and several buffering pH ranges, since phosphoric acid can dissociate three protons with pK_a values of 2.12, 7.21 and 12.67. Compared with sodium borate, the resolution obtained with sodium phosphate is superior but the currents generated are much greater, and narrower bore (25 and $50 \mu\text{m}$) or longer (50 – 100 cm) capillaries are recommended at concentrations exceeding 50 mM . Borate buffers, on the other hand, have low conductivity, and resolution can be improved by using higher buffer concen-

trations. Good separations of MT charge forms can be achieved using organic zwitterions such as Tris [22,23] and mixed buffer systems such as Tris–borate have been used to resolve several components in horse and rabbit MT samples [21]. The advantage in using zwitterionic buffers is their low conductivity at or around the pI and therefore low Joule heating. However, if UV detection is used, particularly below 220 – 230 nm , absorbance by some organic buffers is limiting at high concentrations.

Arguably the best separations and resolution that have so far been achieved in uncoated capillaries have been obtained at low pH using high IS phosphate buffers [24,25]. A comparison of rabbit MT separations in organic and inorganic low pH buffers is shown in Fig. 1 and it is clear that the inorganic phosphate buffer gave a better separation than the organic formate buffer. At low pH, Cd and Zn dissociate from MTs and the separations are therefore of apoproteins [25]. Dissociation of these metals results in a diminution of UV absorbance and hence the concentration of MT sample must be sufficiently high for adequate detection. Separations of Cd, ZnMTs within the pH range 3–5 does not appear to be reproducible, probably due to partial metal dissociation (unpublished observations). The rabbit liver MT-1 and MT-2 charge forms which are available commercially (Sigma-Aldrich, Poole, U.K.) and which were used to obtain the electropherograms in Fig. 1, contain appreciable contamination by the other charge form. Hence, one of the major peaks in the MT-1 separations (Fig. 1C and D) corresponds to the major component in the MT-2 electropherograms (Fig. 1E and F). This confirms previous findings from different laboratories [23,26,27]. Being more highly charged, MT-3 migrates rapidly and separates completely from MT-1 and MT-2 by CE at low and neutral pH [28].

An alternative technique for qualitative evaluation of purified MT samples involves addition of an ionic surfactant to the electrolyte. The technique is known as micellar electrokinetic capillary chromatography (MECC) [29] and has been successfully applied to the separation of MT isoforms in several species [30,31]. Of the surfactants screened in our laboratory, sodium dodecyl sul-

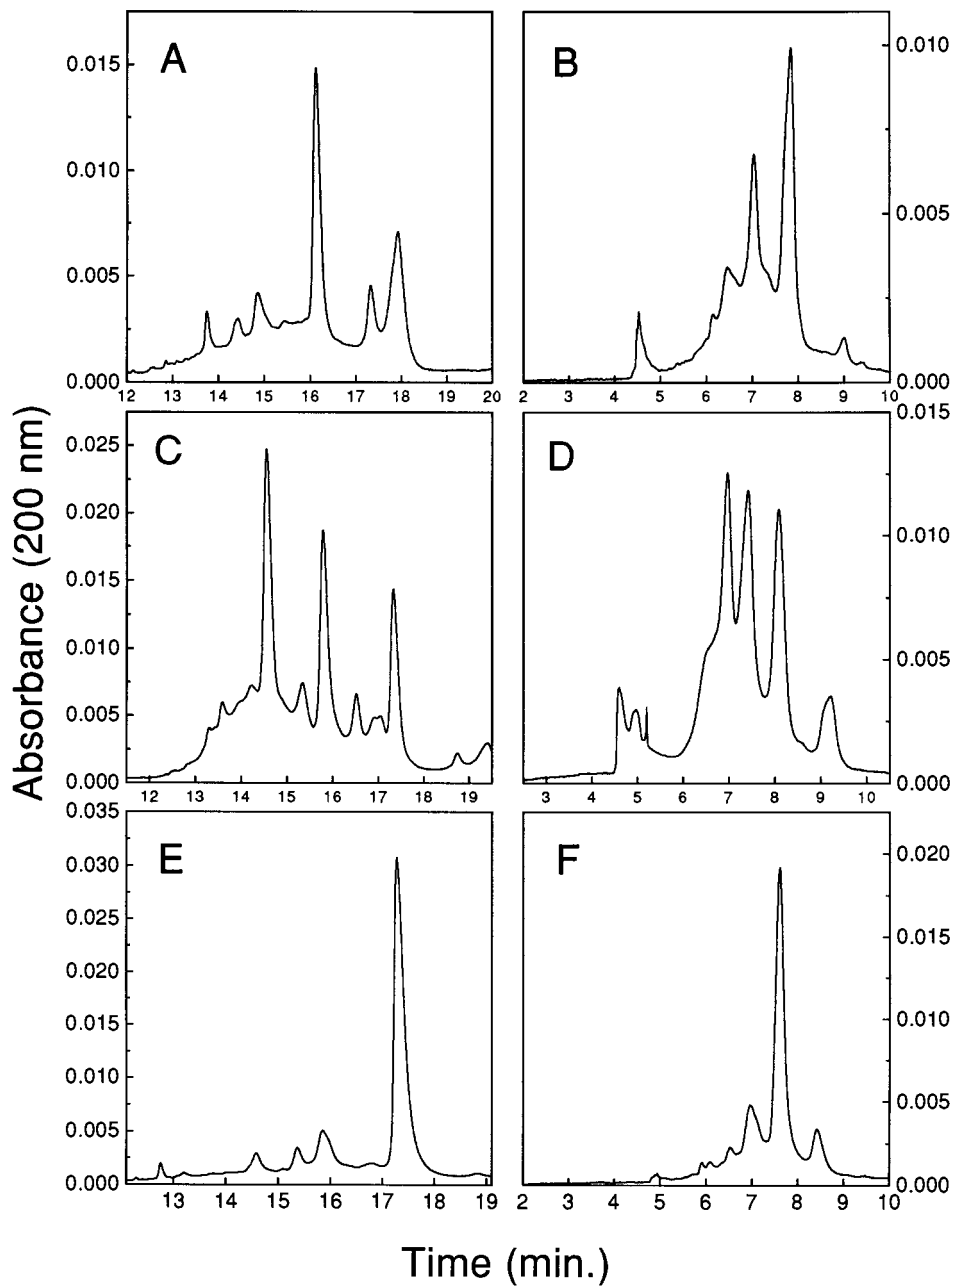

Fig. 1. Comparison of rabbit liver MT (A and B), MT-1 (C and D) and MT-2 (E and F) separations by capillary electrophoresis on a Beckman P/ACE 5000 instrument using an uncoated 57 cm \times 50 μ m fused silica capillary, with a 300 mM sodium phosphate buffer, pH 2.0 (A, C and E), or a 300 mM sodium formate buffer, pH 2.5 (B, D and F). The separation voltages (normal polarity, cathode at outlet) using the phosphate and formate buffers were 20 kV and 30 kV, respectively. MT samples (5 mg ml^{-1} in deionised water) were loaded by pressure injection for 10 s at 0.5 psi and the capillary temperature during all separations was maintained at 25°C.

phate (SDS) has yielded the best separations. The principle of analyte separation in MECC involves their partitioning between the hydrophilic environment of the aqueous electrolyte and the hydrophobic interior of the negatively charged SDS micelles. Hence, separation is made on the basis of differences in hydrophobicity as well as charge. In fact, the M_r cut-off for inclusion into SDS micelles is about 5000 Da and so the principle involved in MT separation may be more influenced by the association of SDS molecules with the protein. The resolution that can be achieved by MECC is generally lower than with other CE techniques but separation efficiency and reproducibility of peak migration time and area are advantageous. For MT isoforms that will not readily separate by changing the pH of phosphate buffers under standard CE conditions (e.g. sheep MT isoforms), MECC can be a robust and useful alternative. As can be seen in Fig. 2, adjusting the MECC separation conditions for sheep and rabbit MTs can yield partial or complete isoform separation. By further manipulation of the buffer and SDS concentrations, complete separation of sheep MT-1 isoforms is readily achieved [31]. When first attempting MECC separations of different MT proteins, use of a 50 cm \times 75 μ m uncoated capillary with a 300 mM borate buffer pH 8.4 containing 85 mM SDS is recommended. In our hands, MECC at 10 kV gives better separations than higher voltages and isoform migration may be considerably modified by varying the pH from 8.4 to 10.4 or the SDS concentration from 60–120 mM.

2.2. Coated capillaries

The internal surface of fused silica capillaries can be modified or coated with a variety of sub-

stances or ligands, thus affecting its surface charge, hydrophobicity or chemistry. At the present time, the most widely available commercial coated capillaries include those with an amine group (+ve charged, reversed EOF), a neutral coating (no charge, no EOF) and various hydrophilic or hydrophobic coatings. The latter capillaries are intended to be used with addition of surfactant or solvent to the electrolyte and the partial blocking of silanol groups reduces wall interaction of some proteins. However, used in the way intended by the manufacturers, these capillaries do not improve separations of purified MT because wall-interactions of this protein do not appear to be a very significant problem.

Neutral capillaries are very suited to protein separations and are very useful for qualitative evaluation of MT isoforms. By changing the polarity appropriately, separation of multiple MT isoforms can be obtained at low and neutral pH [24,25] and a wide range of different electrolyte buffers are compatible with this type of capillary. Both phosphate [24,25] and mixed zwitterionic buffers [27,32] have been used to obtain good separations of MTs from a range of different species.

Because of the positively charged wall, amine capillaries are more suited to the separation of positively charged proteins i.e. at a pH below the protein pI but some types of amine capillary are not suitable for use below pH 3.5. Thus, from a theoretical perspective, MT isoforms, with a pI of 4–4.5 and a charge ranging from over -1 (MT-1 forms) to -13 (MT-3) at neutral pH, should not be ideal candidates for amine capillary separations at neutral or alkaline pH. Nevertheless, good separation and resolution of MTs have been obtained with a pH as high as 8, using a high IS phosphate buffer as electrolyte [33]. Separations

Fig. 2. Comparison of rabbit liver MT (A and B) and sheep liver MT (C and D) separation by capillary zone electrophoresis using a 57 cm \times 50 μ m polyamine coated capillary (A and C) and by micellar electrokinetic capillary chromatography (MECC) using a 57 \times 25 (B) or a 57 \times 75 μ m (D) uncoated fused silica capillary. Separation conditions using the polyamine capillary were as follows: electrolyte of 100 mM sodium phosphate buffer pH 7.0, pressure injection for 5 s at 0.5 psi, separation voltage 30 kV (reversed polarity with anode at outlet). For MECC, the electrolyte was 100 mM sodium borate buffer containing 75 mM SDS, pH 8.4, loading was by pressure injection for 1 s at 0.5 psi and separation was at 10 kV (normal polarity with cathode at outlet). All separations were performed using a Beckman P/ACE 5000 instrument at 25°C and the MT sample concentrations were 1 mg ml⁻¹ in deionised water. Components labeled '1' and '2' correspond to MT-1 and MT-2 charge forms, respectively.

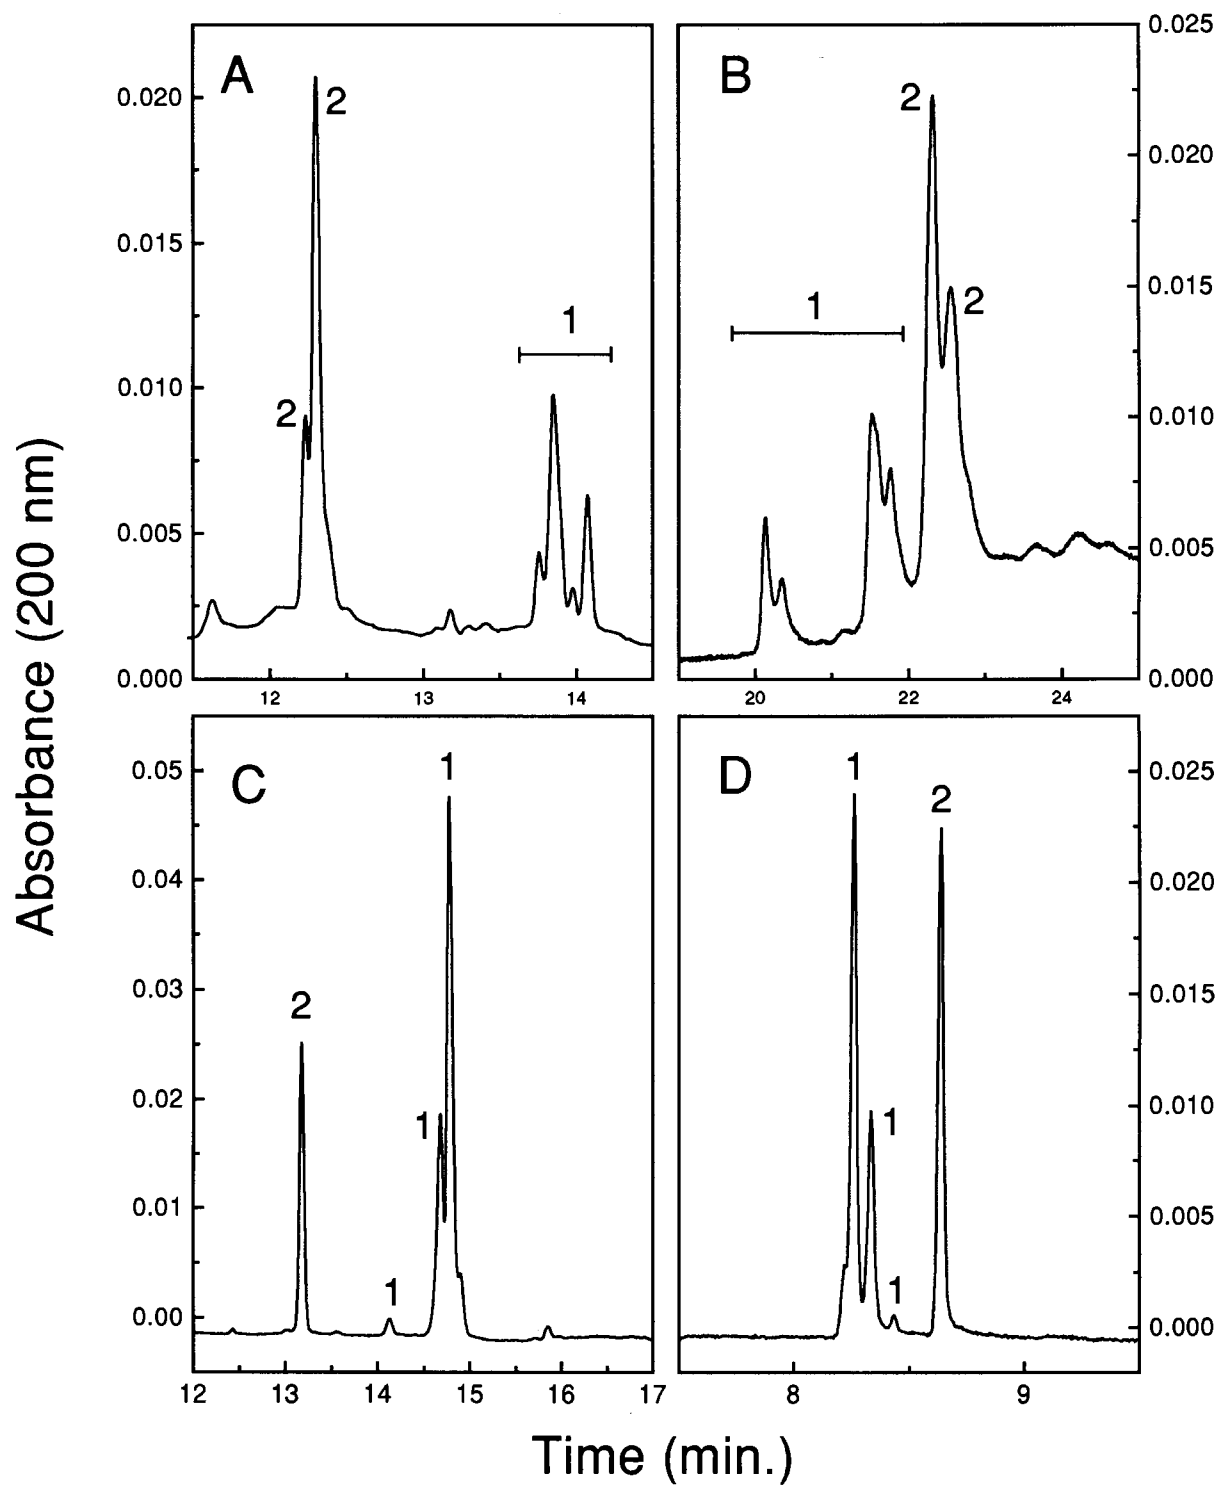

Fig. 2. (Continued)

in an amine capillary can be mirror images of electropherograms obtained by MECC (Fig. 2), which suggests a similar separation principal, possibly involving some unfolding of the MT proteins.

3. Quantitative analysis of MT isoforms

Quantification of MT in biological tissues ideally requires a rapid sample preparation procedure followed by a suitable and compatible analytical technique. In the case of a radioimmunoassay for MT, the analytical technique can be applied directly to diluted tissue cytosols whereas for chromatography or electrophoresis, the MT in samples must initially be completely or semi-purified. Inevitably, more purification steps result in reduced recovery and so there is a need to (a) optimise recovery, (b) optimise precision and (c) find a suitable internal standard and quality control. Recently, the production of an MT standard has been the subject of much debate and, as regards CE, a suitable candidate would be an isoform which shows distinctive migration characteristics and is not expressed in most tissues, such as MT-3.

3.1. Sample preparation

The traditional method of semi-purifying MT from tissue cytosol samples is gel exclusion chromatography [4] using, for example, Sephadex G-75, or more recently, Sephacryl S-100 or Superdex 75 (Pharmacia, Milton Keynes, U.K.). However, for rapid analysis of more than a few samples, this technique is impracticable. CdMT and ZnMT are relatively heat stable and so heat treatment has been used extensively as an initial step in removing contaminating protein. The most commonly quoted protocols describe heat treatment at anything from 60°C for 10 min to 100°C for 1 min and in practice, the temperature–time combination selected should be appropriate for the volume of sample being treated. Unlike many proteins, MTs do not readily denature at low pH and so acidification of tissue extracts has been used for additional deproteinisation of samples

prior to MT analysis [25]. MT is also relatively stable in 50% solutions of water miscible solvents such as ethanol, acetone and acetonitrile whereas many other proteins will precipitate under these conditions. Attempts to analyse 50% solvent extracts directly, reveal a complex variety of contaminating components [30], many of which are low M_r species, since they can be removed by desalting with, for example, Bio-gel P4 or P2 chromatography media (Bio-Rad Laboratories, Hemel Hempstead, U.K.). This procedure results in some sample dilution whereas from an analytical point of view, it is desirable to increase MT concentration. MTs will precipitate, without denaturation, at solvent concentrations of at least 80% and a two-step solvent extraction procedure has been used in the large-scale preparation of MT from animal tissues [34]. Similar 50% and 80–90% two-step solvent techniques have been applied to the rapid deproteinisation of smaller samples and they yield a semi-pure and concentrated extract [35], which is ideal for analysis by CE [31]. Recovery of MT using acetone as the solvent appears to be relatively poor and variable but improved by the addition of 10 mM dithiothreitol to the sample buffer [36]. In our experience, MT recovery using an acetonitrile–ethanol solvent procedure is reproducible and the recovery efficiency can be improved by addition of 0.5 M sodium chloride to the homogenisation buffer of 100 mM Tris–HCL pH 8.0. This sample preparation method has been applied to the analysis by CE of MT-1 and MT-2 levels in developing sheep foetal liver [37].

3.2. Sample analysis

A quantitative method of analysis requires that a predictable relationship is established between concentration of analyte and the signal obtained. In the case of MT analysis by CE, it has been shown, using peak area, that this relationship is linear over a wide concentration range [20,22,33]. However, peak areas of components separated by CE are directly related to their transit rate past the detector, which will decrease with increasing migration time. Peak areas of separated isoforms are therefore not directly comparable until they

are corrected by division with their respective component migration times.

The CE method of choice for quantification of MT isoforms is influenced by the degree of sensitivity and specificity required. In principal, any of the CE techniques described for qualitative evaluation can be applied in a quantitative way but for quantification, sensitivity and reproducibility are critical issues and some methods are therefore more suitable than others. At low pH, metals such as Cd and Zn dissociate from MT and there is a corresponding reduction in UV absorbance, not only at the mercaptide absorbance maxima, but also at lower wavelengths down to 200 nm and below. Therefore, use of low pH is not advisable for quantification. Polyacrylamide-coated neutral capillaries give good separations of isoforms at neutral pH but they have a limited life span and their performance deteriorates at high field strengths. The life span of amine capillaries is also limited and the reproducibility of migration times can be variable when separating complex sample extracts.

When using UV detection with coated or uncoated capillaries, careful thought should be given to the buffer used in the electrolyte. Some organic buffers e.g. HEPES and tricine, will strongly absorb UV light below 230 nm which will limit the use of lower wavelengths for greater detection sensitivity. While this may not be important for qualitative work, it is a distinct disadvantage for quantification. Sodium phosphate and borate do not significantly absorb UV light and are very suitable for quantification work. In addition to low conductivity, SDS also shows low UV absorbance and therefore MECC is a viable alternative to the use of coated capillaries for quantitative analysis. In addition, MECC is a robust technique and sequential separations of tissue sample extracts using borate/SDS electrolytes at alkaline pH show good reproducibility of migration time and peak area. With MT from some species, resolution of all isoforms may be less readily achieved than with neutral capillaries in particular, but on balance, we believe that MECC is best suited for quantitative work.

MECC separations of solvent extracts from the liver of different species are compared in Fig. 3

and the difference in the component migration pattern between species is evident. In the case of sheep and rat samples, MT isoforms were identified by a combination of the techniques described below but the pig isoforms have yet to be confirmed. The migration rate of a major unidentified component partially co-migrating with rat MT-2 was considerably modified by use of a high 2-mercaptoethanol concentration during sample preparation and Fig. 4 shows the resulting separations, using liver from rats injected with different doses of Cd. As might be expected, there was a dose-response effect of Cd injection on both MT-1 and MT-2 levels. The solvent extraction method of sample preparation is particularly effective at removing most non-MT protein but nevertheless, some contaminants remain and can co-migrate with MT isoforms when separated by CE in uncoated capillaries using non-MECC electrolytes at neutral or alkaline pH [38]. Use of SDS in the electrolyte effectively changes the relative mobility of MTs and contaminants so that they no longer co-migrate. In our experience, a two-step solvent extraction procedure followed by MECC separation in 100–300 mM borate/60–120 mM SDS, pH 8.4–10.4 (exact conditions depending on the MT species) is a practical approach to the analysis of MT isoforms in tissues with high basal levels and significant expression of the protein e.g. liver.

4. Identification of putative isoforms

While the separation of multiple putative isoforms in tissue extract and purified MT samples using capillary electrophoresis has proved very successful, identification of the separated components is more problematic due to the limited amount of material that can be collected for subsequent characterisation. It is important to confirm that separated components are MTs and, if possible, identify the isoforms. The first of these tasks is easier to address and the most convenient method of confirmation is to examine the UV spectra of putative isoforms using diode array detection. Characteristically, MTs have no UV absorbance at 280 nm due to the absence of aromatic amino acids. It is also possible to iden-

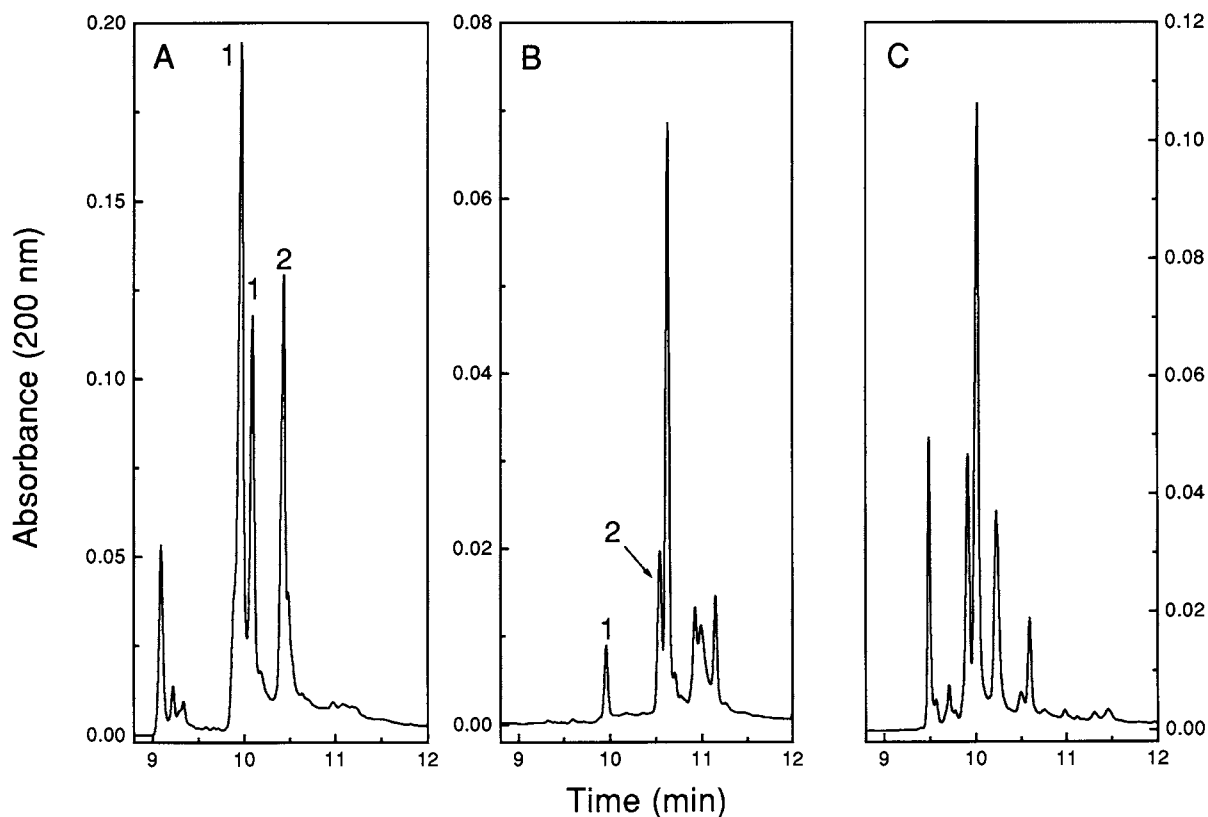

Fig. 3. Separation of liver extracts from Zn-injected sheep (A), Cd-injected rat (B) and Zn injected pig (C). Extracts were prepared using a two-step solvent extraction procedure [31] in which the homogenisation buffer and solvents contained 10 mM 2-mercaptoethanol. Separation was by MECC using a 75 cm \times 57 μ m capillary and conditions specified in the legend of Fig. 2. Components labeled '1' and '2' correspond to MT-1 and MT-2 charge forms, respectively.

tify Zn or CdMT isoforms by an absorbance shoulder at 225 or 250 nm. Examples of the spectral information which can be obtained from diode array detectors is shown in Fig. 5 and comparison of the standard and liver extract spectra strongly support the migration time data which indicate the presence of all the standard isoforms in the extract. Further evidence for this can be obtained by spiking the extract with the purified protein of known isoform identity. Different metalloforms of MT isoforms appear to migrate with identical retention times [30] although addition of metals to the proteins can shift absorbance from MT peaks to a slower-migrating, unidentified component in the case of Hg (unpublished data) and diminish MT isoform absorbance in a concentration dependent manner in the case of Cd [27].

As regards identification of isoforms, or indeed, dimerised or polymerised MT, a more direct approach may be required. Mass spectrometry is one of the few techniques that requires very little sample to obtain spectra and on some CE instrumentation, it is possible to do this off-line by collecting fractions for subsequent analysis. We have used matrix-assisted laser desorption ionisation, time-of-flight mass spectrometry (MALDI-TOF) to verify the purity of MT samples and also the identity of major components from repeated CE separations which are collected, by a brief pressure purge, into a small volume of water (5–10 μ l). A MALDI-TOFMS spectrum of purified sheep MT-1 is shown in Fig. 6 and this information can be obtained rapidly with little experience of mass spectrometry. The major peak

Fig. 4. Separation of liver extracts from rats injected i.p. with saline only (A), 0.1 (B), 0.25 (C) and 0.5 (D) mg Cd kg⁻¹ body weight and killed 24 h after Cd administration. Extracts were prepared using a two-step solvent extraction procedure [31] in which the homogenisation buffer and solvents contained 100 mM 2-mercaptoethanol. Separation was by MECC using a 75 cm × 57 μm capillary and conditions specified in the legend of Fig. 2.

in MT spectra is always composed of apo-protein(s) and low resolution instruments cannot resolve isoforms of similar mass. Nevertheless, partially metallated species can be seen at higher resolution and, in any case, MT spectra have a characteristic 'tailing' on the high mass side of the principal ion, which is caused by the presence of partially metal-saturated isoforms and adduct ions. MTs give much better spectra by high resolution electrospray ionisation mass spectrometry (ESI-MS) [39,40] and we are currently investigating the use of on-line CE-ESI-MS for sequential identification of all separated components. Such equipment is not widely available but new lower resolution bench-top electrospray instruments will make this technique more accessible.

5. Enhancing sensitivity

There are a number of factors that can be optimised before considering the nature of electrolyte and capillary chemistry. UV spectra of MTs show that their maximum absorbance is between 180 and 200 nm (Fig. 5) and the enhancement in sensitivity over absorbance detection at 230 nm is about 4-fold for Zn or Cd proteins and over 10-fold for apoproteins [25]. Light instability increases at lower wavelengths and a monitoring wavelength of 200 nm gives a good signal:noise ratio. While a diode array detector is very useful for characterising components in a separation, the sensitivity achieved by a fixed wavelength UV detector may be superior. Another simple technique for increasing sensitivity is to increase the detector path length, usually by increasing the capillary i.d. Where this is undesirable, the i.d. can be increased only at the point where the UV light passes through the capillary. This is conveniently achieved using extended light path or 'bubble cell' capillaries (Hewlett Packard, Stockport, UK). CE instrument manufacturers offer different sensitivity enhancement features, including methods of focusing the UV light path through the centre of the capillary, or increasing the light path 'window' i.e. the length of capillary through which light passes.

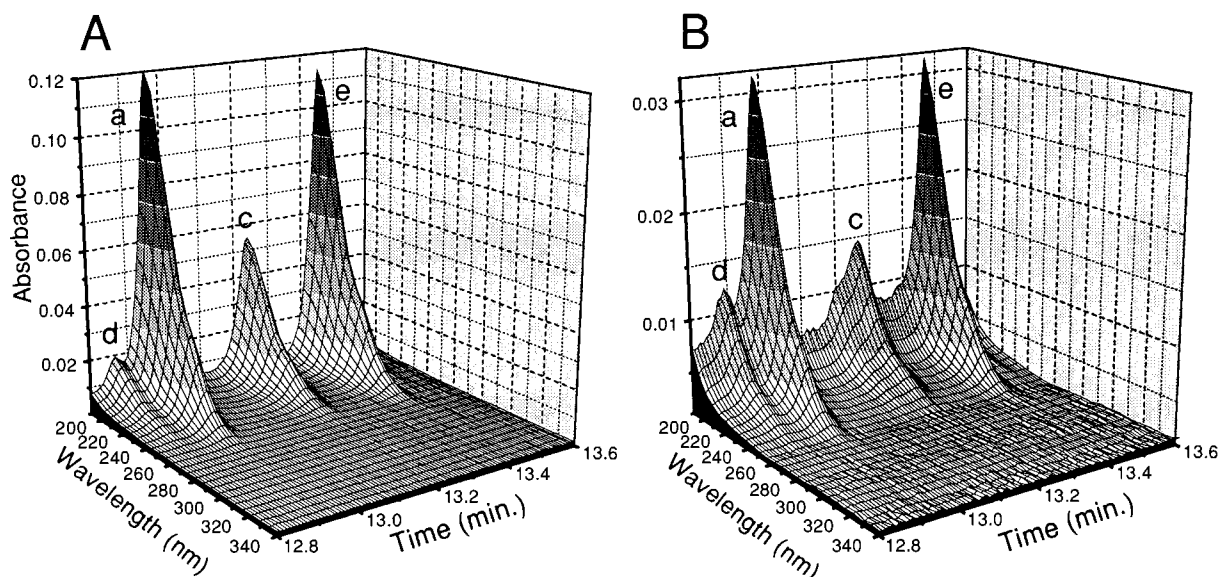

Fig. 5. The utility of diode array detection for characterisation of components separated by capillary electrophoresis. A separation of purified sheep MT (A) is compared with that of a sheep liver extract (B) which was obtained by a two-step solvent extraction procedure [31] without the use of 2-mercaptoethanol. Separation was by MECC using a 75 cm \times 57 μ m capillary and a 300 mM sodium borate buffer containing 85 mM SDS, pH 8.4. All other conditions for MECC are specified in the legend of Fig. 2 and UV scans between 190 and 340 nm were obtained at a rate of 2 Hz. Components labeled a, c and e are isoforms MT-1a, MT-1c and MT-2, respectively and component d is an unidentified MT isoform.

On calculating the quantity of MT in a CE capillary which gives an absorbance peak using a UV monitor at 200 nm, it is clear that femtomole amounts of the protein can be readily detected. Nevertheless, the sample injection volume is very small and it is necessary to use relatively concentrated MT samples to achieve injection of femtomole quantities. Sample loading can be increased by injecting for a longer time, but this will usually adversely affect resolution. Concentration of the sample by reducing its volume is practicable down to about 20 μ l although on many CE instruments, it is possible to inject from as little as 5 μ l. Nevertheless, the physical constraints of the instrumentation and problems such as sample evaporation become significant obstacles with very small volumes.

To an extent, sample concentration can be achieved on-line by processes known as field amplification and 'stacking' [41]. Stacking involves hydrodynamic injection of sample solution which has a lower IS than that of the electrolyte. On

application of an electrical potential across the capillary, a higher electric field is generated within the sample 'plug' than in the electrolyte. The protein molecules therefore migrate at higher velocity within the sample solution and slow down when they reach the interface with the electrolyte. This results in concentration at the interface, which also enhances resolution. However, injection of too much sample will degrade resolution and so investigation of optimal sample injection volume is required. A related way of enhancing sensitivity is to load electrokinetically from a sample of lower IS than the electrolyte. This has been used to advantage in uncoated capillaries but can be even more effective in neutral capillaries which have no EOF. An example of sensitivity enhancement using this method is shown in Fig. 7 but it should be emphasised that electrokinetic injection will result in preferential loading of more highly charged species. This is illustrated in Fig. 7 by the relative increase in the absorbance of the early migrating (more highly charged) of the two princi-

Fig. 6. Analysis of purified sheep MT-1 by matrix-assisted laser desorption–time of flight mass spectrometry (MALDI-TOFMS) using a Finnigan MAT ‘Lasermat’ Mass Analyser instrument. The sample (1 μ l) containing 30 pmol of sheep MT-1 in sinapinic acid (10 mg ml⁻¹), was applied and dried onto the target surface of the metal sample slides. After loading and evacuating the sample chamber, the slide target surface was bombarded with laser light at 30% power and 30 shots were summed to obtain the spectrum. Mass calibration was external using insulin and ubiquitin. $[MH]^+$ is the protonated molecular ion of MT-1 (all isoforms), $[MH_2]^{2+}$ is the double-protonated ion and $[M_2H]^+$ is a protonated MT-1 dimer. $[MAH]^+$ is the putative protonated sinapinic adduct ion of MT-1.

pal peaks following electrokinetic loading as compared with hydrodynamic injection.

Of the on-line pre-concentration techniques, perhaps the most elegant method is isotachopheresis (ITP), since it efficiently enhances both sensitivity and selectivity. However, on-line ITP-CE instruments are not yet commercially available. A less sophisticated but practical method employs on-line solid phase extraction (SPE-CE), which can be adapted to existing instrumentation [42–44] and has been applied to the analysis of MT isoforms [37,38]. Although the solid phase extractors have to be constructed in the laboratory, the procedure is straightforward, taking about 10 min with experience, and the materials are inexpensive and commonly available [37]. With appropriate reversed phase material and loading/separation conditions, the SPE device has been used for at least 100 separations of MT isoforms in tissue extract samples, giving at least a

100-fold sensitivity enhancement for injection times up to 5 min. An example of a SPE-CE separation of rabbit MT (0.1 mg ml⁻¹, 60 s injection) is shown in Fig. 8 and peak areas of the two separated isoforms are almost 40-fold greater than those obtained by a CE separation of the same sample without the SPE device [38].

6. Conclusions

Mammalian MTs often contain multiple isoforms encoded by different genes and various traditional electrophoretic and chromatographic techniques, with the exception of RP-HPLC, have proved inadequate in separating these proteins. Reproducible separations of these isoforms have been demonstrated by a variety of CE techniques, which have the advantages of being rapid (usually under 15 min), requiring very little sample (nl

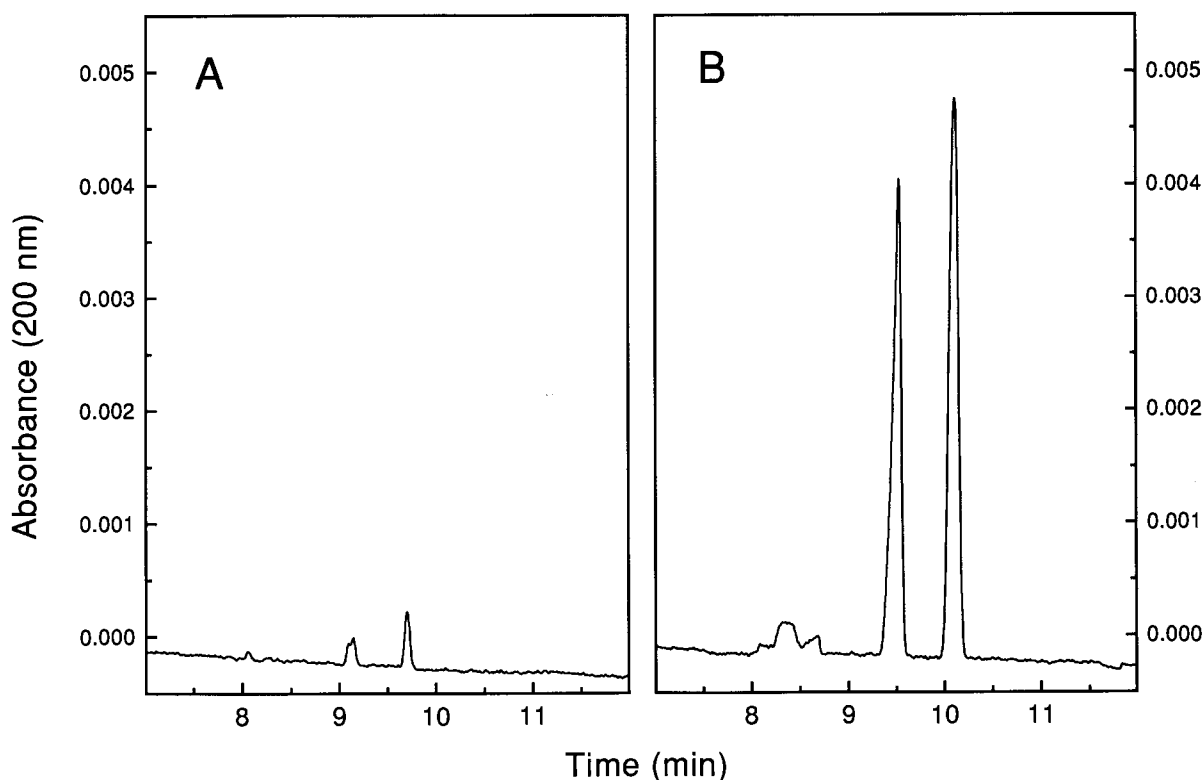

Fig. 7. Sensitivity enhancement using electrokinetic sample loading in combination with a neutral capillary at neutral pH and reversed polarity (anode at outlet). A sample of purified rabbit MT-2 (2 mg ml^{-1} in deionised water) was loaded by pressure injection for 30 s at 0.5 psi (A) or electrokinetically at 5 kV for 30 s (B). A $57 \text{ cm} \times 50 \text{ }\mu\text{m}$ 'Celect-N' stable neutral capillary (Supelco, Poole, UK) was used in combination with a 50 mM sodium phosphate buffer pH 7.0. Electrophoresis was performed at 20 kV and 25°C .

quantities) and having a very high resolution, which in combination with a wide flexibility of electrolyte chemistry and capillary coating, can be utilised to separate proteins of very similar structure. Although many CE techniques can be applied to the qualitative evaluation of isoform composition or their quantitative assay, careful selection of the most appropriate separation conditions and capillaries for the study objective is desirable. Table 1 summarises a variety of separation conditions which have been shown to be advantageous for MT isoform separation. The most appropriate conditions for qualitative evaluation would appear to be low pH phosphate buffers in combination with uncoated capillaries or neutral pH phosphate buffer in combination with a polyacrylamide-coated neutral capillary.

Quantitative work is best attempted using borate–SDS electrolytes at alkaline pH in uncoated capillaries. Samples can be prepared using a rapid two-step solvent extraction method and the identity of separated components can be verified using diode array detection and/or mass spectrometry. Detection sensitivity can be enhanced using a novel on-line solid phase extraction device, whose utility and reproducibility has been recently demonstrated.

Abstract

Analytical chemistry of metallothioneins based on the coupling of a high resolution separation technique with an element or species selective detection technique is discussed. The role of size-exclusion chromatography (SEC) with on-line atomic spectrometric detection for the quantification of metallothionein fraction in cell cytosols is evaluated. Particular attention is given to the conditions for the separation of metallated metallothionein isoforms (MT-1, MT-2, MT-3) and sub-isoforms within these classes by anion-exchange and reversed-phase HPLC. Techniques for interfacing chromatography with atomic absorption spectrometry (AAS), inductively coupled plasma atomic emission spectrometry (ICP AES) and ICP mass spectrometry (MS) are assessed. The potential of electrospray (tandem) mass spectrometry for the characterization of metallothionein isoforms with respect to molecular mass and amino acid sequence is highlighted. Perspectives for capillary zone electrophoresis (CZE), microbore and capillary HPLC with ICP MS and electrospray MS(/MS) detection for the probing of metallothioneins are discussed. Applications of hyphenated techniques to the analysis of real-world samples are reviewed. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Metallothioneins; Coupled techniques; High resolution separation technique

1. Introduction

Metallothioneins (MTs) are a group of non-enzymatic low molecular mass (6–7 kDa), cysteine-rich metal-binding proteins which are resistant to thermocoagulation and acid precipitation [1–3]. The most popular are mammalian MTs that have been isolated from kidney, liver and brain samples; MTs isolated from mussels, plants and fungi

have also been reported. The interest in the determination and characterization of MT-isoforms is a derivative of their role in homeostatic control, metabolism and detoxification of a number of essential (Zn, Cu) and toxic (Cd, Hg) trace metals. Also, being the product of genetic polymorphism characteristic of MT genes in animals and humans, MT-isoforms draw attention to studies on metal-mediated gene expression mechanisms [1–3].

Classical techniques for the determination of MTs include metal-saturation assays [4,5,8,12,13], polarography [6,7,10] and immunological assays, both radioimmunoassay (RIA) [10,11] and en-

zyme-linked immunosorbent assay (ELISA) [5,6,9]. Recent studies on the measurement of metallothionein and its isoforms have been reviewed [14]. Metal saturation assays based on the competitive displacement and the subsequent determination of the initially MT-bound metal (usually Cd and Zn) by a metal with higher affinity to MT (usually Hg and Ag) depend sometimes on speculative assumptions of stoichiometry and lack selectivity with regard to the individual MT-isoforms. Electrochemical techniques based on the quantification of MT-fraction via sulfhydryl groups may suffer from interferences by other redox systems present in the sample and fail to give information both on the initial metal content and on the isoform composition. The unmatched absolute detection limits (down to 1 pg) by immunological assays (RIA or ELISA) are off-set, because of the difficulties encountered in raising high titers of antibodies, by their length, inability to quantify individual MT isoforms in a mixture, and inability to provide information on the original metal composition. The key challenges to the analytical chemistry of metallothioneins include: (1) selectivity with regard to the different MT iso- and sub-isoforms, (2) selectivity with regard to metal, and (3) sensitivity, able to cope with non-induced levels in real-world samples.

The isoform selectivity can be achieved using high performance separation techniques; various modes of high performance liquid chromatography (HPLC) or electrophoresis have become standard [15,16]. The relatively poor sensitivity of quantification based on the UV-signal or on dye-staining does not generally allow the non-induced concentrations of MTs to be determined. More important is that the lack of sufficiently pure calibration standards does not allow for unambiguous identification of MT-isoforms in HPLC and CZE chromatograms whereas the accuracy of molecular mass assessment in SEC leaves a lot to be desired. Additional information totally lost refers to the metal composition of the metallothioneins studied.

In the last decade a universally accepted approach to speciation analysis has been offered using hyphenated (coupled, hybrid) techniques which are undergoing rapid and continuous devel-

opment [17–21]. They are based on a combination of separation techniques (gas chromatography (GC), HPLC, or CZE) with a sensitive and species selective detector (atomic absorption, plasma emission or mass spectrometer). The recent explosion of electrospray ionization MS [22,23], collision induced dissociation (CID) for tandem MS [24], and enhanced fragmentation in the ion-spray source [25] opens new exciting possibilities for the detailed characterization of metallothioneins in terms of molecular mass, amino acid sequence, and metal content, respectively.

The state-of-the-art and opening perspectives for coupled techniques in the field of quantification and characterization of metallothioneins is the topic of this paper.

2. The joy of coupling

There exists various possibilities for on-line coupling between a separation technique and an element (moiety, species) specific detector for the characterization and determination of metallothioneins. They include different modes of HPLC or capillary zone electrophoresis (CZE) on the separation side, and flame AAS, ICP AES, ICP MS or electrospray MS(/MS) on the detection side. The choice of a hyphenated system depends primarily on the research objective. The separation component of the coupling system is favoured when the characterization of the maximum number of iso- or sub-isoforms is of interest, whereas the detector component becomes crucial when a high sensitivity is required.

Various separation mechanisms have been proposed for the separation of metallothionein isoforms. The separation of the MT fraction is usually achieved with SEC, this method, however, is unable to distinguish between the different isoforms. Separation of Cd and Hg-MT-fraction in spiked human urine by affinity chromatography was reported [26]. The characterisation of amino acid microheterogeneities has been achieved by anion-exchange and reversed phase which allowed the definition of the major MT classes (MT-1, MT-2, ...). The resolution of capillary elec-

trophoresis has enabled a further subdivision of the major isoforms into a variety of sub-isoforms.

The presence of a metal bound to MT is a prerequisite when using an “inorganic” atomic spectrometric detector such as atomic absorption, ICP atomic emission or ICP MS spectrometer. The ADLs of several femtograms of the latter often make it possible to detect non-induced metallothioneins in on-line mode (in contrast to immuno assays). The linear range and multielement capability of these detectors make them a rapid alternative to metal-saturation assays. An electrospray mass spectrometer is unmatched when characterising MT isoforms in terms of molecular mass. A CID cell and another mass spectrometer in series are necessary to provide structural information in terms of the amino acid sequence.

An important problem often encountered is the interface between chromatography and spectrometry, as the separation conditions may not be compatible in terms of flow rate and mobile phase composition with those required by the detector. High concentrations of organic solvents in reversed-phase HPLC negatively affect the plasma but enhance the ESI process. On the other hand, the relatively concentrated buffers used in ion-exchange chromatography suppress the signal in electrospray. The nanoliter sample volume and low microliter per minute flow rate makes the dead volume and sensitivity critical in AAS and plasma techniques, whereas they are not far from the optimum nebulization techniques in ESI MS. These considerations make the choice and optimization of the best hyphenated system for a given task difficult and requires some experience.

3. Separation of metallothioneins

Since the complexation equilibria between metallothioneins and metals are strongly pH-dependent, the control of pH on the mobile phase is crucial irrespective of what separation technique is used. Acidic pH is responsible for the depletion of metals leading gradually to apoforms. For instance, Zn is lost at pH 5, at pH 3.0 Cd₄ adducts isoforms are present, at pH 2 copper still

remains attached. Various intermediate forms partially metallated occur at various pH regions. The buffer chosen should therefore ensure that speciation of the analyte be unaltered during its passage through the column.

3.1. Size-exclusion chromatography

Size-exclusion chromatography (SEC) is based on the molecular sieve effect and enables species to be separated according to their size, and to a lesser extent, shape. The average time a substance spends in the pores is determined by its size which for a given shape, can usually be related directly to its molecular weight. The resolution of SEC is insufficient for discrimination of small amino acid heterogeneities, this technique serves in the separation of the MT fraction from samples. Applications of SEC to the quantification of the MT-fraction from biological cytosols are summarized in Table 1.

3.1.1. Packing

Separation by SEC should be independent of the analyte's charge but in practice the stationary phase surface displays charged properties so that a mixed mode separation is observed. This makes the choice of packing critical. The two categories of packing used included silica and organic polymers. At nanogram metal levels, significant silanophilic effects including metal losses in the presence of low ionic strength eluents on silica-based SEC supports were detailed [4,13,38]. A copolymeric styrene-divinylbenzene SEC support which provides a symmetrical peak with negligible losses of Cd during chromatography was proposed [4,13]. The average pore size of the packing used varied from 100 to 1000 Å.

3.1.2. Mobile phase

The optimum eluent should ensure minimum competition between buffer and cytosolic ligands, and between these ligands and the gel. The separation by SEC with H₂O as mobile phase prevented structural changes, denaturation of proteins and destruction of protein–metal complexes [39]. In practice, various aqueous mobile phases of fairly high ionic strength have been used

Table 1
Size-exclusion chromatographic methods for the separation of metallothioneins

Element	Sample	Column	Eluent (flow rate)	Detection	Reference
Cu, Zn	Vegetables	Sephadex G-50 superfine (700 × 30 mm)	20 mM Tris-HCl, pH 8.0 (5°C)	UV (254 nm), off-line GF AAS	[28]
Cu	Mussel tissue (digestive gland)	Progel TSK G3000 SW (30 cm × 7.8 mm)	50 mM K ₂ HPO ₄ -KH ₂ PO ₄ buffer, pH 7.5 (0.7 ml min ⁻¹)	ICP AES	[29] [30]
Cd, Zn	Mussel tissue (digestive gland)	GPC Water ProteinPack 125 Sephadex (100 cm × 1.5 cm) with a 3 cm guard column	50 mM K ₂ HPO ₄ -KH ₂ PO ₄ buffer, pH 7 (0.7 ml min ⁻¹)	UV (254 nm) ICP AES	[31]
Cd, Zn	Cd-induced rat liver	Sephacryl S-100 (120 × 1.6 cm)	10 mM (NH ₄) ₂ CO ₃	AAS	[27,33]
Cd	Pig kidney	Pharmacia Superose-12 (2 cm × 5 mm)	120 mM Tris-HCl, pH 7.5	ICP MS	[33]
Cd	Pig kidney simulated gastro-intestinal digest	Progel-TSK, G 3000PWxL, (30 cm × 7.8 mm)	30 mM Tris-HCl, pH 8.6	AAS, ICP MS	[4], [13]
⁶³ Cu, ⁶⁶ Zn and ¹¹⁴ Cd	Osprey blood, mussels	Progel-TSK G2000 SW (60 cm × 7.5 mm)	100 mM Tris-HCl/100 mM NaCl, pH 7.4/0.02% NaN ₃ (1 ml min ⁻¹)	UV (220 nm), on-line radioactivity	[34]
³⁵ S	³⁵ S-containing hepatoma tissue culture	Asahipak GFA-30F (30 cm × 7.6 mm)	50 mM Tris-HCl pH 7.5 and 200 mM (NH ₄) ₂ SO ₄ /0.1 mM EDTA (0.8 ml min ⁻¹)	ICP MS	[35]
Zn isotope ratios	Chicken meat simulated gastro-intestinal digest	Pharmacia Superose-12 (30 cm × 10mm)	100 mM CH ₃ COONH ₄ 0.1% TFA, pH 6.0	ICP MS	[36]
	Rat liver	Sephadex G-75 column (1 m × 24 mm)	50 mM Tris-HCl pH 6.8 (1 ml min ⁻¹)	UV (254 nm)	[37]
	Freshwater mussels (<i>Anodonta grandis</i>)	TSK SW2000 (30 × 0.75 cm) and a precolumn TSK (7.5 × 0.75cm)	10 mM Tris-HCl-100 mM NaCl-0.03% NaN ₃ (pH 7)(0.5 ml min ⁻¹)	UV (254, 280 nm)	[38]
Cd	Defatted human breast milk	Merck Fracto-TSK-gel SW 55 (6 cm × 4 mm)	H ₂ O (0.5 ml min ⁻¹)	UV (280 nm)	[39]
		TSK gel G3000 SW	Tris-HCl (pH 7.2–8.6) (1 ml min ⁻¹)	UV, AAS	[40]
	Rat kidney	Protein-Pack 125 (30 cm × 7.8 mm)	20 mM HCOONH ₄ buffer of pH 7.65 (1 ml min ⁻¹)	UV (254 nm), off-line radioactivity, liquid scintillation for ²⁰³ Hg	[41]
Cd	<i>M. galloprovincialis</i>	Progel TSK G3000PWxL (30 cm × 7.8 mm)	30 mM Tris-HCl (0.8 ml min ⁻¹)	ICP MS	[42]
⁶³ Cu, ⁶⁸ Zn, ¹¹⁴ Cd	Cyanobacterium	Dupont GF-250 (250 × 9.4 mm)	50 mM Tris-HCl, pH 7.5, 0.2 M (NH ₄) ₂ SO ₄	ICP MS	[43]

to avoid interactions with the packing material. Dilute buffers, in general, may cause adsorption of low molecular weight proteins by the column packing. When silica-based packings cannot be avoided, the addition of a non-complexing salt (e.g. 100 mM NaCl) to the mobile phase was shown to suppress the residual silanol activity of the column packing [38]. Under these conditions no significant exchange of Cd occurred but occasional (for Hg) or appreciable losses (for Zn) were observed for other metals [38].

The addition of EDTA, proposed by some authors to minimize metal ion-gel interactions [43] was found unsuitable by others [33] because of the occasional presence of anomalous Cd peaks in subsequent runs. Polymeric supports suffer from the deposition of excess free Cd^{2+} which interacts with analytes, often causing severe degradation in peak resolution [13]. Because the weak complexing character of Tris is not sufficient to compete with the polymeric support for Cd^{2+} , complexation with β -mercaptoethanol was advised [13].

The wide variety of buffers reported in the literature (Table 2) makes it relatively easy to choose a suitable one for the detection technique. Up to 30 mM Tris-HCl was found to be tolerated in ICP MS whereas 20 mM formate or acetate buffer in 10% methanol was found to be acceptable for ESI. Addition of 0.03% NaN_3 as a retardant of bacterial activity is advised to protect the column from damage resulting from bacterial growth when real-world samples are analysed.

3.1.3. Analysis time

This is a function of column size and flow rate. Even though columns up to 120 cm were used the standard 30×7.6 mm column is a good choice. At a flow rate of 1 ml min^{-1} , the separation requires ca. 20 min to go to completion. Separation of MT-bound and unbound cadmium within 3 min on a 4.0 cm SEC column was reported [42]. The choice of small-bore columns with size-exclusion packings on the market is still limited, such columns enable rapid characterization of various metal-containing molecular weight fractions in unknown cytosols by direct injection nebulization ICP MS or ESI-MS.

3.2. Reversed-phase chromatography (RPC)

The separation of MT-isoforms is most frequently carried out using reversed-phase chromatography between a non-polar stationary phase (usually a covalently bound C_8 or C_{18} linear hydrocarbon), and a relatively polar mobile phase. Reversed-phase HPLC seems to be superior to SEC and ion-exchange, because the packing material for RPC is principally free of ligands for metals [44]. Since hydrophobicity of a polypeptide primarily dictates its retention in RPC, gradual elution of individual MT isoforms of a mixture is achieved by decreasing the polarity of the mobile phase by the addition of methanol or acetonitrile. Isolation of MT-isoforms by RP-HPLC was reviewed [15]. Applications of reversed-phase chromatography to the separation of MT-isoforms is summarized in Table 2.

Wide-bore (4–5 mm) 15–25 cm long columns are the most frequently used. The narrow-bore and microbore columns are expected to gain significance, because of their higher sensitivity and resolution. The presence of a 10–50 mM buffer is necessary. Tris-HCl is the most widely used in the separation of metallated isoforms. Apo-MT-isoforms have been separated using 0.1% trifluoroacetic acid (TFA) [46,48] or sub-percent acetic acid [51]. The resolution of isoforms is affected by pH [47].

Table 2 shows that UV detection has been used so far in most cases. This is because the high content of organic modifier makes the RP HPLC not quite compatible with ICP MS. A set of Pt-cones and the addition of oxygen to the nebulizer gas are highly recommended. Loss in sensitivity is unavoidable. On the other hand, RP separation conditions are close to the ideal for ESI MS detection which is expected to gain popularity in near future.

3.3. Anion-exchange chromatography

MT-1 and MT-2 fractions, which have a negative charge in aqueous solutions can be separated using anion exchange chromatography. High performance liquid chromatography is usually employed but the use of a fast-flow anion-exchange

Table 2
Reversed-phase chromatographic methods for the separation of metallothioneins

Element	Sample	Column	Column	Eluent (flow rate)	Detection	Reference
⁶⁴ Cu	Chicken macrophage and hepatic cytolysis	Pecosphere-3C C ₁₈ (8.3 cm × 4.6 mm × 3 μm)		Gradient elution: 100–90% of aq. 60% CH ₃ CN in 10 mM NaH ₂ PO ₄ in 5 min (1 ml min ⁻¹)	UV (214, 280 nm) (DL 1 μg)	[45]
	⁶⁴ Cu-labelled hepatoma tissue culture incubated for 24 h in a growth medium	μ-Bondapak C ₁₈ Radial Pack (10 cm × 8 mm × 10 μm) with a C ₁₈ precolumn		Gradient elution with 25 mM Tris-HCl buffer of pH 7.4 and 60% CH ₃ CN in the buffer (1.25 ml min ⁻¹)	UV (214 nm), on-line radioactivity detection	[34]
Cd, Cu, Zn	Liver tissue	LiChrospher 100 RP-8 (12.5 cm × 4 mm × 5 μm)		20 min linear gradient from 0.5–30% MeOH in 50 mM Tris-HCl buffer (pH 7.0) (1.5 ml min ⁻¹)	ICP MS	[35]
	<i>Anacystis nidulans</i>	Capcellpak C ₈ (15 cm × 4.5 mm)		CH ₃ CN/50 mM Tris-HCl pH 7.5 (9:91) and 0.1 mM-EDTA (1 ml min ⁻¹)	ICP MS	[35]
	Crab hepatopancreas	Waters C ₁₈		Gradient elution with aq. 0.1% TFA-0.1% TFA in CH ₃ CN (9:1 to 2:3 in 40 min)	UV 254 nm, off-line F AAS, GF AAS	[46]
	Fractions corresponding to the metallothionein peak, were combined and concentrated under N ₂	μ Bondpak C ₁₈ (30 cm × 7.8 mm × 5 μm)		Gradient elution with 100% Tris-HCl (Ph 6.8) (A) and A-CH ₃ CN (2:3, B) from 0–30% B over 30 min (1.25 ml min ⁻¹)	UV (220 nm)	[37]
	Liver, horse kidney and rabbit, human, rat, chicken, pig and sheep liver	Vydac C ₈ (25 cm × 4.6 mm)		Two-step linear gradient elution with CH ₃ CN in 10 mM sodium phosphate buffer of pH 2.5, 7 or 11 (1 ml min ⁻¹)	UV (214 nm)	[47]
Cu, Cd, Zn	Fish tissue (breem)	Merck Purosphere® RP-18 (250 mm × 4 mm × 5 μm)		Gradient elution with 30 mM acetate buffer pH 7 (A) and methanol (B).10–30% B in 15 min. isocratic with 30% B). 0.5 ml min ⁻¹ .	ICP MS	[42]
Cu, Zn	Crab hepatopancreas	Nova-Pak C ₁₈ (30 cm × 3.9 mm × 4 μm)		Gradient elution with 10–60% of 0.1% TFA (II)-CH ₃ CN in 0.1% II- H ₂ O (0.5 ml min ⁻¹)	UV (254 nm)	[48]
	Liver and kidney tissue	μ-Bondapak C ₁₈ (10 cm × 8 mm × 10 μm)		Negative gradient of 10 mM sodium phosphate (pH 7.0) in the same buffer containing 60% of CH ₃ CN (3 ml min ⁻¹)	UV (214 nm)	[49]
Cd, Cu, Zn	Liver or kidney tissues	PLRP-S (15 cm × 4.6 mm × 8 μm)		Gradient elution with 10 mM (NH ₄) ₂ HPO ₄ (pH 8.2)	UV (220 nm), AAS	[50]
	Melphalan-modified peptides released from rabbit liver metallothionein by tryptic digestion	Synchrom C ₁₈ (25 cm × 1 mm × 6.5 μm)		Gradient elution with aq. 0.25% CH ₃ COOH and 0.25% CH ₃ COOH in CH ₃ CN (25 μl min ⁻¹)	UV (206 nm) and ESI MS	[51]

column (40×3 cm) has been reported [32]. Separation efficiency and recovery were the same as the conventional method, but analysis time was reduced to one-third [32]. Usually, metallothioneins before being applied to anion exchange are first pre-separated using SEC. Anion-exchange methods developed for the separation of metallothioneins (summarized in Table 3).

A weak-anion exchanger with diethylaminoethyl functional groups is the only type of the support used. Aqueous buffers are used with a linear concentration gradient. The high potential separation of the MT-1 and MT-2 isoforms by anion exchange is not fully exploited in the coupled systems because the common end-concentration of 0.25 M buffer is not tolerated well by ICP MS and suppresses the electrospray ionization.

3.4. Capillary electrochromatographic techniques

These techniques involve the separation of MT-isoforms in an electrical field [55–57]. Neutral compounds can be trapped in micelles of an ionic surfactant and thus can migrate in an aqueous solution using electrophoresis (micellar electrokinetic chromatography, MEKC) [58]. Application of CE to the separation of metalloproteins and metal binding peptides was reviewed [16]. The rapidity of CZE combined with the high separation efficiency and small sample requirements make this technique useful for the analysis of metallothionein isoforms. A comparison of CZE with reversed-phase HPLC showed these techniques to be complementary and employing both enables maximum information to be acquired [59]. Applications of capillary electrochromatographic techniques to the separation of MT isoform are summarized in Table 4.

The basic parameters that affect the CZE resolution include surface characteristics (untreated or coated capillaries), and the mobile phase composition (the buffer, its pH, concentration, and the presence of zwitterionic reagents, inorganic salts, metal ions, ion-pairing agents and organic solvents). The choice of capillary and running conditions depends on the complexity of the MT-mixture to be resolved. CZE in uncoated silica capillaries provides a rapid analysis of non-

heterogeneous MT-isomers in neutral or alkaline buffers. Most heterogeneous isomers, and those in complex matrices, can be separated using high-ionic strength (0.5 M) buffers [66]. Uncoated capillaries offer high speed analysis and durability but their resolution often leaves a lot to be desired.

Surface-modified capillaries (usually coated with a polyimide, polyamine or a linear polyacrylamide) provide enhanced resolution of MT isoforms [67]. The coating minimizes the interaction of MT with the wall and thus suppresses the electroosmotic flow (EOF), and consequently increases resolution [68]. The numbers of putative isoform peaks resolved from various animal species were human MT-1 (5–6), horse (3–5), pig (4–5), rabbit (3–6), rat (2–3) and sheep (4–5) [59]. The resolution of MT-isoforms is further affected by pH [47]. In neutral or alkaline media, the three basic MT-isoforms classes were well separated at pH 7 in 7 min, with MT-1 migrating the fastest and MT-3 the slowest. The spectra showed differences for the Zn and Cd forms. The order of migration of apoforms (at pH 2) was reversed [69].

Separation of MT-isoforms by MEKC using an SDS-containing borate buffer (pH 8.4) was reported but no advantage over CZE was apparent [63,67].

The basic drawback of electrophoretic techniques is poor sensitivity resulting from very small (a few nanoliters) samples that can be injected onto a capillary. This problem can be overcome by on-line preconcentration prior to the capillary inlet. A C_{18} concentrator was shown to enhance sensitivity (down to 0.1 g ml^{-1}) and specificity of MT isoform separation in sheep liver [70].

4. Interfacing HPLC with atomic spectrometry for probing MT-isoform

LC mobile phases consist typically of some combination of organic solvents, salts of buffer solutions and/or ion-pair reagents. The LC-AS interface should take into account the compatibility of composition and flow-rate of the chromatographic mobile phase with those acceptable by the

Eukaryotic species	2–4 s	Untreated polyimide-clad fused-silica (94 cm × 75 µm)	50 mM-Tris-HCl (pH 9.1)	30		214		[62]
Sheep liver	Low pressure (3.45 kPa) (10 s)	Untreated fused-silica (57 cm × 25 µm)	300 mM-borate-85 mM-SDS, pH 8.4	10	25	200 or 190-340		[63]
	Low-pressure (3.45 kPa) (2 s) for separation at pH 7, (5 s) for separation at pH 2	Uncoated (57 cm × 50 µm, 50 cm to detector)	50 mM-phosphate buffer of pH 2 or 7	30	25	200 or 190-340		
Rabbit liver, horse kidney (commercial)	Pressure (0.5 psi) (5 and 10 s)	Uncoated fused-silica (57 cm × 75 µm)	110 mM Tris-borate, pH 6.9	11	20	200		[64]
Purified and semi-purified MT samples from animal species			20 mM Tris-HCl (pH 9.1)	30			1 to 10–500 µg ml ⁻¹	[65]

detector. This criterion is often much more difficult to be fulfilled than in the case of the UV detector, where the optical transparency of the mobile phase above 200 nm is the only condition.

The requirements of an HPLC-AS interface vary according to the function of the separation mode and the detector used. Size-exclusion chromatography in general shows good compatibility in terms of the flow rates used ($0.7\text{--}1.0\text{ ml min}^{-1}$) and mobile phase compositions, unless concentrated buffers are used with AAS and ICP techniques. Organic solvents are not a problem in anion-exchange chromatography but the buffers used often exceed 0.1 M which can clog the nebulizers. In RPC the organic solvent must be accommodated, whereas the buffer concentration is seldom a problem. The flow rate depends strongly on the column geometry, varying the column inner diameter from 8 to 0.18 mm allows the flow rate to change from 10 ml min^{-1} to $2\text{ }\mu\text{l min}^{-1}$.

4.1. Atomic absorption spectrometry (AAS)

The metals that preferentially bind to MTs (Cd, Zn, Cu) are among the elements which give the most intensive response in AAS. Off-line analysis of MT-bound metals after HPLC by fraction collection and graphite furnace (GF) AAS analysis has been a common approach [54]. Being less sensitive than GF AAS, flame AAS offers the possibility of an on-line approach. This technique is compatible both with the flow-rates and with the mobile phase composition (including organic solvent) commonly used in HPLC. Taking into account the widespread availability of this technique, it is no wonder that HPLC-AAS was the first hyphenated technique to be used in the determination of MT-isoforms [71].

The basic interface is very simple. The outlet of the UV detector is coupled to the nebulizer of an atomic absorption spectrometer and Cd, Cu and Zn are determined at 228.8, 324.8 and 213.8 nm, respectively. This allows the molar ratios of the metals to be calculated for the major MT-isoforms. Calibration graphs were reported to be rectilinear up to 200 g ml^{-1} of metallothionein and up to 20 g ml^{-1} of metal [44,50].

Several advanced interfaces based on thermospray have been proposed [72–74]. A simple and inexpensive thermospray interface was described that could be connected to a flame AAS system without the need to modify the nebulizer and burner assembly [73]. Detection limits at low nanogram levels were reported [73]. Another design included a silica transfer line attached to the HPLC column end and positioned with a guide tube in a thermospray tube, which was fitted with a heating jacket. The super-heated mobile phase then passed to a pyrolysis chamber fitted with gas inlets for H_2 and O_2 . Calibration graphs were linear over two orders of magnitude from near the detection limits (sub-ng) with aqueous or methanolic mobile phases [72]. A micro-atomization interface (made of quartz tubes) which was fuelled by hydrogen and could operate with 100% aqueous mobile phase used in HPLC was developed [74]. The detection limit obtained for HPLC-AAS of Cd-MTs was over 200-fold lower than that obtained with using a conventional flame AAS detector, and ca. 30-fold lower than that obtained by a thermospray-enhanced flame AAS system [74].

The primary interest in HPLC-AAS lies in its simplicity, wide availability and compatibility with mobile phases used in HPLC. AAS is not truly a multielement technique; nevertheless, with the latest instruments, up to four elements can be measured simultaneously, which is sufficient for practical applications. Despite the fact that detection limits obtained with advanced interfaces almost match those of ICP MS, the primary field of application of HPLC-AAS is the characterization of MT-isoforms after metal saturation protocols.

4.2. Inductively coupled plasma atomic emission spectrometry

Compared with flame AAS, ICP AES offers lower (at the 1 ng ml^{-1} level) detection limits [29,30], but lower solvent compatibility. High organic solvent ($> 10\%$) contents may not be easily tolerated. The unmatched advantage of ICP AES is the possibility of the monitoring sulfur together with metals. A detection limit for S below 10 ng ml^{-1} is common. ICP AES instruments with axial

plasmas, recently commercialized, seem to offer lower detection limits for transition metals. Multi-element capability is an advantage of instruments equipped with a polychromator.

4.3. Inductively coupled plasma mass spectrometry

ICP MS has been enjoying considerable popularity because of its multielement character and low detection limits. A wider expansion of high resolution ICP mass spectrometers (with potentially lower detection limit and larger freedom of interferences) is hampered by the prohibitive cost of the instrumentation and high maintenance costs.

4.3.1. Conventional pneumatic nebulization interface

The interface is straightforward—a piece of narrow-bore tubing that connects the outlet of the LC column with the liquid flow inlet of the nebulizer. Typical LC flow rates of 0.5–2 ml min⁻¹ are within the range usually required for pneumatic nebulization. The limitation is the low (1–5%) transfer efficiency, losses in spray chamber, and thus degraded sensitivity. Aqueous eluents with buffer contents up to 50 mM are tolerated. Organic solvents negatively influence plasma performance because of the increasing instability of the plasma (up to extinction in extreme cases) and deposition of carbon on the sampling cone and torch. The use of a water-cooled spray chamber and an increase in RF power (up to 1.7 kW) can help to reduce the solvent load to the plasma and increase its stability. The addition of oxygen (1–3%) to the nebulizer gas flow can help to minimize carbon deposition and clogging of the sample cone at the expense of the cone's lifetime [35,75]. Salts can cause short-term signal depression or enhancement and cause blockage of the nebulizer and the sampling cone [76]. The potential of LC ICP MS for trace metal speciation was discussed [77]. In general, ICP MS needs more dilute buffers or a lower concentration of solvents than ICP AES. Post-column split and makeup with water to lower the concentration of the organic modifier is a possible remedy, however, at the expense of sensitivity [42].

4.3.2. Direct injection nebulizer interface

The direct injection nebulizer (DIN) is a micro-concentric pneumatic nebulizer with no spray chamber; it nebulizes the liquid sample directly into the central channel of the ICP torch. The low dead volume (< 2 µl) and the absence of a spray chamber in the DIN minimizes post-column peak broadening and facilitates the use of microbore LC columns and liquid flow rates (30–100 µl min⁻¹) [78]. Another advantage is the fast sample washout with minimal memory effects which is especially useful for Hg which shows memory effects when a spray chamber is used.

The carbon deposits on the sampler and skimmer orifices are less important than in the case of pneumatic nebulizer. Adding O₂ to the aerosol gas to prevent clogging by the salts dissolved in the mobile phase was not necessary for SEC [78]. Organic solvents in reversed phase chromatography require, however, the addition of oxygen to keep the plasma stable.

4.3.3. Hydraulic high pressure nebulizer interface

The hydraulic high pressure nebulizer (HHPN) not only enhances the sensitivity by one order of magnitude but also allows an optimum adaptation to the low flow-rate by choosing an optimal nebulization nozzle (10 µm instead of 20 or 15 µm) [35]. The HHPN is also less affected by salt content than the pneumatic nebulizer. A dedicated desolvation unit can cope with methanol concentrations usually used in reversed-phase chromatography.

5. Capillary zone electrophoresis interfaced with ICP MS

The major problem with the application of the CZE-ICP coupling is the small sample volume (typically 10–100 nl) which requires a very sensitive detector to cope with the naturally occurring analyte levels. In addition, the low flow rate (1–5 µl min⁻¹) limits the choice of nebulizer. In terms of the practical applications to the characterisation of MT-isoforms, the high resolution of CZE has thus long been off-set by the lack of a suitable element/species selective detector. The recent in-

strumental developments regarding the CZE-ICP MS and CZE-ESI MS coupling are likely to result in numerous contributions to the field of metallothioneins in the foreseeable future.

Olesik et al. [79] developed an interface in which the CZE capillary terminus, which was coated with silver paint (serving as a conductor to complete the electrophoresis circuit), was fitted into the center tube of a concentric, pneumatic nebulizer with a spray chamber. The latter was responsible for some band broadening. In another interface a glass frit nebulizer was used [80]. One end of the capillary was inserted through stainless-steel tubing, while the grounded buffer solution passed over the capillary in the same tubing along with the ground (earth) electrode. The electrical connection was complete to the point of aerosol formation. The clogging and the fairly complex configuration were expected to be overcome by the use of an ultrasonic nebulizer [80]. In another type of interface, the CE capillary was inserted into the nebulizer central tube and another fused-silica capillary was also inserted coaxially around the capillary. A coaxial liquid sheath of 10 mM NaCl was supplied through the outer capillary and used as the return ground for the CE capillary. The variable position of the CE capillary in the interface allowed a compromise between separation resolution and signal intensity [81]. An elegant interface based on commercially available components was built using the DIN [82]. The CE capillary was placed concentrically inside the fused-silica DIN sample introduction capillary. A makeup liquid was pumped at a flow rate of 15 $\mu\text{l min}^{-1}$ into the fused silica DIN sample transfer capillary via a T-connector. The makeup liquid established continuous and stable electrical contact at the exit (grounding) terminus of the CE capillary.

Some of the above interfaces were tested for characterization of MT-isoforms. The detection limit for ^{114}Cd was 4 fg for 74 nl injections which corresponds to 0.05 ng ml^{-1} in the injected sample [81]. This allows for characterization even of non-induced MT-isoforms.

6. Electrospray-ionization mass spectrometry

Electrospray ionization allows multiply charged molecular ions to be obtained without any fragmentation. The envelope of peaks in a mass spectrum is a manifestation of protons attaching to the species to give the multiple-charging phenomenon which is the basis for the very accurate molecular weight determination of polypeptides.

Despite its enormous potential this technique is just at the start of its use in the characterization of MT-isoforms and its complexes with metals. It was used for the determination of the major rabbit metallothionein isoform II [13]. ESI mass spectra of purified rabbit MT-2 revealed the presence of two isoforms in the sample that differed by 30 mass units, and the characteristic spectra for the apoproteins and metal-saturated proteins at acidic and alkaline pH gave information about the number and the identity of metals bound to the protein [83]. Recent unpublished studies showed an even higher number of putative MT-2 isoforms in a commercial MT-2 standard [84]. ESI is more interesting—the metallated proteins seem to produce stable ions in the gas phase. The method can be used to accurately and rapidly determine how many and what cations are incorporated in each molecule of protein. A single measurement provides information about molar distributions and estimates of relative abundances of various complexes in the sample. The method is faster and more sensitive than AAS coupled with protein analysis.

While measurement of molecular weight is a major step towards the characterization of an isoform, information on the amino acid sequence makes this characterization quasi-complete. Some data is likely to be obtained after dissociation of large multiply charged ions by collision with a neutral target gas in the collision cell. The m/z values of dissociation products are then measured in the second mass analyser [24]. Another potential use of the electrospray technique for MT characterization is enhancing fragmentation down to the elemental ion [25]. The combination of these three modes of data acquisition should enable the exhaustive characterization of the MT-isoforms.

6.1. High-performance liquid chromatography-ESI MS(/MS)

Pneumatically assisted electrospray (ion-spray) produces stable ion currents for a wide range of sample flow rates from less than $1 \mu\text{l min}^{-1}$ to greater than $200 \mu\text{l min}^{-1}$. An in-line splitter is provided to accommodate solvent flows up to 2 ml min^{-1} . The electrospray ionization source is compatible with 0.1% TFA buffers but better sensitivities are obtained with peptides using solvents containing 0.5% acetic acid. The use of concentrated buffers should be avoided since they suppress the signal.

In studies with sheep MT, the four isoforms predicted from gene sequencing information were resolved by acidic RP HPLC-ESI MS and their masses determined to within one mass unit of the predicted apoprotein values [85]. In another recently reported application, melphalan-modified peptides were released from rabbit liver metallothionein by tryptic digestion, and separated by LC on C_{18} column. By comparison with chromatograms from unmodified metallothionein, several alkylated peptides were identified [51].

6.2. Capillary zone electrophoresis-electrospray MS(/MS)

The normal electrospray flow rates between $1\text{--}10 \mu\text{l min}^{-1}$ are not much higher than that used in CZE. Interfacing is relatively straightforward using an adapter kit allowing for a makeup flow. A microionspray interface launched recently by SCIEX appears to offer a higher sensitivity.

7. Analysis of real samples

Sample preparation protocols used for the characterization of metallothionein isoforms in real samples are summarized in Table 5. Washing the cells in a Tris-HCl buffer (pH 8) containing 1 M EDTA to remove metal ions reversibly bound to the cell wall was recommended [35]. In most studies, SEC [32,34,37,41,46,48,50] has been preferred to heat treatment [29–31,33,54] for the isolation of the metallothionein fraction from a

tissue cytosol. Guidelines for the preparation of biological samples prior to quantification of MTs were discussed with particular attention to the care necessary to avoid oxidation [86].

Soluble extracts of tissues and cultured cells are prepared by homogenizing tissue samples in an appropriate buffer. Neutral buffers are necessary for extracting MTs since Zn start to dissociate from protein at pH 5. Cd and Cu are removed at lower pH values. A 10–50 mM Tris-HCl buffer at pH 7.4–9 is the most common choice [4,13,29–31,33,35,41,43,44,54,74]. For cytosols containing Cd-induced MTs dilution factors up to 10 have been used whereas for those with natural MT levels equal amounts of tissue and buffer have been found suitable.

Metallothioneins are prone to oxidation during isolation due to their high cysteine content. During oxidation disulphide bridges are formed and the MTs either copolymerize or combine with other proteins to move into the high molecular weight fraction. Since MTs may be oxidized by, e.g. oxygen, Cu(I) or heme components, the homogenization of tissues and subsequent isolation of MT should be performed in deoxygenated buffers and/or in the presence of a thiolic reducing agent [13]. β -Mercaptoethanol is added as antioxidant which also prevents the formation of dimeric forms of MT [44]. Other components added during homogenation include 0.02% NaN_3 , added as antibacterial agent [74,87] and phenylmethanesulfonylfluoride which is added as a proteases inhibitor [4,13,48,74]. The homogenization step is followed by centrifugation. The use of a refrigerated ultracentrifuge ($100\,000 \text{ g}$) is strongly recommended.

As a result a soluble fraction (cell supernatant, cytosol) and a particulate fraction (cell membranes and organelles) are obtained. Only the supernatant is analysed for metallothioneins. It is recommended that it is stored at -20°C under nitrogen prior to analysis [44]. Extraction efficiency by sucrose-Tris at pH 8 was 30–25% [33]. Other workers using experimental animals (rats and mice) have found that 50–80% Cd can be solubilized using similar extraction procedures [33]. The percentage of metals in the cytosols is typically 50–85% and 30–57% in the case of Zn and Cd, respectively [28,88].

Table 5
Sample preparation methods

Sample	Initial sample preparation	Centrifugation	Coagulation method	Preseparation	Reference
Foodstuffs (vegetables)	Homogenization in 20 mM Tris-HCl (pH 8.0)	20 000 rpm			[28]
Mussel tissue (digestive glands)	Homogenization in 20 mM Tris-HCl (pH 8.6), 0.5 M sucrose, in the presence of NaCl, leupeptin and 50 mM toluene- α -sulphonyl fluoride	20 000 rpm (10 min)	Thermocoagulation (10 min, 70°C)		[29] [30]
Cd-induced rat liver		Centrifugation	Treated with ethanol, the precipitate dissolved in 0.01 M Tris-HCl buffer (pH 8.6)	Sephacryl S-200 (90 \times 3 cm), elution with 0.01 M Tris-HCl buffer of pH 8.6 (2 ml min ⁻¹)	[32]
Chicken or sheep liver	Homogenized by sonication in H ₂ O, CH ₃ CN added to the homogenate	Centrifugation	Dried by centrifugal vacuum evaporation dissolved in 100 mM borate buffer, pH 8.4		[60]
Pig kidney	Homogenization in 20 mM Tris-HCl, 0.25 M sucrose, pH 8.0.	10 000 g (20 min)			[33]
Pig kidney simulated gastric and gastro-intestinal digest	Lipoclean addition Enzymolysis with 1% pepsin in saline pH 1.8 (gastric), 3% paeceatin, 1% α -amylase and bile salts in saline (intestinal)	40 000 rpm (4°C, 0.5–5 h)	Thermocoagulation		[33]
Osprey blood	Hemolysis, dilution with 30 mM Tris-HCl (pH 7.6)	13 000 g			[13]
Mussels	Homogenization in 30 mM Tris-HCl (pH 8.6) with 0.1 mM of phenylmethylsulfonylfluoride (protease inhibitor)	145 000 g			[4] [13]
Rabbit and mouse liver	Homogenization in 5 ml of 50 mM Tris-HCl (pH 7.4) with 250 mM sucrose and 5 mM 2-mercaptoethanol	Centrifugation 100 000 g (70 min, 4°C)			[52] [44]

Table 5 (continued)

Sample	Initial sample preparation	Centrifugation	Coagulation method	Preparation	Reference
<i>Anacystis nidulans</i>	Washed three times in Tris-HCl (pH 8) with 1 M EDTA, homogenization by ultrasonification in 10 mM Tris-HCl (pH 8) with 1 mM dithiothreitol	Centrifugation			[35]
Chicken meat [#] , pig kidney [§]	Enzymolysis (4 h, 37°C) with 1% pepsine in dli. HCl (pH 1.8), adjusting to pH 6 with NaHCO ₃ , enzymolysis (4 h, 37°C) with 3% pancreatin, 1% amylase and 1.5 g l ⁻¹ bile salts	20 000 rpm (3 h, 4°C) [#] 40 000 rpm (4°C, 5 h) [§]			[33] [36]
Liver from rats subjected to subcutaneous injections of CdCl ₂ (2 mg kg ⁻¹) ⁶⁵ Zn, ⁶⁴ Cu, ³⁵ S-labelled hepatoma tissue culture incubated for 24 h	Homogenized at 4°C in 100 mM Tris-HCl (pH 7.4) with 25 mM glucose	170 000 g (1 h)		Sephadex G-75 (1 m × 24 mm) with 50 mM Tris-HCl (pH 6.8) (1 ml min ⁻¹)	[37]
	Washed with cold phosphate-buffered NaCl solution, frozen in liquid N ₂ , thawed in 25 mM Tris-acetate (pH 7.4) with 5 mM of β mercaptoethanol and 0.1% aprotinin	105 000 g		TSK G3000 SWG column (60 cm × 21.5 mm) with 100 mM Tris-HCl with 100 mM NaCl (pH 7.4) and 0.02% NaN ₃ (5 ml min ⁻¹) ^a	[34]
Crab hepatopancreas	Homogenization with Tris-HCl (pH 8.6)	25 000 g (3 h)		Sephadex G-50 with Tris-HCl (pH 8.6) with 0.5 mM dithiothreitol	[46]
Crab hepatopancreas	Homogenization in Tris-HCl with 0.1 mM phenylmethanesulfonyl fluoride	Centrifugation		The cell-containing fractions freeze-dried and desalted by passage through a Sephadex G-25, the supernatant soln, prepared on Sephadex G-50 with Tris-HCl (pH 8.6) with 0.5 mM dithiothreitol	[48]
Liver or kidney tissue	Homogenization in 10 mM (NH ₄) ₂ HPO ₄ (pH 8.2)	Centrifugation		Sepharose CL-6B with 10 mM (NH ₄) ₂ HPO ₄ (pH 8.2)	[50]

Table 5 (continued)

Sample	Initial sample preparation	Centrifugation	Coagulation method	Preseparation	Reference
Rat kidney	Homogenization in 10 mM Tris-HCl (pH 8.6) with 250 mM sucrose and 5 mM 2-mercapto ethanol,	105 000 g (4°C, 90 min)		Sephadex G-75 (70 × 2.6 cm i.d.) with 20 mM HCOONH ₄ (pH 7.65)	[41]
Liver and kidney tissue	Homogenization in 10 mM Tris-HCl (pH 8.6)	Centrifugation			[54]
Rat liver	Homogenized in Tris-HCl, the cytosolic homogenate saturated with Cd, removal of excess of Cd	Centrifugation	Thermocoagulation (60°C, 5 min)		[53]
Cyanobacterium	Homogenization in 10 mM Tris-HCl (pH 8.0) with 1 mM of dithiothreitol	164 000 g	Precipitation with and dissolved in mobile phase 50 mM Tris-HCl buffer pH 7.5 containing 0.2 M (NH ₄) ₂ SO ₄		[43]

^a Preseparation employed before anion-exchange only (not used for subsequent RP and SEC).

A heat-treatment (at 60°C for 15 min) of the cytosol extracts (especially of concentrated ones) is recommended to separate off the high-molecular fraction which coagulated from the supernatant (containing MTs which are heat stable). Such a treatment reduces the protein load on the HPLC column not only improving the separation of MT isoforms but also prolonging the column lifetime. Enzymolysis in simulated gastric and gastrointestinal juice was proposed for meat samples [33,36].

Filtration of the cytosol (0.22 µm filter) before introducing it to the chromatographic column is strongly advised [33,36,44]. A guard column should be inserted to protect the analytical column from the effects of lipids, which otherwise degrade the separation [33]. Any organic species that adhere to the column can also bind inorganic species giving rise to anomalous peaks in subsequent runs [33]. A new guard column was used for each injection to prevent adsorption by ligands with a high affinity for cadmium that would otherwise interfere with subsequent injections [33]. An extensive column clean-up was necessary [33]. To avoid contamination of the analytical column by trace elements, buffers should be passed by Chelex-100 [27,33,36].

8. Conclusions

Hyphenated techniques are an attractive tool for rapid, sensitive and comprehensive characterization and quantitative determination of MT-isoforms in biological samples. Unfortunately, since the pioneering work carried out by Suzuki in 1980 [71] advances in coupled techniques have not been widely transferred to MT research. The progress in ICP MS, electrospray (tandem) mass spectrometry and the increasing speed and efficiency of modern separation techniques, are expected to bring valid alternatives to metal saturation assays, immunoassays and electrochemical techniques in the near future.

There is an urgent need to create an interface between biochemists, whose studies on the role and mechanisms of MTs are still hampered by the tediousness and labour-intensive analytical procedures, and analytical chemists for whom metal-

lothionein is nothing more than a sample to demonstrate the usefulness of their newly developed instrumental techniques. The availability of a certified reference material for MT would enable the validation of hyphenated techniques against immunoassays which would facilitate their entry into biochemical and clinical laboratories.

Abstract

A comparative study of MT isoforms in rat liver and in commercial Sigma MT preparations from rabbit liver and horse kidney was performed using capillary zone electrophoresis (CZE). Electropherograms revealed the co-migration of MT forms from these species. A special form, the a-form (not binding Cd), occurred in various MT samples in different amounts, depending on the method used for MT purification. In the rabbit liver electropherogram a main form appeared (the b-form), which might be a modified MT form. A band of unknown composition, running ahead of the rat liver MT-I and -II forms on polyacrylamide gels, not having Cd binding affinity, probably had its counterpart in a yet unidentified CZE peak. CZE electropherograms of purified MT samples may contain main peaks that do not represent genuine and functional MT isoforms. Results are also presented which indicate that at low pH the MT-II form is more unstable than MT-I. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Metallothionein isoforms; Anion exchange chromatography; Polyacrylamide gel electrophoresis; Capillary zone electrophoresis

1. Introduction

Recent interest in metallothionein (MT) research, including ecotoxicological aspects has increased tremendously, this protein is used as a biomarker for heavy metal pollution and various types of stress.

The purification of MT from heat treated liver cytosols of cadmium (Cd) treated animals generally involves gel permeation followed by anion exchange chromatography. Our method differs

from other previous procedures [1,2] in that the gel permeation step was run in Tris buffer of the same low ionic strength as the starting buffer used in the gradient system for anion exchange to obtain the final separation [3]. In this way dialysis and lyophilization were omitted in order to prevent oligomerizations and oxidation of the reactive MT protein [4].

A typical elution profile for rat CdMT obtained by anion exchange chromatography monitored at 254 nm includes three peaks [3]. The fractions corresponding to those eluted as the second and third contain high amounts of added ¹⁰⁹Cd, while

* Corresponding author.

those that correspond to the first peak does not contain the isotope, even though they had a relatively high absorbance at 254 nm (see Fig. 1). It is speculated that the second and third peak contain MT-I and -II, respectively. The first eluting peak was designated the a-form.

Samples of material collected from these three peaks were run on capillary zone electrophoresis (CZE). This was done in a sodium phosphate buffer at low pH. The fused silica capillary was linearly coated with acrylamide [5]. One important advantage of using this neutral hydrophilic surface compared with uncoated or positively coated capillaries (e.g. polyamine polymers) is that appropriate buffers can be designed to produce separations either toward the cathode (normal polarity) or to the anode (reversed polarity). This offers additional selectivity without significant peak broadening caused by electroendosmotic flow.

An important factor in using acidic buffer conditions is metal dissociation (below MTs pI 3.8–4.4) causing apothioneins, thereby adding more resolving power to the system than at high pH [6–10]. At neutral or alkaline pH metal containing isoforms may co-migrate because of little differences in the net charge of the two main MT-I and MT-II types [11].

In our MT measurements using the CZE technique the a-form was also found in commercial rabbit and horse MT preparations. In rabbit liver a major form occurred, designated the b-form, most probably a spontaneous modified MT form. The stability of the various MT forms was also tested. The CZE technique, which separates compounds based on their charge to mass ratio, has proven successful for fast, sensitive and reproducible separation of MT isoforms [6–10,12–15].

2. Experimental

2.1. Animal housing and maintenance

Two male rats (*Rattus norvegicus*, Mol: WIST, 200–300 g) were used in the experiments. The animals were kept in macrolon cages and maintained in 12 h light/12 h darkness at 20°C and

55% relative humidity. They were fed ad libitum with an EWOS commercial pelleted diet (EWOS, Södertälje, Sweden). The animals had free access to water.

2.2. Chemicals

The isotope $^{109}\text{CdCl}_2$ (sp.act. 760 mCi mg^{-1} Cd, carrier free) was obtained from DuPont de Nemours, Wilmington, DE. The column materials Sephadex G-75 and DEAE-Sephadex A-50 were obtained from Pharmacia, Uppsala, Sweden. All chemicals were of analytical grade. 3-Amino-9-ethylcarbazole, bovine serum albumin, cadmium sulphate ($3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$), Coomassie Brilliant Blue R, *N,N'*-dimethylformamide, sodium acetate, Trizma base, Trizma hydrochloride, Trizma pre-set crystals, horse kidney MT (lot 73H9544) and rabbit liver MT (lot 93H9559; new lot 44H9568) were from Sigma, St. Louis, MO. Bromophenol blue, glycerol, glycine buffer substance, methanol, 4-chloro-1-naphthol, perhydrol (30% H_2O_2), ortho-phosphoric acid (99% pure cryst.), potassium chloride, sodium hydroxide pellets and zinc acetate were all from E. Merck, Darmstadt, Germany. Sodium dodecyl sulfate (SDS), *N,N'*-methylene-bis-acrylamide (BIS), acrylamide (99.9% pure), ammonium persulfate, *N,N,N',N'*-tetra-methylethylenediamine (TEMED) and 2-mercaptoethanol were all from Bio-Rad Laboratories, Life Science Group, Richmond, CA. Fluorinert™ liquid (FC-77) came from 3M, Haven, Belgium. The nitrocellulose membrane filter (2 μm) was obtained from Schleicher & Schuell, Dassal, Germany. Peroxidase conjugated IgG fraction of goat anti-rabbit IgG was prepared by Cooper Biomedical, Malvern, PA.

2.3. Metallothionein induction and preparation

Because MT isoforms are labile it was thought necessary to give a rather comprehensive description of the procedure for MT preparation.

Cold $3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$ was injected intraperitoneally to rats each day for a period of 4 days, 0.35 mg kg^{-1} on day 1, then 1.4 mg kg^{-1} on day 2, 3 and 4. After killing the animals on day 6 the livers were quickly removed and chilled on ice.

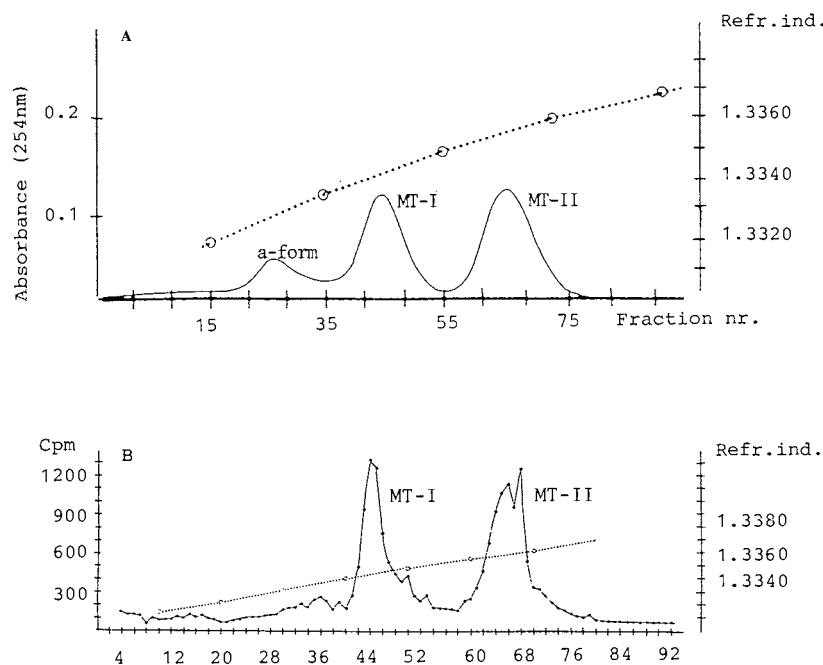

Fig. 1. (A) The major Cd binding fractions from the chromatography of rat liver cytosol on the Sephadex G-75 column pooled and rechromatographed on a DEAE Sephadex A-50 column with a linear Tris buffer gradient from 5 to 500 mM, pH 8.5. Absorbance 254 nm —. Refractive index ······. See text for further details. (B) Individual fractions assayed for added ^{109}Cd marker —•—•—. MT-I is shown to elute at a refractive index of 1.3345, MT-II at 1.3360.

The livers were then homogenized in 5 mM Tris buffer, pH 8.5 (1:4 w/v) using a glass-Teflon homogenizer (Potter-Elvehjem) rotating at 1400 rpm. After centrifugation at 20 300 g for 30 min at 4°C the supernatant was heat treated by equilibrating it on a water bath during temperature elevation from 20 to 80°C. Then the supernatant was kept at this temperature for 2 min, after which it was quickly chilled. The heat treated mixture was centrifuged at 20 300 g for 30 min at 4°C and the supernatant saved.

An aliquot of the heat treated supernatant (6–10 ml) was applied to a Sephadex G-75 column (2.5 × 72.5 cm) and eluted with 5 mM Tris buffer pH 8.5 at a flow rate of 1 ml min⁻¹. Supernatant samples were equilibrated for 5 min with 10 µl of Cd isotope solution, containing 100 000 cpm µl⁻¹ prior to gel permeation. Fractions (each 4.25 ml) were collected and analysed for ^{109}Cd by a Packard Minaxys Auto-gamma counter, model 5550 (Packard Instruments, IL).

The peak radioactivity fractions eluted from the Sephadex G-75 column were pooled and applied directly on a DEAE-Sephadex A-50 anion exchange column (1.5 × 25 cm) equilibrated with 5 mM Tris buffer, pH 8.5. After washing in (100 ml buffer) elution was started with a linear Tris buffer gradient (5–500 mM, pH 8.5, 600 ml). Eluate fractions of 4.25 ml were collected and analysed for UV absorption at 254 nm and for ^{109}Cd . The peak fractions were then pooled and lyophilized to get the final purified MT preparations. Tris salt was not removed.

2.4. Polyacrylamide gel electrophoresis and staining

The Bio-Rad Protean II Slab Cell was used for SDS polyacrylamide electrophoresis using the Laemmli reducing buffer system [16] as well as the native gel system. The stacking gel for the SDS system contained 4% acrylamide (0.35% bis), separation gel 12% (1% bis). The sample buffer con-

sisted of 4.0 ml aq. dest., 1.0 ml 0.5 M Tris–HCl (pH 6.8), 0.8 ml glycerol, 1.6 ml 10% (w/v) SDS, 0.4 ml 2-mercaptoethanol and 0.05% (w/v) bromophenol blue. Protein samples were diluted 1:4 with this buffer and heated to 80°C for 2 min to minimize negative charge differences and disulphide linkages prior to each run.

For native polyacrylamide gel electrophoresis the method by Jovin et al. [17] was used, except for riboflavin being replaced by TEMED and ammonium persulfate for upper gel polymerization. The stacking gel contained 2.5% acrylamide, separation gel 7.5%.

The Protean II slab cell apparatus was run at 40 V (16 h) overnight using the Bio-Rad Power Supply, model 250/2.5. The acrylamide gels were stained with Coomassie Brilliant Blue.

2.5. Electroblooming of MT, identification of Cd binding proteins, Western blotting

The electrotransfer of MT from polyacrylamide gels to nitrocellulose filters was per-

Fig. 2. Polyacrylamide SDS gel electrophoresis, Western blotting, autoradiography and native gel electrophoresis of our purified MT isoforms. In lanes (1), (2) the individual MT-II and MT-I preparations, respectively, Coomassie stained; (3), (4) Western blotting of MT-I and MT-II, respectively; (5), (6) autoradiography. In lane (7) MT-I and MT-II isoforms mixed, subjected to native gel electrophoresis. Arrowheads indicate positions of the SDS molecular weight markers (from top to bottom: ovalbumin, 45 kDa; carbonic anhydrase, 31; soybean trypsin inhibitor, 21.5; lysozyme, 14.4).

formed using the Bio-Rad Trans-Blot Cell according to the method employed by Towbin et al. [18]. The polyacrylamide gels (0.75 mm in thickness) were run as previously described [16]. After electrophoresis the gels were equilibrated in 500 ml Tris–glycine electrotransfer buffer (3.03 g Tris base, 14.4 g glycine, 200 ml methanol, aq. dest. to 1l) for 30 min. Then the electrotransfer was performed for 2 h at 60 V (Bio-Rad Power Supply, model 250/2.5).

To identify Cd binding proteins using autoradiography [19] the filter was equilibrated for 2 h in 400 ml of 10 mM Tris buffer, pH 7.4 at 4°C. The filter was then submerged for 10 min at room temperature in 25 ml of 10 mM Tris buffer, pH 7.4 containing 1 μCi $^{109}\text{CdCl}_2$ ml^{-1} , 0.1 mM zinc acetate and 0.1 M KCl. The filter was then washed twice in aq. dest. at room temperature and completely dried. Autoradiography was performed at -70°C for 38–48 h using Kodak X-Omat AR (XAR-5) film and DuPont Cronex Quanta II intensifying screens. The films were manually processed with Kodak LX 24 developer and AL 4 fixative.

Using nitrocellulose filters prepared as described above, our anti rat MT antibodies (developed in rabbits) were subjected to Western blotting [3,20]. The filters were washed in phosphate buffered saline for 15 min and then kept for 30 min in a solution consisting of 3 g bovine serum albumin to 100 ml phosphate buffered saline. The filter was then treated with antibody (rabbit serum without further purification) at a concentration of 40 μl 10 ml^{-1} blocking solution by gentle shaking overnight. The antibody solution was removed by washing with phosphate buffered saline. The filter was then treated with peroxidase conjugated IgG fraction goat anti-rabbit IgG in the concentration of 10 μl (undiluted) 10 ml^{-1} blocking solution. After shaking for 2 h the filter was developed in a mixture of 2 ml aminoethylcarbazole (AEC, fresh stock), 50 ml sodium acetate buffer, pH 5 and 25 μl hydrogen peroxide. The stock solution consisted of 0.25 g AEC to 25 ml dimethylformamide.

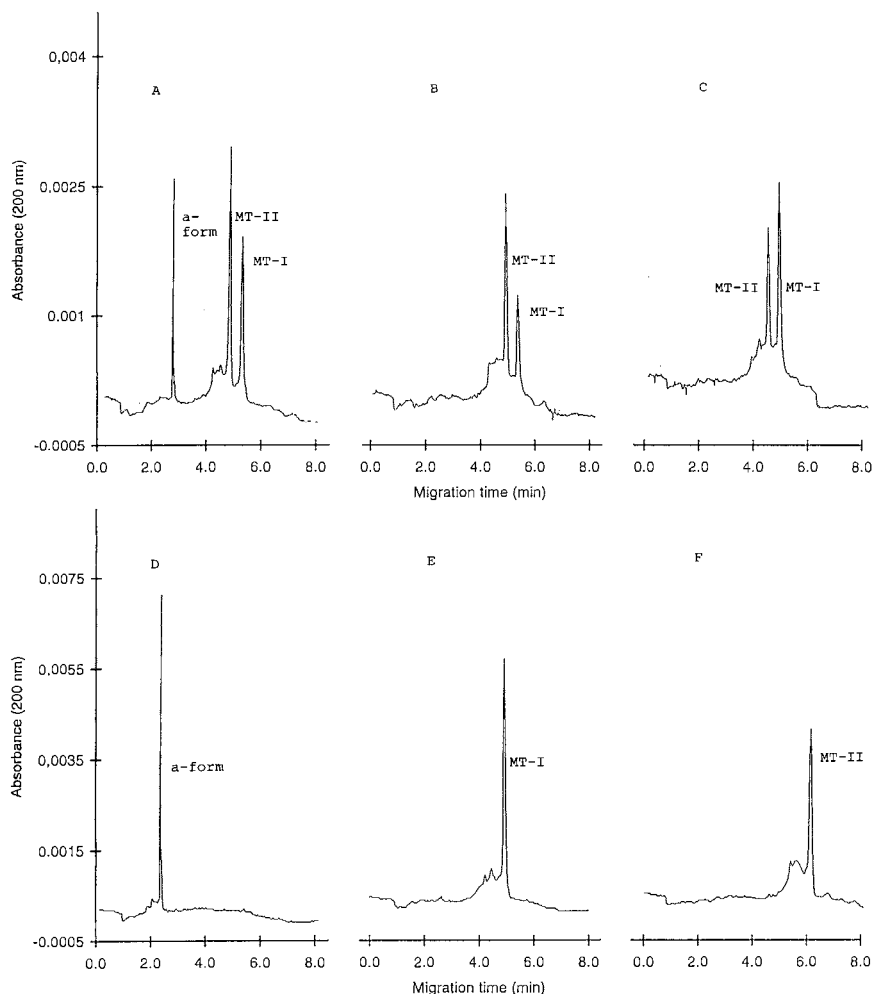

Fig. 3. Mixtures of our rat MT isoforms subjected to capillary zone electrophoresis (CZE) at 200 mM sodium phosphate, pH 2.0. The individual forms were diluted 10 times from stock solutions (see text) and mixed in equal volumes. (A) The a-form ($17 \mu\text{g ml}^{-1}$) + MT-I ($16 \mu\text{g ml}^{-1}$) + MT-II ($29 \mu\text{g ml}^{-1}$), run at 10 kV. (B) MT-I ($25 \mu\text{g ml}^{-1}$) + MT-II ($44 \mu\text{g ml}^{-1}$). (C) MT-I ($37 \mu\text{g ml}^{-1}$) + MT-II ($22 \mu\text{g ml}^{-1}$), volume 3:1. (B) and (C) run at 12 kV. (D–F) the individual a-form ($50 \mu\text{g ml}^{-1}$), MT-I ($49 \mu\text{g ml}^{-1}$), MT-II ($87 \mu\text{g ml}^{-1}$), run at 10 kV. Given concentrations represent end values after mixing.

2.6. Capillary zone electrophoresis of MT samples

The BioFocus™ 3000 Capillary Electrophoresis System with Spectra Software version 3.00, Integration Software version 3.01 and BioFocus Capillary Cartridge, 17 cm \times 25 μm I.D., 375 μm O.D., polyacrylamide coated (12.5 cm to the detector window), from Bio-Rad Laboratories, Life Science Group, Richmond, CA., were used for MT analysis.

The lyophilized a-peak sample prepared in our laboratory was diluted in 200 μl aq. dest., the MT-I sample in 500 μl aq. dest and MT-II in 1 ml (stock solutions). These samples were again diluted 1:9 in aq. dest. before CZE. The commercial Sigma reference samples of rabbit (lot 93H9559, new lot 44H9568) and horse MT (lot 73H9544), claimed to be essentially salt free, were dissolved in 10 mM Trizma pre-set crystal buffer at pH 9.1 to a final concentration of $180 \mu\text{g ml}^{-1}$. Further

Fig. 4. Separation of mixed samples of horse and rat MT isoforms by CZE in 200 mM sodium phosphate, pH 2.0 at 10 kV. (A) Commercial horse MT preparation alone ($180 \mu\text{g ml}^{-1}$) (rat isoform mixture alone shown in Fig. 3), (B) horse MT ($90 \mu\text{g ml}^{-1}$) + rat MT ($93 \mu\text{g ml}^{-1}$), (C) horse MT ($90 \mu\text{g ml}^{-1}$) + the individual rat a-form ($25 \mu\text{g ml}^{-1}$). Given concentrations represent end values after mixing.

Fig. 5. Separation of mixed samples of rabbit, rat and horse MT isoforms by CZE in 200 mM sodium phosphate, pH 2.0 at 10 kV. (A) Commercial rabbit MT preparation alone (old lot 93H9559) ($180 \mu\text{g ml}^{-1}$), (B) rabbit MT ($90 \mu\text{g ml}^{-1}$) + rat MT ($93 \mu\text{g ml}^{-1}$), (C) rabbit MT ($90 \mu\text{g ml}^{-1}$) + horse MT ($90 \mu\text{g ml}^{-1}$). Given concentrations represent end values after mixing.

dilutions of the samples were done in aq. dest. The MT samples were kept as stock solutions at -70°C . Samples were mixed by volume ratio 1:1, except for rat MT-I and MT-II which were also mixed 3:1 (Fig. 3C).

All CZE measurements were performed in 200 mM sodium phosphate at pH 2.0 ($19.6 \text{ g H}_3\text{PO}_4$ diluted

in aq. dest., titrated by 1 M NaOH to pH 2.0 and then aq. dest. to 11). The experiments were done at constant voltage (10 or 12 kV) giving a maximum current of $55 \mu\text{A}$ in the capillary. Detection was performed at 200 nm. The cartridge and the carousel were thermostated at 20°C by the Peltier thermoelectric cooling system with Fluorinert™ liquid.

Fig. 6. Stability of the commercial rabbit MT preparations kept under atmospheric conditions, pH 9.1 at room temperature and measured by CZE in 200 mM sodium phosphate, pH 2.0. (A) Old lot (93H9559), 65 h (old lot, 0 h shown in Fig. 5A), (B) old lot, 60 days, (C) new lot (44H9568), 0 h. The b-form is clearly distinguished from the old lot, not in the new lot. In (B) peaks are merged. (A) and (B) run at 12 kV, (C) run at 10 kV.

All samples were applied hydrodynamically under pressure (20 psi \times s) and analysed using polarity from the positive to the negative electrode. The important washing procedure between each single run was as follows: 15 s with 50 mM H_3PO_4 at pH 1.85; 10 s with electrophoresis buffer (see above); 10 s with 0.25 mM NaOH and finally electrophoresis buffer for 15 s.

3. Results and discussion

Fig. 1A shows that freshly purified MT after anion exchange chromatography on the DEAE-Sephadex A-50 column, monitored at 254 nm, elutes as three peaks. When peak material was tested for ^{109}Cd binding affinity (Fig. 1B), it turned out that the second and third eluting peak contained MT-I and MT-II, respectively. The non metal binding material (Fig. 1) eluting at refractive index of 1.3333 in the Tris buffer gradient, thereby appearing in front of the two MT isoforms, was designated the a-form.

Our rat MT preparations gave three individual bands on Coomassie stained SDS polyacrylamide and native gels (Fig. 2). Both gel systems separated the two common MT isoforms with the I

form running ahead of the II form. The faint band appearing in front of these two isoforms may correspond to an unknown protein discovered previously in the MT-II fraction by Beattie et al. [12] and assumed to be hemoglobin. This band may, however, represent a precursor of active metal binding MT [3]. The functional studies represented by Western blotting, the autoradiography data (Fig. 2, lanes 3–6) as well as the ^{109}Cd binding study shown in Fig. 1B, show that MT-I and MT-II isoforms are only functionally capable of metal binding, not the material in the faint band. The metal binding in this band in lane 6 is probably unspecific caused by presence of the Cd isotope in excess.

When MT samples isolated in our experiments on the DEAE-Sephadex A-50 column were pooled and run through the CZE system, three peaks were seen (Fig. 3A). Runs of mixtures of MT forms in different proportions clearly demonstrates that the first eluting peak in the CZE electropherogram at low pH corresponds to the a-form, the second to MT-II and the third peak to the MT-I isoform (Fig. 3A–C). In addition to the running voltage, the positions of the various MT forms in the electropherogram are largely dependent on ionic strength and pH, at acidic pH the

MT-II form is more positively charged than the MT-I form. In separate runs of individual MT forms, as shown in Fig. 3E, F, MT-I migrates faster than MT-II in spite of the higher charge of the latter. This is explained by the higher ionic strength of the MT-II sample, being eluted at a higher salt than MT-I in the anionic exchange gradient (Fig. 1A). When the MT samples are mixed and thereby run under equal conditions, as in Fig. 3A–C, MT-II migrates faster than the MT-I form.

Further experiments to determine the content of the a-peak were not carried out. It is, however, unlikely that it contains low molecular weight sulphhydryls due to improper heat treatment, as is suggested from the work of Olafson and Olsson [21]. Such species are removed when selecting the MT containing fractions from the Sephadex G-75 column prior to further processing on the ion exchange column. In the commercial rabbit MT

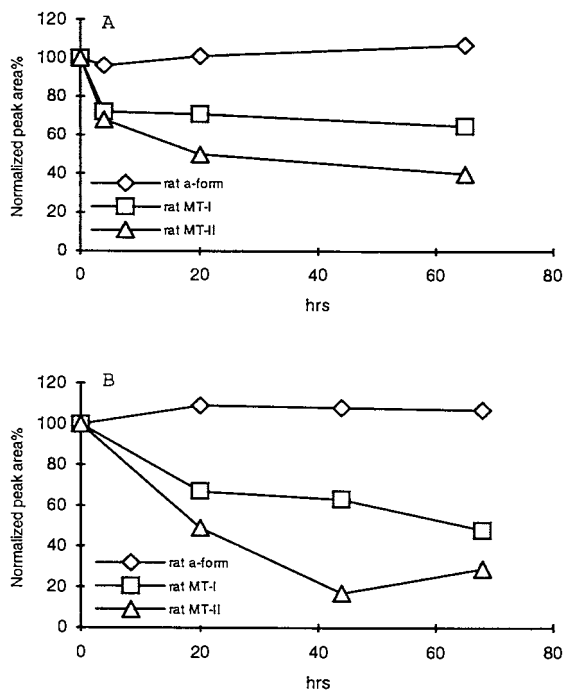

Fig. 7. Stability of the rat MT isoforms kept under atmospheric conditions, pH 9.1 and measured by CZE in 200 mM sodium phosphate, pH 2.0 at 12 kV. (A) Room temperature at 0, 4, 20 and 65 h, (B) refrigerated at 5°C at 0, 20, 44 and 68 h. Each point gives the mean of two or three individual runs.

Fig. 8. Regression analysis of individual isoforms for the rabbit MT preparation (old lot 93H9559) under atmospheric conditions, pH 9.1 and room temperature measured by CZE in 200 mM sodium phosphate, pH 2.0 at 10 kV covering the concentration range of 1.4–180 $\mu\text{g ml}^{-1}$. Migration time and area reproducibility of $\pm 2\%$ was observed. Achieved regression of normalized peak areas ($\text{mV} \times \text{s}/\text{migration time}$, see text) was $r^2 = 0.99896$ for the b-form, $r^2 = 0.99931$ for MT-II, $r^2 = 0.99805$ for MT-I and $r^2 = 0.99903$ for total MT. Individual points represent the mean of three separate runs.

preparation used in the present work the a-form could only be seen in the old lot (lot 93H9559) at concentrations above 500 $\mu\text{g ml}^{-1}$ MT. In a recently purchased preparation (new lot 44H9568) this form could be seen at 200 $\mu\text{g ml}^{-1}$. The a-form was also present in MT preparations studied by others [9,10]. We believe that the presence of this form in MT samples depends on the ability of picking only the MT-I and -II containing fractions in the purification procedure. The isoelectric focusing used as the final step in the isolation of the rabbit liver Sigma MT preparation [22] seems to be more effective in achieving this than the anion exchange procedure used for the Sigma horse kidney MT separation [23,24]. A proper interpretation of the CZE electropherograms of MT samples should include the functionality of separated forms.

When the commercial horse MT preparation and our rat MT preparations were pooled prior to CZE, marked co-migration between peaks was observed (Fig. 4A–C), with only minor differences confined to the a-peak and the MT-II peak. Corresponding results for rabbit commercial and rat MTs as well as for commercial rabbit and horse MT preparations, are shown in Fig. 5A–C with minor differences related only to the MT-I

peak. Co-migration at this level therefore seems to be related to mutual factors between isoforms, no further studies were carried out. It can also be seen that the rabbit MT preparation had one dominant form, marked as the b-form in Fig. 5A, which did not concur with any of those present in horse and rat MTs. In Fig. 6A,B it is shown that this form developed gradually with time at pH 9.1 under atmospheric conditions at room temperature. The electropherogram of the new lot of rabbit MT, however, did not show this peak (Fig. 6C), indicating the rabbit b-form develops spontaneously during storage. In recent work on rabbit MT isoforms by Virtanen et al. [6] their major g-peak was characterized as a modified isoform, which probably corresponds to the b-form described in the present work. A corresponding peak is also seen in electropherograms from other workers [8–10] having run rabbit MT preparations using the CZE technique at acidic conditions. When Fig. 3A is compared with Fig. 5B, it is interesting to note that a small indication of the b-form presence was also seen in our rat liver MT preparation as the part ahead of the MT-II peak in Fig. 3A.

By using our CZE technique, stability of the freshly prepared rat MT preparations were tested at pH 8.5 under atmospheric conditions at room temperature and refrigerated at 5°C over a period of 65 and 68 h, respectively. Analysis of aliquots showed that the a-form did not degrade in contrast to MT-I and -II (Fig. 7). Under these conditions the I form was more stable than the II form. Corresponding results (not shown) were found for the rabbit (pH 9.1) and horse MT (pH 9.1) preparations. At tested levels the a-form was not found in rabbit. The observation that the MT-I form is more stable than the MT-II form is surprising [25]. At pH 2.0, however, at which the stability measurements were performed, metal is stripped from the protein resulting in apoprotein (apothionein) formation. Under these conditions the MT-II form may be more vulnerable than the MT-I form. During degradation experiments, new peaks were not observed in our rat MT forms.

The regression analysis of individual MT forms in rabbit covering the range 1.4–180.0 $\mu\text{g ml}^{-1}$ is shown in Fig. 8. The observed detection limit for

MT preparations below 5 $\mu\text{g ml}^{-1}$ corresponds to the sensitivity level found by others [8,12,13,15]. Other MT preparations studied in the present work gave similar results (not shown). The concentration of the individual isoforms in the rat liver MT preparations was determined by measuring the total and relative percentage levels of the individual forms. These values were then related to the measured total level of forms in the horse Sigma preparation, for which the MT concentration was given by the supplier. This preparation contained similar isoform types as found in rat liver (Fig. 4). In the commercial rabbit preparation the a-form was seen only at higher concentrations, and it contained considerable amounts of the b-form.

It is important to keep in mind that when the sample is applied hydrodynamically (pressure) to the CZE capillary as in this work, the separated forms move through the detector window at different speeds. Peak area is a better measure for actual amounts than peak height when using different running conditions, i.e. voltage and unequal salt concentration in the samples. To compare peak areas in stability testing and regression, however, they must be divided by the corresponding migration times to give normalized values (Fig. 8) [26,27].

Abstract

This paper attempts to link the kinetics of Cd and metallothionein turnover in the intertidal marine snail *Littorina littorea*. The results demonstrate that the turnover of metallothionein is tissue dependent. Metallothionein has an estimated half-life of 69 and 160 days in the gills and kidney, respectively. The half-life could not be calculated for metallothionein in the digestive gland and is probably much longer than the other two tissues. Cadmium elimination from the gill and kidney is considerably slower than the respective metallothioneins (half-life in excess of 300 days) indicating closed cycling of the metal in these tissues. In contrast, cadmium levels in the digestive gland continue to increase during the detoxification period reflecting some remobilization from other tissues. Metallothionein turnover is extremely slow in *Littorina* when compared with mammals and other bivalve molluscs: even though metallothionein degradation is measurable in some gastropod tissues, the released cadmium may induce de novo metallothionein synthesis to which cadmium becomes resequenced. The slow metallothionein turnover rates and the lack of significant cadmium excretion testify to the relatively stable nature of the cadmium-metallothionein complex in this invertebrate. © 1998 Elsevier Science B.V. 1. Introduction

Various marine invertebrates, including several species of gastropod molluscs, have been proposed as indicators of metal contamination, due to their ability to reflect the bioavailability of enhanced environmental metal levels [1]. Exposure of these organisms to elevated concentrations of some essential and non-essential metals can

induce the synthesis of low molecular weight, cysteine-rich, metal-binding proteins known as metallothioneins (MT) [2]. Consequently these proteins are regarded as potentially specific biological-response markers for metal pollution and measurement of MT's are included increasingly in biomonitoring programmes. However, it is necessary to identify suitable marine organisms or specific tissue preparations and to validate responses to metal contamination before widespread field application of the assay can be undertaken. It was

* Corresponding author.

demonstrated in earlier studies that there is sometimes a marked interspecific variability in the net production of metallothionein, even among members of the same phylum [3]. Consequently, the properties and functions of these proteins have often yet to be identified and characterised in marine invertebrates.

Of all the properties which influence the expression of MT induction in marine invertebrates exposed to metals, the turnover rates of metallothioneins must be considered vitally important. Therefore, in order to understand the significance of MT in metal metabolism and detoxification, estimates of turnover parameters are desirable, particularly when attempting to use concentrations of the protein as a marker of the biological effects of metal contamination.

The common periwinkle *Littorina littorea* is considered to be a good bioindicator of metal contamination, particularly for non-essential metals such as cadmium, because metal levels in its tissues usually reflect metal levels in the environment [4–8]. Metals are usually localised in particular tissues (e.g. gill, kidney, mantle and digestive gland) and their presence and concentration is largely dependent on the quantity and nature of the ligands available at the cellular level [5]. Intracellular partitioning of cadmium is, therefore, somewhat variable among tissues, nevertheless a significant proportion of cadmium is always present, for all major tissues, in the metallothionein pool [7,9,10]. The presence of metallothionein in different tissues of *L. littorea* has now been reported in a variety of studies, following exposure to a range of cadmium concentrations in the laboratory, or in individuals collected from the field [6,7,9–12].

We have shown previously, by measuring metallothionein concentrations in component tissues of Cd-dosed *L. littorea* using differential pulse polarography, that the induction of metallothionein synthesis is quantitatively tissue dependent [13]. Thus, metallothionein levels increase by 3- and 4-fold respectively in the kidney and gills of *L. littorea* exposed to cadmium ($400 \mu\text{g Cd l}^{-1}$ for 1 month): However, in the digestive gland, net increases in metallothionein concentration cannot be detected even at these high Cd exposure levels,

due to inherently high levels of constitutive metallothionein in this tissue. Clearly, individual tissues from this gastropod possess significantly different capacities to handle the excess of metals, following contamination [9,10].

The digestive gland contains two thirds of the total metallothionein content in *L. littorea* and can store correspondingly large amounts of metals. Intuitively it would seem a prime candidate for biomarker studies but the poor net response to Cd and the presence of interfering high molecular weight thiolic proteins reduce the value of this tissue preparation for the direct determination of metallothionein concentrations [9]. Although some interfering high molecular weight thiolic proteins are also detected in gills, these are easier to eliminate and subsequently the induction of metallothionein in this tissue (up to 4-fold) is found to be proportional to Cd-exposure, suggesting that gill-MT concentrations can be used as a biological response [10]. Metallothionein determinations in the kidney (an important site of Cd accumulation) suffer from few interferences from other heat-stable proteins and can also be used to quantify biological response to sublethal levels of cadmium on a routine basis [10]. Metallothionein concentrations of $3\text{--}4 \text{ mg g}^{-1}$ (measured by differential pulse polarography, using rabbit metallothionein standards) are typical for kidneys of winkles collected from sites free of cadmium contamination. These concentrations reach $10\text{--}12 \text{ mg g}^{-1}$ following Cd-exposure [10].

The absence of significant cadmium excretion in *L. littorea* [7] seems to indicate that the metabolism of the cadmium-metallothionein complex in winkles is similar to that observed for *Mytilus edulis* [14]. However, no information is available on the turnover rates of metallothionein in *Littorina* or any other marine gastropod. Indeed there is very little information on metallothionein turnover in marine invertebrates, generally. The only other available molluscan data concerns bivalves, where half-lives in *M. edulis*, (whole) for example are of the order of 25 and 300 days, for MT and Cd respectively, following exposure to cadmium [14]. Turnover rates of two metallothionein isoforms in gills of Cd-exposed oysters *Crassostrea virginica* are somewhat quicker (half-lives up to 7 days; [15]).

Turnover rates for metallothionein have been measured in liver and kidney of mammals [16–24] and fish [25,26] and generally appear to be more rapid than most invertebrates, although this may depend on the associated metal. The turnover rates of metallothioneins induced by exposure to cadmium are slow by comparison with those induced by copper or zinc.

With a view to improving our interpretation of biological responses in aquatic biota to pollutant metals, this paper attempts to determine metallothionein turnover in the gills, digestive gland and kidney of the gastropod *L. littorea* exposed to Cd. Experiments were devised to determine the half-life of MT and its associated cadmium in the tissues of *Littorina*, in vivo, by following the incorporation of cadmium and [³⁵S]-cysteine into metallothionein, and observing the subsequent loss of both protein and metal.

2. Materials and methods

L. littorea (shell length 20–22 mm) were collected in April 1990 from Jennycliff, south west England, and acclimated in aerated seawater, salinity 34‰, at 15°C for 1 week prior to the experiments. Subsequently, groups of 50 animals were held in 5 l aquaria and exposed to a cadmium concentration of 400 µg l⁻¹. Although this is considerably above the concentrations likely to be encountered at all but the most highly contaminated of field sites, it was chosen, on the basis of earlier experiments, to ensure a sufficient degree of MT induction against which turnover rates could be adequately determined. Control groups of winkles were maintained in clean seawater (37.2 ± 3.6 ng Cd l⁻¹). Water in each tank was changed twice each week. Losses of Cd from seawater were not significant during this period.

Controls and individuals exposed to cadmium for 2 weeks were anaesthetised in a solution of magnesium chloride (75 g l⁻¹) for 1–3 h before injecting 2.5 µCi of L-[³⁵S]-cysteine, directly into the relaxed foot. The winkles were returned to the tanks from which they had been taken and exposure to cadmium (or uncontaminated seawater in the case of controls) was continued. Four days

after injection (the time taken to allow L-[³⁵S]-cysteine to equilibrate in tissues) the cadmium-exposed *L. littorea* were divided into two sub-groups; one was kept in the same (400 µg l⁻¹) cadmium concentration ('exposed' group) and the other was transferred to clean seawater ('detoxified' group).

Controls, cadmium-exposed and 'detoxified' winkles were sampled for analysis 4, 11, 18, 25 and 32 days after injection with ³⁵S-cysteine. Additional samples of 'detoxified' winkles were sampled after 84 and 115 days of injection. Snail shells were removed after careful cracking in the plastic-covered jaws of a small vice and digestive gland, gills and kidney from six animals were dissected out and pooled at each sampling. Each pooled tissue sample was weighed and homogenised in three volumes of ice-cold 0.02 M Tris-HCl (pH 8.6) buffer and 3–5 ml taken for centrifugation at 30 000 × g for 1 h at 4°C. The supernatant cytosol was separated from the pellet for size-exclusion gel chromatography in order to identify and quantify major ³⁵S-cysteine-containing pools (including metallothioneins).

2.1. Measurement of radio-isotope uptake and loss

The total ³⁵S activity in homogenates of the digestive gland, gills and kidney from winkles injected with labelled cysteine was determined by digesting an aliquot of 0.2 mg of the homogenate overnight in 1 ml of tissue solubilizer (Optisolv). Subsequently 14 ml of liquid scintillant (Optiphase 'MP') was added and samples counted in a LKB Wallac 1215 Rackbeta II scintillation counter. Aliquots of the cytosol (0.5–1 ml), described in the previous section, were chromatographed on a Sephadex G-75 column (1.5 × 60 cm) and eluted with 0.02M Tris-HCl (pH 8.6) to separate the major ³⁵S-containing components by virtue of their molecular size. The ³⁵S activity of each column fraction was determined by adding 14 ml of liquid scintillant to 1 ml of each fraction and counting as described above. The ³⁵S activities were expressed as disintegrations per minute (DPM) as a function of the original dry tissue weight (DPM g⁻¹) and were corrected

for quenching, decay and background. Counting efficiency was $98 \pm 3\%$. The coefficient of variation of counting (analytical precision) was $< 5\%$.

2.2. Cadmium analysis

Cadmium analysis was performed on nitric acid-digested subsamples of the homogenate and cytosol of the digestive gland, gills and kidney of *L. littorea*, using atomic absorption spectrophotometry (Varian AA20).

3. Results

3.1. Incorporation of L-[^{35}S]-cysteine into the metallothionein pool of different tissues, and subsequent degradation of MT

Four days after injection of L-[^{35}S]-cysteine into the foot of the winkles most of the ^{35}S activity (60–80%) was found in the cytosol of the gills, kidney and digestive gland of control, cadmium-exposed and cadmium-detoxified winkles.

Following fractionation on a Sephadex G-75 column most of the ^{35}S present in the cytosol of these tissues from control winkles eluted near the void volume of the column (fractions 10–15-mol wt% $> 75\,000$ Da-HMW protein pool-) and around the total volume of the column (fractions 30–45-mol wt% < 3000 Da-VLMW pool, containing amino-acids, including cysteine). This pattern was maintained throughout the experiment and the absence of any inducible cysteine-rich pool of intermediate molecular weight indicates negligible synthesis of metallothionein in uncontaminated individuals.

The ^{35}S elution profiles of the cytosol from tissues of cadmium-‘exposed’ and cadmium-‘detoxified’ winkles are shown in Fig. 1. In contrast to controls, there was an additional pool (eluting between fractions 20–25) with an apparent molecular weight of about 10 000–20 000 Da, which corresponded to the metallothionein-containing pool in cadmium-‘exposed’ and cadmium-‘detoxified’ winkles (MT has molecular weight variants of 10 and 20 KDa in this species, though to represent monomeric and dimeric forms;

[6,27]). The ^{35}S cysteine activity in this pool tended to increase in the gill (Fig. 1A) and kidney (Fig. 1C) of the ‘exposed’ group, largely at the expense of what is assumed to be free ^{35}S cysteine in the VLMW pool which decreases over time. These results are consistent with MT induction in gill and kidney tissue. In contrast, changes in digestive gland were far less pronounced (Fig. 1E,F) signifying only minor incorporation of labelled cysteine into newly synthesised MT in this tissue.

The summed ^{35}S activity in pooled metallothionein-containing fractions (20–25) were calculated for each tissue, in control, cadmium-‘exposed’ and cadmium-‘detoxified’ *Littorina*. These results, plotted against time, are shown in Fig. 2. Following the first 2 weeks of cadmium-treatment, the rapid incorporation of injected ^{35}S -cysteine into gill metallothionein of the ‘exposed’ group clearly demonstrates the speed and scale of MT induction: This is represented by a 6-fold ($P < 0.01$) increase in ^{35}S -labelled MT levels in contaminated gill tissue, relative to controls (Fig. 2A). Although values subsequently fluctuated over time there was little additional increase in gill-MT in Cd-dosed *Littorina* even after a further 32 days exposure (Fig. 2A). The ^{35}S activity in the gills of ‘detoxified’ *Littorina* indicated a net loss of 34% following 32 days in clean seawater ($P < 0.01$). However in view of the scattered nature of the data points over this period some uncertainty should be attached to the estimated half life. Results do however indicate the slow nature of the turnover. No significant change with time was detectable in the (small) metallothionein pool from gills of controls (Fig. 2A).

A similar pattern with a 7-fold increase in MT levels in exposed animals relative to controls ($P < 0.01$) was observed in the kidney (Fig. 2B). Though even greater fluctuations in ^{35}S levels were detected in the metallothionein pool of Cd-treated individuals throughout the experimental period. Nevertheless, the kidney of ‘detoxified’ individuals had lost only 21% of the ^{35}S activity originally associated with metallothionein after 32 days, indicating again slow and somewhat erratic degradation of the protein. A small increase in ^{35}S -labelled metallothionein was observed in the

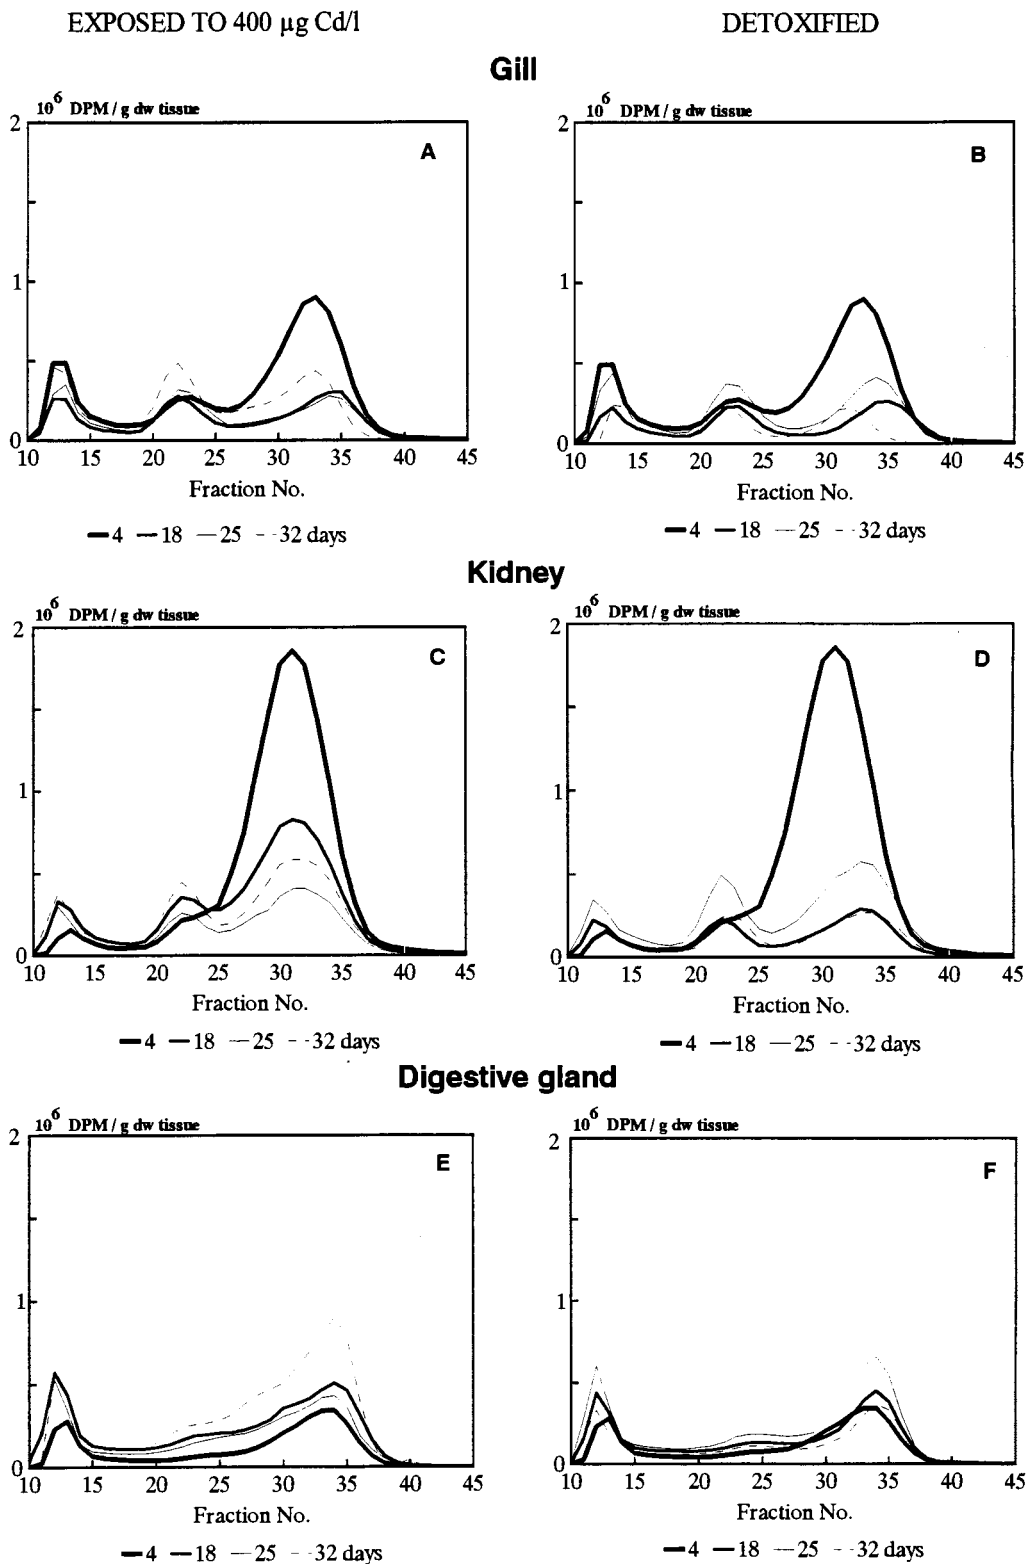

Fig. 1. *L. littorea*. Chromatographic elution profiles of ³⁵S of the cytosol of the gill (A,B), kidney (C,D) and digestive gland (E,F) of exposed and detoxified winkles at different times after injection. Pooled samples of six individuals.

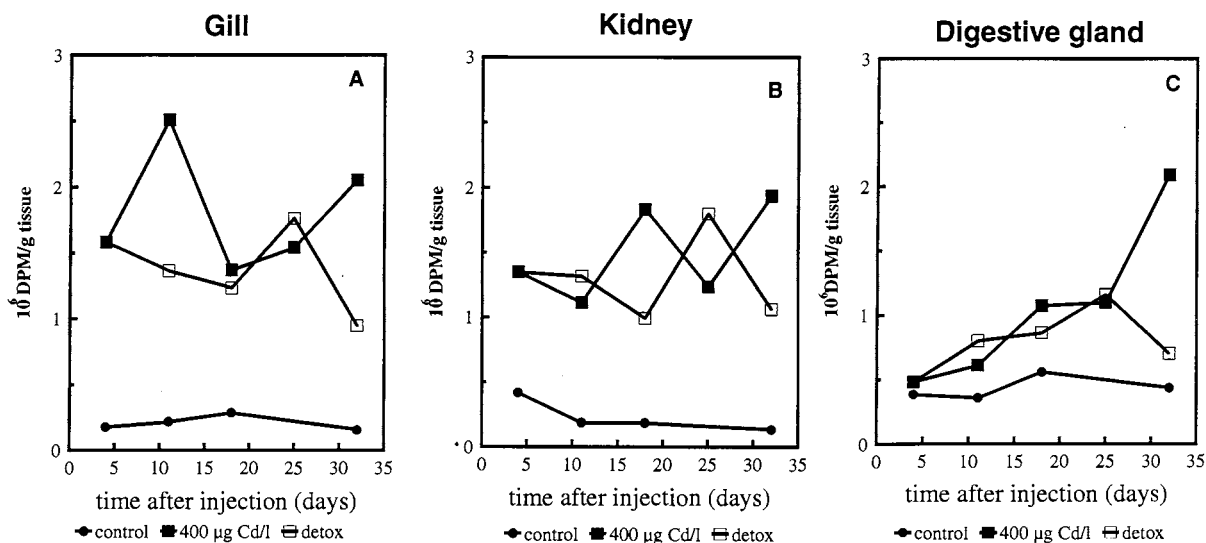

Fig. 2. *L. littorea*. Incorporation of ^{35}S into the metallothionein pool (fraction 20–25 see Fig. 1) of control, Cd-exposed and Cd-detoxified winkles—gills (A), kidney (B) and digestive gland (C)—at different times after injection of the isotope. Tissue pooled from six individuals.

‘exposed’ winkles during this period. No significant changes were detected in controls (Fig. 2B).

As indicated in Fig. 1E,F, the incorporation of L-[^{35}S]-cysteine into the metallothionein fraction of the digestive gland was initially much less pronounced when compared to the gill and the kidney. This is reflected in the relatively small increases ^{35}S -labelled MT in digestive gland of the ‘exposed’ group, relative to controls, following the initial 2 week period of contamination (initial data points in Fig. 2C). Nevertheless activity in this pool continues to increase in the digestive gland of ‘exposed’ individuals ($P < 0.05$), approaching the levels found in the gills and kidney after a further 32 days exposure (Fig. 2C). Interestingly, in the digestive gland of cadmium-‘detoxified’ winkles, there was also a gradual increase in metallothionein ^{35}S activity, until day 25 ($P < 0.05$). Thereafter there are indications that ^{35}S -MT may have been dropping by day 32, although, overall, no net loss was observed when compared with the levels present in the digestive gland at the start of the detoxification period. Again, no significant changes were detected in the activity in the digestive gland of controls (Fig. 2C).

Results depicting degradation of MT in gills, kidney and digestive gland of *Littorina* during longer-term depuration are plotted in Fig. 3 A,B and C, respectively. These semilogarithmic plots of ^{35}S activity in the metallothionein pool of tissues from detoxified winkles have been used to establish the rate of turnover (half-life) of metallothionein which is clearly tissue dependent. Thus, the decrease in the ^{35}S -labelled MT content of both the gills, and, to a lesser extent, kidney, is shown to be statistically significant (ANOVA, $P < 0.05$) following the removal of Cd contamination whilst this was not the case in the digestive gland (ANOVA, $P > 0.05$). The half-lives of metallothionein in the gills and kidney were calculated to be 69 and 160 days, respectively. In contrast the minimal turnover of MT ^{35}S in the digestive gland of cadmium-detoxified winkles prevented the calculation of a protein degradation rate in this tissue. Bearing in mind the variable and limited nature of the data, turnover times of the protein are at best estimates. Nevertheless they represent one of the few attempts at direct quantification in molluscs and testify the nature of the slow turnover in the kidney and gills, and negligible degradation in digestive glands. These

Fig. 3. *L. littorea*. Loss of ³⁵S from the metallothionein containing pool of gills (A), kidney (B) and digestive gland (C) during a 4 month detoxification period. Pooled samples of six individuals.

observations carry important implications for monitoring schemes.

3.2. Accumulation and elimination of cadmium in *L. littorea*

Cadmium concentrations in the gills, kidney and digestive gland of the 'detoxified' group of *Littorina* are shown in Fig. 4, which includes both exposure and depuration phases.

Total, cytosolic and MT-bound cadmium concentrations present in the tissues of *L. littorea* at the end of each phase (after 18 days of exposure and 126 days of depuration), and in controls, are summarised in Table 1. The pattern of total cadmium concentrations in tissues of cadmium-exposed winkles was: kidney > digestive gland > gills. After 126 days of depuration this ranking changed to: digestive gland > kidney > gills (see Table 1). The uptake rates for total and cytosolic cadmium in these tissues, during exposure, are shown in Table 2 and are in agreement with earlier results [7,9].

The variations in total and cytosolic cadmium concentrations in *Littorina* tissues (Fig. 4) contrast somewhat with protein (MT) kinetics. During detoxification/depuration, the loss of cadmium (total and cytosolic) is extremely slow in the gills (Fig. 4A) and the kidney (Fig. 4B) despite

the apparent degradation of MT (described above). In the kidney, large Cd fluctuations of a possible cyclical nature are evident at the end of exposure/beginning of depuration and may signify attempts at Cd homeostasis (Fig. 4B), though this has yet to be confirmed. During the same 126 days depuration period, total and cytosolic cadmium concentrations increased in the digestive gland, by 19 and 24%, respectively (Fig. 4C), suggesting that cadmium which has been lost from other tissues, such as kidney and gills, albeit slowly, may be transported and held here, even after the exposure to cadmium had stopped.

Thus, after 4 months of 'detoxication', following Cd-exposure, winkles still retained much of the original accumulated body burden (95%). The half-life for cadmium in the kidney was calculated to be approximately 300 days. Loss from the gills was not measurable with sufficient accuracy to derive a half-life, whilst in the digestive gland Cd continues to increase slightly, confirming its role as the major storage organ for the metal.

The gel chromatographic profiles of cadmium in the cytosol of the gills, kidney and digestive gland of *L. littorea* revealed that even after 4 months of depuration most of the cadmium was bound to metallothionein in each of these tissues (60, 76 and 54%, respectively; Table 1).

Table 1
L. littorea; cadmium distribution in tissues of winkles exposed to 400 $\mu\text{g Cd l}^{-1}$ for 2 weeks and subsequently depurated for 126 days, together with controls

Tissue	Control			Exposure—day 18			Depuration—day 126					
	Total Cd	Cytosolic Cd	Cd-MT	Total Cd	Cytosolic Cd	Cd-MT	Total Cd	Cytosolic Cd	Cd-MT			
	$\mu\text{g g}^{-1}$	$\mu\text{g g}^{-1}$	(%)	$\mu\text{g g}^{-1}$	$\mu\text{g g}^{-1}$	(%)	$\mu\text{g g}^{-1}$	$\mu\text{g g}^{-1}$	(%)

Fig. 4. *L. littorea*. Total and cytosolic cadmium concentrations in the gills (A), kidney (B) and digestive gland (C) following exposure to $400 \mu\text{g Cd l}^{-1}$ for 18 days and subsequent depuration in clean seawater. Pooled samples of six individuals

4. Discussion

The present study confirms that the rates of synthesis and degradation of Cd-induced metallothionein in *L. littorea* are tissue dependent.

The concentrations of metallothionein-incorporated ^{35}S -cysteine in tissues of unexposed *L. littorea* followed the pattern: digestive gland > gill > kidney, with the level of ^{35}S activity in the MT-pool of digestive gland being twice that of the other tissues. Similar, relative concentrations were observed for baseline metallothionein concentrations determined by differential pulse polarography and are indicative of a high level of constitutive MT in the digestive gland, possibly associated with the regulation of metal during

metabolism of the Cu-containing blood pigment haemocyanin [9,10,27].

In the gills and kidney of *L. littorea* the incorporation of the L- ^{35}S -cysteine label into metallothionein increased significantly (6-fold and 3-fold, respectively) when the animals were treated with cadmium, whilst only a small increase (10%) was detected in the digestive gland. Clearly cadmium strongly induces the synthesis of metallothionein in both the gills and kidney. The respective 6- and 3-fold increase in the ^{35}S -MT content in the gills and kidney of cadmium-exposed winkles, relative to controls, is remarkably similar to the increases in metallothionein concentrations, determined by differential pulse polarography [9,10]. The lack of response of the digestive gland is also a consistent feature. These data therefore validate the application of two widely differing techniques in measuring relative induction of metallothionein.

The slow linear increase in the ^{35}S -labelled MT pool in the digestive gland of 'detoxified' winkles, which is maintained for 25 days after Cd exposure is removed, indicates that metallothionein synthesis may continue here as a result of remobilization of cadmium from other tissues of *L. littorea*, and that the Cd-metallothionein complex formed in

Table 2
L. littorea; cadmium accumulation rates in different tissues during exposure of the winkles to $400 \mu\text{g Cd l}^{-1}$ for 18 days

	Cadmium ($\mu\text{g g}^{-1} \text{d}^{-1}$)	
	Total	Cytosolic
Kidney	6.47	4.68
Gill	3.98	2.40
Digestive gland	9.14	6.84

the digestive gland is extremely stable. A similar phenomenon may explain observations by Olafson [22] who reported that, in mice intestine, a tissue where metallothionein induction is very slow, the incorporation of ^{35}S -cysteine continues after exposure to zinc is stopped.

The disappearance of ^{35}S -labelled metallothionein from gills and kidney of detoxified winkles became significant only after animals had been maintained in Cd-free seawater for 25 days, illustrating that the turnover of MT in these tissues, though faster than the digestive gland, is far from rapid. The half-life of metallothionein in the gills and the kidney of *L. littorea* was calculated to be 69 and 160 days, respectively. Breakdown of metallothionein could not be detected in the digestive gland during the 4 month depuration period.

Cd depuration in these molluscs appears to be even slower than MT turnover, at least in gill and kidney tissue, and implies recycling. In kinetic terms the linear nature of cadmium accumulation in *L. littorea* [7–10] as in many other molluscan species such as oysters and mussels [14,28–32,36,37,39–41] is explained by the extremely slow rate of elimination of cadmium. However, Marigomez and Ireland [8] have observed an exponential loss of cadmium from the whole soft tissues of *L. littorea* exposed to 0.5 and 1.25 mg Cd l^{-1} (higher doses than used in the present study) and determined a half-life for the metal of 69 and 115 days, respectively, at these concentrations. Among bivalves, the half-life for cadmium ranges from 300 days in the whole soft tissues of *M. edulis* [14] to 70 days in the clam *Macoma balthica* [27]. The more rapid elimination of Cd in the latter species may be due to a lack of inducible MT, and hence less effective Cd-binding [27].

In the present work cadmium was accumulated in the gills during exposure but was not lost during the depuration period. Similar results were obtained for the gills when *L. littorea* was exposed to 0.5 mg Cd l^{-1} for 27 days and depurated during 74 days [8,33]. However, an exponential decrease in gill Cd was detected by the latter authors following exposure of winkles to 1.25 mg Cd l^{-1} . Rates of cadmium elimination from gill tissues may, therefore, be related to previous ex-

posure concentrations and appear to be significant only at extreme concentrations, perhaps as normal metal binding ligands became saturated. Loss of Cd in these circumstances may again be a reflection of less effective Cd-binding and possible saturation of MT.

The calculated cadmium half-life in the kidney of *L. littorea* determined in the present study is 300 days. This half-life is of similar magnitude to the one calculated for the kidney and whole soft tissues of *M. edulis* (300 days) [14,34]. However, Marigomez [33] and Marigomez and Ireland [8] calculated shorter half-lives of 78 days and 39 days for Cd in the kidney of *L. littorea* exposed to 1.25 and to 0.5 mg Cd l^{-1} respectively, further illustrating the possible significance of exposure levels on elimination rates.

During depuration, the increase in Cd levels in the digestive gland indicates that transport occurs from other tissues of *L. littorea* such as kidney and gills. These data confirm earlier results obtained by Langston and Zhou [7] which showed an increase of 32% in total cadmium in the digestive gland, and a corresponding decrease in Cd burdens in other tissues, after depuration for 7 months.

Storage and retention of cadmium in the digestive gland of *L. littorea* clearly involves binding of the metal to metallothionein, at least in part. However, X-ray microanalytical studies have detected intracellular accumulations of cadmium and sulphur which usually take the form of membrane bound granular structures and suggests a possible link between protein- and granular-based detoxification systems [35]. Furthermore, Marigomez [33] concluded that the metabolic pathway of cadmium accumulation and elimination is related to the lysosomes of the digestive cells. To date however, these lysosomes and the intracellular granules in the basophil cells of the digestive gland are the only sites of accumulation that have been visualised to date. Between these compartments, the turnover of MT and associated metals may be influenced by a variety of physiological and seasonal variables, which may partly explain the differences in elimination rates observed between studies. Metallothionein turnover in the digestive gland of *L. littorea* was unde-

tectable in the current study supporting the view that the complex of cadmium and MT can, under certain circumstances, be extremely stable.

The fact that cadmium levels in the gills of *L. littorea* remained constant during depuration in the present study, whilst ³⁵S-labelled MT was degraded slowly, suggests that further, newly synthesised, metallothionein efficiently retains any excess, re-released Cd which is present in the cytosol. Turnover of metallothionein in the kidney (half-life 160 days) is intermediate between gill and digestive gland. Although cadmium concentrations vary considerably in the tissue following transfer of winkles to clean sea water, cadmium elimination is undoubtedly slow (half-life 300 days) relative to protein (MT) turnover, indicating possible metal re-sequestration by newly synthesised metallothionein, as indicated also in gills.

There have been few comparable studies on protein-metal kinetics in other molluscs. Nevertheless there appears to be some consistency in the reported behaviour of the Cd-MT complex, even in unrelated species. Thus, Chen et al. [16] demonstrated how, in rat liver, the levels of cadmium in the metallothionein fraction remain constant while the protein itself is metabolised. It is suggested that when the protein degrades the released cadmium immediately stimulates further metallothionein synthesis and that any 'free Cd' is quickly re-sequestered: thus Cd does not disappear with the degraded protein moiety and becomes bound to the newly synthesised protein. The same mechanism is observed in the bivalve *M. edulis* [14].

The difference between metallothionein and cadmium half-lives in *Littorina* gills and kidney therefore indicates that while metallothionein breaks down, the released cadmium is closed-cycled within the cytosol by inducing de novo metallothionein synthesis to which the metal becomes re-sequestered. The resistance of the *Littorina* to cadmium toxicity is clearly related to the efficiency with which metallothionein complexes cadmium, though the apparent stability of the Cd-metallothionein complex may result in virtually irreversible loading of tissues under certain conditions.

In conclusion metallothionein acts as a detoxifying ligand for Cd in the gills and kidney and fulfils an efficient storage/detoxification function in the digestive gland of *L. littorea*. The half-life for metallothionein is of the order of 69 and 160 days for the gills and the kidney; considerably longer in the digestive gland. These results, along with similar data obtained for the mussel *M. edulis* [14], imply that metallothionein turnover for molluscs is slow when compared with fish [25] and mammalian species [16,38]. These are important implications for Cd bio-monitoring schemes involving molluscs, since determinations of MT or Cd concentrations in tissues could reflect previous historical inputs during the life span of the individual, rather than conditions at the time of sampling. This need not be a disadvantage if, for example, an integrated picture of the recent contamination history of a site is required. Where the current situation needs to be assessed, the measurement of fluxes of Cd and MT in transplanted individuals might be more appropriate. In this context the use of injected ³⁵S-cysteine has been shown to be a viable technique in molluscs for measuring MT induction in response to Cd.

Abstract

A study on electrochemical characterisation of three isoforms of human foetal liver Zn-metallothioneins, labelled MT-0, MT-1 and MT-2, has been performed by using differential pulse polarography (DPP). Two different peaks, attributed to two different Zn complexes with metallothioneins, have been detected. The electrochemical behaviour is similar for the three studied isoforms. Studies on the addition of Cd^{2+} and Zn^{2+} as well as studies as a function of pH have been carried out. The association and dissociation equilibria of metal ions with MTs are reversible in the studied pH range. The behaviour of Zn complexes in human foetal liver Zn-metallothioneins is comparable to the Cd complexes obtained using other mammalian Cd, Zn-metallothioneins, particularly as a function of pH. © 1998 Elsevier Science S.A. 1. Introduction

Metallothioneins (MT) are ubiquitous low molecular weight proteins (~ 6000 Da). The peptidic structure bears 61 amino acids, 20 of which are cysteinyl residues. MTs are characterised by a pronounced capability of binding metal ions such as Zn, Cd, Cu, Hg, etc. [1–5].

Studies of MT properties, especially the metal complexation properties, have been performed using a wide variety of analytical methods. During the first studies in our group, the acid-base con-

stants and binding constants with metal ions for MTs were evaluated using spectrophotometric methods [6].

Voltammetric and polarographic techniques have been used for qualitative and quantitative determinations of disulphide and thiolate groups in proteins and in peptides as well as in amino acids [7]. The first systematic study on the characterisation of MTs by cyclic voltammetry was carried out by Olafson [8]. In our team, differential pulse polarography (DPP) has been used for elucidation of the electrochemical systems involved in different commercially available mammalian MTs, such as rabbit liver (RL), horse kidney (HK) and human adult kidney and foetal liver

Cd, Zn MTs. Likewise, the influence of the pH as well as of the additions of Zn and Cd, which are initially contained in MTs, on the polarographic response have been studied [9–12]. Recently, Sestakova et al. [13] have published a work on the electrochemical characterisation of metallothioneins using mercury, glassy carbon and carbon paste electrodes. DPP and voltammetry have been applied for the quantitative determination of MTs contained in different animal tissue [14,15].

The peptidic fragment, Lys-Cys-Thr-Cys-Cys-Ala (56–61) MT I (FT), a molecule intrinsic to the mouse liver MT structure, cluster α , has been taken as a simpler model for the study of complexation and ion exchange properties with cadmium and zinc. The electrochemical behaviour of the peptidic fragment, FT, in the presence of Cd and Zn is very similar to that obtained with Cd, Zn MTs, particularly with respect to the variation of the pH under the same given experimental conditions [16–20]. Likewise, in recently published works, the fact that Zn(II) complexed with FT exhibits two possible forms of co-ordination, like Cd(II) complexes with FT [18,19] has been reported.

In our team, several studies on the characterisation of HK and RL MTs and FT (from Sigma) by HPLC [21,22] and capillary electrophoresis [23] have been performed.

The structure of MTs is intricate and the proposed characteristics determined by several research teams depend on the origin of the animal tissue from which the MTs are isolated. Although several articles have been published about the electrochemical behaviour of MT, most of them describe the protein complexed with Cd or Cd and Zn. In this work, the MT is isolated from human foetal liver, a very important tissue for the developing foetus. The human foetal liver (HFL) MT obtained is not only unique because of its natural origin without any further *in vitro* induction and consequently containing merely Zn, but also because of the occurrence of three isoforms therein. Besides MT-1 and MT-2, the two widespread isoforms, differing from each other in an uncharged amino acid residue at position 11 for MT-1 in comparison to a negatively charged residue for MT-2, a third separable isoform, MT-

0, is present in the human foetal liver [24]. This isoform was previously considered as being a foetal specific isoform because of its presence in foetal liver but not in adult liver. However, MT-mRNA has been found in human adult liver tissue [25] and recently, both at the protein and RNA level, the MT-0 was found in human monocytes after induction with zinc [26]. This MT-0 differs from the other isoforms in having an extra negative charge at amino acid position 8 and a substitution of negatively charged amino acid by a positive one at position 23, a strictly conserved region of the protein. The cysteinyl residues surrounding both substitutions co-ordinate the same metal ion, as shown by X-ray diffraction and ^{113}Cd NMR studies of MT-2 [27], which makes alterations in the strength of the metal binding possible.

In this article a study of complexation properties of HFL MTs by using polarographic techniques is presented for the first time. Comparisons with results previously obtained for HK, RL and human MTs, and the peptidic fragment FT are also made.

2. Experimental

2.1. Apparatus

A potentiostat BAS 100B/W (West Lafayette, IN) coupled to a polarographic stand BAS 'Controlled Growth Mercury Electrode' which is equipped with a static mercury drop electrode, an Ag/AgCl reference electrode and a platinum wire as a counter electrode was used for the polarographic studies.

A potentiostat EG&G PARC model 384B (Princeton, IL) coupled to a polarographic stand EG&G PARC model 303A which is equipped with a static mercury drop electrode, an Ag/AgCl reference electrode, a platinum wire as a counter electrode and a water-jacketed cell was used for the determination of the thiolate groups contained in the MTs.

A flame atomic absorption spectrophotometer Perkin Elmer model 372 (Überlingen, Germany) was used to measure the metal concentration for each MT.

A Shimadzu UV-2100 spectrophotometer (Kyoto, Japan) was used for the UV spectrophotometric measurements.

A pH-meter Orion (Boston, MA) model 920S equipped with a glass combined Ag/AgCl reference electrode from Radiometer Copenhagen (Villeurbanne, France) model XC100 was used for all the experiments.

2.2. Reagents

The human foetal liver Zn–MT isoforms were obtained as described in Section 2.3.

Standard solutions of 5.0×10^{-4} M CdCl₂ and ZnCl₂ were prepared from 1.000 g l⁻¹ Titrisol standard solutions by Merck (Darmstadt, Germany).

Rabbit liver MT 1 from Sigma (St. Louis, MO) Lot 93H9559 containing 3.20 mol Cd(II) and 0.55 mol Zn(II)/mol MT, was used as standard for the determination of thiolate groups contained in the foetal liver MT samples.

All the reagents used were of analytical grade quality and the water was purified by using a Barnstead Nanopure II water deionization in conjunction with a Jencons double distillation still.

2.3. Procedure

The post mortem foetal liver tissues, obtained by autopsy, were immediately frozen in liquid nitrogen and stored at -80°C until use. The MT was isolated by homogenisation of the tissue in 10 mM Tris–HCl, 0.25 M sucrose, pH 7.4 at 4°C (20% w/v) in a Dounce apparatus. After centrifuging at $100\,000 \times g$ for 2 h at 4°C , the homogenate was heated for 2 min at 80°C and centrifuged again at $10\,000 \times g$ for 20 min. The supernatant was eluted on a Sephadex G-75 column (60×6 cm) in 10 mM Tris–HCl, pH 7.4 at a flow rate of 24 ml h^{-1} . The absorbance of the fractions was measured at 218 and 280 nm and the metal content was determined by flame atomic absorption spectrophotometry (FAAS). The zinc containing fractions with a high 218 nm/low 280 nm absorption ratio were pooled, for the purposes of MT concentration and applied on a DEAE-Sephacel anion-exchange column ($17 \times$

2.5 cm). The isoforms were eluted by a linear 10–200 mM Tris–HCl, pH 8.0 gradient and the pooled isoMTs were further concentrated through ultrafiltration.

The concentration of thiolate groups contained in the MTs samples was determined by DPP using the procedure based on the Brdicka method [28]. The experimental conditions are the following: a solution containing 0.78×10^{-3} M hexaminecobalt(III) chloride, 0.20 M ammonium buffer and 1.03% (w/w) of Triton X-100 at pH 9.5 was used as a supporting electrolyte. The scans were carried out from -1.3 to -1.7 V at a scan rate of 2 mV s^{-1} , a drop time of 2 s, a pulse amplitude of 100 mV, a pulse width of 50 ms and a sample width of 17 ms. A water-jacketed cell was used at a temperature of 10°C . The concentration of thiolate groups was determined by standard addition using the RL MT-1 solution as a standard. The total concentration of Zn(II) in the MT samples was determined by FAAS. The values obtained are 6.53, 7.03, and 7.38 mol Zn/mol MT for MT-0, MT-1, and MT-2, respectively. In the three studied MT isoforms studied, the proportion of [Zn]:[MT] is close to saturation, which means [Zn]:[MT] = 7:1.

The solution was purged before the commencement of the experiments with nitrogen for 5 min and the purging time was 2 min between each measurement. A nitrogen stream was passed over the solution during the recording of the polarograms. The supporting electrolyte for all the experiments was 0.01 M phosphate buffer. The polarograms were recorded at room temperature, in the most suitable scan range for the complete development of peaks and the following instrumental conditions were applied: drop time 1.00 s, scan rate 2 mV s^{-1} , pulse amplitude 50 mV, pulse width 50 ms, sample width 17 ms.

The polarographic responses of free cadmium and zinc (Titrisol standard solutions) were determined in the phosphate buffer 0.01 M supporting electrolyte, in the 3–12 pH range.

The study of the variation of the polarographic response with the different ratios of metals with respect to the protein was carried out by adding successive amounts of Cd and Zn to the MT solution.

The study of the variation of the polarographic response with the pH was carried out by addition of suitable amounts of NaOH and HClO₄ to the initial MT solution in order to adjust the pH to a given value.

3. Results and discussion

3.1. Assignment of polarographic peaks

The assignment of the polarographic peaks in this study has been made according to results obtained in previous works [9–12,16–20] using different polarographic and voltammetric techniques. The MTs from HK and RL as well as from human origin and FT alone and in the presence of Cd and/or Zn were used in these works. FT has been widely used for the assignment of polarographic peaks, for the elucidation of electrochemical mechanisms, for the study of diffusion-adsorption process and for assessing the reversibility of each electrochemical system. In fact, this peptide contains three cysteinyl residues which are considered as being the basic structural unit involved in their binding properties [29]. The use of the FT has an advantage over the MT in that it permits the study of the behaviour of free thiol groups and the complexation of each of the cadmium and zinc cations, usually bound to the MT, separately. The studies of FT alone and in the presence of Cd and/or Zn at different ratios metal ion:peptide—effect of concentration, electrocapillary curves, mathematical analysis of I–E waves, effect of adsorption phenomena—using DC and DPP (DME) [16–18] and SWV and CV (HMDE) [19,20] allowed us, on the one hand, to attribute, without any ambiguity, the response due to thiol groups to the reversible oxidation of the mercury electrode and, on the other hand, to establish that the reduction processes in which cadmium and zinc are involved are reversible with the charge rate coefficients being close to $\alpha = 1$. The experimental conditions under which the adsorption phenomena are not prevalent were also determined. It is necessary to point out that results obtained from Cd, Zn metallothioneins are very similar to those found using a mixture of Cd, Zn, FT.

Under our experimental conditions, low concentrations of compounds and the use of a dropping mercury electrode, in a freshly prepared solution of a Cd, Zn–MT at pH 7.5, three polarographic peaks are observed by DPP, which are the following: the MT peak ($E_p = -410$ mV) due to the oxidation of the mercury electrode in the presence of thiol groups; the CdT peak ($E_p = -780$ mV) due to the reduction of Cd(II) bound to MT and the ZnT peak ($E_p = -1100$ mV) due to the reduction of Zn(II) bound to MT. Another peak labelled CdT' ($E_p = -690$ mV) is obtained under particular experimental conditions and is attributed to the reduction of Cd(II) in another complexation form with MTs different to the original CdT. The CdT' peak is detected either after the addition of Cd²⁺ and Zn²⁺ to the MT solution or in the pH range 6.0–10.0 once the MT has previously been at acid pH [10–12].

In Fig. 1, the polarogram of 1.7×10^{-6} M HFL MT-2 in 0.01 M phosphate buffer at pH 8.0

Fig. 1. DPP of 1.7×10^{-6} M HFL MT-2 in 0.01 M phosphate buffer at pH 8.0. Conditions: Scan rate 2 mV s^{-1} , drop time 1 s, pulse amplitude 50 mV, pulse width 50 ms, sample width 17 ms. Dashed line: cathodic peak potential of free Zn²⁺ obtained under the same experimental conditions.

is shown. The dashed line corresponds to the peak potential of free Zn^{2+} under the same conditions. Similar polarograms have been obtained for MT-0 and MT-1. The peak at $E_p = -458$ mV, which is labelled MT(Zn), corresponds to the oxidation of the mercury electrode in the presence of thiol groups of MTs and in the presence of Zn(II). In the potential range between -950 and -1150 mV, three polarographic peaks are observed. Those peaks are not well defined because their peak potentials are very close to each other. The peak at $E_p = -1010$ mV is labelled Zn and is attributed to the reduction of free Zn^{2+} in the solution even if small differences of potential are found between this peak potential and that previously determined for a solution of Zn^{2+} alone under the same experimental conditions. The peak at $E_p = -1066$ mV and the peak at $E_p = -1136$ mV are labelled ZnT' and ZnT respectively. In our previous study of the complexation of Zn with the peptidic fragment FT performed under analogous experimental conditions, two peaks of complexed Zn were found depending on the proportion of Zn with respect to FT [19]; these two signals have been attributed to two different complexes of Zn with FT. By analogy with these results, the possibility of two complexation forms of Zn(II) with MTs, labelled ZnT and ZnT' in accordance with the CdT and CdT' peaks, respectively [10–12], is suggested. The ZnT' and ZnT peaks have never been observed in mammalian HK and RL MTs because of the low concentration of zinc and because of the difficulty distinguishing between the peak potentials of Zn^{2+} and complexed Zn(II). However, in the case of some other MT from human foetal liver and adult kidney, the same kind of response has also been detected [12].

3.2. Variation of the polarographic responses of MT-0, MT-1 and MT-2 with the addition of Zn^{2+} and Cd^{2+}

Additions of Zn^{2+} to these MTs were first carried out since it is the metal ion originally present. This study should allow one to follow the evolution of polarographic peaks which correspond to the reduction of Zn(II) complexed with

Fig. 2. Polarograms of 4.8×10^{-6} M of HFL MT-0 in 0.01 M phosphate buffer at pH 8.0 with the successive additions of Zn^{2+} and Cd^{2+} . Additions: (a) 0.0; (b) 1.6; (c) 4.0 mol Zn^{2+} /mol MT and (d) 0.2; (e) 0.5 mol of Cd^{2+} /mol MT. Other conditions as in Fig. 1. Dashed lines: cathodic peak potentials of free Cd^{2+} and Zn^{2+} obtained under the same experimental conditions.

the MTs. To 4.8×10^{-6} , 7.9×10^{-6} and 1.7×10^{-6} M solutions of MT-0, MT-1 and MT-2, respectively, successive additions of Zn^{2+} were carried out. The final point of the additions is the corresponding amount for which the current of the Zn peak becomes predominant. In Fig. 2 the polarogram (a) corresponds to the initial solution of MT-0 and the polarograms (b) and (c) correspond to those resulting from successive additions of Zn^{2+} in the range of proportions between 0.8 and 4.0 mol Zn^{2+} /mol protein. On the one hand, no variation in the features of the shoulder at $E_p = -1136$ mV corresponding to the ZnT peak is observed with successive additions of Zn^{2+} , while on the other hand, the ZnT' peak increases with additions of Zn^{2+} . The signal observed as a shoulder for a proportion of 3.2 mol Zn/mol protein and its peak current seems to be the predominant for a proportion of 4.0 mol Zn/mol protein. The evolution of polarographic peaks with the addition of Zn^{2+} is similar for the three

isoforms studied, taking into account that the initial proportions of Zn with respect to the MTs are similar. On adding Cd^{2+} to MT-0 after the additions of Zn^{2+} , in proportions of 0.2 and 0.5 mol/mol protein (Fig. 2(d) and (e) respectively), a peak at $E_p = -656$ mV increasing in current is observed. At this pH, addition of Cd^{2+} provokes, as can be expected [9–12], the appearance of the peak corresponding to the reduction of complexed Cd(II), labelled CdT'. This peak is different to the one found at a potential of $E_p = -0.88$ V, labelled CdT, from a freshly prepared MT solution under the same experimental conditions. The CdT' peak has also been detected after the addition of a given amount of Zn^{2+} to a native RL and HK MT. Therefore, for HFL MTs containing only zinc, the detected peak corresponding to the reduction of complexed Cd(II) is CdT'. The appearance of the CdT' peak does not only depend on the proportion of Cd(II) complexed with the MT but also on the total concentration of metal ions complexed by the MT [11,12]. The same behaviour has also been observed in the other two isoforms, MT-1 and MT-2.

From all these results and others previously obtained, a qualitative attribution of peaks is possible, but the proportion in which Zn(II) is complexed with the MT cannot be quantitatively determined because of the small differences between peak potentials. The two peaks of reduction of Zn(II), ZnT' and ZnT, are attributed to two different complexes of Zn–T which suggests the existence of at least two different complexation forms of Zn with MTs.

3.3. Influence of the pH on the polarographic response of MT-0, MT-1 and MT-2

3.3.1. Influence of the pH on the polarographic response of MT-0, MT-1 and MT-2 in their initial forms

The initial pH 8.0 of MT-0, MT-1 and MT-2 solutions was altered up to pH 10.0 by means of small additions of concentrated solution of NaOH, in order to avoid variations in the MT concentration. Afterwards, the pH was changed back to neutral values by additions of small amounts of HClO_4 .

The polarograms recorded from a solution of MT-2 at different pH values are shown in Fig. 3. The peak potentials of each peak shift towards more cathodic values as can be expected in a complexation equilibrium of metal ions with ligands which have acid-base properties. Moreover, because the shift of ZnT peak potentials with pH is greater than that of ZnT', the peaks are more separated and the ZnT peak is better defined. Likewise, the peak current of each peak decreases when the pH increases. The Zn and ZnT' peaks are not observed at pH 9.5 and pH 10.0, respectively. The variation in the peak current ratio between $i_{p\text{ZnT}'}$ and $i_{p\text{ZnT}}$ versus the pH decreases which indicates that the complexation of Zn(II) is more stable in the Zn–T form than in that of the Zn–T' at more basic pH values.

In Fig. 4, the variation of peak potentials of the three isoforms versus the pH is represented. The same values of peak potentials are found for each MT isoform under the same experimental condi-

Fig. 3. Polarograms of $1.7 \cdot 10^{-6}$ M HFL MT-2 in 0.01 M phosphate buffer at the following pH values: (a) 7.0; (b) 7.5; (c) 8.0; (d) 8.5; (e) 9.0; (f) 9.5 and (g) 10.0. Other conditions as in Fig. 1. Dashed line: cathodic peak potential of free Zn^{2+} obtained under the same experimental conditions.

Fig. 4. Variation of E_p from 4.8×10^{-6} M MT-0 (circles), 7.9×10^{-6} M MT-1 (squares) and 1.7×10^{-6} M MT-2 (triangles) in their native form versus the pH.

tions. All studied isoforms behave in a similar way but the predominance of each polarographic peak in the chosen pH range is not identical. The differences in the pH ranges in which the polarographic peaks are observed for the three isoforms are due to the small variations in the proportion of metal ions with respect to MT for each of the studied isoforms.

When the variation of pH is carried out from neutral to basic pH and from basic to neutral pH, the same linear relationships between E_p and pH are obtained as those observed for others MTs [10,12]. Likewise, irrespective of the mode in which the pH was modified, the features of polarographic peaks for HFL MTs at the same value of pH are identical. Therefore, both Zn–T complexes are not modified in the pH range of between 7.0 and 10.0.

Linear relationships are obtained on representing E_p versus pH for all polarographic peaks. A slope of -44 mV per unit of pH was obtained for the ZnT' peak and the ZnT peak potential shifted with the pH giving a slope of -60 mV per unit of pH. In the case of HK and RL MTs [10], the ZnT peak potential shifts with a slope of -90 mV per unit of pH in the pH range of between 6.0

and 10.0 when the pH is modified from neutral to basic and from basic to acid, which does not correspond to the results obtained for HFL MTs. Comparing the results presented in this study with those for HK MT and RL MT 1 in the pH range of between 6.0 and 10.0 and a slope of -60 mV per unit of pH has been found for RL MT 2 and RL MT 1 + 2 in the same pH range. In those cases, the variation of pH was carried out from pH 2.0 to basic pH, to enable the formation of the Cd,ZnMT produced from its depleted form. These values of the slope obtained for the ZnT peak in HK and RL MTs, correspond to one single peak attributed to the reduction of complexed Zn(II).

Depending on the value of the slope, the number of thiolate groups bound to the Zn(II) can be evaluated. In fact, the peak potential shifts with pH according to the equation $E_p(\text{V}) = C + 0.059 \frac{m}{n} \text{pH}$ [30], where C is a constant value, n is the number of electrons transferred and m is the number of protons substituted by Zn(II). The number of protons involved in the electrochemical reaction corresponds to the number of thiolate groups in which a metal ion is replaced by protons.

From the values of the slopes and assuming that the number of electrons transferred is $n = 2$, the ratio between the thiolate groups and the metal ions can be evaluated. The obtained S^-/M ratios are 1.5 and 2.0 for Zn–T' and for ZnT, respectively, which are lower than the results obtained with HK and RL MTs. Furthermore, the S^-/M ratio is equal to 3.0 for the recognised structure of MTs, cluster β , in which the complexed Zn(II) is contained [4]. A ratio of $S^-/M = 2.9$ has been found for Zn(II) complexed with commercial HK and RL MTs with a variation of pH being performed from basic to acid pH [10]. Outwardly, the characteristics of zinc complexes of human foetal MTs are different, especially with respect to the binding with thiolate groups, compared to those observed in HK and RL MTs. Therefore, the Zn(II) complexed with HFL MTs is probably co-ordinated in a different manner than for HK and RL MTs, containing both ions, cadmium and zinc.

3.3.2. Influence of the pH on the polarographic response of MT-0, MT-1 and MT-2 after the addition of $Zn^{2+} + Cd^{2+}$

A study of variation of pH similar to that described in Section 3.3.1 was carried out for the three studied isoforms after additions of Zn^{2+} and Cd^{2+} . Zn^{2+} was added until the Zn peak was predominant with respect to the other two Zn(II) complexes, and additions of Cd^{2+} were made until a well defined CdT' peak was observed. These additions lead to the following proportions of metals with respect to each isoMT: 4.8×10^{-6} M MT-0 + 4.2 mol Zn/mol MT + 0.8 mol Cd/mol MT
 7.9×10^{-6} M MT-1 + 0.5 mol Zn/mol MT + 1.5 mol Cd/mol MT
 1.7×10^{-6} M MT-2 + 1.8 mol Zn/mol MT + 2.2 mol Cd/mol MT
 in which the MT(Zn), CdT', Zn, ZnT' and ZnT peaks are well defined for the given experimental conditions at pH 8.0.

The polarograms obtained for MT-1 in the pH range of 8.0 and 10.0 are shown in Fig. 5. For the three isoforms, the MT(Zn) peak current decreases when the pH increases and the MT(Zn) peak potential is almost maintained constant in the entire pH range which was studied.

The pH-dependent evolution of polarographic peaks attributed to the reduction of complexed Zn(II) is the same as that previously observed without the addition of metal ions (Section 3.3.1). On the one hand, the Zn and ZnT' peak currents decrease when the pH increases until their disappearance at a given value of pH. The pH value at which they disappear is different for each isoform and depends on the concentration of metals which has been added. On the other hand, the ZnT peak current increases with the increase of pH up to pH 9.0 and thereafter it decreases for higher pH values. Therefore, ZnT becomes the predominant peak for pH values higher than 9.0. The evolution of Zn, ZnT' and ZnT peaks indicates that the complexation of Zn(II) with MT is not influenced by the presence of Cd, at the given concentration but, in agreement with results already observed using HK and RL MTs [11], Cd(II) complexed with MT is influenced by the presence of Zn(II).

The potential of the CdT' peak, the only one which corresponds to the reduction of complexed Cd(II) with MTs at the given proportion of metal ions, does not shift with pH in agreement with the behaviour observed in previous studies [9,10]. For pH values higher than 9.5 (polarogram 5 (g)), this peak disappears and another peak at $E_p = -896$ mV at pH 10.0 (polarogram 5 (i)) is observed. This peak is labelled CdT and is the peak obtained from freshly prepared native HK or RL MT solutions. The change from CdT' peak at pH values higher than 9.0 is the typical behaviour of other mammalian MTs [10–12], indicating that the prevalent form of complexation of cadmium is Cd–T at high pH. Whatever the direction of pH variation from neutral to basic or from basic to neutral, the features of the polarographic peaks remain identical at a given pH. Hence, the complexation equilibria are reversible in the studied pH range. The equilibrium between CdT and

Fig. 5. Polarograms of 7.9×10^{-6} M HFL MT-1 + 0.5 mol Zn/mol MT + 1.5 mol Cd/mol MT in 0.01 M phosphate buffer at the following pH values: (a) 8.00; (b) 8.25; (c) 8.50; (d) 8.75; (e) 9.00; (f) 9.25; (g) 9.50; (h) 9.75; and (i) 10.00. Other conditions as in Fig. 1. Dashed lines: cathodic peak potentials of free Cd^{2+} and Zn^{2+} obtained under the same experimental conditions.

Fig. 6. Variation of E_p from 4.8×10^{-6} M MT-0 + 4.2 mol Zn/mol MT + 0.8 mol Cd/mol MT (circles), 7.9×10^{-6} M MT-1 + 0.5 mol Zn/mol MT + 1.5 mol Cd/mol MT (squares) and 1.7×10^{-6} M MT-2 + 1.8 mol Zn/mol MT + 2.2 mol Cd/mol MT (triangles) versus the pH.

CdT' peaks is also reversible for HFL MTs and each peak can simply be obtained by changing the solution pH.

Fig. 6 shows the variation of peak potentials versus pH. The shift of Zn, ZnT' and ZnT peak potentials with pH is equal to that observed in Section 3.3.1. The pH ranges where those peaks are obtained are different for each studied MT isoform. The $E_{pZnT'}$ and E_{pZnT} peak potentials shift with a slope of -44 mV and -60 mV per unit of pH respectively, for the three isoforms. The variation of $E_{pCdT'}$ is not pronounced enough to consider that the protons of thiolate groups of MTs are involved in the complexation reaction with Cd(II) for the given experimental conditions.

The most stable complexation forms are Cd–T and Zn–T at basic pH values. In this case, the change of ZnT' to ZnT occurs at pH values higher than 9.5, where the ZnT peak becomes predominant. A similar phenomenon was observed in the study of HK and RL Cd–T complexes, in which the equilibrium between CdT and CdT' peaks depends on the solution pH [11].

4. Conclusions

This work constitutes the first study on electrochemical characterisation of human foetal liver MTs. DPP is a simple technique which provides results easy to interpret. In this case, the electroactive species are the free and the complexed metals ions as well as the organic part of the metallothionein throughout the thiol groups. Hence, the use of electroanalytical techniques allows one to study the characteristics of Zn–MTs, especially concerning their complexation of metal ions.

Because the rate to reach the chemical equilibrium is very high, significant modifications in the polarograms are observed after a short period of time (2 min of nitrogen purging between the measurements) on slightly changing the conditions such as pH, metal concentration, etc.

The existence of two peaks ZnT' and ZnT which have been observed here for the first time in this type of MT, could be attributed to two different Zn(II) complexes with MTs. The ZnT peak is better defined at basic pH values and it is suggested that the behaviour of ZnT' and ZnT peaks is similar to that observed for CdT' and CdT peaks for Cd, Zn MTs. Hence, the behaviour of these HFL MTs, after the addition of Cd^{2+} and consequently when both metal ions are complexed with the MT, is comparable to other mammalian Cd, Zn–MTs.

The results presented in this paper are of interest in order to obtain a better interpretation of structural data. Particularly, the fact that two different electrochemical signals for both Cd(II) and Zn(II) complexes have been distinguished and attributed to two different Cd–T and Zn–T complexes. Those complexes possess different characteristics not mentioned in works on MT characterisation using analytical methods other than electroanalysis. Hence the use of electroanalytical methods can be considered as a useful complement for the interpretation of nuclear magnetic resonance and circular dichroism data determined by other authors with native and reconstituted MTs.

Abstract

Very little information is available concerning the relationship between metallothionein (MT) and diseases in humans. Several methods to measure MT levels exist but many of these assays are not sensitive to measure MT in human sera. A new sensitive competitive ELISA system has been developed using MT labeled with horseradish peroxidase as a conjugate and high-titre polyclonal antibodies obtained from rabbit immunoglobulin G for MT determination in human sera. The cELISA proposed here permits a reliable determination of MT in the range 10–2 000 000 pg ml⁻¹. The method was compared with Cd-hem assay and showed good agreement of results. The recovery of the assay was determined by spiking rat MT into rat and human sera, and comparing it with spiked diluent controls. The overall recoveries of the added MT were 101% for rat sera and 89% for human sera. The variation within-assay and between assay were 3 and 6%, respectively. A significant difference ($P < 0.001$) was found between the MT-level in human sera from patient with essential hypertension (646 ± 223 ng ml⁻¹, $n = 90$) and normotensive subjects (21 ± 18 ng ml⁻¹, $n = 236$). A correlation between arterial hypertension and MT-level seems possible. A very sensitive new cELISA method was presented for determination of MT in sera and tissues. It enables investigation of possible correlations between sera MT-concentration and certain diseases. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Metallothionein (MT) is a low molecular weight protein with a very important role in heavy metal detoxification and metal homeostasis [1,2]. This protein contains 20 cysteine (CYS)

* Corresponding author. Tel.: + 359 2 9515664; fax: + 359 2 517278; e-mail: margo@ns.medfac.acad.bg

residues and no aromatic aminoacids [3]. MT genes are highly conserved and have strong inducible promoters [4]. The synthesis of MT is induced by various metal ions (Cd^{2+} , Zn^{2+} , etc.) [3], glucocorticoids [4], catecholamines, IL-1 and IL-6 and interferons [5–7]. Structural analysis of MT shows two domains, the first one includes the carboxyl-terminal part and binding four bivalent metal ions and the second domain containing three bivalent metal ions. Immunological studies of MT have suggested that the N-terminal region is the most immunogenic domain [8]. An epitope consists of a region of five to seven aminoacids residues [9].

Different methods for quantitative determination of MT have been described [10–12]. MT can be measured indirectly, based on the known binding stoichiometries between metals and MT, by quantifying the number of atoms the Cd- or Hg bound to the protein [13,14]. Radioimmunoassays (RIA) and an enzyme linked-immunoassays (ELISA) have been developed for determination of MT [15–18]. Immunological studies using different antisera against MT showed that the antibodies were crossreactive with various kinds of mammalian MT [19]. These methods have a typical detection limit of about 0.1–1 ng of MT and determination of MT in body fluids is difficult due to low MT concentrations.

In previous studies [20], we have found that the basal MT levels in liver from spontaneously hypertensive rats (SHR) were higher than that in the Wistar–Kyoto rats (WKY). The close similarity of the SHR-model and human hypertension disease makes the investigation of the relation between MT homeostasis and arterial hypertension in humans interesting.

In order to investigate physiological functions and roles of metallothionein in humans, the aim of this study was to develop a new competitive ELISA system for MT determination in human sera with low detection limit.

2. Experimental

2.1. Reagents

Cadmium chloride, Tris-(hydroxymethyl)-

amino-metan, $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, $\text{NaH}_2\text{PO}_4 \cdot 6\text{H}_2\text{O}$ were obtained from Sigma (St. Louis, MO). The acrylamide, bis-acrylamide and sodiumlaurylsulfate (SDS) were acquired from Merck (Darmstadt, Germany). All other reagents were purchased from Aldrich Chemical (Windsor, ON, Canada).

The aqueous solutions were prepared with highly purified water ($< 18 \text{ M}\Omega$) using Milli-Q reagent water system (Millipore, Milford, MA, USA).

2.2. Animals and human sera

Male Wistar rats and guinea pigs were obtained from the animals laboratory (Medical Academy, Sofia, Bulgaria). Rats weighing 170–190 g (10 weeks old) were housed in groups of five per cage in an environmentally controlled room (light 7–19 h, $23 \pm 1.5^\circ\text{C}$).

Four male New Zealand rabbits (3 kg) were received from the laboratory of molecular immunology (Institute of Reproduction, Bulgarian Academy of Sciences, Sofia, Bulgaria). Animals were supplied with water and a commercial laboratory chow, ad libitum.

The human sera from patients with essential hypertension ($n = 90$) and normotensive subjects ($n = 236$) were received from the Department of Internal Medicine II, Clinic of Cardiology (Medical Academy, Sofia, Bulgaria) and National Institute for Blood Collection (Sofia, Bulgaria).

2.3. Purification of MT-antigen

Fresh or frozen liver from rats, in which the MT concentration has been induced by CdCl_2 were cut into small pieces and homogenized in 25% (w/v) of 0.1 M Tris–HCl buffer pH 8.6, containing 0.25 M with Teflon-glass homogenizer ($8\text{--}10 \text{ strokes min}^{-1}$). The homogenate was centrifuged at $10\,000 \times g$ for 10 min. The resulting supernatant was heated for 1 min at 100°C . The precipitate was removed by centrifugation at $100\,000 \times g$ for 30 min and 5 ml from the supernatant were applied into a Sephadex G-75 gel-filtration column (2.6 cm/1 m, Pharmacia,

Uppsala, Sweden). Elution was carried out with 50 mM Tris–HCl buffer, pH 7.4 at a flow rate of 1 ml min⁻¹. The absorbency of elute at 254 and 280 nm was continuously recorded using a flow cell and UV detector (Pharmacia, Uppsala, Sweden). Fractions of 5 ml were collected. All fractions corresponding to MT were combined and concentrated under nitrogen on an Amicon (Danvers, MA) YM 2 membrane. Aliquots of the concentrated solution (300 µl) were used for HPLC separation of MT isoforms (MT1 and MT2). HPLC was performed on a semi-preparative µBondapak C₁₈ column (300 mm/7.8 mm/5 µm) obtained from Waters (Milford, MA). The details concerning the MT separation by HPLC systems have been discussed in previous papers [20,21]. The MT concentration was determined by Bradford assays [22]. We used as a standard MT produced by Sigma (St. Louis, MO, Cat # M7641).

The Zn and Cd contents were determined in all samples by electrothermal atomic absorption spectrometry (Perkin-Elmer Zeeman 5000) with an HGA-500 graphite furnace, AS-40 autosampler and ASDS-10 data station.

2.4. Preparation of antibodies

Fig. 1 shows the homogeneity of MT1 and MT2 used as immunogen. The conjugation of MT with lysozyme (Sigma, St. Louis, MO) was carried out essentially using the method of Reichlin et al. [23]. Rat MT (mixture from MT1 and MT2, 0.5 mg ml⁻¹ for each one) and lysozyme (2 mg ml⁻¹) were dissolved in 500 µl of 0.1 M potassium phosphate buffer, pH 7.0. A total of 250 µl of 1% glutaraldehyde was added dropwise to the protein solution while constantly stirring and the reaction mixture was incubated for 60 min at room temperature. Then 1 ml of physiological saline was added to conjugated MT solution and the mixture was emulsified with 2 ml of Freund's complete or incomplete adjuvant (DIFCO Laboratories, Detroit). Male New Zealand rabbits were injected s.c. with 2 ml from the emulsion 2–6 mg of the conjugates. The first four injections of the antigen emulsified with Complete Freund's adjuvant were given at

2 weeks interval. The amount of MT in the conjugates were 6, 4, 2 and 2 mg per each interval. The final injection, after 2 months, consisted of MT emulsified with mixture from complete and incomplete adjuvants.

Blood was drawn from rabbits before immunization (in order to obtain preimmune serum) and 7 days after each injection to obtain anti-serum. It was kept at 37°C for 1 h and at 4°C for 2 h. After the serum was separated by centrifugation, the immunoglobulin fractions were separated by ammonium sulfate precipitation. The serum was stored at –80°C until ready to use.

2.5. Characterization of the rabbit anti-rat MT antibodies

The antibodies formation was checked by double diffusion with 1% agar on a glass plate at room temperature. The antigenic reactivities of various MT and lysozymes and the potency of

Fig. 1. SDS-PAGE of metallothionein 1 (line 2 and 4) and metallothionein 2 (line 3 and 5). Line 2 and 3 were developed without β -mercaptoethanol in the sample buffer, line 4 and 5 with β -mercaptoethanol.

various rabbit antisera were determined by the direct ELISA systems [17].

2.6. SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting

SDS-PAGE was performed by the method of Laemmli [24]. The separating gel containing 15% (w/v) acrylamide was 6×9 cm in size and 1 mm thick. Samples were dissolved in a sample buffer (125 mM Tris-HCl, pH 6.8 containing 15 (w/v) SDS, 10% (w/v) glycerol and 0.01% bromphenol blue with or without β -mercaptoethanol) and incubated in a water bath at 80°C for 5 min. After the electrophoresis, the gel was soaked in a transfer buffer (25 mM Tris/192 mM Glycin/20% (v/v) methanol) and the proteins in the gel were transferred electrophoretically to a nitrocellulose membrane (Bio-Rad, Richmond, CA) using the modified method of Towbin et al. [25].

2.7. Detection of MT on the nitrocellulose membrane

The membrane was soaked in 10 mM PBS (KCl, KH_2PO_4 , NaCl, $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$) pH 7.4 containing 10% (v/v) Tween-20 for 1 h. The MT on the membrane were detected immunochemically using rabbit anti-rat MT serum (1:10 000) diluted in TBS for 1 h, at room temperature. After the membrane was washed with TBS (PBS + 0.05% (v/v) Tween-20) buffer, it was incubated in a peroxidase conjugated goat anti-rabbit IgG and the membrane method was developed according to the manufacturer's instructions.

2.8. Conjugation of enzyme (horseradish peroxidase, HRPO) to antigen (MT*)

HPLC-purified rat MT1 and MT2 (4 mg each) were dialyzed against 0.1 M carbonate buffer pH 7.0, overnight at 4°C. A total of 250 μl from 4 mg ml^{-1} HRPO (dissolved in 0.1 M carbonate buffer, pH 8.7) was mixed with 200 μl of freshly prepared 0.1 M NaIO_4 and incubated at room temperature for 20 min in the dark. After that, the mixture was dialyzed against 1 mM acetate buffer, pH 4.4. Immediately after dialysis the pH

was adjusted to 9.0–9.5 with 0.2 M carbonate buffer and MT (mixture from MT1 and MT2, 8 mg) was added. This solution was stirred gently for 2 h at room temperature. Freshly prepared 0.1 ml NaBH_4 (4 mg ml^{-1}) solution was added and incubated for 2 h at 4°C. The excess of unbounded HRPO was separated by gel chromatography (Superose 12™ column, FPLC, Pharmacia, Sweden) gel-chromatography. The HRPO labeled MT (MT*) was mixed with glycerol as a cryoprotector mixed with glycerol and stored at -20°C until ready to use.

2.9. Competitive ELISA system (cELISA)

The 50 μl from MT-antibodies diluted in 10 mM carbonate buffer, pH 9.7 was adsorbed on the flat type microwell plates overnight at 4°C. After 1 h incubation with PBS plus 1% (v/v) Tween-20 (200 μl), the MT* (25 μl , 1:400 dil.) and the samples (25 μl) to be studied were added and incubated for 2 h at 37°C. The reaction was visualized by means of orthophenylenediamine in phosphate citrate buffer, pH 5.5, 0.006% H_2O_2 and stopped with 10% H_2SO_4 . The absorption at 492 nm was measured by ELISA reader (Dynatech, Germany). After each step the plates were washed three times with TBS for 5 min.

2.10. Statistical analysis

The statistical evaluation of the obtained results was performed by regression and ANOVA analysis, $P < 0.001$ (Microcal Origin, version 3.5). The data were expressed as mean \pm SD.

3. Results

3.1. Development and optimization of a sensitive competitive ELISA for human sera

In order to develop a competitive ELISA, rat metallothioneins were coupled to HRPO and different combinations between MT* and Ab were tested in order to obtain an optimal cELISA condition all combination. A highly sensitive ELISA was obtained by the absorption of MT

Fig. 2. Competitive ELISA, using absorption of antigen (MT) on the microwell plate and MT* (MT conjugated with horseradish peroxidase) as a conjugate. Rat liver MT was assayed in the range 10–2 000 000 pg ml⁻¹.

antibodies on the microwell plate in combination with the analyzed samples and MT* (see Section 2) as a conjugate. This cELISA permitted determination of MT as low as to 0.5 pg well⁻¹ MT (Fig. 2). MT concentrations of 10–2 000 000 pg ml⁻¹ can produce changes in the percentage binding that are linearly related to the logarithm of the MT concentrations. Metallothionein concen-

Table 1
Quantification of MT in different tissue cytosols by cELISA and Cd-hem assay

Type MT	Concentration of MT ($\mu\text{g g}^{-1}$ tissue)	
	Cd-hem ^a	cELISA ^a
Rat liver		
Control	6.6 \pm 1.4	5.2 \pm 1.7
Cd-injected	511 \pm 17	504 \pm 23
Rat kidney		
Control	6.1 \pm 1.3	9.7 \pm 2.3
Cd-injected	174 \pm 11	182 \pm 25
Guinea pig		
Control	6.9 \pm 2.1	8.9 \pm 1.5
Cd-injected	497 \pm 32	475 \pm 14

^a Mean \pm SD of 66 determinations.

trations were determined by linear regression (Fig. 3).

Regression analysis of the total MT concentrations in Table 1 obtained by Cd-hemoglobin assay and cELISA using the MT* show good linear relationship, with the slope of the regression line = 0.843. The sensitivity of the competitive ELISA assay, permitted us to measure MT concentration in human and animal sera with low detection limits.

In order to assess the metal-dependency of the ELISA, single different derivatives, prepared from rat hepatic MT by metal exchange ($\text{Zn}_{6.22}\text{Cu}_{0.52}\text{MT}$, $\text{Cd}_{5.33}\text{Zn}_{1.33}\text{MT}$, $\text{Cd}_{6.54}\text{MT}$, AMT), were compared. As shown in Fig. 4, the Zn-loaded and apometallothionein (AMT) forms yield the highest signal on equal molar ratio.

3.2. Specificity, recovery, reproducibility and sensitivity of the assay

The specificity of the antisera was examined by the Ouchterlony's method. A single precipitation line was observed between the rat hepatic MT and the antiserum (after the antiserum was immunoaffinity purified, data not shown). As shown in Fig. 5 similar competitive inhibition patterns were obtained when the rabbit anti-rat MT serum reacted with MTs from mammalian organs: rat hepatic MT, guinea pig hepatic MT, human

Fig. 4. Metal-dependence of competitive ELISA using MT*, as a conjugate. MTs derivatives (CdMT: Cd_{6,24}MT; ZnMT: Zn_{6,22}Cu_{0,52}MT; CdZnMT: Cd_{5,33}Zn_{1,33}MT, AMT) were obtained from rat liver.

serum MT. Lysozyme solution used for conjugation of MT did not show any cross reactivity (Fig. 5).

The recovery of the assay has been determined by spiking normal rat and human sera with known amounts of rat MT and comparing them with the controls (Table 2). The overall average

Fig. 5. Binding (%) of different MTs and lysozyme with the rabbit anti-rat MT antiserum by competitive ELISA.

Table 2
Recovery of serum MT by cELISA

MT pg well ⁻¹	Rats ^a	Human ^b
	Recovery (%)	Recovery (%)
1.5	96 ± 5	89 ± 7
2.5	97 ± 7	97 ± 5
5.5	103 ± 4	83 ± 7
25.5	99 ± 6	91 ± 3
50.5	105 ± 5	88 ± 2
75.5	111 ± 12	90 ± 9

The recovery in the cELISA has been determined by spiking rat MT in rat and human sera and comparing with spiked standard diluent controls.

^a, ^b Mean ± SD of 15 experiments.

recoveries of the added MT* were 101% for rat sera and 89% for human sera.

Table 3 summarizes the within-assay and between-assay reproducibility obtained by cELISA system. The assay gave reliable results for analyses of MT in both sera and tissue cytosols. The within-assay coefficient of variation was less than 3% and the between-assay coefficient of variation was less than 6%.

From the standard curves and all the data described above, it appears that reliable results can be obtained for MT in sera and tissue in the range 10–2 000 000 pg ml⁻¹, using the cELISA method described here.

3.3. Detection of MT from rat and guinea pig liver by Western blotting technique

MT was isolated from the liver of several mammals. The MT fraction (10 kDa) from all cytosols

Table 3
Reproducibility of MT in human sera by the cELISA

MT pg well ⁻¹	Within-assay	Between-assay
	Coefficient of variation (%)	Coefficient of variation (%)
10	1.3	5.9
20	2.4	5.7
50	3.3	6.1

n = 30.

Fig. 6. Detection of different MT forms by Western blotting. Line 1—molecular weight standard markers: 71 kDa, BSA; 42 kDa, carbonic anhydrase; 31 kDa, soybean trypsin inhibitor; 18 kDa, lysozyme; 7 kDa, aprotinin. Lines 2–6, cytosols from: rat liver in which MT synthesis was induced by (2) CdCl₂, (3) ZnCl₂, (4) control. Lines 5–6, cytosol from guinea pig liver, (5) CdCl₂, (6) control

were separated by gel chromatography and investigated by an immunoblotting technique. The results from Fig. 6 indicate that different amounts of MT can be detected by Western blotting. The limit of detection for each MT isoform from the animals studied was 4 ng. The control MT content or MT induced in the rat liver after Cd or Zn administration were detected by the method described above.

3.4. Detection of MT in the sera from patients with essential hypertension and normotensive subjects

The MT concentrations in sera from patients with essential hypertension ($n = 90$) and normotensive subjects ($n = 236$) obtained with this competitive ELISA method showed that, the MT level in human serum from patients with essential hypertension is significantly higher than that in the sera from normotensive subjects (Fig. 7).

4. Discussion

The purpose of this report is to describe the development and usefulness of a simple competitive ELISA, capable of reliable determination of MT concentration in sera and tissues in the range

as low as 0.5 pg well⁻¹ of MT. After optimizing the reagents concentration, the incubation times and temperature, the IgG fraction of our antiserum provided a level of sensitivity better than the lowest range reported up to now—by ELISA [16,26]. The IgG fraction of the antiserum containing antibodies showed greater affinity for rat MT than for human MT because our rabbit antiserum was obtained against rat liver MT1 and MT2. Most of the rabbit or sheep anti-MT antisera obtained against either MT1 or MT2 have been reported to show greater cross reactivity to both isoforms [18,27]. In the present study it is shown that MT from rat liver, guinea pig and human serum exhibit very similar inhibition patterns (Fig. 5). The complete cross reactivity with various mammalian MT is due to similarities in their primary structure and epitope sequence [9]. On the basis of the primary and the tertiary structure of the MT, it seems reasonable to speculate that the epitopes detected by our IgG fraction are not exposed to very essential stereochemical changes. The data also suggests that the conformation changes in the MT after binding with HRPO, at least in the vicinity of the epitopes, are also smaller. This cELISA method demonstrated that the affinity of the IgG fraction against the purified rat Zn_{6,22}Cu_{0,52}MT and Cd_{5,33}Zn_{1,33}MT was similar. The observed increase in the immunological affinity of the antibodies for AMT indicate that the metals which determine the MT conformation are not very important for reaction of the antibody obtained by us with MT. However, this result contrasts with earlier reports, showing that the removal of the metals from MT results in a decrease [18,28] or in a significant difference [26] in its antigenicity.

A highly sensitive cELISA was developed with labeling of the antigen (MT) with HRPO. This assay allowed the detection of 0.5 pg well⁻¹ of human serum MT and exhibited a relatively smaller metal-dependent response for Apo-, Zn- and Cd-MT derived from rat liver. A potential change in MT during the sample preparation was checked by the Western blotting method. It was shown that the MT genes were differently induced by Cd and Zn [4]. The immunoblot results showed good correlation with these data and proved that

Fig. 7. Metallothionein concentration determined by competitive ELISA in sera from patients with essential hypertension ($n = 90$) and normotensive subjects ($n = 236$).

the anti-MT antiserum is highly sensitive in detecting the basal level of MTs in rat liver.

Several methods for MT determination in biological materials have already been described [10–12]. These procedures rely on rather unspecified parameters such as the total metal content of determination of metals by atomic absorption spectrometry or HPLC analyses. The immunological studies of course, represent an exception in this respect. More specific are RIA [18] and ELISA with monoclonal antibodies [16,29]. They allow the detection of 60 pg well^{-1} MT and are sufficiently sensitive to assess the basal MT level in biological materials. The cELISA method, here proposed, with its detection limit of 0.5 pg well^{-1} , is therefore an alternative to the existing RIA [15,18] and monoclonal ELISA [16,28].

The successful determination of MT in sera from animals and humans in normal and pathological conditions described in the present report show that this cELISA can be applied not only for determination of the basal MT level but also for investigation of minor deviations in MT concentrations. The present studies not only confirm the earlier observations on the appearance of MT

in the body fluids but also provides evidence for an increased of MT level in serum during the development of essential hypertension in humans. The MT concentration in patients with essential hypertension is significantly higher in comparison to the MT levels of the healthy controls. The results for the MT evaluation in human sera suggest that the intracellular MT can be leached out extracellularly and transported by the serum. Several key enzymes and biologically active substances which are connected with regulation of blood pressure are metal-containing and related to the zinc and copper homeostasis (dopamine- β -hydroxylase, tyrosinase, angiotensin converting enzyme). The Zn level also, paralleled the metabolite-to-precursor fatty acid ratios, being constantly higher in hypertensive patients [30,31]. Zn ions have been identified as constitutive cofactors of desaturase activity in human, animal, and in vitro studies [32–35]. The MT level strongly affects Zn and Cu concentration and its very wide distribution, made MT a crucial factor in the metabolism of these metals. The possible causative interrelation between MT and arterial hypertension can not be excluded.

Received 04 November 1996; received in revised form 10 April 1997; accepted 07 August 1997

Abstract

The aim of this study was to present a new analytical method for the quantitative determination of metallothionein (MT) proteins in human body fluids and tissues, in order to determine the level of environmental and industrial exposure to heavy metals. For MT isolation, covalent affinity chromatography with thiol-disulphide interchange (CAC-TDI) was applied. Fundamentals of indirect determination of the contents of metallothionein proteins were worked out through estimation of the quantities of metals bound with metallothionein protein and adsorbed on covalent affinity chromatography gel as on solid-phase extraction support during separating process. The (CAC-TDI) gel, specially prepared, was used as a solid phase extraction support (SPE) for preconcentration of Hg–thionein (Hg-Th), Cd–thionein (Cd-Th), Zn–thionein (Zn-Th) and Cu–thionein (Cu-Th) proteins and Hg, Cd, Zn and Cu bonded with MTs from water, human fluids such as: urine, human plasma, breast milk and tissues homogenates. © 1998 Elsevier Science B.V. Keywords: Metallothionein; Covalent affinity chromatography; Heavy metal

1. Introduction

Exposure to heavy metals is a big problem in environmental toxicology. Acute intoxication to metals and their compounds is now rather the

exception and the present type of exposure has rather a chronic character. The metals and their compounds are adsorbed through the air passages and alimentary canal with food and drinking water. Most of the heavy metals, especially: Hg, Co, Cd, Bi, Zn, Cu, Ag, Au, Pb, Pt, Sn, Ni, Rb and Tc are very dangerous for a human body. They disturb the economy of endogenous metals and

biochemical equilibrium. They have an etiological effect on hypertension, cancer, decrease the ventilation of the lungs and other lung diseases. Heavy metals are the source of degeneration, reduction of pancreatic efficiency and dysfunction of kidneys [1–3]. Exposure to Cd is the source of Itai–Itai disease which is characterized by acute damage of the kidneys. Poisoning with Hg brings about Minamata disease [4,5]. In both cases intoxication was produced through the alimentary canal by consumption of fish living in waters contaminated with heavy metals. The daily doses of Cd differ from country to country and depend on their industrialization, density of population and the condition of environmental protection. The daily doses reach: 10–20 $\mu\text{g d}^{-1}$ in Sweden, 15–35 $\mu\text{g d}^{-1}$ in England, 20–70 $\mu\text{g d}^{-1}$ in the USA and above 215 $\mu\text{g d}^{-1}$ in Japan [6]. One of the indicators of exposure to Cd and other heavy metals is the measurement of their concentration in urine, blood, liver and kidneys. Another indicator is the content of endogenous metals (Zn, Cd) in these tissues [7–10]. The specificity of these methods was rather low and the results depended on: the type of metals, the type of exposure time from the last doses obtained, etc. The obtained results were difficult to interpret and the determination of correlation coefficients between time of exposure and value of metals deposited was very difficult or sometimes even impossible.

In 1956, for the first time, increased content of amino acids in urine after exposure to Cd was noticed [11]. The presence of the low molecular weight proteins (MW < 40.0 kDa) was observed in urine, resulting from damage of the kidney ducts [12–15]. Among these peptides the most important ones are: β -microglobulin (11.8 kDa), orosomucoid (44.0 kDa), retinol binding protein-RBP (21.4 kDa), β_{2x} -globulin (21.0 kDa), post- γ -protein (10.0 kDa), ribonucleases (13.0; 20.0; 32.0 kDa), lysozyme (14.6 kDa), minialbumin (10.0 kDa), β - and γ -trace free immunoglobulin light chains (30.0 and 10.0 kDa), carbonic anhydrase B (25.0 kDa) and immunoglobulin free light chains (23.0 kDa) [16–19]. Other indicators of exposure to Cd are total content of amino acids and proteins in urine

and plasma. All these proteins have no good correlation coefficients between concentration of these proteins in human fluids and concentration of heavy metals in human tissues and fluids. The correlation coefficient (r) between Cd and other heavy metals concentrations in blood and urine, and the concentrations of these proteins were about 0.1–0.6, which means that they are not good as specific indicators of exposure to Cd, similar to determination of metals concentrations [16,19,20].

Specific protein appearing in urine, plasma and human milk only after exposure to metals is metallothionein (MT). MT was discovered in 1957 by Margoshes and Vallee and characterized by Kagi and Vallee as the low molecular weight protein of about 6.5 kDa. MT is rich in –SH groups, containing about 30% of cysteine in the molecule. It is chelated with: Cd, Zn, Cu, Hg, Au, Ag, Bi, Co which are stimulators of its biosynthesis and all these metals bind to the induced protein [21–25]. The mammalian MTs binding a total seven equivalents of the multivalent ions and have the higher stoichiometries (12 equivalents) with univalent d(10) ions such as: Cu(I), Ag(I) and Au(I). The affinity of the metal ions for the binding sites of mammalian MTs follows the order of the thiolate-metal complexes: Zn(II) < Pb(II) < Cd(II) < Cu(I), Ag(I), Hg(II), Bi(III) [26]. MTs have two domains ($-\alpha$)[31–61] and ($-\beta$)[1–29] of about 15–20 Å diameter, which contain two metallothiolate clusters of different structures and different affinity to individual metals ([A—three-metal cluster, preference Cu, Zn, Cd], [B—four-metal cluster, preference Cd, Zn, Cu]) [27–30]. In physiological states it exists in trace amounts, as confirmed by radio-immunological or latex-immunological methods (RIA or LIA). Metallothionein concentration in plasma and urine was found to be about $2.4 \pm 2.2 \mu\text{g MT protein/g creatinine}$, where 100–200 pg of MT is the detection limit for using analytical methods. After exposure to Cd, metallothionein concentration in urine and plasma ranged from 20.0 to 2500.0 $\mu\text{g/g creatinine}$ [31–38]. The application of this technique allowed determination of quite a satisfactory correlation between the contents of MT

in human fluids and concentration of Cd in the blood, urine, kidney and liver, ranging from 0.74 to 0.95. These correlations are very good indicators of the environmental exposure to these metals [32,36–38].

In experiments using RIA and LIA techniques, the main problem is however obtaining metallothionein antibodies, because the molecular mass of MT is too low as a hapten and there is also need for the long period of immunization of experimental animals. The metallothionein protein before being used must be polymerized, but in this process random aggregation also occurs. The immunological answer of an immunological system is not homogenic and antibodies in RIA or LIA techniques give unspecific reactions with the other proteins present in plasma and urine and the analysis is not quantitative. In order to avoid all these difficulties, investigations on quantitative concentration of metallothioneins the new method was tested. MTs were carried out by covalent affinity chromatography gel as a solid phase extraction (SPE) support, specific for the thiol proteins, gives better results than the classical physico-chemical methods [39–44]. The idea of this method was based on earlier results obtained for separation of different metallothioneins by CAC-TDI method and our proposed mechanism of separation [45–48].

Covalent affinity chromatography with thiol-disulphide interchange (CAC-TDI) is one of the special techniques of separation of affinity chromatography based on the exchange reaction between disulphide bridges (–S–S–) fixed on the insoluble support and thiol groups (–SH) of the proteins being separated [49,50]. CAC-TDI technique was first applied for the separation of MTs from tissues by Squibb, Cousins, Ryden and Deutsch in 1977/78 [51,52]. The yields of separation of different MTs were about 10–50% for applied protein and about 15–80% for metals bonded formerly with MTs and depend on pH of using buffers, type of MTs, length of spacer arm and type of dithiol ligand [52–58](Fig. 1).

2. Experimental

2.1. Preparation of metallothioneins

The prepurified metallothioneins (Hg–thionein (Hg-Th); Cd–thionein (Cd-Th); Zn–thionein (Zn-Th) and Cu–thionein (Cu-Th) and cadmium apothionein (Apo-Th) were obtained from critical tissues (Hg-kidney; Cd, Zn, Cu-liver) of the experimental female white rats (Wistar, 190–210 g of body weight) after exposure to the salts of heavy metals, administered subcutaneously in the form of physiological salt solutions (HgCl₂ 1.0 mg of Hg/kg body weight (b.w.) 3 times per week for 4 weeks; CdCl₂ 1.0 mg of Cd/kg b.w. 3 times per week for 4 weeks; ZnSO₄ 20.0 mg of Zn/kg b.w. 7

Fig. 2. The chromatogram of postmitochondrial supernatant obtained from the livers of female white Wistar rats after exposure to CdCl_2 , separated by gel permeation chromatography (GPC) method on Sephadex G-75 (column K26/100, Pharmacia, Uppsala, 0.1 mol l^{-1} ammonium-formate buffer, pH = 8.0, ionic strength $\mu = 0.1$, 0.05% NaN_3 , flow rate 20.0 ml h^{-1} , fractions of 5.0 ml were collected).

times per week for 2 weeks, CuSO_4 3.0 mg of Cu/kg b.w. 7 times per week for 2 weeks). The homogenates of tissues [liver 25% (w/v) and kidney 20% (w/v)] in 1.15% KCl were prepared. Homogenates were centrifuged ($3000 \times g$ for 30 min) and after initial dialysis (dialysing bag Serva 20/32 and Aquacide II from Serva), the supernatants (5.0 ml) were separated by low pressure gel permeation chromatography (LPGPC) method on

Sephadex G-75 (column K26/100, Pharmacia, Uppsala, 0.1 mol/l ammonium-formate buffer, pH = 8.0, ionic strength of buffer $\mu = 0.1$, 0.05% NaN_3 , flow rate 20.0 ml h^{-1} , fractions of 5.0 ml). The fractions of MTs were collected and the concentration of protein, thiol groups and metals were determined. The molecular weight and the control of quality of obtained MTs and their physicochemical parameters were measured by

Sepharose-1,6-diaminohexylo-X (where X was 5,5'-dithiobis-(2-nitrobenzoate) [Sepharose-DTNB] or 2,2'-dithiobis-(2-nitropyridine)-[Sepharose-DTNP]) were prepared by own methods [44]. The CH-Sepharose 4B gel (Pharmacia, Uppsala), DTNB (Windsor Laboratories), DTNP (BDH) and *N*-cyclohexyl-*N'*-[2-(*N*-methylmorpholino)ethyl] carbodiimide-*p*-toluene sulphonate (carbodiimide CMC, BDH) were used for covalent affinity chromatography gels synthesis. The degree of substitution was about 0.15–0.18 mmol DTNB or DTNP per gram of Sepharose gel and were similar to these types of the commercial materials.

2.3. Preparation of biological material.

Physiological human urine, plasma and human milk were collected from five people (non-smokers) in a good state of health after clinical control. All samples were collected and pooled. The samples were protected by addition of sodium azide (NaN_3) in final concentration 0.05% (w/v). The concentration of protein, thiol groups and metals (Hg, Cd, Zn and Cu) were measured and physico-

chemical parameters of urine, plasma and milk were checked by low- and high-pressure GPC method (Sephadex G-75, Sephadex G-200 and Sephadex G-10, Superdex 75HR-Pharmacia, Uppsala) [39–43,59–61].

2.4. Chromatographic preconcentration of metallothionein samples with application of covalent affinity chromatography gel and quantitation.

Hg-Th, Cd-Th, Zn-Th and Cu-Th were added to triple distilled water, physiological human urine, plasma or human breast milk in different concentrations (1, 5, 10, 25, 50, 100 and 250 $\mu\text{g ml}^{-1}$). Proteins were applied on Sepharose DTNB or Sepharose-DTNP columns (130×10 mm i.d. $v \sim 10$ ml) in volume 5.0 ml and were eluted with: (a) 0.05 mol/l phosphate buffer, pH 8.0; (b) 0.04 mol/l β -mercaptoethanol in phosphate buffer. 2.0 ml fractions were collected at the flow rate 30.0 ml h^{-1} . The CAC-TDI columns were regenerated by DTNB or DTNP in concentration 0.04 mol l^{-1} in phosphate buffer. The concentrations of MTs were calculated from

metals concentrations on CAC-TDI supports, determined by atomic absorption spectrometry (AAS) technique and correlation coefficients between known concentrations and calculated by indirect methods were determined [39–43,59–61].

The concentrations of MTs protein in samples were calculated according to Eq. (1) [39–44]

$$c = (A \times 100\% \times M_{\text{MT}}) / (M_{\text{M}} \times m \times R\%) \quad (1)$$

where: (c) is calculated concentration of MTs in the sample [μg], (A) is content of metals bonded to the CAC-TDI gel [mg], (M_{MT}) is molecular weight of metallothionein protein [g mol^{-1}], (M_{M}) is molecular weight of the determined metals [g mol^{-1}], (m) is the coefficient determined experimentally, characterizing the content of the metals in metallothionein molecule [$\text{mol metal/mol protein}$] and (R) is the mean recovery of adsorption of the metals in the process of metallothionein separation with use of the CAC-TDI method [%], obtained in experiments with separation of MTs on CAC-TDI supports. The added amounts of MT proteins to the samples with different concentration have been compared with the contents as determined by the use of the

indirect method based on determining of the heavy metals as: Hg, Cd, Zn or Cu contents in biological samples.

2.5. Analytical methods

In the investigations the following determinations were carried out: protein concentration by Lowry method [62–66], tannin method [67], BCA method (Pierce, USA) [68–71], CBB method (Bio-Rad, USA) [72–75], thiol groups concentration [76,77], heavy metals (Hg, Cd, Zn and Cu) concentration by the atomic absorption spectrometry (AAS method) [53,54,56–58].

3. Results and discussion

The typical separation of metallothionein (Cd-thionein, Cd-Th) from postmitochondrial supernatant, obtained from the liver of rats after exposure to CdCl_2 , by gel permeation chromatography on Sephadex G-75 and rechromatography

after preconcentration by dialysis are presented in Figs. 2 and 3. The separation of Cd-Th protein by CAC-TDI method with two-step elution is presented in Fig. 4. The correlations between MT protein concentration added to the different mediums (water, urine, plasma, human milk, homogenate) and determined by indirect method are given in Table 1. The correlation coefficients (r) between MT protein concentration added to the same mediums and determined by chemical methods (Lowry, tannin, BCA and CBB) are given in Table 2. The mean errors between the added amount of MT protein and that determined by chemical method and indirect method for two concentrations (5.0 and $250.0 \mu\text{g ml}^{-1}$) are given in Tables 3 and 4. The mean detection limits for different MTs in different mediums with quantitation by indirect method with CAC-TDI gel as SPE support are given in Table 5.

Previous results showed the mechanism of separation of polythiolmetalloproteins was very complicated and that separated proteins change their native structures [45–48] and yields after protein

separation were rather low. Additionally metals formerly bonded with MTs were adsorbed on the CAC-TDI gel not only via immobilized proteins, but also by direct adsorption on the supports and, what is very important, the yields of these reactions are very constant [45–48]. As follows from previous data (Fig. 1)[52–58], the direct concentration of metallothionein protein for analytic purposes is very difficult or even impossible, because of too low yield of binding the MTs protein with CAC-TDI gel, due to the occurrence of reactions, competitive to the binding ones [45–48] and very high detection limit ($0.1\text{--}5.0 \mu\text{g ml}^{-1}$) of chemical methods (Lowry, BCA, tannin and CBB) used for the protein quantitation [62–75]. The binding of 10–50% for different MTs is too low for quantitative isolation, and variations in these values are too big for its theoretical estimation. The situation is not improved even by higher efficiency of binding MT protein in case of its small concentrations in a sample. This fact was observed in synthesis in polysomal cell-free system, where the reaction of intermolecular oxida-

tion of protein –SH groups is much less [51,78–82]. An important fact is the very high and constant content of metals (Hg, Cd, Zn and Cu) in fractions bounded to the CAC-TDI gels. Thus, it is possible to determine the contents of Hg-Th, Cd-Th, Zn-Th and Cu-Th indirectly by the estimation of Hg, Cd, Zn and Cu concentration in the fractions bounded to CAC-TDI gels [39–43,59–61].

The data presented show that the actual contents of protein as well as the ones determined by the indirect method demonstrate a very good correlation in a wide range of concentrations (Table 1). The correlation coefficients ranged between 0.69 and 0.97. The lowest correlation coefficients were for plasma, tissue homogenate and milk while higher correlation were found for urine and water. In comparison, the correlation coefficients (r) between the present concentration of MT and that determined by chemical methods (Lowry, tannin, BCA and CBB methods) ranged from 0.53 to 0.92 for tannin method, 0.40 to 0.91 for the Lowry method, 0.43 to 0.90 for the BCA

Table 5

The mean detection limits for different metallothioneins protein obtained from different mediums with preconcentration by solid phase extraction method on CAC-TDI support

No.	Materials	The detection limits (ng ml ⁻¹)			
		Hg-Th	Cd-Th	Zn-Th	Cu-Th

^a Homogenates was obtained from liver of rats exposed to CdCl₂.

and 0.44 to 0.91 for CBB but for all physiological fluids were lower than 0.83 for tannin, lower than 0.75 for Lowry, lower than 0.80 for BCA and lower than 0.81 for the CBB method (Table 2). The errors between the actual content of protein in the sample and the concentration as determined by the indirect method consisting in metals analysis of the metals bound with CAC-TDI does not exceed 2.4% for the highest concentration of MT protein added (250 µg ml⁻¹) and 4.3% for the lowest concentration (5 µg ml⁻¹). For the chemical methods the errors ranging between 3.8 and 11.3% for the tannin method, 5.1–13.3% for the modified Lowry method, 5.1–13.4%, for the BCA and 5.0–13.7% for the CBB and were higher than for proposed indirect CAC-TDI method (0.8–4.3%) (Tables 3 and 4). The detection limits for CAC-TDI methods are about 5.47–9.28 ng ml⁻¹ for different types of MTs (Table 5). Thus, the described method may be applied to the indirect determination of metalloproteins in physiological fluids by means of evaluation of the metal contents on the CAC-TDI gel after adding the metalloprotein samples. The process of metal binding itself has a quantitative character unlike binding of thiolproteins where a complex mechanism of interaction CAC-TDI gel-separating protein causes lowering of binding efficiency [45–48]. The yields of adsorption depend on the structure of CAC-TDI gel (length of spacer arms, their modification and type of ligand) and pH of using buffers. Additionally buffer has the influence on the mechanism of adsorption reaction (cationic or anionic) and yields of separation of the thiol-

proteins [44,83–86]. Thus, the described method of indirect evaluation of protein content may be applied in clinical and toxicological analysis. The CAC-TDI gel itself may function as a sorbent for preconcentration of thiol- and metallothiol-proteins at solid phase extraction (SPE) technique allowing us to concentrate proteins. It may also function in a similar way in relation to heavy metals as: Hg, Cd, Co, Cu, Mo, Zn, Au, Ag, etc. acting both on free ions of these metals and those bound with proteins. The metals bound with the CAC-TDI gel with participation of mercaptide bonds of metal-sulphur may be easily washed from it by means of low-molecular thiolcompounds. Ease of adsorption and desorption are among the basic factors qualifying deposits of CAC-TDI types as sorbent in the SPE method. With detection limits for AAS method about 1.0–0.01 ng of metals (Hg, Cd, Zn, Cu) ml⁻¹ [87–99] and with conversion factors of 3–8 mol metal/mol MT protein and with yields of adsorption of heavy metals with 30–40% of applied doses. The detection limit for MT protein at in-direct method can be about 1–10 ng ml⁻¹. This detection limit for presented indirect method is lower than for chemical methods (100–500 ng ml⁻¹) but higher than for immunological method as RIA or LIA (0.1–0.01 ng ml⁻¹). The very important fact is that sensitivity of proposed indirect method with application of CAC-TDI gel has a proper level for clinical analysis.

Urine, plasma, human milk samples and corresponding solutions of tissue must be collected. After addition of MTs to urine, plasma or other

physiological fluids, they play a role in the model of physiological fluids containing MTs, from people after exposure to heavy metals. It seems necessary to carry out pretreatment by the high- or low-pressure GPC method, in order to remove proteins heavier than MT, and also amino acids, oligopeptides and low-molecular metal compounds, mainly Hg ones (Fig. 5). This procedure

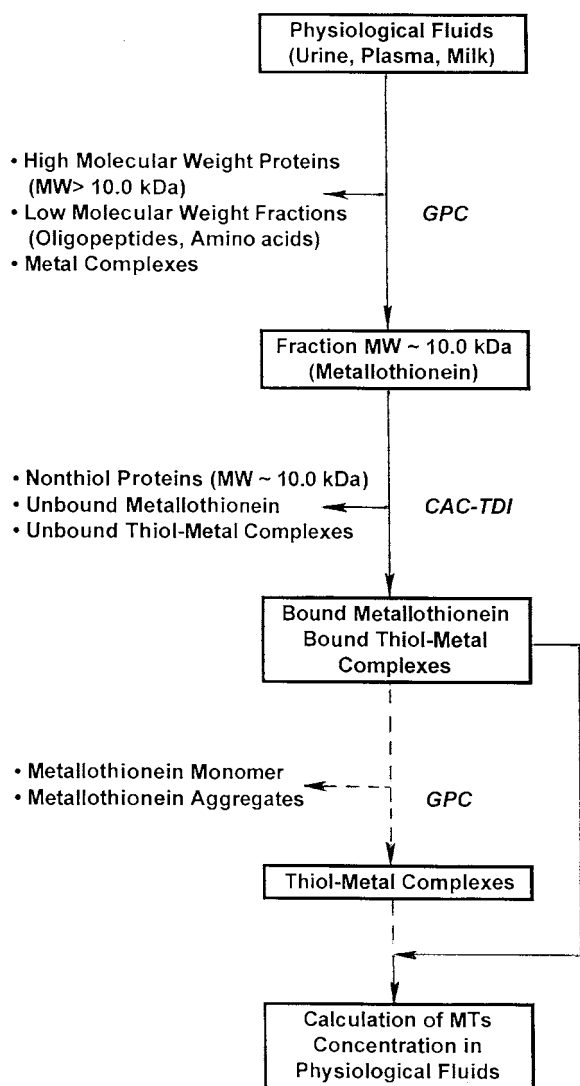

Fig. 5. The scheme of procedure of metallothioneins and metals pre-concentration on covalent affinity chromatography with thiol-disulphide interchange (CAC-TDI) gel as support for solid-phase extraction (SPE) method.

is essential while investigating MTs in the human urine, plasma and milk, which contains small amount of proteins, oligopeptides and amino acids with quite high contents of -SH groups. The other important problem during the investigations is carried out a short time after exposure to heavy metals appearing in the body fluids in the form of low-molecular compounds [100,101]. The preparation obtained in this way can be considered to be the initial fraction. Application of CAC-TDI method at a further stage allows recovery of only about 20–30% of applied MT protein, about 30–40% of Cd, Zn or Cu and about 80% of Hg (Fig. 5). The sample, prepared in this way does not contain any other ballast proteins of 10|000 Da mass, which could contain only a few -SH groups or none at all [102,103]. This method allows us to obtain concentrated preparations, containing Hg, Cd, Zn and Cu mobilized from mercaptide bonds in Hg-Th, Cd-Th, Zn-Th and Cu-Th. The metals can be determined by AAS method already at this stage, in the presence of MTs protein [39–44,59–61].

4. Conclusions

In conclusion we can emphasize that, the supports for covalent affinity chromatography with thiol-disulphide interchange (CAC-TDI) can be used as a solid phase extraction (SPE) gel for pre-concentration of metallothioneins protein and metals bonded to them. The concentration of metallothioneins in human fluids (urine, plasma and milk) can be determined by the indirect method, based on calculation of MTs concentration from content of metals bonded to the covalent affinity chromatography column and the detection limits for these methods are about 5.47–9.28 ng ml⁻¹, a proper level for clinical analysis. The correlation coefficients for the presented indirect method are 0.69–0.97. The presented method can be used in toxicological analysis for the determination of industrial and environmental exposure to heavy metals, and environmental analysis for determining the value of intoxication of the environment by heavy metals.

Received 4 November 1996; received in revised form 5 August 1997; accepted 27 September 1997

Abstract

Metallothionein (MT) isoforms of mouse liver cytosol were separated by capillary zone electrophoresis (CZE) using a polyacrylamide-coated tube at neutral pH, samples prepared from non-treated, heat-treated, and ethanol-precipitated specimens were compared. The liver was homogenized in three kinds of media, 0.25 M sucrose containing 100 mM Tris-HCl buffer at pH 7.4 (BS), BS containing 1% ascorbic acid (BS-C), and BS containing 5 mM β -mercaptoethanol (BS-M). Mouse liver was used 24 h after subcutaneous injection of 50 mg Zn kg⁻¹. In the non-treated specimen of the cytosol fraction, the MT-2 isoform was separated in all three media, while the MT-1 isoform was difficult to identify. In the ethanol-precipitated specimen, MT isoforms were separated well using either BS or BS-C. However, when BS-M was used, a small MT-2 peak was obtained the MT-1 peak could not be identified. MT-1 isoform in the heat-treated specimen was difficult to identify. In contrast, MT-2 isoform was separated well in all three kinds of media. In the non-treated specimen of the control liver cytosol, the MT-2 isoform was detected using all three media, the MT-1 peak was undetected. Based on these results, MT isoforms can be detected in the crude cytosol fraction of liver using CZE combined with a polyacrylamide-coated tube at neutral pH. © 1998 Elsevier Science B.V. Keywords: Metallothionein; Isoform; Capillary zone electrophoresis; Polyacrylamide-coated tube

1. Introduction

Metallothionein (MT) is a protein induced by various stimuli such as metals, stress, and some chemicals [1,2]. MT is necessary for absorbing

and storing essential metals, and for maintaining both Zn and Cu levels in tissues. Detoxification of heavy metals and scavenging of free radicals are also reported as important actions of MT. However, the essential role of MTs in a variety of tissues is still unknown. MTs in mammalian tissues have two major isoforms, MT-1 and MT-2. In addition, two new isoforms, MT-3 and MT-4, were recently found in brain and tongue, respectively [3–5]. Among these isoforms, it is interest-

* Corresponding author. Present address: Laboratory of Cell Biology, Department of Anatomy, Nara Medical University, 840 Shijo-Cho, Kashihara, Nara 634, Japan. Tel.: +81 744 223051 (Ext. 2229); fax: +81 744 248432; e-mail: minami@nmu-gw.cc.naramed-u.ac.jp

ing to observe the functions of MT-1 and MT-2, as these isoforms have very similar amino acid sequences and are induced in the same organs by the same stimuli.

Capillary zone electrophoresis (CZE) is an effective method for the separation and quantification of various substances, because of high speed, resolution and sensitivity [6]. However, factors affecting electroosmotic flow and nonspecific adsorption to the inner surface of the tube can interfere with the separation of fractions. MT isoforms have also been separated by CZE [7,8]. As suggested by Richards and Beattie [9], optimal separation of MT isoforms can be obtained using the correct choice of capillaries, buffers, and sample separation techniques. We previously reported that a polyacrylamide-coated tube was effective in separating tissue MT isoforms at neutral pH [10], although there have been several reports that used uncoated tubes for MT isoforms separation [11,12]. Polyacrylamide-coated tube has a neutral surface over the whole pH range, up to pH 10, it is independent of pH in the electrophoresis buffer, sample buffer and in the buffer of the coating medium. Therefore, in the present study, we investigated various media and sample preparation methods in order to improve the separation of tissue MT isoforms on CZE using a polyacrylamide-coated tube at neutral pH, and tried to separate MT isoforms from other proteins in crude samples.

2. Materials and Methods

2.1. Materials

Acrylamide, ammonium persulfate, *N,N,N',N'*-tetramethyl ethylene diamine (TEMED), tris (hydroxymethyl) aminomethane (Tris), ascorbic acid, and β -mercaptoethanol were purchased from Wako, (Osaka, Japan). 3-Methacryloxypropyltrimethoxysilane (3MTMS) was purchased from Shin-Etsu, Tokyo, Japan, and *N*-2-hydroxy ethyl piperazine-*N'*-ethanesulfonic acid (HEPES) was purchased from Dojindo, Kumamoto, Japan. The other reagents were purchased from Wako, Osaka, Japan.

2.2. Experimental animals

Male ddY mice (6-weeks old) were obtained from Japan SLC (Shizuoka, Japan). Before experiments were carried out, they were housed for 1 week during which time they were fed standard mouse food (MF, Oriental Yeast, Tokyo, Japan) and were given free access to tap water.

2.3. Coating of the inner surface with polyacrylamide and zone electrophoresis

The polyacrylamide-coated tube was prepared by the modified method of Hjertén [13]. Details are given in a previous report [10,14]. A fused-silica capillary tube (75 μm i.d., Otsuka Electronics, Osaka, Japan) was cut to a length of 50 cm. The capillary tube was flamed to remove polyimide, and a UV detection window was made on the wall of the tube about 16 cm from one end. The capillary tube was flushed with water, 0.1 M sodium hydroxide, 0.1 M hydrochloric acid, acetone, and 1:1 mixture of acetone and 3MTMS, sequentially. The tube was then filled with 3MTMS, and allowed to stand overnight at room temperature. After washing the tube, the tube was filled with a mixture of acrylamide, ammonium persulfate, and TEMED in sodium phosphate (50 mM, pH 7.0), and the mixture was allowed to polymerize overnight. After washing the tube, both ends of the polyacrylamide-coated capillary tube were cut to give a final column length of 42 cm.

The polyacrylamide-coated tube was installed in an Otsuka CAPI-3000 (Otsuka Electronics) capillary electrophoresis system. The running buffer was 25 mM HEPES–Tris buffer (pH 7.4). Samples were loaded onto the column (by gravity) for 10 s. The inlet of the capillary was at the cathode. The analysis was performed at 25 kV and $25 \pm 1^\circ\text{C}$, and peaks of MT isoforms were monitored at 200 nm as suggested by Richards and Beattie [8].

2.4. Drug administration

Mice were subcutaneously injected doses of 50 mg Zn kg^{-1} in the form of zinc sulfate. In the

Fig. 1. Scheme of preparation of specimens for MT analysis

control, mice were subcutaneously injected with 10 ml saline kg^{-1} instead of zinc. Zinc-injected mice and saline-injected control mice were decapitated after 24 h, and the livers were removed.

2.5. Preparation of MT samples from mice liver

The liver was divided into six parts, and each part was homogenized to make a 20% homogenate with three kinds of media: 100 mM Tris-HCl, pH 7.4, 0.25 M sucrose (buffered sucrose solution: BS), BS containing 1% ascorbic acid (BS-C), and BS containing 5mM β -mercaptoethanol (BS-M), respectively, with an ultra-speed blender (Phycotron, NITI-ON, Kanagawa, Japan). Non-treated, heat-treated, and ethanol-precipitated specimens were obtained as shown in Fig. 1.

Each specimen was passed through a filter (0.45 μm , Chromatodisk 4A, Kurabo, Osaka, Japan) before CZE analysis. Peaks corresponding to MT-

1 and MT-2 isoforms of the specimens were identified by co-electrophoresis with purified MT-1 and MT-2, which were obtained from the liver of a Cd-administered mouse [10]. Each purified MT-1 and MT-2 appeared as a single peak on the CZE chromatograms, as described in our previous report [10].

3. Results

In the case of CZE analysis, it is difficult to measure the metal contents of the sample for the identification of MT isoforms, because the sample loading volume for analysis is small, and because fractionation after separation is difficult. Therefore, both MT-1 and MT-2 isoforms of the samples were identified by their migration times which coincided with those of standard MT-1 and MT-2 isoforms, and further identified by the addition of standard isoforms to the samples.

MT-1 and MT-2 isoforms were found in the non-treated specimen prepared from the liver of a zinc-injected mouse with BS (Fig. 2a). MT-2 was clearly distinguished from the other peaks, but MT-1 was difficult to identify. The ratio of the peak areas (MT-1/MT-2) was 0.95 ± 0.32 (mean \pm SD, $n = 3$). When BS-C or BS-M was used, the MT-1 and MT-2 peaks were detected as well as they were with BS (Fig. 2b and 2c), and the ratios of MT-1/MT-2 were 1.11 ± 0.55 (BS-C) and 0.24 ± 0.14 (BS-M), respectively.

In the ethanol-precipitated specimen, the MT-1 and MT-2 isoforms were separated with BS (Fig. 3a), and the ratio of MT-1/MT-2 was 1.75 ± 0.95 . MT-1 and MT-2 isoforms prepared with BS-C were also separated clearly (Fig. 3b), and the ratio of MT-1/MT-2 was 3.65 ± 1.38 . However, in the sample prepared with BS-M, a small MT-2 peak was obtained, and MT-1 peak was not identified (Fig. 3c).

In the heat-treated specimen, a small and broad MT-1 peak was detected in the sample prepared with all three media, while MT-2 peak was identified clearly in all three media (Fig. 4).

In the non-treated specimen from the control mice, the MT-2 isoform was detected clearly with all three media. However, no peak corresponding to the MT-1 isoform was found with any of the three media (Fig. 5).

4. Discussion

The MT-1 isoform is related to metal uptake or detoxification of heavy metals, while the MT-2 isoform is related to cell growth or various stresses [15]. However, the different role of these two MT isoforms is still unclear. Several methods have been reported for the separation of the MT

Fig. 2. (Continued)

Fig. 2. Electropherograms of MT isoforms in non-treated specimens of liver from a zinc-injected mouse. The liver was homogenized with three kinds of media: (a) BS; (b) BS-C; (c) BS-M. The non-treated specimen was loaded onto the column by gravity for 10 s at the cathode side, and the analysis was performed at 25 kV and $25 \pm 1^\circ\text{C}$ using 25 mM HEPES–Tris buffer at pH 7.4 as running buffer. Detection of MT isoforms was monitored at 200 nm.

Fig. 3. Electropherograms of MT isoforms in ethanol-precipitated specimens of liver from a zinc-injected mouse: (a) BS; (b) BS-C; (c) BS-M. Ethanol-precipitated specimen was loaded onto the column by gravity for 10 s.

Fig. 4. Electropherograms of MT isoforms in heat-treated specimens of liver from a zinc-injected mouse: (a) BS; (b) BS-C; (c) BS-M. Heat-treated specimen was loaded onto the column by gravity for 10 s.

isoforms, such as anion-exchange chromatography, high performance liquid chromatography (HPLC) and enzyme-linked immunosorbent assay (ELISA) [3]. Recently, CZE analysis was used. We have shown that a polyacrylamide-coated tube is effective for separating tissue MT isoforms at neutral pH with CZE [10]. As MT is stable at heat treatment, heat treatment is usually used for measuring MT contents in the tissue, Cd–heme method [3,16]. In contrast, the ethanol-precipitated method is a well known method for purification of MT [17]. MT isoforms of specimens obtained from non-treated, heat-treated, and ethanol-precipitated methods were separated by CZE at neutral pH, and compared. The present results show that MT isoforms can be identified in the both non-treated and ethanol-precipitated specimens from the livers of zinc-injected mice. In the heat-treated specimen, both MT isoforms were separated, even though a small and broad MT-1 peak was obtained. In the control mice, the MT-1 isoform was not detected in the non-treated liver specimen as shown in Fig. 5. The MT-1 isoform was detected in ethanol-precipitated specimens of livers from control mice, as described in previous reports [10,14]. It was difficult to identify the MT-1 isoform in the control liver from the non-treated specimen.

It is known that each MT isoform has several sub-isoforms [15,18,19]. Indeed, each MT isoform of a commercial standard was shown to have several peaks [10]. Virtanen et al. [12] reported that some sub-isoforms were found in the commercial standard, and that CZE could separate sub-isoforms. However, we could not detect sub-isoforms for each MT isoform in the present study, because using CZE, each purified MT isoform was observed a single peak as shown in our previous report [10]. In addition, as we could not determine the metal contents in those peaks, it was difficult to identify the presence of MT sub-isoforms. Standards used in the present study were Cd-MTs instead of Zn-MTs. In the previous report [14] as the peak of MT-1 decreased significantly following the addition of Cd, it is thought that a change in the MT electric charge occurred. Suzuki and Yamamura [20] also reported that the dimer forms of MT isolated from rabbit liver

Fig. 5. Electropherograms of MT isoforms in non-treated specimen of control mouse liver: (a) BS; (b) BS-C; (c) BS-M.

accumulated a large quantity of Cd. MT may form dimers and/or polymers easily in the presence of excess Cd, and there is doubt as to whether Cd-MTs are adequate standards, as MT isoforms are identified using both the migration times and co-electrophoresis with purified Cd-MT isoforms. The peak areas identified as MT isoforms increased after zinc injection, the peak ratio of MT-1/MT-2 was similar to that reported previously [15], purified Cd-MT isoforms may be used as standards. In addition, the baseline was not stable during analysis, although we calculated the peak ratio of MT-1/MT-2 from their migration times. It is necessary to obtain a stable baseline for quantification of MT isoforms.

It is known that the MT-1 isoforms in less stable to air-oxidation than the MT-2 isoform and Zn-MT is unstable in comparison with Cd-MT [21]. Therefore, denaturalization by air-oxidation must be considered at each step of MT isoforms preparation. In the present study, as both MT isoforms are well separated with BS-C in comparison with BS and BS-M, BS-C may be useful for preparation of MT.

In conclusion, CZE analysis with a polyacrylamide-coated tube at neutral pH is effective for separating tissue MT isoforms in mouse liver cytosol.

Abstract

In mice, autoimmune diabetes can be induced with multiple low doses of streptozotocin (MLD-STZ). Specific T cell-dependent immune reactions and non-specific inflammatory damage induced by reactive oxygen species (ROS) are involved in the pathogenesis of MLD-STZ diabetes. Metallothionein (MT) can be significantly ($P < 0.05$) induced with $ZnSO_4$ in pancreatic islets in vivo and in vitro. In vitro, preincubation of isolated islets with $ZnSO_4$ prevented STZ-induced loss of β -cell-function and in vivo, intraperitoneal pretreatment with $ZnSO_4$ prevented MLD-STZ-induced diabetes. It is proposed that $ZnSO_4$ -induced MT rescued β -cells by scavenging STZ-generated hydroxyl-radicals ($\cdot OH$). © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Streptozotocin (STZ) is a naturally occurring antibiotic and potent toxin for insulin-producing β -cells in mice, rat, and humans [1]. To induce diabetes in mice by STZ, two experimental protocols that involve different pathogenic pathways are being used. A single injection of a high dose (HD-STZ) exerts direct toxicity on the insulin-producing β -cells, which results in necrosis within 48–72 h and overt hyperglycemia. A form of

autoimmune diabetes can be induced with multiple low doses (MLD-STZ), i.e. intraperitoneal injections of 40 mg STZ kg^{-1} body weight on five consecutive days. STZ is a bipartite molecule that is composed of a glucose moiety and a methylnitrosourea (MNU) moiety. With MLD-STZ, two different effects are being exerted, namely direct β -cell toxicity followed by T cell-dependent inflammatory immune reactions [2,3]. The glucose moiety of STZ specifically directs the agent to the β -cells while toxicity is inflicted on the cells by the MNU moiety [1,4]. It has been suggested that in the HD-STZ diabetes model β -cell damage may be mediated by STZ-generated hydroxyl radicals

(\cdot OH) [5,6], which are the most toxic of the group of reactive oxygen species (ROS). In the MLD-STZ-induced autoimmune diabetes model ROS are also suspected to be involved in the pathogenesis, namely as non-specific mediators of inflammatory reactions. We studied the possibility that induction of metallothionein (MT) in pancreatic islets may protect against STZ-induced toxicity and loss of β -cell function.

MT are cytosolic proteins, they are present in a wide variety of eukaryotic species, and it is assumed that they have essential biological roles. Although the precise function of MT is still not known, the ability to both bind and be induced by heavy metal ions strongly suggest a central role in metal metabolism and detoxification [7,8]. Other possible functions for MT might be control of intracellular redox potential and scavenging of \cdot OH [9–11]. In order to resolve the function of MT numerous attempts have been made in vitro and in vivo using various experimental protocols. In vitro, e.g. resistance of MT-I-transfected chinese hamster cell line to spontaneous mutagenesis was observed [12] and MT was found to be superior to glutathione (GSH) in inhibiting \cdot OH-generated DNA degradation [10]. Thus, a concentration of 13 μ M MT was equivalent to 10 mM GSH in preventing DNA degradation and for an equivalent protective potential a 38.5 higher thiol content was required for GSH than for MT. In vivo, e.g. significant reduction of nickel-induced mortality by MT induction in mice was reported [13] and significant reduction of STZ-hyperglycemia in rats [14].

Recently, this laboratory was first to report that MT is constitutively expressed in pancreatic islets of mice and that it can be induced significantly by zincsulphate (ZnSO_4) in vivo [15] and in vitro [16]. Here, we present data demonstrating that pre-treatment with ZnSO_4 protected islets from STZ-induced loss of β -cell function in vitro and in vivo.

2. Experimental design and results

C57BL/6 male mice, 5–6 weeks old, were purchased from Bomholtgard (Bomholtvej, Den-

mark). They were kept under specific pathogen-free conditions and received tap water and rodent chow ('Ssniff M', Ssniff, Soest, Germany) ad libitum. They were 7–8 weeks old when used for experimental investigations.

For in vitro studies, islets were isolated by collagenase digestion as described previously [15]. Duplicates of 10 islets each were used for a given experimental protocol. To analyze the effect of ZnSO_4 -induced MT on STZ toxicity four different groups of cultures were set up, two of these were used as experimental and two as control cultures. One culture group containing each of the experimental and control ones was preincubated with 0.05 mM ZnSO_4 (Merck, Darmstadt, Germany) as final concentration for 24 h. Following a washing procedure the experimental cultures were incubated for 30 min with a toxic dose of STZ (Boehringer Mannheim, Mannheim, Germany), i.e. 3 mM STZ as final concentration and the control cultures with the solvent of STZ. After a washing procedure a β -cell function test was performed as described [17]. Then the islets were cultured for another 3 days before repeating the β -cell function test. In this assay basal and glucose-stimulated insulin release are determined and the results are calculated as index of glucose-stimulated insulin release which is the ratio of glucose-stimulated insulin release over that of basal insulin release. Islets were stimulated with 16.7 mM glucose as final concentration. Insulin release was determined as immune reactive insulin levels by RIA kits (Pharmacia Biotech, Freiburg, Germany) according to the manufacturer's instruction. For each analysis the mean values of duplicate cultures were used. To analyze the effect of ZnSO_4 -induced MT in pancreatic islets on MLD-STZ-induced diabetes, groups of ten mice each were injected intra-peritoneally with either MLD-STZ, i.e. 40 mg STZ kg^{-1} body weight on 5 consecutive days or in addition with 10 mg ZnSO_4/kg body weight 24 h before each of the five STZ injections. Blood glucose was determined by the hexokinase method as described previously [3]. Blood glucose concentrations were measured before and at weekly intervals after starting treatment. Mice which had a blood glucose level of ≥ 250 mg dl^{-1} (= 13.88 mM) on 3 consecutive weeks were diagnosed as diabetic.

Fig. 1. Index of glucose-stimulated insulin release of pancreatic islets of C57BL/6 mice in vitro. The islets were incubated with either STZ only or preincubated in addition with ZnSO₄. The indices represent the ratio of glucose-stimulated insulin release over that of basal insulin release. The indices were calculated by using the mean values of duplicate cultures.

As shown in Fig. 1, incubation of islets with STZ abolished glucose-stimulated insulin release, whereas pretreatment with 0.05 mM ZnSO₄ rescued the physiological β -cell function as indicated by an index of approximately 4 which is similar to those obtained in control cultures (not shown). This protective effect of MT induction was also observed after pretreatment with 0.1 mM ZnSO₄. Since preincubation of control cultures with ZnSO₄ failed to exert essential effects on glucose-stimulated insulin release the results are not shown.

This laboratory recently reported that MT is constitutively expressed in isolated pancreatic islets of mice and that MT can be induced by intraperitoneal injection with either ZnSO₄ or STZ [15]. MT concentrations were assessed by using both the Cd-hemoglobin saturation assay [18] and the more sensitive Cd-Chelex assay [19]. A significant ($P < 0.001$) and dose-dependent MT induction was obtained by treatment with both ZnSO₄ and STZ. MLD-STZ treatment proved to be the most potent MT inducer with an index of 8.6. In a first series of experiments we analyzed the effect of MT induction in pancreatic islets on MLD-STZ-induced diabetes. As shown in Fig.

2A, pretreatment with ZnSO₄ significantly ($P < 0.05$) prevented MLD-STZ-induced hyperglycemia and resulted in a significantly ($P < 0.05$) higher prevalence of euglycemic recipients, namely 75% compared with only 20% euglycemic mice in the group treated with MLD-STZ only (Fig. 2B).

3. Discussion

Besides being involved in metal metabolism [7,8], MT have been proposed to play a protective role against ROS-mediated cellular damage at sites of inflammation [7,8] and have been found to efficiently scavenge $\cdot\text{OH}$ in vitro [9–11]. Based on the protective role of MT in many in vitro observations, it is necessary, however, to evaluate if there is also an essential role for MT as cellular antioxidant in vivo under physiological conditions and in disease.

Our aim was to analyze if the induction of MT in pancreatic islets of mice by treatment with ZnSO₄ may protect against the β -cell toxin STZ. The present data demonstrate that preincubation of isolated pancreatic islets with ZnSO₄ prevented STZ-induced loss of glucose-stimulated insulin re-

lease in vitro. In vivo pretreatment with ZnSO_4 conferred significant protection toward MLD-STZ-induced diabetes. It is assumed that the protective effects observed are due to MT induced by ZnSO_4 in the β -cells. Similar effects of ZnSO_4 -induced MT on STZ-induced diabetes were reported by Yang and Cherian [14]. Just as we did it with mice, they injected rats also with $10 \text{ mg ZnSO}_4 \text{ kg}^{-1}$ body weight prior to STZ and obtained significant reduction of STZ-induced hyperglycemia. Their rat model, however, differs

from our mouse model because the rats were injected with a single high dose of STZ mediating acute toxicity and subsequent β -cell necrosis which results in immediate hyperglycemia, whereas in the MLD-STZ system diabetes develops more slowly. The underlying mechanism, however, of the protective effects of ZnSO_4 -induced MT might be comparable.

Based on our data it is hypothesized (Fig. 3) that STZ-induced generation of $\cdot\text{OH}$ results in preferential damage of the glucose transporter 2 which is pivotal for β -cells to respond to extracellular glucose concentrations to initiate the signal transduction for adequate insulin secretion. Induction of MT is assumed to scavenge $\cdot\text{OH}$ and thus rescue the β -cells from oxidative damage. The rationale for this working hypothesis is that: (1) STZ-induced H_2O_2 -mediated DNA fragmentation has been reported in pancreatic islets [6], therefore, $\cdot\text{OH}$ can be generated in the presence of adventitious iron (Fe^{++}) due to a Fenton-type reaction [7]; (2) we found MLD-STZ to preferentially and significantly reduce glucose transporter 2 protein and mRNA expression in pancreatic islets ex vivo, whereas MLD-STZ failed to affect mRNA expression of glucokinase, a pivotal enzyme required for glucose metabolism, mRNA expression of proinsulin, a β -cell specific molecule, and mRNA expression of β -actin, a house-keeping gene [20]; and (3) that $\cdot\text{OH}$ have been directly detected in pancreatic islets of untreated donors rats by electron spin resonance spectroscopy [21]. Further aims are to apply this technology to evaluate the role of $\cdot\text{OH}$ generation and MT induction under the pathological conditions in the MLD-STZ diabetes model in mice. These investigations as well as the use of MT-transgenic [22] and MT-knockout mice are expected to contribute to resolve the possible function of MT in induced diabetes.

Fig. 3. Hypothesis of STZ-mediated damage on β -cells and the role of MT as cytosolic scavenger of STZ-generated OH^\bullet . The glucose transporter 2 is a crucial target molecule for STZ and its severe reduction or loss abolishes the insulin response to glucose. Induction of MT prior to this diabetogenic insult might prevent OH^\bullet -mediated toxicity on the glucose transporter 2 and rescue β -cell function.

Abstract

A quick leaching test procedure for monolithic waste materials has been developed by a Nordic expert group using experimental factorial design. The Dutch quick leaching test proposal in which the wetting time of the test specimen is reduced by applying vacuum was chosen as a starting point. The influence of the following parameters were studied: vacuum, stirring, open or closed vessel, water renewal frequency, leachant quality and laboratory or batch differences. The study was performed with test specimens prepared from a cement stabilised soil containing As, Cr and Cu. The test specimens were immersed in water and the water was renewed at certain time intervals. The study clearly showed that the use of vacuum had a strong effect on the release rate and that the open vessel lowered the pH-values of the eluates due to uptake of carbon dioxide in the water. The results also indicate higher emissions when stirring was applied. The following test conditions are recommended: application of vacuum prior to testing, use of closed test vessel, use of stirring, a test time of 3 days with four water renewals after 15 min vacuum steps, and then after e.g. 2 h, 23 h and 3.2 days, use of demineralised water as leachant. The amount of water must be selected according to the size of the test specimen. A liquid to surface (L/A) ratio of 5–10 ml cm⁻² is recommended. All four eluates collected are filtered and analysed. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

A Nordic expert group was formed in 1994 with the task of developing a Nordic quick leaching test for monolithic materials. In the expert

group the following institutes were represented: VTT (Finland), Swedish Geotechnical Institute (Sweden), Water Quality Institute (Denmark), SINTEF SI (Norway) and Icelandic Building Research Institute (Iceland). The experimental work was set up in the expert group. Each participating laboratory performed a given test series on a

* Corresponding author.

cement stabilised test material. The work was organised by VTT.

The primary mechanism of contaminant release from monolithic materials is through diffusion or dissolution from the surface [1]. Monolithic materials cannot be studied using same test methods as granular materials. The containment of the contaminants is neglected, if the monolithic material is crushed for testing. The leaching behaviour of monolithic or stabilised materials is usually studied by a tank leaching test [1,2]. The amount of contaminants available for leaching can be estimated from crushed material by the Dutch availability test [1] or by the Canadian sequential chemical extraction test [2].

The Dutch tank leaching test for monolithic materials [3] was recommended by the Nordic expert group for studies on the leaching behaviour of monolithic material [4]. In the Dutch tank leaching test a specimen is immersed in water and the water is renewed at certain time intervals. The leaching mechanism, the diffusion coefficient and the release per surface area of the specimen are estimated in the test. The test time in the tank leaching test is long (64 days).

A quick test for monolithic materials is needed especially for screening, quality control and for regulatory purposes. A quick test means shorter testing time and lower testing costs. The requirements for a quick test on monolithic materials were the following:

- easy to perform
- a test time of less than 1 week
- reasonable testing costs (not more than three to four eluates to analyse)
- indication of the leaching mechanism of constituents
- indication of the diffusion coefficients of constituents
- a measure of the release per surface area.

The starting point in the development of a quick test was the Dutch quick test proposal [5]. The initial leaching of stabilised materials occurs from the surface. Leaching governed by diffusion from the inner parts of the specimen can take place first when the outer layers of the specimen are wetted. In a Dutch test proposal the wetting time is minimised by applying vacuum.

2. Experiments

2.1. Test material

Soil samples contaminated with As, Cr and Cu were taken from an old site of a wood preserving plant. The samples contained sand, till and humus. The average concentrations of the contaminants in the soil samples were: As 50 000 mg kg⁻¹ dry matter, Cr 9000 mg kg⁻¹ dry matter, and Cu 14 000 mg kg⁻¹ dry matter. The soil samples were homogenised and the test specimens (cylinder with diameter 10 cm and height 10 cm) were prepared by mixing the soil in batches with cement and water (no additives were used in order to have measurable concentrations in the eluates). The ratio of cement to soil was 1:4.5. The compression strength of the test specimen was 5–6 MPa.

2.2. Test methods and experimental plan

2.2.1. Standardised test methods

The availability of As, Cr, Cu, Ca and Na for leaching was studied using the Dutch availability test [6]. Crushed and milled samples from two batches were studied as duplicates. Finely ground material, 95% < 125 μm, is mixed with water at a liquid to solid ratio 100. The test is carried out in two consecutive leaching steps. In the first step, pH 7 is held constant for 3 h by the addition of nitric acid. The mixture is filtered through a 0.45 μm filter and the eluate is stored. In the second step the filter containing the waste material is mixed with fresh water and the pH of the mixture is kept at pH 4 for 3 h by the addition of nitric acid. The eluate is separated from the mixture by filtration. The eluates from both leaching steps are combined. The metals were analysed using AAS/flame.

The leaching of Na, Ca, As, Cr and Cu from the test specimens was studied using a Dutch full long (64 days) tank leaching test [3]. In the tank leaching test a test specimen with a known surface area is immersed in a weakly acidified water at pH 4 in a closed vessel by a nylon string. At certain time intervals, 0.25, 1, 2.25, 4, 9, 16, 36 and 64 days after start of the test, the water is replaced

by fresh water and analysed for pH and constituents of interest after filtration through 0.45 µm filter. The metals were analysed using AAS/flame or AAS/graphite furnace (low concentrations).

2.3. Experimental plan

The experiments were planned so as to indicate the effects of the relevant parameters. The following parameters were identified:

- application of vacuum prior to testing
- leachant to surface area (L/A) ratio
- frequency of water renewal
- stirring
- leachant medium
- use of open or closed vessel.

The following leaching test was designed for the study: a test specimen was placed in a vacuum tank. Vacuum was applied (alternatively not applied) for 5 min. before the addition of water to the vacuum tank, 10 min after immersing the test specimen in water. The test specimen was removed from the vacuum tank and placed in a test vessel which contained weakly acidified water with an initial pH of 4 (alternatively demineralised water). The amount of water (L, liter) to the surface (A, cm²) of the test specimen was L/A 2.5 (alternatively 5 and 10). The test vessel was closed (alternatively open) during the test. The water in the test vessel was renewed after 0.5, 2, 7, 23, 47 h and 3.2 days (alternatively after 2, 23 h and 3.2 days). All eluates were filtered. The pH and conductivity of the eluates were measured and the eluates were analysed for Na, Cu and Cr. The metals were analysed using AAS/flame or AAS/graphite furnace (low concentrations)

The experimental plan is attached as Appendix A. The design was based on the orthogonal array [7]. The effect of seven parameters (including laboratory and batch differences) can be determined. Moreover, the influence of interactions between these parameters (e.g. L/A and vessel and L/A and stirring) can be studied.

The experimental study with 16 runs was performed in four Nordic countries (with specimens from four batches). The confirmation tests with four runs were performed later after analysis of the results from the 16 runs.

3. Results and discussion

3.1. Influence of selected parameters on leaching

3.1.1. Interpretation of pH values

The pH-values varied from 10.4 to 11.5 in the eluates collected after 3.2 days. The use of open vessel had the strongest influence on pH value at 3.2 days. The pH values was on average about 0.4 higher in an open vessel than in a closed vessel. The influence of pH was not as significant at 23 h. The uptake of carbon dioxide from air with time is the main reason for the lower pH-value in the open vessel. The effects of other parameters were not significant.

The contribution ratio to the variations of pH and conductivity were estimated after 1 day of leaching and at 3.2 days of leaching (Fig. 1).

3.1.2. Interpretation of conductivity

The conductivity varied between 15 and 67 mS m⁻¹ in the eluates collected after 3.2 days. The vessel had the strongest effect on conductivity after 3.2 days. Closed vessel had on average 20 mS m⁻¹ higher values. This means that the leachant composition was different in open vessel due to lower leaching rate or precipitation. A similar effect could also been seen at time 23 h (Fig. 1).

The use of larger L/A decreased the conductivity only in closed vessels. The conductivity was not clearly influenced by the increase of L/A in the open vessel, which indicated a strong influence of air on the leachant composition. The effects of other parameters were not significant.

3.1.3. Interpretation of leached amounts

It was not possible to evaluate the results obtained for chromium. It is also likely that chromium was bound to several compounds with different leaching properties. The concentrations of chromium in the eluates was also lower than the concentration of copper.

The effects of parameters were studied by comparing the cumulative measured release during the test period of 3.2 days. The release included the release from the vacuum or wetting step (which was 2–4% of the total amount for copper and around 4% for sodium).

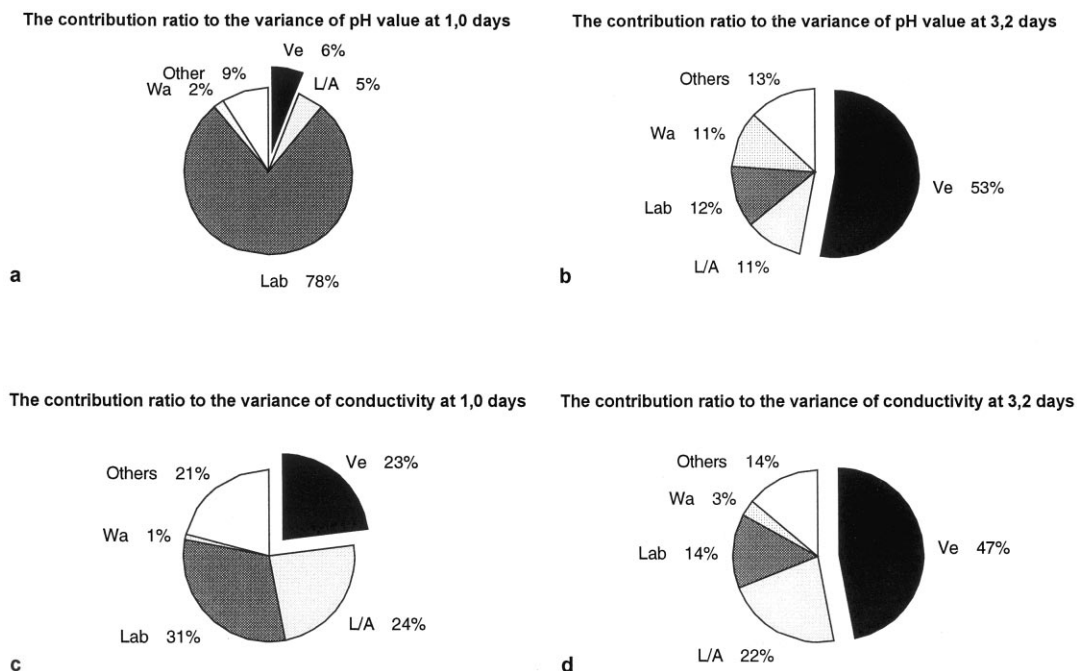

Fig. 1. The contribution ratio to the variations of pH and conductivity at day 1 and 3.2 days of leaching.

The results for copper have been summarised in Fig. 2a. The blocks in the figure indicate the gain in release due to selected test parameters. The use of vacuum had the strongest effect. The release was on average 32 mg m^{-2} days when vacuum was applied and on average 21 mg m^{-2} days with no

vacuum. The increase in release was due to the wetting of the material, which enabled the leaching process to proceed. The effect of stirring increased the result on average by 4.9 mg m^{-2} . The differences in results from different batches or laboratories were high, which is indicated by the blocks in the figures.

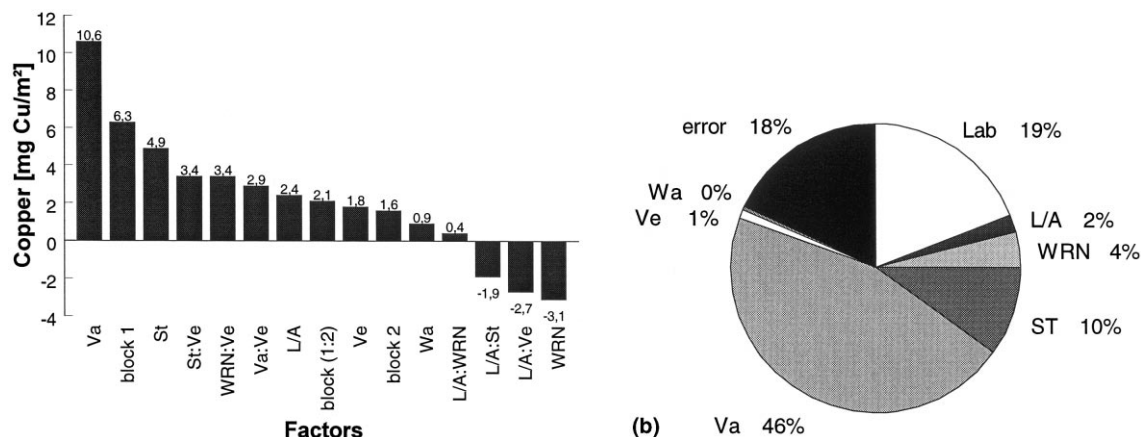

Fig. 2. (a) The gain of changing the levels of parameters on the leaching of copper. (b) The contribution ratio to the variations on the leaching of copper at 3.2 days.

Fig. 3. Correlation of leached amounts to the density of the specimen.

The laboratory and batch strongly influenced the leaching of sodium. The use of vacuum also had a strong effect. The release was on average 640 mg m^{-2} when vacuum was applied and on average 470 mg m^{-2} with no vacuum. The use of stirring increased the results to 70 mg m^{-2} . The

other parameters had very little effect on the results.

3.1.4. Influence of batch and laboratory

There were large batch and laboratory influences on both copper and sodium leaching as indicated by the blocks in the Fig. 2a. The differences in the physical structure of the specimens from different batches can be studied from the density of the specimen. A low density (which indicates a high porosity) was assumed to give larger leaching. In Fig. 3. the leached amounts of copper and sodium are compared with the density of the specimen. Leaching of copper, when applying vacuum, correlated with densities. A low density (batch C) resulted in large leaching. When vacuum was not applied the density did not correlate with the leached amounts. Leaching could in this case have been controlled by surface reactions. The leaching of sodium also indicates a correlation with density.

In this study it was not possible to analyse the influence of batch and laboratory separately due to the design of the experimental plan.

3.1.5. Results from confirmation runs

The effect of vacuum, use of stirring and use of high water renewal effect were checked in the confirmation runs. The results from the confirmation study are summarised in Table 1. The conclusions from the confirmation runs were,

1. Comparison of the results from Conf-4 to Conf-2 confirms the strong effect of vacuum. The effect of vacuum on leaching was estimated for a given set of test conditions in Table 2.

Table 1
Experimental conditions and results in the confirmation tests

Run	WRN ^a	Stirring	Vacuum	Leached amount of copper (mg m^{-2})	Leached amount of sodium (mg m^{-2})
Conf-1	4	Stirring	Vacuum	42.0	622
Conf-2	4	No stirring	Vacuum	27.7	594
Conf-3	7	Stirring	Vacuum	38.1	538
Conf-4	4	No stirring	No vacuum	16.4	435

^a WRN, water renewal frequency

Table 2

Estimations of the effects of vacuum and stirring on the leaching of copper and sodium

	Copper		Sodium	
	In experiments (%)	In confirmation test (%)	In experiments (%)	In confirmation test (%)
Effect of vacuum	25	51	28	31
Effect of stirring	19	41	13	5

Calculated for a given set of test conditions: use of vacuum, L/A 5, WRN 4, use of stirring, closed vessel and pH 4 adjusted water.

- Comparison of results from Conf-2 to Conf-1 confirms the effects of stirring effects. The effect of stirring on leaching was estimated for a given set of test conditions in Table 2. The effect of stirring was also dependent on two other parameters, namely L/A and vessel. Stirring was much more effective with L/A at low level (e.g. for copper: increase 6.8 mg m^{-2}) than with L/A at high level (e.g. for copper: increase only 2.9 mg m^{-2}). Stirring was also more effective with closed vessel (e.g. for copper: increase 8.3 mg m^{-2}) than with open vessel (e.g. for copper: increase 1.46 mg m^{-2}).
- Comparison of the results from Conf-3 to Conf-1 showed no advantage using higher water renewal frequency.
- The test conditions in Conf-3 were expected to give the maximum leaching conditions for sodium. The confirmation experiment does not confirm this. However, the results of confirmation experiments for leaching of sodium are similar to the results of the leaching of copper. This inconsistency to the predicted values may be due to the relatively large differences between batches/laboratories that effects the accuracy of the predictions for sodium.

3.2. Comparison of results from the Nordic quick test to a full long test

The results from the availability test and the tank leaching test are shown in Table 3. An average effective diffusion coefficient has been calculated for all constituents, even if the leaching was not diffusion controlled for all constituents during the whole test time. In the calculations of the diffusion coefficient the average results from the availability test was used. The effective diffusion coefficient pD_e

indicated that Na, Ca, As, Cr and Cu had a low mobility.

The leaching results has been compared with the full long test (Fig. 4). In the figure all the data were collected from experiments performed with the specimen from the same batch in order to eliminate the batch difference in the comparison. The results from other experiments and batches were in accordance with these results.

Comparing these results from the quick tests it must be noticed that the samples were stored at different time periods before testing (the full long tests were performed 2 months after preparation of test specimen and the quick tests 4 months). Storage of specimen often lowers the solubility of several constituents.

A comparison of effective diffusion coefficients from experiments with specimen from the same batch is presented in Table 4. In the full long test the diffusion coefficients was calculated for that period where leaching was diffusion controlled and in the short test it was calculated for the period between 23 h and 3.2 days. The results indicated that the magnitudes of effective diffusion coefficients for the studied constituents were lower for a full long test than for a short test. The tests performed with vacuum naturally gave higher diffusion coefficients.

4. Conclusions and recommendations

The study of the influence of relevant test parameters in a quick leaching test for monolithic materials showed clearly the increase in release, when vacuum was applied, and increase in pH, when closed vessel was used. The leaching results also indicate an increase in release when stirring was used. The other parameters did not have a significant influence and can therefore be chosen

Table 3

^a An average effective diffusion coefficient ρD_e ($= -\log D_{er} \text{ m}^{-2} \text{ s}^{-1}$) was calculated for all elements for the whole test period even if the leaching was not diffusion controlled according to the Dutch tank leaching test

Fig. 4. Comparison of leaching results for Na and Cu in a quick 3.2 days test and a full long test.

based on practical reasons. The recommendations for test conditions in a quick test are summarised in Table 5. This project clearly showed the benefits of using experimental design to systematically study the effects of relevant parameters.

The results from the quick test and from the full long test were comparable for constituents studied here. The quick test gave higher release as was expected due to the wetting before testing. The quick leaching test also gave an indication of the magnitude of diffusion coefficients.

Table 4

Comparison of diffusion coefficients calculated from a short test and a full long test for specimen from same batches.

	Batch D		Batch G	
	$\rho D_{e,Na}$	$\rho D_{e,Cu}$	$\rho D_{e,Na}$	$\rho D_{e,Cu}$

Quick test without vacuum (3.2 d)	12.3	14.8	12.3	15.0
Quick test applying vacuum (3.2 d)	12.1	14.6	12.3	14.9
Quick test applying vacuum (3.2 d)	12.2	14.6	12.1	14.3

Table 5

Recommended test conditions in a quick test for monolithic materials.

Operation	Preferred option	Remark
Pretreatment of specimen	Use of vacuum	The vacuum process shortens the water uptake (wetting process)
Amount of water	L/A 5–10	A practical amount of water is dependent on the size of the test specimen. A sufficient amount of water is needed for water immersion of the specimen and to ensure sufficient amount eluates for analysis. On the other hand, too much water leads to very small concentrations in eluates.
Test time	3 days	Practical for a suitable water renewal frequency, which enables calculation of diffusion coefficient, smaller deviations in e.g. pH and conductivity when applying 3 test days
Water renewal frequency	Wetting+three water renewal under 3 days of testing	Practical to perform as a routine testing
Stirring	Use of stirring	Stirring minimises a concentration build up at the surface of the specimen
Vessel	Use of closed vessel	Open vessel leads to uptake of carbon dioxide from air
Leachant	Use of distilled (demineralised) water	The amount of distilled water or weakly acidified water does not strongly influence the result for alkaline waste materials

Abstract

Leaching tests are essential in the environmental assessment of stabilized wastes. Research programmes were conducted on their interpretation in order to develop tools for the evaluation of long term release of pollutants contained in solidified wastes. Models for the leaching of porous materials are discussed in this paper according to the specificity of the chemical species (i.e. transport model with total dissolution of species-diffusional model; transport model with progressive dissolution of species due to limitation of solubility-shrinking core model; and the model coupling transport and chemical phenomena). The leaching behaviour of pollutants (i.e. lead) solidified in a cement matrix was studied under different chemical conditions. Results have shown that the release of species whose solubilities depend on the physico-chemical conditions, and especially the pH (e.g. amphoteric metals), is governed by the solubility of the species in the pore water at local conditions and by the pH evolution within the matrix. A coupled dissolution/diffusion model was developed to describe the release of chemically complex species contained in a porous medium in contact with water. Leaching tests of cement matrices and artificial porous matrices containing calcium hydroxide and pollutants were conducted in order to validate the coupled dissolution/diffusion model. A good assessment of the retention of some pollutants contained in cement matrices could then be obtained by the association of two tests: solubilization of the pollutants related to the chemical context (pH) under steady state conditions and monolithic long term dynamic leaching tests in order to characterize the evolution of the chemical context (pH) and consequently the release of pollutants. The objective is to integrate this approach in the standardization process (CEN TC 292- WG 6, in progress). © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

The development of stabilization/solidification processes using hydraulic binders is a result of the

increasingly stringent regulations in the field of environmental protection. The new evaluation tools that have resulted from research programs carried out for authorities, producers or waste disposers have reoriented the issue of environmental assessment towards better knowledge and pre-

* Corresponding author.

diction of long term behaviour and eco-compatibility. The evaluation of the long term performance of stabilized processes requires model research, depending on the environmental level of exposure corresponding to the considered scenario according to new standardization in the development of the CEN TC 292- WG 6 framework.

The characterization of the leaching behaviour of stabilized/solidified wastes is crucial in most reuse/disposal scenarios; water plays a multiple role in pollutant transfer from the stabilized/solidified wastes and their dispersion in the environment. Leaching tests are very important tools in this field.

2. Modeling pollutant leaching behaviour from solidified wastes

The objective of leaching tests is to provide an assessment of pollutant release from a solid material (i.e. waste) to the surrounding environment. In the environmental exposure scenario two modes of water contact may occur: percolation through the waste, water flow around the waste or through fractures. This paper deals with scenarios for which the solid block (i.e. a solidified waste) is in contact with static solutions (i.e. there is no convective flow around or through the solid) that are renewed periodically or continuously at a very slow rate. In the laboratory we used serial batch tests where the water is renewed after fixed contact time to avoid approaching saturation of the solution and thus preventing a solubility-control phenomenon in the leachate. An average flux of the constituent species of interest can then be determined by measuring concentrations in each leachant solution.

The overall release of soluble species contained in a porous cement block in contact with water is the result of complex and coupled phenomena.

- Water transfer in the porous medium up to aqueous saturation.
- Dissolution of species in the pore water according to local chemical conditions.
- Change of species solubilities in the pore water (including possible reprecipitation) if the chem-

ical conditions are changed due to the release of species controlling the pH (e.g. portlandite).

- Transport of species from the porous medium to the leaching solution due to the effect of concentration gradients.
- Transport of species in the leaching solution.

Up to now, the interpretation of leaching results has generally not accounted for this coupling of physical and chemical phenomena.

Most researchers in this field consider that mass transfer during leaching can often be globally described by an apparent diffusion mechanism [1]. Whereas certain models only take into account Fick's diffusion law by proposing the 'analytical' solution (semi-infinite solid) or the numerical one (finite solid volume), other models account for a coupling effect (i.e. diffusion and chemical reactions [2] or mass transfer at the interface).

In order to develop tools for the evaluation of long-term release of soluble pollutants contained in cement-based solidified wastes, we have conducted several research programs on the interpretation of leaching tests. From the obtained experimental results [3], two cases may be distinguished: species whose solubilities do not change according to physico-chemical conditions (case of relatively soluble species); and species whose solubilities depend on physico-chemical conditions and especially pH (case of amphoteric metals).

2.1. Case 1: Soluble species whose solubilities do not change with physico-chemical leaching conditions (e.g. Na^+ or Cl^- or Ca^{2+})

In this case, a diffusional model based on Fick's law or a shrinking core model correctly describes the released flux. The diffusional model is essentially based on the assumption that the pollutant is initially present in an homogenous medium and mass transfer is caused by concentration gradients. This model is a good representation of the reality in the case of a completely dissolved pollutant in pore water (e.g. case of sodium). The shrinking core model is more realistic: the pollutant is assumed to be initially present in the matrix in the solid phase.

Fig. 1. Comparison of diffusional model prediction and experimental data. The sodium flux during a leaching test with demineralized water is shown.

2.1.1. Diffusional model

Two parameters characterize the intensity and the dynamics of the release: C_0 , the initial leachable concentration (available release potential) and D_e , the effective diffusion coefficient of the species in the porous medium. The model can be resolved in 3D to account for depletion of the species in the solid core [3]. This may occur with highly soluble species incorporated in very porous matrices in permanent contact with water. Long term simulation for any scenario involving contact between the solid and leaching solution is then theoretically possible. The limits of the model are reached when the physical characteristics of the material itself are modified (e.g. increase of porosity or destruction of the porous structure). Fig. 1 shows typical results obtained for sodium. The points represent the average experimental flux; the continuous curve represents the simulation results obtained using the 3D diffusional model.

After 500 h of leaching, a residual flux (which is quantitatively speaking low compared with the original one) can be observed. This flux, greater than the theoretical diffusional one, appears while the quasi-totality of sodium has been removed. A possible explanation of this phenomenon could be a dissolution of the constitutive phases of the matrix itself.

2.1.2. Shrinking core model

Two zones, separated by a dissolution front, can be distinguished in the solid block: a zone, within the solid near the solid–liquid interface, in which the

solid form of the species (S_0 concentration) has been dissolved and in which the species, in the pore water, is transported by diffusion towards the leaching solution (D_e effective diffusion coefficient); a second zone, near the solid core, in which there is no mass transfer (the species concentration in the pore solution is then the saturation concentration). Solubilization is assumed to be instantaneous. This model is well suited to describe the release of calcium without coupling with other species.

From the experimental results obtained during a monolithic leaching test (i.e. species mass released in the leachate), it is not possible to distinguish between the diffusional model and the shrinking core model, as long as the solid ‘remains’ semi-infinite, the mass released is proportional to the square root of time.

A very important difference between the two models exists in the case of portlandite release contained in cement blocks. Shrinking core or diffusional models can describe well the release of calcium hydroxide. Though with the shrinking core model it is possible to calculate the evolution of the pH profile in the pore water and at the solid/liquid interface.

2.2. Case 2: Species whose solubilities depend on the physico-chemical conditions and especially pH (e.g. amphoteric metals)

In this case, our experiments have shown that pollutant release is controlled by the solubility of

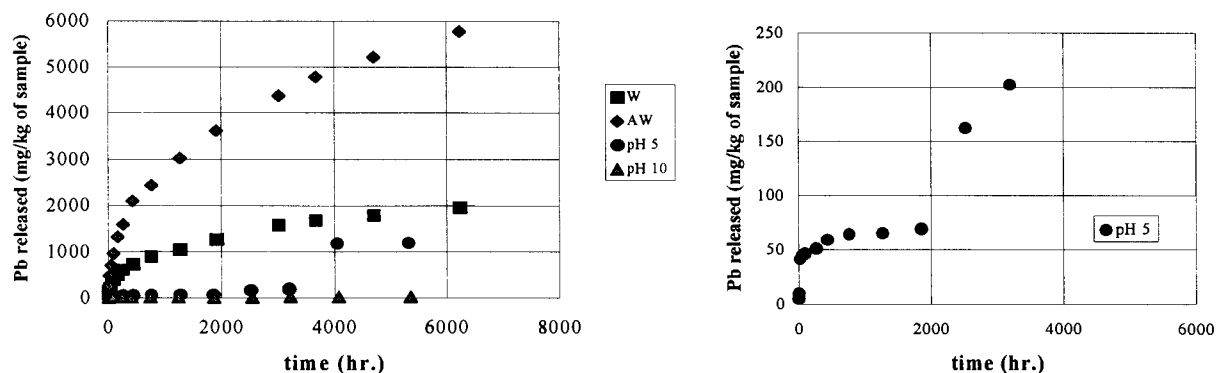

Fig. 2. Leaching of lead under different chemical conditions.

the species in the pore water at the local conditions and by the pH evolution within the solid, especially at the solid–liquid interface [4].

Lead is a typical case of such behaviour. The release of lead from a Portland cement-based matrix under different chemical conditions (demineralized water—W; controlled pH 5 and 10; alkaline water at pH 12.5—AW) is presented in Fig. 2 (i.e. sequential leaching tests of identical samples of the same monolithic material containing PbO). The leaching tests were conducted at a liquid to solid ratio of 10 ml g⁻¹ during 8 months with periodic renewals.

The least aggressive leaching solution (near to the equilibrium with the matrix—AW) results in the highest release of lead due to a high pH maintained at the interface. The amphoteric character of lead at this high pH results in increased solubility and thus the large release.

The most aggressive solution (pH 5) leads to a low release of lead: a pH 5 in the leachant provides within the matrix a pH situated between 5 and the initial pH of the pore water (close to the pH of a solution saturated with calcium hydroxide ~ 12.4), according to the important buffer capacity of cement matrices. However, it is important to note that after 4 months (~ 3000 hours) of leaching under these conditions, the release of lead increases dramatically.

The chemical conditions which change with time inside the monolithic material are the result of successive equilibria between the acid neutral-

ization capacity of the matrix and the surrounding leaching medium. Lead release is sensitive to the chemical conditions of the leaching solution and cannot evidently be interpreted by the simple diffusional model.

A coupled dissolution/diffusion model has been developed to describe the release of chemically complex species contained in a stable porous matrix in contact with water [5]. The model was used to simulate the case of a porous matrix containing only two leachable components: calcium hydroxide and lead hydroxide. Indeed, this is the typical case of an ordinary Portland cement-based solidified waste containing lead and leached with demineralized water. The main assumption of the model is local equilibrium: dissolution is assumed to be instantaneous. The porosity of the medium is also assumed to be constant: this implies that phase dissolution or phase precipitation does not affect the porous structure of the matrix.

The coupled dissolution/diffusional model can be divided into several stages:

- Release of portlandite using a shrinking front model;
- Calculation of the induced pH profile, assuming that the thermodynamic equilibrium takes place in the pore water;
- Determination of local lead solubility (by calculation assuming the main equilibria or from experimental results from ANC type tests, which is proposed for standardization at the European level as ‘influence of pH under

Fig. 3. Simulation of the pH and lead solubility within a leached cement matrix.

steady state conditions'), and; Description and calculation of lead transport by diffusion in the pore water.

In Fig. 3, the influence of a significant release of calcium on the pH evolution of the pore water and its consequences on the lead solubility are presented according to the coupled dissolution/diffusional model. The role of the leaching interface is apparent in the simulations.

3. Validation of the coupled dissolution/diffusion model

In order to validate the coupled dissolution/diffusion model, a specific experimental approach has been developed [4]: it consists of the study of the leaching of an artificial porous matrix. The matrix is obtained by 'sintering' a mixture of glass powder (diameter $< 160 \mu\text{m}$), calcium hydroxide and pollutants and is assumed to be a simplified representation of a cement matrix (i.e. porous medium, alkaline pore water). This approach allows better knowledge and better control of the studied medium. A wider range of pH variation at the leaching interface can be obtained and consequently prediction of the pollutants behaviour tendency can be carried out on a longer term.

3.1. Leaching behaviour of artificial porous matrices—experimental and theoretical solubility tendencies

The leaching behaviour of artificial matrices made of a mixture of glass powder, calcium hydroxide and lead oxide or cadmium oxide was studied. These matrices are supposed to simulate a Portland cement-based solidified waste containing lead or cadmium. Lead and cadmium were chosen because of their different levels of solubility and their different pH values of the lowest solubility: pH 9.3 for lead and pH 11.1 for cadmium (Fig. 4). Leaching tests by using demineralized water were conducted during 3 months with periodic renewals. The average experimental flux of lead and cadmium are pre-

Fig. 4. Comparison of solubility curves for $\text{Pb}(\text{OH})_2$ and $\text{Cd}(\text{OH})_2$ [7].

Fig. 5. Comparison of experimental flux of lead and cadmium.

sented in Fig. 5 (i.e. logarithm of released flux [$\text{mg m}^{-2} \text{s}^{-1}$] versus the logarithm of time [h]).

The study of these two heavy metals provides qualitatively an analogous behaviour of the released flux that is shifted in time and two different leaching intensities. These results are in good agreement with the solubility curves.

3.2. Leaching behaviour of artificial porous matrices—modeling

This approach allowed an initial qualitative validation of the model: a good representation of the experimental results with diffusional or shrinking core model for Na^+ , Cl^- or Ca^{++} was obtained. For lead and cadmium, the coupled dissolution/diffusion model allows us to hypothesize the main phenomena involved in mass transfer, on the time scale of laboratory leaching tests (3 months). Simulations have shown that there is no depletion of lead in solid form at the solid–liquid interface (i.e. at the interface between the matrix and the leaching solution). The simulated flux of lead is then the result of a solubilization phenomenon at the solid–liquid interface. Comparisons between experimental and simulated leaching results for calcium and lead are presented in Fig. 6.

A calculation from the percentage of lead released by assumption of a uniform release, allows us to estimate that after 3 months of leaching, only $15 \mu\text{m}$ of porous medium have been affected by the leaching phenomenon. This ‘theoretical depth’ affected by the ‘depletion’ of the solid form

confirms that phenomena take place near the interface. Besides, the presence of lead in solid crystallized form was experimentally observed at the surface of the matrix by using a magnifying glass.

Comparison between the simulation obtained for the flux of calcium and the flux of lead is presented in Fig. 7.

While the decrease of the flux of calcium is due to a depletion of calcium in solid form within the matrix, the decrease of the flux of lead is only due to a decrease of the solubility. Release of calcium and release of lead appear to be governed by two different phenomena: a shrinking core phenomenon for calcium and a solubilization phenomenon at the solid–liquid interface for lead.

4. Application of the coupled model to the leaching of cement matrices

Long term leaching tests using demineralized water were conducted on matrices containing lead (i.e. cement matrices spiked with lead oxide having a cylindrical geometry with a 4 cm diameter and a 2 cm height). The leaching solution was renewed periodically until 8 months (contact time used: 3, 5, 16, 24 h; 2, 3, 4 days; 1, 2, 3, 4 weeks and every month). A liquid-to-solid ratio of 10 ml g^{-1} was used. All the results have been reported elsewhere [4].

The use of the coupled dissolution/diffusion model allows us to represent the experimental results obtained and confirms the interfacial character of lead release. As long as lead is present in solid form in the matrix zone near the leaching surface, its release is controlled by a solubilization phenomenon at the solid–liquid interface. In this case, the leaching model can be simplified. The diffusional transport of lead within the matrix can be neglected and the flux of lead can be expressed in terms of a transfer coefficient of global mass and the difference between the saturation concentration and the concentration of the leaching solution.

Consequently, a model based on the shrinking core model to describe the release of calcium and taking into account pH evolution at the solid–

Fig. 6. Comparisons of experimental and simulated flux of calcium and lead using the coupled dissolution/diffusion model for porous artificial matrix.

liquid interface and variable lead solubility according to this pH, well represents the leaching phenomena of lead (Figs. 8–11). Indeed, simulation of the calcium release (Fig. 8) allows us to calculate the pH profile within the matrix and especially at the solid–liquid interface (Fig. 9). The knowledge of the pH at the solid–liquid interface allows us, from the experimental solubility curves (Fig. 10), to assess the saturation concentration of lead at this interface. The amount of lead released (Fig. 11) can then be obtained by using an interfacial transfer coefficient. In Figs. 8–11, the points represent the average experimental flux; the continuous curves represent the simulation results. Discontinuities observed in the simulation of the pH evolution at the solid–liquid interface (Fig. 9) are the result of the sequential

character of the leaching test used (i.e. periodic renewals of the leaching solution).

The experimental curve of the lead solubility was obtained from a leaching test carried out on samples of finely crushed material contacted with nitric acid solutions of different concentrations. This test, based on the Acid Neutralization Capacity test [6] was developed [4] in order to measure the alkalinity of the matrix and to determine the effects of variations in the matrix pore water conditions on the pollutants solubility.

The direct use of the experimental pollutants solubility curves (Fig. 10) in the model to determine the equilibrium concentrations according to the pH appeared to be an interesting approach. This technique allows us to account for the total chemical conditions, which avoids the use of a

Fig. 7. Comparison of simulated flux of calcium and lead ($\text{mg m}^{-2} \text{s}^{-1}$) using the coupled dissolution/diffusion model for porous artificial matrix.

Fig. 8. Simulation of the calcium release.

Fig. 9. Simulation of the pH profile at the solid-liquid interface.

simplified representation of the pore water of the cement matrix (i.e. by assuming the main equilibria) that would provide a simplified estimate compared to the whole real phenomena.

5. Conclusions

Simple tests and the diffusional model are generally sufficient to describe the leaching of highly soluble species contained in solidified wastes. For amphoteric metals (e.g. lead), the results obtained demonstrate the importance of chemical interactions and, in particular, the coupling of phenomena concerning solubiliza-

Fig. 10. Experimental lead solubility.

Fig. 11. Comparison of experimental and simulated cumulative release of lead using the coupled dissolution/diffusion model.

tion and diffusional transport during leaching: on the time scale of laboratory leaching tests, the release is governed by solubilization phenomena at the solid-liquid interface which is controlled by the evolution of pH, consequence of the release mainly of portlandite.

In the framework of CEN TC 292 WG 6 'basic characterization of leaching behaviour' a methodology guideline was developed and proposed as a pre-standard. Now a toolbox of several leaching tests is being developed to address different aspects of the behaviour: influence of pH under steady state conditions, percolation through a granular waste mass, dynamic release from monolithic waste,...

The objective of the authors is to valorize the research works conducted in this field to contribute at the French level to help selection and use of the appropriate tests from the complete toolbox and then to interpret the results according to the considered scenario and the relevant behavioural models.

Received 25 May 1997; accepted 14 October 1997

Abstract

The coupling of an enzyme immunoassay with a superheated water extraction is an attractive technique because of the reduced use of hazardous solvents, due to their hostile impact on the environment. This paper describes the use of superheated water extraction and enzyme immunoassay (EIA) for the determination of polycyclic aromatic hydrocarbons (PAHs) in native (not spiked) surface soil and sediment samples. The extraction recoveries with superheated water were comparable to those achieved with conventional Soxhlet techniques. The benefits of superheated water extraction-EIA includes replacement of harmful organic solvents used in extraction, fast extractions (15–30 min.) with an inexpensive extractant, reduced number of steps in the determination of the target compounds, and the application of sensitive and relatively inexpensive assays. Further advantages of the superheated water extraction are higher extraction efficiencies compared with the methanol based extraction kits associated with the EIA and direct measurement of the extracts with EIA. Both techniques can be used as efficient screening methods in the field since the type of equipment used in superheated water extraction and EIA can be loaded into a van and operated on a car battery or a small generator. © 1998 Elsevier Science B.V. 1. Introduction

In the last few years there has been an increase in the demand for rapid and especially reliable field portable methods for the quantification of organic pollutants present at waste sites.

In order to make appropriate decisions regarding site clean-up and remediation, fast and accu-

rate determinations are necessary. In the meantime several methods, like portable gas chromatography (GC) or gas chromatography-mass spectrometry (GC/MS) have become available for field determinations. However, there has been a lack of rugged quantitative extraction methods for field measurements.

Conventional extraction methods based on organic solvents like Soxhlet and sonication are hardly applicable in the field, because of the time needed to achieve quantitative extractions, the

* Corresponding author. Fax: +49 251 9802890; e-mail: kleiboe@uni-muenster.de

fragile, elaborate glassware and the large amounts of organic solvents employed. In the last few years, supercritical fluid extraction (SFE) with CO₂ has been shown to yield good recoveries for a range of organic pollutants from real environmental samples using short extraction times (10–60 min) with a minimum of organic solvents only. Especially for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and organochlorine pesticides, various working groups have reported good agreements between SFE and conventional extraction methods [1–4]. In addition, the US-EPA has recently adopted SFE as the official method for the extraction of total petroleum hydrocarbons (TPHs) and PAHs from environmental matrices and is presently in the process of adapting a method for the extraction of PCBs and organochlorine pesticides [5–7].

Consequently, SFE with CO₂ as extractant is a natural choice for field extractions because they can be performed quite efficiently with only a minimum of solvents and equipment required and can yield real time results that facilitate on-site decisions.

Another environmentally friendly solvent like CO₂ is water. However, at ambient temperature and pressure, water has a dielectric constant of $\epsilon \approx 80$ and is therefore extremely polar and thus not a suitable solvent for non-polar organics [8,9]. For water under these conditions the solubility of naphthalene is 32 mg l⁻¹, chrysene is 0.002 mg l⁻¹ and benz[ghi]perylene is 0.0003 mg l⁻¹ [10]. Up until now there have been very few papers dealing with water as an analytical extraction fluid for non polar compounds.

Water has a much lower dielectric constant and higher solubility for non-polar compounds under supercritical conditions ($T > 374^\circ\text{C}$ and $P > 22.1$ MPa). The dielectric constant for supercritical water varies between $\epsilon = 5$ and $\epsilon = 15$ depending on temperature and pressure. Supercritical water is an effective solvent for organic pollutants [8,9,11]. However, supercritical water is not suitable for routine extractions because of the necessary temperature and pressure requirements.

Steven Hawthorne and his group showed that the dielectric constant of water under much milder conditions can be dramatically lowered by increas-

ing the temperature at moderate pressures (5 MPa) up to 250°C [11–13]. Doing this the dielectric constant decreases from $\epsilon = 90$ –130. Hawthorne demonstrated that superheated water at 250°C and 5 MPa is an efficient extraction fluid for the extraction of chlorophenols, PAHs and PCBs from soil and sediment. With optimized conditions quantitative extractions were achieved in less than 15 min, if only pure water was used as extraction solvent [11–13].

In field analysis nearly always wet samples (soil, sediments, sludges) have to be analyzed. However, all common extraction methods (Soxhlet, sonication, SFE and ASE) require dried sample material. The water content of the sample can be determined separately, but drying of all sample material is very time consuming and hardly suitable for fast field analysis. For the extraction with superheated water no drying is necessary. The sample can be extracted almost as it was taken.

As such for several reasons water is the ideal extraction solvent for field and also for laboratory application.

The analysis of SFE extracts by field portable GC methods has proven to be relatively resource-intensive. However, immunoassay technologies, such as the enzyme immunoassay (EIA), has shown a potential for providing rapid, low-cost methods for the determination of environmental pollutants, including PCBs, PAHs, polychlorinated dibenzodioxins (PCDDs). Several EIA-based, semiquantitative or quantitative field methods for the determination of the total amount of PAHs are available. In general, these methods allow the determination of the samples that contain PAHs above or below a decision threshold [14,15].

An important disadvantage of the commercially available EIA is the associated extraction kit. For the extraction of PCBs and PAHs the samples are mixed with an extraction solution (provided with the kit) that consists of 20 ml of methanol containing a soil-dispersing agent, and are shaken vigorously for at least 60 s. The samples are then left to settle, filtrated and diluted with a buffer solution. This procedure is more or less the same for all EIA test kits. Knowing that even Soxhlet extractions of several hours can show incomplete extraction rates or have different analyte and/or

matrix depending extraction efficiencies, it is no surprise that there is a gap between the results obtained with an EIA test kit and those obtained with conventional analytical methods. The study presented here was carried out with the aim of narrowing this gap by coupling superheated water extraction with EIA.

2. Experimental

2.1. Samples and reagents

For the evaluation of our method, native samples were used. The PAH containing soil sample was taken from a polluted industrial site. The sample was freeze-dried and homogenized in an electric mill. The certified reference material is a marine sediment (HS-3 of the National Research Council of Canada) purchased from Promochem (Wesel, Germany). All solvents and reagents were purchased from Merck (Darmstadt, Germany) or Baker (Griesheim, Germany) in the highest purity available. The sample extracts were investigated using HPLC to determine the content of the following PAHs: naphthalene (N), acenaphthene (A), fluorene (Fluo), phenanthrene (Phen), anthracene (Anth), fluoranthene (F), pyrene (Py), benz[a]anthracene (B[a]A), chrysene (Chry), benzo[b]fluoranthene (B[b]F), benzo[k]fluoranthene (B[k]F), benzo[a]pyrene (B[a]P), dibenz[a,h]anthracene (D[a,h]A), benzo[ghi]perylene (B[ghi]P) and indeno[1,2,3-c,d]pyrene (I[c,d]P). The EIA method was used to quantify the total PAH amount in the extracts.

3. Reference method

3.1. Soxhlet extraction

Soxhlet extraction of soil samples was performed according to DIN 38414, part 1 [17]. Soil (5 g) was transferred to a cellulose extraction thimble and extracted for 8 h with 150 ml *n*-hexane/acetone (1:1). The solvent volume was reduced to 50 ml using a rotary evaporator.

A 1 ml aliquot was transferred to a silica-solid phase extraction (SPE) cartridge for clean-up. The column was eluted with 5 ml *n*-hexane/dichloromethane (1:1) and the solvent was removed under a gentle stream of nitrogen. Phthalic acid diethylester (50 μ l) was added to prevent evaporation to dryness. Acetonitrile (950 μ l) was added to the remaining residue and the solution was analysed by HPLC.

3.2. HPLC method for the quantification of PAHs

HPLC separation was performed on a HP 1050 liquid chromatograph equipped with a diode-array detector (DAD) and a fluorescence-detector (FLD). The DAD signal was used to ascertain peak purity and the FLD signal for quantification. A wavelength program was used to detect the different PAHs at optimal absorption and emission wavelengths. Separation was achieved on a Bakerbond PAH 16 Plus 250 \times 3 mm i.d. column with a gradient elution [16].

3.3. Superheated water extraction

The water extractions were performed at 5 MPa and 250°C analogous to the extraction described by Hawthorne et al. [11]. Extraction time was 30 min. For soil extraction 1 g of sample was used, while for extractions of the sediment 50 mg of sample was used. A schematic diagram of the extraction system is shown in Fig. 1. The carefully degassed water was pumped at a flow rate of 1–1.5 ml min⁻¹ in the constant pressure mode (5 MPa) with an ISCO Model 260D syringe pump (Axel Semrau GmbH, Sprockhövel, Germany) through a 2 m stainless steel pre-heating coil to the extraction cell. All extractions were performed in 3.5 ml stainless steel cells (Keystone Scientific, Bellefonte, PA). The pre-heating coil and the extraction cell were placed inside a Carlo Erba Model Series 4160 GC oven. The outlet of the extraction cell was connected by stainless steel transfer line to an ISCO Model variable restrictor (Axel Semrau GmbH, Sprockhövel, Germany).

Fig. 1. Basic set up for the superheated water extraction system. (1) Deionised water reservoir; (2) syringe pump; (3) GC-oven; (4) extraction vessel; (5) adjustable restrictor; (6a + 6b) collection devices

For HPLC analysis the extracts were collected at 0°C in 10 ml of *n*-hexane as collection solvent. After the extraction and cooling down of the system the transfer line and the restrictor were rinsed with 3 ml of *n*-hexane into the collection vial. The water extract and the collection solvent were vigorously shaken and the *n*-hexane phase was separated from the water phase. The water phase was again extracted with 10 ml *n*-hexane. The *n*-hexane phases were united and a keeper (50 µl phthalic acid diethylester) was added to the sample prior to the evaporation of the solvent under a gentle stream of nitrogen. 950 µl acetonitrile was added to the remaining residue and the solution was analysed using HPLC.

For the coupling with EIA 10 ml of methanol was used as collection solvent. After extraction, the methanol–water volume was filled up to 100 ml with water and a 1 ml aliquot was used for EIA.

3.4. Enzyme immunoassay

The PAH content of the two investigated samples were measured with a commercial magnetic bead-based EIA. The test kit (PAH RaPID Assay, Ohmicron, Axel Semrau GmbH, Sprockhövel, Germany) employs polyclonal anti-phenanthrene antibodies and shows a general sensitivity to PAHs. The functional description of the immunochemical detection is exemplified in Fig. 2.

The assay procedure was executed following the test kit instructions. Specific amounts of sample extract, enzyme conjugate and analyte specific antibody coated on magnetic particles were added to a test tube and incubated for 30 min at room temperature (Fig. 2A). The calibrant solutions provided with the assay kit were treated similarly.

The tubes were then placed in the magnetic rack. All magnetic particles were pulled and held to the tube wall while excess reagents could be

Fig. 2. Detection principle of the magnetic bead-based EIA. (A) Immunological reaction; (B) separation; (C) colour reaction

decanted. The particles were washed twice with a washing solution (Fig. 2B). A mixture of enzyme substrate (hydrogen peroxide) and chromogen (3,3',5,5'-tetramethylbenzidine) was added to the tube and allowed to react for 20–30 min at room temperature (Fig. 2C). After this the colour reaction was stopped by the addition of 2 mol l⁻¹ sulfuric acid. Since the labeled analyte and the analyte in the sample were competing for the antibody sites, colour development is directly dependent on the concentration of the enzyme labeled analyte and indirectly dependent on the concentration of analyte in the sample.

The absorption of the coloured complex was measured with a photometer at 450 nm.

4. Results and discussion

4.1. Superheated water extraction versus Soxhlet extraction

To estimate the efficiency of new extraction methods in most cases the recoveries were compared with those obtained using the Soxhlet ex-

traction or compared with certified values of a reference material. We used Soxhlet extraction, because it is the most standardised method.

Our superheated water extraction investigations were executed using the experimental conditions described by Hawthorne et al. [11]. Critical parameters are the flow rate and temperature, but the selected conditions are within an optimal region. Even with the first extraction, we obtained recoveries comparable with the Soxhlet extraction. In Table 1 the concentrations obtained with superheated water extraction and with Soxhlet extraction for the sediment HS-3 are compared with certified values. The results of our superheated water extraction do not differ significantly from those of the conventional Soxhlet extraction and both results are very close to the certified values or at least within the standard deviations specified on the certificate. The differences between the certified values and the superheated water and Soxhlet extraction are difficult to interpret because no information about the analytical procedure used for the certification of HS-3 was available.

extraction. We could not quantify naphthalene and acenaphthene in the Soxhlet extract since losses occurred during the solvent reduction steps because of their low vapour pressure. As shown in Table 2, there is no significant difference between the PAH values obtained with superheated water extraction and Soxhlet extraction.

It should be kept in mind that the superheated water extraction method was not optimized, but applied as published by Hawthorne [11]. So further optimization of the trapping system, extraction pressure, temperature and the adaption of some minor technical problems can lead to higher extraction efficiencies and to improved reproducibility.

4.2. Superheated water extraction-enzyme immunoassay

Coupling the extraction with the detection technique is straightforward. Since immunoassays are typically conducted in aqueous media, the extracted material can be collected in a solvent that is already used in the immunoassay. When water is used as extraction solvent, the extracted analytes should be collected in methanol to have sufficient solubility for the PAHs. Methanol is

Fig. 3. HPLC-chromatogram of a superheated water extract of the soil sample

Table 3

Comparison of the PAH concentrations quantified by HPLC and by Ohmicron EIA using the supplied phenanthrene calibrant solution

	EIA (mg kg ⁻¹)	HPLC (mg kg ⁻¹)
HS-3	3100	253.5
Soil	477	27.4

already provided as an extractant with the test kit and can easily be diluted with buffer prior to EIA. By this denaturation of the antibodies by an organic solvent can be avoided.

The methanol–water mixtures were analyzed with a PAH specific assay, and the first results obtained for the certified reference material and the soil sample were not very encouraging as can be seen in Table 3. The sum values obtained with the EIA were about a factor 10 higher than the values obtained with HPLC. While the calibration of the HPLC was performed with a certified reference solution (NIST SRM 1647b) the calibration of the EIA was carried out with phenanthrene calibrant solution provided with the test kit. Checking this calibrant solution with HPLC resulted in the discovery that a 50 ~ µg kg⁻¹ labeled phenanthrene solution actually had a concentration of 5 ~ µg kg⁻¹! We assume that with this shift in the calibration curve a low extraction efficiency of the test kit should be compensated. In combination with the efficient extraction method, however this calibration leads to incorrect results.

After correction of EIA results using this factor, the sum values for the PAHs obtained with HPLC and those of the EIA are very similar (HS-3: EIA = 310 mg kg⁻¹, HPLC = 253 mg kg⁻¹; real soil sample: EIA = 47.7 mg kg⁻¹, HPLC = 27.4 mg kg⁻¹). Nevertheless the results for EIA are slightly higher than those for HPLC. We assume that this may be caused by the cross reactivity of the EIA. In the fluorescence chromatogram (Fig. 3) it can be seen that there are much more compounds in the extract than the 15 quantified analytes. These compounds most probably are isomeric or substituted analogues to the 15 quantified PAHs and they can react with the antibody leading to slightly higher results.

Other current research includes the evaluation of other antibodies.

5. Conclusion

Two sets of environmental samples, a certified reference material and a real soil sample, were analyzed using a superheated water extraction method and a quantitative PAH-EIA. The quantitative results were nearly identical with the certified values and with results obtained by conventional Soxhlet extraction and HPLC methods. This suggest that the superheated water extraction-EIA method is an appropriate screening method.

Extraction and analysis using superheated water extraction-EIA results in a greater sample throughput, allowing rapid screening of environmental samples. Furthermore both techniques can be used in the field because no toxic organic chemicals are needed and the type of equipment used can be loaded into a van and operated on a car battery or a small generator. With the superheated water extraction it is possible to extract wet samples directly, thus avoiding the time consuming drying step, as required for SFE or for other extraction methods. Superheated water extraction is a very fast method, it allows quantitative extraction within 15–30 min.

For laboratory use the extraction as well as EIA can be automated for multianalyte analysis and high sample throughput. Because of the high sensitivity of EIA only a very small aliquot of the extract is needed, so that the result can be verified using a different technique (e.g. HPLC) if required.

Speciation of organotin in environmental sediment samples

M. Ceulemans, S. Slaets, F. Adams *

Department of Chemistry, University of Antwerpen (UIA) B-2610 Wilrijk, Belgium

Received 25 May 1997; accepted 14 October 1997

Abstract

An optimized sample preparation procedure for organotin speciation in sediment samples has been applied to the analysis of sediments collected in the environment. The method is based on tropolone complexation of the ionic organotins, followed by extraction into a hexane–ethylacetate mixture and derivatization by NaBEt₄. The method was applied to the determination of organotin in various harbour, shipyard and dry-dock sediments in Belgium. Butyltin compounds were detected in all samples analyzed, often at high mg kg⁻¹ levels. A limited number of samples showed the presence of phenyltin compounds. Further, the method was adapted to the analysis of river sediments sampled from the vicinity of shipyards. Butyltin concentrations were detected at the µg kg⁻¹ level in the majority of samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Speciation; Organotin; Gas chromatography; Atomic emission spectrometry

1. Introduction

The input levels of organotin compounds in the environment have been considerably restricted in the recent past in most countries due to legislation. Tributyltin (TBT), and to a lesser extent triphenyltin (TPT) used as biocides in anti-fouling paints, nevertheless remain common pollutants of the marine environment, particularly in the sediment matrix. It appears that tri-organotins and the products of their degradation accumulate in the sediment. Attention given to sediment analysis is increasing, considering that the sediment is recognized as the ultimate ‘sink’ for organotin compounds which are released into the aquatic

environment and may create an eco-toxicological risk long after anthropogenic sources are banned from a given area. Therefore, the short residence time of TBT in the water column alone is not an adequate criterion for evaluating its potential environmental hazards. Hence, it is essential that reliable analytical methods are developed for the determination of butyl- and phenyltin compounds in sediments.

In natural waters, TBT has a short residence time, with a half-life in the range of several days to weeks [1,2]. Adsorption of TBT onto suspended particulate matter is thought to be an important removal process. Randall and Weber reported that between 57 and 95% of TBT in the water column is sorbed under simulated estuarine conditions [3]. In this way a significant proportion

* Corresponding author. Fax: +32 3 8202376.

of TBT appears to be deposited, and concentration factors of $\sim 10^3$ relative to the overlying waters are common [4–6]. Slow degradation of TBT in sediments would increase its persistence in the aquatic environment. Studies of TBT degradation in sediment/water mixtures under experimental conditions have been carried out by Maguire et al. [7] and Stang et al. [8] and suggested that TBT has a half-life in sediments of several months. An alternative approach consists in obtaining profiles of TBT concentrations within sediment cores [9], which yields a longer half-life of 1.85 years. Similarly, Quevauviller et al. [10] in a study of sediment cores of Arcachon Bay, France, reported that TBT concentration remains high long after regulation was implemented, hence that this compound is not rapidly degraded in sediment as was previously assumed. Further, TBT has been found to accumulate to concentrations which can probably inhibit biological degradation. The same is valid for TPT compounds which have been shown to have low mobility, low aqueous solubility, and strong binding to soil and sediments in the aquatic environment [11].

Sample preparation procedures for organotin speciation analysis in sediments are generally more complicated than those for water samples. Since organotin compounds are not involved in mineralogical processes and bind onto the surface of the sediment the complete dissolution of the sediment matrix prior to the analysis is not considered necessary. The basic approach to release organotin compounds from the sediment involves, e.g. acid leaching in aqueous or methanolic medium by sonification, stirring or Soxhlet extraction with an organic solvent. Generally, sample preparation procedures for the separation of organotin compounds from sediments are time consuming (several hours). A recent alternative is the use of a low power microwave field which was shown to accelerate the leaching of the organotin species from the sediments considerably and to reduce actual leaching times to a few minutes [12,13].

Data of organotin contents detected in sediments originating from the environment in Belgium are scarce. The only study on TBT contamination, to our knowledge, was carried out

in the frame of a quality survey of dredging sludge originating from some important marine yacht- and fishing harbours [14]. The highest TBT concentrations were found in the harbour of Zeebrugge, as can be seen from Table 1. Further, it was found that locations displaying a high TBT content were also characterized by a strong organic pollution, mainly polycyclic aromatic hydrocarbons. Since TPT compounds strongly adsorb to suspended matter and sediments, they are readily detected in this matrix. During a Belgian survey on the presence of various pesticides in the environment, phenyltin compounds were found in 15% of the sediment samples, with contents ranging from 120 to 190 $\mu\text{g kg}^{-1}$. The highest concentrations were found in the mouth of the Yser river, in the Gaverbeek, a small tributary of the river Scheldt at Harelbeke and in the river Scheldt itself at Doel [15].

This paper presents the application of a sample preparation procedure based on tropolone complexation, liquid–liquid extraction and NaBeT_4 derivatization in a monitoring study to assess the organotin pollution in a number of environmental sediments originating from various waterways in Belgium. The aim was to investigate the impact of dry-docking operations on the contamination of both surficial sediments from shipyard terrains and in river sediments originating from the vicinity of shipyards with regard to their organotin content.

2. Experimental

2.1. Apparatus

GC–AES. Organotin species were separated on an HP-1 capillary column using a Model 5890

Table 1
TBT concentrations detected in marine Belgian harbours [14]

Series II gas chromatograph and detected by means of an HP Model 5921 A atomic emission detector (Hewlett–Packard, Avondale, PA). The GC was equipped with a KAS 503 (Gerstel, Mulheim, Germany) programmable temperature vaporization (PTV) injector.

GC–AAS. A Varian Model 3700 gas chromatograph (Varian, Sunnyvale, CA) fitted with a RSL-150 (RSL, Eke, Belgium) megabore column, or an HP Model 5890 Series II gas chromatograph fitted with an HP-1 capillary column were used to separate the analytes prior to the detection by quartz furnace atomic absorption spectrometry (QFAAS); PE Model 2380 (Perkin Elmer, Norwalk, USA). For megabore column GC, samples were introduced on-column through a septum in a wide bore hot on-column liner. Injections on the capillary column were done using PTV as described earlier [16].

Injector, gas chromatograph, interface and detector operating conditions have been described in detail earlier for GC–AAS [17] and GC–AES [18].

2.2. Reagents

Analytical reagent grade chemicals obtained from Merck (Darmstadt, Germany) were used unless otherwise stated. Deionized water, further purified in a Milli-Q system (Millipore, El Paso, TX) system was used throughout. Pentylmagnesiumbromide (2 mol l^{-1} in diethylether) was obtained from Aldrich (Milwaukee, WI). Sodium tetraethylborate was obtained from Strem Chemicals (Bischheim, France). A 0.3% (w/v) aqueous solution was prepared daily. Diethyldithiocarbamic acid was prepared by dissolving 2.25 g of sodium diethyldithiocarbamate (NaDDTC) salt in water. The solution of DDTC in pentane was obtained by shaking the aqueous solution with 20 ml of 0.5 mol l^{-1} of H_2SO_4 and extracting with 10 ml of pentane for 5 min. Acetate buffer (pH 5; 0.1 mol l^{-1}) was prepared by dissolving 13.6 g of sodium acetate trihydrate in 1 l of water, followed by pH adjustment with concentrated acetic acid. A 0.05% tropolone solution was prepared by dissolving the appropriate amount in hexane/ethylac-

etate (1/1). The sources, purity and synthesis of organotin standards have been described earlier [19].

2.3. Procedure

Circa 1 g of sediment was accurately weighed and placed in a centrifugation vessel with glass stopper together with 2 ml of hydrochloric acid (32%) and 8 ml of water; 25 ml of the hexane/ethylacetate mixture (1/1), containing 0.05% tropolone were added and the mixture was sonicated for 1 h, followed by centrifugation at 3000 rpm for 5 min. The organic phase was transferred into an extraction vessel and evaporated to dryness using rotary evaporation. Then, 0.5 ml of hexane, containing Pe_3SnEt as an internal standard, were added and the complexes were derivatized by addition of 1 ml of the NaBEt_4 solution together with 50 ml of acetate buffer solution. The mixture was shaken manually for 5 min and after phase separation the hexane phase was sampled for clean up/analysis. A detailed description and discussion of extract clean-up has been presented previously [20]. A Pasteur pipette was filled with basic alumina to form a plug of 5 cm. The sediment extract was introduced onto the clean-up column. After elution of the original extract volume, an additional volume of 1 ml diethylether was brought onto the clean-up column. The diethylether was evaporated from the combined eluate using a gentle stream of nitrogen.

2.4. Sampling

Sampling of superficial sediments was done using a Peelman drill, or by simple collection by means of a spade. Water-underlying sediments were collected using a Van Veen grab. After removal of stones, leaves and pieces of wood, the sediment was grounded with an agate mortar and pestle. Sediments were either oven-dried at 50°C or freeze-dried and stored at -20°C until analysis, i.e. in agreement with recommendations on sampling and storage procedures for organotin analysis in the marine environment [21,22].

2.5. Certified reference materials

To evaluate the performance of the plethora of existing sample preparation procedures and instrumental setups used among different laboratories, certified reference materials (CRM's) were prepared by different organizations for the quality control of analytical results. Analysis results of CRM's presented in some reports show that the reliability of sample preparation is often not sufficient and that several limitations still remain. Especially the accurate determination of monobutyltin (MBT) remains doubtful since, according to some reports on certification experiments [23–25], no reliable method for the determination of this compound has been reported up to now. This is apparent from Table 2.

Analysis of CRM's proved that the method presented is able to accurately determine TBT and dibutyltin (DBT) in sediments, while MBT determination in general still remains doubtful due to the absence of reliable, or no or only indicative values for this compound in reference materials. However, the method was shown to be suitable for MBT determination in certain sediments [16].

An attempt to apply the developed procedure to the analysis of phenyltin compounds led to the conclusion that the determination of these species is most favorable in the absence of any tropolone complexing agent and using acetic acid for leaching.

3. Results

3.1. Determination of organotin in harbour and dry-dock sediments

3.1.1. Shipyard located in the Antwerp harbour

Huge point sources such as dry-dock facilities are responsible for the release of the largest fraction of TBT into the aquatic environment. An investigation was carried out to assess the contamination of a shipyard terrain after years of intense dry-docking activities. Further, the influence of these activities on the contamination of the harbour sediment was also investigated.

Fig. 1 shows the location of the sampling sites with the sampling points indicated. A total of five surface samples was taken from the shipyard terrain, three at places where grit blasting activities had taken place, and two samples from other locations at the yard, this in order to assess the background concentration found at the terrain. The investigated ship repair yard was located in the Antwerp harbour, which itself is characterized by intense shipping in an almost enclosed environment with a low flushing rate.

In a previous study on the determination of organotins in waters of the Antwerp harbour, which was carried out over a 4-month period between May and August 1991, two sampling locations (W1, W2) were situated in the vicinity of the shipyard investigated in the present study [26].

Fig. 1. Sampling locations.

This previous study indicated an overall TBT contamination level in the harbour in the range of 10–45 ng l⁻¹. The concentrations detected at locations W1 and W2 were significantly higher with concentrations ranging between 50 and 440 ng l⁻¹ over the 4-month study period for these two locations. These elevated concentrations found in the water column at these two locations were found due to the discharge of hazardous amounts of TBT in hosing-down water which originates from the washing of ships' hulls, with a high-pressure hosing system before repainting activities. The contaminated water first remains for several days in a sinking-basin and is afterwards released into the poorly flushed harbour dock area. This study already showed the impact of dry-dock activities on the contamination levels in waters of the Antwerp harbour.

In the present study, the impact of dry-docking operations on the contamination of the yard terrain, and harbour sediment was evaluated. The results of the analyses are presented in Table 3. From the results it can be seen that sediments 1, 3 and 6, sampled at locations where grit blasting takes place, generally display very high TBT concentrations at the mg kg⁻¹ level. Comparison with the Environmental Quality Target (EQT) value for TBT in sediments, set at 1–2 µg kg⁻¹ and implemented now in most European countries indicates severe contamination of these surface sediments [27]. Especially the concentration found in sediment 6 (141 mg kg⁻¹), originating from another smaller dry-dock located in the Antwerp harbour, is at extremely high level. Also

DBT and MBT, the intermediate products of TBT degradation to inorganic tin, were found in all the samples. Further, phenyltin compounds were as well detected in these samples, however at much lower concentrations. The presented concentration figures for monophenyltin (MPT) should be considered as indicative values, as extraction and derivatization for this compound was found to be irreproducible as shown earlier [28]. Triphenyltin compounds (mainly TPT fluoride and small amounts of TPT chloride) are used in anti-fouling paints, however to a much lesser extent compared to TBT compounds. About 80% of all anti-fouling paints used contain TBT oxide or TBT metacrylate/methylmetacrylate copolymer, ~12% are TBTF based and ~8% are TBTF based [29,30]. Since TPT compounds are only used in free-association paints, and since there seems to be a general agreement to discontinue the use of this type of paint it is expected that discharges of TPT compounds from anti-fouling paints will decrease in the near future.

The detected contents in samples 2 and 4 taken at places on the yard where no dry-docking operations such as grit blasting, washing, painting, etc. take place display much lower contents at µg kg⁻¹ level. However, the fact that butyltin compounds are detected at these locations may be attributed to an overall contamination of the yard terrain. Sediment 5, collected in the harbour, displays very high TBT concentrations, most probably originating from the hosing-down of TBT waste water in the harbour water and accumulation in the underlying sediments which act as a 'sink' for TBT. A chromatogram for this sediment after sample preparation and GC–AAS measurement is shown in Fig. 2.

The results of this study indicate the need for strict dockyard management to minimize waste generation from dry-docking activities and treatment of contaminated waste waters. Potential waste minimization methods for marine maintenance and repair operations include the minimization of fugitive oversprays of paint (e.g. by changing application methods), the minimization of abrasive blast wastes and of chemical stripping wastes. Apart from high pressure hydro-washing abrasive blasting is often used to remove paint

layers. The most commonly used blasting media are sand or grit together with a large volume of water. The presence of paint chips containing hazardous metallic and/or organometallic biocides makes abrasive blasting wastes potentially hazardous. Blast waste water generally constitutes the largest single waste stream for many yards. For instance, wet abrasive blasting of an average sized naval vessel can generate up to 180 tons of wet abrasive and ca. 2 000 000 l of contaminated water [31]. At the moment research and testing is underway on a number of innovative alternatives to both grit blasting and chemical stripping [32]. Segregation and recycling of blast media is possible because of the difference in density between the grit materials and the waste paint chips. Therefore, in many cases the contaminated grit can be reused several times before becoming too contaminated and requiring off-site disposal. An

approach to prevent fugitive dust emissions would be to enclose the area with plastic sheeting or screening, this confining the waste to the immediate vicinity of the blasting. After blasting has been completed, the waste should be collected and transported to a licensed landfill. Chemical stripping wastes primarily consist of the stripping agent, of which methylenechloride is the most commonly used, and paint sludges. Waste minimization would include the use of less toxic stripping agents such as inorganic strippers consisting of aqueous solutions of caustic soda, and the reuse and recycling of contaminated strippers.

Waste water should be treated in such a way that its TBT contents reduced to a level acceptable for discharge to river or estuarine waters. Equipment for this purpose is commercially available and generally uses a 4-stage process, two concerned with solids (principally paint solids) reduction and two concerned with removing TBT from the water. Briefly, the different stages are as follows: (1) flocculation and settling in which the pH of the raw wash water is adjusted to effect flocculation and agglomeration of the solids present; (2) filtration where the supernatant water from the settling stage is pumped to a 2-stage filtration system, and particles are removed to the sub-micron diameter range to ensure that paint particles which could still release TBT to the surrounding water are not present in the subsequent treatment steps; (3) carbon adsorption where the first stage of dissolved TBT removal is effected by adsorption onto activated carbon; (4) after passing through the carbon bed, the process water passes through a filter, to remove residual carbon particles and then to a device whereby it is irradiated with short-wave UV light. The concentrations of TBT can be effectively reduced to concentrations less than $0.2 \mu\text{g l}^{-1}$ by oxidation reactions induced by the UV light, producing harmless tin oxide. The UV light irradiation step is the final stage in this type of waste water treatment plant. However, the majority of commercial shipyards discharge their effluents directly to the aquatic environment at no direct costs. Any treatment system thus becomes an additional cost burden to their operations. This cost burden will only be acceptable commercially if all yards (in-

side and outside EU) are required to undertake environmental protection measures simultaneously. It is estimated that through the use of waste water treatment plants a reduction of emissions up to 85% could be accomplished.

3.1.2. Dredging sludge from the Ostend harbour

Dredging sludge samples were originating from various locations in the Ostend harbour where dredging activities had taken place. The harbour is characterized by intense shipping activities from pleasure crafts and ferry ships. Samples were analyzed in order to assess the organotin levels present in the Ostend harbour. Further, analyses of these samples would give an idea about the organotin contamination which may be introduced into non-contaminated areas, through dumping of these dredging sludges.

The results of the analyses are presented in Table 4. All samples showed the presence of butyltin compounds at concentrations up to mg kg^{-1} level, indicating contamination of the Ostend harbour due to shipping activities. Further, results suggest that dredging sludges originating from harbours and marinas should be collected and treated with care in order to avoid contamination of other areas through dumping of this sludge. Contaminated soils must be removed and either incinerated in special plants or be deposited at special waste disposal sites according to local or government regulations. Generally, it was found that dredging activities reduce TBT concentrations in harbours and marinas [33]. Dredging removes TBT-contaminated sediments, and because of the sediment-water partitioning, finally results in lower TBT concentrations in the water phase.

3.1.3. Shipyard for pleasure crafts

A surface sediment was taken from a small shipyard located at the Zuidwillemsvaart (Bocholt, Limburg). The yard is mainly used for the maintenance of small vessels and pleasure crafts. Amounts detected were $6.60 \pm 0.08 \text{ mg kg}^{-1}$ for TBT, $1.67 \pm 0.20 \text{ mg kg}^{-1}$ for DBT and $1.15 \pm 0.05 \text{ mg kg}^{-1}$ for MBT. A chromatogram for this sediment, after sample preparation and GC-QFAAS measurement is shown in Fig. 3. The

height of the TBT concentration detected, plus the pattern of the concentrations of the degradation products DBT and MBT, which were found in much lower concentrations, indicate recent dis-

charges of TBT, suggesting the illegal usage of TBT-containing anti-fouling paints, since following current legislation the use of these paints is forbidden on ships smaller than 25 m.

3.1.4. Determination of organotin in river sediments

Analyses of sediment samples originating from shipyards and dry-dock terrains revealed the presence of very high concentrations of various organotin compounds. In cooperation with the Flemish Environmental Agency (VMM) a sampling campaign was carried out (Summer '95) in which river sediments were taken from the vicinity of shipyards. The aim of the study was to investigate whether the pollution is restricted to the yard and dock terrains itself or also has a wider effect on the contamination of the adjacent rivers. A total of 35 river sediments, originating from the vicinity of five different yards located in Flanders were analyzed. For a given shipyard sampling was carried at different locations in the river. Further, for each shipyard sediments were also taken at larger distances from the yard, up- and down-stream on the river, in order to assess the polluting impact of shipyard activities over longer distances.

The results of all 35 sediments are presented in Table 4. Generally, butyltin compounds were detected in all river sediments which were sampled in the vicinity of the shipyards. Phenyltin compounds were not detected in any of the samples. The detected levels are, in comparison with contents detected on the yard terrain itself, generally much lower, however in the majority of the samples analyzed they are a multiple of the EQT value for TBT in sediments, set at $1\text{--}2\ \mu\text{g kg}^{-1}$. Concentrations detected in river sediments sampled at larger distances, generally display contents below detection limits or at the low $\mu\text{g kg}^{-1}$ levels indicating the local impact of dry-dock operations on the contamination of adjacent rivers. A chromatogram for a sample of river sediment is shown in Fig. 4.

TBT concentrations detected in the river sediments originating from the vicinity of the Rupelmonde shipyard range between $17\text{--}77\ \mu\text{g kg}^{-1}$ representing an overall contamination level in the seven sediments sampled in the vicinity of the

Fig. 4. Chromatogram for a sample of river sediment: (1) MBT; (2) DBT; (3) TBT; (is) internal standard (Pe_3SnEt).

yard. TBT contents detected in the river Scheldt in the vicinity of the Nieuwe Scheldewerven range between 54 and 95 $\mu\text{g kg}^{-1}$ for the seven sediments analyzed, with one peak value of 227 $\mu\text{g kg}^{-1}$. This higher value may be attributed to the fact that this sampling location could have been close to a waste water disposal line of the shipyard. TBT contents detected in Scheldt river sediments taken from the vicinity of the Boelwerf display more varying concentrations ranging between 44 and 316 $\mu\text{g kg}^{-1}$, a concentration level suggesting a high transfer of TBT contaminants from the yard into the river. The concentrations detected in the Wintham–Brussel Canal near the Fulton Marine yard are more variable and range from 4 to 271 $\mu\text{g kg}^{-1}$. The same variability of detected contents occurs in the vicinity of the yard in Langerbrugge with concentrations between 35 and 105 $\mu\text{g kg}^{-1}$. Analysis of water samples taken from the draining system of this particular yard already showed butyltin concentrations up to the $\mu\text{g l}^{-1}$ level.

The results of this study clearly indicated that organotin contamination of the environment through dry-docking activities is not only restricted to the yard terrain itself, but also has wider polluting effects on the adjacent waterways. Further, it was shown that through the analysis of sediments originating from larger distances that the polluting impact is restricted to the immediate vicinity of the yard.

4. Conclusions

This work describes the application of a novel method for the speciation analysis of organotins to a number of environmental sediment samples. Through the analyses of surficial sediments originating from shipyards and dry-docks it was concluded that dry-dock operations may create severe organotin contamination of the yard territories. Further, the results from the analysis of river sediments sampled in the vicinity of dry-docks and shipyards showed the transfer of organotin contaminants from shipyards to the adjacent rivers and show the need for effective dry-dock management and waste water treatment in order

to protect the aquatic environment. TBT was detected in the majority of the samples analyzed, often at concentrations much higher than the Environmental Quality Target for TBT in sediments, indicating that the problem of contamination of the marine environment is far from solved, despite recent alternative anti-foulants, legislation and EU directives towards the use of this compound.

Abstract

Management of domestic wastes often relies on incineration, a process that eliminates large amount of wastes but also produces toxic residues that concentrate heavy metals. Those hazardous secondary wastes require specific treatment. Vitrification is seen as a powerful way to stabilise them. However, concern exists about the long term behaviour of these glass wastes and the potential release of toxic species into the environment. The answers will come with further investigation into the physico-chemical evolution of the vitrified wastes and the mobility of hazardous elements within the matrix with appropriate analytical methods. Laser ablation coupled with inductively coupled mass spectrometry (LA-ICP-MS) is a challenging technique for the chemical analysis of trace elements in solid materials. This paper presents an evaluation of the potential of LA- ICP-MS for macro and microanalysis of trace metals in domestic vitrified wastes with regards to other physical analytical techniques of solids such as scanning electronprobe X-ray energy dispersive spectroscopy (SEM-EDXS). Two typical samples, vitreous and crystallised, are used to compare the analytical performances of the two techniques. SEM-EDXS was used for mineralogical characterisation and chemical analysis of the mineralogical phases. Relative micro-analysis and bulk quantitative analysis of 30 major, minor and trace elements was performed by LA-ICP-MS: precision was between 10 and 20% for most elements and quantitative analysis proved possible with an accuracy of 20% and relative detection limits of 0.1 mg kg⁻¹. © 1998 Elsevier Science B.V. 1. Introduction

Management of domestic waste is an important issue for the community in a changing context of

regulations requiring wastes to be treated and recycled. One popular elimination technique is based on the incineration of wastes followed by the treatment of fumes. This process reduces the volume of waste but also generates secondary toxic wastes: ashes and residues of filtration of

* Corresponding author.

fumes (REFIOM in French). REFIOM concentrate metals such as Zn, Cu, Pb, Sn, Cr, Ni coming from batteries, plastic or metallic cans, inks etc. Therefore specific treatment is needed to stabilise these wastes before they can be considered as ultimate wastes. Two methods of stabilisation and neutralisation are investigated i.e. incorporation in a solid matrix (cement or concrete) or vitrification. Investigations of hazardous wastes employing vitrification in a plasma torch at temperatures over 6000°C have been carried [1]. This original process produces glasses from the wastes themselves. Vitrified glasses from ashes collected after the thermal incineration of domestic wastes are ceramic-like glasses. This matrix seems to be an ideal host for toxic elements. However, before classification of these 'ultimate wastes' it is necessary to understand the long term behaviour of their matrix and evaluate the potential release of toxic species to the environment. Risk assessment studies require evaluation methodologies based on experimental predictive models and analytical tools to monitor the evolution of vitrified waste matrix and the fate of hazardous elements trapped in the matrix.

Chemical analysis of solids often requires samples to be dissolved prior to analysis which is often time consuming, difficult to perform and might result in some contamination.

Instrumental techniques that allow direct analysis of solid samples are mostly based on physical techniques: so far non destructive methods such as X-ray fluorescence (XRF), particle induced X-ray excitation (PIXE), electronprobe microanalysis (EPMA) and destructive methods like neutron activation analysis (NAA), ion microprobe (SIMS) have been extensively used for micro, bulk and surface analysis.

Micro-beams coupled with trace element techniques provide new tools for the direct analysis of trace elements in solid samples. LA-ICP-MS is a tandem analytical technique where the laser beam is used as a sampling probe and the ICP-MS as a detector. When targeted to the sample surface the laser beam generates microparticulate material that is brought with an argon stream into the inductively plasma where it is atomised and ionised, ions are then separated and detected within the mass spectrometer.

LA-ICP-MS has been extensively reviewed, for its fundamental aspects [2,3], technology [4] and application to geochemical analysis [5,6]. Although it can be used for bulk analysis its key feature is the ability to spatially resolve chemical analysis at different space scales. LA-ICP-MS can perform micro-analysis with high spatial resolution up to 10 µm as well as lateral profiling, surface mapping and depth gradients. Therefore LA-ICP-MS can deal with heterogeneous samples without losing information.

Little work has been carried out with in-situ characterisation of trace metals in the REFIOM vitrified wastes. SEM-EDXS was used for chemical analysis of mineralogical phases but the analysis is limited to major and minor elements [7]. So far chemical analysis of trace elements in REFIOM relied on the use of conventional ICP-MS after dissolution of the material or were performed on leaching solutions [8]. Therefore no spatial information is available for trace metals distribution in vitrified wastes.

The aim of this work is to perform spatially resolved chemical analysis of trace metals in vitrified wastes using LA-ICP-MS. Two real vitrified waste samples were used as models to investigate the analytical potential of LA-ICP-MS and its performances compared with analytical techniques of solids such as SEM-EDXS.

2. Experimental

2.1. Samples

Two typical samples representative of vitrified domestic wastes generated by plasma techniques were used in the present sets of experiments.

The original material originated from a single melting bath at 1616°C after elaboration by plasma techniques. The material from the melting bath underwent fractionated crystallisation during the cooling process and two phases (vitreous and crystallised) could be distinguished at macroscopic level. The two samples 1C and 1V were extracted respectively from the crystallised and vitreous phase by diamond drilling and then manufactured in the form of pellets (1 cm diameter, 2

mm high). The two samples showed different structure and texture. These wastes have been characterised elsewhere for their mineralogy and chemical composition using conventional ICP-MS [8]. The REFION glass wastes contains vitreous and crystallised phases, mostly sorosilicates and spinels.

2.2. Instrumentation

2.2.1. AAS

The chemical composition of the matrix (major and minor elements) were established with the Perkin Elmer 3110 Atomic Absorption Spectrometer (AAS). Samples were fused into strontium metaborate after grinding into a fine powder that was dissolved with acid prior to analysis using a conventional protocol defined previously [9].

2.2.2. XRD

Each sample was crushed and ground up to a micrometer size powder before analysis. An X-ray diffractometer PHILIPS PW1729 (X-Ray lamp with an Co anticathode at a voltage of 30 kV with an emission current of 40 mA) with a Bragg Goniometer (rotation speed $0.02^\circ \text{ s}^{-1}$ and acquisition time 2 s by step) was used to investigate the structure and the mineralogy of the samples.

2.2.3. SEM-EDXS

The texture of the samples at micrometer scale was studied with a Scanning Electron Microscope (SEM). A JEOL 6400C SEM equipped with an tungsten filament (voltage 15 keV, filament current 200 μA and current emission 10 μA) was used. To access the submicrometric chemistry the SEM was fitted with a Kevex X-ray Energy Dispersive Spectroscopy (X-EDS) detector (Si–Li diode, ultra-thin parylene window). Electron beam size modulation allowed investigation at different space scales, from 1 μm^2 in punctual mode up to 1000 μm^2 in the window mode. Acquisition parameters were the following: 25 mm height, 30° take-off angle, 120 s acquisition time. Each spectrum was treated using the following procedure: background subtraction, gaussian deconvolution and ZAF correction using a standard database [10]. With this configuration a rela-

tive precision of about 5–6% for elements with an atomic number above 10 and a concentration above 10 g kg^{-1} can be expected [11]. Before the analysis samples were polished (optical quality) and metallized by amorphous carbon. SEM-EDXS was used to fingerprint elements within specific locations and to measure concentration variations in a given sample.

2.2.4. LA-ICP-MS

The CETAC LSX 100 laser sampling device has been coupled to the standard Perkin-Elmer ELAN 5000 ICP-MS. The Nd:YAG laser was operated at the fourth harmonic wavelength of 266 nm with a pulse frequency of 1–20 Hz and maximum energy of 4 MJ per pulse in the Q-switched mode. The laser beam was focused 1 mm under the sample surface. The sample was translated to allow analysis of a specific area. The sampling pattern was therefore a straight line. The ICP-MS was tuned while firing the NIST 612 glass standard to produce a continuous signal. B11, La 139 and Th232 were used as tuning elements to maximise sensitivity and limit signal fluctuations to 5% RSD.

Laser and ICP-MS operating conditions are presented in Table 1. Cr^{52} was used to correct for isobaric interference of Fe^{54} . Rastering the sample generated a continuous signal. The blank was subtracted from the raw signals further processing. The time resolved analysis mode allows signals to be on-line normalised to a reference signal. Absolute or relative signals were then averaged over the acquisition. Glass NIST 612 was used for calibration. This certified reference material is a homogenous glass with 61 elements at a nominal concentration of 50 mg kg^{-1} . Thirty elements are certified: SiO_2 (720 g kg^{-1}), CaO (120 g kg^{-1}), Na_2O (140 g kg^{-1}), Al_2O_3 (20 g kg^{-1}), Ba (41 mg kg^{-1}), B (32 mg kg^{-1}), Ce (39 mg kg^{-1}), Co (35.5 mg kg^{-1}), Cu (37.7 mg kg^{-1}), Dy (35 mg kg^{-1}), Er (36 mg kg^{-1}), Eu (36 mg kg^{-1}), Gd (39 mg kg^{-1}), Au (5 mg kg^{-1}), Fe (51 mg kg^{-1}), La (36 mg kg^{-1}), Pb (38.57 mg kg^{-1}), Mn (39.6 mg kg^{-1}), Nd (36 mg kg^{-1}), Ni (38.8 mg kg^{-1}), Rb (31.4 mg kg^{-1}), Sm (39 mg kg^{-1}), Ag (22 mg kg^{-1}), Sr (78.4 mg kg^{-1}), Tl (15.7 mg kg^{-1}), Th (37.79 mg kg^{-1}), Ti (50.1 mg kg^{-1}), U (37.38 mg kg^{-1}).

kg^{-1}), Yb (42 mg kg^{-1}). The uncertainty of these certified values are 5% or better.

2.3. Method

The matrix of the vitrified wastes was first characterised for physico-chemical properties such as bulk composition and mineralogy using physical analytical techniques of solids. SEM-EDXS was used to perform chemical analysis of different mineralogical phases. LA-ICP-MS was used to study trace elements at different space scales. The investigation strategy is summarised in the flowchart (Fig. 1).

2.3.1. Physico-chemistry of the matrix

The vitrified wastes were characterised for their matrix properties by physical analytical techniques. Physico-chemical characterisation of the matrix included determination of chemical com-

position, structure and texture. Bulk chemical composition samples 1C and 1V were analysed using AAS. The structure of the two samples was investigated by XRD and the texture was studied using optical microscopy and SEM. Matrix physico-chemical properties are summarised in Table 2.

2.3.1.1. Chemical composition of the matrix.. The average chemical composition of the matrix was similar for the two samples. Vitrified REFION were calco-silico-alumino glasses with Fe, Mg, Ti, P, K, Zn occurring as minor elements ($\sim 10 \text{ g kg}^{-1}$).

2.3.1.2. Structure.. For sample 1V, XRD analysis recorded typical patterns of amorphous materials. For the crystallised sample 1C the presence of Gehlenite and Melilite was noticed together with some amorphous parts.

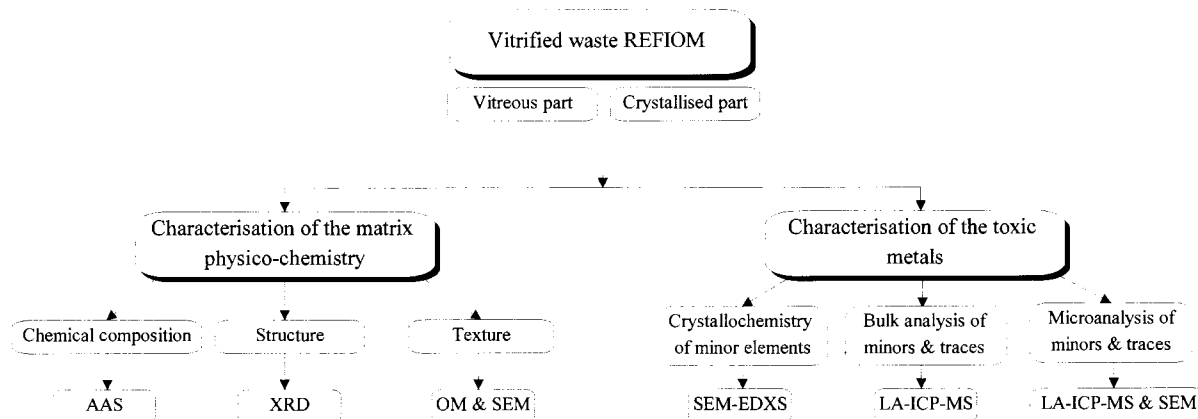

Fig. 1. Characterisation of hazardous elements in vitrified wastes—Methodology

2.3.1.3. Texture. Optical microscopic examination led to distinguishing two textural sets: amorphous dominant (1V) and crystallised dominant (1C). At this scale sample 1V appeared homogeneous (aphanitic texture) with some rare crystallised zones (square crystals with dark extinction in polarised light, typically spinels). SEM observation confirmed the homogeneity of this sample. Sample 1C was heterogeneous at the microscale level. The texture was a microlitic one including large automorphous crystals (10–100 μm size) surrounded by a thin amorphous matrix. At SEM scale cavities of 100 μm size occurred. Some of these cavities contained automorphous micrometric crystals (10–100 μm size) such as spinels (cubic crystals, XY_2O_3) and sorosilicates ($\text{X}_x\text{Y}_y\text{Si}_z\text{O}_7$). The spinel crystals were precipitates of oxides of Fe or Al such as Gahnite (ZnAl_2O_4) and Franklinite (ZnFe_2O_4). The sorosilicates were Melilite ($\text{NaCaAlSi}_2\text{O}_7$) and Gehlenite ($\text{Ca}_2\text{Al}_2\text{SiO}_7$).

2.3.2. Crystallochemistry of the wastes

Chemical characterisation of the mineralogical phases was performed using SEM-EDXS to investigate the partition of metals between the crystallised and the vitreous phase. The metal chemistry of the two REFIOM samples 1V and 1C were compared. SEM-EDXS was used as a relative technique to investigate the variations of major and minor elements between individual

mineralogical phases.

The analysis of one spinel crystal in sample 1C was performed in the punctual mode (1 μm^2 window). A larger window (100 μm^2 window) was used to scan the vitreous phase (sample 1V) and the crystallised sample 1C at two typical locations: one with automorphous crystals and the other with microlitic crystals. SEM-EDXS data for different mineralogical phases are presented in Fig. 2.

The sorosilicates crystals contained more Fe, Zn, Na, Cr, and Mn than the vitreous phase. Zn, Fe and Cr were slightly enriched in the automorphous crystals compared with the microlitic ones. The spinel crystal showed depletion in Si, P, K and Ca together with strong enrichment of Al and Mg and also some enrichment of Fe and Zn compared with the sorosilicates crystals and the vitreous phase.

2.3.3. Chemical analysis of trace metals by LA-ICP-MS

Characterisation of the trace metals trapped in vitrified wastes was based on bulk and also microanalysis by LA-ICP-MS. LA-ICP-MS was used for quantitative bulk analysis of samples 1C and 1V. For microanalysis, LA-ICP-MS was used as a relative technique to study the variations of trace metals between different mineralogical phases in sample 1C.

Table 2
Physico-chemical characterisation of the vitrified waste matrix

Sample	1V	1C
Structure (DRX)	Mainly amorphous Minor crystallised phase	Mainly crystallised Sorosilicates Melilite($\text{NaCaAlSi}_2\text{O}_7$), Gehlinitite ($\text{Ca}_2\text{Al}_2\text{SiO}_7$) Spinel Gahnite(ZnAl_2O_4), Franklinite(ZnFe_2O_4) Minor amorphous phase
Texture (OM&SEM)	Vitreous matrix with micrometric automorphous crystals Homogeneous texture	Auto morphous crystals 10–50 μm (sorosilicates and spinels) and microlitic crystals (sorosilicates) included in a vitreous phase Heterogeneous texture with cavities (100 μm) containing spinels and sorosilicates

MnO	0	0
Cr_2O_3	0	0
ZnO	1	1

2.3.3.1. *Sampling and analytical strategy.* When defining the sampling scale and the analytical strategy, there is a compromise between the amount of ablated material, the number of elements scanned by the mass spectrometer and the limits of detection expected. With a pulse frequency of 20 Hz, an energy of 4 MJ pulse⁻¹ and 10 $\mu\text{m s}^{-1}$ sampling translation rate, the laser drills 50 μm size pits, thus generating a continuous straight line, width 50 μm . The sampling probe is therefore bigger than the size of the individual components of the sampled matrices. In fact 1V was homogeneous at this scale and 1C was heterogeneous at the micrometric scale. The elemental ablation pattern chosen was a 2 mm long line. With this sampling pattern and the acquisition settings of the ICP-MS, sufficient material can be sampled to allow the acquisition of 30 elements.

The signal dispersion from one acquisition reflected fluctuations in the ablation process. Fluctuations of the ablation conditions were partly caused by variations in the laser parameters such as energy or focus and could be compensated working with relative signals. Fluctuations due to the sample itself were caused by textural variations, that can be partly compensated with relative signals, or by uneven elemental distribution within the mineralogical phases. Therefore elemental signals were on-line normalised to Si^{29} , minor isotope of a matrix element, to limit these variations.

2.3.3.2. *LA-ICP-MS bulk analysis.* LA-ICP-MS analysis was performed at three different locations for samples 1C, 1V and glass NIST 612. Signals were normalised on-line to Si^{29} to allow intercomparison between samples to compensate for varia-

Fig. 2. Microchemistry of different mineralogical phases of vitrified samples by SEM-EDXS

tions in the total amount of sampled material. Each individual acquisition generated averaged relative signals and the mean of the three individual analysis was finally retained.

Bulk composition of samples 1C and 1V were determined using NIST-612 glass for calibration. Composition of sample 1C was also determined using 1V as a calibrant taking the ICP-MS data from Colombel [8] as reference values.

2.3.3.3. Microanalysis by LA-ICP-MS. LA-ICP-MS was used to investigate the distribution of metals within the mineralogical phases of the vitrified wastes. Sample 1V had a globally vitreous matrix whereas sample 1C had a heterogeneous crystallised matrix with a vitreous phase between the crystals.

Analysis was carried out at different locations for samples 1C and 1V. SEM was used to locate and characterise the laser impacts. Fig. 3 shows a laser raster in the vitreous phase (sample 1V). For sample 1C the laser probe was focused on two different locations containing different crystals: the first laser pit was located at a textural set dominated by automorphous crystals included in a vitreous matrix (Fig. 4) and the second one contained microlitic crystals also included in a vitreous matrix (Fig. 5).

LA-ICP-MS signals were normalised to Si to work with relative concentrations. Relative concentrations are then normalised to relative concentrations of the pure vitreous phase (sample 1V) to enhance differences between the crystallised phases and the vitreous matrix.

2.3.4. Characterisation of the laser impacts.

SEM-EDXS was used for in-situ characterisation of the laser impacts. The morphology, location and surface chemistry of the sampled areas were considered. The surface chemistry of the sample 1V was investigated at two different locations by SEM-EDXS: inside the channel drilled by the laser beam and outside the ablated area (scanning window of 250 μm^2). For sample 1C the analysis of a laser raster in the microlitic crystals area was performed using the same operating conditions.

Fig. 3. SEM picture of an ablation raster on sample 1V ($\times 1000$)

Fig. 4. SEM picture of an ablation raster on sample 1C (microlitic crystals texture) ($\times 1000$)

3. Results and discussion

3.1. Quantitation with LA-ICP-MS

LA-ICP-MS can be used for bulk quantitative analysis of trace metals in solid materials. When using a multi-size sampling tool such as the laser probe, one has to be careful about statistical representativity of the sampled material to assess the significance of the chemical analysis, especially for heterogeneous samples. Depending of the ana-

Fig. 5. SEM picture of an ablation raster on sample 1C (automorphous crystals texture) ($\times 250$)

lytical strategy, macro or microanalysis, there must be an adequate relation between the sampling scale and the size of individual components of the sample or the heterogeneity scale of the material. Sampling at different locations and averaging the information was used for bulk analysis. Estimated reproducibility of the LA-ICP-MS bulk analysis was 5% RSD for NIST-612 glass standard and higher for the vitrified waste samples (10% RSD for sample 1V and 10–20% RSD for sample 1V) for elements in the mg kg^{-1} up to the 10 g kg^{-1} concentration range. For bulk analysis of heterogeneous samples the spatial resolution of the analytical technique has to be higher than the homogeneity scale of the sample. The Nd:YAG laser device working at the fourth harmonic at 266 nm can drill 10 μm diameter pits in glasses. For heterogeneous samples the amount of material sampled and analysed has to be increased to be representative of the bulk sample. This can be done by averaging the local chemical information given by LA-ICP-MS by defocusing the laser beam, rastering large areas or performing statistics from individual local analysis. The effects of the sampling scale on bulk analysis of heterogeneous samples by LA-ICP-MS have been investigated by some authors. Scholze analysed heterogeneous powdered soils by LA-ICP-MS and studied the influence of sample inhomogeneity on the precision of analytical results using a correlation function [12]. To achieve reliable information on the bulk composition of heterogeneous samples, the crater size and number have to be increased according to the grain size. For bulk analysis using LA-ICP-MS the heterogeneity of the matrix can therefore limit the level of precision. Quantification is based on external calibration and a solid material is used as a calibrant together with an internal standard (IS). This strategy requires an independent method to determine at least one element, the IS in the unknown sample and in the standard. Si is used as an internal standard. For the vitrified wastes samples, Si concentration comes from AAS data. Concentration of an analyte E in the unknown sample is then given by the relation $C_{\text{un}}(\text{E}) = C_{\text{standard}}(\text{E}) \cdot I_{\text{un}}(\text{E}) / I_{\text{standard}}(\text{E}) \cdot I_{\text{standard}}(\text{IS})$

Fig. 6. Bulk quantitative analysis of vitrified wastes by LA-ICP-MS using NIST 612 as a calibrant

$I_{un}(IS) \cdot C_{un}(IS) / C_{standard}(IS)$ where I stands for LA-ICP-MS response and C for concentration. Fig. 6 shows the results of analysis by LA-ICP-MS of vitrified wastes samples 1C and 1V using NIST 612 glass standard for calibration. Results for 16 major, minor and trace elements are presented. LA-ICP-MS data is compared with nebulisation ICP-MS data [8] to check the validity of the analytical technique for quantification. From the ICP-MS data samples 1C and 1V have the same bulk composition for most major, minor and trace elements. An interesting feature is the occurrence of several toxic metals such as Ti, Fe, Zn, Cr, Pb, Sn at high concentration levels (from 1 up to 20 g kg⁻¹). Other metals such as As, Cu, Sb, Co, Ni, W are present at trace levels and up to 400 mg kg⁻¹. Analysis of samples 1V and 1C by LA-ICP-MS with NIST-612 gave globally lower values compared with the ICP-MS data. The LA-

ICP-MS values range within 10 and 50% of the ICP-MS data for most elements. Results from the analysis by LA-ICP-MS of the crystallised waste (sample 1C) using vitreous waste (sample 1V) as a calibrant are presented in Fig. 7. The concentrations obtained range within 10 and 20% of the ICP-MS values for most elements.

Accuracy of quantitative analysis of vitrified wastes depends on the external standard used. LA-ICP-MS analysis with NIST 612 gives lower results than ICP-MS data for vitrified wastes, with concentrations ranging from 10 to 50% from the ICP-MS data for samples 1C and 1V. This maybe due to differences in the concentration range between the wastes and the NIST 612 glass standard that has much lower concentrations for some elements. But the technique could also be slightly matrix-dependant because of specific ablation behaviour of the different glass matrices due

Fig. 7. Analysis of REFION 1C by LA-ICP-MS with REFION 1V as a calibrant

to their particular structural, textural and chemical properties.

Using a REFION calibrant for LA-ICP-MS quantitative analysis gave better results than NIST 612 with respect to ICP-MS data. Using this strategy the LA-IP-MS concentrations are between 10 and 20% of the ICP-MS data. The two samples have close matrix properties and therefore give similar responses to the LA-ICP-MS.

The potential of LA-ICP-MS for quantitative analysis of glass material has been investigated by many authors. Results on domestic vitrified wastes are compared with results of LA-ICP-MS analysis on analogue materials from the literature. The closest materials to the vitrified wastes are synthetic or natural glasses for the vitreous phase and silicates for the crystallised phase. The results on these analogues are presented in Table 3. Moenke-Blankenburg analysed fluorophosphate glasses for seven elements with an IR laser. She demonstrated the ability of LA-ICP-MS to analyse for major elements using liquid solid calibration [13]. The same calibration method was applied by Cromwell for the analysis of synthetic glasses. Cromwell achieved semiquantitative anal-

ysis of nine minor elements with an UV laser [14]. Other authors performed solid calibration using a certified reference glass such as NIST-612. Stix worked with natural glasses such as felsic and mafic glasses. Micro-analysis of trace metals was performed using an UV laser with NIST-612 for calibration [15]. Fedorowich analysed trace elements in silicates. The reference basalt BIR-1 prepared in glass fused beads was analysed using an IR laser and NIST-612 for calibration [16]. Heuzen also analysed trace elements within silicates. Samples were prepared in glass beads and an IR laser was also used. This author achieved more accurate results using synthetic calibration standards prepared from the fusion of oxides in glass silicates [17].

As indicated by Shuttleworth [18], UV laser provides better results in LA-ICP-MS analysis for glass-like material. Whereas much of the previous work on glass material was done with IR lasers, the use of UV laser probes gives better analytical results for trace element analysis in glass materials. More accurate results are obtained when using a matrix-matched calibrant. Therefore quantitation of vitrified wastes should be performed using a reference waste. The vitreous

Fig. 8. Microchemistry of laser impacts on vitrified wastes by SEM-EDXS

waste sample seems ideal for this purpose because it is homogeneous material. It can be characterised for its trace metals content using alternate techniques such as digestion ICP-MS.

LA-ICP-MS can be used as a quantitative technique for the bulk analysis of heavy metals occurring in vitrified wastes at trace levels. The relative limits of detection were estimated at 0.1 mg kg^{-1} which is sufficient to investigate toxic trace metals in solid wastes.

3.2. Comparison between chemical analysis based on digestion and LA-ICP-MS

For laser ablation like any other introduction technique it is important to assess to what extent the material analysed by the ICP-MS is truly representative of the original material. Potential

transformation of the material is likely to occur during the ablation process such as physical and chemical fractionation. The interaction of the laser beam with solid material is a complex process controlled by both laser parameters such as wavelength, energy, pulse frequency and the physico-chemical structure of the sample.

Chemical analysis by SEM-EDXS is used to investigate at the microscopic level the chemical fractionation patterns. Fig. 8 shows the SEM-EDXS analysis of two laser rasters in the vitreous (sample 1V) and crystallised phase (sample 1C). Data is presented for major and minor elements. For the vitreous phase there is no significant variation between the bulk matrix and the ablated area in the vitreous phase. The SEM-EDXS data shows no significant variations between the ablated area and the unaltered matrix for the mi-

colitic crystals. Therefore, major and minor element surface chemistry of the vitrified or crystallised matrix is the same before and after sampling by the laser beam. This indicates that with the laser conditions used, i.e. with an energetic UV laser beam, laser ablation should not modify the composition of the sampled material. Fractionation studies can also be done using the ICP-MS as a detector. Shuttleworth investigated fractionation occurring in the ablation of synthetic vitrified glasses containing wastes [18]. The effects of laser fluence on the ICP-MS signal was studied for two Nd:YAG lasers at 1064 nm and 266 nm. Fractionation occurred only with the IR laser.

Characterisation of the laser impact at microscopic level can also bring information about the sampling process and potential fractionation. SEM picture of laser impacts in the vitreous phase and in the crystallised phase are presented in Figs. 3 and 4 respectively. The Nd:YAG UV laser produces well shaped craters free of any deposits. Thermal effects are likely to be limited in the ablation process. SEM was often used to study the morphology of the laser impacts on glass-like material. Fedorowich analysed silicates prepared in a fused glass bead with a Nd:YAG IR laser (1064 nm). The occurrence of solidified droplets of melt ejected around the crater was noticed [16]. Jeffries compared IR and UV Nd:YAG lasers (1064 nm and 266 nm) for the microanalysis of single mineral phases. For some minerals showing specific orientation (cleavage plans) catastrophic ablation patterns were noticed for the IR laser [19]. Bea performed microanalysis of minerals in thin sections using an Excimer laser at 308 nm and made some comparisons with an IR Nd:YAG laser. Laser craters comprised an internal zone where laser matter interaction is stronger and a peripheral halo caused by thermal effect. This halo appeared to be much smaller for the UV laser [20].

With energetic and short pulse (ns) laser beams in the UV, the interaction of laser with solid material is mainly ablation i.e. explosion generating fragmentation of the target and expulsion of micro-particulate material [2]. Therefore chemical fractionation should be limited. UV lasers ap-

peared to be more suitable for the analysis of glass-like material by ICP-MS.

Laser ablation is a sampling tool that allows direct and rapid extraction of material from solid samples. For the analysis of solid samples that are difficult to dissolve such as REFION, LA-ICP-MS is a good alternative to conventional analysis by ICP-MS. Moreover the laser sampling probe allows direct extraction with no modification of the mineralogical phases of the matrix as in methods based on dissolution. The sampled material should then be more representative of the original sample.

3.3. Microanalysis of trace metals by LA-ICP-MS

For microanalysis of trace metals in glass wastes, LA-ICP-MS is used as relative technique to monitor the variation of elemental concentration between the different mineralogical phases. Microanalysis of two different groups of crystals of the crystallised sample 1C (microlitic crystals and automorphous crystals) was performed by LA-ICP-MS. Relative to Si concentrations of crystals normalised to those of pure vitreous phase are presented in Fig. 9. Within an individual sampling area the signal dispersion for trace elements is 10% or less in the vitreous phase (sample 1V) and higher for the crystallised sample 1C (20% or more). This dispersion reflects the local heterogeneity in the elemental or micro-phase distribution.

Li, B, Cs, Nd, As, Ag, Nd, Bi and Mo show higher relative concentrations, from five to 10 times, in the vitreous phase compared with the crystallised phases. These elements seem therefore to be depleted in the crystals. The relative concentration of Ti, Cr, P, Fe, Mn, Ni, Cu, Zn, Sn, Sb, Pb, W, Mg, Co, Ce and Ba is higher, from 20 up to 100%, in the automorphous crystals texture compared with the vitreous phase. The relative concentrations of Cu, Zn, Sn, Sb, W and Pb are also slightly higher in the microlitic crystals texture compared with the vitreous phase.

LA-ICP-MS data show a partition between the vitreous and the crystallised phases. Since major elements such as Ti, Fe and Zn, minor elements

Fig. 9. Microanalysis by LA-ICP-MS of different mineralogical phases of REFIOM IC

like Cr, Sn, Mn, Ba and traces such as Sb, Ni, Cu, Pb show higher concentrations in the automorphous crystals texture compared with the vitreous phase, they are likely to be incorporated in crystals (sorosilicates and spinels).

Estimation of the absolute concentrations of these metals in the crystals are obtained from relative concentrations using Si concentrations of the different mineralogical phases from SEM-EDXS data. Sorosilicates have a bulk composition similar to the vitreous phase. Therefore those crystals should at least incorporate Ti, Fe and Zn in the 10–30 g kg⁻¹ concentration range, Cr, Sn, Mn and Ba from 1 g kg⁻¹ up to 2.5 g kg⁻¹ and Sb, Ni, Cu and Pb in the 20–350 mg kg⁻¹ range. As spinels are depleted in Si compared with the vitreous phase (50 g kg⁻¹ compared with 300 g kg⁻¹), more metals should concentrate. Therefore spinel crystals could at least incorporate Ti, Fe and Zn in the 60–200 g kg⁻¹ concentration range, Cr, Sn, Mn and Ba up to 10 g kg⁻¹ and Sb, Ni, Cu and Pb in the 100–1000 mg kg⁻¹ range.

Clozel studied the crystallochemistry of toxic metals such as Ti, Sr, Cr, Zn and Pb in vitrified

domestic wastes (REFIOM) within individual crystals by SEM-EDXS [7]. He found that Cr, Sn, Ti, Mn and Zn have an affinity for the spinel crystals whereas Zn can also be incorporated in sorosilicates and Pb is trapped in the vitreous phase.

In the vitrified waste, crystals concentrate in toxic metals. These hazardous elements can be part of the crystal matrix as Al and Fe for spinels and Al for sorosilicates. They can also be trapped in crystals (spinels and sorosilicates) like Sn, Ti, Mn, Fe, Cr, Zn but also Ni, Ba, Sb, Cu and W.

LA-ICP-MS adds new information about the chemistry of trace metals in REFIOM.

Despite the fact that it is important to characterise the bulk composition of trace metals in the vitrified wastes, this approach is however not sufficient. In fact, further knowledge of the distribution of trace metals in the waste material is needed. Knowledge of the partition of toxic metals between the mineralogical phase and particularly the partition between the vitreous and the crystallised phase is a fundamental requisite to assess the potential mobility and release of hazardous elements in the environment. Obtaining

Table 4
Comparison of LA-ICP-MS and SEM-EDXS for the characterisation of toxic metals in vitrified wastes

		LA-ICP-MS	SEM-EDXS
Probe	Macro	Bulk analysis	Not applicable
	Micro	10 μm	10 nm
	Spatial resolution specific information	Automorphous crystals group of microlitic crystals	Individual crystals
Analysis	Physical	No information	Structure & texture
	Chemical		
	Sensitivity	Traces	Major&minors
	Detection limits	0.1 mg kg ⁻¹	10 g kg ⁻¹
	Precision	10–20% RSD	5% RSD
Quantitation		Absolute analysis with external calibrant	Relative analysis
	Accuracy	10–20% RSD	

good correlation between trace metal chemistry, structural and textural patterns is the first step toward this objective.

Key-features of LA-ICP-MS and SEM-EDXS for the characterisation of toxic metals in vitrified domestic wastes is presented in Table 4. LA-ICP-MS can monitor local concentrations of trace elements in the mineralogical phases but cannot deal with individual micro-crystals. On the other hand SEM-EDXS can perform chemical analysis on individual microlitic crystals but is limited to minor elements. LA-ICP-MS is more sensitive than the physical analytical techniques of solids such as SEM. However so far SEM-EDXS provides higher spatial resolution than LA-ICP-MS.

Further finer investigation of the affinity of heavy metals to specific mineralogical phases by LA-ICP-MS should be possible with new laser microprobes. Developments of laser technology will generate laser probes with a spatial resolution lower than 10 μm . Investigation of the distribution of trace metals within the microlitic individual crystals in REFION by LA-ICP-MS would then be feasible. As commercial lasers are basically designed for bulk analysis some modifications are necessary to build up the laser micro-probe using compound focusing objectives. Chenery demonstrated the ability of laser ablation microprobes for the analysis of single mineral

grains [21]. Their laser device produces craters of 5 μm or less that are almost comparable to the spatial resolution provided by SEM-EDXS.

4. Conclusion

A trace analytical method for the in-situ characterisation of trace metals in vitrified wastes based on LA-ICP-MS was developed and validated. LA-ICP-MS is an attractive tandem technique that combines sensitive trace multi-elementary analysis and rapid spatially resolved analysis. LA-ICP-MS allows spatially resolved chemical analysis at different space scales from the bulk characterisation to the microanalysis within mineralogical phases.

It can perform precise and accurate analysis of trace metals for both bulk and micro-analysis down to the microscale. LA-ICP-MS can monitor relative concentrations between the mineralogical phases. Quantitative bulk analysis proved to be possible when using a matched-matrix reference material. However the weakness of this technique for absolute quantitative analysis is the need of a well-characterised external standard, with a matrix similar or close to the samples. LA-ICP-MS appears as an efficient in-situ characterisation

technique of trace metals in complex solid matrixes. Performances of this technique for both relative micro-analysis and bulk quantitative analysis was evaluated with regard to SEM-EDXS. With the laser probe the ICP-MS can cope with microscale analysis and therefore compete with physical analytical techniques.

LA-ICP-MS is also more sensitive than physical techniques of analysis such as SEM-EDXS although its spatial resolution is still lower. However LA-ICP-MS is blind to structural or textural variations. This can be a serious problem when analysing heterogeneous samples at the microscale level. Therefore LA-ICP-MS requires a complementary technique. In-situ investigation of vitrified wastes relies on the use of LA-ICP-MS together with SEM-EDXS to correlate chemical and textural information. Complementary to lixiviation studies, LA-ICP-MS together with SEM-EDXS can monitor the evolution of wastes from the point of the altering matrix. This is an interesting combination of physical and chemical analytical tools for studying the long term behaviour of solid wastes and the mobility of hazardous elements. Information about the structure and texture of the wastes is important to understand the behaviour of their matrix. Vitrified wastes will have different evolution during the leaching process under altering conditions, according to their structure and texture. Information about the affinity of heavy metals to specific crystalline phases will give answers to the potential mobility of hazardous elements and therefore predict the release of toxic species into the environment.

Received 25 May 1997; accepted 14 October 1997

Abstract

In an effort to develop common analytical methods for contaminated soil samples the Environmental Authorities of the Nordic countries have, together with Nordtest, published the report Nordic Guidelines for Chemical Analysis of Contaminated Soil Samples. The aim of these guidelines has been to describe analytical methods which could be accepted in all the Nordic countries and in that way contribute to reducing the variation in the analytical results between laboratories. The methods covered, reflects environmental concerns and priorities in the Nordic countries for now, i.e. heavy metals, chlorophenols, creosote, volatile organic compounds, PCB, THC and PAH. The repeatability and reproducibility of the guideline methods were determined in a Nordic inter-laboratory test in 1996, and the results showed some variations. The analytical methods and the results from the inter-laboratory tests are given for heavy metals, chlorophenols, creosote, volatile organic compounds and PCB. © 1998 Elsevier Science B.V. Keywords: Contaminated soil; Chemical analysis; Reproducibility; Nordic laboratories; Heavy metals

1. Introduction

Extensive work has been and is being done to identify and remediate landfills and hazardous 'waste' contaminated sites, the so called 'past

sins', in Nordic countries. When facing the large costs for cleaning up contaminated sites, it is necessary that chemical analysis provides a foundation for cleanup efforts to be comparable, reproducible and reliable.

Sample treatment and preparation, along with chemical analysis are often performed differently

* Corresponding author.

at different laboratories and may provide different results, despite the fact that some of these laboratories are accredited. It was therefore a priority to develop complete guidelines that could contribute to make the results comparable and reproducible even when the analyses are performed in different laboratories in Nordic countries. This is especially important when the effects of remedial action need to be verified.

An environmental survey of a site is carried out in order to obtain information about the kind, extent and distribution of contaminants, and if needed, to select the most appropriate cleanup methods. Guidelines for soil investigations have already been developed in Denmark, Finland, Norway and Sweden [1,6,12]. These guidelines give appropriate methods for sampling and are meant to be used for planning, executing and reporting these types of environmental surveys.

Samples from such surveys (soil, groundwater, leachate, air, etc.) are sent to an analytical laboratory for chemical analyses in order to ascertain the composition of the polluting contaminants. The results from the analyses will in turn be used when deciding upon further action. For example, if high concentrations of environmentally hazardous compounds are found, costly cleanup efforts may be initiated, while any further activity could be halted and the site declared acceptable if low concentrations are found. Errors in these results from such analysis can have environmental and economic consequences.

Advanced chemical analyses are complicated to perform and can be fraught with error. These errors can be minimised, however, with adequate routines. Another uncertainty factor which can be eliminated, is the use of different methods or conditions for the same analysis at different laboratories. However, the laboratories should still have the opportunity to use their own or alternative methods, but this should preferably be validated and compared with the proposed method in the guideline, to give an estimate of the performance.

The Nordic Guidelines [5] describes methods for heavy metals, chlorophenols, creosote, volatile organic compounds, PCB, THC and PAH, and covers also quality assurance, sampling strategy

and validation. The analytical methods are first of all based on the already existing national or international standards, i.e. ISO/TC 190 and various CEN standards, and/or on common practice.

The repeatability and reproducibility of the proposed methods in this guideline were determined in a Nordic inter-laboratory test according to ISO 5725-2.

2. Analytical methods

The following paragraphs give a brief description of the analytical methods for the determination of heavy metals, chlorophenols, creosote, volatile organic compounds and PCB.

2.1. Heavy metals: As, Cd, Cr, Cu, Hg, Ni, Pb and Zn

The method for determination of heavy metals is a partial digestion method using air dried (24 h) and sieved (< 2 mm) samples. Approximately 1 g of the dried sub sample is introduced into a 100 ml digestion bottle, made of uncoloured pyrex glass with polypropylene screw caps or suitable closures. Bottles and closures should be temperature resistant up to 120°C and a pressure of 200 kPa. Nitric acid (HNO₃) (20 ml of 7 mol l⁻¹) is added and the mixture is heated in an autoclave at 120°C (200 kPa) for 30 min. The solution is cooled, filtered and transferred to a 100 ml flask, diluted with distilled or deionized water. The solution should be transferred to a plastic bottle prior to instrumental analysis. Blank solutions are prepared in the same way. Alternatively, samples could be digested in polytetrafluoroethylene (PTFE) bombs, heated in a microwave oven. The laboratory is free to choose the instrumental methods for determination of analytes.

2.2. Chlorophenols

Field moist soil samples are extracted with acidic acetone:hexane (1:1) by sonication for 6 × 2 min during 1 h. The clear part of the mixture is further extracted (twice) with NaOH and acidified by HCl. The extract is then extracted twice with

hexane, and the hexane phase further extracted (twice) with K_2CO_3 . The chlorophenols in the alkaline extract are then acetylated by acetic anhydride, after which the acetylated chlorophenols are extracted with hexane. The extract is dried using Na_2SO_4 . Chlorophenols in the hexane phase are determined by gas chromatography using a dual column system and electron capture detection. The calibration is based on peak height and on the response of internal standard, 2,4,6-tribromophenol.

2.3. Creosote

Soil samples are extracted with acetone including internal standard by rotation for 1 h. The supernatant is removed after centrifugation. This procedure is repeated once and the organic phases are combined and evaporated to 2–4 ml with nitrogen. An equal volume of water is added and the extract is extracted twice with 5 ml of *n*-hexane. The hexane phases are combined and evaporated to a volume of 1–2 ml. The target compounds are determined by GC-FID.

The target compounds in the analyses of creosote in soil are the following: PAH: naphthalene, 2-methylnaphthalene, 1-methylnaphthalene, biphenyl, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benz(a)anthracene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(e)pyrene and benzo(a)pyrene. Phenols: *o*-cresol and *p*-cresol. *O*-heterocyclics: dibenzofuran. *N*-heterocyclics: carbazole. *S*-heterocyclics: dibenzothiophene.

2.4. Volatile organic compounds-VOC

The guideline describe two methods, with no preference for one or the other. Method 1 is based on solvent extraction. Internal standards and the extraction solvent (pentane) are introduced through the vial septum. The solvent/soil mixture is shaken manually until a slurry is obtained, then treated for a minimum of 5 min in an ultrasonic bath, and extracted for at least 45 min on a mechanical shaker. The pentane extract is isolated after addition of pH 2 water, and after drying with sodium sulphate, analysed with gas chromatography/mass spectrometry (GC/MS).

2.5. PCB

Dry samples are moistened with water. Prior to extraction recovery standards (PCBs 53, 112, 198; 100–1000 ng depending on the level of contamination) are added and the samples shaken gently to mix. Acetone (3–5 ml g^{-1}) is added, the samples are sonicated for 5 min and then shaken vigorously for 1 h. After repeating the extraction with acetone:hexane (1:3) (3–5 ml g^{-1}) the organic phases are washed with 50 ml of 0.2 mol l^{-1} NaCl 0.1 mol l^{-1} H_3PO_4 . After separation the water phase is washed twice with 10 ml hexan:diethylether (9:1) and the organic phases are combined and evaporated almost to dryness at 60°C in a waterbath. The samples are cleaned with H_2SO_4 (conc.) and/or with TBA to remove sulphur and/or the samples are fractionated by silica gel.

The individual PCB congeners are analysed by GC-MSD or GC-ECD with 60 m capillary columns of two polarities. GC-conditions should be optimised in respective laboratories which could for example be: injector 270°, ECD 290°, MSD interface 290°; oven 85° for 2 min, 30° min^{-1} to 210°, hold 28 min, 2° min^{-1} to 250°, 7° min^{-1} to 280° (DB1701) or 310° (DB5), hold as necessary to elute PCB 209. A long isothermal period early in the temperature program is necessary to separate components like PCB 28 and PCB 31.

Prior to injection, the sample is dissolved in isooctane containing the injection standard (for example tetrachloronaphthalene). The calibration is based on the peak height of individual PCBs/peak height of the injection standard. Detection limits will vary with amount and type of contamination. It should be close to $10 \mu\text{g kg}^{-1}$ for each congener but needs to be determined on a case to case basis.

3. Inter-laboratory tests

All laboratories in the Nordic countries which analyse heavy metals and organic pollutants in contaminated soil, were invited to take part in the inter-laboratory test. The invitation was sent out to more than 90 laboratories.

The inter-laboratory test was arranged as a test of repeatability and reproducibility of a standard measurement method. The statistical treatment was performed according to the international standard ISO 5725-2, First edition 1994-12-15: 'Accuracy (trueness and precision) of measurement methods and results, part 2: basic method for the determination of repeatability and reproducibility of a standard measurement method' [3].

A balanced uniform level experiment was performed. The aim was to test one or two different levels of contamination in soil and one test solution, each with three replicates. Each group of replicate measurements ($n = 3$) belonging to one level should be carried out under repeatable conditions, i.e. within a short interval of time and by the same operator. The statistical program involved the testing of the within-laboratory standard variances by Cochran's test and the testing of the variation of means by Grubb's test after which statistical outliers were excluded from the final calculation of the repeatability and reproducibility of the method. Some datasets contained some extreme values which could be due to the use of incorrect units, dilution errors and lack of analytical performance. These extreme values were rejected from the dataset before calculation. Symbols and abbreviations used in the following tables:

Level j	sample types (described for each parameter)
N	number of laboratories participating (or replicates)
p_j	number of laboratories used for calculation
m_j	mean value (for solid samples mg kg^{-1} , for solutions mg l^{-1})
S_r	standard deviation within laboratory (the repeatability)
S_R	standard deviation for the reproducibility
CV_r	the variation coefficient within laboratory (%)
CV_R	total variation coefficient reproducibility (%)
Ref. value	reference value, for certified reference materials or solutions

3.1. Heavy metals

Two real soil samples (samples A and B), one EPA certified reference real soil sample (sample C: CRM 021-100) and one standard solution (sample D) were tested [11].

The real soil samples were sandy soil obtained from sites of polluted soil in Norway. The two real soil samples were air-dried at room temperature. Coarse material (e.g. stones) was removed manually, after which the material was sieved through a 2 mm sieve, followed by sieving through a 500 μm sieve. The real soil samples were mixed for several days using a tumbler. The homogeneity was checked by randomly taking eight sub-samples prepared as wax pellets and subsequent determination of Cr, Fe, Ni, Cu, Zn and Pb with X-ray fluorescence spectrometry. This homogeneity test revealed that the spread among the test samples for most of the measured elements was less than 5%.

The reference material (C) was used as received, without any further homogenisation. The dry matter content was 98.8, 98.8 and 99.7% for samples A, B and C, respectively. The organic matter content (determined as loss of ignition; 2 h ignition at 550°C) was 5.9, 7 and 2% for samples A, B and C, respectively.

Table 1

^a indicated value

The soil samples were polluted with an unknown level of heavy metals. The calibrant solution (D) containing As, Cd, Cr, Cu, Hg, Ni, Pb and Zn was prepared in water using 1000 mg l⁻¹ certified solutions of individual elements and diluting the mixture to a final volume of 2.5 l and adjusting the matrix to 5% HNO₃.

Each laboratory received 25 g of sample A and B, 8 g of sample C and 100 ml of sample D. The soil samples were sent out in small plastic bags, tightly closed, and the test solution in a screw-capped plastic bottle. The samples were sent out on May 2, 1996, and the last date of accepted results was June 30.

The samples were also analysed by the producers laboratory according to the guideline method. The relative standard deviation within the laboratory (the coefficient of variation, CV_r) varied between 2

and 10% for soil A and B and between 7 and 22% for soil C (Table 1). The larger spread in sample C could be due to some inhomogeneity in the sample itself, caused by potential settling and stratification in storage, shipping and handling.

Thirty-eight laboratories from Denmark (13), Finland (11), Iceland (2), Norway (7) and Sweden (5) took part in the inter-laboratory test for heavy metals. Two of the laboratories participated only using their own method and five laboratories performed their own method in addition to the guideline method. The majority of participants submitted full datasets with the exception of As and Hg where relatively fewer data were submitted. The results of this test are summarised in Table 2.

The overall performance on the test solution was good with a total coefficient of variation CV_R between 3.73% for Cu to 13.9% for Hg. The

^a indicated value

laboratories seem to have larger difficulties analysing As and Hg than the other elements, 90% of the laboratories were able to analyse the test solution within 25% of the assigned values for Cd, Cr, Cu, Ni, Pb and Zn and around 80% of the laboratories were able to analyse the test solution for the same elements within 10% of the assigned values. For As and Hg respectively 85 and 80% of the laboratories were able to analyse within 25% and 55% and 40% within 10% of the assigned values.

For the soil samples the coefficient of variation CV_R varied between 6 and 26% for soil A and B, and between 6 and 40% for soil C. Around 85% of the laboratories were able to analyse the soil samples within 25% of the assigned values for all the elements except As and Hg. Around 65% of the laboratories were able to analyse As and Hg within 25% of assigned values. The exception was the level of high content of As in soil B, which was analysed satisfactory by 85% of the participants.

Table 3
Homogeneity of samples used in the inter-laboratory test ($n = 5-10$)

Sample	246-TCP		2346-TeCP		PCP	
	m_j	CV_r	m_j	CV_r	m_j	CV_r
A	0.19	8.2	1.95	9.6	4.9	12.2
B	0.08	18.3	2.8	21.6	1.4	15.8
C	0.74	2.3	208	10.3	1500	6.7
Solution	47.8	4.1	47.6	1.3	171	5.0

Soil C gave a higher coefficient of variation CV_R than soil A and B. This reflects a larger degree of inhomogeneity of soil sample C. The number of outliers were between 1 and 6, indicating systematic errors in some laboratories. Poor performance on the calibrant solutions was often reflected in the results for soil samples.

Five laboratories tested their own method in addition to the guideline method and two laboratories tested their own method only. Three laboratories digested the sample in aqua regia, two used a mixture of HNO_3/H_2O_2 , one used 10% HNO_3 , and one used a 5 g sample in concentrated HNO_3 . Some of these laboratories reported 'out of range' results. In general, however, no significant differences were found between the Nordtest method and their own methods.

3.2. Chlorophenols

Three real soil samples (samples A, B and C) and one calibrant solution (sample D) was used in the inter-laboratory test [4]. The real soil samples were obtained from a sawmill site. They were sieved through an 8 mm sieve. The dry matter content was 80.0, 78.9 and 75.6% for samples A, B and C, respectively. The organic matter content was 5.3, 5.6 and 9.3% for samples A, B and C, respectively. Sample A was of the same batch as sample B, but it was spiked with 2 mg kg^{-1} of 2,4,6 trichlorophenol (TCP), 2 mg kg^{-1} of 2,3,4,6-tetrachlorophenol (TeCP), and 5 mg kg^{-1} of pentachlorophenol (PCP). The soil samples had a natural content of more than 16 different chlorophenol congeners. The samples were homogenised in a tray and then sub-sampled into glass jars. Sample D was prepared in water from

stock solutions of 16 different chlorophenol congeners. The homogeneity of the samples was tested and the coefficient of variation varied between 1.3 and 21.6% (Table 3).

Twenty laboratories from Denmark (4), Finland (10), Norway (1) and Sweden (5) participated in the inter-laboratory test. Several laboratories reported results for up to 16 different chlorophenol congeners, but the majority reported results only for 2,4,6-trichlorophenol, 2,3,4,6-tetrachlorophenol and pentachlorophenol. The amount of data only allowed statistical handling for results of three of these compounds. The results are given in Table 4.

3.3. Creosote

Three samples were sent to the participants [7]. One creosote contaminated soil and two extracts in *n*-hexane from the soil. The soil was collected in Sweden at an old impregnation site. It was dried in a fume hood and then sieved through a 2 mm sieve. The dry matter content was 99.7%. Before sending the soil sample to the participants it was tested for homogeneity. The standard deviation of the determination of the target compounds in 15 sub samples was between 4.5 and 10.8%. The two soil extracts were spiked with compounds which originally were present at low concentrations in the soil. The variation for the solutions was between 1.1 and 6.0%. The concentrations of the target compounds were between n.d. to 51 mg kg^{-1} .

Twelve laboratories reported results, Denmark (4), Finland (2), Norway (1) and Sweden (5). Five laboratories participated using their own methods. One laboratory used its own method only.

	C	18	15	1418	183	12.9	646	45.6	
	Solution	17	14	158	12.7	8.1	51.9	32.9	

The results are summarised in Table 5. The results clearly show that the sub sampling and/or extraction step is critical, the soil sample (sample A) showing a variation that is approximately a factor of two larger than that of the solutions. The highest variation was seen for the compounds present at the lowest concentrations. The within laboratory variation was quite acceptable, although there is room for improvement especially for the soil sample.

The between laboratory variation was quite large, probably due to a number of reasons. For instance, the 60% variation for naphthalene in the soil sample is likely explained by evaporative losses being controlled to a varying degree among the laboratories. In addition, the high variation for benzo(e)pyrene in sample B and C may be explained by differing chromatographic performance, since imperfections in the chromatographic systems primarily are reflected in high variations for the higher molecular species (and those present at low concentrations). Another plausible reason for high between laboratory variations is the fact that the laboratories used their own calibration solutions.

A comparison between the guideline method and the laboratories own methods, showed that the results were quite similar, with a tendency for the recommended method to give somewhat higher yields (in the order of 10%) for lower molecular weight compounds, which also were

present in higher concentrations. It should be taken into account, however, that the statistical basis for this statement is rather weak.

3.4. VOC

Two soil samples (samples A and B), of two different levels of contamination, and one standard solution in methanol were prepared [10]. The soil samples were sandy soil obtained from sites of polluted soil in Norway. The soil was air dried at room temperature. Coarse material was removed manually. The material was sieved through a 2 mm sieve and ground to an average size $< 500 \mu\text{m}$. The organic content was 5.9 and 7.4% for samples A and B, respectively. No background levels of the target VOC compounds was detected in the blank soils. Aliquots of the soil was transferred to 40 ml vials with an open hole screw cap, and a Teflon coated septum. Water was added to the soil to represent 83% dry weight. The soil was spiked with test solutions containing the target compounds, and conserved with methanol before the vial with its content was sealed. The 11 target compounds included benzene, toluene, ethylbenzene, cumene, *p*-cymene, *n*-butylacetate, chlorobenzene, chloroform, 1,1,1-trichloroethane, trichloroethene, and tetrachlorethene.

Each laboratory received three replicates of

the calibrant solution on May 1st and had to report their results before July 1st 1996.

Eleven laboratories submitted datasets, Denmark (4), Finland (5), and Sweden (2). No laboratories from Norway or from Iceland participated. Eight of the laboratories used a solvent extraction method, while two of the laboratories used the purge and trap method. One of the laboratories participated with its own method only. The participants submitted full datasets with the exception of cumene, *p*-cymene and *n*-butylacetat, which some of the laboratories did not report.

The nominal concentrations of the VOC target compounds in the calibrant solution were used as assigned values. The grand mean was used as the assigned values for soil A and B. The results of the test are summarised in Table 6.

The test solution was reported with a reproducibility ranging from 15 (1,1,1-trichloroethane) to 40% (*p*-cymene). A similar range was observed for the soil samples. The results indicate that there were no significant differences in the performance of the calibrant solution compared with the soil

samples. On the average 65% of the laboratories reported test results within $\pm 25\%$ of the theoretical value. However, within the dataset, all laboratories had one or several values extending to the $\pm 25\%$ level.

Most laboratories seemed to perform the analysis of nonhalogenated VOCs (benzene and alkylated benzenes) better than the haloforms. However, the number of participating laboratories was low for statistics to be conclusive. Only six of the participating laboratories reported test results for *p*-cymene and *n*-butylacetate, whereas eight laboratories reported test results for cumene. One laboratory did not report results for the calibrant solution and three laboratories reported only single results for the calibrant solution.

The majority of laboratories conducted the analysis within 2 weeks of receiving the sample set. One laboratory conducted the analysis after 7–8 weeks. Most of the reported values from the latter laboratory were within acceptable limits, but contained some extreme values. One laboratory conducted its own method only (static

ni, not included

headspace). The reported calibrant solution results from this laboratory were good, but the results from the soil samples were only approximately 50% of the theoretical values. This is consistent with observations made by SINTEF, suggesting that a static headspace technique is not an appropriate method for quantitative analysis of VOC residues in soil.

3.5. PCB

The inter-laboratory test [9] concerned the analysis of nine different PCB congeners (28, 52, 101, 105, 118, 138, 153, 156, 180) in one level of contaminated soil. Every laboratory tested the proposed guideline method in three sub samples of the soil containing 0.3 g of CRM 481 from

BCR mixed with 2.7 g of PCB-free soil and if desired their own method on a different set of the same soil. All laboratories were also supposed to analyse a solution that contained all nine PCBs to give an idea of the calibration and chromatographic performance. The analyte solution was made from neat crystals of respective congeners and PCB 31 from Promochem, Germany, and dissolved in isooctane p.a. The soil samples were sent out in screw-capped glass vials and the analyte solution in sealed glass-ampoules.

The samples were sent out on May 7, 1996. The number of laboratories receiving samples were 28 but only 21 returned results. Last date of accepted results was August 31, 1996. The results, which are summarised in Table 7, revealed that

many of the participating laboratories have problems concerning calibration of the individual PCB congeners and can therefore not be expected to give accurate results when analysing soil samples. It is evident that the preparation of calibrants and the method of calibration are a major source of error in the determination of PCBs. One of the 21 labs returning results did not analyse the analyte solution, but of the remaining 20 laboratories only 7–14 laboratories were able to determine the analyte solution within 25% deviation from the expected values.

Generally, higher variability was found with lower level congeners and it has been proposed by CEN to allow 100% variation at levels close to the detection limits of individual PCBs (around

0.01–0.05 mg kg⁻¹ for the soil), 50% variation at a level 10 × higher than that and 25% variation at still higher levels (prEN 1528-1:1996). Many laboratories did not analyse PCBs 105 and 156. These are usually present at low levels but are nevertheless very important congeners toxicologically (mono-*ortho*).

The treatment of PCB 138 was questionable, because it was unclear whether the laboratories were analysing 138 + 163 together, in which case the total amount detected would have been 12.3 instead of 9.2 for only PCB 138. The mean values were in-between these figures, so most laboratories were probably analysing the two together although they did not indicate that in their results and we therefore used 9.2 as the expected value.

Fourteen laboratories tested their own method and in general not much difference was found between the guideline method and their 'own methods'. Seven laboratories reported very good results, indicating that the method is sufficient for the purpose.

4. Discussion

4.1. Heavy metals

The nominal concentration of the metals in the calibrant solution was used as the assigned values. The overall performance on the test solution was good with a total coefficient of variation CV_R between 3.73% for Cu to 13.9% for Hg. The laboratories seem to have larger difficulties analysing As and Hg than other elements. The performance of the calibrant solution was regarded acceptable, although some poor results were reported.

The grand mean were used as the assigned values for soil A and B. For soil samples the coefficient of variation CV_R varied between 6 and 26% for soil A and B, and between 6 and 40% for soil C. At least 75% of the participants were able to analyse the soil samples regarding Cd, Cr, Cu, Ni, Pb and Zn within 25% of the assigned values, but only between 60 and 75% were able to analyse As and Hg within 25% of assigned values, respectively. The testing of homogeneity of the test

samples showed a variation which was less than 5%.

Soil C was certified for all the elements of interest except for Pb. It was revealed during the test that this soil sample was not completely homogeneous and gave a higher coefficient of variation CV_R than soil A and B.

The proposed method for analysing heavy metals in contaminated soil seems to work sufficient for its purpose. All datasets contained extreme values, and indicate that some of the participating laboratories need to improve their quality assurance.

4.2. Chlorophenols

The test material was field moist, obtained from a contaminated site, representing a relevant composition of soil and sawdust. Homogeneity experiments revealed a variation of 2–22%, which was deemed acceptable for this kind of samples. The repeatability variation coefficient, CV_r , which indicates the within-laboratory variation was also satisfactory. It was lower than 8.1% for the test solution and less than 17% for all the soil samples. The results of the inter-laboratory test showed, however, that the reproducibility between the laboratories to analyse the chlorophenol solution was very poor. The coefficient of variation, CV_R , for the solution ranged from 17.3 to 34.1% and for soil samples from 31.8 to 71.1%.

The variation may be due to the fact that the laboratories used the tested method for the first time and thus had problems finding the right level of concentration. However, this problem can be overcome by better validation in separate laboratories. At present there is no commercial reference material available. The reason for the variation in the results for the soil samples, however, was not due to the quality of the test material, but rather due to problems with analytical performance, as was evident from the results of the calibrant solution. The CV_R was highest for soil C, which had a very high concentration. For soils A and B it varied from 31.8 to 47.9%.

4.3. Creosote

The within laboratory variation was quite acceptable, although there is room for improvement especially for the soil sample [8]. The between laboratory variation was quite large, probably due to a number of reasons. For instance, the 60% variation for naphthalene in the soil sample is likely explained by evaporative losses being controlled to a varying degree among the laboratories. The within laboratory variation for the 21 compounds was:

Sample A, between 4.0 (for biphenyl) and 21% (for naphthalene).

Sample B, between 1.4 (for fluorene) and 11% (for carbazole).

Sample C, between 2.3 (for acenaphthene) and 6.2% (for *p*-cresol).

The between laboratory variation was:

Sample A, between 17 (for dibenzofuran) and 60% (for naphthalene).

Sample B, between 8.4 (for 2-methylnaphthalene) and 42% (for benzo(e)pyrene).

Sample C, between 6.13 (for dibenzofuran) and 48% (for benzo(e)pyrene).

The results from the methods evaluation showed that it is a good candidate for recommendation on a Nordic basis. It should however be pointed out that a less contaminated soil probably requires a more specific method, e.g. gas chromatography in combination with mass spectrometry (GC-MS). Also, it should be kept in mind that soil samples of different origin may have substantially different properties, and that the soil used in this investigation should not be regarded as being representative of the majority of contaminated soils. There may very well be other soil types, e.g. with higher humic content that would yield less favourable results as far as the method evaluation is concerned.

4.4. VOC

The overall reproducibility was considered to be acceptable, but there is room for improvement. The results suggest that some of the observed differences are related to factors within the laboratories, and are not related to obvious

weaknesses in the proposed method. A strong indication of this is the fact that the reproducibility results of the test solution were comparable with the results of the soil samples.

The test solution was reported with a reproducibility ranging from 15 (1,1,1-trichloroethane) to 40% (*p*-cymene). A similar range was observed for soil samples. Most laboratories were able to analyse the samples within $\pm 25\%$ of the theoretical values. Some extreme values were observed, but can probably be related to errors in the analytical performance of the laboratory in question rather than to limitations in the proposed method. The proposed guideline method includes some critical steps which, when handled improperly, can give erratic analytical results. One is the proper handling of the VOA vial when extractant solvent is added to the soil/methanol phase.

The soil/methanol phase should be mixed well in the sealed vial prior to the addition of extractant solvent. It is recommended to add the extractant and the internal calibrant solution directly into the sealed vial. Opening of the vial first may result in loss of VOCs. The second critical step is calibration. Calibration solutions should be freshly prepared. Stock calibrant solutions must be controlled and preferably renewed every 3 months. Keeping control of the critical steps above, most VOCs can be quantitatively analysed using the proposed guideline method.

4.5. PCB

After the exclusion of outliers the reproducibility (CV_R) for the analyte solution ranged from 8–29%, except for PCB 28 where the reproducibility was only 39%, most likely because some laboratories were not separating PCBs 28 and 31 adequately. For soil, reproducibility was dependent on the level found, so that when close to the detection limit it was close to 100%, but when levels were higher, the reproducibility improved to about 30% except for PCB 118 with only 68% reproducibility, possibly due to insufficient separation from PCB 149.

5. Conclusion

The most crucial step in attaining a comparable analytical method, apart from the sampling, is pre-treatment (i.e. crushing and sieving), the preparation step (i.e. extraction and digestion) and accurate and careful calibration of the instrument.

It is also important that the test report for organic compounds always contains a copy of the chromatograms from the analysis. In this way it can be seen which compounds are analysed and identified and the number of unidentified peaks. The water content of the sample should always be measured and reported, and the test results should normally be reported as mg kg^{-1} dry matter.

If the sample is sieved before analysis, this should be described in the report, and the mass of the two (or more) particle fractions from the sieving process should be reported. Only in this way is it possible to relate the concentration to the whole sample.

The inter-laboratory tests showed variable repeatability and reproducibility for the different methods, but this is more likely due to the lack of adequate quality routines in the participating laboratories than to the method. In general, the guideline methods had better reproducibility than the laboratories own methods. However, there is also room for improvement for some of the guideline methods.

Use of microwave digestion for estimation of heavy metal content of soils in a geochemical survey

D. McGrath

Teagasc, Johnstown Castle Research Centre, Wexford, Ireland

Received 25 May 1997; accepted 14 October 1997

Abstract

A procedure for the rapid and safe analysis of soils with widely differing organic matter contents has been investigated and validated. Surface soils, totalling 295 and sampled on a grid basis, representing 22% of the land-base of the Republic of Ireland, have been analysed for cadmium, chromium, copper, nickel, lead and zinc. Soil concentrations of cadmium, chromium, lead and nickel exhibit patterns of regionalised elevation. Implications of this elevation are considered in relation to sewage sludge application to land, future requirement for baseline surveys and concerns over concentrations in food products. © 1998 Elsevier Science B.V. Keywords: Soils; Microwave digestion; Heavy metals

1. Introduction

Trace element content of soil is largely determined by geochemical factors, the nature of the parent material and by soil forming processes, including glaciation. The influence of man is also evident in many areas [1] including Ireland [2]. Elevated concentrations of some elements including Se [3], Mo [4] and Cd [5] have been found. A recent investigation has raised concerns in relation to anthropogenic pollution of soils in urban areas by Pb in particular [2] and of geochemical pollution by Cd [5], which had previously remained undetected, in a rural area. This has led to the initiation of a National Soil Geochemical Survey, similar in many respects to that already conducted in England and Wales [6]. To date almost a quarter of the country has been sampled and

analyses performed for a suite of heavy metals. Soils were collected in 1995 (138 samples) and 1996 (157 samples).

Chemical analysis of heavy metals in soils requires matrix destruction particularly of siliceous material [7]. This can only be ensured by using HF. The procedure followed [8], using microwave digestion, has been most widely used for plants [9] but has also been used for organic soils [10] and for soil major component analysis in particular [11,12].

The heavy metals analysed, Cd, Cr, Cu, Ni, Pb and Zn are those, which in addition to Hg, are listed in the EU Directive on the Use of Sewage Sludge in Agriculture: the latter has taken legal effect in Ireland by SI 183 of 1991 [13]. This legislation is the only such relating to Irish soils and the listed metals, together with concentrations

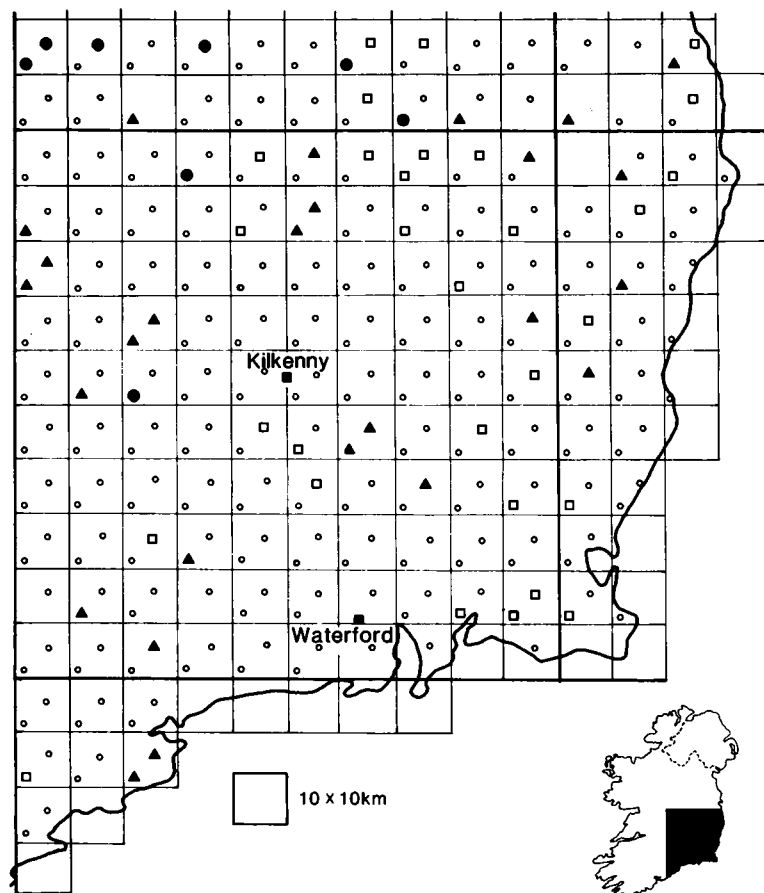

Fig. 1. Land use at sampling points; pasture (○), tillage (□), forest (▲), peat (●).

of each that are tolerated in soil that may legally receive sewage sludge, are the only threshold values available. Results are thus considered against this backdrop.

2. Experimental

2.1. Soil sampling

Sampling locations were determined using Ordnance Survey maps assisted by a Global Positioning System. Samples were taken at fixed points, two from each 10 × 10 km segment of the National Grid. In the event of it not being possible to sample at a particular location a default procedure, similar to that used for the Geochemi-

cal Survey of England and Wales [6], was put in place, subject to a deviation of not more than 400 m. Soil was sampled to a depth of 10 cm, one soil core being obtained at 5 m intervals from each intersection on a grid measuring 20 × 20 m. The combined sample of 25 cores weighed approximately 2 kg. Soil was dried at $t < 30^{\circ}\text{C}$ and sieved to pass a 2 mm mesh. A subsample was ground in a mortar and pestle and sieved to pass a 0.42 mm mesh.

2.2. Sample digestion

The procedure used was that described for digestion of soil in the CEM Digestion Applications Manual [8]. Soil (0.500 g) was placed in a Teflon vessel (100 ml capacity) with water (10 ml), HNO_3

Table 1

(5 ml), HF (4 ml) and HCl (1 ml). It was then subjected to treatment for 30 min, in a CEM Digestion System Model MDS 2000 (CEM Corporation Matthews, NC.). Each set of 12 digests consisted of 10 treatments, a certified reference material CRM 142 R [14] and a reagent blank. Since power input, maximum 630 W, was interrupted when the pressure within the control vessel reached 0.828 MPa, and since pressure generation within vessels was influenced largely by the organic matter content of soil, it was important on the grounds of safety to place the most labile sample in the control vessel. To facilitate this, samples were attended to in order of decreasing organic matter. Digests were treated with crystalline H_3BO_3 (2 g) to neutralise excess HF, transferred to polythene containers and made up to a weight of 53.95 g (equivalent to 50 ml).

2.3. Analyses

Analysis for Cu, Ni and Zn was performed by flame atomic absorption using a Varian AA-1475. Standards within the range 0–2 $\mu\text{g ml}^{-1}$, were made up in a synthetic digestion mix. Cr was similarly determined using 1% Na_2SO_4 modifier [15]. For accurate quantification of Pb at low concentrations by atomic absorption it was found necessary to extract metals as their chelates with ammonium pyrrolidine carbodithioate into 4-methylpentan-2-one (APCD). Cd was measured by atomic absorption with electrothermal atomisation using a Varian Spectra AA-400 with GFA-96 and Pd–ascorbic acid as modifier. Samples, for which measured values were higher than the threshold value for sewage sludge use [13], were reanalysed for the relevant metal after redigestion.

Fig. 2. Frequency distribution of heavy metal concentration ($\mu\text{g g}^{-1}$) in soils

Pb was reanalysed using the electrothermal procedure with NaH_2PO_4 as modifier. Background correction was used in all instances.

Organic carbon in soil was determined by the Walkley Black method [16].

3. Results And Discussion

3.1. Soil selection

The sampled area represented 22% of the land base of Ireland. Because sampling locations were predetermined, sampling bias was eliminated. Collected soils totalled 295 with 10 associated failures, due largely to inaccessibility. Four categories of land use were identified (Fig. 1), namely, permanent pasture ranging in quality from well-managed ryegrass pastures to mountain heath (78.2%), tillage, largely barley production (10.2%),

forest, largely coniferous, (8.8%) and basin peat (2.7%).

3.2. Analysis for heavy metals

Complete digestion of mineral soil matrix was achieved for all samples. Soils with a wide range of organic carbon contents, ranging from less than 2% to more than 44% were digested in the pressure control vessel. Nevertheless no depression in content of any analyte was encountered in the certified reference material, which was digested with each set despite the decreasing energy input. In a separate replicated trial there was no significant decrease in values obtained for a low carbon (12.03 mg g^{-1}) soil when the control vessel contained this soil, the reference soil or a high organic matter (peat) soil.

Values found for the certified reference material were considered satisfactory (Table 1). A problem

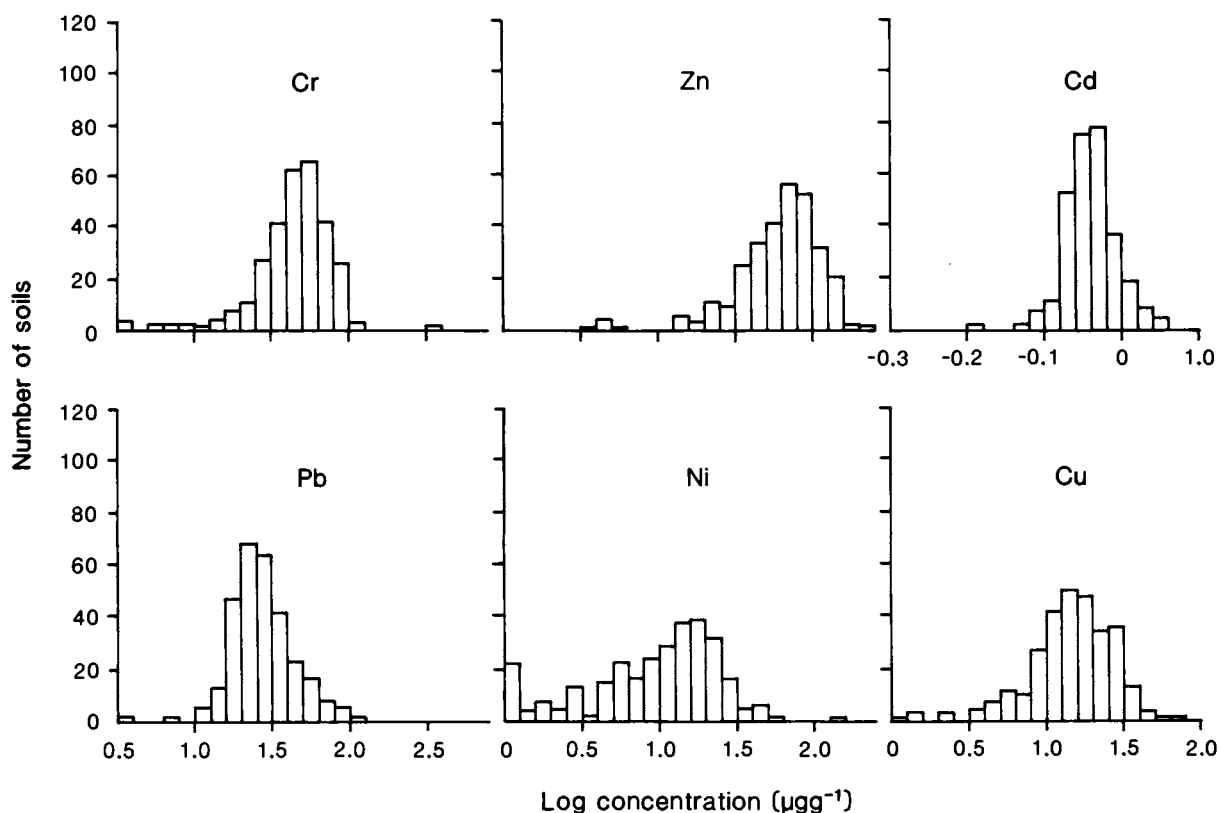

Fig. 3. Frequency distribution of log-transformed heavy metal concentration ($\mu\text{g g}^{-1}$) in soils

was encountered with the quantification of Pb which was not overcome using the method of additions. Solvent extraction of APCD chelates [17] gave accurate results. Results for high value soils were confirmed using electrothermal atomic absorption. Indeed, except for two samples collected at an early date which initially had erroneously high values for Ni and Cr, first measurements were found to be essentially correct.

3.3. Heavy metal levels in Irish soils

Mean concentrations determined for heavy metals (Table 2) were not greatly dissimilar to those reported elsewhere [18–20]. Plotted frequency distributions (Fig. 2) showed departures from normality with severe skewness (asymmetry) and curtosis (influence of peripheral values). These were only partially remedied by the usual

device of employing log-transformation (Fig. 3). Interestingly, high values were best highlighted in untransformed distributions whereas low values were highlighted by transformation.

Low values were not infrequent especially for Cu, Cr, Ni and Zn. Examination in relation to land use (Table 3) showed that concentrations of these metals were low in both forest and peat soils, albeit Cr concentrations were not greatly depressed in forests.

Elevated values (Figs. 2 and 3), those exceeding the threshold fixed by Irish legislation [13], were found for all metals (Table 2). High concentrations were most common for Pb, Cd and to a lesser extent Ni. Some high values were associated with forest soils (Table 3) but not with peat soils as noted by others [21].

Highest mean concentrations of Cd, Cr and Ni were associated with tillage soils. Though it may be tempting to speculate that this may have arisen

Table 3
Heavy metal concentrations by land use

Land use (n)	Carbon (mg g ⁻¹)	Heavy metal (ug g ⁻¹ in soil)					
		Pb	Ni	Cu	Cr	Zn	Cd
Pasture (231)							
Mean	73.1	30.0	13.4	18.0	49.5	73.1	0.52
SD	32.7	14.1	9.2	9.5	19.5	32.7	0.42
Tillage (30)							
Mean	37.0	30.3	23.3	19.1	67.6	88.6	0.76
SD	34.3	14.6	26.6	8.5	52.6	42.4	0.71
Forest (26)							
Mean	152.8	38.1	5.5	8.7	42.5	38.0	0.29
SD	111.1	10.8	5.6	5.9	24.3	25.2	0.29
Peat bog (8)							
Mean	437.7	17.6	4.4	4.9	6.0	26.2	0.35
SD	15.9	11.7	4.2	3.3	2.0	25.2	0.20

as a consequence of anthropogenic activity, perhaps through fertiliser application, as fertilisers are known to contain significant concentrations of all heavy metals [22], the reason may in reality be different as considered later.

Strong associations existed between metals as shown by regression (Table 4). In particular Cr was associated with Ni and Zn with Cu. The significance of these relationships were not greatly weakened by ignoring peat and forest soils.

3.4. Geographic distribution of heavy metals

In order to evaluate regional distribution the strategy adopted was to plot values exceeding the threshold value and also those amounting to 75% of such values. Only two soils had Cu values above the threshold and these were from areas

where there had been mining activity in the past. On the other hand, thirty soils exceeded the threshold value for Cd. Of the affected soils seven were under tillage: the proportion with pH > 7.0 was 40% compared with 10% for all soils. Soils of the main areas affected (Fig. 4) are derived primarily from limestone till [23] and it is known that such soil can show moderate elevations of Cd and other heavy metals [24]. A lesser number of soils with elevated Ni and some with Zn concentrations in excess of 75% of the threshold also fell within the northern section of the Cd affected area.

There appeared (Fig. 5) to be a low (to 75% of threshold), but widespread, enrichment of chromium in soils of the southeast. This was not apparent for Ni despite its association with Cr. It is known [25] that Cr₃ with an ionic radius of

Table 4

Cr					—	0.307***	-0.086
Zn						—	0.445***
Cd							—

Fig. 4. Locations showing concentrations of Cd exceeding 1.0 (■) and 0.75 (○) $\mu\text{g g}^{-1}$ in soil.

0.064 readily substitutes for Fe with atomic radius of 0.067 nm. Fe content of soils in this area are exceptionally high, generally exceeding 30 mg kg^{-1} . The pattern of enrichment also coincides with mapped [26] extrusions of gabbro and basalt which tend to be enriched in both Cr and Ni [25].

The pattern of enrichment for Pb (Fig. 6) was quite different to that for Cd or Cr. Elevation of Pb in soils to concentrations well above those found in the present investigation is known to occur as a consequence of emissions from petrol fume exhausts in Ireland [2] and elsewhere [27]. It is known that deposition rates fall off rapidly within a short distance from the roadway but that a small proportion of emitted Pb can travel long distances [27]. In the present investigation inspection of site distances from thoroughfares, gener-

ally rural roads, with low traffic density, and associated soil Pb values did not encourage the belief that short-range deposition of Pb was involved. Longer range transportation from the United Kingdom and Continental Europe, as is known to happen with SO_2 [28] remains a possibility but an unlikely one in view of the quantities that would be necessary to cause the elevations mentioned.

3.5. Significance of results

A large number of soils totalling 64 or 22% of soils examined would be disqualified under legislation, S1 183 of 1991, from receiving sewage sludge. This together with the proportion of tilled soils that were affected and their proximity to

Fig. 5. Locations showing concentrations of Cr exceeding 100 (■) and 75 (○) $\mu\text{g g}^{-1}$ in soil.

high population centres in the east of Ireland has relevance to future plans to expand sludge use in agriculture.

The fact that some metals, including Cd, Ni, Cr and Pb, and also Hg [29] all exhibit strong localised concentration effects, makes it imperative that information be obtained for the rest of country, otherwise baseline surveys, which need to be conducted prior to industrial/mining development, cannot be properly planned or evaluated.

The mildly elevated concentration of Cd, similar in intensity to that already reported for an area in the West of Ireland [5], makes it imperative that follow up investigations be conducted to

ensure that this has no significant impact on plant, animal or human health [24].

Acknowledgements

The author wishes to thank S. McCormack for technical assistance, T. Cowman for electrothermal atomic absorption analysis for Cd and Pb and W.E. Murphy for statistical analysis. Gratitude is also extended to the EU for financial assistance under the Structural Funding Programme.

Extraction procedures for the determination of heavy metals in contaminated soil and sediment

Gemma Rauret

Dept. Química Analítica, Universitat de Barcelona, Barcelona, Spain

Received 25 May 1997; accepted 14 October 1997

Abstract

Extraction tests are commonly used to study the mobility of metals in soils and sediments by mimicking different environmental conditions or dramatic changes on them. The results obtained by determining the extractable elements are dependent on the extraction procedure applied. The paper summarises state of the art extraction procedures used for heavy metal determination in contaminated soil and sediments. Two types of extraction are considered: single and sequential. Special attention is paid to the Standard, Measurement and Testing projects from the European Commission which focused on the harmonisation of the extraction procedures and on preparing soil and sediment certified reference materials for extractable heavy metal contents. © 1998 Elsevier Science B.V. Keywords: Extraction procedures; Heavy metals; Contaminated soil; Sediment; Certified reference materials

1. Introduction

Trace metals in soils and sediments may exist in different chemical forms or ways of binding. In unpolluted soils or sediments trace metals are mainly bound to silicates and primary minerals forming relatively immobile species, whereas in polluted ones trace metals are generally more mobile and bound to other soil or sediments phases. In environmental studies the determination of the different ways of binding gives more information on trace metal mobility, as well as on their availability or toxicity, in comparison with the total element content. However, the determination of the different ways of binding is difficult and often impossible. Different approaches are used for soil and sediment analysis, many of them

focused on pollutant desorption from the solid phase; others are focused on the pollutant adsorption from a solution by the solid phase. Among those approaches based on desorption, leaching procedures are the most widely accepted and used.

Extraction procedures by means of a single extractant are widely used in soil science. These procedures are designed to dissolve a phase whose element content is correlated with the availability of the element to the plants. This approach is well established for major elements and nutrients and it is commonly applied in studies of fertility and quality of crops, for predicting the uptake of essential elements, for diagnosis of deficiency or excess of one element in a soil, in studies of the physical-chemical behaviour of elements in soils

and for survey purposes. To a lesser extent they are applied to elements considered as pollutants such as heavy metals. The application of extraction procedures to polluted or naturally contaminated soils is mainly focused to ascertain the potential availability and mobility of pollutants which is related to soil-plant transfer of pollutants and to study its migration in a soil profile which is usually connected with groundwater problems [1].

For sediment analysis, extraction is used to assess long term emission potential of pollutants and to study the distribution of pollutants among the geochemical phases. As far as heavy metals are concerned sediments are usually a sink but may also become a source under certain conditions, especially in heavily contaminated areas or in drastically changing environments. Chemical extraction of sediments has proven to be adequate for determining the metal associated with source constituents in sedimentary deposits [2], but the general aim of many studies involving chemical extraction is the determination of element distribution among different phases of a sediment. Single extractants are usually chosen to evaluate a particular release controlling mechanism such as desorption by increasing salinity or complexing by competing organic agents. Generally, fractions can be isolated more specifically by using sequential extraction schemes. For sediments these procedures are frequently used and are designed in relation to the problems arising from disposal of dredged materials.

Extraction tests, either in soils and sediments, are always restricted to a reduced group of elements and as far as soil is concerned they are applied to a particular type of soil; silicious, carbonated or organic. In a regulatory context, two applications for leaching tests can be recognised: the assessment or prediction of the environmental effects of a pollutant concentration in the environment and the promulgation of guidelines or objectives for soil quality as for example for land application of sewage sludge or dredge sediments. The data obtained when applying these tests are used for decision makers in topics such as land use of soil or in countermeasures application.

2. Commonly used extraction procedures in soils

During the last decades several extraction procedures for extractable heavy metals in soils have been developed and modified. In this respect, two groups of tests must be considered: the single reagent extraction test, one extraction solution and one soil sample, and in the sequential extraction procedures, several extraction solutions are used sequentially to the same sample although this last type of extraction is still in development for soils. Both types of extraction are applied using not only different extracting schemes but also different laboratory conditions. This leads to the use of a great deal of extraction procedures. In Table 1 a summary of the most common leaching test are given.

United Kingdom	EDTA 0.05 mol l ⁻¹ at pH = 4	Cu availability evaluation	[20]

From Table 1 it can be observed that a single extraction including a large spectra of extractants are used. It ranges from very strong acids, such as aqua regia, nitric acid or hydrochloric acid, to neutral unbuffered salt solutions, mainly CaCl₂ or NaNO₃. Other extractants such as buffered salt solutions or complexing agents are frequently applied, because of their ability to form very stable water soluble complexes with a wide range of cations. Hot water is also used for the extraction of boron. Basic extraction by using sodium hydroxide is used to assess the influence of the dissolved organic carbon in the release of heavy metals from soils. A large number of extractants are reviewed by Pickering [13] and Lebourg [14].

The increasing performance of the analytical techniques used for element determination in an extract, together with the increasing evidence that exchangeable metals better correlate with plant uptake, has lead extraction methods to evolve towards the use of less and less aggressive solutions [10]. These solutions are sometimes called soft extractants and are based on non buffered salt solutions although diluted acids and complexant agents are also included in the group. Neutral salts dissolve mainly the cation exchangeable fraction although in some cases the complexing ability

of the anion can play a certain role. Diluted acids dissolve partially trace elements associated to different fractions such as exchangeable, carbonates, iron and manganese oxides and organic matter. Complexing agents dissolve not only exchangeable element fraction but also the element fraction forming organic matter complexes and the element fraction fixed on the soil hydroxides. Nowadays it is generally accepted that extractants are not selective and that minor variations in analytical procedures have significant effects on the results.

Some leaching procedures for soils have been adopted officially or its adoption is under study in different countries with different objectives [14]. An account of these methods are given on Table 2.

3. Commonly used extraction procedures in sediments

As for soils, exchangeable metal in sediments are selectively displaced by soft extractants. Other extractants used are less selective and they co-extract the exchangeable fraction together with metals bound to different sediment phases more

or less extensively. The phases considered relevant in heavy metals adsorption in sediments are oxides, sulphides and organic matter. Fractionation is usually performed by using sequential extraction schemes. The fractions obtained, when applying these schemes, are related to exchangeable metals, metals mainly bound to carbonates, metals released in reducible conditions such as those bound to hydrous oxides of Fe and Mn, metals bonded to oxidable components such as organic matter and sulphides and residual fraction. The extractants more commonly used in sequential extraction schemes are generally applied according to the following order: unbuffered salts, weak acids, reducing agents, oxidising agents and strong acids.

In Table 3 the extractants most commonly used to isolate each fraction are given [21]. The water soluble fraction may be obtained by two ways, by sampling sediment pore solution using in situ filtration, dialysis tubes or bags, or by a leaching procedure in the laboratory. When this procedure is used the pH may be indeterminate because of

Table 3
Most common extractants used in sequential extraction schemes

Group	Type and solution strength
Water soluble fraction	H ₂ O
Exchangeable and weakly adsorbed fraction	NaNO ₃ 0.1 mol l ⁻¹
	KNO ₃ 0.1 mol l ⁻¹
	MgCl ₂ 1 mol l ⁻¹
	CaCl ₂ 0.05 mol l ⁻¹
	Ca(NO ₃) ₂ 0.1 mol l ⁻¹
Carbonate bound fraction	NH ₄ OAc 1 mol l ⁻¹ pH = 7
	HOAc 0.5 mol l ⁻¹ HOAc/NaOAc 1 mol l ⁻¹ pH = 5
Fractions bound to hydrous oxides of Fe and Mn	NH ₂ OH.HCl 0.04 mol l ⁻¹ in acetic or nitric acid NH ₄ Ox Sodium ditionite, sodium citrate, sodium bicarbonate (DCB)
Organically bound fraction	H ₂ O ₂ NaOCl

the low buffering capacity of the extractant and problems with readsorption occurs. Exchangeable fraction uses an electrolyte such as salts of strong acids and bases or salts of weak acids and bases at pH 7 to prevent oxyhydroxy phases precipitation. The carbonate bound fraction generally uses an acid such as acetic or a buffer solution acetic acid-sodium acetate at pH 5. These reagents are not able to attack all the carbonate content, as for example dolomitic carbonates, neither to attack carbonate selectively as they also remove partially organically bound trace metals. The fraction obtained when a reducing solution is used as extractant is mainly related to metals bound to iron and manganese oxides. Hydroxylamine in acid solution is the reducing agent most widely used to solubilise these oxides although iron oxide is not completely dissolved. Ammonium oxalate seems to be most effective when used in the dark, although some problems in heavy metals oxalate phase precipitation may occur even at low pH. The sodium dithionite/citrate/carbonate reagent dissolves the oxide and hydroxyoxides but can attack iron rich silicates. So reducing extractants are neither selective nor completely effective for iron and manganese oxides. Other group of extractants used sequentially includes oxidising reagents which destroy organic matter and also oxidises sulphides to sulphates. The extractants most widely used in this group are H₂O₂ and NaOCl. Hydrogen peroxide seems to be more efficient if used after the oxide extraction step.

The most widely used extraction scheme is the one proposed by Tessier [22] which has been modified by several authors [23–25]. Many of these modifications make more specific the isolation of the iron and manganese oxide and hydroxide phases. The Tessier procedure is schematised in Table 4 together with the modified procedures of Förstner [26] and of Meguelatti [24].

4. Harmonisation and method validation

Owing to the need of establishing common schemes in Europe for extractable trace metals in soils and sediments the EC Standards, Measurement and Testing Programme, formerly BCR (Bu-

Table 4
Sequential extraction schemes

reau Community of Reference), has sponsored from 1987 several projects focused on single extraction for soils and sequential extraction for soils and sediments. The project started with the intercomparison of existing procedures tested in an interlaboratory exercise [27]. The next step was to adopt common procedures for single extraction of trace metals from mineral soils. The second step was to adopt a common procedure for sequential extraction of sediment. As a conclusion of the first step, single extraction procedures using acetic acid, 0.43 mol l⁻¹, and EDTA, 0.005 mol l⁻¹ for mineral soils and a mixture of DTPA, 0.005 mol l⁻¹ diethylenetriamine pentaacetic acid, 0.01 mol l⁻¹ CaCl₂ and 0.1 mol l⁻¹ triethanolamine for calcareous soils were adopted for extractable Cd, Cr, Cu, Ni, Pb and Zn. In order to improve the quality of the determination of extractable metal content in different types of soil using the procedures previously adopted, the extraction procedures were validated by means of intercomparison exercises [28,29]. Moreover the lack of suitable certified reference materials for this type of studies did not enable the quality of the measurements to be controlled. With the purpose to overcome this problem three certified reference materials: a terra rossa soil, a sewage amended soil and a calcareous soil have been

prepared and their extractable trace metal contents were certified (CRM 483, CRM 484 and CRM 600) [30,31].

The second step of the EC, Standards, Measurement and Testing was focused on a feasibility study on the adoption and validation of a sequential extraction scheme for sediment samples. In a workshop held in 1992 in Sitges (Spain) a sequential extraction scheme was proposed which includes three steps: acetic acid, hydroxylamine hydrochloride or a reducing reagent and hydrogen peroxide or an oxidising reagent. This procedure is schematised in Table 5. Moreover in this workshop the main analytical limitations in sequential extraction of trace metals in sediments were thoroughly discussed and practical recommendations were given [32,33]. These recommendations deal with sampling and sample pre-treatment, practical experiences with reagents and matrices and analytical problems after extraction.

Once the scheme was designed, it was tested through two round robin exercises using two different type of sediment, silicious and calcareous [34]. In these exercises some critical parameters in the protocol were identified such as the type and the speed of the shaking and the need of an optimal separation of the liquid–solid phases after the extraction. It was stated that the sediment

should be continually in suspension during the extraction. In these intercomparison exercises an important decrease was noted on the acceptable set of values for concentration in the extract lower than $10 \mu\text{g l}^{-1}$, which illustrates the difficulties experienced by a number of laboratories in the determination of such concentration levels in these matrices. It was concluded that when electrothermal atomic absorption spectrometry is used for the final determination, the method of standard additions is strongly recommended for calibration. The results obtained in the round robin exercises encouraged to proceed with the organisation of a certification campaign in order to produce a sediment reference material following the sequential extraction scheme adopted. So the next step of the project was the preparation of a sediment certified reference material for the extractable contents of Cd, Cr, Cu, Ni, Pb and Zn, following the three-step sequential extraction procedure. A silicious type sediment with rather high trace metal content was chosen for this purpose. This material has been recently certified for five metals, Cd, Cr, Ni, Pb and Zn in the first step, Cd, Ni and Zn in the second step and Cd, Ni and Pb in the third step [35]. Not all the elements

were certified because the lack of reproducibility attributable to non adherence to the protocol, in the acceptance of too large tolerances in the conditions specified in it or in the existence of critical aspects in the procedure referred mainly to the second step. These aspects were mainly pH, redox conditions and possible losses of sediment in the transfer. The results obtained in the certification exercise recommended to continue the development of the extraction protocol in order to increase reproducibility. Consequently the causes of non reproducibility are now under study in a new SMT project.

5. Conclusions

The advantages of a differential analysis over investigations of total metal contents and about the usefulness of single and sequential chemical extraction for predicting long-term adverse effects of heavy metals from polluted solid material, soils and sediments, is beyond any doubt. The advances in this field, especially to make available soil and sediment certified reference materials for extractable element contents by using harmonised procedures, is going to increase the quality of the results due to the possibility of verifying the analytical quality control.

Nevertheless some problems need to be solved with these procedures for example: (1) reactions are not selective and are influenced by the experimental conditions so it is necessary to identify the main variables which involves a lack of reproducibility when applying a procedure, to write very well defined protocols and to validate them; (2) labile fractions could be transformed during sample preparation and during sequential extraction schemes application so problems encountered when preparing certified reference materials are not representing all the problems to be found when working with environmental samples such as wet sediments, some work in this area is needed; (3) analytical problems due to the low level of metals to be measured in the different fractions especially when using soft extractants; and (4) the procedures need to be optimised and validated for different type of soils, including organic soils and sediments.

The EC Standards, Measurements and Testing Programme in support of the quality control of waste analysis

Ph. Quevauviller *

European Commission, Standards, Measurements and Testing Programme (M075 3/9), 200 rue de la Loi, B-1049 Brussels, Belgium

Received 25 May 1997; accepted 14 October 1997

Abstract

Projects funded within the EC Standards, Measurements and Testing Programme (SM&T) of the European Commission aim to contribute to the harmonization and improvement of methods and measurements carried out within the European Union and hence to the comparability of data necessary for e.g. trade activities, monitoring of environment, food and health control, etc. This goal may be achieved by e.g. the organization of interlaboratory studies and certifications of reference materials, the development of new methods and pre-normative research. Examples of projects undertaken in support of the quality of waste analysis are given in this paper, covering different aspects, namely interlaboratory study and certification of extractable trace metals in sewage sludge amended soil reference materials, pre-normative research for the characterisation of stabilized waste (interlaboratory study), and development of field-measurement device for the monitoring of waste water quality; this paper gives also an account of a network aimed at harmonising leaching/extraction tests used for environmental risk assessment. Finally, the main topics of the workshop on Standards, Measurements and Testing for Solid Waste Management are given in the annex, along with a list of participants. © 1998 Elsevier Science B.V. Keywords: SM&T programme; Quality control; Waste analysis; Interlaboratory studies; Pre-normative research; Method development

1. Introduction

The lack of quality control of analyses, performed in routine, industrial and research laboratories may create strong economic losses due to the possible misuse of inaccurate data. In relation to waste management, this may lead to an incorrect evaluation of environmental risks due to e.g.

leaching of wastes or impossibilities to comply with regulations (standards or directives) which will have an impact on re-use of stabilised wastes (e.g. decisions on use for landfill purposes or dumping). Quality is one of the salient feature of the 1990's and a wide variety of actions have been undertaken in many countries to verify the quality chemical data produced e.g. by control laboratories; these actions included the implementation of accreditation systems, QA guidelines and norms (e.g. ISO 9000 and EN 45 000 series), organization

* Tel.: +32 229 63351; fax: +32 229 58072; e-mail: Philippe.quevauviller@dg12.cec.be

of interlaboratory studies, proficiency testing and production of laboratory and certified reference materials. This paper describes the objectives of the SM&T programme and some examples of RTD projects in support of the quality of waste analysis.

2. Objectives of the SM&T programme

The Standards, Measurements and Testing Programme [1], SM&T, of the European Commission aims to improve the quality of measurements and consequently harmonize the results obtained within the European Union particularly in support of EC regulations (compliance with EC Directives), standardization (pre-normative research) and means of calibration (transfer standards in metrology, CRMs in chemistry). Emphasis is given to the support of Measurements for Quality European Products and Written Standards for Industry (Theme I), Research related to Written Standards and Technical Support to Trade (Theme II) and Measurements related to the Needs of Society (Theme III). Equally to other RTD programmes of the DG XII of the European Commission, the participation in the SM&T programme is open to all legal entities. RTD projects may be submitted in the frame of time-limited calls for proposals. Two calls have been opened on Theme I in 1994 and 1996 [1,2]; two other calls have been concluded in 1995 and 1997 on Themes II and III. In parallel to these calls, dedicated calls in support of Community policies are organised at regular intervals in response to requests from other General Directorates or standardization bodies, e.g. to establish technical basis for the implementation of directives or standards. The SM&T programme also offers the possibility of proposing thematic networks on various topics with the aim being to create links between research organizations and industry. Finally, accompanying measures may be proposed, e.g. organization of scientific workshops or training actions, submission of doctoral or post-doctoral grants (in support of projects selected for funding) etc.

3. Examples of projects in support of the quality of waste analysis

The projects currently selected in the frame of SM&T calls for proposals that deal with four main types of activities, namely (i) interlaboratory studies, (ii) certification of reference materials, (iii) pre-normative research and (iv) development of new methods or instrumentation. The projects described below were selected for funding by the SM&T programme.

3.1. *Interlaboratory study and certification of sewage sludge amended soil*

One of the best ways of assessing the performance of analytical methods is to compare them within the frame of interlaboratory studies [3]. The comparison of different techniques as applied in different laboratories allows the detection of errors due to a particular method, or part of a method (e.g. insufficient extraction, uncontrolled interferences), or due to a lack of quality control within one laboratory. The participation in such interlaboratory studies may then help in establishing the state of the art in a particular field of analysis and to improve the quality of the measurements. These studies are often carried out to remove all sources of error in the application of techniques to be used in certification campaigns or to test the performance of a standard prior to its implementation. The example given below describes an interlaboratory study on extractable trace metal contents in a sewage sludge amended soil, followed by a certification campaign.

Single extraction tests are commonly used to study the eco-toxicity and mobility of metals in soils and sludges, e.g. to assess the bioavailable metal fraction (and thus to estimate the related phyto-toxic and nutritional deficiency effects) and the environmentally accessible trace metals upon disposal of e.g. sediment on to a soil (e.g. contamination of ground waters). However, lack of uniformity in different procedures does not allow the results to be compared worldwide or the validation of procedures. The results obtained are defined by the determination of extractable elements using a given procedure, therefore, their

significance is highly dependent on the given extraction protocol applied. Moreover, the lack of suitable reference materials for this type of study did not, in the past, enable the quality of the measurements to be controlled. Because the pitfalls likely to occur in the use of extraction protocols for soil analysis, the SM&T programme has hence launched a project aiming at harmonizing measurements for extractable trace metal contents in soil. This project followed a stepwise approach (through interlaboratory studies) of which the final aim was to certify soil reference materials for their extractable trace element contents [4,5]. The choice of operationally-defined procedures tested was directed towards single step methods rather than sequential extraction ones; in a first stage, EDTA (ethylene-diamine-tetra-acetic acid) and acetic acid were selected for interlaboratory studies on a sewage sludge amended soil which was followed by the certification of two reference materials for their extractable contents of Cd, Cu, Cr, Ni, Pb and Zn [4]. Another project was launched on a sewage sludge amended calcareous soil for which EDTA and DTPA (diethylene-triamine-pentaacetic acid) were selected as extractants: the organisation of a preliminary study was considered to be essential prior to certification in order to test the extraction procedures and possibly amend them. To do so, a sewage sludge contaminated calcareous soil was selected from the bank of reference materials of the Environment Institute of the Joint Research Centre of Ispra (Italy) in order to present both the characteristics of a calcareous soil (CaCO_3 content of 228 g kg^{-1}) with high heavy metal contents. The most critical steps discussed in the technical scrutiny of the results of the interlaboratory study were the type and speed of shaking, filtration and centrifugation. As a general remark, it was stressed that the use of standard additions for calibration was a prerequisite for electrothermal absorption spectrometry. It was also recalled that the use of an end-over-end shaker was required, therefore, the data obtained using a horizontal shaker was rejected. The DTPA extraction was criticized owing to the high mass/volume ratio which limited the vol-

ume of extract collected after centrifugation. This procedure was not considered to be applicable to Cr determination. On the basis of the results obtained in this exercise, the choice of EDTA and DTPA for certification was discussed. Whereas EDTA was widely accepted, the choice of DTPA was further criticized because of its operational difficulties; the wide use of the latter would, however, justify the certification of DTPA extractable trace element contents, providing that its limitations in comparison with EDTA were clearly identified. Following the interlaboratory study, a candidate CRM was prepared and its homogeneity and long term stability were verified on the basis of the observed variations in EDTA- and DTPA- extractable heavy metal contents. The material was shipped to a group of ca. 20 laboratories which were requested to make a minimum of five independent replicate determinations of each element on at least two different bottles of the CRM on different days, following strictly the EDTA and DTPA extraction protocols previously defined. The techniques of final determination were electrothermal atomic absorption spectrometry (ETAAS), flame atomic absorption spectrometry (FAAS), inductively coupled plasma emission spectrometry (ICPAES) and inductively coupled plasma mass spectrometry (ICPMS). All the results were discussed at a technical evaluation meeting to confirm the accuracy of the methods of analysis. At the technical meeting, it was recalled that strict observance of the extraction protocols would be a criterion for considering the results for discussion. The participants recommended that a tolerance of $\pm 30\%$ be included in the extraction protocols for the shaker speed. Most of the errors detected were due to calibration errors rather than the application of the extraction procedures. The certification of this material (CRM 600) has been accepted by the board of evaluators for BCR-certifications and it is now available on the market.

3.2. Pre-normative research for leaching tests applied to stabilized wastes

As mentioned previously, one approach for testing a proposed standard method consists of preparing reference materials to be analysed by a group of expert laboratories and to possibly improve or adopt the method on the basis of the results obtained. The example above shows that CRMs certified for operationally-defined parameters (following a standardized method, e.g. single or sequential extraction) may be prepared for the quality control of the measurements. The SM&T programme may hence provide support to the technical evaluation of proposed standardized methods on which basis official bodies such as CEN, ISO etc. will discuss the adoption of a standard.

In this paper, the pre-normative aspect is exemplified by the results of a study of leaching tests for stabilized wastes [6]. The potential environmental hazards caused by waste materials vary strongly between wastes from different sources. Although elimination and minimization of waste streams have the highest priority, it is obvious that significant waste release remains. These have to be dealt with in an environmentally acceptable manner. Some bulk wastes and treated wastes can be beneficially applied in construction [7]. Several waste streams will require treatments, such as stabilization, before disposal to minimize adverse environmental effects. At present, proper methods to address potential environmental effects from monolithic waste forms are not implemented in regulation. Therefore, proper performance criteria for the evaluation of the effectiveness of the immobilization technologies are lacking. Current regulatory test procedures based on single extraction of crushed material at a fixed liquid to solid ratio are inadequate to assess the environmental impact from these types of solid specimens [8]. The mechanism controlling the release from monolithic specimen is neglected when crushed materials are used. In addition, reference materials are needed in this field for quality control purposes. With respect to the harmonization of standard leaching tests, an interlaboratory study on leaching tests was carried out with 23 labora-

tories from the EU and Associated Member States. After a preliminary study of homogeneity and reproducibility of testing within one laboratory, the intercomparison of leaching tests for monolithic stabilized wastes (samples of cement-based stabilized wastes) was carried out using a tank leaching test procedure as a common method. Other test methods have been applied to put the test results in perspective. A standard leachate was provided to verify between laboratory variability of the analytical methods applied. The results of the interlaboratory study indicated that the agreement was quite good for the elements measured (Ba, Ca, Cd, Cl, K, Na, Pb, SO₄, Sr, Zn) with sufficient analytical precision. Both the within and between laboratory standard deviation was poor for elements present at low concentration levels such as Pb and Zn. In the case of sulphate, between laboratory standard deviation was relatively high in spite of sufficient analytical sensitivity. Changes in the predominant leaching mechanism with aging of the cement-based matrix was the main reason for this effect. The continued hardening of the cementitious matrix after 28 days of curing caused changes in the release rates due to an increase of the tortuosity of the matrix. This aspect of leaching of cementitious matrices needed to be taken into account in evaluating the test results. This intercomparison was carried out when changes in material properties were largely stabilized.

The results of other tests, largely consisting of regulatory tests for granular materials, could be placed in perspective using a pH static leaching procedure. It was shown that the equilibrium pH reached in these tests largely dictates the leached quantity. Based on these observations, the Unified Approach for Leaching as developed for granular materials can be extended to monolithic materials by combining dynamic aspects of leaching from the tank leach test with solubility control of leaching from a pH static leaching test. This allows interpretation of changes in release under different exposure conditions (e.g. carbonation). The tank leach test provides a means of assessing physical and chemical parameters controlling release which is useful in the improvement of stabilization product development. In the discussion of

results with the participants, it was concluded that the tank leach tests are a good characterization tool to assess the release from stabilized wastes for regulatory purposes. Further work in data interpretation is needed to make full use of the information contained in the test. A short version linked closely to the extended test should be developed for quality control purposes. The method has been proposed for standardization to CEN. The preparation of cement stabilized specimen as reference material for leach tests was recommended. The preparation of standard leachates at high and low concentration levels was recommended for quality control in leachate analysis.

For additional information, please contact the co-ordinator of the project: Dr H.A. van der Sloot, Energieonderzoek Centrum Nederland, P.O. Box 1, NL-1755 ZG Petten (e-mail: vanderlsoot@ecn.nl).

3.3. Network to harmonise leaching/extraction tests

The above projects are complemented by the establishment of a network of experts for discussing possible strategies to harmonise leaching and extraction schemes used for environmental risk assessment (analysis of waste, contaminated soil, compost, construction materials, concrete etc.). This network was launched after a workshop held in Maastricht in 1994 [9] where scientists from different fields of expertise discussed various approaches to improve the present situation which does not allow data to be compared from one field to another, and sometimes within a single field, owing to the operational character of the procedures used. The experts recommended in particular the creation of a network and the organisation of interlaboratory studies to test the various existing schemes. These recommendations had two effects (1) creation of a network as a pilot action between 1994 and 1996, which will be followed by a wider action, starting in 1998, and (2) technical work in support of this network.

With respect to the pilot network, expert discussions aimed to harmonize the approaches in existing leaching tests used in the fields of soils, sediments, sludges, waste, stabilized waste and

construction materials, to exchange information among different fields and define the problems in specific fields, to facilitate the development of a generic approach by intensive expert consultations, to form a strong network of experts, and to formulate recommendations for the implementation of more generally applicable approaches and identify research needs. This pilot action was carried out in 1994–1996 and resulted in the production of a comprehensive book [10] which will serve as a basis for the further development of a wider network which was selected for funding by the SM&T programme at the end of 1997.

The basis for this technical work in support of the above described network was based on the growing concern on the environmental impact of waste disposal, re-use of waste, recycling of materials, transport of waste, waste treatment, clean-up of contaminated soil, re-use of cleaned soil and utilization of secondary materials in construction has led to an increased demand for leaching and/or extraction procedures that would be able to assess the environmental consequences of these different activities. As stressed above, these operationally-defined procedures are usually developed within a specific field, without much interaction from outside that field. When the use and development of such procedures are not co-ordinated in a wide context and harmonized, it may result in the multiplication of different tests which may lead to an almost unmanageable situation with respect to drafting regulations and evaluating environmental risks. The overall objective of this work is to provide a technical basis for discussion about harmonization of leaching /extraction tests developed in very diverse fields such as soil, contaminated soil, sediment, sludge, compost, waste, stabilized waste, construction materials, drinking water pipes and impregnated wood, and to provide recommendations for test use, test modification, unified data reporting, presentation, and implementation of tests in the various fields. To meet these objectives a selection of materials from the different fields-soil, contaminated soil, sediment, sludge, compost, waste, stabilized waste, construction materials, drinking water pipes and impregnated wood-will be subjected to different leaching/extraction tests covering different aspects

of leaching. A range of inorganic constituents of environmental concern will be analysed to ensure that general conclusions can be drawn on the validity of the comparisons. Comparisons between test results within one field and between different fields will be feasible using the experimental set-up. Modelling of leaching behaviour will be carried out to allow the prediction of release under different exposure conditions. The information generated will be discussed with representatives from the different fields at expert meetings organised by the Network on Harmonization of Leaching/Extraction Tests, and disseminated through this channel and through regulatory bodies. For additional information, please contact the co-ordinator of the projects: Dr H.A. van der Sloot, Energieonderzoek Centrum Nederland, P.O. Box 1, NL-1755 ZG Petten (e-mail: vandersloot@ecn.nl).

3.4. Waste water monitoring

As mentioned in Section 1, the SM&T programme funds RTD projects aimed at developing new instruments/methods for measurements and testing; this section exemplifies the reasoning for selecting one project.

The European Community decided in 1991 to oblige all EU Member States with wastewater treatment plants for all cities whose wastewater organic load is greater than 15 000 equivalent-inhabitants (before the 31st December 2000) and 2000 equivalent-inhabitants (before the 31st December 2005). The quality of the treated wastewaters must be better than reference values for parameters such as Biological Oxygen Demand (BOD), Chemical Oxygen Demand (COD), Total Suspended Solids (TSS) and even the global nitrogen and total phosphorus. These dispositions are of great importance but unfortunately surveys are not very satisfying since the chosen parameters are not easy to measure without sampling, storage and laboratory analysis. A SM&T project has, therefore, developed a simple wastewater quality monitoring device based on spectrophotometric methods for the measurement of BOD, COD, TSS, global N (sum of nitrate, nitrite and Kjeldahl nitrogen) and total P; other parameters such as nitrate, nitrite, ammonia and orthophosphate were also considered.

The prototype was developed by three universities (France, Greece and Spain) in collaboration with a French SME. The multiparameter monitor was built around a single spectrophotometric detector with modules for the simple pre-treatment of the sample if required (using a simple reagent to obtain a whole absorption spectra). The project initially focused on the optimization of the UV spectrophotometric method proposed by one of the partners for the measurement of COD, BOD and computation of the concentration of nitrate and nitrite and then the development of simple pseudo-FIA (Flow Injection Analysis) methods for the determination of total Kjeldahl nitrogen and total phosphorus (involving a digestion step). The results enabled the design of a simple UV detector for the estimation of global pollution parameters (TOC, BOD, COD, TSS) and the determination of specific compounds (e.g. nitrate and anionic surfactants), and to design a set of Sequential Injection Analysis (SIA) procedures for the determination of non-absorbant species (ammonia, organic nitrogen, orthophosphates and organic phosphorus). These findings served to build a prototype including the UV detector, the SIA system and a simple visible detector which is designed as a portable UV-spectrophotometer to enable field-measurements of wastewater quality to be performed. A full description of the development phase of the prototype is available elsewhere [11]. This project is a good illustration of partnership between universities and SME (Small and Medium Enterprise).

For additional information, please contact the Co-ordinator of the project: Prof. O. Thomas, Ecole des Mines d'Alès, 6 avenue de Clavières, F-30319 Alès Cédex (e-mail: othomas@ensm-ales.fr).

3.5. The workshop on standards, measurements and testing for solid waste management

The new regulations related to industrial waste management have the ambitious objective of stopping the direct release of wastes by the year 2002, implying that wastes from different origins should be treated for possible recycling. The effects of different waste treatment processes should be

accurately determined to ensure a correct waste management and the industry is aware that much effort is required to optimize these treatments for obvious economic reasons. The quality of treatment processes and of final (recycled) products rely upon the availability of standards (such as those prepared by CEN or ISO) and testing methods (e.g. chemical analysis for the assessment of environmental risks or landfill use). There is a clear need to develop (and validate) methods for the control of treatment processes or for the characterization of the end-products in view of their use for in landfill, concrete, construction materials etc. In this respect, the collaboration between industry and research organizations should be strengthened. As a response to this need, the workshop on Standards, Measurements and Testing for Solid Waste Management was held in Pau (France) on 5–7 May; its aim was to stimulate partnership between industry and research, for the identification of possible actions to be undertaken in this field, to discuss the state of the art of solid waste analysis, to define the applicability of current methodologies, to investigate where limitations exist and identify possible progressive developments in this field. The following topics were debated in roundtables during the workshop (see programme in the annex).

- Field measurements and screening tests
- Rapid techniques for physico-chemical characterization
- Elaborated measurement techniques
- Modelling, expert systems and data-bases
- Standards, reference materials and quality control

Each topic was introduced by a plenary lecture, followed by discussions chaired by a selected expert. Minutes of the discussions were taken by a rapporteur. A summary of these discussions has been published in a special issue of *Trends in Analytical Chemistry* [12].

4. Additional information

The programme publishes an information bulletin, the 'Measurements and Testing Newsletter', describing the calls for proposals and including

summaries of on-going and finished projects, which can be obtained free of charge (please contact the author by fax: +32 229 58072 or e-mail: philippe.quevauviller@dg12.cec.be).

CRMs produced by the SM&T programme are available at the Institute for Reference Materials and Measurements (IRMM), Retiesweg, B-2440 Geel (fax: +32 14 590406); they are provided with a certification report describing their preparation, homogeneity and stability studies, and give details on the methods used, all individual results and a summary of the statistical evaluation. The report also contains detailed instructions for use that should be strictly followed when analysing the CRM

Abstract

The performance of electrochemical biosensors developed for the determination of inhibiting species is considered. The role of various factors affecting the analytical characteristics of biosensors, their selectivity toward inhibitors to be tested as well as operational characteristics is discussed. The choice of enzyme-inhibitor system, the influence of enzyme immobilization on the behaviour of a biosensor, the modes of the optimization of working conditions are discussed. Most conclusions are illustrated with the models of the application of biosensors for monitoring environmental pollutants. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Sensitivity; Selectivity; Electrochemical; Enzyme sensors; Inhibitor determination

1. Introduction

The development of biosensors is most promising in the progress of analysis of biologically active compounds. In the past two decades biosensors had emerged from laboratories and in some cases became conventional devices for routine analysis [1–3] owing to the advantages biosensors possess, such as simple measurement procedure, short response time, sufficient sensitivity and selectivity. This refers to the analysis of

glucose, urea, lactate, cholesterol and of several medications [4–8]. Traditional monitoring methods are often slower and call for expensive equipment which makes them unsuitable for real time control. This makes biosensors more attractive, especially for unqualified users and for field applications.

The commercial production of biosensors is associated with the biomedical analysis of a limited number of metabolites and pharmaceuticals [2–4]. As substrates of appropriate enzymes they can be determined directly in biological fluids with detection limits down to 10^{-6} – 10^{-7} mol l^{-1} . This is more than sufficient for most practical purposes. Substrate biosensors are often considered to be reagentless methods of analysis. Such

biosensors can be simply introduced in various automatic analyzers with operating efficiency up to 100 samples per hour. Recently, current efforts in the progress of substrate biosensors are devoted to improving the operation features, i.e. long-term response stability, the possibility of sterilization, specific problems of implantable biosensors etc. [9,10]. The selectivity of such biosensors is provided for by the high substrate specificity of the enzymes used and by a limited number of interfering species presented in the fluids analyzed. The selectivity of the electrochemical detection of enzyme response in the presence of some components, e.g. ascorbic acid or bilirubin is attained by lowering the operating potential owing to the application of redox-mediators or the additional protecting films [11–13].

The situation is quite the opposite if biosensors are developed for the determination of inhibitors. This kind of biosensors offers huge possibilities for the determination of a wide range of toxic compounds, some of which being common environmental pollutants [14–16]. In special cases the detection limits down to $n \cdot 10^{-12}$ – $n \cdot 10^{-13}$ mol l⁻¹ can be attained without time-consuming pretreatment of the sample tested (cholinesterase based detection of isopropylmethylphosphonofluoridate and *O*-ethyl-*S*-diisopropylaminoethylmethylphosphonothiate in sea water [17], cholinesterase based determination of 2,4-dichlorophenoxyacetic acid (2,4-D) in aqueous solutions and in milk in the presence of activating additives of calcium ions [18], the determination of Malathion based on carboxylesterase from northern deer [19]). This is lower than the appropriate maximum permissible concentrations of environmental pollutants and than their detection limits typical for traditional analytical techniques, i.e. chromatography or spectrometry, except immuno- and radiochemical methods. For this reason biosensors for the determination of inhibitors seem to be very attractive for environmental monitoring, especially for field applications [14–16].

The unbalance between the prospects and the observed moderate level of R and D activities in the field of inhibitor biosensors is mostly the result of the problems concerning the selectivity of determination. Contrary to the substrates, the

specificity of the enzymes towards inhibitors does not usually allow the determination of separate compounds [20]. Apart from the presence of inhibitors, biosensor response depends on the other species in the sample tested which affect the sensitivity of biosensors towards inhibitors. A high sensitivity of inhibiting effect to the operating parameters (i.e. pH value, buffer capacity of the working solution, the nature and the concentration of the substrate) and sample content is considered to be a weak point of inhibitor biosensors. Hence, as a rule the inhibitor biosensors do not refer to reagentless methods, and the estimation of the content of inhibitors involves a two-step procedure, including the measurement of the initial response of a biosensor and its decay after the contact with the inhibitor solution. This results in the directions for the measurement of inhibition being too complicated. Though the mechanism of the enzyme-inhibitor interaction is usually well-known, the immobilization of the enzyme and the heterogeneous kinetics of the enzymatic reaction affect both the experimental kinetic parameters of inhibition and the optimal conditions of the determination of inhibitors, and the analytical characteristics of inhibitor determination are often far from those obtained with native enzymes.

On the other hand, the high sensitivity of biosensor characteristics opens up new opportunities for purposeful modification of the sensitivity and selectivity of the determination of inhibitors. Careful investigation of the substrate-inhibitor system, both for native and immobilized enzyme, the optimization of the measurement procedure and of the detection system make it possible, not only to elaborate the analytical characteristics of the determination of inhibitors, but also to control the dynamic range and detection limits depending on the particular analytical problem to be solved.

In this review factors concerning analytical and operational characteristics of inhibitor biosensors have been discussed and approaches to their optimization summarized. It is not meant to be an exhaustive description of the reports in the field of development of inhibitor biosensors. The objective is to demonstrate the feasibility of the researches in the optimization of biosensor

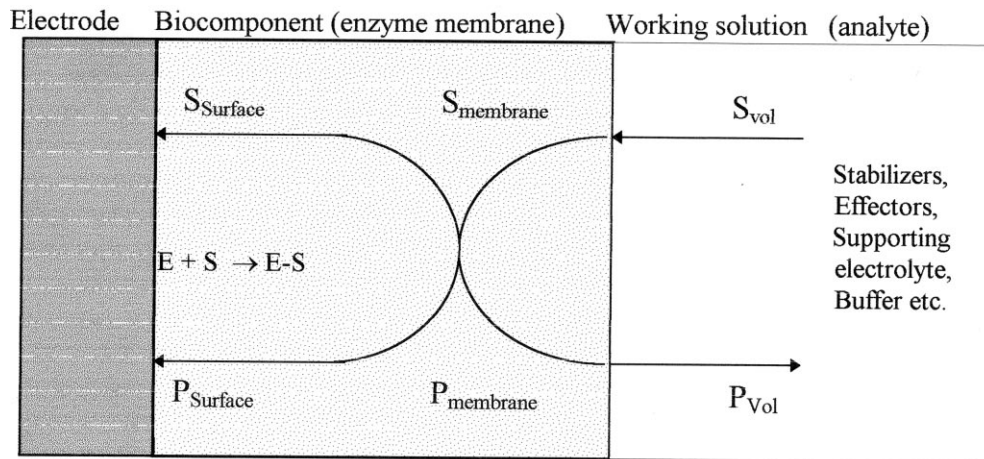

Fig. 1. General scheme of the formation of the response of an enzyme biosensor, S, substrate; P, product of the enzymatic reaction. Electrode biocomponent (enzyme membrane) working solution (analyte).

characteristics and the linkage between the inhibition results obtained for native and immobilized enzymes. The main attention is given to the application of biosensors for monitoring environmental pollutants. Apart from electrochemical biosensors, some principles of biosensor optimization are illustrated with the reports relating to optic biosensors and experiments with native enzymes.

2. General

A biosensor is a measurement system based on a combination of a biochemical and electronic elements which are in close contact with each other and are incorporated in a single unit. A biochemical component (i.e. an enzyme or biological material with the enzyme activity such as microorganisms [21], plant [22] or animal tissues and cells [23], etc.) is chosen for its selectivity toward the substrate or the inhibitor to be determined. The electronic signal-transducing element (e.g. electrode, optical detector, piezo crystal etc.) converts the biochemical response into electric and optic signals which are amplified, measured and decoded by an appropriate electronic unit. Mostly biosensors are based on electrochemical transducers owing to the advantages they possess,

e.g. simple user-friendly design, compatibility with the standard commercial equipment, the possibility of sensor miniaturization and automated measurement and a well-developed theory of the behaviour of electrochemical biosensors [24,25]. For determination of inhibitors, the results obtained with electrochemical sensors can often be extended to some other detection systems if the measurement conditions are similar to each other. A scheme of a typical biosensor is shown in Fig. 1.

The resulting response of a biosensor to the addition of a substrate is determined by the concentration of the product (P) of enzymatic reaction on the sensing surface of the sensor. The latter is controlled by the rates of two conjugated processes, i.e. the enzymatic conversion of the substrate (S) and the diffusion of the product being formed from the body of the membrane to the bulk solution.

In membrane with a high level of enzyme activity, the decrease of a substrate concentration is not compensated in full measure by the transfer from the bulk solution due to the diffusion limitations. Because of this, only a part of the enzyme active centers is involved in the interaction with a substrate. In this case (diffusion control of a response) the sensitivity of immobilized enzyme toward inactivation, be it heating or inhibitor

effect, is lower than that of the native enzyme. The inactivated centers are replaced by the centers remained active in the inner layers of the membrane [26]. The lower the specific activity of immobilized enzyme the higher the sensitivity of a biosensor toward inactivation, including specific inhibition. In an extreme case, each enzyme active center in the membrane is occupied by a substrate molecule, so the response of a biosensor depends on the specific activity of an enzyme but not on the concentration of a substrate (kinetic control of a response). The response of such a biosensor is much lower than that in the case of diffusion control but highly sensitive to the inhibitors. The theoretical evaluation of the influence of diffusion limitation on the sensitivity of immobilized enzyme and biosensor response toward various inactivating factors are supported by numerous experimental results irrespective of the enzyme, membrane material or inhibitor [20,24–26].

The choice between diffusion and kinetic control can be made by enzyme loading and substrate concentration [25]. In practice, the measurement conditions and membrane content are a compromise between the requirements of sensitivity and those of accuracy of response determination, and the substrate concentration is usually no less than $n \cdot 10^{-4} \text{ mol l}^{-1}$.

The inhibiting effect of the chemicals on the response of the biosensor can be expressed as a relative decay of the response value after the contact of the biosensor with the sample tested, e.g. inhibition degree ($I, \%$). In place of the inhibition degree, the absolute value of the response of a biosensor can be used for plotting the calibration curves. This does not change the slope of the curve but hampers the comparison of the results obtained with various enzymatic membranes.

The empirical linear calibration curve can be used for irreversible inhibitors in plots $I, \%$ (or biosensor response) vs. $\lg C_1$ where C_1 is the inhibitor concentration [20]. For reversible inhibitors, calibration is plotted in linear coordinates, i.e. $I, \%$ (respectively, response value)- C_1 .

The sensitivity of a biosensor toward an inhibitor can be defined as a slope of an appropriate calibration curve. A steeper slope does not mean a

lower concentration range of the inhibitor to be determined because the reproducibility of the response may not be as high.

The determination of the inhibiting effect and the inhibitor concentration, respectively, involves at least three stages:

1. Determination of the initial response value. If not specially indicated, this is implied to be performed during the preliminary study of a biosensor performance;
2. The contact of a biosensor with an inhibitor solution (incubation stage). For irreversible inhibitors the inhibition procedure is usually performed with no substrate and the resulting decay of the enzyme activity and of the response of the biosensor increase with the duration of the contact (i.e. with the time of incubation). For reversible inhibitors the sample tested is injected into the working solution together with the substrate solution or later so that the incubation takes place in the presence of the substrate;
3. The repeated determination of a reduced response of the biosensor with the following calculation of the inhibition degree as the relative decrease of the response value.

It follows from the above that the accuracy of the determination of inhibitor concentration should be at least twice lower than that of the substrate determination as it is based on two consecutive determinations of the response value with one and the same biosensor. If the relative standard deviation (R.S.D.) of the response determination for electrochemical biosensors is commonly in the range 1–3%, the detection limit should retain the inhibitor concentration that results in at least 4–6% of the inhibition degree. For commercial biosensor devices developed for the monitoring the environmental contamination, the inhibition degree referring to the minimal detectable level of the pollutant is assumed more than 10% [27,28].

The selectivity of biosensors towards various inhibitors is estimated by comparing the dynamic ranges of concentrations or by the ratio of calibration slopes or the experimental kinetic parameters of the inhibition determined for the immobilized enzyme. The comparison should be

Table 1
Enzyme-inhibitor systems utilized in electrochemical biosensors for inhibitor determination

Enzyme	Inhibitor	Reference
Cholinesterase	Organophosphorus and carbamate pesticides, heavy metal salts, non-ionic surfactants, pharmacuetics (nitrogen containing drugs with anticholinesterase activity, antagonists), fluorides, azides	[17,19,27,28,33–65]
Urease	Fluorides, heavy metal salts	[66–68]
Glucose oxidase	Heavy metal salts	[69,70]
Tyrosinase (phenol oxidases)	Thiourea, ethylenethiourea and other derivatives of thiourea, cyanides, azides, atrazine, benzoic acid, chlorophenols	[71–79]
Alcohol dehydrogenase	Cyanides, heavy metal salts	[80–82]
Amino oxidase	Plant growth regulators, primary and secondary amines	[83–85]
Aldehyde dehydrogenase	Fungicides	[86]
Cytochrome c	Cyanides, sulfur hydrogen	[87–90]
Catalase	Heavy metals	[69,91]
Peroxidase	Cyanides, heavy metal salts, respiration poisons	[92–96]

performed for the same or close concentrations of the substrate used. However, for field applications, the value of these calculations is often restricted by the non-additive combination of certain inhibition effects of the inhibitors in multi-component media.

Three main modes of improvement of performance of inhibitor biosensors and analytical characteristics of inhibitor determination are considered: the choice of enzyme-substrate system, the optimization of the immobilization of the enzyme and the fitting of working conditions.

3. Optimization of the enzyme-inhibitor system

3.1. The choice of an enzyme for inhibitor determination

The choice of an enzyme for the determination of certain chemicals affecting its activity is determined by the mechanism of their toxic effect on living beings. As for common environmental pollutants, their toxicity is usually investigated enough. Thus, the cholinesterase of insects is a target for the commercial preparations of

organophosphorus and carbamate insectoacaricides, (e.g. Parathion, Malathion, Zolone etc.) [29], and, therefore, they may be determined with this enzyme. Dithiocarbamate fungicides can be determined with the biosensors based on aldehyde dehydrogenase, which is considered as a target [30]. Herbicides suppress photosynthetic reactions, tyrosinase or peroxidase. Cyanide ions inhibit cytochrome oxidase [31]. Many chemicals, i.e. heavy metal ions, thiourea, fluoride and azide ions exert an inhibiting influence on several enzymes [32]. In this case the availability of commercial enzyme preparations, the stability of the enzyme during storage and application, and the convenience of the detection of the enzymatic reaction are taken into account.

A summary of the enzymes utilized in the electrochemical biosensors described for the inhibitor determination is presented in Table 1.

Cholinesterase is one of the most popular enzymes used for the inhibitor determination. This enzyme provides for the hydrolysis of natural neurotransmitter, acetylcholine Eq. (1), and is common in various living beings, from insects to humans.

Scheme 1.

The application of native or immobilized cholinesterase makes it possible to determine a wide range of pollutants, some of which refer to the common environmental pollutants, i.e. organophosphorus and carbamate pesticides, heavy metal ions, fluorides, cationic surfactants etc. [33].

Recently tyrosinase and peroxidase is often introduced into the biosensor assembly, owing to their high stability and activity in organic solvents. These enzymes promote the oxidation of various phenolic compounds Scheme 1 and are inhibited by heavy metal ions, herbicides, respiration poisons etc.

The measurement of their activity is based on the anodic detection of hydrogen peroxide or cathodic reduction of the quinones formed.

The list of enzymes used in electrochemical biosensors for inhibitor determination does not exhaust the potentialities of the enzyme based determination of inhibitors. Hence, the application of carboxylesterases from various sources has been described for the determination of primary and secondary amines, and organophosphates [18,83,84]. Alkaline phosphatase is effectively inhibited by the traces of ions of beryllium and lead [97–99]. Zinc exhibits either an inhibiting or activating effect on apo-enzyme and active form of alkaline phosphatase in separate concentration ranges [100]. However, these methods are based on spectrometric detection or the immobilized enzyme is separated from the sensor used for the measurement of response.

Even promising enzymes with high sensitivity and/or selectivity towards certain chemicals are often unsuitable for practical application in a biosensor assembly because of their low stability, difficulties of detection of the enzyme activity or problems of isolation from living tissues or cell culture. Hence, the selective determination of tin could be attained with aminolevulinic acid dehydratase (ALAD) [101] while the isolation of a raw enzyme fraction results in a rapid loss in the activity of an enzyme.

In this respect the application of whole living cells or organelles with the essential enzyme activity presents an alternative to the isolated enzymes [102–109]. Hence, microbial sensors have been designed for the monitoring systems of waste water treatment [102–108]. They are based on the quantitative estimation of oxygen consumption of the sludge or of yeast microorganisms in standard conditions of air saturation and in the presence of toxic substances in the waste waters to be tested. The phytotoxicity test based on the response of thylakoids on the presence of herbicides is also described [109].

The choice of enzyme determines the nature of the substrate used and the appropriate detection system for the measurement of a response (i.e. the transducer incorporated into a biosensor assembly). The following optimization might include the variation of the source of the enzyme and the immobilization procedure.

In a number of cases the sensitivity towards an inhibitor can vary even with isoenzymes from one source. Thus, carboxylesterase from northern deer is electrophoretically separated into two fractions, one of which, in gelatin gel, was used for the determination of Malathion with the detection

limit of $10^{-12} \text{ mol l}^{-1}$, whereas, that for the other was 10 000 times higher [19]. The application of potentiometric biosensor involving the acetylcholinesterase from electric eel makes it possible to reach the detection limit for Malathion down to $10^{-10} \text{ mol l}^{-1}$ but after preliminary oxidation of the analyte with bromine water into the more toxic oxygen analog, i.e. Malaoxon [38]. The application of carboxylesterase allows the omission of any pre-treatment of the sample tested. It was proposed and confirmed by kinetic analysis, that Malathion affects the enzyme activity as a specific substrate of carboxylesterase, so the enzymatic conversion of the indophenyl acetate used for the spectrometric detection of the enzyme activity begins only after the full hydrolysis of Malathion. This results in the occurrence of the induction period on the kinetic curve and in the decrease of the biosensor response measured at a fixed time after the substrate addition.

Cholinesterases from insects are more sensitive to insecticides than those from mammals [45,85,110]. However, the isolation of these enzymes and their stabilization are considered to be the weak point in their practical application.

For mitochondrial monoaminoxidase from mouse and rat liver, the sensitivity towards reversible and irreversible inhibitors depends on the nature of the substrate used [83–85]. This is assigned to the presence of two forms of the enzyme in the raw preparations, one of which is more sensitive to serotonin and the other one to benzylamine as substrates. This made it possible to develop high-sensitive and selective methods for the determination of some pharmaceuticals and pesticides with detection limits down to $10^{-9} \text{ mol l}^{-1}$. An appropriate biosensor has been designed as a combination of the monoaminoxidases immobilized in gelatin gel with an NH_3 -sensitive air gap electrode [83].

For peroxidase from horseradish, used in solution or immobilized on chromatography paper, the detection limits of mercury(II), affecting the activity as an irreversible inhibitor, vary from $5 \times 10^{-2} \text{ mg l}^{-1}$ for *o*-phenylenediamine to $1 \times 10^{-5} \text{ mg l}^{-1}$ for tolidine as substrates [111].

The purification of raw enzyme preparations can also give rise to a change in the selectivity of

an enzyme towards inhibitors. Thus, the purification of plant peroxidases results in the increase in the detection limit of mercury(II) and alkylmercury compounds. The stepwise isolation of monoaminoxidase from dog intestine results in the change of both the selectivity towards primary and secondary amines, (e.g. substrates) and towards heterocyclic compounds used as plant growth regulators, (e.g. reversible inhibitors) [112]. The possible reasons for this phenomenon comprise the local concentration of the inhibitor at the inert protein, the change of the isoenzyme ratio in the enzyme preparation, changes in conformation of the active center and its environment and the removal of the natural enzyme stabilizer.

The future progress in the optimization of the enzyme-inhibitor system involves the purposeful modification of the enzyme to attain higher sensitivity and/or selectivity, the search for novel non-traditional sources of enzymes with a higher selectivity, the development of novel methods for isolation and stabilization of enzymes which demonstrate higher sensitivity and selectivity to the inhibitors to be determined.

3.2. Kinetics of enzyme-inhibitor interaction

The optimal procedure of the measurement of inhibiting effect depends essentially on the mechanism of enzyme-inhibitor determination.

For irreversible inhibitors, enzyme-inhibitor interaction results in the formation of covalent bond between enzyme active center and the inhibitor.

The term 'irreversible' means that the decomposition of the enzyme-inhibitor complex results in the destruction of the molecule of the inhibitor, e.g. its hydrolysis, oxidation etc. This process proceeds usually stepwise, as for phosphorylated cholinesterase Scheme 2, and can be accelerated by special reagents.

Scheme 2.

Scheme 3.

For irreversible inhibitors the following equation can be used for the determination of either the concentration of the inhibitor C_I or the bimolecular rate constant of the enzyme-inhibitor interaction k_{II}

$$\ln(v_0/v_i) = k_{II} C_I \tau \quad (2)$$

where τ is the incubation time, v_0 and v_i are the initial rates of an enzyme reaction prior to and after the contact of the enzyme with the inhibitor, respectively [113]. This equation is valid for a short incubation period ($\tau < 10\text{--}15$ min) and when the concentration of the inhibitor is much higher than that of the active centers of the enzyme.

The influence of reversible effector (i.e. inhibitor I or activator) on the two-step enzyme reaction can be presented by the general scheme Scheme 3 in assuming that the effector reacts with the enzyme E or enzyme-substrate complex ES in the ratio 1:1, where K_I and K_S are the equilibrium constants of dissociation of enzyme-inhibitor and enzyme-substrate complexes, C_E , C_S and C_I are the initial concentrations of the enzyme, substrate and inhibitor, respectively. It is assumed that C_S , $C_I \gg C_E$.

The initial rate of enzymatic reaction $v_i = 0$ can be expressed by the Eq. (3)

$$v = \frac{k_2 \frac{\alpha K_I + \beta C_I}{\alpha K_I + C_I} C_E C_S}{\alpha K_S \frac{K_I + C_I}{\alpha K_I + C_I} + C_S} \quad (3)$$

Beresin and Martinek [114] have given a full kinetic analysis of the possible cases of both inhibition and activation in accordance with the Eq. (2). Several special cases of prime importance are

often used for the description of experimental results. This refers to the competitive ($\alpha \rightarrow \infty$, non-competitive ($\alpha = 1$, $\beta = 0$), uncompetitive ($\alpha = \beta < 1$) and mixed type ($\alpha \neq 1$, $\beta \neq 1$) inhibition.

Thus, for purely competitive inhibition, the inhibitor binds with enzyme active center but not with enzyme-substrate complex. In this case the Eq. (3) is simplified to the well-known Eq. (4).

$$\begin{aligned}
 v &= \frac{k_2 C_E C_S}{K_S (1 + C_I/K_I) + C_S} \\
 &\approx \frac{K_m C_S}{K_m (1 + C_I/K_I) + C_S} \quad (4)
 \end{aligned}$$

where K_m is the Michaelis constant. The equilibrium constant of reversible inhibition K_I corresponds to the reciprocal value of the inhibitor concentration which involves a 2-fold decrease of the rate of enzyme reaction: $K_I = C_I^{-1}$ at $v_i/v_0 = 0.5$. This concentration value or, more commonly, its logarithm $pI_{50} = -\log C_I$ can be used for the characterization of the sensitivity of the enzyme towards reversible inhibitors. It should be mentioned that the pI_{50} value does not carry any information on the dynamic range of the inhibitor concentration to be determined and the appropriate detection limits could be achieved.

Similar approaches, based on the dependence of the rate of enzymatic reaction or of the experimental values of K_m on the concentrations of the substrate and inhibitor are also developed for other cases of inhibition.

Thus, the generalized kinetic equation Eq. (5) was proposed for the mixed type reversible inhibition.

$$v_0/v_i = \frac{K_m (1 + C_I/K_I) + C_S (1 + C_I/K'_I)}{K_m} \quad (5)$$

where v_0 and v_i are the rates of the enzyme reaction without any inhibitor and in the presence of the inhibitor and K_I and K'_I are equilibrium constants of the competitive and non-competitive inhibition, respectively. The relationship between K_I and K'_I determines the mechanism of inhibition. Thus, for competitive inhibition $C_I/K'_I \ll 1$, for non-competitive inhibition $K_I = K'_I$ etc.

The effectivity of inhibition in this case is characterized with the generalized equilibrium constant Eq. (6) which makes it possible to compare the affect of various inhibitors with different mechanisms of inhibition.

$$\frac{K'_1 + K_1}{K_1 K'_1} = \frac{1}{K_1} \quad (6)$$

The appropriate experimental data are linearized in plots $v_0/v_i - C_1$ and a generalized experimental equilibrium constant of inhibition is calculated from the slope of the curve for various substrate concentrations.

The determination of the kinetic parameters of inhibitors makes it possible to identify inhibitors owing to the investigation of their inhibiting effect on enzymes from different sources.

For irreversible inhibitors this can be evaluated from Eq. (2) for the same incubation time.

$$(k_{11})_1/(k_{11})_2 = \{\ln(v_0/v_i)\}_1/\{\ln(v_0/v_i)\}_2 \quad (7)$$

and for reversible inhibitors, respectively,

$$(K_1)_1/(K_1)_2 = (v_0/v_i)_1/(v_0/v_i)_2 \quad (8)$$

where subscripts 1 and 2 refer to the data obtained with enzymes from different sources and is a generalized equilibrium constant of reversible inhibition. As a practical matter, it is important that Eq. (7) and Eq. (8) do not contain the concentrations of inhibitor, so the identification can be attained for the samples of unknown content. Ideally, when increasing the number of the enzymes with different inhibitor selectivity it is possible to completely rely on the identification of the inhibitor. In fact, this approach is limited by the lack of the necessary kinetic data. For example, the identification of 53 preparations of organophosphates was proposed on the base of the kinetic data of their inhibition by four cholinesterases from various sources [115].

A similar approach was used for the selective determination of various substituted phenols and chlorophenols [76] which affect, as substrates and competitive inhibitors, the response of amperometric biosensor utilizing immobilized polyphe-noloxidase.

On the other hand, the enzyme mixture can be used with the same substrate for the extension of

the number of inhibitors determined with the required sensitivity in a single measurement. This was attained by the co-immobilization of acetyl- and butyrylcholinesterase in one membrane introduced into the assembly of an amperometric biosensor with acetylthiocholine as a substrate [51]. The developed biosensor demonstrates wider abilities for monitoring the contamination of organophosphorus pesticides.

The possibility of the identification of eight pesticides in the presence of heavy metal salts is attained due to the simultaneous determination of the inhibiting effect of the mixture with multi-enzyme biosensing system [116]. The system consists of three pH sensors whose sensitive surfaces are connected with a membrane on which one enzyme (i.e. acetylcholinesterase, alkaline and acid phosphatases) is immobilized at a time. The selectivity results from the optimization of the measurement conditions and from the chemometric analysis of the inhibiting effect on each biosensor.

4. Enzyme immobilization and the role of surface factors

All the kinetic equations (Eqs. (2)–(5) and Scheme 3) mentioned in the previous section are based on the assumption of homogeneous kinetics of the enzyme-substrate and enzyme-inhibitor(s) interactions. The appropriate parameters of inhibition (i.e. k_{11} , K_1 , K'_1 etc.) indicate the potentialities of an enzyme which could be extended or reduced through the immobilization and incorporation of the enzyme into the membrane material.

The immobilization of an enzyme is an indispensable part of the development of biosensors. The multiplicity of application of the enzyme due to immobilization reduces the cost of measurement. The immobilized enzyme is more stable towards extreme working conditions, e.g. high temperature, and can be easily combined with an appropriate sensor in the biosensor assembly.

For inhibitor determination, the economic advantages are not so compelling because the inhibition proper implies the decay of the enzyme activity and therefore a limited number of consecutive measurements with the same batch of immo-

bilized enzyme, be it a membrane or a reactor. Based on this, the practical application of the inhibitor biosensor was stated primarily for reversible inhibitors. More precisely, the initial response of a biosensor devoted to field applications should be recovered after inhibition in a reasonably short period of time. For reversible inhibition the initial response can be recovered with a washing out procedure after contact with inhibitor. For heavy metals, the complexing reagents such as EDTA or cysteine for mercury can be used [17,20,39,47,48]. Much more important is the application of special reactivators for irreversible inhibitors.

The treatment of an inhibited enzyme with special chemicals (i.e. reactivators) makes it possible to accelerate the spontaneous recovery of the enzyme activity to a degree, depending on the nature of the enzyme-inhibitor complex and the period of time from the initial contact with the inhibitor to the reactivation procedure. Reactivation prolongs the lifetime of a biosensor but complicates the whole cycle of the inhibitor determination. Reactivation is specific for a particular inhibitor and an enzyme. In several cases, pharmaceutical medications, i.e. antidotes, are used. 2-Pyridinealldoxime methiodide (2-PAM) or 1,1'-trimethylenebis-4-(hydroxyiminomethyl)

pyridinium bromide (TMB-4) are a well-known example of reactivators used for phosphorylated cholinesterase [20,35,38,45,49,51–54,57,59–63]. The specificity of reactivation in combination with simple kinetic investigations (i.e. the dependence of the inhibiting effect on the presence of the substrate during incubation or on the period of incubation) can provide for the identification of the inhibitor or simplify the choice between several possible inhibitors available in the sample tested [20].

However, the problem of reactivation and the prolonged lifetime of a biosensor is more likely to be related to the economic aspects of the practical applications of inhibitor biosensors. Of a greater significance is that the immobilization procedure very much alters the analytical characteristics of the determination of inhibitors. This might occur owing to the following reasons:

1. The slow transfer of the substrate from the bulk solution into the membrane body (diffusion limitations);
2. The changes in the microenvironment of the active center of the immobilized enzyme;
3. The interaction of the substrate and/or inhibitor with the membrane material (sorption effect).

First of all, the transfer of the consideration of the enzyme-inhibitor interaction from homogeneous kinetics to the heterogeneous conditions of the enzyme membrane calls for an essential study of the role of diffusion. As was briefly shown earlier, if the rates of consumption and of the transport of a substrate in a membrane are comparable, the active centers of the immobilized enzyme are not saturated with the molecules of the substrate. The inactivation of active centers is compensated for by the other free active centers, and the resulting decay of biosensor response is lower than it would be in a homogeneous solution. Mostly reports describe the increase of the detection limits of the inhibitors after immobilization [20,41,42,50,58]. Hence, the inhibition degree of biosensors, based on immobilized acetylcholinesterase and urease in the presence of fluoride ions, decreases with the loading of the enzyme and thickness of the membrane formed, i.e. with the increase of the specific activity of the enzymes. A similar result is attained by varying the time of treatment of the membrane with cross-linking glutaraldehyde [20]. The detection limit of Paraoxon obtained with an amperometric biosensor based on three enzymes (i.e. cholinesterase, choline oxidase and peroxidase immobilized in methacrylate gel), was $0.75 \mu\text{g l}^{-1}$ for native cholinesterase and $125 \mu\text{g l}^{-1}$ when the enzymes are co-immobilised in the membrane [50].

The use of multi-enzyme biosensors is reported for the determination of the inhibitors of cholinesterase [41,42,50,55,56,58]. The introduction of additional enzymes (i.e. choline oxidase) makes it possible to use the standard Clark-type electrode for the determination of biosensor response and techniques developed mainly for the glucose electrodes. The choline formed in the enzymatic hydrolysis of acetylcholine (see Eq. (1)) is oxidized to betaine in the second consecutive reaction promoted by choline oxidase Eq. (9).

The rate of the latter reaction is measured from the decrease of oxygen concentration with a Clark-type amperometric sensor. However, this does not contribute to the improvement of analytical characteristics of the determination of cholinesterase inhibitors.

A 2–10-fold increase in the detection limits of both reversible and irreversible inhibitors was reported for monoamine oxidase, carboxylesterase and cholinesterase followed by their immobilization in gelatin and agar membranes [84,85,112].

The influence of the content of the membrane on the analytical characteristics of the determination of an inhibitor is much more pronounced for thick membranes with a high activity of the enzymes such as gelatin membrane in the latter case. For thin enzyme films, formed directly on the electrode surface, the diffusion limitation is not as high and the results obtained are much more affected by the nature of the enzyme and by the specific enzyme activity. Hence, the detection limits of organophosphorus pesticides obtained with pH-sensitive field effect transistor (FET) covered with an ultra-thin layer of cholinesterase [43], and potentiometric biosensors with a replaceable membrane [63] are similar to each other.

For reversible inhibitors, the experimental value of the inhibition degree must depend on the ratio of the rates of diffusion of a substrate and an inhibitor. Usually, they are assumed equal for low molecular compounds, but for charged substrates and/or inhibitors this ratio in a membrane body can essentially differ from that in a solution. Even if this does not occur, the time necessary for attainment of equilibrium in a membrane body can exceed the duration of the measurement, therefore for a typical reversible inhibitor the experimental value of inhibition degree depends on the period of incubation. The use of isotopes of zinc and thallium showed that the stationary concentration of zinc ions in a gelatin membrane is established only after 40 min after the addition of appropriate salts into a solution contacting with the gelatin membrane [53].

An additional effect is observed, when the inhibitor is non-specifically adsorbed on the membrane material. This diminishes the actual concentration of the inhibitor interacting with the active center of the enzyme and consequently the inhibition degree of the biosensor response. The sorption can be suppressed with the addition of surfactants. This results in an increase of the sensitivity of cholinesterase biosensors to organophosphorus pesticides [60,62].

For biosensors based on potentiometric pH-sensitive ion-selective electrodes or FETs, the consideration of kinetic limitations should be extended to the acid formed in the enzyme reaction. In a weak buffer medium the pH shift to 1–1.5 units can be observed in a membrane body. This involves both the changes in the activity of an enzyme and in the kinetic parameters of inhibition which are also pH sensitive. This phenomenon is more conspicuous for a higher response of the biosensor, i.e. for a higher enzyme activity.

The pH value of the working solution is commonly selected close to the pH maximum of the enzyme activity observed for a native enzyme. Hence, the pH shift in the membrane body results in an additional decrease in the sensitivity of an immobilized enzyme to the inhibitor in comparison with that of a native enzyme in similar working conditions.

Another effect of the excess of H^+ ions in an enzyme membrane is that the response of such biosensors does not reflect only the enzyme activity.

The results of the determination of irreversible inhibitors with a potentiometric cholinesterase biosensor were recalculated from the units of the relative response decay (i.e. inhibition degree I , %) to the ratio of the rates of the cholinesterase reaction before and after the contact with the inhibitor: $v_0/v_i = (100 - I)/I$ [63]. However, the linear curve in plots $\ln(v_0/v_i) - C_1$, predicted in Eq. (2), was obtained only for small inhibiting effects ($I < 20\text{--}25\%$) when the pH shift is considered to be nearly constant. On the contrary, the response of amperometric biosensors to various inhibitors is often considered to be a linear function of the enzyme activity, and the calculations of kinetic

parameters based on this assumption are in a good agreement with the results obtained with traditional measurements of the specific activity of the immobilized enzyme [89,95].

Most enzyme carriers, and the immobilized enzyme proper, possess buffer properties to a certain degree. It follows that the pH dependence of the response differs from that of the activity of the native enzyme. Thus, the immobilization of butyrylcholinesterase on cellulose dinitrate results in a shift of the pH maximum of the enzyme activity from pH 8–9 (native enzyme) to 9.5–10 (immobilized enzyme) [18,37,45]. On the other hand, the dependence of a biosensor response on the pH value of the working solution is relatively lower than that of the native enzyme.

Apart from the pH changes, the immobilization of the enzyme can cause other changes in the local microenvironment of the active center of the enzyme, e.g. variations in ionic strength, electrostatic interactions etc.

Of particular interest are the cases when the decrease of the detection limits of certain inhibitors is observed. Extra low detection limits down to 10^{-11} mol l^{-1} of dimethyl-2,2-dichlorovinyl phosphate (DDVP) and 10^{-12} mol l^{-1} of 2,4-D were reported for the amperometric biosensor based on the silver amalgamated electrode and the butyrylcholinesterase membrane obtained by the combination of two techniques: the cross-linking with glutaraldehyde and the microcapsulation of the enzyme aqueous solution into the cellulose nitrate matrix [18]. This is much more surprising as 2,4-D does not affect the native enzyme in the same working conditions and the minimal detectable concentration of DDVP in experiments with the native enzyme is 10 000 times higher. Undoubtedly, this calls for additional factors amplifying the actual decay of the enzyme activity. They can involve the sorption of the inhibitor on the hydrophobic membrane material resulting in a pre-concentration of the inhibitor, as in solid-phase extraction. In this case, the interaction of the inhibitor with calcium ions in a working solution can promote the transfer of the inhibitor in the form of salt from water solution into the body of the membrane. This biosensor is the only one with the cathodic detection of

the cholinesterase reaction. This prevents the accumulation of the H^+ ions in a membrane and the shift of local pH value from its optimum for the enzyme reaction. A similar increase of sensitivity toward inhibitors has been demonstrated for other biosensors when the enzyme is immobilized on commercial membranes of cellulose nitrate (Sartorius, Amersham) or disposable films of cellulose trinitrate formed directly on the active surface of a sensor, but not on a very large scale [45,61–63].

The response of the potentiometric biosensor based on a glass pH electrode covered with a cellulose trinitrate film with immobilized butyrylcholinesterase is sensitive to 2,4-dinitrophenol and Dieldrin which do not affect the native enzyme [117]. Unfortunately, the immobilization of cholinesterase on such hydrophobic materials is followed by the loss of 80–95% of the initial activity of the enzyme and the lifetime of the biosensor is not as high [63].

As to other membrane materials, the biggest changes in the analytical characteristics of the determination of the inhibitors are observed for rather thick membranes of gelatin, agar and methacrylate polymers swelling in aqueous solutions. The results obtained for thin non-swollen membranes are much closer to each other, irrespective of the transducer used [61,62].

The sensitivity toward inhibitors is moderately higher if the enzyme is immobilized directly on the surface of the transducer, be it a standard ion-selective electrode or a FET than if replaceable membranes of the same material are used for the same transducers. This might be the result of the inflow of the working solution in between the transducer and the membrane, followed by smoothing the response.

A special case is when the enzyme is incorporated into the material of the electrode, usually carbon paste [49,89,118]. In this case, only a very thin layer of the enzyme in contact with the working solution provides for the response observed. After inhibition, the mechanical polishing and removal of the outer layer of the electrode makes it possible to recover the initial response. Due to the bulk modification of the carbon paste a high reproducibility of the response is achieved

(R.S.D. < 1%). For oxidoreductases, such as peroxidase or cytochrome c oxidase, the electric contact and electron transfer between the enzyme and the electrode are simplified and, consequently, the working potential is lower. Other compounds required for the activity of enzyme or the response detection can be introduced into the carbon paste, i.e. lipids, mediators of electron transfer etc. Thus, 7,7,8,8-tetracyanoquinodimethane (TCNQ) was introduced together with cholinesterases from electric eel, horse serum or bovine erythrocytes into carbon-epoxy resin composition to reduce the working potential from 0.7 V vs. Ag/AgCl to 0.3 V [119]. Such carbon-paste biosensors are free from many drawbacks characteristic of membrane covered electrodes, i.e. diffusion limitations, high ohmic resistance, and contact of the membrane with the sensor. The same is true for screen-printed planar electrodes covered with ultra-thin enzyme layers [55,56]. The manufacture of such disposable biosensors maintains a high accuracy of the response determination (R.S.D. down to 0.7–1.3%) and a low background signal. This makes it possible to decrease the working concentration of the substrate and the detection limits of competitive inhibitors, respectively. Furthermore, the decrease of the working concentration of the substrate makes it possible to simplify the procedure of measurement, when the irreversible inhibiting effect is determined in the presence of the substrate. Generally, this results in the decrease of the appropriate detection limit of the irreversible inhibitor owing to the so called ‘protecting effect’ of a substrate [45,46]. The less the concentration of a substrate, the lower the shift of sensitivity of inhibitor determination. However, for such a biosensor the improvement of operation conditions is not, as yet, followed by notable changes of the sensitivity of the determination of an inhibitor, as compared with traditional membrane biosensors.

5. Working conditions

The determination of the response of a biosensor is usually performed in weakly buffered media containing a supporting electrolyte, stabilizers of

enzyme, cofactors, (e.g. NADH, ATP, etc.), an organic solvent, etc. Apart from their target function they can alter the analytical characteristics of the determination of inhibitors.

5.1. pH value of working solution

The pH value of the working solution is usually regarded as a most important factor determining the performance of the biosensor and its sensitivity toward inhibitors. As a rule, the pH maximum of the enzyme activity is evaluated as most appropriate, both for the substrate and inhibitor determination. Indeed, the pH-dependence of the observed inhibiting effect often corresponds to that of the response of a biosensor. Thus, enzyme sensors utilizing various esterases are most sensitive to organophosphates at the pH 8–9 when the response of a biosensor is maximal.

Carbon paste electrode, modified by cytochrome c and cytochrome oxidase, demonstrates the peak of sensitivity toward cyanide at pH 6.3, and the equilibrium constant of inhibition K_i remains approximately the same in the range pH 5.5–7.5 [89].

Urease is proposed for the determination of heavy metal ions at pH 8–10 [19,26,67,120], whereas glucose oxidase or catalase are sensitive to heavy metal ions at pH 5–8 [69,70,91]. As mentioned earlier, enzyme immobilization can shift the pH optimum to a higher value relative to the measurements with a native enzyme owing to the accumulation of H^+ ions in the membrane body.

Certain inhibitors are converted to the active form only in aqueous solution in the reaction of reversible protonation or hydrolysis. In this case the pH optimum of inhibition can be sufficiently shifted from the optimum for the enzyme-substrate interaction. This is typical for secondary amines which inhibit carboxylesterase and cholinesterase after preliminary protonation and the maximum of inhibition is observed in weakly acidic media (pH 6.0–7.0) [45,84,85]. If the reaction of the formation of an active form of the inhibitor (i.e. protonation) is hindered, the pH shift can be higher. Hence, intermolecular binding diminishes the basicity of the nitrogen atom in

α -aminophosphonates. As a result, they exhibit an inhibiting effect on native microbial carboxylesterase at pH 3–4.5 [121]. The activity of cholinesterase in this pH range is too slow, this retards quantitative measurement of the inhibiting effect of this compounds. Incidentally, the immobilization of cholinesterase on a paper membrane makes it possible to detect these compounds with the pH maximum of the inhibition at pH 6–6.5. Similar results were obtained for hydrazones of benzaldehyde and cinnamaldehyde.

For multicharged ions, the inhibiting effect on cholinesterase is preceded by their partial hydrolysis and the formation of hydroxy ions MeOH^+ . Hence, the pH maximum of inhibition depends on the appropriate equilibrium constants of hydrolysis.

Apart from the pH value of the working solution, the actual pH shift in a membrane body during the formation of the response of a biosensor is determined by the nature of the buffer solution. The change in the inhibition degree with the buffer used can result from the change of the capacity of the buffer or the ion strength. Some of the buffer solutions (e.g. borate buffer for cholinesterase) demonstrate a weak inhibiting effect of the enzyme. In this respect the basicity of the working solution is commonly not as high, even for amperometric biosensors which do not measure the pH shift, and do not exceed $10^{-2} \text{ mol l}^{-1}$.

For biosensors exploiting two enzymes, co-immobilised in the same membrane or separated in different compartments of a biosensing device (e.g. membrane and solution), the pH value of the working solution is usually chosen according to the pH optimum of the key enzyme determining the response of a biosensor. Hence, for a two-enzyme biosensor, utilizing cholinesterase and choline oxidase, the determination of cholinesterase inhibitors was performed at pH 7.0, referring to the optimum of activity of choline oxidase [41,42]. Such an approach is rewarding if it contributed to the performance of a biosensor and the pH sensitivity of inhibition is not as high. In other cases this can result in the decline of the analytical characteristics of inhibitor determination.

The shift of the pH value from the optimum for the enzyme-substrate or enzyme-inhibitor interaction can arise to meet the needs of detecting the enzyme reaction or the stability of a sensor. Hence, electrodes based on the composition of epoxy resin and carbon are unstable in basic media. Therefore, when this composition containing cholinesterase is used for inhibitor determination, all the measurements are performed at pH 7.0 [49].

For irreversible inhibitors, the incubation procedure is performed before the substrate is added. The conditions of inhibition and of the following determination of reduced response can differ, and some of the limitations can be avoided. The incubation of a cholinesterase biosensor in non-buffered media at pH 7–7.5 with the following determination of the response in standard conditions for this enzyme (pH 8.0, phosphate buffer) makes it possible to detect both heavy metal ions and organophosphorus pesticides [45]. The incubation in a phosphate buffer at pH 8.0 with the same conditions of response measurement results in the selective determination of organophosphates in the presence of heavy metal ions. For determination of organophosphorus pesticides, the incubation can be conducted immediately in organic solvents used for extraction. Following washing eliminates the interfering influence of the organic solvent on the response of the biosensor in standard buffer solution [52].

The concentration of supporting electrolyte is not so important for biosensor response as the pH value of the working solution. Most measurements are performed at constant ion strength which rarely exceeds 0.1 mol l^{-1} . The increase of electrolyte concentration contributes to the reproducibility of biosensor response together with the decay of the response value and the lifetime of the immobilized enzyme. This can be followed by the decrease of the sensitivity of the enzyme toward reversible and irreversible inhibitors, i.e. the increase of the pI_{50} and K_i values and the minimal detectable concentration of the inhibitor [27,89]. As a result, most procedures for the determination of the inhibitor specify the highest permissible content of the salts both in the working solution and the sample tested [27,28].

5.2. Measurements in organic media

In several reports, the influence of organic solvents on the response and sensitivity of biosensors for the determination of inhibitors has been described [52,77–79,94,122–127]. The measurements in non-aqueous media are very attractive because they offer new opportunities for the application of such biosensors, as in-line control of industrial processes or the detectors for HPLC. The employing enzymes in organic media allows the increase in the solubility of non-polar substrates and/or inhibitors and to shift the sensitivity of the enzymes toward various substrates and effectors [127].

Only a few enzymes retain their activity when the content of water does not exceed several percent. Tyrosinase and peroxidase based biosensors are the most investigated ones for the determination of various substrates and inhibitors in organic solvents containing various amounts of water, i.e. acetonitrile, alcohols, 1,4-dioxane, acetone, chloroform, etc.

The measurement in organic solvents places more stringent requirements upon the immobilization of the enzyme. The appropriate carrier must neither dissolve nor swell in organic media and the immobilized enzyme must retain its activity in the working conditions. The application of photocrosslinkable polymer, PVASbQ (Toyo Gosei Corp., Tokyo) [52], cellulose derivatives [79], conducting PVC-copolymers [78], Eastman AQ-55D [124,125] has been described for this purpose. The physical sorption of the enzyme on the graphite surface [126] or dialyze membrane [77] was also found appropriate for water-immiscible solvents and emulsions.

The response of the tyrosinase biosensor increases with water content to the limit, determined by the concentration of the substrate used. The minimal amount of water required for the measurements of the response depends on the polarity of the solvent and the substrate. When phenol was used as a substrate of tyrosinase, the detectable amounts of water consist of 0.01–0.005% v/v [125].

The measurements in non-aqueous media makes it possible to determine the compounds,

the solubility of which in water is insufficient. This refers to the derivatives of thiourea, inhibiting tyrosinase [77]. The determination was performed in n-hexane saturated with phosphate buffer. The presence of a water phase is used for establishing electric conductivity, which is necessary for electrochemical measurements. For non-polar solvents two-phase solutions can be also used, in which the organic phase forms reversed micelles with a low amount of aqueous buffer solution maintaining both the enzyme activity and the electric conductivity. Described cases of enzyme catalysis in dehydrated solvents (cholesterol oxidase, cholesterol esterase and others) [128] have not, as yet, been definitely applied for the determination of inhibitors.

Most enzymes reduce their activity in the presence of water-miscible solvents. Their addition pursues the same goals as the use for the measurements of organic media: the increase of solubility of the inhibitors to be determined, the possibility of direct analysis of extracts from plants or soil without the evaporation of the extract, etc. The maximum part of solvents to be used in the working solution depends on the nature of the enzyme and the membrane material. The immobilization decreases the sensitivity of the enzyme toward organic solvents. Thus, for acetyl- and butyrylcholinesterase immobilized in agar films and on tracing paper the tolerable content of ethanol and acetone is reported up to 20% [45], whereas 20% ethanol is used to stop the Ellman reaction in the standard technique of the determination of activity of native cholinesterase [129]. The immobilized enzymes retain their activity during at least 30 min after the addition of the solvent. For horseradish peroxidase the increasing hydrophilicity of the solvent (i.e. methanol > acetonitrile > acetone) results in a decrease of sensitivity of the biosensor toward thiourea and ethylenethiourea [94].

An alternative method of overcoming limitations of organic solvents (i.e. insufficient electric conductivity, low enzyme stability) is to perform the incubation in organic media and the biosensor response measurement in aqueous standard solution. Thus, 30-min incubation in pure alkanes C₆–C₁₂, benzene, butyl acetate, ethyl ether, ace-

tonitrile does not significantly alter the activity of acetylcholinesterase whereas alcohols, DMSO, chloroform diminish the enzyme activity by 50–100% [52]. The stability of immobilized was higher than that of free acetylcholinesterase. This was explained by the hydrophilic properties of the enzyme carrier PVA-SbQ which stabilizes the essential water layer around the enzyme. The influence of the solvent on the enzyme activity was characterized with the parameter $\log P$, defined as the logarithm of the partition coefficient in a standard octanol-water two-phase system ($P = (C_{\text{solvent}})_{\text{octanol}} / (C_{\text{solvent}})_{\text{water}}$). The highest enzyme activities (up to 120% for free enzyme and up to 115% for immobilized cholinesterase) were obtained after the incubation in hydrophobic solvents ($\log P > 4$ for free and > 2 for immobilized enzyme).

As to inhibitory effect, the role of organic solvents is ambiguous. For reversible inhibition, it may depend on the hydrophilic/hydrophobic properties of the substrate and inhibitor. Thus, for cholinesterase immobilized in a gelatin membrane the addition of ethanol results in the decrease of the reversible inhibiting effect of certain amines when butyrylcholine iodide is used as a substrate. An opposite effect is reported for the same inhibitors and working conditions, when indophenyl acetate is used as a substrate [130]. The altering effect of organic solvents on the Michaelis constants and apparent equilibrium constants is described for peroxidase biosensors with thiourea and ethylenethiourea as reversible inhibitors. For irreversible inhibitors, the influence of organic solvents on the inhibiting effect is considered to be lower than that for reversible inhibitors.

The addition of small amounts of methylcellulose to the buffer solution was also described [28] for automated alarm systems for the detection of traces of anticholinesterase pesticides in air and fresh waters based on cholinesterase immobilized in pad reactors and galvanostatic detection. For the same purpose 1% of acetonitrile was added to the buffer solution for the determination of anticholinesterase pesticides with screen printed choline biosensor and native acetylcholinesterase [131]. Acetone, tetrahydro-

furan and ethyl acetate were found inappropriate, due to their inhibiting affect on the response of the biosensor.

5.3. The use of enzyme effectors

The working solution can involve stabilizers and effectors of the enzyme incorporated in the biosensor assembly. This is a most promising and a less investigated direction of the progress in the development of biosensors for the determination of inhibitors. Thus, the detection limits of mercury(II), which inhibit peroxidase from horse serum, can decrease by a factor of 1000, when the enzyme is preliminary incubated in diluted solution of thiourea [111]. Moreover, this treatment prevents the interfering effect of the other heavy metals. With the choice of appropriate substrates, this approach resulted in the development of high selective methods of mercury determination with the detection limits down to 10^{-6} mg l⁻¹ if native enzyme is used. The immobilization of peroxidase on paper or cellulose derivatives decreases the sensitizing effect of thiourea. As thiourea exhibits a general denaturing effect on peptides, its influence is observed for small concentrations and the limited duration of the contact with the enzyme, during which the decay of initial enzyme activity does not exceed 40%.

The activating effect of calcium and some other doubly charged cations is described on the response of amperometric biosensor utilizing butyrylcholinesterase immobilized in cellulose dinitrate and its sensitivity toward irreversible inhibitors [18]. The sensitizing effect is observed within narrow limits of experimental conditions, i.e. at pH 9–10 and low concentration of supporting electrolyte. The more the concentration of supporting electrolyte, the less influence of effectors on response and sensitivity of biosensor toward inhibitors. Similar measurements with cholinesterase immobilized at paper membrane in Tris buffer (pH 6–8) containing 0.1 mol l⁻¹ of NaCl do not demonstrate any changes of analytical characteristics of inhibitor determination in the presence of such effectors.

Aluminum ions in the concentration range from 10^{-4} – 10^{-3} mol l^{-1} increase the activity of native butyrylcholinesterase by 15–20%. Moreover, the sensitivity of native enzyme to Paraoxon is increased in the presence of this amount of aluminum by 10–15%. Meanwhile, the response of cholinesterase biosensor utilizing the enzyme immobilized on paper membrane diminishes by 20–25%, and the decay of the response of biosensor after incubation in the solution of Paraoxon containing 10^{-4} mol l^{-1} of aluminum ions is lower than that observed without any additives as if aluminum exhibit typical ‘protecting effect’ [45,46]. One of the possible reasons of differ influence of activators on native and immobilized enzyme assumes the sorption of ions effecting enzyme activity on the polar hydrophilic material of membrane. Sorption and possible partial hydrolysis of aluminum salts hinders the access of a substrate and/or inhibitor in membrane body followed by the decrease of apparent inhibition degree.

This is borne out by the results of joint action of reversible effectors (both activating or inhibiting enzyme) and surfactants on the response of biosensor and its sensitivity toward irreversible inhibitors [62]. The addition of 10⁻³% w/v of non-ionic surfactants not only diminishes the reversible inhibiting effect of traditional inhibitors, i.e. fluoride and copper(II) ions, but also suppress ‘protecting effect’ of such reversible inhibitors on the determination of irreversible inhibitors: the slope of appropriate calibration curves of Paraoxon or Diazinon decreases when effectors are added to the working solution but returns to the initial value in the presence of surface active compounds, i.e. PEG-10 000, Triton-X-100 or Tween-20. In the concentration range 10^{-1} – 10^{-3} % the above compounds diminish the response of the biosensor as reversible inhibitors.

This may be important for the possible application of membrane biosensors for direct monitoring of environmental pollution. Indeed, some components of environment, i.e. water-soluble peptides, humic and fulvic acids, biogenic polyphenols, clays exhibit in variable degrees surface-active features and can alter the actual

inhibition caused by the contamination of the sample tested.

6. Future prospects of biosensors for inhibitor determination

Although practical application of inhibitor biosensors seems currently much more complicated than that of substrate biosensors, their potentialities are far from being exhausted. First of all this refers to the application of biosensors for environmental monitoring. Contrary to the conventional techniques and analytical equipment, inhibitor biosensors make it possible to detect directly dangerous pollutants (i.e. heavy metal ions, pesticides, cyanides, respiration poisons, etc.) without any preconcentration or sample treatment. The achieved detection limits in most cases refer to the maximum permissible levels of pollution in environmental objects. Simple procedure or response measurement as well user-friendly design make such biosensors very attractive for preliminary estimation of pollution especially in field conditions.

However the realization of these advantages calls for the solution of several problems, i.e. the selectivity of response, the calibration of biosensors in multi-component media, the influence of natural enzyme effectors and last but not least—the directional regulation of biosensor performance depending on particular analytical problems. Recently, various results of the biosensor based testing of the real samples (fruits, vegetables, wastewaters, river sediments) have been described [131–133].

The interpretation of biosensor response in multi-component media, i.e. waste and natural waters, extracts etc. is based commonly on the presentation of cumulative inhibiting effect of all pollutants presented in the sample in the units of concentration of a standard inhibitor, i.e. DDVP [28] or Paraoxon [59]. This approach does not account for non-additive combination of partial effects as takes part for reversible and irreversible inhibitors due to the ‘protecting effect’. On the other hand, the variety of the factors effecting biosensor response (i.e. sorption of

surface-active compounds and hydrolyzing salts, presence of natural enzyme effectors, etc.) offers novel possibilities to use inhibitor biosensors as indicators of general pollution or toxicity of the samples tested. In this case for calibration the estimation of acute toxicity of sample on hydrobionts (e.g. *Daphnia* or *Infusoria*) can be used for the calibration of the response of the biosensor. The combination of several enzymes or joint interpreting the results of biosensor based measurements and biotesting extend the potentialities of the application of biosensors [132].

Recently, modes for the further improvement of biosensors based on well-known enzymes, i.e. cholinesterases, peroxidase, tyrosinase, must be related to the development of novel sensors-transducers providing for better operation conditions (response time, lifetime of enzymatic membrane, etc.). The improvement of sensitivity can be afforded by the optimization of working conditions, including the incorporating enzyme activators into membrane or electrode material as well as in working solution.

The expansion of the list of species to be detected can also be attained by using enzyme process for indication of the changes in the membrane body or on the surface of the sensor, which are not connected directly with enzyme, as such. Thus, the determination of benzoic acid based on mediated tyrosinase biosensor is described [74]. Competitive inhibition observed arises from the interaction of benzoic acid with the active form of mediator, generated through enzymatic process. Similarly, sorptional membrane effects described earlier [62] are detected with cholinesterase reaction.

New opportunities are considered with the application of novel enzymes or enzyme sources as well as biocomponents with necessary enzyme activity. Besides the improvement of sensitivity or selectivity of the determination of traditional pollutants, this biosensors can serve as models of toxic effects of appropriate compounds or their mixtures on living cells and living being. Combined with traditional biosensors and test kits this biosensing devices can be applied as alarm monitors of environmental pollution.

Liquid chromatographic determination of cobalt(II), copper(II) and iron(II) using 2-thiophenyaldehyde-4-phenyl-3-thiosemicarbazone as derivatizing reagent

M.Y. Khuhawar *, S.N. Lanjwani

Institute of Chemistry, University of Sindh, Jamshoro, SindhPakistan

Received 28 October 1996; received in revised form 2 July 1997; accepted 7 July 1997

Abstract

The complexing reagent 2-thiophenyaldehyde-4-phenyl-3-thiosemicarbazone (TAPT) was examined for high performance liquid chromatographic (HPLC) separations of cobalt(II), copper(II) and iron(II) or cobalt(II), nickel(II), iron(II), copper(II) and mercury(II) as metal chelates on a Microsorb C-18, 5- μm column (150 \times 4.6 mm i.d.) (Rainin Instruments Woburn, MA, USA). The complexes were eluted isocratically with methanol:acetonitrile:water containing sodium acetate and tetrabutyl ammonium bromide (TBA). UV detection was at 254 nm. The solvent extraction procedure was developed for simultaneous determination of the metals, with detection limits within 0.5–2.5 $\mu\text{g ml}^{-1}$ in the final solution. The method was applied for the determination of copper, cobalt and iron in pharmaceutical preparation. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Chromatographic determination; Complexing reagent; Solvent extraction

1. Introduction

A number of complexing reagents have been used for high performance liquid chromatographic (HPLC) determination of cobalt, copper and iron, including 8-hydroxyquinoline [1,2], 6-hydroxy-5-nitrosonaphthalene-2-sulphonic acid [3], acetylacetone [4], diethyldithiocarbamate [5] and various azo derivatives [6–10].

Thiosemicarbazones and phenylthiosemicarbazones are interesting complexing reagents, because they form highly stable and intensely coloured complexes immediately, by bonding through the sulphur and hydrazino nitrogen atoms, which are ideally suited for spectrophotometric detection. Different thiosemicarbazones and phenylthiosemicarbazones have been reported as spectrophotometric [11–14] and spectrofluorimetric [15] reagents for metal ions. They have also been investigated as indicators for

* Corresponding author. Tel.: +92 771 328.

complexometric titrations [16,17]. Some of useful HPLC separations have been reported using these ligands [18–23]. Uehara et al. [20] have reported picolinaldehyde-4-phenyl-3-thiosemicarbazone for the separation of bismuth(III), cadmium(II), cobalt(II), copper(II), nickel(II) and iron(III) from an ODS column by including pyridine in the mobile phase. 2-Acetylpyridine-4-phenyl-3-thiosemicarbazone [21] has been used for the separation and determination of copper(II), iron(II) and cobalt(II) from reversed phase HPLC columns. Biacetyl bis-(4-dimethylaminophenyl)-3-thiosemicarbazone [23] has been used for the separation of bismuth(III), copper(II), nickel(II) and palladium(II) from RP-80 polymeric resin as well as for separation of indium(III), copper(II) and mercury(II) from a C-18 silica column. The reagents glyoxal dithiosemicarbazone, glyoxal bis(4-phenyl-3-thiosemicarbazone) and dimethylglyoxal bis(4-phenyl-3-thiosemicarbazone) coated on Amberlite XAD resin have been used for preconcentration of mercury(II), copper(II), zinc(II), cadmium(II), lead(II) and palladium(II) [23], followed by reversed phase HPLC separation of palladium, copper, mercury or cadmium, lead and copper. Uehara et al. [24] have compared several hydrazone derivatives for reversed phase HPLC. They have reported 2-thiophenylaldehyde-4-phenyl-3-thiosemicarbazone (TAPT) Fig. 1 for HPLC detection of iron(II) and nickel(II). In the present paper, TAPT has been assessed for the HPLC separation of cobalt(II), copper(II), iron(II), mercury(II) and nickel(II) and for the determination of copper(II), cobalt(II) and iron(II).

Fig. 1. Structural diagram of 2-thiophenylaldehyde-4-phenyl-3-thiosemicarbazone.

2. Experimental

2.1. Preparation of 2-thiophenylaldehyde-4-phenyl-3-thiosemicarbazone (TAPT)

4-Phenyl-3-thiosemicarbazide (1.67 g) dissolved in 20 ml methanol:water (1:1) was added to 1 ml of 2-thiophenylaldehyde in 10 ml of methanol. To the mixture was added 0.5 ml glacial acetic acid and it was then refluxed for 30 min. The mixture was cooled and the precipitate obtained was recrystallized from methanol m.p. 212°C. $C_{22}H_{22}N_3S_2$ required (%): C = 55.17, H = 4.21, N = 16.09; found (%): C = 55.29, H = 3.92, N = 16.0.

2.2. Analytical procedures

2.2.1. Aqueous methanolic solutions

A solution (1–5 ml) containing cobalt(II), copper(II) and iron(II) (0–200 μ g) was transferred to a 10-ml volumetric flask and the volume was adjusted to 5 ml. Reagent solution (2 ml, 7.7 mM in methanol) was added and the contents were mixed well. This was followed by 2 ml sodium bicarbonate buffer pH 9 and the volume was adjusted with methanol. The solution (5 μ l) was injected onto a Microsorb C-18 5- μ m column (Rainin Instruments Woburn, MA, USA) and the complexes eluted with methanol:acetonitrile: water:sodium acetate (1 mM):tetrabutyl ammonium bromide (TBA) (1 mM) (70:18:10:1:1 v/v/v/v) using a flow rate of 1 ml min⁻¹. Detection by UV was at 254 nm.

2.2.2. Solvent extraction of metals

A solution (1–20 ml) containing cobalt(II), copper(II), iron(II), mercury(II) and nickel(II) (0–100 μ g each) was transferred to well-stoppered test tubes and 2 ml reagent solution was added (7.7 mM in methanol) as well as 2 ml sodium acetate–acetic acid buffer pH 6 (1 M). Chloroform (2 ml) was added and the layers were mixed well. The organic layer was separated and to the aqueous layer was added 0.5 ml reagent solution (7.7 mM in methanol) and 2 ml of sodium bicarbonate–sodium carbonate buffer pH 9. Extraction was repeated with 2 ml chloroform. Exactly 2 ml of chloroform from the combined extract was

transferred to a sample vial and the solvent was evaporated. The residue was dissolved in 1 ml methanol and 5 μ l of the solution was injected onto a Microsorb C-18, 5- μ m column. The complexes were eluted with methanol:acetonitrile:water:sodium acetate (1 mM):TBA (1 mM) (78:10:10:1:1 v/v/v/v) using a flow rate of 1.0 ml min⁻¹. Detection by UV was at 254 nm.

2.2.3. Recovery (%) of metals on solvent extraction

Extraction was carried out on a 20-ml solution containing copper, iron, nickel and cobalt (50 or 100 μ g of each) and reagents as described in Section 2.2.2. The aqueous phase was collected, 2 ml nitric acid (65%) was added and it was heated to near dryness. The residue was dissolved in water and the volume was adjusted to 25 ml. The metal ion contents were determined using an air-acetylene flame atomic absorption spectrophotometer. The amounts of metal ions remaining in the aqueous phase were evaluated using a standard calibration curve for each element.

2.2.4. Analyses of copper, iron and cobalt in a pharmaceutical preparation

To a 1.3991-g Centrum tablet (Lederle Laboratories Division, Cyanamide Pak, Karachi) was added 0.5 g potassium bisulphate dissolved in 2 ml of water, 10 ml hydrochloric acid (37%) and 5 ml nitric acid (65%) spiked with 20 μ g cobalt(II). To this was added 2–3 mg solid ascorbic acid, 2 ml reagent solution (7.8 mM in methanol), 2 ml sodium carbonate buffer pH 9 and 2 ml chloroform. The contents were mixed well, the organic layer was collected and extraction was repeated with 2 ml chloroform. After the addition of 0.5 ml reagent solution (7.7 mM in methanol), the procedure was continued as described in Section 2.2.2.

Elemental micro-analysis of TAPT was carried out at the HEJ Research Institute of Chemistry, University of Karachi. Spectrophotometric studies were carried out using a Hitachi 220 spectrophotometer. A Hitachi 655A liquid chromatograph connected to a variable wavelength UV monitor, Rheodyne 7125 injector and Hitachi D2500 chromato-integrator was also used, in addition to a Microsorb C-18, 5- μ m

Fig. 2. Effect of variation in pH on the formation of (1) mercury(II); (2) iron(II); (3) cobalt(II); (4) copper(II); and (5) nickel(II) as complexes of TAPT against reagent blanks. Final concentration 10, 2, 1, 1 and 1 μ g ml⁻¹, respectively.

column (150 \times 4.6 mm i.d.) and a YMC Pack ODS (150 \times 4.6 mm i.d.) (YMC, Japan). A Varian Spectr AA 20 atomic absorption spectrometer with air-acetylene flame atomization was used according to the manufacturer's instructions.

Phenylthiosemicarbazide, 2-thiophenylaldehyde, tetrabutyl ammonium-bromide (Fluka), G.R. Grade acetonitrile, methanol, sodium acetate and hydrochloric acid (Merck) were used. Freshly prepared double distilled water was used for HPLC studies.

3. Results and discussion

The reagent reacts with copper(II), nickel(II), cobalt(II) and mercury(II) in aqueous methanolic solution to develop colour immediately in pH range 3–10, but for iron, the pH must be adjusted to within pH 5–10 after addition of the reagent. Mercury(II) developed turbidity in aqueous methanolic solution, but when extracted in chloroform, a clear solution was obtained. The colours of the complexes are highly stable both in aqueous methanolic solution and in chloroform and no change in absorbance was observed for up to 8 h. The maximum colour development of mercury(II) occurs at pH 6, cobalt(II), nickel(II), copper(II) at pH 8.5 and iron(II) at pH 9 (Fig. 2).

Table 1
% Recovery of the metals using solvent extraction (% C.V)

Metal ions	Single extraction	Double extraction
Iron	85.25 (1.1)	93.5 (1.2)
Copper	75.00 (1.7)	92.5 (1.6)
Cobalt	82.00 (1.6)	96.2 (1.8)
Nickel	92.00 (1.4)	98.0 (1.3)

The transfer of metals from the aqueous to the organic phase was examined. Recovery % of copper, iron, nickel and cobalt, based on the metals remaining in aqueous phase was 75–92% using single extraction and 92.5–98% using double extraction (Table 1).

The composition of metal chelates was investigated by changing the metal:ligand mole ratio spectrophotometrically. The absorbances of nickel(II), cobalt(II), copper(II) and iron(II) were measured at 393, 398, 390 and 388 nm in aqueous methanolic solution. Mercury(II) was monitored at 397 nm after extraction in chloroform. The results, shown in Fig. 3, suggest that nickel(II), cobalt(II), copper(II) and iron(II) form a 1:2 complex but mercury has a 1:3 composition.

Fig. 3. Effect of variation in molar ratio of metal (4×10^{-5} M) and ligand TAPT (4×10^{-5} – 16×10^{-5} M) for the formation of maximum metal complexes: (1) nickel; (2) cobalt; (3) copper; (4) iron(II); (5) mercury.

Fig. 4. HPLC separation of (1) TAPT; (2) cobalt(II); (3) iron(II); and (4) copper(II) complexes. Conditions as described in Section 2.2.1.

Copper(II), iron(II) and cobalt(II) form water soluble complexes. Their solutions were injected on a Microsorb C-18 column and complexes were eluted with acetonitrile–water or methanol–acetonitrile–water containing sodium acetate and tetrabutyl ammonium bromide, as reported for the separation of related metal chelates [21,22]. An optimal separation was obtained when eluted isocratically with a mixture of methanol–acetonitrile–water containing sodium acetate and TBA, using a flow rate of 1 ml min^{-1} , with UV detection at 254 nm (Fig. 4). The metals could also be extracted as metal chelate compounds in chloroform with a preconcentration factor of at least

ten. A mixture of cobalt(II), nickel(II), iron(II), copper(II) and mercury(II) on a Microsorb C-18 column completely separated when eluted with a mixture of methanol:acetonitrile:water:sodium acetate (1 mM):TBA (1 mM) (78:10:10:1:1 v/v/v/v/v) with a flow rate of 1 ml min⁻¹. UV detection was at 254 nm. Excess reagent added for derivatization eluted before metal chelates and did not interfere with the determinations. The resolution factor (R_s) between two adjacent peaks was > 1.66 (Fig. 5).

Additions of sodium acetate and TBA had a significant effect on the elution and separation of metal chelates. When sodium acetate was added in the eluent, cobalt and mercury eluted as symmetrical peaks, but copper(II), nickel(II) and iron(II) chelates were retained for longer, with elution time > 15 min. However, when TBA was included in the mobile phase, the retention times of nickel(II), iron(II) and copper(II) were reduced to 5.88, 7.26 and 8.10 min, respectively (Fig. 5). The effect of TBA concentration on the elution, retention time and capacity factor (K') of TAPT, cobalt(II), nickel(II), iron(II), copper(II) and mercury(II) was investigated. The concentration of TBA in the eluent was varied between 1.25 to 25 μ M. It was observed that K' decreased in TBA concentrations from 1.25 to 15 μ M. However, further increases in the concentration of TBA up to 25 μ M resulted in an increase of K' and an increase in the back pressure of the column (Fig. 6). Therefore, the concentration of TBA was fixed at 10 μ M for this study.

Thiosemicarbazones are reported [22] to form water soluble cationic complexes. Also, it is possible that acetate and bromide ions present in the eluent form ion pairs, thus influencing the elution and separation of metal chelates. Qian and Fritz [22] have observed a decrease in the retention time of metal chelates of thiosemicarbazones by including cation generating ions (TBA) in the mobile phase. They have attributed the reduction in retention times to the adsorption of bulky, positively charged groups on the surface of stationary phase and the repulsive force to the cationic metal chelates.

Linear calibration curves, calculated by measuring average peak height ($n = 3$), were within 0–50

μ g ml⁻¹ of each metal ion with correlation coefficient (r) 0.994, 0.984, 0.988 and 0.996, for cobalt(II), mercury(II), copper(II) and iron(II), respectively. Detection limits, measured as three times the background level for simultaneous detection, were 2.5 μ g ml⁻¹ mercury and 0.5 μ g ml⁻¹ cobalt, copper, nickel and iron, corresponding to 12.5 ng mercury and 2.5 ng cobalt, copper, nickel and iron per 5- μ l injection.

Finally, a pharmaceutical product (Centrum tablet) was analysed for cobalt, copper and iron content using the HPLC method. Cobalt content

Fig. 5. HPLC separation of (1) TAPT; (2) cobalt(II); (3) iron(II); (4) nickel(II); (5) copper(II); and (6) mercury(II) complexes on a Microsorb C-18 5- μ m column (150 \times 4.6 mm id) using elution with methanol:acetonitrile:water containing sodium acetate (1 mM): tetrabutylammonium bromide (1 mM) (78:10:10:1:1 v/v/v/v/v), at a flow rate of 1.0 ml min⁻¹ and with UV detection at 254 nm.

Fig. 6. Variation in capacity factor (K') with concentration of TBA. (1) mercury; (2) copper; (3) iron; (4) nickel; (5) cobalt; and (6) TAPT. Conditions: YMC pack ODS 5- μm (150×4.6 mm id) column. The eluent is methanol:acetonitrile:water:sodium acetate (1 mM):TBA (0.125–2.5 mM) (78:10:10:1:1 v/v/v/v/v), with a flow rate of 1 ml min^{-1} and UV detection at 254 nm.

of the tablet was determined by standard addition technique, after spiking the sample with $20 \mu\text{g}$ of cobalt. Copper and iron content was evaluated from a calibration curve. The amounts of cobalt, copper and iron found were $43 \mu\text{g}$, 2.66 and 8.50 mg/tablet respectively, with RSD 3.6, 5.2 and 4.8%, respectively. The tablet was also analysed using air-acetylene flame atomic absorption and the results were $39 \mu\text{g}$, 2.79 and 8.7 mg/tablet cobalt, copper and iron respectively, with RSD 4.4, 1.8 and 1.1%, respectively.

4. Conclusion

A good yield of the reagent TAPT can be easily prepared from inexpensive chemicals ($> 80\%$) and reacts immediately with a limited number of metal ions to form stable coloured complexes. Reverse phase liquid chromatographic method has been developed for the separation of cop-

per(II), nickel(II), cobalt(II), iron(II) and mercury(II) using TAPT. The detection limits are obtained at 2.5–12.5 ng/injection. This method is applied for the determination of copper, iron and cobalt in a pharmaceutical preparation with RSD within 3.6–5.2%.

Received 12 November 1996; received in revised form 18 April 1997; accepted 11 July 1997

Abstract

The overall formation constants of 1:1:1 ternary complexes of Cu(II), Zn(II), Cd(II) with glycine, DL-alanine or DL-leucine as primary ligands and *o*-hydroxyphenylazo derivatives of 2-cyanomethyl benzimidazole (ABI) and barbituric acid (ABA) as secondary ligands have been investigated potentiometrically in 40% (v/v) EtOH. Formation constants of binary systems were also determined under the same experimental conditions (37°C and $\mu = 0.15 \text{ mol dm}^{-3}$). The stability of ternary complexes have been quantitatively compared with those of the corresponding binary complexes in terms of the parameters $\Delta \log K$, $\log X$ and $\log X'$. The data were interpreted on the basis of statistical considerations and the nature of complexes. The concentration distribution of various species formed in solution was evaluated. The Cu(II) complexes have been synthesized and the coordination sites of the ligands were characterized by means of IR spectroscopy. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

It has been shown that the arylazo derivatives of benzimidazole and barbituric acid play an important role in biochemistry because their imidazole and barbiturate moieties were the principle sites on the proteins, enzymes and nucleic acids [1–5]. Much attention has been paid recently to the study of ternary complexes of transition metals with molecules of biological and pharmaceutical interest [6–9]. Mixed complexes of transi-

tion metals containing an imidazole or pyrimidine group as ligands are commonly found in biological media and may have important roles in processes as catalysis of drugs interaction with biomolecules [10,11]. Furthermore, it has been suggested that the presence of metal ions in biological fluids, could have a significant effect on the therapeutic action of drugs [12,13]. The work reported on the interaction of Cu(II), Zn(II) and Cd(II) with imidazole derivatives and amino acids demonstrated that imidazole moiety is the principal site responsible for metal binding [10,14,15]. This was attributed to its capacity to form both σ and π bonds with metal ions.

To obtain a more understanding of the driving forces leading to complexation in biological systems, we are reporting in the present paper, the results of pH-metric studies on the mixed ligand complexes of Cu(II), Zn(II) and Cd(II) with glycine (GLY), DL-alanine (ALA) and DL-leucine (LEU) as primary ligands and expected biologically important 2-[-*o*-hydroxyphenylazo] 2'-cyanomethyl benzimidazole (ABI) and 5-[-*o*-hydroxyphenylazo]barbituric acid (ABA) as secondary ligands. The work is aimed to establish the various equilibria that exist in solution, and to determine the dissociation constants of the free ligands and stability constants of binary and ternary complexes in 40% (v/v) EtOH-H₂O at 37°C and $\mu = 0.15 \text{ mol dm}^{-3} \text{ NaClO}_4$. Although the aqua-organic solvent mixtures are of little interest, since these media are not present in the human body, these systems were studied for comparison.

2. Experimental

2.1. Materials and solutions

All the chemicals used were of A.R. grade (Merck) and were used without further purification. The azo compounds 2-[-*o*-hydroxyphenylazo]-2-cyanomethyl benzimidazole (ABI) and 5-[-*o*-hydroxyphenylazo] barbituric acid (ABA) were synthesized by the usual procedure as described by Vogel [16]. The Cu(II) complexes were prepared as described in our earlier paper [17]. Ligand stock solutions were prepared by dissolving the calculated amounts in 20% (v/v) EtOH-H₂O mixture and were standardized by pH-titration with standard HClO₄. Solutions of the metal ions Cu(II), Zn(II) and Cd(II) (Merck or BDH products) were prepared in doubly-distilled water and the metal content was determined by complexometric EDTA titration [18]. Carbonate-free solutions of NaOH (0.1 mol dm⁻³) was prepared and standardized against standard potassium hydrogen phthalate solution. 1.0 mol dm⁻³ NaClO₄ and 0.1 mol dm⁻³ HClO₄ stock solutions were prepared from analytical grade samples and freshly used. The solutions were diluted as necessary.

2.2. Apparatus and procedure

The Vis. and IR spectral measurements were the same as described before [19]. PH-metric titrations were carried out at 37°C (± 0.1) in a double-walled glass cell. Temperature control was achieved by means of a liquid circulation proceeding from a thermostat. pH measurements were carried out on a MV 87 digital pH-Messgerate accurate to ± 0.005 unit and equipped with a glass electrode and saturated calomel electrode.

In both the acidic and alkaline regions, the electrode system was calibrated in terms of hydrogen ion concentrations instead of activities. The following mixtures (total volume of 50 ml) were titrated against CO₂-free 0.0825 NaOH, HClO₄ (a); a + amine (b); b + metal ion (c); a + azo dye (d); d + metal ion (e), and a + amine + azo dye + metal ion (f). The ionic strength was adjusted to 0.15 mol dm⁻³ by addition of NaClO₄ as supporting electrolyte. Magnetic stirrer was used during all titrations. Oxygen free nitrogen gas was bubbled through the solution before and during titrations. Multiple titrations were carried out for each system. All titrations were made in 40% (v/v) EtOH-H₂O in order to overcome the weak solubility of the studied systems in pure aqueous medium. The pH meter reading (*B*) recorded in 40% (v/v) EtOH-H₂O solutions were converted to hydrogen ion concentration [H⁺] by means of relation of Van Uitert and Hass [20] namely

$$-\log [H^+] = B + \log U_H - \log(1/\gamma^2)$$

Where γ is the activity coefficient of the solvent composition and is U_H the correction factor at zero ionic strength for the solution under investigation.

3. Results and discussion

3.1. Proton-ligand systems

Representative pH-metric equilibrium titration curves for the free and metal complexed ligands are depicted in Fig. 1. The acid dissociation constants of ABI and ABA in 40% (v/v) EtOH-H₂O are determined from curves (a) and (b) using

computer program based on Irving-Rossotti equations [21]. The details regarding the potentiometric method were reported in the experimental section. The values of the dissociation constants of amines: GLY ALA and LEU are also redetermined under the same experimental conditions (37°C, $\mu = 0.15 \text{ mol dm}^{-3} \text{ NaClO}_4$). The SUPERQUAD computer program [22], were used to refine the overall protonation or formation constants by minimizing the sum of squared residual, U between the observed, E_{obs} and calculated E_{calc} emf values

$$U = \sum W_i (E_{\text{obs}} - E_{\text{calc}})^2$$

The weighting factor, W_i is defined as the reciprocal of the error in the potential and volume readings, σ_E and σ_v , respectively. The W_i values were calculated from the equation

Fig. 1. Titration curves for the Cu(II)-GLY-ABA system at 37°C and equal to 0.15 and 40% EtOH; (a) 0.02 HClO₄; (b) solution (a) + 2×10^{-4} GLY; (c) solution (b) + 1×10^{-4} Cu(II); (d) solution (a) + 2×10^{-4} ABA; (e) solution (d) + 1×10^{-4} Cu(II); (f) solution (e) + 2×10^{-4} GLY, concentration of NaOH $0.0825 \text{ mol dm}^{-3}$.

Table 1
Ionisation constants of the free ligands and stability constants of binary systems

Constants	ABA	ABI	GLY	ALA	LEU
H⁺					
log β_1	7.27	8.02	—	—	—
log β_2	16.43	19.35	9.65	9.72	9.58

Cd(II)					
log β_1	5.04	4.85	5.13	5.09	4.21
log β_2	8.90	8.64	9.35	9.42	7.62

Temp = 37°C, $\mu = 0.15 \text{ M (NaClO}_4)$, error limit $\pm (0.02-0.06)$.

$$W_i = 1/\sigma^2 = 1/[\sigma_E^2 + (dE/\delta v)^2 \sigma_v^2]$$

The quality of the fit was judged by the values of the sample standard deviation, S , and the goodness of fit, X^2 , (Pearson's test). At $\sigma_E = 0.1 \text{ mV}$ (0.001 pH error) and $\sigma_v = 0.005 \text{ ml}$, the values of S in different sets of titrations were between 1.0 and 1.8, and X^2 was between 12.0 and 13.0, thus indicating good fit of the experimental data. The $\text{p}K_a$ values obtained through the refinement of several sets of potentiometric data are quoted in Table 1. The obtained $\text{p}K_a$ values of the studied amines show good agreement with the literature values after allowing for changes in experimental conditions as well as methods of calculation. It is worth mentioning that the $\text{p}K_{a1}$ values for amino acids studied are too low (≤ 2.35) [23], and exist only in strongly acidic solutions and thus these values are not used in calculations, since the pH-metric data are measured in the range $3 \leq \text{pH} \leq 10.5$.

3.2. Metal-ligand binary systems

Analysis of the complexed ligands curves (e) and (d) (Fig. 1) indicates that the addition of metal ion to the free ligand solutions shifts the buffer region of the ligand to lower pH values. This shows that complexation reaction proceeds

by releasing of protons from such ligands. The curves reveals that the magnitude of the horizontal displacement of the complex curves (e) and (d) from the free ligand curves (b) and (c) is longer in case of Cu(II) than in case of Cd(II). This means that the Cu(II) strongly interacts than Cd(II) with the same ligand. Generally, it is observed that MA complexes (curve c) begin to form at lower pH range (~ 3.5) than MB complexes (curve e) ($\text{pH} \geq 4.3$). The complexes are quite stable up to high pH values. Precipitation occurred at $\text{pH} > 10.7$ and thus, no calculations have been performed beyond this point. Therefore, the hydroxo species likely to be formed after precipitation point could not be investigated.

The present study shows that 1:1 and 1:2 metal: ligand type of species are the important types in both metal ion-amino acid (A) and azo ligands (B) systems. This is based on the presence of two inflections in case of MA species and a single steep one in case of MB species, after addition of two moles of NaOH per 1 mol of ligand. This suggests the dissociation of two protons from amino acids in stepwise manner, while for MB systems the complexation is suggested to be simultaneous. These equilibria can be represented as follows, (charges are omitted for the sake of clarity)

$$\log K_{\text{MA}}^{\text{M}} = \log[\text{MA}] - (\log[\text{M}] + \log[\text{A}]) \quad (2)$$

$$\log K_{\text{MA}_2}^{\text{M}} = \log[\text{MA}_2] - (\log[\text{MA}] + \log[\text{A}]) \quad (4)$$

similarly, for azo ligands B

$$\log K_{\text{MB}}^{\text{M}} = \log[\text{MB}] - (\log[\text{M}] + \log[\text{B}]) \quad (5)$$

$$\log K_{\text{MB}_2}^{\text{M}} = \log[\text{MB}_2] - (\log[\text{MB}] + \log[\text{B}]) \quad (6)$$

Complex formation constants for binary systems expressed in terms of overall formation constants $\{\log \beta = \log K_{\text{MA}}^{\text{M}} + \log K_{\text{MA}_2}^{\text{M}}\}$ are computed using standard procedures based on the calculation of the average number of ligands bound per metal ion, n^- and the free ligand exponent, pL as described previously [21]. The best linear fit for the subject binary complexes are obtained by applying the relation $n^-/(1 - n^-)[L] = \beta_1 +$

$(2 - n^-)/(1 - n^-) \beta_2[L]$. The obtained values for $\log \beta_1$ and $\log \beta_2$ for different binary complexes are given in Table 1 and represented as shown in Fig. 2. The $\log \beta$ values reported in this Table were limited to those before the onset formation of hydroxo complexes. Other species were taken into consideration but were rejected during refinement for large sum of squared residual U and standard deviation σ .

The data listed in Table 1, clearly reveals that the stability of metal-amino acids are very close to those already published after allowing for changes in experimental conditions [10]. The results shows that the stability order of binary systems in terms of amino acids is $\text{GLY} > \text{ALA} > \text{LEU}$. This trend is not follows the basicities as expected, probably because the pK values of the amino acid studied are so similar. It is suggested that the absence of alkyl chain in GLY is responsible of the higher stability of its complex. Substitution of CH_3 group (ALA) or lengthening of GLY, skeleton (LEU) produces a small decrease in $\log \beta$ values. In terms of the nature of metal ion, the complex stability follow the trend $\text{Cu(II)} > \text{Zn(II)} > \text{Cd(II)}$, which is in agreements with the decrease in ionic potential (charge/ionic radius) of metal ions in the same direction. On the other hand, the results indicates that MA complexes are more stable than those of MB. This behaviour can be interpreted based on the bidentate nature of amino acids studied which coordinated through the α -amino nitrogen and the carboxylic oxygen atoms forming stable five-membered chelate ring, unlike the azo ligands ABI and ABA which act as monobasic tridentate ligands, coordinated through the o -hydroxy oxygen, the azo nitrogen atoms, and C=O of barbiturate or $N-3$ of benzimidazole moieties leading to the formation of five-six-membered rings. It is well known that 3-D metal ions prefer five-membered to six-membered rings during chelation [24].

3.3. Metal-ligand ternary systems

A set of typical titration curves for the different 1:1 Cu(II)-GLY, Cu(II)-ABA and 1:1:1 Cu(II)-GLY-ABA systems at (37°C and $\mu = 0.15 \text{ mol dm}^{-3} \text{ NaClO}_4$) are shown in Fig. 1 (curve f).

Table 2
Stability constants of M^{2+} amino acid-azo dye ternary systems

Metal ion	$\log \beta_{MAB}^M$	$\log K_{MAB}^{MA}$	$\log K_{MBA}^{MB}$	$-\Delta \log K$	$\log X$	$\log X'$	$\log \beta_{stat}$

Cd(II)	8.47	4.26	3.62	0.59	0.68	0.21	8.42

Other mixed ligand systems show similar behaviour with Zn(II) and Cd(II) chelates. In our study, the amino acids (A) are considered as primary ligands and azo compound (B) as a secondary ligands, since MA species are formed at lower pH values than for MB species. The observed lowering of ternary MAB curve (f) in comparison to binary MA and MB curves (c) and (e) as well as its deviation from the theoretical composite curve (constructed by graphical addition of the horizontal distance of the 1:1 MA (or MB) curve to free ligand B (or A) titration curve), indicates the formation of ternary complexes in solution. The best-fit computer models in the investigated ternary systems showed the only 1:1:1 species, and the another species were very minor importance below pH 6.0. Further, it is worth mentioning that these systems show no precipita-

tion during titration. Thus, they not hydrolyzed under the experimental conditions, even in the high pH's. This behaviour may be explained on the basis that the electron density of the metal-ligand bonds in ternary chelates is redistributed in such a way that the ternary chelates are more polar than the binary chelates and hence, are not easily hydrolyzed in the high pH region.

Generally, the titration curves e and f (Fig. 1), reveals the overlapping of MA and MAB titration curves at low pH values, and then they diverges at higher pH's. This suggests that the azo ligands (B) does not participate in ternary system at lower pH values. Further, the formation of mixed ligand chelates MAB is proved by the observed and inflection point at $m = 1$, followed by buffer region in the higher pH range, ($m =$ the number of moles of alkali added per mol of metal ion). Up

to this point the MAB curve is almost coincident with MA curve, but beyond it, runs much below the MA curve.

To discuss the stabilization of ternary chelates, the following two methods has been considered. In the first method, the ternary complexes formation was considered to take place in simultaneous manner according to the following equilibria (charges omitted for brevity).

$$\log \beta_{MAB}^M = \log[MAB] - (\log[M] + \log[A] + \log[B]) \quad (7)$$

$$\text{since } \log[M] + \log[A] = \log[MA] - \log K_{MA}^M, \text{ Eq. (2)}$$

$$\therefore \log \beta_{MAB}^M = \log[MAB] - \log[MA] + \log K_{MA}^M + \log[B] \quad (8)$$

In the second method, the MAB chelate was consider to be formed in stepwise manner, assuming that the MA is practically formed in the lower buffer region followed by addition of the second ligand (B) in the upper buffer region. This equilibria can be represented as follows:

$$\log K_{MAB}^{MA} = \log[MAB] - (\log[MA] + \log[B]) \quad (9)$$

similarly:

$$\log K_{MBA}^{MB} = \log[MBA] - (\log[MB] + \log[A]) \quad (10)$$

The experimentally determined β_{MAB}^{MD} , is connected with K_{MAB}^{MA} and K_{MBA}^{MB} by the following equations

$$\log \beta_{MAB}^M - \log K_{MA}^M = \log K_{MAB}^{MA} \quad (11)$$

$$\log \beta_{MBA}^M - \log K_{MB}^M = \log K_{MBA}^{MA} \quad (12)$$

The average number of secondary ligand molecules associated with 1 mol of binary complex, n_{mix}^- was computed from the horizontal distance between curve (c) and (f). The values n_{mix}^- were used for compute the free secondary ligand exponent, pL_{mix} . The formation constants of ternary systems were evaluated from the n_{mix}^- - pL_{mix} curves (Fig. 3, Fig. 4). The results presented in Table 2 indicate that calculations based on Eq. (11) is more favoured than that based on Eq. (12), and thus, the ternary complex is formed simultaneously according to Eq. (7). This also confirms the assumption that the amino acids under study acts as primary ligands in our ternary systems. such observation is in line with those reported for ternary complexes of amines [25], and is contrary to earlier findings [26].

According to Sigel [6,27], the relative stability of ternary complex MAB as compared with that corresponding binary complex MB can be quantitatively expressed in different ways. The most suitable comparison is in terms of $\Delta \log K$. This parameter can be calculated from the reaction of secondary ligand (B) either with MA or with free metal ion, hence $\Delta \log K = \log K_{MAB}^{MA} - \log K_{MB}^M$. The above two reactions represent the following overall equilibrium, $MA + MB \leftrightarrow MAB + M$ and hence,

$$\Delta \log K_M = \log \beta_{MAB} - (\log K_{MA} + \log K_{MB}) \quad (13)$$

Fig. 2. Formation curves for metal ion-ABA binary systems. (a) Cd(II); (b) Zn(II); (c) Cu(II).

Fig. 3. Formation curves for metal ion-GLY—ABA (Fig. 3) or ABI (Fig. 4) systems (a) Cd(II); (b) Zn(II); (c) Cu(II).

A comparison of stability constants (Table 1) of binary complexes indicates that $K_1 > K_2$. Thus, in binary systems $\Delta \log K (= \log K_{MA_2}^{MA} - \log K_{MA}^M)$ values are generally negative which indicates the formation of 1:2 species. Similarly in case of ternary complexes formation, $\Delta \log K$ should also display the same trend. This behaviour can be explained on the base of the presence of fewer number of coordination sites on the MA mono-complexes than on the aquated metal ion. Thus, the secondary ligand (B) are expected to bind the MA complex with smaller stability constant than that with aquated metal ion. Therefore, $\Delta \log K$ should be negative values, generally between -0.5 and -2.0 [6,28], depending on the geometry of the complex. A positive or less negative $\Delta \log K$ value, suggests a significant stabilization of ternary system.

The quantitative stabilization of ternary complexes can also be expressed in terms of disproportionation constant X [29,30] as defined by the equation, $MA_2 + MB_2 \leftrightarrow 2MAB$, hence $X = [MAB]^2/[MA_2][MB_2]$

$$\log X = 2 \log \beta_{MAB}^M - (\log \beta_{MA_2}^M + \log \beta_{MB_2}^M) \quad (14)$$

The values for $\log X$ expected on statistical grounds is $+0.6$ [30] for all geometries. The more positive values than those expected statistically indicate the marked stabilities of ternary complexes. Further, the $\log X$ values can only indicate the coordination tendency of secondary ligand towards MA, but it fail to throw any light on the stabilizing order of metal-ligand bonds after the ternary complex formation. Hence to discuss the new stabilization constant $\log X'$, the following equilibria have been considered $MA_2 + MB \leftrightarrow MAB + MA$

$$\Delta \log X' = (\log \beta_{MAB}^M + \log K_{MA}^M) - (\log \beta_{MA_2}^M + \log K_{MB}^M) \quad (15)$$

The computed $\Delta \log K$, $\log X$ and $\log X'$ values for various ternary system are listed in Table 2. Some general observation about the behaviour of the various systems are as follows:

(a) The $\Delta \log K$ values obtained in the above ternary systems are generally do not deviate from the statistical expectations [27], where the statistical, steric and electrostatic factors result in the

Fig. 4. Formation curves for metal ion-GLY—ABA (Fig. 3) or ABI (Fig. 4) systems (a) Cd(II); (b) Zn(II); (c) Cu(II).

lower stability constants for the ternary complexes as compared with the corresponding binary systems. The absence of stabilization is compatible with the explanations given by Sigel et al. [31–33] for the possible stabilization of ternary complexes. The data indicate that the $\Delta \log K$ values obtained for M-GLY-B species are more positive than the values obtained for M-ALA-B species indicating the marked stability of M-GLY-B. This is due to the limited tendency of alanine for interligand interaction [34] while glycine complexes sometimes exhibit exceptional stability [35]. Based on the fact that $\Delta \log K$ values depend on the coordination number of metal ion and the ligands [36,37], the change in $\Delta \log K$ values obtained may also be attributed to the change in the geometry of the complex. For square planar complexes with bidentate ligand, the $\Delta \log K$ values is -0.6 units. For a regular and distorted octahedral geometry, the values are -0.4 and -0.9 units, respectively [6].

(b) The $\log X$ values in the title systems are in general, found to be in the range of the statistically expected values (0.6). The statistically expected $\log X'$ value is 0.3. In Cu(II) ternary complexes, the $\log X'$ values are found to be greater than 0.3, suggesting that MA and MB bonds in ternary systems are stronger than those in corresponding binary systems. By varying the amino acid in ternary chelates, not much variation is observed in $\log X'$ values. This means that the stabilization of MA in ternary systems is influenced by the change in the size of amino acid. Hence $\log X$ values probably influenced by steric differences of ligands. The data reveals that $\log X'$ values of Cd(II) chelates (0.08–0.21) are smaller in magnitude than the statistical value, indicating the marked instability of Cd(II) ternary chelates compared with other species. Thus, it may be concluded that $\log X$ values probably influenced by the large size of Cd(II) ion.

(c) The stability of the studied ternary complexes is also calculated using statistical method [6,25] according to the equation:

$$\log \beta_{\text{state}} = \log 2 + 1/2 \log \beta_{\text{MA}_2}^{\text{M}} + 1/2 \log \beta_{\text{MB}_2}^{\text{M}} \quad (16)$$

The $\log \beta_{\text{stat}}$ values and the difference between stability constants measured and calculated ($\log \beta_{\text{MAB}} - \log \beta_{\text{stat}}$) are reported in Table 2. The results indicate that the above difference has a small positive values, reflecting that MAB system is more stable than both MA_2 and MB_2 . This stability enhancement is referred as a 'ligand effect' which is related to the electrostatic factors originated by charge neutralization, since in the formation of MAB^+ , one positive charge of MA^{2+} is neutralized by ligand B^- . This leads to increase in σ covalence. Moreover, the enhanced stability can also be explained in terms of metal to ligand $d_{\pi}-p_{\pi}$ back bonding which causes metal ion to be more positive or more electronegative [38], as compared with the hydrated metal ions. This permits stronger $\text{M} \leftrightarrow \text{B}$ interaction.

3.4. Distribution diagrams

Using the obtained stability constants of the complexes and equilibrium constants of the ligands under the same experimental conditions, the percentage concentration of each complex species involving metal ion and ligand as a function of pH has been calculated [39]. The pH species distribution profiles for the Cd-GLY binary and Cd-GLY ternary systems taken as a representative are shown in Fig. 4, Fig. 5 and Fig. 6, respectively. Similar trends were obtained for the other systems. The distribution profiles for binary systems show that at lower pH's (2.0–3.0) almost all Cd(II) ions will be present as free ions ($\infty = 88\%$). Over pH range 6.0–7.8 the predominant change is the conversion of Cd(II) into Cd-GLY with a maximum degree of formation 60% at pH 7.3. At pH circa 9.0 the Cd(II) ions are completely disappeared ($X = 3.09\%$) and Cd-GLY complex has low value ($\infty = 8.6\%$) while the concentration of $\text{Cd}(\text{GLY})_2$ predominates ($\infty = 78\%$).

In the case of ternary system, the plots (Fig. 6) show that between pH 7.5–9.3, the concentration of Cd-GLY complex decreases, while the concentration of Cd-GLY-B ternary systems increases. At pH = 8.9 the ternary system reaches maximums, $\infty = 57\%$ while the concentration of binary systems are of small values.

Fig. 5. Species-distribution diagrams for Cd(II)-GLY binary system.

3.5. Structure of the complexes

The synthesized complexes decompose above 300°C and soluble only in polar solvents. The

Fig. 6. Species-distribution diagrams for Cd(II)-GLY-ABI system.

electronic spectra of the solid complexes in DMF solutions show a weak band in the region 480–520 nm, can be assigned to $2E_{2g} - ^2T_{2g}d \rightarrow d$ transition in tetragonal distorted octahedral geometry about Cu(II) [40]. The two broad bands located at circa 410 and 430 nm are characterized by high molar absorptivity. Therefore, these bands may be due to *L*-M(CT) transition environment [41].

The bonding centres can be deduced on the basis of the following IR evidence:

(i) (I) The IR spectra of the azo ligands ABA and ABI exhibit a broad band at circa 3400 cm^{-1} due to the H-bond νOH mode, and a weak multiplet bands in the region 3180–3050 cm^{-1} assigned to νNH reflects strong intramolecular H-bonded to C=O group of the barbiturate ring. The absence of νOH in the IR spectra of the complexes suggests that the *o*-OH group is involved in bonding.

(ii) In ABA, the two strong bands at 1720 and 1660 cm^{-1} are due to free and H-bonded $\nu\text{C}=\text{O}$ stretching vibration, respectively. The absence of the first $\nu\text{C}=\text{O}$ on complexation indicating Cu-O interaction. The shifts of $\nu\text{C}=\text{O}$ stretching located at circa 1250 cm^{-1} in the free ligand, confirming the involvement of the phenolic-OH in chelation.

(iii) The IR spectra of ABI exhibit a band at 1610 cm^{-1} can be ascribed to $\nu\text{C}=\text{N}$ belonging to the imidazole ring. This band is shifted to lower frequencies on complexation, suggesting that N-3 imidazole ring involved in bonding.

(iv) The strong band appearing in the IR spectra of the free ligands ABA and ABI at 1445 and 1440 cm^{-1} , respectively, is attributed to $\nu\text{N}=\text{N}$ stretching mode [41]. On complexation, this band is located at lower frequencies (1430–1415 cm^{-1}) confirms the coordination of the nitrogen of the azo group to Cu(II).

Thus, the IR results reveal that the studied azo ligands in forming of the Cu(II) complexes are behaving as monobasic tridentate through the phenolic *o*-OH, N=N and C=O of barbiturate ring or the heterocyclic N-3 of benzimidazole moiety. This confirms our conclusion that only the phenolic *o*-OH group is deprotonated during complex formation in solution.

Spectrophotometric determination of isoproturon using *p*-aminoacetophenone and its application in environmental and biological samples

Omi Agrawal, Joyce V. Das, V.K. Gupta *

School of Studies in Chemistry, Pt. Ravishankar Shukla University, Raipur 492010 (M.P.), India

Received 4 March 1997; accepted 14 July 1997

Abstract

A simple and sensitive method for the determination of isoproturon, a widely used herbicide is described here which is based on alkaline hydrolysis of isoproturon to its corresponding primary amine followed by diazotization and coupling with *p*-aminoacetophenone in alkaline medium. The absorption maxima of the coloured compound formed is measured at 525 nm. Beer's law is obeyed over the concentration range of 0.5–5.0 μg in a final solution volume of 25 ml (0.02–0.2 ppm). The molar absorptivity and Sandell's sensitivity were found to be $8.6 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$ and $0.0002 \mu\text{g cm}^{-2}$, respectively. The method has been satisfactorily applied to the determination of isoproturon in environmental and biological samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Spectrophotometry; Isoproturon; *p*-Aminoacetophenone; Biological samples

1. Introduction

The phenylurea herbicide *N,N*-dimethyl-*N'*-[4-(1-methylethyl)phenyl]urea popularly known as isoproturon used in wheat, grain, cereals and vegetables [1–3]. Isoproturon is similar to metoxuron in its action as an herbicide but with less toxic effects on crop cultivation [4]. Severe crop damage have been reported at 2 kg/ha, for isoproturon [5].

Few analytical methods such as titrimetric [6], GC [7], and UV-spectrophotometric [8], are available for the purpose of analysis. Spectropho-

metric methods using *p*-dimethylaminobenzaldehyde [9], and ethyl acetoacetate [1] as reagents are also available in the literature for the determination of isoproturon but these are less sensitive and use methanolic sodium hydroxide for the hydrolysis that can affect the colour development of the solution [1]. Hence, there is a need for a simple method for the routine analysis of isoproturon in environmental and biological samples.

Here is a simple, sensitive and selective method using a new reagent, *p*-aminoacetophenone, reported for the determination of isoproturon in various samples. The proposed method is based on the alkaline hydrolysis of isoproturon, followed by diazotization and coupling with *p*-

* Corresponding author.

aminoacetophenone in alkaline medium. The method has been satisfactorily applied for the determination of isoproturon in various environmental and biological samples.

2. Experimental

2.1. Apparatus

A Systronics UV-vis spectrophotometer model 108 with matched silica cells was used for all spectral measurements and a Systronics pH meter model no. 331 was used for pH measurements.

2.2. Reagents

Standard isoproturon solution (of certified grade)—1 mg/ml solution was prepared by dissolving 100 mg of isoproturon in 100 ml methanol [9]. Further working standard solution was prepared by appropriate dilution with deionised water. Sodium hydroxide—4 M aqueous solution. Hydrochloric acid—4 M aqueous solution. Sodium nitrite—1% aqueous solution. *p*-Aminoacetophenone (E. Merck, Germany)—a 2% solution in 25% ethanol. Sulphamic acid—1% aqueous solution.

2.3. Procedure

An aliquot of the test solution containing 0.5–5.0 µg of isoproturon was taken in calibrated tubes to which 1 ml of 4 M sodium hydroxide was added and allowed to stand for 15 min to ensure complete hydrolysis at room temperature. Then 2 ml of 4 M hydrochloric acid and 1 ml of 1% sodium nitrite was added at 0°C temperature, respectively, and allowed to stand in a ice bath for 10 min with thorough shaking. Then the tubes were removed from ice bath and 1 ml of 1% sulphamic acid was added to decompose the excess of nitrite and after 5 min 2 ml of 2% *p*-aminoacetophenone and 2 ml of 4 M sodium hydroxide solution were added

to each tube. Then the solution were kept for 15 min for complete colour development and made up to the mark with distilled water. The absorbance of the solutions were measured at 525 nm against distilled water.

2.4. Determination of isoproturon in polluted water

River water samples receiving run-off water from agricultural fields sprayed with isoproturon were collected. These samples were filtered through a Whatman no. 40 filter paper. Aliquots of water samples were taken in a 25 ml graduated tube [10] and analysed as described above (Table 1).

2.5. Determination of isoproturon in vegetables, foliages, and grains

Various samples, such as beans, onion bulb, oilseed, and wheat [11–14] were collected from the fields where isoproturon was used as a herbicide. The samples were weighed (50 g) and crushed with 20 ml of methanol and filtered. The filtrate was coloured due to presence of organic materials from the plants. The filtrate was passed through a silica gel column (10 × 1 cm) to remove chlorophyll and other interfering materials [15]. The column was washed with 10 ml methanol. The washings were collected in a 50 ml calibrated flask and made up to the mark with distilled water and aliquots were analysed as recommended above and in parallel by the reported method [9] (Table 1).

2.6. Determination of isoproturon in biological samples

Blood and urine samples were collected from the local pathology laboratory. Since these samples were found to be free of isoproturon, synthetic samples were prepared by adding a known amount of isoproturon to these samples and analysed as described above after adding 1 ml of trichloroacetic acid for deproteination and 2 ml EDTA for masking [16,17].

3. Results and discussion

The absorption maxima of the azo dye formed was found to be at 525 nm. The reaction conditions have been optimised to obtain maximum colour development varying one reagent at a time while keeping others constant. It was found that 1 ml of 4 M sodium hydroxide, waiting time of 15 min at room temperature and 2 ml of 4 M hydrochloric acid, 1 ml of 1% sodium nitrite, waiting time 10 min at 0°C temperature are required for complete hydrolysis and diazotization of isotroturon, respectively. One ml of 1% sulphamic acid was sufficient to destroy excess of nitrite. It has been reported that insufficient quantity of sulphamic acid leads to variation of the blank solution due to excess of nitrite [18]. Two ml of 2% *p*-aminoacetophenone followed by 2 ml of sodium hydroxide was sufficient for coupling. In acidic medium the colour obtained was negligible (Fig. 1).

Beer's law was obeyed over the concentration range of 0.5–5.0 µg of isotroturon of the final solution (0.02–0.2 ppm). The apparent molar absorptivity and Sandell's sensitivity were found to be $8.6 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$ and $0.0002 \text{ µg cm}^{-2}$, respectively.

The validity of the method was assessed by investigating the effect of common foreign species and pesticides in the analysis of isotroturon. The tolerance limit values of different foreign species in a solution of isotroturon containing 3 µg per 25 ml of isotroturon are given below in ppm. Ethanol (3000), formaldehyde (2500), 2,4-D and 2,4,5-T (2300), Ca^{2+} , Cu^{2+} (2000), Ethion, Dimethoate (1800), Paraquat (950), SO_4^{2-} (500), Zineb (450).

The S.D. and R.S.D. of absorbance values were found to be ± 0.015 and 2.88%, respectively, for 3 µg/25 ml of isotroturon observed over a period of 7 days.

Application—the method has been satisfactorily applied for the determination of isotroturon in polluted water, environmental and biological samples. The results are in good agreement with the reported method [9]. The results are given in Table 1. To check the recoveries in environmental and biological samples a known amount of isotroturon were added to these samples and analysed by both the proposed and reported method [9]. The recoveries were found to be (92–98.5%). (Table 1).

Fig. 1. Colour reaction. The colour reaction involves the following steps:

1. Hydrolysis of isotroturon to its corresponding primary amine;
2. Diazotisation of resulting primary amine;
3. Coupling of diazotised primary amine with *p*-aminoacetophenone under alkaline condition to form wine red coloured azo dye showing a λ_{max} at 525 nm.

Table 2
Comparison with other spectrophotometric methods

Parameter	<i>p</i> -Aminoacetophenone (proposed method)	Ethyl acetoacetate [1]	<i>p</i> -dimethylaminobenzaldehyde [9]
λ_{max} (nm)	525	398	438
Beer's law range ($\mu\text{g ml}^{-1}$)	0.5–5.0	1.5–15.0	1.125–11.25
Molar absorptivity ($\text{l mol}^{-1} \text{cm}^{-1}$)	8.60×10^5	1.37×10^4	3.09×10^4
Sandell's sensitivity ($\mu\text{g cm}^{-2}$)	0.0002	0.015	0.006

4. Conclusion

The proposed method has been compared with other spectrophotometric method and found to be more sensitive and selective (Table 2).

This method is a good alternative to some of the reported costly instrumental methods. The advantage of the proposed method is mainly its sensitivity, simplicity and selectivity and higher stability of the coloured solution. The proposed method has been successfully applied for the determination of isotroturon in polluted water, environmental and biological samples.

Acknowledgements

The authors are grateful to Pt. Ravishankar Shukla University Raipur for providing facilities. The authors are also thankful to SRF Fine Chemicals, Bangalore for providing the standard isotroturon sample.

Extraction of phenols using polyurethane membrane

Kathy Rzesutek, Art Chow *

Department of Chemistry, University of Manitoba, Winnipeg, MB R3T 2N2, Canada

Received 3 March 1997; received in revised form 14 July 1997; accepted 16 July 1997

Abstract

The extraction of various phenols from aqueous and organic solutions using polyurethane membrane has been investigated. The effects of solution concentration, extraction time, surface area, pH, salts, and temperature on extraction were studied. The phenols are extracted as neutral species and the extraction is governed by a combined effect of intra- and intermolecular hydrogen bonding and nonspecific hydrophobic interactions. The ether-type membrane showed higher extraction capability for the phenols than the ester-type polyurethane membrane. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Phenols; Polyurethane membrane; Extraction

1. Introduction

Polyurethanes have been conventionally used as elastic fibers, rubber foams, and coatings since the 1940s [1]. However, the use of these polymers as sorbents of various organic and inorganic species was proposed only in 1970 [2]. Since then, polyurethanes have been employed in many separation techniques [2]. Most recently, polymer membranes have been preferably used over other polyurethane materials in a variety of industrial, environmental and membrane science applications [3,4]. The extraction of inorganic species by thin polyurethane membrane has been already shown to be feasible [5,6]. The extraction of organic species, on the other hand, has not been as extensively studied. The most significant findings in-

volving extraction of organic compounds have been reported for thick polyurethane membranes by Aminabhavi and coworkers [7–10]. Most of these studies have been concerned either with the effects of organic solvents on the physical properties of the membrane, or with elucidation of the mechanism governing the extraction of the solvent. Nevertheless, a complete understanding of the sorption mechanism at the molecular level is still not well understood. Polyurethanes are linear block polymers containing the characteristic linkage group

where R is a substituted aromatic group and R' is usually a polyether or a polyester [1]. The bulk

* Corresponding author. Fax +1 204 2750905.

structure of polyurethanes is considered to consist of a microcrystalline domain (hard segments) separated by amorphous, random coil regions (soft segments). The isocyanates and the chain backbone comprise the hard regions. The soft segments are the polyether or polyester groups.

This study investigates an extraction mechanism of various phenols by thin polyurethane membrane. Phenols are widely used in industry and so far no single efficient method has yet been developed for their removal [3]. Information on the extraction of phenols can provide a basis for useful predictions of the sorption process of other organic compounds by polyurethane membrane.

2. Experimental

2.1. Apparatus

Spectra and absorbance readings were taken using a Hewlett-Packard Model 8452A diode-array spectrophotometer. Gas chromatographic data was obtained using a Hewlett-Packard 5710A gas chromatograph equipped with a Chromosorb W column coated with 5% bentone 34 and 5% diisodecyl phthalate. Solution pH was measured with an Orion Expandable Ion Analyser EA 940. A modified Burrell Wrist-Action shaker was used for sample agitation at room temperature. A Fisher Versa-Bath® shaking water bath was used for experiments at higher temperatures. Water was obtained from a Barnstead Nanopure II™ purification system fed with water purified by reverse osmosis. Polyurethane membranes, ether-type XPR625-FS and ester-type MP1495-SL were obtained from Stevens Elastomerics/Urethane Products, Northampton, MA. Three thicknesses of 0.025 mm, 0.051 mm, and 0.127 mm were used. All chemicals were of reagent grade. The apparatus used for membrane testing was a 40-ml Kimble Glass Inc. amber glass vial (60960A-912) with a plastic cap and a Teflon™-faced silicone liner. For experiments involving different surface areas of membrane exposed to the sample solution, glass containers having larger caps were used.

2.2. Procedure

Phenol stock solutions were prepared by accurately weighing an appropriate amount of phenol, dissolving it in the solvent and transferring this to a 500-ml volumetric flask which was then filled to volume. Sample solutions of about 2×10^{-4} M (unless otherwise specified) were prepared by transferring an aliquot of the phenol stock solution to a 100-ml volumetric flask. Parameters such as salt, acid, or base concentrations were adjusted prior to dilution to volume.

Sample solutions of *ortho*-, *meta*-, and *para*-xylenes were prepared by diluting a known amount of a particular xylene isomer to 25 ml using hexane. Ten-millilitre aliquots of the phenol and xylene sample solutions were then transferred, using volumetric pipettes, into the sample vials. The polyurethane membranes (ether-type 0.051 mm thick unless otherwise specified) were placed on the openings of the vials and covered with the Teflon™ silicone disks and screw caps and carefully tightened. The vials were then inverted to put the samples in contact with the membranes and shaken for 3 h, except when extraction with time was investigated. The surface of the membrane exposed to the sample solutions was 2.54 cm². For each experiment, triplicate samples were prepared and the experiment was repeated several times to establish reproducibility. The vials containing the samples were weighed prior to and after the extraction to determine if any loss due to leakage may have occurred. The UV visible spectra (190–820 nm) of the phenol sample solutions were taken and the absorbances (A_F) compared with the absorbances of the solutions prior to extraction (A_I). The absorbance readings for the *ortho* and *meta* isomers of bromo and chlorophenols were taken at 274 nm and the *para* isomers at 280 nm. The degree of extraction is reported as the % E which is the % decrease of absorption from the solution assuming a Beer's Law dependence.

$$\%E = 100(A_I - A_F)/A_I \quad (1)$$

Xylene sample solutions were analysed using gas chromatography. To determine whether a particular xylene was extracted by the membrane,

<i>p</i> -Chlorophenol	5.55	22	25	28	30

Conditions: $25.0 \pm 2.0^\circ\text{C}$, 10-ml aliquot of an aqueous phenol solution, 0.051 mm ether-type membrane, active surface area of 2.54 cm², % *E* \pm 3% at equilibrium at 3 h.

ratios of the xylene to the internal standard were obtained for the sample solutions and compared with those for the stock sample which was not exposed to the polyurethane membrane. A known amount of an internal standard was added to the sample solution after the extraction and to the same volume of the stock sample solution. *Ortho*-xylene was used as the internal standard for the analysis of *meta*-, and *para*-xylenes; *meta*-xylene was used as the internal standard for the analysis of *ortho*-xylene. The GC injection port and detector temperatures were 150°, the column temperature was 70°C, and the carrier gas (helium) flow rate was approximately 5 ml min⁻¹.

3. Results and discussion

3.1. Effect of phenol concentration on extraction

The choice of the concentration was limited by the solubility of various phenols in the solvents and by the detection limit of the UV-visible spectrophotometer. Solutions having concentrations of 2×10^{-6} M, 2×10^{-5} M, 1×10^{-4} M, and 3×10^{-4} M were extracted. Solutions having 2×10^{-6} M concentration of phenols were extracted more poorly with both ether- and ester-type membranes than the more concentrated solutions (Table 1). For later experiments, 2×10^{-4} M phenol solutions were used.

Table 1 shows that all of the phenols studied are extracted by the polyurethane membrane to a

greater extent when higher solution concentrations are used. During the extraction process three steps are occurring [11,12]: transfer of the phenol from the bulk solution to the solution–membrane interface, penetration of the phenol into the membrane surface, and migration of the phenol from the membrane surface into the bulk of the membrane.

phenol in solution

↓↑

phenol at solution–membrane interface

↑↓

phenol in membrane surface

↑↓

phenol in membrane bulk

(2)

The amount of phenol sorbed from the solution is controlled by the slowest of the above steps in the sorption process [11,13] which in this case may be the transfer of the phenol from the solution–membrane interface to the membrane surface or the migration of the phenol through the membrane bulk [11,13]. If the extraction efficiency was controlled by the distribution coefficient alone, an equal percent extraction of phenol would be expected regardless of the solution concentration. The fact that an increase in extraction was observed with the increase in concentration suggests that another factor must be influencing the sorption of the phenol. At lower phenol solution

concentrations, the concentration gradient created is smaller than at the higher phenol solution concentrations. For the less concentrated phenol solutions, although an equilibrium was attained between the phenol in solution and the phenol sorbed on the surface of the membrane, such an equilibrium may not have been reached within the bulk of the membrane. At lower phenol solution concentrations, the migration rate of the phenol from the surface through the bulk of the membrane will be slower due to the smaller concentration gradient. Since the number of the phenol molecules entering the membrane is lower, there are fewer of these phenol molecules to interact with the membrane. Therefore, there will be less disruption of the intramolecular forces between the membrane groups and migration deeper into the membrane will be slower than when a higher phenol solution concentration is used [13]. Consequently, a lower percentage of phenol is sorbed from the less concentrated solution at the observed equilibrium.

3.2. Effect of extraction time, surface area, and thickness of the membrane on extraction

An attempt was made to estimate the time needed for the extraction to reach equilibrium at room temperature. Extraction over a wide range of time (30 min to 48 h) was measured. All solutions were mechanically shaken for the desired amount of time, and samples were analysed after 30 min and subsequently at 1-h periods up to 10 h. Final readings were taken at 24 and 48 h. These experiments showed that equilibrium was attained within approximately 3 h for solutions containing 2×10^{-4} M concentration of phenols extracted with 0.051-mm thick ether- and ester-type polyurethane membranes. No significant increase in extraction was observed at 48 h as illustrated by the extraction of *m*-bromophenol (Fig. 1). The effects of an increased membrane surface and thickness of the membrane on sorption of phenols from solution were investigated. Results displayed in Table 2 show that the increase in surface area of the 0.051-mm thick membrane exposed to the phenol solution resulted in greater extraction nearly proportional to the area.

Fig. 1. Extraction of *m*-bromophenol with time using the ether- and ester-type polyurethane membranes. Conditions: $25.0 \pm 2.0^\circ\text{C}$, 10-ml aliquot of $\approx 2 \times 10^{-4}$ M aqueous phenol solution, 0.051 mm ether- and ester-type membranes, active surface area of 2.54 cm^2 , $\%E \pm 3\%$. Extraction with the ether-type membrane, ●; extraction with the ester-type membrane, ▲.

The thick membranes (0.051 mm and 0.127 mm) of identical surface area were found to have a higher sorptive capacity than the thin membranes (0.025 mm). This is shown by the results for the extraction of *m*-bromophenol (Table 3) over two time periods with both the ether- and ester-type polyurethane membranes.

When species extract into the solid phase from a solution, the steps shown in Eq. (2) are believed to take place [11,12]. The initial transfer of the phenol is from solution to the membrane surface followed by the migration of the molecule into the bulk of the polymer. Thus the overall sorption

process is basically an absorption and cannot be described solely as adsorption. However, the first step of this process could be considered analogous to the adsorption of gas on a solid surface as described by Langmuir [14]. According to Langmuir, the extent of adsorption is determined by the equilibrium that results from adsorption of gas molecules on the surface and their evaporation from the surface and is proportional to the area of the surface exposed to the gas [14]. Assuming that the phenol molecules in solution behave similarly to the gas molecules, we can represent the initial sorption of the phenol in solution onto the membrane surface, *y*, by a modified Langmuir equation

$$y = by_m C / (1 + bC) \quad (3)$$

where y_m is the amount of phenol sorbed from solution when the monolayer is complete, *C* is the concentration of phenol remaining in solution, and *b* is a sorption coefficient which is constant at a given temperature. Using the above analogy, the initial sorption of phenol from solution onto the membrane surface would be expected to proceed rapidly, which is in part controlled by the solubility of the phenol in the aqueous phase and attraction to the membrane surface, until an equilibrium is reached between the phenol in solution and the phenol sorbed on the surface of the membrane. If the sorption of the phenol by the membrane were only an adsorption process as the one described by Langmuir, no more phenol would be expected to be removed from the solution after an equilibrium at the solution–mem-

brane interface had been attained. We observed that the amount of phenol sorbed by the thin membranes (0.025 mm) does not significantly change with time, but membranes 0.051 mm and 0.127 mm thick sorbed more of the phenol when a longer extraction time was allowed. Because all of the membranes had an identical surface area exposed to the phenol solution, the results show that the phenol must be migrating into the bulk of the thicker membranes, and not back into the solution as described by the Langmuir model. As the phenol migrates into the polymer, the concentration at the solution–membrane interface will be depleted. A concentration gradient is therefore created and more phenol will be extracted by the membrane. No increase in sorption with extended times was observed for extractions with the 0.025-mm thick membranes probably because the material became saturated. Extraction of the phenol from solution using polyurethane membrane cannot therefore be described as an adsorption process because it involves migration of the phenol into the bulk of the membrane and not just its adsorption onto the surface of the polymer.

The smaller change in sorption over time observed for the 0.127-mm ester-type membrane indicates that migration of the phenol through this membrane is probably much slower than through the ether-type membrane. The difference in the rate of transfer of the phenol through the two membrane types suggests that the structure of the membrane may be an important factor in the extraction process. The ester-type polyurethane has a more compact structure than the ether-type

Table 4
Effect of base and acid addition

Acid or base added	% <i>E</i>				
	Zero addition	0.10 M final concentration	0.50 M final concentration	1.00 M final concentration	2.00 M final concentration
HCl	41	41	41	43	42
NaOH	41	9	0	0	0

Conditions: $25.0 \pm 2.0^\circ\text{C}$, 10-ml aliquot of $\approx 2 \times 10^{-4}$ M *m*-bromophenol solution, 0.051 mm ether-type membrane, active surface area of 2.54 cm^2 , % *E* $\pm 3\%$ at equilibrium at 3 h.

because the ester groups are more polar and have a better probability of forming intramolecular hydrogen bonds than the ether groups. Thus, the migration of the phenol through the ester-type membrane may be hindered due to more intramolecular interactions between the membrane ester groups. These interactions may be too strong to be disrupted effectively by the phenol and this can account for the consistently lower sorption obtained with the ester-type polyurethane membrane.

3.3. Effect of pH on extraction

Phenols can be involved in various equilibria with protons which result in neutral, positively, or negatively charged species. It was found that when substituent groups are ionizable, the pH plays an important role in extraction (Table 4). The addition of base resulted in a dramatic decrease in extraction due to the formation of a charged species. Addition of acid did not significantly alter the extraction. This suggests that the phenols must have already been protonated at the 'natural' pH (Table 1) prior to the addition of the acid. The oxygen present in the polyurethane ether and ester groups does not become protonated because the extraction capabilities of both membrane types did not change with the addition of acid. If protonation of the oxygen took place, a decrease in extraction would be observed due to formation of a charged surface which would interact with the neutral phenols less favourably.

3.4. Effect of salts on extraction

The extraction of phenols by polyurethane membrane from salt solutions is shown in Table 5. It is known that charged species which are not extracted by the membrane sometimes can be extracted as ion pairs [16]. Formation of ion pairs can be accomplished using the 'salting out' effect in which a highly concentrated salt solution is added to the solution so that an ion pair is formed which can then extract.

As shown in Table 5, no change in extraction was observed with the addition of salt, therefore no ion pair formation took place. This suggests that the phenols must be present in a non-ionized form in aqueous solution and extract as a neutral species. Furthermore, the ether groups in the membrane probably do not have an initial electrostatic charge when in contact with water because the addition of salt had no effect on sorption. If a charge was present on the membrane surface, the formation of an ion pair would have eliminated this charge resulting in a neutral surface. The neutral surface is more capable of extracting the uncharged phenol molecules, and therefore sorption would have increased. These results are consistent with the data obtained from the experiment involving the effect of pH on extraction.

3.5. Effect of solvent type on extraction

The initial experiments involved the extraction of phenols from water; however, the extraction from organic media could provide additional in-

Table 5
Effect of salt addition

Compound	% <i>E</i>

<i>m</i> -Chlorophenol	34	34	32
<i>p</i> -Chlorophenol	29	29	28

Conditions: $25.0 \pm 2.0^\circ\text{C}$, 10-ml aliquot of $\approx 2 \times 10^{-4}$ M aqueous phenol solution, 0.051 mm ether-type membrane, active surface area of 2.54 cm^2 , % *E* $\pm 3\%$ at equilibrium at 3 h.

formation about the mechanism. The results of the extraction of phenols from various solvents are presented in Table 6. The *meta* and *para* isomers do not show a significant difference in extraction from water, hexane or cyclohexane. The *ortho* isomer, on the other hand, extracts well from water, but very poorly from hexane and cyclohexane. None of the compounds extracted from acetonitrile or ethyl acetate.

Water seems to be the best solvent from which to extract the halophenols. Water may interact with the polar groups of the polyurethane soft segments and swell the membrane. The movement of the larger phenol molecule into the membrane will therefore be easier because the soft segments of the membrane become more widely spaced. Therefore, the sites on the membrane, that may be important in extraction, become more accessible to the phenols. Water may also be acting as a carrier for the phenols which interact with water through hydrogen bonding. Water can bring the phenols into closer contact with the membrane groups and make the transfer of the phenols from the solution into the membrane more favourable. It has been shown that surface tension of the solvent has an effect on the extraction of organic compounds [17]. If the surface tension of the solvent is reduced by the solute, then the solute molecules will concentrate at the surface, whereas if the surface tension is raised, the solute will move away from the surface into the bulk of the solution. Most water-soluble organic compounds are known to reduce the surface tension of water

[17]. Therefore, phenols in water may tend to accumulate in regions of lower concentration, i.e. at the interface between the membrane and water, and then they may be carried by water into the membrane or interact directly with the membrane through nonspecific attraction forces. Hexane has a lower surface tension than water when in contact with the membrane, so the phenols would be expected to extract comparably well from hexane which is observed for the *meta* and *para* isomers but not for the *ortho* isomer. The *ortho* isomer possesses a higher localized charge than the other isomers since the hydroxyl and the halo substituents are closer together. Therefore, this isomer may not be solvated well by hexane or cyclohexane molecules. Since the membrane may itself hold some electrostatic charge in hexane, the *ortho*-phenol may be repelled from the membrane surface and less extraction will result. Extraction from polar organic solvents such as ethyl acetate and acetonitrile was not observed. The phenols are much more soluble in these solvents than in water or hexane. This suggests that the interactions of phenols with the membrane which are responsible for the extraction must be much weaker than the interactions with ethyl acetate and acetonitrile and thus no extraction can result.

3.6. Importance of hydrogen bonding and other nonspecific interactions

Intermolecular and intramolecular hydrogen bonding was found to be important in the extrac-

Table 6

<i>p</i> -Chlorophenol	30	25	28	0	0

Conditions: $25.0 \pm 2.0^\circ\text{C}$, 10-ml aliquot of $\approx 2 \times 10^{-4}$ M phenol solution, 0.051 mm ether-type membrane, active surface area of 2.54 cm², % *E* \pm 3% at equilibrium at 3 h.

tion of phenols by the polyurethane membrane. An example of intermolecular hydrogen bonding would be the bonding between oxygen atoms on the membrane groups and the hydroxyl group or other substituents on the phenol. Intermolecular bonding can also occur between the ether and ester groups on the membrane segments or the membrane groups and solvent molecules. Intramolecular bonding can take place between the hydroxyl group and the other substituents present on the phenol ring. Such hydrogen bonding interactions can only be formed if the two interacting atoms are very close to each other. The bond is quite weak (8–41 kJ) and can be easily formed and broken [18]. The intra and intermolecular hydrogen bonds together appear to collectively influence the extraction of phenol by the polyurethane membrane. These effects can be shown by comparing the extraction of halophenols, in which an intramolecular hydrogen bond is unlikely, with alkyl phenols which can form such bonds. As shown in Table 7, the dialkyl phenols extract to a lesser extent than the halophenols in water (Table 6). The extraction of trialkyl phenols is comparable to the extraction of halophenols. The trialkyl phenols have one methyl group that is not involved in intramolecular hydrogen bonding which therefore is available for interactions with the membrane. The trialkyl phenols are also more non-polar and may preferentially partition into the membrane. The much lower extraction of alkyl phenols in hexane suggests that the phenols must be more soluble in hexane than in the mem-

brane, and thus tend to stay dissolved in the solvent. The isomers which can form the strongest intramolecular hydrogen bonds extract slightly poorer than those in which such bonding is less likely to take place. From this observation it follows that the ability to form intermolecular hydrogen bonds is equally important. Halophenols which are unlikely to form intramolecular hydrogen bonds, can be involved in intermolecular interactions with the membrane or the solvent through the hydroxyl group and the halo substituents. Therefore, they extract better than the dialkyl phenols in which the intramolecular interactions may be competing with the intermolecular interactions. Phenols with trialkyl substituents or compounds that can form more intramolecular hydrogen bonds with the membrane extract even better as shown in Table 7. Extractions obtained with the ether-type membrane are higher than those done with the ester-type membrane. This can be explained by the ability of the ester and ether groups to form hydrogen bonds. The $\text{p}K_{\text{a}}$ for the protonation of the ether oxygen is -3 and the $\text{p}K_{\text{a}}$ for the protonation of the carbonyl oxygen is -6 [19]. The ether oxygen is more basic and therefore better at forming hydrogen bonds with phenols or solvent molecules.

Other weak nonspecific hydrophobic interactions seem to be important in extraction as well. Molecules having a certain balance between the polar hydrogen bond-forming substituents and the non-polar substituents are extracted. Molecules which are either very polar (e.g. 2,4-di-

Conditions: 25.0 ± 2.0°C, ≈ 2 × 10⁻⁴ M solutions, 0.051 mm ether-type membrane, active surface area of 2.54 cm², 10 ml solution, % *E* ± 3% at equilibrium at 3 h.

*Data were obtained using gas chromatography and therefore aqueous solutions were not extracted.

hydroxybenzoic acid, 3,5-dihydroxybenzoic acid) or non-polar (e.g. xylenes) do not extract, as illustrated in Table 7. Thus, sorption of phenols on the membrane is probably accounted for by a combined action of weak dispersion forces together with stronger hydrogen bond forces which depend on the proximity of the hydroxyl group to other substituents.

3.7. Effect of temperature on extraction

When phenols are being sorbed by the membrane, they can be thought of as distributing between the solution (a liquid phase) and the membrane (a solid phase). This can be represented by a distribution ratio, which is the equilibrium concentration in a liquid phase, K_s , divided by the concentration of the phenol in the solid phase, K_m . This ratio will change with temperature because the solubility of the phenol in the two phases changes with temperature. The extraction of organic molecules from liquids into solids is usually expressed as standard affinity, $\Delta\mu^\circ$, which, being a thermodynamic function, is exchangeable with Gibbs free energy [3], ΔG . Thus, if $\mu_m + RT \ln [K_m]$ is the free energy of the phenol in the membrane, and $\mu_s + RT \ln [K_s]$ is the free energy of phenol in aqueous solution,

these will be equal at equilibrium [3], i.e. $\mu_m + RT \ln [K_m] = \mu_s + RT \ln [K_s]$. Thus, at any temperature T , the affinity of the phenol will be

$$\begin{aligned}
 -(\mu_m + \mu_s) &= -\Delta\mu^\circ = RT \ln[K_m] - RT \ln[K_s] \\
 &= RT \ln[K_m]/[K_s] = RT \ln K \quad (4)
 \end{aligned}$$

where, K is the partition ratio. The heat (ΔH°) and entropy (ΔS°) of sorption can be calculated from the partition ratios at two different temperatures or over a temperature range [3]. The assumption is that ΔH° and ΔS° are independent of temperature which holds if a plot of $\log K$ vs $1/T$ is a straight line. Therefore,

$$\Delta H^\circ = -2.303RT_1T_2/(T_2 - T_1) \log K_1/K_2 \quad (5)$$

$$\Delta S^\circ = -2.303R \log K_1/K_2 \quad (6)$$

where T_1 and T_2 are the two temperatures, and K_1 and K_2 are the partition ratios at the two temperatures.

The percentage of extraction of bromophenols and chlorophenols was measured at equilibrium at various temperatures. The results of the extraction of various phenols by ester- and ether-type membranes are presented in Table 8. As an example, the plots of $\log K$ vs $1/T$ for the bromophenols are shown in Fig. 2 and Fig. 3. Extractions of all bromo and chlorophenols at low temperatures

Table 8

Conditions: 10-ml aliquot of $\approx 2 \times 10^{-4}$ M aqueous phenol solution, 0.051 mm ether- and ester-type membranes, active surface area of 2.54 cm², % *E* $\pm 3\%$ at equilibrium, temperature $\pm 1.0^\circ\text{C}$ (for extractions at 4 and 12°C using the ester-type membrane, the equilibrium was reached after 72 h rather than 3 h).

(4 and 12°C) using the ester-type polyurethane membrane (Fig. 3) required 72 h rather than 3 h to reach an equilibrium. The values for K , ΔH° , and ΔS° for bromo- and chlorophenols calculated for extractions with ester- and ether-type membranes are shown in Table 9.

Extractions of all bromophenol and chlorophenol isomers with the ether-type membrane and the *meta* and *para* isomers with the ester-type membrane (Table 8), show a gradual decrease in % *E* with an increase in temperature. Both ΔH° and ΔS° for these extractions are negative, and the entropy change for the sorption is quite small (Table 9). When these phenol isomers move from solution into the membrane, their motion becomes more restricted, and therefore we observe the negative entropy. Since the sorption process also involves a decrease in free energy, then from the thermodynamic relationship $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$, it follows that ΔH° should be negative

which is confirmed by the data. Thus the sorption of these isomers on membrane is an exothermic process and from LeChatelier's principle, it would follow that the extent of sorption (under equilibrium conditions) should decrease with increasing temperature which is observed. Another explanation for the decrease in extraction with an increase in temperature is that the physical structure of the membrane may change at an increased temperature so that the matrix is less accessible to phenol molecules. The higher energy of the membrane segments and the phenol molecules provided by the increased temperature may prevent any stable interactions between the membrane groups and the phenol from forming, therefore producing a lower extraction. A smaller change in entropy observed for the extraction with the ester-type membrane suggests that the freedom of motion of the bromo and chlorophenol molecules in this membrane is higher. This indicates that dur-

ing extraction with the ester membrane, the phenols are more solvated and not as tightly bound as they are to the ether-type membrane.

The *ortho* bromo and chlorophenols showed a different sorption pattern when extracted with the ester-type polyurethane membrane over the 4–90°C temperature range. Extractions of the *ortho* isomers with the ester-type membrane show an extraction maximum at 25°C, and a slight decrease at higher and lower temperatures. Two sets of data were calculated corresponding to two straight line plots for which Eq. (5) and Eq. (6) are valid at equilibrium. The non-linearity of the $\log K$ vs $1/T$ plot for the extraction of the *ortho* isomers using the ester-type polyurethane membrane is due to the combined effect of structure of the *ortho* isomers and the more polar nature of the ester-type polyurethane membrane. Unlike the *meta* and *para* isomers, the *ortho* isomer undergoes a so-called *ortho* effect [15]. The proximity of the substituents allows for intermolecular noncovalent interactions such as hydrogen bonding and charge transfer which may result in the forma-

Fig. 2. Change in partition ratio with change in temperature for extraction of bromophenols using the ether-type polyurethane membrane. Extraction equilibrium was reached at 3 h. Bromophenols: ● *ortho*-, ▲ *meta*-, ■ *para*-.

Fig. 3. Change in partition ratio with change in temperature for extraction of bromophenols using the ester-type polyurethane membrane. Extraction equilibrium was reached at 3 h except for solutions extracted at 4 and 12°C for which the equilibrium was attained after 72 h. Bromophenols: ● *ortho*-, ▲ *meta*-, ■ *para*-.

tion of a localized electronic field [15] in the molecule. The strength of this *ortho* effect is susceptible to temperature changes [15]. The overall sorption of the *ortho* phenols may be a result of a combined effect of the electrostatic interactions with hydrophobic interactions and hydrogen bonding. Because the ester-type membrane is more polar than the ether-type membrane, the electrostatic interactions between the phenol and the membrane are stronger and may induce the formation of more resonance structures of the *ortho* phenol which in turn contribute to the nonlinearity of the plot shown in Fig. 3. The extractions of the *ortho* phenols with both membrane types are generally lower compared to extractions of the *para* and *meta* isomers most likely due to the *ortho* effect. In the *para* and *meta* isomers, the hydroxyl group is separated from the substituent by the largest distance. Therefore, the hydroxyl group can interact more freely with the membrane substituents through hydrogen bonding interactions.

4. Conclusion

The study of the sorption of various phenols by the polyurethane membrane shows that these compounds are extracted in their neutral form.

Ester (4– 90°C)	2.720	–9.66	–8.32

Conditions: 10-ml aliquot of $\approx 2 \times 10^{-4}$ M aqueous phenol solutions, 0.051 mm ether- and ester-type membranes, active surface area of 2.54 cm². Extraction equilibrium was reached at 3 h except for solutions extracted at 4 and 12°C with the ester-type membrane for which the equilibrium was attained after 72 h.

Intra and intermolecular hydrogen bonding interactions of the phenols appear to be important factors governing the extraction process. An increased sorption of the phenol can be attained by providing either a larger surface area exposed to the phenol solution or a thicker membrane that has higher sorption capabilities. Strong intramolecular hydrogen bonding reduces the intermolecular interactions between the phenol and the membrane and results in a lower extraction. The relative solubility of the phenol in the liquid phase and the membrane was also found to influence the sorption. The ether-type polyurethane membrane showed a higher extraction capability for the phenols than the ester-type polyurethane membrane which is related to the differences in the structure of these two membrane types and their ability to interact with the phenols. Room temperature was shown to be optimal for the extractions of phenols. Future studies will involve investigation of these extractions for a wider range of organic compounds in order to obtain a clearer view of the extraction mechanism taking place.

Calix(6)arene carboxylate derivative for solvent extraction separation of iron(III)

R.M. Khandwe, S.M. Khopkar *

Department of Chemical Technology, University of Bombay, Matunga, Bombay 400019, India

Received 24 January 1997; received in revised form 25 July 1997; accepted 29 July 1997

Abstract

Hexaacetatocalix(6)arene was used for the solvent extraction of iron(III). About 7.5×10^{-2} M extractant was used at pH 7.0 for the quantitative extraction of iron(III). The metal from the organic phase was stripped with 1.0 M hydrochloric acid and determined spectrophotometrically as its thiocyanate complex at 480 nm. Iron(III) was separated from large excesses of alkali and alkaline earths in the ratio 1:20. The transition and main group elements were tolerated in the ratio 1:10. The method was extended for the analysis of iron from its mineral, alloy and pharmaceutical preparation. The method is reproducible with $SD \pm 1.10\%$. © 1998 Elsevier Science B.V. Keywords: Iron (III); Separation; Solvent extraction calix(6)arene; Spectrophotometry; Analysis of alloy; Mineral and pharmaceutical samples

1. Introduction

Calixarenes are a class of macrocyclic compounds which show promise as complexing ligands for metals due to their chemical architecture [1,2]. The existence of upper, as well as lower, rim permits effective substitution of the functional group. One such replaceable group is the carboxylene group, i.e. acetate. Hexaacetato calix(6)arene was used in the solvent extraction of cobalt [3] and palladium [4].

Solvent extraction of iron(III) was carried out using several chelating extractants, such as dibenzoylmethane, 8-hydroxyquinoline or dithizone [5]. These methods were not satisfactory however, as either many other metals were coextracted, or anions such as EDTA created strong interference. Extraction with oxygenated solvents, including ethers, were not satisfactory, as in few instances iron(III) was incompletely extracted.

An attempt to use macrocyclic polyethers for solvent extraction of iron was not very encouraging. Dicyclohexyl 18crown6 (DC18C6), dibenzo 18crown6 (DB18C6), or 18crown6 (18C6) extracted iron(III) from 0.1 M hydrochloric acid only in the presence of salting agents such as

lithium chloride [6]. In such extractions, iron(III) was extracted with dicyclohexyl 18crown6 in the presence of titanous chloride from 9 M hydrochloric acid, but in such extraction [7] bivalent iron was only partially extracted.

Supramolecular compounds were never used for the solvent extraction separation of iron(III). In view of our earlier work on extraction of cobalt and palladium [3,4] it was thought worthwhile to explore the possibility of extracting iron(III) with an acetyl derivative of calix(6)arene. An endeavour is made to present such systematic investigations in this paper.

2. Experimental

2.1. Apparatus and reagent

A Jasco V-530 UV-visible spectrophotometer with matched 10 mm glass cuvetts was used.

A stock solution of iron(III) was prepared by dissolving 1.08 g ferric chloride in 250 ml of distilled water containing 5 ml of hydrochloric acid. When the solution was standardised complexometrically [8], it contained 500 µg/ml of iron(III). A diluted solution containing 50 µg/ml of iron(III) was prepared by tenfold dilution of the stock solution.

Hexaacetato-calix(6)arene was synthesised by the procedure reported earlier [3]. Potassium thiocyanate was used in a 2% aqueous solution. Buffer solution of pH 7.0 was prepared in usual manner [8].

2.2. Procedure

An aliquot of a solution containing iron(III) was taken and its pH was adjusted to 7.0 with diluted solution of acetic acid or ammonia solution. The total volume of the solution was made up to 10 ml. Following this, 10 ml of buffer solution (pH 7) was added before extraction. This practice was generally followed during routine extraction in preference to adjusting the pH of the solution. The solution was then transferred to a separatory funnel. To this was added

Table 1
Extraction of iron(III) as a function of pH

10 ml of a 7.5×10^{-2} M solution of hexaacetato-calix(6)arene in toluene. The solution was then shaken for 7 min. The two phases were allowed to settle and separate. Iron(III) from organic phase was stripped with 1 M hydrochloric acid and was determined spectrophotometrically as its thiocyanate complex [9] at 480 nm against the reagent blank. The iron content was computed from the calibration curve.

3. Results and discussion

3.1. Extraction as a function of pH

Iron(III) extracted in the pH range of 1.0–10.0 with 7.5×10^{-2} M hexaacetato calix(6)arene in toluene, when the extraction commenced at pH 4.0, was found to be 63% at pH 6.0 and was quantitative at pH 7.0 (Table 1; Fig. 1). Beyond pH 8.0 extraction began to decrease to 89.1%. Therefore, all extractions were carried out at pH 7.0 in the presence of the ammonium acetate–acetic acid buffer.

3.2. Extraction as a function of reagent concentration

Iron(III) was extracted with varying concentrations of hexaacetato calix(6)arene. The concentra-

tion of the reagent was varied from 1×10^{-2} to 10×10^{-2} M in toluene (Table 2). The extraction was 74% with 1×10^{-2} M extractant, but it was quantitative with 7.5×10^{-2} M of hexaacetato calix(6)arene. There was no special advantage in using higher concentrations of the reagent. The variation in the volume of reagent indicated that the large volume of 1×10^{-1} M of reagent led to no significant improvement in the extraction. Therefore, 10 ml of 10×10^{-2} M of extractant was used throughout these investigations for quantitative extraction of iron(III).

3.3. Extraction with various diluents

Iron(III) was extracted with 7.5×10^{-2} M hexaacetatocalix(6)arene with different solvents used as the diluents (Table 3). The extraction was quantitative only with toluene as the diluent. With

Pt(IV), Rh(III), Co(II), Cr(IV)	0	Interfere

Fe(III), 50 µg.

all other solvents, it was incomplete. For instance, with xylene, nitrobenzene and cyclohexane it was less than 90%, while chloroform, carbon tetrachloride and benzene proved to be poor diluents. Therefore, for routine work, toluene was preferred as the diluent as it also allowed better phase separation.

3.4. Extraction with various stripping agents

After extraction of iron(III), the iron stripped using various mineral acids (Table 4). With 1 M

hydrochloric or 1 M nitric acid, the stripping was quantitative, while with all other acids stripping was incomplete. Stripping was 80% with perchloric acid and 70.0% with 2 M acetic acid. Therefore, 1 M hydrochloric acid was used as the stripping agent, as it facilitated colorimetric determination of iron(III) in chloride media.

3.5. Period of equilibration

The period of equilibration was varied from 1–10 min when iron(III) was extracted at pH 7.0 with 7.5×10^{-2} M hexaacetato-calix(6)arene. The extraction became quantitative within 5 min of shaking. Therefore, the equilibration period of 7 min was maintained during extraction.

3.6. Nature of extracted species

Iron(III) was extracted at pH 7 with varying concentration of an extractant. The plot of log *D* versus log [HR] where [HR] represents extractant concentration showed a slope of 1.45. Therefore, the probable composition of the extracted species is 1:2. Calixarene is a three dimensional network with varying annular space and basket like structure. The metal was trapped in the cone. In the absence of covalent bonding, the metal was held in winged the conformation, wherein aryl groups in the 1,4 position projected outwards like a pair of wings, perpendicular to the aryl groups viz. 2,3,5,6 forming a channel into which other molecules may sit. Thus, iron(III) was held firmly between two calixarene molecules by truly ionic attraction due to the substituted oxygen. However, these findings require further evidence in the form X-ray crystallographic investigations [10].

Table 6
Analysis of real samples

Sample	Iron(III) certified	Iron(III) found (g)	Recovery (%)	Error (±%)
Mineral	25.80	0.26	26.20	+0.40
Alloy	61.80	0.62	62.10	+0.30
Pharmaceutical preparation	36.00	0.025	36.05	+0.05

Average error, ±0.25%.

3.7. Effects of various ions

Iron(III) was extracted in the presence of varying proportions of different ions (Table 5). The tolerance limit was set as the amount of foreign ion causing an error of $\pm 2\%$ in the recovery of iron(III). Most of the anions were tolerated in the ratio 1:60, while alkali and alkaline earths were tolerated in the ratio of 1:20. Indium, aluminium and magnesium were tolerated in the ratio of 1:10 and zinc and cadmium were tolerated in the ratio of 1:5. Molybdenum(VI) and vanadium(V) were tolerated in the ratio of 1:1. However, nickel, copper, cobalt(II), chromium(VI), uranium(VI), palladium(II), platinum(VI) and thorium(IV) showed strong interference. Such interference was eliminated by using either sequestering agents or by resorting to the process of selective extraction.

3.8. Analysis of iron from real samples

The method was extended for the separation and determination of iron(III) from real samples. Such samples consisted of an alloy, mineral and pharmaceutical preparation.

The alloy or mineral samples (0.5 g) were dissolved in 10 ml of concentrated hydrochloric acid and diluted to 25 ml. An aliquot of solution (1 ml) was extracted at pH 7.0 with 10 ml of 7.5×10^{-2} M of hexaacetato calix(6)arene and iron(III) was stripped as usual. It was determined spectrophotometrically as its thiocyanate complex. The results of the analysis are shown in Table 6.

The sample of pharmaceutical (0.5 g) preparation containing iron(III) was dissolved in 10 ml of a mixture of nitric and hydrochloric acid (1:3) evaporated, dissolved in water and made up to a known volume. Iron(III) from the sample was extracted and was determined as per general procedure. The results are shown in Table 6.

4. Conclusion

The proposed method is simple, rapid and selective. It is suitable for separation of iron(III) from vanadium(V), molybdenum(VI), manganese(II) and aluminium(III), with which it is generally associated in minerals. The relative standard deviation was $\pm 1.1\%$ and the entire process of separation and determination requires just 30 min. As little as 10 μg of iron(III) can be easily separated and determined by the proposed method.

Abstract

In the present paper, *N,N'*-dinaphthyl-*N,N'*-diphenyl-3,6-dioxaoctanediamide acts as a specific reagent for enhancing the fluorescence intensity of Eu(III) complex with thenoyl trifluoroacetone (TTA), the spectrofluorimetric determination of trace amounts of Eu(III) based on the above system was carried out and its luminescence mechanism was studied. The excitation and emission wavelengths are 343.6 and 613.3 nm, respectively. The fluorescence intensities vary linearly with the concentration of europium(III) in the range 3.647×10^{-3} – $3.039 \mu\text{g ml}^{-1}$ for the original fluorescence with a detection limit down to $2.279 \times 10^{-4} \mu\text{g ml}^{-1}$ and the standard deviation is $0.063 \mu\text{g ml}^{-1}$ for 10 times measurements, and in the range 7.598×10^{-4} – $0.0243 \mu\text{g ml}^{-1}$ (SD = 0.035 for 15 times measurements), 0.06078 – $0.6100 \mu\text{g ml}^{-1}$ (SD = 0.52 for 10 times measurements) for the first derivative fluorescence signal with a detection limit down to $8.566 \times 10^{-5} \mu\text{g ml}^{-1}$. The interferences of other rare earths and some of inorganic ions are described. This method is a direct, rapid, selective and sensitive analytical method for the determination of trivalent europium in rare earth ore samples and high purity of rare earth oxides. © 1998 Elsevier Science B.V. Keywords: Europium determination; Fluorimetry; Thenoyltrifluoroacetone; *N,N'*-dinaphthyl-*N,N'*-diphenyl-3,6-dioxaoctanediamide

1. Introduction

The chemical properties of the rare earth elements are very similar, consequently, it is difficult to find specific reactions for individual ions, espe-

cially in their mixtures. Due to higher sensitivity and selectivity, fluorescence analyses of rare earth elements have attracted much attention and have also long since become a major subject of our studies [1–6].

Macrocyclic crown ethers, and their open-chain analogues show a high complexation selectivity,

* Corresponding author.

which makes them suitable reagents for investigation of separation and determination of lanthanide ions [7]. When delocalized groups, such as phenyl-, naphthyl-, are introduced onto these polyethers, they will serve as potential luminescent label reagents.

The purpose of this work is to develop a highly sensitive, well selective fluorescent system for the determination of trivalent europium based on the Eu^{3+} ternary complex with thenoyl trifluoroacetone (TTA) and *N,N'*-dinaphthyl-*N,N'*-diphenyl-3,6-dioxaoctanediamide (DDD) in *N*-cetylpyridium chloride (CPC) solution and study its luminescence mechanism.

2. Experimental

2.1. Reagents

Stock solution of Eu^{3+} was prepared by dissolving a desired amount of Eu_2O_3 (99.99% pure), purchased from Hunan rare earth metals institute, People's Republic of China, in concentrated hydrochloric acid, evaporating to near dryness and diluting to the scale with water. *N,N'*-dinaphthyl-*N,N'*-diphenyl-3,6-dioxaoctanediamide (DDD) was synthesized according to the literature [8] and recrystallized product was directly dissolved by acetone to prepare working solution. Other reagents used were of analytical reagent grade and were at least 99.5% pure. Ultrapure deionized water was employed for all dilutions. In experiments, acetone above 4% (V/V) strongly quenches the fluorescence of the complex, so the amount of acetone should be strictly controlled.

2.2. Apparatus

Fluorescence measurements were made on a Shimadzu RF-540 spectrofluorophotometer equipped with a Xenon light source, quartz cuvettes of 1 cm path length and a DR-3 data recorder. The excitation and emission slits were 10 nm. The pH of the solutions used was measured with a SPM-10 acidity meter made in Shanghai, People's Republic of China.

2.3. Procedure

Apparent fluorescence excitation and emission spectra were obtained at room temperature and optimum excitation and emission wavelengths were found from the recording spectra. An appropriate amount of Eu^{3+} , 0.30 ml of $1 \times 10^{-2} \text{ mol l}^{-1}$ TTA, 0.40 ml of $5 \times 10^{-3} \text{ mol l}^{-1}$ DDD, 0.50 ml of $5 \times 10^{-3} \text{ mol l}^{-1}$ CPC and 1 ml of NaAc-HAc (pH = 4.75) buffer were pipetted onto

a 25-ml calibrated tube, respectively. The mixture was diluted to 25 ml with deionized water. After 10 min, fluorescence determination was carried out at 613.5 nm keeping the excitation wavelength at 343.6 nm.

3. Results and discussion

3.1. Fluorescence spectra

The complex of europium(III) with TTA and DDD emits strong Eu^{3+} characteristic fluores-

cence sensitized by the ligands in surfactant CPC and NaAc-HAc ($\text{pH} = 4.75$) buffer solution, and Eu(III) is the only lanthanide ion which is appreciably fluorescent under these conditions. Other lanthanide ions do not show measurable fluorescence in this system except for trivalent samarium ion that shows a very weak luminescent signal.

Fig. 1 shows excitation and emission spectra of Eu(III)-TTA-DDD ternary system (I) in $2.5 \times 10^{-4} \text{ mol l}^{-1}$ CPC solution with $\text{pH} = 4.75$ and corresponding Eu(III)-TTA binary system(II).

Eu^{3+} -TTA binary system fluoresced weakly at $\lambda_{\text{em}} = 613.2 \text{ nm}$ when irradiated with ultraviolet light $\lambda_{\text{ex}} = 348.4 \text{ nm}$. But when DDD was introduced in the above system the fluorescence inten-

sity of the mixture solution was enhanced by 10–100-folds, λ_{ex} shifted to 343.6 nm and λ_{em} to 613.5 nm. For hydrate trivalent europium ion, very weak emission was observed at $\lambda_{\text{em}} = 609.2$ nm with 279.6 nm exciting. Under optimum conditions, no appreciable emissions at above emission wavelengths were observed for the free reagents without Eu(III) ion. It is evident that DDD sensitizes luminescence of europium(III) binary complex with TTA through intramolecular energy transfer [9].

Under the determinate conditions, other β -diketone, such as dibenzoyl methane, acetylacetone, benzoylacetone, or 1-phenyl-3-methyl-4-benzoyl-pyrazolene-5 as primary ligand and DDD as secondary ligand did not sensitize Eu(III) fluorescence.

3.2. Factors affecting relative fluorescence intensity

Because DDD does not dissolve in water, appropriate surfactant must be added to enhance its water-solubility. In this paper, two kinds of cationic surfactants, i.e. *N*-cetylpyridium chloride (CPC), cetyltrimethyl ammonium bromide (CTMAB); three kinds of anionic surfactants, i.e. sodium dodecylbenzene sulfonate (DBS), sodium naphthyl-1,5-disulfonate (NDS) and sodium lau-

ryl sulfate (LS); and two kinds of non-ionic surfactants, i.e. Triton X-100 and polyethylene glycol octaphenyl ether (emulsifier OP) were tested. It was shown that all of the surfactants mentioned above made DDD soluble in water media. However, in CPC solution the ternary complex of trivalent europium ion with TTA and DDD emits the strongest fluorescence, so CPC was applied in further experiments.

The effect of *N*-cetylpyridium chloride concentration on the fluorescence intensity was investigated. Fig. 2 shows that when CPC concentration is less than $4.0 \times 10^{-6} \text{ mol l}^{-1}$, the fluorescence intensity increases with CPC concentration increasing. When the concentration of CPC reaches $4.0 \times 10^{-6} \text{ mol l}^{-1}$ the fluorescence intensity reaches constant until $1.5 \times 10^{-4} \text{ mol l}^{-1}$ where the fluorescence intensity starts to decrease. In further experiments a $1.0 \times 10^{-4} \text{ mol l}^{-1}$ CPC solution was employed.

Fig. 3 shows the influence of the amount of TTA on luminescence intensity. When the concentration of TAA was controlled between 8.0×10^{-5} and $1.6 \times 10^{-4} \text{ mol l}^{-1}$, the system showed the strongest fluorescence intensity, and the excess of TTA made the complex fluorescence quench slightly owing to the reagent self-absorption. Therefore, $1.2 \times 10^{-4} \text{ mol l}^{-1}$ was selected as optimum TTA concentration. Fig. 4 shows the

^b Containing 0.8891 μg ml⁻¹ Y(III).

effect of the DDD concentration on the determination signal fluoresced by the ternary complex solution containing 4.0×10^{-7} mol l⁻¹ of europium. The maximum fluorescence intensity lies between 6.0×10^{-5} mol l⁻¹ and 2.0×10^{-4} mol l⁻¹, and higher DDD concentration decreased the fluorescence intensity. Besides, in a solution containing higher concentration of DDD appeared some deposit. So a reagent concentration of 8.0×10^{-5} mol l⁻¹ was taken as optimum.

The pH effect was studied in the range of 2.00–11.00 by adjusting the pH with 0.5 mol l⁻¹ hydrochloric acid or the same concentration of sodium hydroxide solution. The results indicate that the emission intensity remained constant in the pH range of 4.50–6.50. After having studied a series of different buffer systems, it was found that the fluorescence was the strongest in sodium acetate—acetic acid buffer. Hence this buffer with pH = 4.75 was used. And the results showed that 1 ml was the optimum amount of NaAc-HAc buffer.

The effect of the time on the fluorescence intensity was investigated with 0.06078 μg ml⁻¹ Eu(III) in NaAc-HAc buffer solution (pH = 4.75). The results show that the solutions were allowed to stand under normal laboratory conditions. The maximum fluorescence intensity can keep at least 5 h. Continuous irradiation for 24 h caused reduction of 10.9% in the fluorescence intensity.

3.3. Composition of the ternary complex

The stoichiometry of the Eu(III)-TTA-DDD

ternary complex in CPC and NaAc-HAc buffer solution was measured by Job's continuous variation method. The results were shown in Fig. 5. As shown in Fig. 5(a), in the ternary complex the composition ratio of DDD and Eu(III) is 1:1, and similarly the composition ratio of TTA and Eu(III) is 3:1. So the ternary complex has a composition formula of Eu(TTA)₃DDD.

3.4. Calibration graph

The calibration graph for the determination of Eu(III) was constructed under the optimal conditions with original signal and the first derivative fluorescence signal ($\Delta\lambda = 5$ nm) respectively. Excellent linearity $F = 0.3174 + 117.52 C_{Eu}$ ($R = 0.99953$, and $SD = 0.063$ for 10 times measurements) was obtained over the range 3.647×10^{-3} – $3.039 \mu\text{g ml}^{-1}$ Eu³⁺ for the original fluorescence, and $F = 2.4317 + 1221.60 C_{Eu}$ ($R = 1$, $SD = 0.035$ for 15 times measurements) over the range 7.598×10^{-4} – $0.02431 \mu\text{g ml}^{-1}$ Eu³⁺ and $F = 3.4744 + 70.517 C_{Eu}$ ($R = 0.99932$, $SD = 0.52$ for 10 times measurements) over the range 0.06078 – $0.6100 \mu\text{g ml}^{-1}$ Eu³⁺ for the first derivative fluorescence signal. The detection limits were down to 2.279×10^{-4} and $8.566 \times 10^{-5} \mu\text{g ml}^{-1}$, respectively, that were calculated by multiplying the standard derivation of 15 blank measurements by three and dividing by the slope of the linear calibration curve. The results showed that the first derivative method is more sensitive than original fluorescence method in this system.

Table 3
Analysis of the rare earth ore sample

Baotou ore sample ^a	Known Eu ₂ O ₃ %	Found Eu ₂ O ₃ %	Average Eu ₂ O ₃ %	Recovery (%)	RSD (%)
	0.20%	0.205, 0.208, 0.213, 0.197, 0.215	0.208	103.8	3.43

^a Rare earth chloride ore sample was supplied as present by Baotou Rare Earth with a composition La₂O₃ (23.0%), CeO₂ (50.0%), Pr₆O₁₁ (4.60%), Nd₂O₃ (15.0%), Sm₂O₃ (1.10%–1.40%), Eu₂O₃ (0.20%), Gd₂O₃ (0.36%), all of other heavy rare earth oxides are less than 1.0%.

The effects of various ions on the determination of Eu(III) ion with a concentration of 0.1520 µg ml⁻¹ were investigated by the proposed method in order to determine its selectivity and its potential application to the assay of Eu(III) in ore samples and rare earth oxides. The results are given in Table 1. Tolerance limit in Table 1 is the highest tolerance amount of foreign ions when relative error is not more than 5% for europium determination.

4. Application of the method

The procedure was used to the determination of trace amounts of europium in high purity of Y₂O₃ matrix and Baotou rare earth ore samples. The results shown in Tables 2 and 3 revealed that the developed method is very suitable and can be successfully used. From the results presented it can be concluded that the proposed method is a simple, rapid, stable, sensitive and selective method for the determination of trace europium.

Determination of yttrium, scandium and other rare earth elements in uranium-rich geological materials by ICP–AES

G.V. Ramanaih *

Chemical Laboratory, Atomic Minerals Division, Department of Atomic Energy, Begumpet, Hyderabad-500 016, India

Received 6 March 1997; received in revised form 25 August 1997; accepted 28 August 1997

Abstract

A rapid method is described for the determination of yttrium, scandium, and other rare earth elements (REEs) in uranium-rich geological samples (containing more than 0.1% U) and in pitch blende type of samples by inductively coupled plasma atomic emission spectrometry (ICP–AES) after separation of uranium by selective precipitation of the analytes as hydroxides using $H_2O_2/NaOH$ in the presence of iron as carrier. Uranium goes into solution as soluble peruranate complex. The precipitated rare earth hydroxides (including Y and Sc) are filtered and dissolved in hydrochloric acid prior to their aspiration into plasma for their individual estimation after selecting interference free REE emission lines. The method has also been applied to some international reference standards like SY-2 and SY-3 (by doping a known amount of uranium) along with one in-house pitch blende sample and the REE values were found to be in agreement with the most usable values, offering an R.S.D. of 1–8.8% for all the REEs, Y and Sc. The method compared well, with the well-established cation exchange separation procedure. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Rare earth elements; Yttrium; Scandium; Geological materials; Inductively coupled plasma atomic emission spectrometry

1. Introduction

The determination of the rare earth elements in silicate rocks and their constituent minerals is of fundamental importance to modern petrological studies on the origin of igneous, metamorphic and sedimentary rocks. The processes by which rocks have formed have been greatly helped, by a knowledge of the rare earth elements (REE) con-

tents, and accurate determination of the concentrations of these elements in a wide variety of rocks has formed the basis for much research effort by geochemists in recent years. The comparative behaviour of the rare earths together with major elements, trace elements and selected isotopic concentrations are the most widely used data recorded in the recent geochemical literature.

The use of U, Th in nuclear reactors places stringent demands on the levels of impurities and about 35 trace elements are listed in the C787 [1] specifications issued by ASTM for UF_6 and high

* Tel.: +91 40 844101; +91 40 849940; e-mail: Dir@amdhyd.ernet.in

purity ThO₂. Therefore, some of the REEs' like Sm, Gd, Dy, Tb, Er, and Tm, if present in uranium are harmful to the efficient functioning of a nuclear reactor, even in sub microgram level due to their large neutron absorption cross-section. Furthermore, the determination of REEs' is important due to an increasing demand in the industrial and metallurgical fields. Accurate determination of the REEs' in uranium-rich geological materials, as well as in nuclear grade uranium, is therefore, essential prior to its use as a nuclear fuel at different stages.

In case of high uranium-bearing geological samples a preliminary separation of the REEs' is to be carried out to avoid spectral, as well as the matrix interferences of uranium on Sm, Gd, Tb, Er and Tm. Furthermore, uranium being a line rich emitter in inductively coupled plasma (ICP)-source, emits more than 1500 lines [2] thereby interfering on almost all emission lines of the studied elements. Therefore, uranium has to be separated from the trace REE as soluble peruranate complex by treating the sample solution with H₂O₂ in the presence of NaOH prior to their quantification by inductively coupled plasma atomic emission spectrometry (ICP-AES). Iron is used as carrier substrate for trace rare earth hydroxides during the separation of uranium.

A number of instrumental methods are now available for accurate determination of REEs' at various concentration levels viz. instrumental neutron activation analysis (INAA) [3], atomic absorption spectrometry (AAS) [4], spectrophotometry [5], X-ray fluorescence spectrometry (XRF) [6], DC arc emission spectrography [7], electron microprobe analysis (EMPA) [8], ICP-AES [9–13] and inductively coupled plasma mass spectrometry (ICP-MS) [14]. ICP-AES has now been established as a powerful analytical technique for the estimation of REEs' in the presence of high amounts of matrix elements preferably after separation of major elements by cation exchange column chromatography [15,16], solvent extraction [13] from uranium before quantification. Several workers have studied the applications of ICP-AES for the determination of REEs' in high uranium bearing samples [13,17–19] after chemical separation.

The present investigation reports separation of REE from U-dominant geological samples and subsequent estimation using ICP-AES. Uranium is separated as soluble peruranate complex formed using NaOH and H₂O₂ while REEs' are removed as insoluble hydroxides in the presence of 'Iron' as carrier. Furthermore, the proposed separation technique is very simple, rapid and without the need of costlier ion exchange resins. The method can be applied on a routine basis for such type of samples without adhering to any stringent operating conditions of acidity, elution rate, aqueous-to-organic volume ratio, etc. with more sample throughput, unlike in other cases of separation methods like ion exchange/solvent extraction technique.

2. Experimental

2.1. Instrumentation

All measurements were made using a ICP-AES model-8410 (GBC, Australia) plasmascan spectrometer, employing a computer controlled rapid scanning monochromator with the operating parameters presented in Table 1. The readings were obtained using a single point calibration method by calibrating the instrument with 1 µg/ml for, Sc, Eu, Yb, and Lu and 10 µg/ml for Y and the rest of the REE. The detection limits obtained under the above optimised conditions

are in the range of 0.00014 $\mu\text{g/ml}$ in case of Lu (261.542 nm) to 0.0099 $\mu\text{g/ml}$ for Pr (422.293 nm), as reported [20] in an earlier publication from our laboratory.

2.2. Chemicals

All single element REE, Y, Sc (as oxides) 1.0 mg/ml standard stock solutions are made by dissolving Spec Pure rare earth oxides in hydrochloric acid, except CeO_2 (dissolved in a mixture of HNO_3 and H_2O_2 and later converted to HCl medium. Single element working standards were prepared (10 $\mu\text{g/ml}$) by dilution of the stock solution with 0.5 M HCl. Acids and all other chemicals used are of analytical reagent grade.

2.3. Procedure

2.3.1. Uranium rich samples (pitch blende) and other geological samples (U-content 0.1% and above)

Rock sample, 1.0 g, was weighed into 100 ml beaker and treated with 10 ml of 1:2 (HNO_3 :HCl)

mixture and evaporated to dryness on water bath (90°C). The process was repeated, and digested with 50 ml of 0.5 M HCl and filtered. The residue, after ignition in a platinum crucible, was treated with HF and then with HCl, finally fused with 1 g of Na_2CO_3 and dissolved in 0.5 M HCl solution. Both filtrate and residue solutions were combined. Ammonium chloride/ammonium hydroxide precipitation was carried out and if no precipitate was observed, 5 mg of iron solution was added as carrier. The resultant precipitate, after filtration, dissolved in a minimum quantity of HNO_3 and evaporated to dryness in a 100 ml beaker. The residue was digested with 5 ml of 1:4 HNO_3 and treated with 5 ml of H_2O_2 (100 vol) and 20 ml of NaOH (12.5 M) solution and digested in the cold with another 30 ml of distilled water and kept aside for 1 h to allow the precipitate to settle. The precipitate was filtered and washed with 1 M NaOH and 1% (v/v) H_2O_2 solution to make it free from uranium. The process repeated again to decontaminate uranium from the rare earth hydroxides. Finally, the precipitate was transferred from filter paper into a beaker with a few drops of

concentrated HCl and distilled water and dissolved. The solution was made up to 100 ml in 0.5 M HCl.

The estimation of REEs', Y, Sc was carried out at the wavelengths listed in Table 2, Table 3, Table 4, and Table 5 using operating parameters presented in Table 1.

The above separation procedure was tested by adding a known amount of U (200 mg) to CCRMP standards like SY-2 and SY-3.

The method was applied to pitch blende sample and to geological samples. The geological sample solutions were doped with 200 mg of uranium and the decontamination of U was effected using the above recommended procedure. The results obtained along with their % R.S.D. are presented in Table 2, Table 3, Table 4 and Table 5 to validate the efficacy of the proposed procedure. The major matrix element composition of the inhouse pitch blende sample is presented in Table 6.

3. Results and discussion

Calcium, if present, in the sample solutions was found to adsorb uranium while separating uranium as peruranate with NaOH and H_2O_2 and incomplete separation of uranium was observed. For this reason calcium was separated at the stage of solution preparation by carrying out $\text{NH}_4\text{Cl}/\text{NH}_4\text{OH}$ precipitation. This also removes other matrix elements, e.g. Mg including Na from the Na_2CO_3 flux.

Fig. 1(a) shows the chondrite normalized (C_1) plot in respect of REEs' present in the pitch blende sample. $X_{(\text{CN})}$ represents the REE value in the sample divided by the respective REE value of chondrite [21]. The ratios of individual REEs' were plotted against the respective at. no. of the element. REE concentrations in rocks or minerals are usually normalized to a common reference standard, which most commonly comprises the values for chondritic meteorites. Chondritic mete-

orites were chosen because they are thought to be relatively unfractionated samples of the solar system dating from the original nucleosynthesis. However, the concentrations of REE in the solar system are very variable because of the different stabilities of the atomic nuclei. REE with even atomic numbers are more stable and, therefore, more abundant than the REE with odd atomic numbers, producing a zig-zag pattern on a composition abundance diagram.

Therefore, chondrite normalization (i.e. the REE value in the sample divided by the respective REE value of chondrite, $X_{(CN)}$) has two important functions:

1. it eliminates the abundance variation between odd and even atomic number elements; and
2. it allows any fractionation of the REE group relative to chondritic meteorites to be identified like in the case of the Eu- or Ce-anomaly.

The anomaly is positive if $(X_{(CN)} \div X_{(CN)}^*) > 1$ where $X_{(CN)}^*$ is the extrapolated value between the two successive points in the chondrite-normalised plot, and the anomaly, is negative, if the ratio < 1 , indicating oxidizing or reducing conditions or the environment, respectively, during the paragenesis of various crystallising phases. The value of $Y_{(CN)}$ was plotted between those for $Dy_{(CN)}$ and $Ho_{(CN)}$ because of the similarity in properties and ionic radii of the three elements. The crustal abundance [22] of yttrium, Fig. 1(b) shows an excellent agreement with the interpolated value. The REE pattern with a striking negative Eu-anomaly indicates that the studied pitch blende was formed either from Eu-depleted solutions or under a reducing environment during its paragenesis from the solidifying magma.

In geological samples containing high uranium (> 1000 ppm) due to its line rich emission spectra interferes on all the REE ion emission lines and although alternate (interference free) lines could

be selected for some of the REE, extreme care has to be exercised in selecting the line for Sm, Tb, Er, and Tm. Since the correction factors due to inter REE interferences on some of the alternate emission lines do not follow the additive principle and

the spectral bias by uranium is also not always additive, a separation of the REE from uranium has been carried out by the above procedure. Separation of rare earths from high concentration of matrix elements and trace elements in the studied geological materials, including the pitch blende sample and uranium doped CCRMP certified reference standards SY-2 and SY-3 has also been carried out using the often-recommended cation exchange [15,16] separation method. The results obtained by both the methods are in very good agreement in case of all the studied samples including the certified reference standards, SY-2 and SY-3. The method is simple and rapid and easy to operate on a routine basis. The proposed

method offers an R.S.D. of 1.0% at the 398 $\mu\text{g/g}$ level in the case of Sm and 8.8% at 1.7 $\mu\text{g/g}$ level in the case of Lu.

4. Conclusion

The determination of REE, Y, Sc and Th in several U-rich (> 0.1%) geological materials including the pitch blende type of samples has been successfully accomplished by ICP-AES, after separating the analytes from U-matrix by complexing uranium with NaOH/H₂O₂ system and the values are in very good agreement with the reported results. The method is simple, rapid, precise and accurate and has been applied to the certified reference standards, SY-2 and SY-3 (after doping with huge amount of U). In U-rich geological materials, it is important to separate the analytes from U-matrix before estimating by ICP-AES, due to its several spectral interferences on many

of the REE emission lines. In the present system, the U was efficiently complexed by H₂O₂ in presence of NaOH and all the analytes are precipitated quantitatively as hydroxides by using iron as the carrier before dissolving in hydrochloric acid for quantification by ICP-AES.

The proposed separative preconcentration method can be applied successfully to different type of U-rich samples like uraninite, pitch blende, brannerite, etc. on a routine basis.

Abstract

Water-insoluble 8-quinolinolato metal chelates were formed and were stably solubilized in the aqueous solution of a water-soluble polymer, poly(*N*-isopropylacrylamide)(PNIPAAm), at room temperature. When the solution was heated at 50°C, PNIPAAm precipitated and then formed a gum-like aggregate (polymer phase) having a very small volume. Accompanying the polymer precipitation, hydrophobic 8-quinolinolato chelates with cobalt(II), iron(III), nickel(II), and copper(II) ions were efficiently incorporated into the polymer phase. At 0.5% (w/v) of PNIPAAm and 8.0 mM of 8-quinolinol, the recoveries in the incorporation of four metal chelates were quantitative. The fluorescence spectra of a probe suggests that the hydrated polymer in the aqueous solution provides hydrophobic portions which can incorporate hydrophobic metal chelates. The polymer phase was easily taken out from the solution and was dissolved with a small amount of acetonitrile. The resulting solution could be directly introduced into a graphite furnace of atomic absorption spectrometry. The signal intensities for the absorbance of cobalt after concentrating the chelate were 100-fold greater than those before the concentration. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Aqueous solutions of a water-soluble polymer, poly(*N*-isopropylacrylamide) (PNIPAAm) (Fig. 1), when subjected to an increase in temperature, became turbid over a narrow temperature range,

which is referred to as their lower critical solution temperature (LCST) [1–3]. Above the LCST (32–34°C), the polymer becomes water-insoluble and then, forms gum-like precipitates (polymer phase) with a small amount of water separated from the bulk aqueous solution (aqueous phase) containing only a very small percentage (less than 0.001%) of the polymer. In contrast, the polymer phase becomes water-soluble when cooled below the

* Corresponding author. Tel.: +81 426 766793; fax: +81 426 765354; e-mail: saitoht@ls.toyaku.ac.jp

LCST. Therefore, we can conduct reversible precipitation and solubilization of the polymer by warming or cooling the solution.

Such reversible thermo-responsive properties of PNIPAAm have been extensively applied to the methodologies for the separation or the detection of biomolecules such as enzymes, antibodies, cell receptors and DNAs [4–6]. PNIPAAm–biomolecule conjugates and their complex with other biomolecules also exhibit precipitation phenomena at almost the same temperature as the LCST of PNIPAAm. Based on the bio-affinity between biomolecules and PNIPAAm-conjugated biomolecules, highly efficient recovery or highly specific detection of desired biomolecules in the presence of matrix components has been successfully achieved. In contrast, very few studies have been performed on the use of the thermo-responsive polymer as an extracting medium which can incorporate solutes [7].

Recently, we employed the precipitation phenomena of the thermo-responsive polymers, PNIPAAm and poly(vinylmethyl ether), to design a kind of efficient extraction system (polymer-mediated extraction) for hydrophobic compounds such as poly-aromatic hydrocarbons, steroid hormones, and lipids [8–11]. That is, in aqueous polymer solution, any hydrophobic materials present will be solubilized and incorporated into the thermo-responsive polymer assembly. As the polymer aggregates are condensed to an extremely small polymer phase, the hydrophobic compounds that are solubilized in the aqueous polymer solution are efficiently concentrated into this polymer phase. At room temperature, the polymer phase can be dissolved by adding small amounts of water or organic solvent. The resulting solutions containing highly concentrated analytes can be directly applied to several analytical methods such as absorption spectrophotometry, fluorescence spectrophotometry, or high-performance liquid chromatography [8–11].

The important advantage of using polymer-mediated extraction is in the ability to concentrate a variety of hydrophobic analytes (with high-concentration factors) by very simple and rapid procedures. The polymer precipitates could be condensed to a small piece of paste-like solid,

which can be easily taken up from the solution, by just heating and shaking the solution for a few seconds. Thus, instruments, such as a centrifuge, are not necessary for the phase separation. Next, the method is quite safe and cost-saving, because it requires only very small amounts of relatively nonflammable, nonvolatile and nontoxic polymers. This eliminates the need to use the larger volumes of organic solvent. Nontoxic properties of PNIPAAm have been clearly observed based on the extensive application of the polymer in the support of cell-growth [12,13]. Thus, using PNIPAAm is hazard free to the user and the environment. Additionally, the polymer phase can be easily disposed of, because the phase containing small amounts of water can be easily burned with other flammable materials. These facts indicate the great potential of the polymer-mediated extraction for concentrating hydrophobic analytes.

As yet, there appear to be no reports concerning the application of the polymer-mediated extraction to the concentration of hydrophobic metal chelates. Our idea was to use a relatively water-soluble chelating reagent to react with metal ions in water so that the resulting hydrophobic metal chelates would predominantly partition to the hydrated polymer media and thus, become concentrated to the polymer phase following the polymer precipitation. The method would provide a simple and rapid method for concentrating metal ions in water which is compatible with several spectrometric determinations of metals.

Fig. 1. Structure of PNIPAAm.

In this paper, we report the incorporation of metal chelates into the polymer phase to establish the basis for the use of the polymer-mediated extraction as a pre-concentration method of metal ions prior to their determination with graphite furnace atomic absorption spectrometry. 8-quinolinol (Hox) was employed as a chelating reagent, because it can form highly hydrophobic metal chelates with a variety of heavy metal ions. The conditions for achieving efficient concentration of the chelates were studied. Furthermore, the features in the solubilization and incorporation of hydrophobic metal chelates in hydrated polymer media were discussed on the basis of the spectral data of some spectrophotometric probes in the aqueous polymer solution.

2. Experimental

2.1. Apparatus

A Shimadzu atomic absorption spectrometer (AAS) with a graphite furnace atomizer GFA-4A was used for the determination of the metals in the polymer phase. A Jasco double-beam absorption spectrophotometer with 1-cm micro quartz cells (1-mm width) was employed for monitoring the formation or incorporation of metal chelates. The fluorescence spectra of a probe were measured using a Jasco spectrofluorometer FP-777 with a 1-cm quartz cell, in which the cell position was thermostated as $25 \pm 1^\circ\text{C}$.

2.2. Reagents

PNIPAAm was synthesized by free radical polymerization using 2,2'-azobis(isobutyronitrile) (AIBN) as an initiator [14]. *N*-isopropylacrylamide (NIPAAm), obtained from Aldrich (Milwaukee, WI), was purified by recrystallization from the mixture of diethyl ether and petroleum ether (1:10). A 10 g portion of NIPAAm and 0.10 g of AIBN were dissolved in 100 ml dry tetrahydrofuran. The solution was placed into a three-necked round bottom flask and heated at 40°C for 24 h under nitrogen atmosphere. After the solution volume was reduced to approximately 50 ml

by evaporation, it was poured into 1 l of dry diethyl ether. The white precipitates obtained were washed with dry ether and dried in vacuo (9.0 g, yields: 90%, average molecular weight; $M_w = 38\,000$ (by GPC)). A chelating reagent, 8-quinolinol (Hox), received from Wako (Tokyo, Japan) was used after triplicate recrystallization from 50% (v/v) aqueous ethanol. A fluorescence probe, 8-anilinonaphthalene sulfonate (spectrophotometric grade), was obtained from Tokyo Kasei (Tokyo, Japan). Other reagents used were of analytical grade.

2.3. Procedure for LCST determination

LCSTs of PNIPAAm were visually measured. The aqueous solution of PNIPAAm containing prescribed amounts of buffer components or salts were placed in a glass vial, and slowly warmed until it turned turbid. The slope of the temperature change was less than 1°C per 15 min. The temperature at which the solution became turbid was regarded as the LCST.

2.4. Procedure for the extraction of metal chelates

Prescribed amounts of the aqueous solution of 10.0% (w/v) PNIPAAm, 0.100 M Hox, and buffer components were added into the sample solution containing metal ions. The volume of the sample solution was typically 50 ml. After incubating at 50°C for 5 min, the solution was shaken to induce the condensation of the polymer phase. A piece of the polymer phase was taken from the solution and was then dissolved into 5 ml of acetonitrile. The recoveries of the metal chelates incorporated into the polymer phase were calculated from the absorbance at 480 nm for $[\text{Fe}(\text{ox})_3]$ or at 420 nm for other metal chelates.

2.5. Application to graphite furnace AAS

The sample solution (50.0 ml) containing cobalt(II) ion ($< 1 \times 10^{-8}$ M), 0.50% (w/v) PNIPAAm, 8.0 mM Hox, and 50 mM phosphate buffer (pH 7.0) was heated at 50°C . After shaking, the formed polymer phase was recovered

Table 1
Instrumental conditions for graphite furnace AAS

Temperature program	Step	Temperature (°C)	Hold (s)	Ramp (s)	Analytical wavelength (nm)
	1	150	30	0	—
	2	400	0	60	—
	3	500	20	0	—
	4	2300 (Co)	5	0	240.7
		2300 (Cu)	4	0	324.7
		2300 (Fe)	4	0	248.3
		2400 (Ni)	4	0	232.0

from the solution and dissolved using 250 μ l of acetonitrile. A 20 μ l portion of the resulting solution was introduced into the graphite furnace of AAS. The analytical conditions for the graphite furnace AAS are listed in Table 1.

3. Results and discussion

3.1. Phase separation of aqueous PNIPAAm under analytical conditions

Several investigators have studied the effect of salts on the LCSTs of PNIPAAm and other synthetic polymer and related it to the Hofmeister series [15,16]. Under analytical conditions, salts or buffer components are necessary for conducting the formation of metal chelates and thus, would influence the LCST of PNIPAAm.

Fig. 2 summarizes our observations regarding the sensitivity of the LCSTs of PNIPAAm to some salts and buffer components, which are often present in the aqueous solution for the complexation of metal chelates. The polymer precipitates in the region above the respective curves, while homogeneous aqueous solution is obtained below the curves. All of the salts and buffer components examined in this study lowered the LCST of PNIPAAm. Thus, they were useful for conducting the precipitation of PNIPAAm at a lower temperature of the LCST. Among them, sulfate and phosphate salt precipitate more effectively than acetate, chloride, nitrate, or perchlorate.

3.2. Formation and solubilization of metal chelates in aqueous PNIPAAm solution

Four metal ions tested in this study: cobalt(II), copper(II), iron(III), and nickel(II), formed metal chelates with Hox within 1 min in the aqueous solutions of PNIPAAm. Because the solution was homogeneous at room temperature, the complex formation could be conducted by just mild mixing of the solution. It is well-known that uncharged metal-ox chelates are barely dissolved in water [17]. However, the absorbance of the 0.20% (w/v) PNIPAAm aqueous solution containing 2.00×10^{-5} M of iron(III), 2.00 mM of Hox, and 50

Fig. 2. LCST of 2.00% (w/v) of PNIPAAm as a function of the concentration of salt or buffer components. The solutions become turbid in the region above the respective curve, while clear solutions are obtained in the region below the curve. Fig. 3. Recoveries of 8-quinolinolato-metal chelates as a function of pH. Concentration of PNIPAAm is 0.50% (w/v), [metal ion] = 1.00×10^{-5} M, [Hox] = 8.00 mM, (○), Co(II); (●), Fe(III); (□), Ni(II); (■), Cu(II). The values of pH are those at room temperature.

mM of phosphate buffer (pH 7.0) at 480 nm was independent of time, at least for 48 h. This fact indicates quite stable solubilization of the $[\text{Fe}(\text{ox})_3]$ chelate in the aqueous solution of PNIPAAm. Other metal chelates were also stably solubilized in the aqueous polymer solution. PNIPAAm homogeneously solubilizing in the aqueous solution may provide portions which can incorporate hydrophobic chelates.

3.3. Extraction of metal chelates into the polymer phase.

When the solution was heated at 50°C, PNIPAAm precipitated and then formed a yellow-colored (dark gray colored in the case of iron(III) chelate) polymer phase due to the predominant incorporation of metal chelates. Fig. 3 illustrates the extent of metal-ox chelate incorporation into the polymer phase as a function of pH. The fraction of the respective metal chelates in the polymer phase increased with increasing solution pH, reflecting the pH-dependent formation of the metal chelate. At pH 7.0, the recoveries of iron(III), nickel(II), and cobalt(II) were almost quantitative, while they decreased over the higher

pH region probably due to their hydrolysis. In contrast, copper(II) chelate was predominantly incorporated into the polymer phase above pH 9.0. Obviously, the features in Fig. 3 indicate that this system can be regarded as a kind of solvent extraction where the polymer phase acts as an extracting solvent. In Fig. 3, there is a plateau region in the recoveries of the copper(II) chelate from pH 6.5 to 7.5, where the chelate was not quantitatively incorporated into the polymer phase. This plateau region reflects the distribution of 1:1 charged chelate, $[\text{Cu}(\text{ox})]^+$. The charged chelate is probably extracted accompanied by a counter ion such as phosphate. This is one of the unique features in the extraction to the polymer phase. To obtain high recoveries of four metal chelates, a pH 7.0 solution was selected in subsequent experiment.

The dependence of Hox concentration on the recoveries of the respective metal chelates was studied. Fig. 4(a) shows the recoveries of cobalt(II) into the polymer phase as a function of the concentration of Hox. Above 4.0 mM, the recoveries incorporated were quantitative. In the case of other metal chelates, 4.0 mM was adequate for obtaining sufficient recoveries. In this study, the concentration of Hox was adjusted to 8.0 mM.

The concentration of PNIPAAm also influences the recoveries of metal chelates. As illustrated in Fig. 4(b), the extent of cobalt(II) extraction increased with increasing concentration of PNIPAAm. The volume fraction of the polymer phase is expected to be almost proportional to the polymer concentration. The increase in recoveries was the result of increased volume of the phase which can incorporate the chelate. The concentration of PNIPAAm required for the almost quantitative recoveries of cobalt(II) was 0.3% (w/v). On the other hand, the addition of excess polymer lowered the concentration factor, as the formation of the polymer phase had a large volume fraction. The polymer concentration of 0.5% (w/v) was the foremost choice for easy recoveries of the polymer piece with quantitative recoveries and high-concentration factors of metal-ox chelates.

As previously described, the concentration of buffer components lowered the LCST of PNIPAAm.

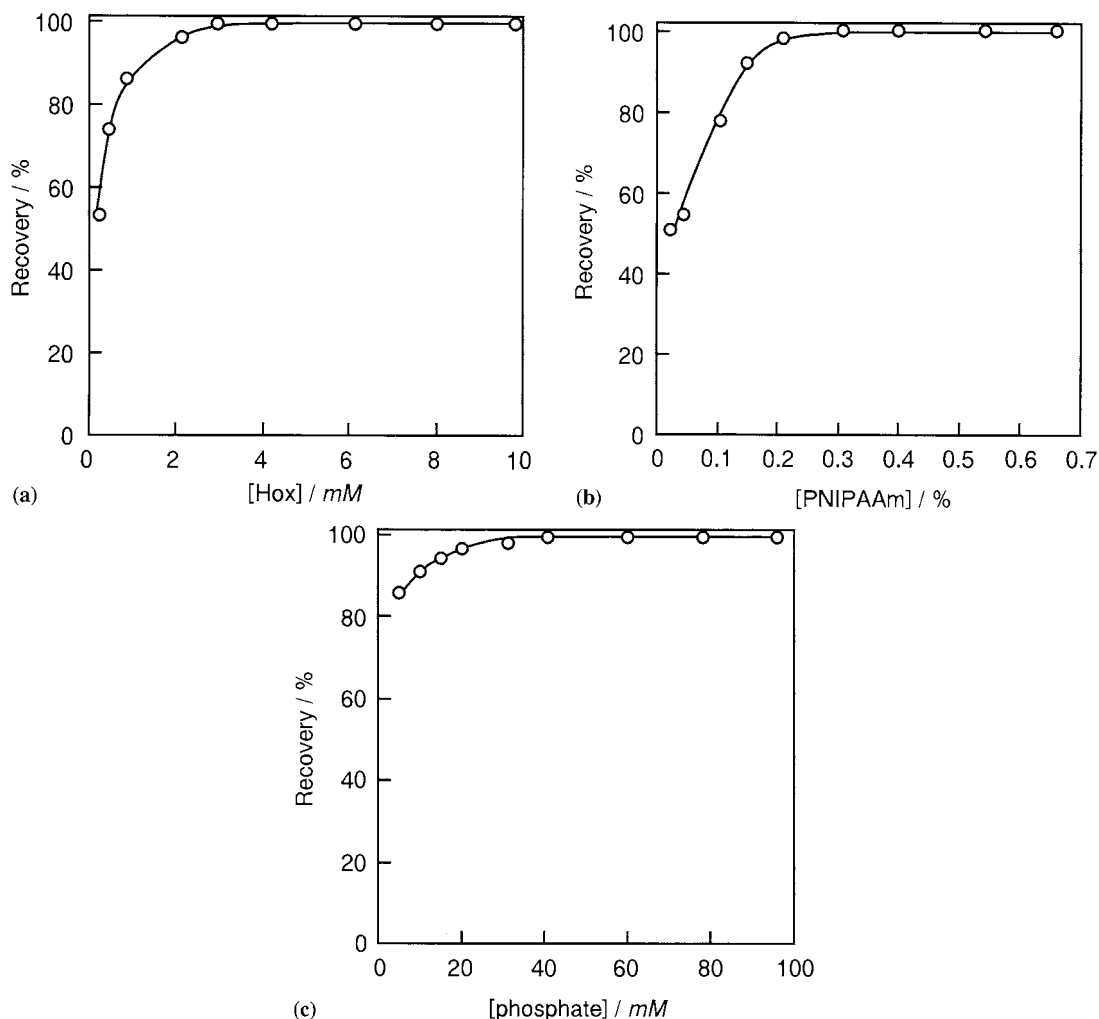

Fig. 4. Recoveries of cobalt(II) as a function of the concentration of Hox (a), PNIPAAm (b), or buffer components (c). (a), Concentration of PNIPAAm; 0.50% (w/v), $[\text{Co}^{2+}] = 1.0 \times 10^{-5}$ M, 0.05 M phosphate (pH 7.0); (b), $[\text{Co}^{2+}] = 1.0 \times 10^{-5}$ M, $[\text{Hox}] = 8.00$ mM, 0.05 M phosphate (pH 7.0); (c), Concentration of PNIPAAm; 0.50% (w/v), $[\text{Co}^{2+}] = 1.0 \times 10^{-5}$ M, phosphate (pH 7.0).

PAAm. In contrast, the temperature (50°C) for conducting polymer precipitation in this study is far higher than the LCST of PNIPAAm. Additionally, the 50 mM concentration of phosphate, described in Section 2 as an optimum condition for the recoveries of metal chelates, can only lower the LCST of PNIPAAm 2°C when it compared with the value in the aqueous solutions containing no buffer components. Thus, the concentration of buffer components does not seem to

be important for effective recoveries of metal chelates. As drawn in Fig. 4(c), however, the recoveries of cobalt(II) were not sufficient in the phosphate concentration region below 40 mM and increased with increasing concentration of phosphate buffer, while becoming almost quantitative above that concentration.

In the absence of salts or buffer components, the solution became turbid but the resulting precipitates still had a tendency to disperse. In con-

trast, the polymer precipitates efficiently condensed and formed a droplet of the polymer phase at the concentration of the phosphate above 40 mM. Buffer components were found to act not only as pH-adjusting reagents, but also as reagents for inducing the condensation of the polymer precipitates. When the phosphate was used as a buffer component, the concentration of 50 mM was recommended.

3.4. Mechanism of the extraction.

As previously mentioned, the stable solubilization of the water-insoluble metal chelates in the aqueous polymer solution strongly suggests that the hydrated PNIPAAm provides certain regions where hydrophobic metal chelates can be incorporated. In order to clarify the presence of these regions, we measured the fluorescence spectrum of 8-anilinonaphthalene sulfonate, ANS, which is a typical fluorometric probe responsible for the polarity of the media [18,19]. As shown in Fig. 5, the fluorescence intensity of ANS in the aqueous solution of PNIPAAm is significantly enhanced when

Fig. 5. Fluorescence spectra of ANS in the aqueous solution containing 1% (w/v) of PNIPAAm (solid lines), no PNIPAAm (dotted lines). $[ANS] = 1.0 \times 10^{-6}$ M, 25°C. Relative intensity is defined by the ratio of the fluorescence intensity against the maximum intensity in the aqueous solution containing no PNIPAAm. Arrows point to the wavelength at the maximum excitation or emission.

compared with that in the solution containing no polymers. Additionally, the wavelength at the maximum emission in the excitation spectrum shifts to the longer side, while that in the emission spectrum shifts to the shorter side. These facts indicate that the hydrated PNIPAAm in the aqueous solution provides hydrophobic regions rather than bulk aqueous solution and that some fractions of ANS were distributed in the regions. Rapid and efficient incorporation of hydrophobic metal-ox chelates into the precipitated polymer phase could be explained by their predominant distribution of the highly hydrophobic chelates into the hydrated polymer media. However, the specific sites for binding hydrophobic solutes in this polymeric material are obscure, because PNIPAAm, whose structure is illustrated in Fig. 1, seems to have no highly hydrophobic moieties. Probably, the hydrated polymer media would have only very low hydrophobicity.

It may be mentioned that the present method is comparable to the extraction of metal chelates on the basis of temperature-induced phase separation in aqueous micellar solutions of nonionic surfactants (termed 'cloud point extraction' in some articles) [20–22]. In contrast to the surfactant micelles, the polymer does not have a critical concentration for forming aggregates. Thus, higher concentration factors can be achieved, if the polymer concentration is set to be very low. The lack of requirement for instruments such as a centrifuge for inducing the phase separation is an additional advantage of the polymer-mediated extraction. The most important advantage of this method is that almost free ligands are present in the bulk aqueous phase. In cloud point extraction, relatively hydrophilic cationic (H_2ox^+), anionic (ox^-), and neutral (Hox) species of 8-quinolinol are also predominantly distributed into the micellar phase not only after but also before the phase separation [23]. The distribution lowers the activity of ox^- in the bulk aqueous phase, significantly decreasing the rate of complexation of ox^- with the metal ions [24]. The rapid formation of 8-quinolinolato-metal chelate in the aqueous PNIPAAm solution can be ascribed to the predominant distribution of free ligand to the bulk aqueous phase.

3.5. Application to graphite furnace AAS.

As already described, hydrophobic metal-ox chelates were efficiently concentrated into the small volume of the polymer phase. Thus, the concentration is expected to significantly enhance the signal intensity in analytical methods. In order to demonstrate the compatibility of the present method with a graphite furnace AAS, we examined the determination of cobalt(II) ion in mineral waters and their spiked samples by graphite furnace AAS after forming ox chelate and then extracting it into the polymer phase.

A piece of the polymer phase could be placed directly into the graphite furnace of AAS. However, the direct injection of the polymer piece had difficulties in the auto-sampling of a number of samples. Thus, we tested the solubilization of the polymer phase with some solvents including water, methanol, ethanol, methoxyethanol, *N,N*-dimethylformamide, dimethylsulfoxide, tetrahydrofurane, and acetonitrile. Among them, acetonitrile was the best choice for obtaining the least viscous sample solution by adding the smallest amounts of solvent.

The conditions for determining cobalt(II) in the sample solution, being composed from the aqueous-acetonitrile solution of concentrated polymer, are listed in Table 1. The conditions consisted of the same time course of temperature for drying and atomization as those recommended by the manufacture for determining cobalt(II) ion in water. Furthermore, the concentrated polymer matrix did not influence the signal intensity of cobalt or the background intensity. These facts indicate a good compatibility of the present method with the graphite furnace AAS.

Fig. 6 illustrates the signals of cobalt over the concentration range from 0 to 5.0×10^{-8} M before (a) and after (b) the concentration. When the concentration was carried out using procedures described in Section 2, approximately 100-fold concentration of cobalt was successfully achieved. The recoveries of cobalt(II) were almost quantitative and independent of its concentration. The relative deviation in the signal for 1.0×10^{-8} M cobalt(II) was 3% ($n=6$) which is almost the same as the measurement with the graphite fur-

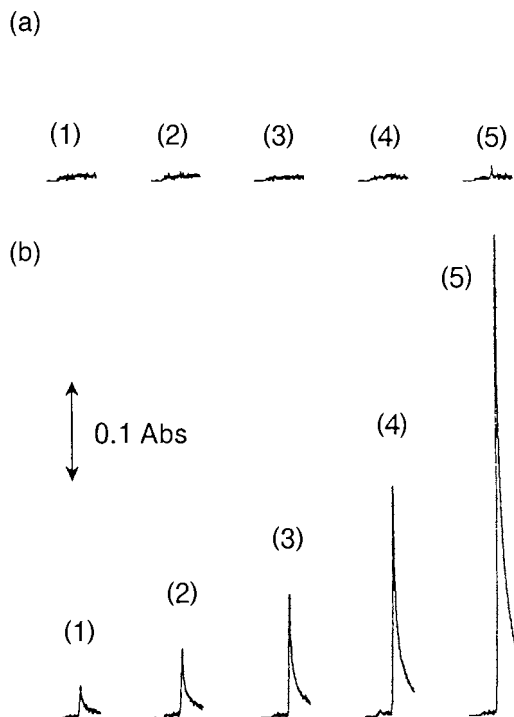

Fig. 6. Illustration of signals for cobalt in graphite furnace AAS. (a), before concentration; (b), after concentration. $[\text{Co}^{2+}]/10^{-8}$ M; (1), blank; (2), 0.5; (3), 1.0; (4), 2.0; (5) 5.0.

nance AAS, meaning quite high reproducibility of the concentration factor in the polymer-mediated extraction. Similarly, iron(III), copper(II), and nickel(II) were also effectively concentrated. The detection limit ($S/N=3$) and linear range of calibration curve were 1 nM, 2–100 nM ($r=0.995$) for cobalt(II), 5 nM, 10–250 nM ($r=0.998$) for iron(III), 1 nM, 2–100 nM ($r=0.998$) for copper(II), and 5 nM, 10–250 nM ($r=0.996$), respectively.

Table 2 lists the tolerance limits of various ions when 1.0×10^{-8} M cobalt(II) is determined by the present method. More than 0.1 M of lithium(I), sodium(I), potassium(I), chloride, bromide, nitrate, sulfate, phosphate, and acetate did not interfere with the signal intensity of cobalt(II). In contrast, the tolerance limit, 1×10^{-5} M, of calcium(II) and barium(II) was very low due to the precipitation of their phosphate salts. In order to heighten their tolerance limits up to 0.05 M, the

Table 2
Tolerance limits of foreign ions for the determination of cobalt (II)^a

Tolerance limit (M)	Foreign ion
>0.1	Na ⁺ , Li ⁺ , K ⁺ , Cl ⁻ , Br ⁻ , NO ₃ ⁻ , SO ₄ ²⁻ , ClO ₄ ⁻ , PO ₄ ³⁻ , acetate
0.05	Mg ²⁺
2 × 10 ⁻⁵	Citrate
1 × 10 ⁻⁵	(Al ³⁺ , Fe ³⁺ , Ni ²⁺ , Cu ²⁺ , Zn ²⁺) ^b (Ca ²⁺ , Ba ²⁺) ^c

^a Tolerance is the concentration which gives less than 5% error in the signal of 1.0 × 10⁻⁸ M of cobalt(II).

^b Not examined in the presence of more than 1 × 10⁻⁵ M foreign ion.

^c Tolerance limit was increased up to 0.05 M using HEPES as a buffer component.

use of 2-[4-(hydroxyethyl)-1-piperazinyl] ethane-sulfonic acid (HEPES) buffer components including 0.1 M sodium chloride was found to be a good alternative. In the case of metal ions which can complex with 8-quinolinol, no influences appeared in the signal of 1 × 10⁻⁸ M cobalt(II) even if 1 × 10⁻⁵ M of iron(III), aluminum(III), copper(II), and nickel(II) were present in the sample solution. The relatively low tolerance limit, 2 × 10⁻⁵ M, of citrate is ascribable to the strong

complexation with cobalt(II) ion.

Table 3 summarizes the recoveries and concentration factors of cobalt(II) when the polymer-mediated extraction is applied to the determination of cobalt(II) in real samples: mineral water and tap water taken from a water cooler. The concentrations of cobalt(II) in waters including spiked samples were successfully determined with very high reproducibility in the recovery and concentration factor. This result indicates that the polymer-mediated extraction of hydrophobic 8-quinolinolato-metal chelates provided an efficient method for concentrating metal ions in water prior to their determination with a graphite furnace AAS. The criteria for optimizing the concentration of metal chelates were almost the same as those for designing the liquid-liquid solvent extraction using the distribution of species between water and water-immiscible organic solvent. However, the procedures in the polymer-mediated extraction of metal chelates were simpler than those of conventional solvent extraction. The application of this method to other samples or the use of other chelating reagents, which form hydrophobic metal chelates, will greatly extend the potential of this method in the pre-concentration of metal ions for spectrometric analysis.

Abstract

Alkali Blue 6B-attached poly(2-hydroxyethyl methacrylate) (poly(HEMA)) microporous films were investigated as chelate forming sorbents for heavy metal removal. Poly(HEMA) microporous films were prepared by UV-initiated photo-polymerization of HEMA in the presence of an initiator (azobisisobutyronitrile (AIBN)). Alkali Blue 6B was attached covalently. These films with a swelling ratio of 58%, and carrying 14.8 mmol Alkali Blue 6B m⁻² which were then used in the removal of Cd(II), Zn(II) and Pb(II) from aqueous media. Adsorption rates were very high, equilibrium was achieved in about 30 min. The maximum adsorption of heavy metal ions onto the Alkali Blue 6B-attached films were 41.4 mmol m⁻² for Cd(II), 52.4 mmol m⁻² for Zn(II), and 64.5 mmol m⁻² for Pb(II). When the heavy metal ions competed during the adsorption from a mixture the adsorption values for Cd(II), Zn(II) and Pb(II) were quite close. Heavy metal ions were desorbed by using 0.1 M HNO₃. A significant amount of the adsorbed heavy metal ions (up to 95%) could be desorbed in 30 min. Repeated adsorption/desorption cycles showed the feasibility of these novel dye-attached microporous films for heavy metal removal. © 1998 Elsevier Science B.V. All rights reserved.

1. Introduction

Heavy metal ions have become an ecotoxicological problem of prime interest and increasing sig-

nificance owing to their tendency to accumulate in living organisms. The necessity to reduce the amount of heavy metal ions in waste water streams of hydro-metallurgical and other industries, and subsequent possible re-use of these metal ions, has led to an increasing interest in selective sorbents [1–3]. Membrane separation, in which semipermeable membranes (mostly micro-

* Corresponding author. Mailing address: P.K. 51. Samanpazari, 06242 Ankara, Turkey. Tel. and fax: +90 312 2352330; e-mail: denizli@eti.cc.hun.edu.tr

porous) are used as selective barriers, is a promising technology from the energy-saving point of view for the selective separation of heavy metal ions [4]. There are basically three phases in the membrane extraction processes for heavy metal removal. Two immiscible phases are separated by a membrane phase which is immiscible with the other two phases. Extraction of metal ions is achieved by the mass transfer between two miscible phases through the membrane phase [5–8].

In the present study, we also utilized microporous membranes in our heavy metal removal system. However, in our case the microporous membrane (film) was not used as the rate and selectivity control phase, but rather as a carrier matrix. A swellable and macroporous carrier film was first prepared by photo-polymerization of 2-hydroxyethyl methacrylate (HEMA). Alkali Blue 6B was then attached covalently as a dye-ligand for heavy metal adsorption. This specific sorbent system in the film form was studied in adsorption/desorption of some selected heavy metal ions, i.e. Cd(II), Zn(II) and Pb(II) from aqueous media.

2. Experimental

2.1. Alkali Blue 6B-attached poly(HEMA) films

The poly(2-hydroxyethyl methacrylate) (poly(HEMA)) film was prepared as previously described [9]. The monomer, HEMA, was obtained from Fluka (Buchs, Switzerland), distilled under reduced pressure in the presence of hydroquinone and stored at 4°C until use. Two ml of HEMA containing 5 mg azobisisobutyronitrile (Fluka, Switzerland) as polymerization initiator was mixed with 3 ml 0.1 M SnCl₄. The mixture was then poured into a round glass mould (9 cm in diameter) and exposed to ultraviolet radiation (12 watt lamp, P.W. Allen, USA) for 10 min under a nitrogen atmosphere. The film obtained was washed several times with distilled water, and cut into square pieces (0.5 cm in length) with a perforator.

Preparation and characterization of the poly(HEMA) films are reported in our previous pa-

pers [10,11]. In order to prepare the films carrying 14.8 mmol Alkali Blue 6B m⁻², the following procedure was applied: 10 ml of solution containing 300 mg Alkali Blue 6B (BDH, UK) was poured into 90 ml of the solution of the poly(HEMA) film pieces in distilled water, and then 4.0 g of NaOH was added. These were then heated in a sealed reactor at 80°C for 4 h at a stirring rate of 400 rpm. The Alkali Blue 6B-attached poly(HEMA) films were filtered, and washed with distilled water and methanol several times until all the physically adsorbed dye molecules were removed. The amount of Alkali Blue 6B molecules covalently attached to the poly(HEMA) film was calculated from the elemental analysis data of the dried samples obtained using an elemental analysis device (Leco, CHNS-932, USA).

FTIR spectra of the Alkali Blue 6, plain poly(HEMA) and Alkali Blue 6B-attached poly(HEMA) films were obtained by using a FTIR spectrophotometer (FTIR 8000 Series, Shimadzu, Japan). The dry poly(HEMA) film (about 0.1 g) was thoroughly mixed with KBr (0.1 g, IR Grade, Merck, Germany), and pressed into a pellet, and the spectrum was then recorded.

2.2. Heavy metal adsorption/desorption

In the first group of experiments, adsorption of Cd(II), Zn(II) and Pb(II) from aqueous solutions containing single metal ions was investigated in batch adsorption–equilibrium experiments. Effects of the initial concentration of metal ion and pH of the medium on the adsorption rate and capacity were studied. 0.02 l Of aqueous metal ion solution with different concentrations (in the range 0.25–4.5 mmol l⁻¹) were treated with the plain and Alkali Blue 6B-attached poly(HEMA) films at different pH (in the range 2.5–7.5, adjusted with HCl and NaOH) at room temperature, in flasks agitated magnetically at 600 rpm. At the end of the adsorption process, the films were separated from the adsorption medium and the concentration of the metal ions in the aqueous phase was measured by using a graphite furnace atomic absorption spectrophotometer (GBC 932 AA, Australia). The amount of adsorbed ions per unit film surface was calculated from the following expression.

$$Q = [(C_0 - C) \cdot V] / A \quad (1)$$

Here, Q is the amount of metal ions adsorbed onto unit surface area of the poly(HEMA) film (mmol m^{-2}); C_0 and C are the concentrations of the metal ions in the solution initially and after adsorption, respectively (mmol l^{-1}); V is the volume of the aqueous phase (l); and A is the surface area of the poly(HEMA) film used (m^2).

In the second group of experiments, competitive adsorption of Cd(II), Zn(II) and Pb(II) from their mixture was investigated in a batch manner. A solution (20 ml) containing 1 mmol l^{-1} from each metal ion was incubated with a Alkali Blue 6B-attached poly(HEMA) film at a pH of 5.0 at room temperature, in flasks agitated magnetically at 600 rpm. After adsorption, concentration of the metal ions in the supernatant was determined with the atomic absorption spectrophotometer.

Desorption of heavy metal ions was studied in 0.1 M HNO_3 . The poly(HEMA) film loaded with metal ions were placed in this desorption medium and stirred at 600 rpm for 30 min at room temperature. The final metal ion concentration in the aqueous phase was determined by using an atomic absorption spectrophotometer. The desorption ratio was calculated from the initial amount of metal ions on the film and the final metal ion concentration in the desorption medium, by using the following equation.

Desorption ratio =

$$\frac{\text{Amount of metal ions desorbed to the elution medium}}{\text{Amount of metal ions adsorbed on the film}} \times 100 \quad (2)$$

In order to evaluate the reusability of the Alkali Blue 6B-attached poly(HEMA) films, the adsorption–desorption process was repeated 3 times with the same film.

3. Results and discussion

The poly(HEMA) films used in the present study were prepared and characterized in our previous papers [9–11]. These films are hydrophilic, cross-linked structures which swell but

do not dissolve in aqueous media depending on the degree of cross-linking density. The equilibrium swelling ratio is 58% (w/w).

Alkali Blue 6B was selected as the affinity dye-ligand, and covalently bonded to the poly(HEMA) films. In Fig. 1, the chemical structure of Alkali Blue 6B is shown. Note that the possible groups to react with divalent heavy metal ions are SO_3H –, NH and OH groups. FTIR spectra of plain poly(HEMA), Alkali Blue 6B and poly(HEMA)-Alkali Blue 6B are given in Fig. 2. FTIR spectra of both poly(HEMA) and poly(HEMA)-Alkali Blue 6B have the characteristic stretching vibration band of hydrogen bonded alcohol, O–H, around 3500 cm^{-1} . The FTIR spectra of Alkali Blue 6B-attached poly(HEMA) has some absorption bands different than those of poly(HEMA). These are at 3510 , 1500 and 670 cm^{-1} and characteristic of N–H stretching, N–H bending (scissoring) and S–O stretching, respectively observed also in Alkali Blue 6B (Fig. 1). Alkali Blue 6B-attached poly(HEMA) has a sharp shoulder absorption band at about 3500 cm^{-1} and is interpreted as the N–H absorption. The bands at 1075 and 1155 cm^{-1} represent symmetric stretching of S=O and asymmetric stretching of S=O, respectively, and are due to Alkali Blue 6B bonded to poly(HEMA). These bands, however, do not appear, because plain poly(HEMA) also has some absorption bands in the same region. Thus, absorption bands of plain poly(HEMA)

Fig. 1. Chemical structure of Alkali Blue 6B.

Fig. 2. FTIR Spectra of: (A) poly(HEMA); (B) Alkali Blue 6B; and (C) Alkali Blue 6B-attached poly(HEMA) film.

overlap with those of the Alkali Blue 6B at around these wavenumbers. The dye attached poly(HEMA) adsorption band intensities in this region are higher than those of poly(HEMA), but the intensity increase is quite small because of the low concentration of Alkali Blue 6B on the polymeric surface. On the other hand the hydrogen bonded alcohol O–H stretching band intensity of plain poly(HEMA) is higher than that of poly(HEMA)-Alkali Blue 6B film. The reason for the loss of the –OH groups is as a result of the condensation reaction between –OH groups of the poly(HEMA) and –NH groups of the Alkali Blue 6B.

Elemental analysis of the plain and Alkali Blue 6B-attached poly(HEMA) films were performed, and the incorporation of the Alkali Blue 6B was found to be 14.8 mmol m^{-2} from the nitrogen and sulphur stoichiometry.

Alkali Blue 6B leakage was also followed. There was no leakage in any of the adsorption and desorption media, which ensured that the washing procedure used for the removal of physi-

cally adsorbed Alkali Blue 6B molecules from the poly(HEMA) film was satisfactory.

3.1. Adsorption of heavy metal ions

3.1.1. Adsorption time

The equilibrium adsorption time of heavy metal ions (i.e. Cd(II), Zn(II) and Pb(II)) on the Alkali Blue 6B-attached poly(HEMA) film was investigated (Fig. 3). Note that these batch experiments were performed by using single (not mixed) solutions of the relevant ions. The initial concentrations of the ions within the aqueous phase were varied in the range $0.25\text{--}4.50 \text{ mmol l}^{-1}$. As seen from Fig. 3, adsorption amounts of metal ion were very high at the beginning of adsorption, and saturation levels were gradually reached within 30 min for all metal ions. Adsorption of metal ions was very fast especially, when the metal ion concentration was high. This may be due to the high driving force, which is the metal ion concentration difference between the liquid (i.e. adsorption medium) and the solid (i.e. the

film) phases, in the case of high metal ion concentration. Notice that Pb(II) was adsorbed

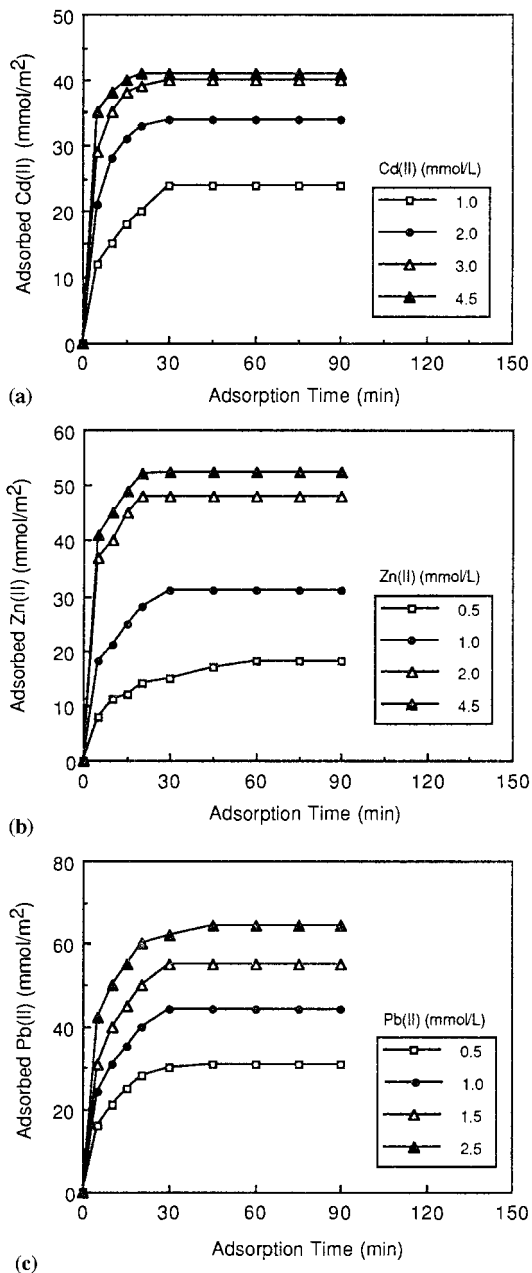

Fig. 3. Adsorption rates of heavy metal ions on the Alkali Blue 6B-attached poly(HEMA) film: (A) for Cd(II); (B) for Zn(II); and (C) for Pb(II). Temperature 20°C and pH 6.0; total film surface area in each batch 0.01 m² l⁻¹.

much faster than Cd(II) and Zn(II) due to the much higher affinity of the ligand (i.e. Alkali Blue 6B) molecules to these ions.

In the literature adsorption kinetics of heavy metal ions by various sorbent systems in film and microsphere form have shown a wide range of adsorption rates. For example, Marchese et al. [5] have investigated separation of cobalt, nickel and copper ions with alamine liquid films and they reported that equilibrium was achieved in about 4–5 h. Teramoto et al. [8] reported that a spiral type supported liquid film module reached the steady state in about 4 h. Reed and Matsumoto [12] have considered 6 h as a short equilibrium time in their cadmium adsorption kinetic studies, in which they have used activated carbon as sorbent. Shreedhara-Murthy and Ryan [13] have investigated mercury, copper, cadmium, lead and uranium adsorption on cellulose-dithiocarbamate resins and reported that the adsorption rates were very slow. Egawa [14] has studied uranium adsorption on polyacrylonitrile fibers containing amidoxime groups and reported 7 h equilibrium adsorption time. Denizli et al. [15] have used Alkali Blue 6B-attached poly(EGDMA-HEMA) sorbents for sorption of Cu(II), Cd(II), Zn(II) and Pb(II) ions and they reported that adsorption was completed in 30–90 min. Note that in such an adsorption process, there are several parameters which determine the adsorption rate, such as sorbent structural properties (e.g. size, porosity, topography and surface area), amount of sorbent, metal ion properties (e.g. hydrated ionic radius), initial concentration of metal ions, chelate-formation rate, and of course existence of other ions which may compete with the ions of interest for the active adsorption sites. All these studies published in the literature has been carried out under different experimental conditions. Hence, it is too difficult to compare the equilibrium adsorption times reported. However, the adsorption equilibrium times are less than 30 min in the case of our film-form sorbent system, which seems to be satisfactory.

Fig. 4. Heavy metal ions adsorption capacity of the Alkali Blue 6B-attached poly(HEMA) films. Temperature 20°C and pH 6.0 and total film surface area in each batch $0.01 \text{ m}^2 \text{ l}^{-1}$.

3.2. Adsorption capacities

3.2.1. Effects of metal ion concentration

The heavy metal ion adsorption capacities of the Alkali Blue 6B-attached poly(HEMA) film are given as a function of the concentration of metal ions in the aqueous phase (Fig. 4). The amount of heavy metal ion adsorbed per unit surface area of the film (i.e. the adsorption capacity) first increased significantly with the initial concentration of metal ions, and then the change in adsorption was much less, after a heavy metal ion-concentration of 2–3 mmol l^{-1} depending on the metal ions. The maximum adsorption capacities achieved in the studied range are 41.4, 52.4 and 64.5 mmol m^{-2} of the sorbent film for Cd(II), Zn(II) and Pb(II), respectively. Note that the dye content of the adsorbent films used in this group of experiments was 14.8 mmol m^{-2} . It seems that a stoichiometry of around 3 metal ions per dye molecule depending on the metal ions. As mentioned before the possible groups to react with divalent heavy metal ions are SO_3H^- , NH and OH groups. N and O atoms with the unpaired electrons are available for these interactions, which means each dye molecule may adsorb more than 3 metal ions (see Fig. 4). But it was not the case here, maybe because of the low initial concentration of the metal ions. Note that it was not possible to get higher initial metal ion concentrations because of the precipitation problem.

It should also be noted that the non-specific adsorption values (adsorptions on the plain poly-(HEMA) film) of heavy metal ions were relatively low, 1.07, 0.94 and 1.21 mmol m^{-2} of the film for Cd(II), Zn(II) and Pb(II), respectively. This adsorption could actually be absorption (or entrapment) of heavy metal ions within the pores of the film. OH groups of HEMA (the unpaired electrons of O atoms) may contribute to these interactions.

Sorbents used in heavy metal removal are in particulate form in most of the cases. Reed and Matsumoto [12] reported 90–120 $\text{mmol Cd(II) m}^{-2}$ with activated carbon having different porosities. Egawa et al. [16] have found 62.1 $\text{mmol uranium m}^{-2}$ removal by amidoxime containing acrylonitrile–divinylbenzene copolymer beads. Maeda and Egawa [17] showed very low adsorption capacities which 1.5 $\text{mmol Pb(II) m}^{-2}$ and 1.6 $\text{mmol Cu(II) m}^{-2}$ with methylmethacrylate–divinylbenzene copolymer beads-amino methyl–phosphonic acid macroreticular chelating resin-containing poly(styrene-divinylbenzene) sorbents. Denizli and colleagues [10,11] used dye-affinity membranes for heavy metal adsorption. The maximum amounts of adsorption capacities achieved were 22.2–61.0 mmol m^{-2} Cd(II), 34.2–79.0 $\text{mmol Pb(II) m}^{-2}$ and 16.8 $\text{mmol Zn(II) m}^{-2}$. Comparing these data it seems that the adsorption capacities achieved with the dye-attached films are satisfactory.

3.2.2. Effect of pH

Heavy metal adsorption is pH dependent [15,18,19]. In the absence of complexing agents, the hydrolysis and precipitation of the metal ions are affected by the concentration and formation of soluble metal species. The solubility of metal ions is governed by hydroxide or carbonate concentration. As discussed in detail by Reed and Matsumoto [20], hydrolysis of metal ions becomes significant at basic pHs. In the present case, precipitation of Cd(II), Zn(II) and Pb(II) ions occur approximately pH 8.5, 7.0, and 7.5, respectively, which also depends on the concentration of metal ions in the medium. Therefore, here, in order to establish the effect of pH on the adsorption of metal ions onto the Alkali Blue 6B-attached

poly(HEMA) films, we repeated the batch equilibrium studies at different pH in the range 2.5–7.5 at low metal ion concentration. Fig. 5 shows the specific adsorption (i.e. adsorption by chelating with the Alkali Blue 6B molecules attached to the poly(HEMA) film) of metal ions. Adsorption of Cd(II), Zn(II) and Pb(II) ions first increased with increasing pH and almost reached a plateau value around pH 4.0–5.0 for all ions.

3.2.3. Competitive adsorption

Competitive adsorption of Cd(II), Zn(II) and Pb(II) ions were also studied. Solutions containing 1 mmol l^{-1} of each metal ion were incubated with the Alkali Blue 6B-attached poly(HEMA) films in batch fashion as described above. Fig. 6 shows that the amount of adsorption for each heavy metal ion is as follows: 31 mmol m^{-2} for Cd(II), 38 mmol m^{-2} for Zn(II), and 52 mmol m^{-2} for Pb(II). It is quite interesting to note that the competitive adsorption capacity of the Alkali Blue 6B-attached poly(HEMA) films for all metal ions were much higher than non-competitive conditions. The total heavy metal adsorption is much higher than one expects from considering the stoichiometry, i.e. the possible number of active sites on the dye molecules. It seems that heavy metal ions on the adsorbed form are interacting with each other, and therefore resulting a multi-

Fig. 5. Effect of pH on adsorption of heavy metal ions on the Alkali Blue 6B-attached poly(HEMA) film. Temperature 20°C and total film surface area in each batch $0.01 \text{ m}^2 \text{ l}^{-1}$. Initial concentration of metal ions 1.0 mmol l^{-1} .

Fig. 6. Competitive adsorption of Cd(II), Zn(II) and Pb(II) ions on the Alkali Blue 6B-attached poly(HEMA) films. Initial concentration of metal ions 1 mmol l^{-1} ; temperature 20°C and pH 6.0; total film surface area in each batch $0.01 \text{ m}^2 \text{ l}^{-1}$.

layer type adsorption (non-Langmuir type). The order of affinity for competitive conditions is as follows: $\text{Pb(II)} > \text{Zn(II)} > \text{Cd(II)}$. This order is the same with non-competitive conditions.

3.3. Desorption and repeated use

Desorption of the adsorbed metal ions from the Alkali Blue 6B-attached poly(HEMA) films was also studied in a batch experimental set-up. The poly(HEMA) films loaded with the maximum amounts of the respective metal ions were placed in the desorption medium containing 0.1 M HNO_3 and the amount of metal ion desorbed in 30 min was measured. The desorption ratio was then calculated by using the expression given in Eq. (2). Table 1 clearly shows that the Alkali Blue 6B-attached poly(HEMA) films can be used repeatedly without significantly losing their adsorption capacities for all metal ions studied here.

4. Conclusions

Macroporous, hydrogel (swelling ratio: 58%) poly(HEMA) films were prepared by photo-polymerization of HEMA. Alkali Blue 6B was then covalently attached to these films with a film phase concentration of $14.8 \text{ mmol Alkali Blue 6B m}^{-2}$ as a dye-ligand. Adsorption/desorption of

Table 1

Heavy metal ions adsorption capacity of Alkali Blue 6B-attached poly(HEMA) films after consecutive adsorption and desorption

Cycle	Cd(II) (mmol m ⁻²)	Zn(II) (mmol m ⁻²)	Pb(II) (mmol m ⁻²)
1 Adsorption	24.1 ± 0.3	31.2 ± 0.4	44.1 ± 0.5
Desorption	23.8 ± 0.2	30.6 ± 0.2	43.8 ± 0.3
2 Adsorption	23.7 ± 0.3	30.4 ± 0.3	43.5 ± 0.4
Desorption	23.5 ± 0.2	30.1 ± 0.2	43.1 ± 0.3
3 Adsorption	23.4 ± 0.4	29.9 ± 0.1	42.7 ± 0.3
Desorption	23.2 ± 0.3	29.7 ± 0.2	42.4 ± 0.4

Total film surface area in each batch 0.01 m² l⁻¹. Initial concentrations of metal ions 1 mmol l⁻¹.

Cd(II), Zn(II) and Pb(II) from aqueous media on these films led to the following conclusions: adsorption equilibria were reached in about 30 min and therefore adsorption rates were very high. Adsorption capacities of these films were 41.4 mmol m⁻² for Cd(II), 52.4 mmol m⁻² for Zn(II) and 64.5 mmol m⁻² for Pb(II). When the heavy metal ions competed (in the case of the adsorption from their mixture) the amounts of adsorption for Cd(II), Zn(II) and Pb(II) were higher with respect to non-competitive conditions, which were 31 mmol m⁻² for Cd(II), 38 mmol m⁻² for Zn(II), and 52 mmol m⁻² for Pb(II). Adsorbed metal ions were desorbed up to 90% by using 0.1 M HNO₃ as the desorption agent. Repeated adsorption/desorption processes showed that these novel dye-attached films are very suitable for heavy metal removal.

Received 12 May 1997; received in revised form 2 September 1997; accepted 3 September 1997

Abstract

A rapid, precise and low cost spectrophotometric method is proposed for the determination of methyl dopa and dopamine in pharmaceutical formulations. The crude extract of sweet potato root (*Ipomoea batatas* (L.) Lam.) was used as an enzymatic source of polyphenol oxidase (PPO; EC.1.14.18.1). This enzyme catalyses the oxidation of catecholamines to the corresponding methyl dopaquinone and dopaminequinone. Those compounds are converted by a rapid spontaneous auto-oxidation to methyl dopachrome and dopaminechrome which have a strong absorption at 480 or 470 nm, respectively. The calibration graphs are linear from 2.0×10^{-4} to 6.0×10^{-3} M. The results obtained by the proposed enzymatic method are in close agreement with those obtained using a Pharmacopoeia procedure and also with the label values. The detection limit (three times the signal blank/slope) was 3.4×10^{-5} and 3.0×10^{-5} M for methyl dopa and dopamine, respectively, the recovery of methyl dopa and dopamine from three samples ranged from 97.5 to 102.9% of the added amount. © 1998 Elsevier Science B.V. Keywords: Methyl dopa; Dopamine; Polyphenol oxidase; Sweet potato (*Ipomoea batatas* (L.) Lam.); Pharmaceutical formulations

1. Introduction

Catecholamines are compounds that consist of amines attached to a benzene ring bearing two hydroxyl groups (catechol). The main sites of catecholamine production are the brain, chromaffin cells of the adrenal medulla and the sympathetic neurons [1]. Methyl dopa (α -methyl-3,4-

dihydroxyphenylalanine) is a centrally acting anti-hypertensive agent and dopamine (3,4-dihydroxyphenylethylamine) is a central neurotransmitter particularly important in the regulation of movement and possesses important intrinsic pharmacological properties. It is used for the correction of hemodynamic disorders associated with shock episodes [2].

Several methods have been employed to determine catecholamine drugs in biological specimens and/or pharmaceutical formulations. The determi-

* Corresponding author. Fax: +55 16 2748350; e-mail: doff@power.ufscar.br

nation of catecholamines in biological fluids normally requires the use of trace analysis techniques, mainly chromatography with fluorimetric or electrochemical detection [3]. Catecholamines are present in relatively large amounts in pharmaceutical formulations and much effort has been devoted to the development of simple, rapid, accurate and precise analytical procedures. Of those methods cited in the literature, some spectrophotometry has been used to determine methyl dopa [4–9] and dopamine [6,10].

A differential UV spectrophotometric procedure has been proposed for the determination of methyl dopa in pharmaceutical formulations in the presence of germanium dioxide at 292 nm. [4]. Methyl dopa has been determined in the visible region after reaction with vanillin [5], metaperiodate [6], potassium bromate [7], 2,3,5-triphenyltetrazolium chloride [8] and Fe(III)-*o*-phenantroline [9] at 420, 473, 485, 485 and 510 nm, respectively. Dopamine has been determined by vis spectrophotometry after a derivatization reaction with metaperiodate in a moderate acid medium [6] and an aqueous alcoholic medium [10], at 473 and 465 nm, respectively. However, there are no enzymatic spectrophotometric procedures for determining those catecholamines described in the literature and only dopamine biosensors using enzymes [12] and vegetal tissue [11,13–15] have been proposed.

In the present work, a spectrophotometric procedure is reported for determining methyl dopa and dopamine in pharmaceutical formulations. A crude extract of sweet potato root (*Ipomoea batatas* (L.) Lam.) was used as an enzymatic source of polyphenol oxidase (PPO; EC.1.14.18.1). This enzyme catalyses the *ortho*-hydroxylation of phenols and the oxidation of other catechol derivatives such as catecholamines to methyl dopaquinone and dopaminequinone. These quinones are converted to leucomethyl dopachrome and leucodopaminechrome and oxidized to methyl dopachrome and dopaminechrome which present a strong absorption at 480 and 470 nm, respectively. The use of an insoluble polyvinylpyrrolidone (Polyclar SB-100) to remove natural phenolic compounds (e.g. chlorogenic and isochlorogenic acids) from solution in the preparation of the crude extract of sweet potato root

led to a considerable increase in enzyme activity. The simple, sensitive and rapid enzymatic method proposed here for determining these catecholamines could be used as an economical alternative to those procedures that use chromogenic reagents [4–10] and/or biosensors [11–15].

2. Experimental

2.1. Apparatus

A DuPont Instruments (Newtown, CN) Model RC-5B centrifuge, provided with a Model SS-34 rotor, was used in the preparation of the crude extract of the sweet potato.

A Hewlett-Packard (Boise, ID) Model 8452A UV-visible spectrophotometer with a quartz cell (optical path 1 cm) was used in all spectrophotometric measurements.

2.2. Reagents and solutions

All reagents were of analytical reagent grade and all solutions were prepared with water from a Millipore (Bedford, MA) Milli-Q system (Model UV Plus Ultra-Low Organics Water). Standard catecholamines (methyl dopa or dopamine) were purchased from Aldrich (Milwaukee, WI); 1.0×10^{-2} M stock solutions were prepared daily in 0.1 M phosphate buffer of pH 7.0 and standardized using a conventional method [16]. Standard solutions from 2.0×10^{-4} to 6.0×10^{-3} M were prepared from stock solutions in 0.1 M phosphate buffer of pH 7.0.

Sucrose, glucose, fructose, lactose, starch, poly(ethylene glycol) 1500, sodium chloride and magnesium stearate were purchased from Sigma (St. Louis, MO). In the interference study, solutions containing 2.0×10^{-4} , 2.0×10^{-3} and 2.0×10^{-2} M of each one of the excipients was carried out using 2.0×10^{-3} M methyl dopa or dopamine solutions.

Polyclar SB-100 was used as a protective and/or stabilizer agent in the crude extract preparation and was kindly donated by GAF (Wayne, NJ). This polyvinylpyrrolidone was initially purified as described by McFarlane and Vader [17]. It was

boiled for 10 min in 10% v/v HCl and washed with distilled water until free of chloride ion, then washed with acetone and dried.

Healthy sweet potato roots (*Ipomoea batatas* (L.) Lam.) purchased from a local producer were selected, washed, hand-peeled, chopped and frozen in liquid nitrogen or in a freezer.

2.3. Preparation of the crude extract

Twenty-five grams of the frozen peeled sweet potato root were homogenized in a liquefier with 100 ml of 0.1 M phosphate buffer (pH 7.0), containing 2.5 g of Polyclar SB-100 for 2 min at 4–6°C. The homogenate was rapidly filtered through four layers of cheesecloth and centrifuged at $25\,000 \times g$ ($18\,000 \text{ rev min}^{-1}$) for 30 min at 4°C. The resulting supernatant was stored at this temperature in a refrigerator and utilized as the enzymatic source after the determination of polyphenol oxidase activity and total protein.

2.4. Measurement of polyphenol oxidase activity

The activity of soluble polyphenol oxidase (PPO) present in the crude extract was determined in triplicate by measuring the absorbance at 410 nm of melanin-like pigments formed in the polymerization of quinone produced by the reaction between 0.2 ml of supernatant solution and 2.8 ml of 0.05 M catechol solution in 0.1 M phosphate buffer (pH 7.0) at 25°C. The initial rate of the enzyme-catalyzed reaction was a linear function with time for 1.5–2.0 min. One unit of polyphenol oxidase activity is defined as the amount of enzyme that causes an increase of 0.001 absorbance min^{-1} under conditions described above [18,19].

2.5. Protein determination

The protein concentration was determined in triplicate using the Lowry et al. method [20] i.e. using bovine serum albumin as standard.

2.6. Spectrophotometric procedure

In a quartz cell, 0.2 ml of the crude extract containing $585 \text{ units ml}^{-1}$ PPO at pH 7.0 was

added to 2.8 ml of sample or standard solution in 0.1 M phosphate buffer (pH 7.0), shaken and the absorption of methyl dopachrome or dopaminechrome was measured at 480 and 470 nm, respectively; (after 10 min of homogenization). It is important to point out that 10 min sampling period is within the linear regime of the reaction.

2.7. Preparation of sample catecholamines in pharmaceutical formulations

The contents of twenty tablets, were mixed well; from the fine powder an accurately weighed portion was taken and dissolved in phosphate buffer (pH 7.0, 0.1 M at 25°C). Using a mechanical shaker or an ultrasonic bath, the powder was completely disintegrated and the solution was clarified by passing it through No. 1 filter-paper, after which appropriate dilutions were made.

For liquid samples an appropriate dilution with phosphate buffer solution was made (pH 7.0, 0.1 M at 25°C).

3. Results and discussion

3.1. Characteristics of the crude extract activity

The activity and total protein of the crude extract of the sweet potato root varied according to the extraction procedure and medium used. The buffer-to-tissue ratio was an important factor in the preparation of PPO from sweet potato root. In this study, the enzyme was extracted using ratios of 2–6:1 v/w and the highest specific activity was obtained at a ratio 4:1 v/w. It was also found that PPO could be extracted with a phosphate buffer solution of low concentration such as 0.05–0.4 M with the maximum yield achieved at a concentration of 0.1 M. The effect of buffer pH on the extraction of PPO was also investigated in the pH range of 6.0–8.0. The highest enzymatic activity was reached at pH 7.0. The natural phenolic compounds (chlorogenic and isochlorogenic acids) and the oxidation by atmospheric oxygen are responsible for the decrease of the PPO activity in the crude extract. In order to minimize this effect, a protective agent

and/or stabilizer such as polyvinylpyrrolidones (PVPs), ion-exchange resins, L-cysteine and/or other reducer compounds have been used. It was found that the Polyclar SB-100 in the concentration ratio of 2.5:25.0 w/w was the best protective agent, once it completely removes the natural phenolic compounds present in this root. The same concentration was found in our previous work [19]. The enzyme activity of crude extract obtained using this PVP did not vary for at least 5 months when it was stored in a refrigerator at 4°C.

3.2. Reaction between methyl dopa and/or dopamine with polyphenol oxidase

Fig. 1 shows the reaction steps of the enzymatic oxidation of catecholamines (methyl dopa and dopamine) [21,22] (A) by polyphenol oxidase of the crude extract to the methyl dopaquinone and dopaminequinone (B), respectively. Furthermore, these quinones are converted to leucomethyl dopachrome, leucodopaminechrome (C) by a fast spontaneous auto-oxidation which are in turn oxidized to the corresponding aminochromes (methyl dopachrome and dopaminechrome) (D), which have a strong absorption at 480 or 470 nm, respectively. The absorption of these chromophores increased rapidly for 9–10 min, than decreased very slowly when converted to 5,6-dihydroxyindole (E), indole-5,6-quinone (F) and finally melanin (G), as shown in this figure.

3.3. Effect of enzyme concentration, pH and temperature

The effect of PPO concentration from 7.8 to 62.6 units ml⁻¹ on the analytical signal (absorbance) for 5.0 × 10⁻³ M dopamine was investigated (Fig. 2). The absorbance signal increases with increasing concentration of enzyme solution used up to 37.0–39.0 units ml⁻¹ PPO and then leveled off between 39.0 and 62.6 units ml⁻¹. Consequently, a concentration of 39.0 units ml⁻¹ was used in this work.

The effect of pH in the range from 5.0 to 8.0 on the absorbance of 5.0 × 10⁻³ M methyl dopa and dopamine solution and 39.0 units ml⁻¹ PPO en-

zyme was also studied and is shown in Fig. 3. As observed, the optimum pH value for PPO activity was 7.0. The same optimum pH was found by Lourenço et al. [18] in pure and crude extracts of sweet potato and by us in previous work [19].

The effect of temperature was studied between 5 and 50°C. The enzyme exhibited highest activity in range 15–25°C after which a gradual decline in its activity by heat inactivation was observed (between 25 and 50°C), a temperature of 25°C was decided on and used in this work.

Fig. 1. Reaction steps of the catalytic oxidation of catecholamines by polyphenol oxidase.

Fig. 2. Effect of polyphenol oxidase concentration from 7.8 to 62.6 units ml^{-1} on the absorbance signal for 5.0×10^{-3} M dopamine in 0.1 M phosphate buffer (pH 7), at 25°C.

3.4. Interference, recovery and repeatability studies

The effect of excipient substances frequently found with catecholamines in pharmaceutical formulations, such as sucrose, glucose, fructose, lactose, starch, poly(ethylene glycol), sodium chloride and magnesium stearate were evaluated using the developed method. The ratios of the concentrations of methyl dopa or dopamine to those of the excipient substances were fixed at 0.1, 1.0 and 10.0. None of these substances in-

Fig. 3. Effect of the pH from 5 to 8 on the absorbance signal for 5.0×10^{-3} M catecholamines: (■ ■ ■), methyl dopa and (● ● ●), dopamine, at 25°C.

Table 1
Results of addition–recovery experiments using methyl dopa and dopamine with three different standard concentrations

Sample	Methyl dopa ^a or Dopamine ^b (mg) ^c		
	Added	Found	Recovery (%)
Aldomet tablet	2.38	2.45	102.9
	4.76	4.82	101.3
	7.15	7.09	99.2
Dopamine injection	1.90	1.87	98.4

terfered with the proposed spectrophotometric method.

Recoveries varying from 97.5 to 102.9% of methyl dopa or dopamine from two pharmaceutical formulations samples ($n = 6$) were obtained using the spectrophotometric procedure (Table 1). In this study, 2.38, 4.76 and 7.15 mg of methyl dopa and 1.90, 3.79 and 5.69 mg of dopamine were added to each sample. This is good evidence of accuracy of the proposed method.

In the repeatability study, the relative standard deviations were 1.27 and 1.68% for solutions containing 5.0×10^{-3} M methyl dopa and dopamine ($n = 10$), respectively.

3.5. Analytical curves and applications

Under the optimum conditions established, i.e. enzyme concentration of 39.0 units ml^{-1} in 0.1 M phosphate buffer, pH 7.0, temperature of 25°C and reference solutions containing 2.0×10^{-4} – 6.0×10^{-3} M of methyl dopa or dopamine were employed to construct the calibration curve ($A = 0.014 + 125.11C_1$, $r = 0.9990$ and $A = 0.011 + 110.92C_2$, $r = 0.9988$ where C_1 and C_2 are the concentrations of methyl dopa and dopamine in M, respectively. Table 2 presents a comparison between the label values and the results obtained for these samples using the Pharmacopeia (HPLC: dopamine and spectrophotometric: methyl dopa)

Table 2

Determination of methyl dopa and dopamine in pharmaceutical formulations using the pharmacopeia and enzymatic spectrophotometric procedures

Sample	Catecholamine	Label value	Pharmacopeia	Enzymatic	Relative error(%)	
					(RE ₁)	(RE ₂)
Aldomet tablet	Methyl dopa ^a	250	254.3	248.7 ± 0.2	−0.5	−2.2
Dopamine injection	Dopamine ^b	50	48.4	47.3 ± 0.1	−5.4	−2.3

$n = 6$, confidence level 95%.

^a (mg tablet^{−1}) and ^b (mg ml^{−1}).

RE₁, enzymatic vs. label value; RE₂, enzymatic vs. pharmacopeia value.

[23] and proposed enzymatic spectrophotometric methods. The results are in close agreement with those reported and within an acceptable range of error. The detection limits (three times the signal blank/slope) were 3.4×10^{-5} M and 3.0×10^{-5} M methyl dopa and dopamine, respectively. The enzymatic method for determination of methyl dopa or dopamine in pharmaceutical formulations reported in this paper is rapid, precise and of low cost and it may be suitable for routine analysis.

Abstract

A new sensitive chemiluminescent detection method for capillary electrophoresis is described. Underivatized amines and amino acids were detected following capillary electrophoresis separation by their chemiluminescent reaction with $\text{Ru}(\text{bpy})_3^{3+}$ generated in situ at 35 μm carbon fibers. Detection limits for triethylamine and proline were 5 and 3 fmol, respectively at a SNR of three. The noise limiting the detectability of separated analytes was determined to exist at the level of the dark noise limit of the PMT used for these studies and additional noise reduction strategies are expected to improve the quantitative aspects of the method. Theoretical plate numbers for proline were approximately 20 000. End column addition of $\text{Ru}(\text{bpy})_3^{2+}$ coupled with in situ generation of $\text{Ru}(\text{bpy})_3^{3+}$, has been shown to be compatible with the nanoliter elution volumes characteristic of capillary electrophoresis. © 1998 Elsevier Science B.V. 1. Introduction

Since initial work involving electrophoretic separations in small diameter tubes by Mikkers et al. in 1979 [1], and Jorgenson and Lukacs, in 1981 [2], much interest has developed around separations based on the CE technique. This interest is primarily due to the unparalleled resolving power associated with CE and the relative simplicity of

the requisite instrumentation. Separation efficiencies approaching 400 000 theoretical plates for selected amino acid derivatives has been demonstrated [2].

The detection of analytes following CE separation is much more challenging than detection following HPLC. The characteristics which make CE an attractive separation technique also make detection difficult. This is due to the small dimensions of the capillary itself and the nanoliter injection volume necessary to maintain the separation efficiency of the CE process. Construction of off-

column detection cells analogous to the detection cells used for UV-vis, fluorescence, and electrochemical detection in HPLC is problematic due to the small dead-volumes required to provide efficient detection without causing excessive zone broadening. Frequently absorbance, fluorescence, or other optical techniques employ on-column detection. In on-column detection, the polyamide coating on the capillary is removed at a position along the separation capillary, and this region is then used as the 'detection cell'. The pathlength of such a configuration is defined by the i.d. of the capillary and the sensitivity of absorbance detection is limited by this short pathlength [3].

An additional problem associated with detection following CE is the electric field used to drive the separation process. This electric field does not present a problem for optical techniques, but it presents a major problem for electrochemical (amperometric) forms of detection. Electrophoretic currents in the order of microamp are much larger than the nanoamp to picoamp Faradaic currents which would be expected for the micro-electrodes appropriate for amperometric detection in CE. Large electrophoretic currents make direct amperometric detection in CE difficult unless the electrophoretic potential field is first decoupled from the amperometric detection cell.

Effective decoupling of the electrophoretic field from the amperometric detection cell was first achieved by Wallingford and Ewing [4]. A porous glass capillary (decoupler) having an internal bore of the same diameter as the outside of the separation capillary was placed over a carefully formed fracture made in the separation capillary. The porous glass decoupler allowed ionic transport, but not bulk liquid flow. This results in a continuation of the electroosmotic flow past the fracture and into a section of capillary which extends beyond the capillary fracture. This region of the capillary is called the detection capillary and it is effectively decoupled from the electric field. Amperometric detection can then be performed by inserting a small electrode fiber into the end of the capillary. Other decouplers have been developed based on this general strategy [5–7]. End-column amperometric detection has also been demon-

strated in CE using small internal diameter capillaries ($< 25 \mu\text{m}$). Such capillaries produce small electrophoretic currents, in the order of nanoamps, a level which does not interfere with typical amperometric detection currents [8].

The development of an analytical methodology for the general detection of amino acids is challenging due to the absence of any easily identifiable property which is common to the 20 naturally occurring amino acids, and which can be exploited to facilitate detection. Thus, existing methodology has relied upon the formation of chemical derivatives to enhance detection. Pre-column derivatization is relatively straightforward and there have been a variety of recent reports describing new reagents and derivatization protocols [9–17]. Post-column derivatization has also been implemented [18–20], but it is more difficult because of the zone broadening which may be introduced by the post-column addition of the derivatization reagent. While derivatization schemes have greatly improved the quantitative aspects of amino acid detection, many of the derivatives are difficult to form, others are unstable, and some reagents form more than one adduct with the amino acid which complicates the analysis. In addition, since various experimental protocols rely upon either chromatographic retention or electrophoretic migration information for qualitative purposes, the added moiety may dominate the chromatographic or electrophoretic properties of the derivative thereby degrading the qualitative aspects of the analysis. Thus it would be advantageous to develop methodology which could provide for the sensitive detection of amino acids without requiring derivatization.

Native amino acids have been detected following CE separation using indirect methods. Kuhr and Yeung [21] have described the indirect laser induced fluorometric (LIF) detection of native amino acids, and Olefirowicz and Ewing have used indirect amperometry for the detection of underivatized amino acids [22]. The limit of detection for both of these techniques is in the micromolar range.

Direct amperometric detection of amino acids under strongly alkaline conditions has been reported at a copper wire electrode [23] following

CE separation. The copper electrode is the key to the success of this approach as other electrode materials do not provide a response for all amino acids. Alternately, pulsed amperometric detection (PAD) and integrated pulsed amperometric detection (IPAD) using a gold electrode have been successfully adapted to CE [24]. In these methods, detection limits at the 10 fmol level have been achieved with proper experimental design.

Chemiluminescence (CL) has been shown to be a very sensitive method for the detection of both derivatized [25] and underivatized [26,27] amino acids following HPLC separation. There has only been a few reports on the use of CL for detection of amines and amino acids following CE separation [17,28–33]. The first, [17], detection was accomplished by exploiting the energy transfer reaction between peroxalate and dansylated amino acid derivatives. The method required the use of two syringe pumps in addition to the electrophoretic apparatus. Detection limits were in the femtomole range. Other reports have shown that attomole detection limits are possible with proper experimental design using chemiluminescence detection in CE. The use of $\text{Ru}(\text{bpy})_3^{3+}$ -based chemiluminescence detection in CE has not been reported although previous work with this reaction scheme has suggested that this approach has much potential in terms of detection sensitivity and experimental simplicity.

This work will describe the instrumental development and subsequent application of in situ generated $\text{Ru}(\text{bpy})_3^{3+}$ -based chemiluminescence detection of underivatized amines and amino acids following CE separation. The experimental protocol uses a post-capillary reservoir of $\text{Ru}(\text{bpy})_3^{2+}$, which is then converted to $\text{Ru}(\text{bpy})_3^{3+}$ at a carbon microfiber for reaction with eluting amines and/or amino acids. This detection approach has been found to provide a reproducible electrophoretic separation and be compatible with the nanoliter detection volumes required to maintain CE separation efficiencies. The quantitative characteristics of the methodology will be evaluated and compared with existing analytical methods.

2. Experimental

2.1. Apparatus

2.1.1. Electrophoresis system

The high voltage (HV) for electrophoresis was applied using a Glassman (Whitehouse Station, NJ, model EH30R03.0) 30 kV power supply. Capillaries (75 and 100 μm i.d., 360 μm o.d.) were obtained from Polymicro Technologies (Phoenix, AZ). Capillaries were filled by pumping the desired solution into the capillary with a peristaltic pump. Electrical connection was made to both the anodic and cathodic ends of the capillary with Pt electrodes partially submerged in buffer. The HV (anode) end of the capillary was contained in a Plexiglas box which was equipped with an interlock to prevent accidental operator contact with the HV. A microammeter was placed in-line between the cathode and the common terminal of the HV power supply to allow monitoring of the electrophoretic current passing through the capillary. The entire apparatus was attached to and supported by a 2' \times 4' optical bread-board which was held at ground potential. Samples separated by CE were injected electrokinetically at 20 kV for 8 s. Oxygen ($\text{Ru}(\text{bpy})_3^{3+}$ luminescence quencher) was used as the marker for electroosmotic flow in order to determine the injection volume (45 nl). For the FIA study, injection was achieved hydrodynamically by placing the analyte solution 20 cm above the cathode for 5 s.

2.1.2. Preparation of the on-column Nafion joint

The electrochemical cell used to generate the $\text{Ru}(\text{bpy})_3^{3+}$ was decoupled from the electrophoretic field by the formation of an on-column fracture covered with a Nafion tube. The joint was located approximately 4 cm from the end of the capillary. This configuration is similar to that used by O'Shea et al. [5] for off-column amperometric detection following CE.

Microfiber electrodes were prepared from 35 μm carbon monofilament fibers (AVCO, Lowell, MA), 0.2 mm copper wire, and glass capillaries by following a procedure similar to that described earlier [5]. The final electrode length varied from 1 to 4 mm. Fig. 1 shows the cyclic voltammetric

(CV) response of $\text{Ru}(\text{bpy})_3^{2+}$ at one of these fibers.

2.1.3. Experimental arrangement for the observation of electrogenerated chemiluminescence

The electrochemical cell was assembled at the end of the detection capillary which extended beyond the Nafion joint and support beaker. The carbon fiber electrode assembly was mounted on a three-axis stage (Daedel, Harrison City, PA) using a small three-finger lab clamp (Fisher, Pittsburgh, PA). The three-axis stage was used to center the carbon fiber at the end of the detection capillary using $5\times$ magnification for precise placement. The carbon fiber served as the working electrode (WE) of a three-electrode assembly. A stainless steel (SS) spatula, held by a three-finger lab clamp served as the auxiliary electrode (AE). The spatula was held at one end by the lab clamp, and the other end acted as a support for a small pool of electrolyte which contacted the carbon fiber and the saturated calomel (SCE) reference electrode (RE). The end of the spatula which supported the electrolyte pool could be raised or lowered by varying the pressure of the adjustment screw of

Fig. 1. Cyclic voltammetric response of $\text{Ru}(\text{bpy})_3^{2+}$ at a $35\ \mu\text{m}$ carbon microfiber electrode. Electrochemical electrolyte, 15 mM sodium borate; pH 9.8; sweep rate, $50\ \text{mV s}^{-1}$; electrode length, 3 mm. (A) 1.0 mM $\text{Ru}(\text{bpy})_3^{2+}$ present in the electrolyte; (B) No $\text{Ru}(\text{bpy})_3^{2+}$ present.

Fig. 2. Schematic diagram of the off-column electrochemical cell used for the in situ generation of $\text{Ru}(\text{bpy})_3^{2+}$ and the chemiluminescent detection of amines and amino acids. Components are as follows: (1) PMT; (2) $\text{Ru}(\text{bpy})_3^{2+}$ reservoir; (3) reference electrode (SCE); (4) detection capillary; (5) auxiliary electrode (stainless steel spatula); (6) carbon microfiber electrode assembly; (7) support beaker and Nafion joint; (8) Platinum cathode; (9) dark box; (10) PVC pipe; (11) rubber stopper.

the three-finger clamp holding the spatula. The SCE contacted the electrolyte pool at a point very close to the carbon fiber electrode, and it was supported by the spatula serving as the AE. The photomultiplier tube (PMT) (Hamamatsu, NJ, model R928) was mounted over the electrochemical cell so that the photocathode was positioned approximately 2 cm above the electrolyte solution. HV was supplied to the PMT by either a Bertan (Hicksville, NY, model 215) or Hewlett-Packard (Palo Alto, CA, model 6515A) HV power supply. Potential control of the electrochemical cell was accomplished using a Princeton Applied Research (Princeton, NJ) model 173 potentiostat and a model 363 universal programmer.

The beaker which supported the capillary joint, the electrochemical cell, and the PMT assembly were all contained in a light tight box. The segment of separation capillary located between the Plexiglas box and the light isolating box was contained inside a 0.75 inch diameter polyvinyl chloride tube which was sealed on both ends with a rubber stopper. The PVC tube prevented accidental operator contact with the capillary which was under high voltage, and helped to prevent light-piping by the capillary into the dark box. A schematic of the experimental arrangement is given in Fig. 2.

2.1.4. Data collection

The output of the PMT was sent to a Keithley (Cleveland, OH) model 485 picoammeter, the output of which was filtered by a 0.15 s time constant before undergoing analog to digital (A/D) conversion by a Stanford Research Systems (Stanford, CA) SR575 lock-in amplifier. Data were transferred to a personal computer (PC) for storage and analysis. Cyclic voltammetric data were also collected using this data system, with the exception that the electrode current during the CV experiments was filtered with a 5 ms time constant.

2.2. Reagents.

Amino acid standards were purchased from Sigma (St. Louis, MO) and were used without further purification. The water used for the preparation of the electrophoretic buffers was deionized by a mixed-bed ion-exchange cartridge (model # 09-034-3, Fisher). Triethylamine and $\text{Ru}(\text{bpy})_3\text{Cl}_2$ were purchased from Aldrich (Milwaukee, WI). $\text{Ru}(\text{bpy})_3\text{Cl}_2$ was converted to the perchlorate salt before use. Sodium hydroxide, used in the preparation of the electrophoretic buffers was reagent grade (Fisher).

Capillaries used for electrophoretic experiments were pretreated overnight with 0.1 M H_2SO_4 , unless otherwise noted.

3. Results and discussion

As described earlier, chemiluminescent detection in CE has several potential advantages which make it appropriate for such applications. Of most significance is the excellent quantitative characteristics demonstrated for CL detection in general, and the fact that the method does not have a path requirement for sensitive detection, as do absorption-based methods. In spite of these advantages, in many chemiluminescent protocols, the need to mix several reagents under the volume constraints of CE has proven problematic.

$\text{Ru}(\text{bpy})_3^{3+}$ based chemiluminescence has several advantages which suggest its application in CE. Excellent detection limits have been demon-

strated using $\text{Ru}(\text{bpy})_3^{3+}$ based chemiluminescence for both amines and amino acids separated by HPLC, or introduced into the detection system via flow injection analysis [26,27]. More importantly, the chemiluminescent reagent, $\text{Ru}(\text{bpy})_3^{3+}$ can be prepared in its active form at the site of interaction with the reagent. This simplifies the experimental arrangement eliminating the need for several reagent streams and subsequent mixing. Although much work has been reported involving the use of $\text{Ru}(\text{bpy})_3^{3+}$ as a chemiluminescent reagent [34–39], $\text{Ru}(\text{bpy})_3^{3+}$ based CL detection in capillary electrophoresis has not been demonstrated to date.

Fig. 3 shows the CE separation of triethylamine, proline, valine and serine at pH 9.5 with detection via $\text{Ru}(\text{bpy})_3^{3+}$ based chemiluminescence. The mixture was injected in triplicate. In this approach, the $\text{Ru}(\text{bpy})_3^{2+}$ is located in a 100 μl reservoir placed at the exit end (cathode) of the capillary. The 100 μl reservoir was adequate for over 4 h of operation, at which time the $\text{Ru}(\text{bpy})_3^{2+}$ solution was replenished. A 35 μm carbon fiber is used as the working electrode to convert the $\text{Ru}(\text{bpy})_3^{2+}$ to the active $\text{Ru}(\text{bpy})_3^{3+}$ form. The working electrode is placed as close as

Fig. 3. Electropherogram of selected amino acids with end column addition of 1 mM $\text{Ru}(\text{bpy})_3^{2+}$. Separation conducted at 20 kV with injection of analytes for 8 s at 20 kV. Capillary, 75 μm i.d., 62 cm long with a 4 cm detection capillary. Buffer, 15 mM borate, pH 9.5. The electrode used for the in situ generation of $\text{Ru}(\text{bpy})_3^{3+}$ was a 35 μm diameter carbon fiber, 3 mm long held at 1.15 V vs. a SCE. The PMT was biased at 900 V. Peak identification: (1) 100 fmol TEA, (2) 70 fmol pro, (3) 1.6 pmol val, (4) 50 pmol ser. Injection points denoted by (*).

Table 1
Limit of detection for triethylamine and selected amino acids using $\text{Ru}(\text{bpy})_3^{3+}$ -based chemiluminescence following separation by CE

Compound	t_r (min.)	Concentration LOD	Mass LOD
Triethylamine (TEA)	4.4	120 nM	5.4 fmol
Proline (Pro)	6.2	68 nM	3.1 fmol
Valine (Val)	7.6	5.8 μM	0.3 pmol
Serine (Ser)	9.1	100 μM	4.5 pmol

possible to the exit without coming in physical contact with the capillary. Although the physical dimensions of the electrode are small, sufficient $\text{Ru}(\text{bpy})_3^{3+}$ is generated to react efficiently with the analyte eluting from the CE capillary. The carbon fiber did not require pretreatment.

From the data in Fig. 3, several points can be made. First, the detection sensitivity of the $\text{Ru}(\text{bpy})_3^{3+}$ -based chemiluminescent detection method is good, particularly when considering the analytes did not require derivatization prior to detection. Detection limits are summarized in Table 1 and they range from approximately 100 nM for TEA and proline, the most efficient luminescing species, to approximately 100 μM for serine. This difference in luminescence efficiency has been reported earlier and attributed to both the molecular characteristics of the reacting species [26], and the kinetics of the reaction [27]. The experimental precision is also very good considering the manual requirements of the injection procedure.

Second, the $\text{Ru}(\text{bpy})_3^{3+}$ based CL detection method using in situ generation of the active reagent is adequate to maintain the separation efficiency of the CE technique. The number of theoretical plates for the serine peak in Fig. 3 is estimated to be approximately 15 000 using the width at half-height. This plate number is smaller than previous reports involving derivatized amino acids and micelle enhanced running buffers [9]. However, the efficiency observed in the present study is comparable with that reported earlier in which underivatized amino acids were separated by CE and detected by an indirect method ([21]).

In order to thoroughly evaluate the quantitative characteristics of the CL detection approach described here, a capillary flow-injection technique was used to estimate the LOD and response linearity for leucine. Leucine was chosen for these more extensive studies since previous reports have shown that its response is approximately in the middle of the 20 naturally occurring amino acids [26]. Thus, from this data, one can judge the efficacy of this approach with respect to the other 20 amino acids. The FIA technique provided reproducible introduction of the analyte into the detection system. Further, by placing the $\text{Ru}(\text{bpy})_3^{2+}$ in the FIA buffer, data could be obtained over extended periods of time without depleting the $\text{Ru}(\text{bpy})_3^{2+}$ reservoir. For these flow injection experiments, a 75 μm i.d. \times 60 cm long capillary was used and samples were gravity injected by raising the injection end of the capillary 20 cm above the detection end of the capillary for 5 s. The buffer used for these studies was 15 mM borate at pH 9.8 with 1 mM $\text{Ru}(\text{bpy})_3^{2+}$ added for in situ detection. The LOD determined for leucine (SNR = 2) was 330 nM (15 fmol). A log-log plot of concentration versus signal for leucine showed a linear response from 1 μM to 100 μM injected leucine ($N = 6$, $y = 1.22(\pm 0.04)x - 0.18(\pm 0.05)$, $r^2 = 0.996$). This concentration LOD is not as low as an earlier report in which a larger flow cell and a glassy carbon disk working electrode (1 mm diameter) were utilized [27]. In that application, leucine was determined to have a LOD of 45 nM.

As described earlier, the likely reason for the slightly diminished detection limits with the capillary-based system is related to the very low light levels which must now be detected. The noise in the baseline which is limiting the detectability of the measurement is very periodic. It was determined in a separate experiment that the standard deviation in this background is essentially the same (approximately 0.2 nA) with, and without the electrochemical cell activated. From this data, it was concluded that the major contributor to the experimental noise with the capillary system is located within the electronics of the light detection system and not within the electrochemical system used to generate the $\text{Ru}(\text{bpy})_3^{3+}$. Although

the exact source of the noise is not known, random thermal emission from the photocathode of the PMT is a likely source. The PMT used for these studies is not designed for applications requiring the detection of ultralow light levels. According to specifications supplied by the manufacturer, the observed experimental noise is almost identical in magnitude to the random fluctuations in the dark current characteristic of this PMT at room temperature. Thus, cooling of the PMT or use of a PMT specifically designed for low light level detection should substantially improve the quantitative capabilities of the methodology. While these limits of detection in terms of amino acid concentrations are slightly higher than those demonstrated with the larger electrochemical cell [27], they are still very competitive with other methods used to detect native amino acids in CE [21,23]. By identifying the major contribution to the total noise, it is clear that these results can be substantially improved by improving the light detection system.

The $\text{Ru}(\text{bpy})_3^{3+}$ and eluting amine or amino acid are mixed by convection and diffusion. Although no design features were incorporated into the detection zone to enhance this mixing, this approach does appear to provide sufficient mixing such that the CL reaction can proceed with almost the same efficiency as when the $\text{Ru}(\text{bpy})_2^{2+}$ is present in the running buffer, as in the FIA study. The limit of detection for the two approaches is the same. The major advantage to this approach is that the electrophoresis will not be inhibited by the presence of $\text{Ru}(\text{bpy})_3^{3+}$ in the running buffer. Thus the method will be generally applicable to the separation and detection of all 20 amino acids and their important derivatives, such as the PTH amino acids which are products of protein sequence analysis.

4. Conclusion.

The chemiluminescent detection of amines and amino acids by reaction with in situ generated $\text{Ru}(\text{bpy})_3^{3+}$ at microcapillary dimensions has been demonstrated. The limit of detection for both triethylamine and proline were found to be below

the 10 fmol level. Leucine was analyzed by a capillary flow-injection technique and found to provide a linear response over two orders-of-magnitude in concentration with a LOD below 30 fmol. A noise analysis has shown that noise within the light-detection electronics is limiting the sensitivity of the technique. This is not expected to be a fundamental limitation and additional noise reduction measures will likely improve the quantitative aspects of the technique. Although neither the separation process nor the detection protocol are fully optimized, the results show the potential of the method for direct detection of amines or amino acids without requiring derivatization to enhance detection. Future work will focus on continued development of the end-column detection technique and its application to a wider range of amino acids including derivatives which may be produced as a consequence of protein sequence analysis.

Abstract

The response of a monoaza-15-crown-5 with an optically active aminobenzoxazinone moiety to divalent cations was investigated. The crown ether was found to undergo a strong emission shift to the blue when complexed with specific divalent metals that have ionic diameters between 1.9–2.4 Å. Consequently the photoactive macrocycle is responsive to Mg^{2+} , Ca^{2+} , Ba^{2+} , Sr^{2+} , Cd^{2+} , and particularly responsive to Hg^{2+} and Pb^{2+} . Macrocycle emission spectra are shown to be a function of cation concentration. Alkaline metal cations and smaller transition metals ions such as Ni^{2+} , Co^{2+} and Zn^{2+} do not cause significant changes in the macrocycle emission spectra. Emission, absorption, and complex stability constants are determined. Mechanisms of cation selectivity and spectral emission shifts are discussed. Challenges involving immobilization of the macrocycle while preserving its spectral response to cations are explored. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Benzoxainone derivative; Monoaza-15-crown-5; Divalent heavy metals

1. Introduction

Crown ethers are a class of organic compounds known to complex preferentially with metal ions. Cation selectivity in crown ethers has been shown to be a function of matching ionic radius and crown cavity size, crown structure, and charge transfer [1–7]. Attaching an optically active ligand to a crown ether can produce a photoactive ion selective compound, or a chromoionophore [8–21]. Without a photoactive group responsive

to the macrocycle cavity environment the spectral activity of crown ethers has been shown to have cation sensitivities in the millimolar range limiting their analytical utility [22,23]. For analysis of low concentrations of cations, micromolar and below, crown ethers with fluorescent groups are of interest since fluorescence is known to be more sensitive than absorption spectroscopy [24]. A fluorescent macrocyclic compound which is selective for regulated heavy metals such as Cd^{2+} , Pb^{2+} , and Hg^{2+} could be of particular interest for analysis of environmental samples. Ideally the macrocycle would provide the desired selectivity

* Corresponding author.

while the fluorescent ligand would provide the necessary sensitivity for trace level cation species analysis.

An optically active crown ether, reported in the literature [16] and shown in Fig. 1, is the photoactive benzoxazinone derivative of monoaza-15-crown-5 {3-(*p*-13-Aza-1,4,7,10-tetraoxa-cyclopentadecan-13-ylstyryl)-7-(dimethylamino)-1,4-benzoxazin-2-one}}, hence forth referred to as the BOZ-crown. The BOZ-crown ether was reported to have a high fluorescence quantum efficiency and selectivity for the divalent alkaline earths, particularly Ca^{2+} . The maximum wavelength of emission of the free ligand is shifted from 642 to 574 nm upon complexation with Ca^{2+} . Smaller spectral shifts occur for other alkaline earths. The absorption peak, centered at about 490 nm ($328\,200\text{ l mol}^{-1}\text{ cm}$) in acetonitrile, is only slightly perturbed by metal ion complexation. The quantum yield of the uncomplexed crown is 0.33 which increases to 0.64 when complexed with Ca^{2+} .

Despite the lack of reported information on complexation with any toxic heavy metal ions of interest, BOZ-crown was selected for further investigation for several reasons. (1) It has excellent emission characteristics (high quantum efficiency and a large peak shift upon complexation) and absorption in the blue which eliminates interferences from many ultraviolet absorbing species. (2) Azo-crown ethers with photoactive groups are known to be selective for the softer heavy metals [2,13,21]. Reported here are new studies on BOZ-crown, focusing on toxic heavy metals, with observations on; cation selectivity, emission mechanisms, effects of anions upon the complex, and issues concerning immobilization for analytical applications.

2. Experimental

The BOZ-crown was synthesized using previously reported procedures [16]—purified on silica columns and 50 μM stock solutions were utilized. All metal salts were of high purity (Aldrich) and 10 mM metal ion stock solutions

were prepared from these salts. All stock solutions were prepared by weighing out the compound into a 500 ml volumetric flask and diluting to the volume with acetonitrile. Aldrich HPLC reagent grade acetonitrile was chosen as the solvent since it has a very low fluorescence background and the BOZ-crown is insoluble in water. However, acetonitrile is a polar, aprotic solvent and is unable to solvate many materials. All perchlorate salts utilized were found to be soluble in acetonitrile. All hydrated nitrates with divalent cations were soluble in acetonitrile with the most readily soluble nitrate salts being the transition metals from manganese to zinc. Anhydrous nitrate salts including: the alkaline metals, alkaline earths, and most trivalent metals were found to be insoluble in acetonitrile at room temperature. Some iodide and chloride salts were soluble in acetonitrile at room temperature. Solutions were stirred until the salt completely dissolved. Those solutions in which the salt was not visually determined to go completely into solution were not utilized. All glassware was washed with nitric acid and then triple rinsed in acetonitrile.

All emission spectra were collected using a 0.25 m Chromex spectrometer with 150 grooves mm^{-1} grating, blazed at 500 nm, with a slit width of 200 μm . The detector was a 256×1024 element Princeton Instruments charge coupled device (CCD) cooled to -50°C with a thermoelectric cooler and controlled with a Princeton Instruments ST-130 Controller. The CCD was read out with a 16 bit A/D converter at 50 kHz and analyzed with a 486 PC computer. Unless otherwise noted a 30 s collection time was utilized with background subtraction. Since full slit illumination was achieved, the entire array was read out and the 256 vertical pixels were binned together to produce spectra with 1024 channels. Calibration of the spectrometer was achieved using Hg and Ar atomic line sources. Calibration was verified with a 632.8 nm dielectric notch filter. Absorption spectra were collected with a Guided Wave Model 200 Fiber Optic Spectrometer using a transmission probe with a 1.00 cm optical path.

Fig. 1. The BOZ-crown ether. Ionic selectivity of the compound is determined by the monoaza-15-crown-5 cavity size (1.7–2.2 Å). Fluorescent properties of the compound are determined by the optically active aminobenzoxazinone moiety.

3. Results and discussion

3.1. Emission and selectivity

The BOZ-crown was previously reported to complex with alkaline earth and alkali metals [16]. We have found that the BOZ-crown complexes strongly with certain transition metal cations. As shown in Fig. 2, the 1 μM BOZ-crown in acetonitrile undergoes a strong blue shift of the emission peak and an increase in quantum efficiency when complexed with divalent cations with ionic diameters around 2Å. Consequently the BOZ-crown ether was found to be optically very responsive to Ca^{2+} , Ba^{2+} , Sr^{2+} , Cd^{2+} , Hg^{2+} , and Pb^{2+} .

Pb^{2+} and Hg^{2+} are particularly reactive with the BOZ-crown. At 15 μM , Pb^{2+} and Hg^{2+} ,

Fig. 2. Fluorescence spectra of cations with 1 μM BOZ-crown in acetonitrile. Pb^{2+} and Hg^{2+} are at 15 μM and other cations are at 1.5 mM. All cations are from perchlorate salts.

Fig. 3. BOZ-crown (1 μM) fluorescence spectrum with different concentrations Hg^{2+} in acetonitrile. Note the large 50 nm blue shift of the emission peak with increasing Hg^{2+} concentration. In addition to changing position, the peak intensity also increases with Hg^{2+} concentration until complete complexation has occurred at approximately 10 μM Hg^{2+} .

cause larger shifts in the BOZ-crown fluorescent peak wavelength and intensity than other cations at concentrations of 1.5 mM (Fig. 2). Other cations, such as Mg^{2+} , are observed to be only partially complexed at concentrations of 1.5 mM. The simultaneous shift in the spectral peak position and emission intensity with cation concentration can be observed in Fig. 3. The ion selectivity of the macrocycle and large dynamic range of the optical response shown in Figs. 3 and 4 demonstrate the potential of utilizing this fluorescing crown ether for trace level analysis of metals.

Unlike most macrocycle compounds with cavity sensitive fluorogenic groups, the emission of the BOZ-crown is not quenched upon complexation by spin orbit coupling, or the heavy atom effect [25,26]. The observed variations in the BOZ-crown emission spectrum with cation species is believed to be due to charge transfer between the BOZ-crown azo group and the aminobenzoxazinone moiety [16]. The macrocycle provides a rotational nonradiative deexcitation pathway for the ligand. Strong cation interactions with the macrocycles azo groups lone pair forces the nitrogen from an sp^3 configuration to a rigid sp^2 configuration deactivating the rotational nonradiative mechanism. Without the rotation deexcitation pathway the complex has larger quantum efficien-

cies and an increased Stokes shift in the emission spectrum with optical characteristics resembling the benzoxainone chromophore (BOZ-H). Those cations closely matching the crown cavity in size, complex stronger, binding to the nitrogen lone pair, creating the largest shift in the emission peak and intensity of the alkaline earths. This mechanism is supported by our observations of the BOZ-crown immobilized on a silica surface. The BOZ-crown was immobilized upon silica by slow evaporation from solvent (acetonitrile). This process has been shown to be a simple, effective method of immobilizing crown ethers without substantially altering their cation selectivity [27]. When surface immobilized upon silica the BOZ-crown becomes cation insensitive and has an emission maxima 568 nm very similar to that of the BOZ-H (463 nm) or a strong, solvated BOZ-crown-metal complex (474 nm). This cation insensitivity is interpreted as surface restricted rotation between the macrocycle and the aminobenzoxazine moiety similar to the restricted rotation resulting from complexation of the BOZ-crown with cations. Since surface restricted rotation renders

Fig. 4. Fluorescence intensity of 1 μM BOZ-crown in acetonitrile at 574 nm versus cation concentration. Note the difference in concentration range between Hg^{2+} , Pb^{2+} , and the other cations.

the BOZ-crown spectroscopically cation insensitive, any immobilization method must not sterically hinder the BOZ-crown. Liquid membranes and sol-gel are two techniques which might accomplish BOZ-crown immobilization without interfering with its spectroscopic response to cations.

Closely matching the crown cavity in size,— Ca^{2+} has been previously shown to complex strongly with the crown ether, binding with the lone pair of the macrocycle's azo group, creating the largest wavelength and intensity shift in the fluorescence emission peak of the alkaline earths [16]. The other alkaline earths cause significantly smaller shifts than Ca^{2+} while the univalent alkaline metals cations cause negligible shifts. The 15-crown-5 macrocycle complexes with univalent cations, but the univalent ions do not interact with the macrocycles nitrogen lone pair sufficiently to cause large changes in the fluorescence spectra.

The alkali metal cations (Li^+ , Na^+ , K^+), Ni^{2+} (1.38Å), Co^{2+} (1.10Å) and Zn^{2+} (1.48Å) do not cause significant changes in the BOZ-crown emission spectra. The univalent alkaline metals do not have sufficient charge to cause a shift in the emission spectra. While the divalent transition metals Ni^{2+} , Co^{2+} , Zn^{2+} have sufficient charge to affect the emission spectra, the small size precludes effective complexation in the 15-crown-5 cavity. The benzoxainone chromophore (BOZ-H) and consequently the BOZ-crown, complexes with Cu^{2+} to form an emission quenched purple complex which interferes with all other divalent complexes.

It can be seen in Fig. 2 that Ca^{2+} (2.00Å) and Cd^{2+} (1.90Å) have very similar spectroscopic responses while Mg^{2+} (1.44Å) and Zn^{2+} (1.48Å) which are more closely matched in ionic diameter, have very dissimilar emission characteristics. This difference in spectroscopic response for the two sets of divalent cations is particularly curious when the similarity in the electron configuration is examined. In each set the alkaline earth has a completely filled s shell and the transition metal has a completely filled d shell. Mg^{2+} will complex strong enough to cause the BOZ-crown spectrum to shift while Zn^{2+} will not. Since both Ca^{2+} and

N.A., not available; Φ , quantum efficiency; $K_s = [ML^{2+}]/([M^{2+}][L])$.

Cd²⁺ shift the BOZ-crown spectra, the effect cannot be attributed to the difference between the alkaline earths and transition metals. The difference in behavior between Ca²⁺ and Cd²⁺ and Mg²⁺ and Zn²⁺ could be a function of solvation coordination. Ca²⁺, Cd²⁺ and Mg²⁺ have preferred coordination numbers (CN) of six while Zn²⁺ has a preferred coordination numbers of four. It appears solvation coordination significantly influences complexation into the BOZ-crown cavity with a coordination number six being preferred.

For a fixed concentration of BOZ-crown, the fluorescence intensity is proportional to cation concentration. Fig. 4 shows the response of 1 μ M BOZ-crown to cation concentration. The difference in concentration ranges clearly show the BOZ-crown-selectivity for Pb²⁺ and Hg²⁺. The decrease in emission intensity at higher cation concentrations is attributed to ionic quenching [16]. Ionic quenching can begin well before complete complexation occurs. BOZ-crown spectral intensities will increase with cation concentration up to a specific concentration unique to each metal ion. Subsequent increases in cation concentration will result in a blue shift of the fluores-

cence peak but with a net decrease in intensity.

Figs. 3 and 4 clearly show that the BOZ-crown spectra are a function of cation concentration. The monotonous dependence indicates a 1:1 stoichiometry within the concentration range investigated. Any particular BOZ-crown spectrum is a composite of fluorescence emissions from both the complexed and uncomplexed BOZ-crown ethers. The ratio of complexed to uncomplexed BOZ-crown is determined by the relative cation and ligand concentrations and the complex stability constant, K_s . Where the stability constant is given as: $K_s = [ML^{2+}]/([M^{2+}][L])$. K_s was determined with linear least squares analysis of $I_o/(I-I_o)$ vs. $1/[M]$. The intercept/slope of these plots provided K_s with correlation coefficients better than 0.96.

K_s and other constants for the BOZ-crown complexes are presented in Table 1. The maximum spectral shifts of the BOZ-crown peak, λ_{em} , occurs upon complete complexation with the cation. Due to ionic quenching, λ_{em} typically occurs at higher cation concentrations than the peak emission intensity.

The large stability constant and subsequent sensitivity of the BOZ-crown to Pb²⁺ and Hg²⁺ can be attributed to soft-soft interactions between

cations and the nitrogen in the macrocyle [28]. The softer nature of Pb^{2+} and Hg^{2+} can interact with the azo groups stronger than the harder alkaline earths. Similar selectivity effects for Pb^{2+} and Hg^{2+} by macrocycles containing azo groups have been noted in previous studies [1,2,13,21].

With the exception of Sr^{2+} , Fig. 5 shows the emission intensity of the BOZ-crown complexes improves with cavity fit, with the optimum cation ionic diameter ranging between 1.9 Å–2.4 Å. The emission intensities were divided by the complex's absorption coefficient, to adjust for differences in the molar absorptivities, and a trend line is shown. Fluorescent intensity of the BOZ-crown complex is affected by many factors including coordination number (CN), valence, and cation hardness but optical activity clearly increases as the macrocycle cavity and cation diameter are closer in size.

3.2. Complex stability

It can be seen in Fig. 6 that K_s increases with ionic diameter, regardless of cation hardness, until approximately 2.4 Å, after which the stability constant decreases significantly. This is very similar to the trend exhibited in Fig. 5. Unlike Fig. 5, Fig. 6 clearly shows that the stability of the complex is not a function of cavity fit alone. While complex stability improves as cation diameter approaches 1.9–2.4 Å it can be observed that

Fig. 5. BOZ-crown complex emission intensity (474 nm) versus ionic diameter. The macrocycle diameter is 1.7–2.2 Å. Emission intensities adjusted for different ϵ values and a line of best fit is shown. The complex peak emission intensities, which occur of different cation concentrations, and are listed in Table 1.

Fig. 6. BOZ-crown complex stability constant versus ionic diameter. Note the separation between the hard and soft cations. The macrocycle diameter is 1.7–2.2 Å. The uncertainty in K_s is ± 0.1 .

the softer cations form significantly stronger complexes than the hard cations of similar ionic diameters. For example, the BOZ-crown complexes with Hg^{2+} (2.04 Å) almost $100\times$ stronger than the similarly sized Ca^{2+} (2.00 Å).

As shown in Fig. 7, emission intensity is also related to the stability constant of the complex. The harder complexes, such as the alkaline earths, demonstrate an almost linear relationship. The large soft cation, Hg^{2+} and Pb^{2+} , with much higher K_s values are clearly separated from the hard cations. There is a nearly linear relationship between emission intensity and $\log K_s$ over almost four orders of magnitude. Clearly the stronger the complexation the more intense the emission from the complex.

The BOZ-crown is insoluble in polar solvents such as methanol and water. In low dielectric solvents which are partially miscible with water,

Fig. 7. BOZ-crown complex emission intensity (474 nm) versus complex stability constant. Note the near linear relationship over four orders of magnitude. The uncertainty in K_s is ± 0.1 .

such as methyl iso-butyl ketone and acetonitrile, the BOZ-crown emission intensity is reduced upon addition of water. The fluorescence of the BOZ-crown is quenched by the addition of high dielectric polar cosolvents such as ethanol and water. Therefore applications of the BOZ-crown to metal detection are limited to low dielectric constant lipophilic environments.

3.3. Quantum efficiency

The measured quantum efficiencies, Φ , of the BOZ-crown complexes is very dependent upon cation concentration and determination methods. Low concentrations result in incomplete complexation and high concentrations reduce the emission intensity through ionic quenching. The Φ values given in Table 1 were determined at peak intensity concentrations and referenced to the previously reported Φ values for the BOZ-crown (0.33) and Ca^{2+} -BOZ-crown complex (0.64). There is no simple functional relationship between Φ and K_s . However, in general quantum efficiencies can be observed to increase with K_s . Similarly, Φ generally improves with cavity fit between cation and macrocycle but other factors such as the cation hardness preclude any simple relationship.

3.4. Absorption

Absorption parameters are shown in Table 1. The changes in λ_{abs} and ϵ increase with the stability of the complex. Absorption spectra do not undergo the large shift seen in fluorescence spectra because cation complexation does not alter the excitation pathways as significantly as de-excitation pathways. However, changes in absorption spectra clearly do occur, with substantially larger changes for divalent cations than monovalent, indicating that electronic energy states in the BOZ ligand are being affected by the coulombic charge of the complexed cation. Like λ_{em} and Φ , measured values of λ_{abs} and ϵ change with cation concentration and determination of true complex values is difficult.

Fig. 8. Emission spectra of Cd^{2+} with different anions, competing with $1 \mu\text{M}$ BOZ-crown in acetonitrile.

3.5. Anion effects

Fig. 8 depicts the anion effects that are observed with BOZ-crown complexing with Cd^{2+} acetonitrile. CdCl_2 is insoluble in acetonitrile and is not shown. Soluble chloride, iodide, and perchlorate salts of the cations listed in Table 1 were found to have similar spectra with only slight differences in peak heights. Nitrate salts of the cations in Table 1 have a significantly different emission peak structure.

The mono-azo crown ether is known to be stable in nitrate solutions [2], however all nitrate salts soluble in acetonitrile were found to cause an intensity decay in the BOZ-crown emission spectrum. Nitrate, chloride, iodide, perchlorate salts were tested with a variety of cations and only nitrate salts were observed to cause the decay of emission spectra with time. The decay rate was found to be dependent upon the specific cation and the cation concentration. Simple addition of NaNO_3 will cause an intensity decay in the unshifted BOZ-fluorescence spectra. Addition of trace amounts of nitric acid will cause the peak to shift to 572 nm (protonation on the crown azo group) followed by a slow decay in fluorescence intensity. The decay in fluorescence intensity and change in emission spectra in nitrate solutions appear to be functions of the photoactive BOZ ligand and not caused by macrocycle interactions. Previous literature has shown the BOZ ligand (7-dimethylamino-3(*p*-formylstyryl)-1,4 benzoxazine-2-one) to be stable in a number of solvents

but there is no discussion of exposure or reactions of the BOZ ligand with nitrate [16,29–31]. A likely explanation for the observed behavior is a nitrate reaction with the highly conjugated chromophore group (BOZ ligand) resulting in loss of optical activity.

4. Conclusions

Reported here, is a fluorescing crown ether which increases emission intensity upon complexation with specific transition metal cations. The BOZ-crown undergoes a strong emission blue shift from 629 to approximately 574 nm when complexed with divalent cations that have ionic diameters between 1.9–2.4 Å. Consequently the BOZ-crown ether is responsive to Mg^{2+} , Ca^{2+} , Ba^{2+} , Sr^{2+} , Cd^{2+} , Hg^{2+} , and Pb^{2+} . Alkaline metal cations, Ni^{2+} , Co^{2+} and Zn^{2+} do not cause significant changes in the BOZ-crown emission spectra. Due to the soft-soft interactions of the macrocycles azo group, Pb^{2+} and Hg^{2+} have stability constants 100 times larger than any other metal cation and consequently induce changes in the BOZ-crown emission spectrum at substantially lower concentrations.

The measured constants such as K_s and Φ for Ba^{2+} , Ca^{2+} and Mg^{2+} are consistent with the values previously reported [16]. These constants have been determined and analyzed for many of the transition metals, particularly those of environmental interest. The large jump in K_s and emission intensity for Pb^{2+} and Hg^{2+} can be understood through soft-soft interaction with the macrocycles azo group. The lack of reaction for Zn^{2+} , Ni^{2+} , and Co^{2+} has been explained based on coordination number and ionic size. There is no apparent reason why Sr^{2+} has a lower K_s than Ba^{2+} with the BOZ-crown. Subsequent work is needed to explore and explain the observed differences in K_s and Φ , between Sr^{2+} and other divalent cations.

The BOZ-crown selectivity for the toxic heavy metals Pb^{2+} and Hg^{2+} coupled with the large optical response to the cations make the BOZ-crown a promising candidate for numer-

ous environmental analytical applications. Future work will examine immobilization issues, solvent extraction, and liquid membrane configurations for analytical applications.

Photoinitiated gold sol generation in aqueous Triton X-100 and its analytical application for spectrophotometric determination of gold

Anjali Pal *

Civil Engineering Department, Indian Institute of Technology, Kharagpur 721 302, India

Received 20 June 1997; received in revised form 2 September 1997; accepted 3 September 1997

Abstract

Gold complex, HAuCl_4 has been transformed into pink-coloured stable gold sol having λ_{max} at 523 nm ($\epsilon = 3.06 \times 10^3 \text{ l} \cdot \text{mol}^{-1} \cdot \text{cm}^{-1}$) at room temperature in aqueous Triton X-100 (TX-100) upon photoirradiation. It is a very rapid and simple process and the absorbance at 523 nm is a direct measure of gold concentration. Beer's law is obeyed in the range of 0–150 ppm of gold. The relative standard deviation for 22.7 and 90.9 ppm of gold are 2.8 and 2.5% respectively. The 95% confidence limit (ten determinations) for 22.7 ppm of gold is 23.6 ± 0.5 ppm. Sandell sensitivity is $6.44 \times 10^{-2} \mu\text{g cm}^{-2}$. TX-100 acts both as a reducing agent and a stabilizer here. Statistical parameters, effects of TX-100 concentration, irradiation time and interferents are studied. The method is applicable for ore and synthetic mixture analysis. © 1998 Elsevier Science B.V. Keywords: Gold complex; Photoinitiated gold sol; Synthetic mixture analysis

1. Introduction

To discover a convenient method for gold sol preparation could be a challenging problem for many reasons. Colloidal gold could be used for staining proteins electrotransferred onto nitrocellulose membranes [1]. It could also serve as a medium for surface enhanced Raman scattering (SERS) [2]. There are many methods of gold colloid preparation, among which the method described by Moeremans et al. [3] is relatively trou-

blesome and requires refluxing. The method of Yamaguchi et al. [1] however, requires several hours stirring under appropriate pH conditions and for maturation of gold sol, an additional vigorous overnight stirring is necessary. In most cases, for obtaining SERS spectra, gold sol was prepared from gold(III) by various reducing agents but needed a control [4]. Generation of gold sol from gold(III)–gelatin complex using common reducing agents such as ascorbic acid, hydrazine etc. were also carried out [5], but required proper conditions. Light induced reactions could be an ideal alternative in this respect, because controlling the reaction may be less difficult

here and the methodology could be very simple, quick and easy [6,7].

Several spectrophotometric methods for gold (III) determination involving binary complex formation between gold (III) and chromogenic reagents are known [8–12], but these methods lack sensitivity. Several extractants for the photometric determination of gold in complex materials have also been reported [13–17]. Conventional methods, in general, involve lengthy procedures due to the necessity of multiple extractions [14] and suffer from interference by other metal ions [12–18]. Sometimes, loss of photometric selectivity arising from the use of reagents such as amides [19] also results.

A very simple and quick photochemical method for gold determination through the formation of pink gold sol in poly (oxyethelene)isooctylphenyl ether known as Triton X-100, or TX-100, which acts both as a reducing agent and a stabilizer, is reported here.

2. Experimental

2.1. Apparatus

All absorbance measurements were carried out in a Shimadzu UV-160 digital spectrophotometer. Photochemical reactions were carried out in 1-cm well stoppered quartz cuvettes. Photoirradiations were carried out with an ordinary germicidal lamp (Sankyo Denki, Japan) of 15 W capacity. The cells were kept at a distance of 3 cm from the light source.

2.2. Reagents

All reagents were of AR grade. A stock solution of gold(III) chloride was prepared by dissolving 1 g of chloroauric acid (Johnson Matthey, Royston, Hertfordshire, UK) in 500 ml double distilled water and it was standardised by the quinol method [20]. TX-100 solutions were prepared by dissolving appropriate volumes of this in known volumes of distilled water.

2.3. Procedure

Aliquots of standard gold(III) solutions were taken in the quartz cuvettes and mixed with 10^{-2} M TX-100 so that the total volume is 2 ml for each and gold concentration varies from 2 to 150 ppm. Each was then irradiated for 20 min. Pink-coloured gold sol was produced. The absorbance value measured at 523 nm was proportional to the gold concentration. The colour was stable for more than a week at room temperature and for more than a month at $< 5^{\circ}\text{C}$.

3. Results and discussion

3.1. Photochemical reaction between HAuCl_4 and TX-100

Redox reactions occurring between gold(III) complex and air saturated aqueous solutions of poly (ethylene glycol) (PEG) and poly (vinyl alcohol) (PVA) have recently been reported [21] where gold(III) is converted to pink gold sol by PEG and PVA. This occurs at room temperature, but at a slow rate, requiring ~ 8 h for PEG and ~ 6 days for PVA. The fact that PEG polymers have been oxidised to acetoxy compounds has been confirmed from infrared (IR) spectral analysis. Recently, the photochemical reduction of aqueous HAuCl_4 in the presence of 2-propanol and acetone has been reported [22,23], using a steady-state xenon lamp or repetitive laser pulses to produce important and useful nanoscale gold particle. Sodium polyphosphate was used as a particle stabilizer in this system. The photooxidation of phenols [24] or alcohols [25] were used in synthetic organic chemistry but have not been used for analytical purposes. Here, we report our findings on the photochemical reaction of TX-100 in aqueous medium with gold(III) to form and stabilize small gold particles which may be very useful for material research [26]. The average size of the metal particles in the sol system produced was found using a Coulter N4 particle analyzer at an angle of 90° and was found to be 14 nm.

Curve A of Fig. 1 shows the surface plasmon absorption band of TX-100 stabilised zerovalent

gold ($\lambda_{\max} = 523 \text{ nm}$) obtained from the photoreduction of HAuCl_4 by TX-100. Curve B shows the spectrum of TX-100 after 20 min. irradiation. Without TX-100, gold(III) failed to give any colour, even after 1 h irradiation. If kept in the dark, aqueous TX-100 failed to generate gold sol, even after 8 h. However, if kept for more than 24 h, a slight pink colour was developed. Since the reagent blank did not absorb at 523 nm, it was not necessary to use a blank in the determinations. Deoxygenation of the sample followed by irradiation for 20 min. did not cause any change in the absorbance at 523 nm. The advantage of this method was that pH maintenance was not necessary. To the best of our knowledge, such a reaction has not been used for either gold sol preparation or gold determination.

Identification of the product formed in this process was attempted through infrared spectral analysis. A higher concentration of HAuCl_4 was attempted in this experiment in order to increase the product concentration. The resulting solution after irradiation was vacuum evaporated. The IR spectra obtained from the blank experiment without HAuCl_4 was compared with that of the sample. The appearance of a new band at 1613 cm^{-1} indicated the presence of the carboxylate group [21] generated due to the oxidation of the primary hydroxyl function of TX-100 by gold(III). Ultra-violet light of shorter wavelength ($\approx 254 \text{ nm}$) or visible light could not bring about such a reaction. This type of selectivity of wavelength is not un-

Fig. 1. Absorption spectra of: (a), gold sol (150 ppm) generated by the photoirradiation of HAuCl_4 in aqueous TX-100; (b), aqueous TX-100 after photoirradiation.

Fig. 2. Effect of irradiation time on the absorbance ($\lambda_{\max} = 523 \text{ nm}$) of gold sol (38 ppm).

usual and has been found in many reactions [6,7]. Photooxidation of aliphatic alcohols in aqueous medium are already known [25] and therefore, such a process is not unlikely. Yet, to gain a clear insight into the mechanism, further elaborative studies are needed.

3.2. Effect of irradiation time

As the reaction is based on the kinetic action brought about by the co-existence of TX-100 and gold(III) under UV light, it is enormously influenced by the exposure time. The kinetics were studied in order to obtain the optimum irradiation time for the system (the results are shown in Fig. 2). It was observed that an irradiation time of 12 min was sufficient to achieve the maximum absorbance at 523 nm, although further irradiation, at least up to 35 min, did not bring about any change. Hence, an irradiation time of 20 min was chosen for further studies.

3.3. Effect of TX-100 concentration

The use of TX-100 is vital, as the reduction of gold(III) to gold particle is carried out by TX-100 and light. TX-100 has another role: being a micelle forming agent it also acts as a stabilizer, otherwise, the particles may be precipitated. It also influences the particle size. In comparison to polymers and ligands, micelles have better size controlling capability with better reproducibility. Studies have been conducted with TX-100 in the

Table 1
Determination of gold in various samples

Sample (ppm)	Gold found ^a (ppm)	Relative standard error (%)
Synthetic samples		
Cu(II) (39)+Ag(I) (185)+Au(III) (50)	46.5	-7.0
Cd(II) (113)+Zn(II) (37)+Au(III) (50)	48.3	-3.4
Pt(IV) (39)+Pd(II) (45)+Au(III) (50)	47.0	-6.0
Gold ore (Au: 17 ppm)	15.0	-11.7

^a Average of three determinations.

concentration range of 10^{-1} – 10^{-4} M and 10^{-1} – 10^{-3} M was found to be the optimum. TX-100 of 10^{-4} M, which is below the critical micelle concentration, caused the λ_{\max} to be red shifted and absorbance to be decreased. When TX-100 \cong 1 M it was too viscous to be used. Other neutral surfactant and polymers such as Triton X-114, PEG and PVA were tried and found to produce very faint blue colour after 20 min irradiation.

3.4. Calibration graph and other statistical parameters

The sample solutions containing TX-100 (10^{-2} M) and gold(III) (0–150 ppm final concentrations) were exposed to UV light for 20 min. A linear calibration graph was obtained over this range of gold concentration. Linear regression performed over the linear response region provided a correlation coefficient of 0.999 with an intercept of 5.4×10^{-3} and a slope of 1.4×10^{-2} ppm. It was observed that gold can be determined down to a concentration level of 1 ppm. The molar absorptivity of pink gold sol was 3.06×10^3 l·mol⁻¹ cm⁻¹. The precision of the method (RSD, five determinations) was found to be ± 2.8 and $\pm 2.5\%$ for 22.7 and 90.9 ppm of gold, respectively. The Sandell sensitivity (with respect to gold) was 6.44×10^{-2} μ g cm⁻². The 95% confidence limit for 22.7 ppm of gold was 23.6 \pm 0.5 (for ten replicates).

3.5. Effects of diverse ions

Ag(I), Cu(II), Ni(II), Cd(II), Pt(IV), Pd(II), Zn(II) did not produce any colour during the procedure discussed. With 50 ppm of gold(III), the presence of the following anions SO₄²⁻, NO₃⁻, Cl⁻, NO₂⁻ (up to 250 ppm) did not cause any change in the absorbance value at 523 nm.

3.6. Applicability of the method

In order to confirm the applicability of the proposed method, it was applied to the determination of gold in three synthetic mixtures and to a concentrate of low grade Canadian RM gold ore. In aqua regia, on a low Bunsen flame, 1 g of ore was digested and finally evaporated to dryness in a water bath. During this process, all nitric acid was expelled. The dry residue was then extracted in distilled water and filtered, giving a final volume of 1 ml. The gold in the sample was then determined using the procedure described above. The results are summarised in Table 1.

4. Conclusion

A novel photochemical method of gold sol preparation is described, which has been used for spectrophotometric determination of gold. The method is simple, quick and reliable and has been used for the analysis of gold in synthetic mixtures and an ore sample.

Determination of milk-oxidised ketone bodies as an acetone derivative by electron capture gas chromatography

I. Sarudi *, É. Visi-Varga

Department of Chemistry, Faculty of Animal Science, Pannon University of Agriculture, PO Box 16, Guba S.u. 40, 7401 Kaposvár, Hungary

Received 12 December 1996; received in revised form 4 August 1997; accepted 5 September 1997

Abstract

Following the deproteination of the milk sample by means of zinc hexacyanoferrate, acetoacetic acid was decarboxylated by heating; the acetone originally present was then determined together with the acetone formed. The essence of the determination was that acetone reacted with bromine in the presence of sulphuric acid, following which, the bromoacetone formed was extracted into toluene, separated by gas chromatography and measured using an electron capture detector. The calibration curve was found to be linear up to a concentration of 2 mmol l^{-1} acetone. The detection limit calculated from the threefold noise level and the slope of the calibration curve was $9 \times 10^{-7} \text{ mol l}^{-1}$. The reliability of the method meets the practical requirements. Its application may be recommended above all for the establishment of subclinical ketosis. © 1998 Elsevier Science B.V. Keywords: Oxidised ketone bodies; Milk; Bromoacetone; Gas chromatography

1. Introduction

An increase in acetone, acetoacetic acid and 3-hydroxybutyric acid in biological fluids generally indicates some kind of energy metabolism disturbance in animals or humans. Thus, their estimation in blood, milk or urine is important with respect to diagnosis. In clinical chemistry the collective term ketone bodies is used for these compounds, while the sum of acetone and acetoacetic acid (given in mmol l^{-1}) is termed oxidised ketone bodies. Ketosis is a common disease

in dairy cows of high milk yield and it has been established that the level of oxidised ketone bodies in milk correlates closely with the concentration of blood ketone bodies [1,2].

In practice, the determination of oxidised ketone bodies is generally based on the assay of acetone, which is obtained after the decarboxylation of acetoacetic acid by heating. Some decades ago various non-automated photometric methods were most frequently used for the determination of milk acetone and in the 1980s photometric flow injection analysis [2] also began to appear in the specialist literature. Although traditional photometric methods provide accurate results, they are too time-consuming for serial tests. This is due to

* Corresponding author. +36 82 314155; fax: +36 82 313562.

the fact that photometric measurement in the presence of milk matrix is impossible, so acetone must be separated from the sample beforehand, by distillation [3,4], extraction [5,6] or diffusion [7–9]. Gas chromatography is now preferred to these laborious techniques. Out of all of the methods of gas chromatography previously developed [9–16], including the applications of the head-space technique [12–15], flame ionisation detection is used.

The present paper demonstrates another potential method for the determination by gas chromatography of oxidised ketone bodies in milk. The principal objective of this study was to achieve a high level of sensitivity by the application of electron capture detection.

2. Experimental procedure

2.1. Chemicals and solutions

Analytical reagent grade chemicals and triply distilled water were used throughout the study. The clarifying agents used were 4.8 g/100 ml ZnSO_4 and 3.7 g/100 ml $\text{K}_4[\text{Fe}(\text{CN})_6]$. Other solutions and chemicals used were: ca. $4.5 \times 10^{-2} \text{ mol l}^{-1}$ Br_2 solution prepared by the dilution of saturated bromine water in a ratio of 1:4; 4 mol l^{-1} H_2SO_4 ; aqueous 5 g/100 ml phenol solution; and in addition toluene purified by vacuum distillation at a pressure of ca. 15 mbar once every 2 weeks.

Aqueous standard solutions containing 0.10, 0.25, 0.50, 0.75, 1.00, 1.50, 2.00, 2.50 and 3.00 mmol l^{-1} acetone respectively, were diluted from a 0.10 mol l^{-1} stock solution, which was made up using acetone (99.5% p.a.) obtained from Merck AG, Germany. Acetone was redistilled before use. The stock solution could be kept in a refrigerator for about 3 weeks, but the calibrating standards were replaced with fresh ones once a week.

In the preparation of a 0.1 M acetoacetate solution lithium acetoacetate (supplied by Aldrich Chemical) was used. As acetoacetic acid and its salts dissolved in water are unstable, even at low temperatures, the lithium acetoacetate solution was made up directly prior to use.

2.2. Apparatus and conditions for chromatography

The gas chromatograph used was a Chrompack model 437 S, equipped with a ^{63}Ni electron capture detector and a fused silica capillary column ($50 \text{ m} \times 0.25 \text{ mm}$) coated with CP-Sil-8CB (supplied by Chrompack, The Netherlands). Nitrogen, at an inlet pressure of 90 kPa, was used as the carrier gas. The tests were performed under isothermal conditions. The temperatures of the column, the inlet and the detector were 110°C , 250 and 270°C , respectively. The split ratio and the degree of electrometer attenuation were 50:1 and 2^7 respectively.

2.3. Procedure

In a 30 ml centrifuge tube, 10 ml of the milk sample was mixed with 7 ml water and 1.5 ml of both clarifying agents. After a 10 min period of centrifuging at $750 \times g$, a portion of 5 ml of the clear supernatant was measured into a 10 ml

Fig. 1. Chromatograms of oxidised ketone bodies analysed as bromoacetone (BA): (a) reagent blank; (b) standard of 1.50 mM; and (c) a milk sample containing 1.42 mmol l^{-1} oxidised ketone bodies.

Fig. 2. Detector response (y) as a function of the concentration of acetone (x) in aqueous solution.

glass-stoppered test tube; the latter was then closed and kept in a boiling water bath for 35 min.

After cooling, 1.5 ml of the Br_2 solution, 1 ml of the H_2SO_4 solution and 2.5 ml toluene were added to the carboxylated sample solution, then the test tube was sealed and allowed to stand at room temperature for an hour and a half, with vigorous shaking every 15 min.

In order to bind the excess of bromine, 0.2 ml of the phenol solution was added to the mixture in the test tube (this reaction was also advanced by vigorous shaking until the brownish colour disappeared). Finally, 1 μl aliquots of the organic phase were injected manually into the gas chromatograph using a micropipette. For each sample, three injections were made. The peak area was used for quantitation and for the calculations. With the exception of heating in the water bath, the blank (triply distilled water) and the standard acetone solutions were subjected to the same procedure as that described above.

If the concentration of milk-oxidised ketone bodies was found to be more than 2 mmol l^{-1} , the analysis was repeated using 4 ml of the milk sample and 13 ml water instead of 10 and 7 ml,

respectively and the result obtained in such a manner was accepted.

3. Results and discussion

First, the milk sample was deproteinated by means of zinc hexacyanoferrate precipitate, then acetoacetic acid was decarboxylated by heating [2]. Following this, the acetone formed due to the decomposition of acetoacetic acid and the acetone which already existed in the sample were determined together. The procedure for this was as follows: acetone was allowed to react with bromine in the presence of sulphuric acid and the propanone derivative formed was extracted into toluene, then measured by gas chromatography using electron capture detection. Prior to gas chromatography, the excess bromine was bound by phenol.

The conditions detailed above yielded a single propanone derivative, namely monobromoacetone, the peak corresponding to which appeared on the chromatogram after the retention time of 6.4 min (Fig. 1). The identification of this substance was performed by gas chromatography with the aid of a monobromoacetone standard solution prepared according to the method of Maros et al. [17], where the bromoacetone preparation is described in connection with the bromine determination.

In the initial stage of the study *n*-hexane and also toluene were tried out as solvents for the extraction of the bromoacetone formed in the aqueous medium. As the partition coefficient of the propanone derivative mentioned above was found at room temperature to be 0.7 between *n*-hexane and water and 1.5 between toluene and water, it was decided to use toluene. In the latter case, the contact time of the two phases did not significantly affect the results for contact times up to 2 h. The amount of reaction product in the toluene extract when separated from the aqueous solution was stable.

The detector response to bromoacetone into toluene was directly proportional to the acetone concentration (or more precisely, the concentration of the oxidised ketone bodies) in the sample up to 2 mmol l^{-1} . Fig. 2 also shows a typical

Table 1
Results of recovery tests for acetoacetate added to different samples

Sample	Sum of acetone and acetoacetate determined in the original sample ^a (mmol l ⁻¹)	Acetoacetate	
		Added (mmol l ⁻¹)	Recovered (%)
1 mM acetone	0.985	0.54	105.7
Cow's milk (I)	0.375	0.27	91.9
Boiled cow's milk (I) ^b	0.008	0.27	94.8
Cow's milk (II)	0.610	0.81	103.5
Cow's milk (III)	1.728	1.08	95.8
Cow's milk (IV)	3.231	1.08	101.7
Mare's milk	0.182	0.27	113.0
Sheep's milk	0.264	0.27	96.7

^aThe number of replicates analyses was three in each case.

^bThe sample was boiled in an open vessel for 20 min prior to analysis.

standard curve. The standard deviations of the intercept and the slope are 1.48 and 1.46, respectively. It was shown by the *t*-test that the intercept differs significantly from zero ($p < 0.01$), probably due to impurities in the reagents used.

To establish the limit of detection, the blank (triply distilled water) was subjected twelve times to the procedure detailed above, with the excep-

tion of heating following the use of the clarifying agents. The mean and the standard deviation of the signals obtained were 5.080 and 0.072 respectively, in arbitrary units. The limit of detection (LOD) was calculated from the standard deviation of the blank signals (noise, N) and the slope of the calibration curve mentioned previously (S), as follows [18]: $LOD = 3N/S = 9 \times 10^{-7} \text{ mol l}^{-1}$ oxidised ketone body in the sample. The concentration value thus calculated corresponds to 52 pg of acetone in the sample if 10 ml of the milk sample is measured and a 1 μl aliquot of the organic phase is injected into the gas chromatograph.

In order to check the reproducibility, the complete procedure described above was repeated fifteen times with one milk sample taken from a non-ketotic cow and twelve times with another sample from a cow suffering from hyperketonaemia. The mean and the relative standard deviation (RSD) of the results obtained were 0.36 mmol l⁻¹ and 7.5% respectively, for the healthy cow and 4.57 mmol l⁻¹ and 3.8% respectively, for the hyperketonaemic cow.

To estimate the day-to-day reproducibility, the oxidised ketone bodies in a milk sample were determined once a day on five consecutive days. Each time the complete procedure (including the deproteination, as previously described, with clarifying agents) was carried out. The mean of the results obtained was 1.48 mmol l⁻¹, their RSD

Fig. 3. Comparative results obtained by the gas chromatographic method (x) and a widely accepted spectrophotometric method (y) for oxidised ketone bodies in various milk samples.

being 6.6%. The sensitivity of the measuring system applied was not higher than 4.5%.

The accuracy of the method described in the present paper was also checked by means of a recovery test and a method comparison study. As Table 1 indicates, recovery of the acetoacetic acid added to the sample ranged from 92 to 113%, the mean being 100.4%. This gas chromatographic method and a widely accepted spectrophotometric method [9] were used to analyse 23 samples. It was proven by regression analysis that the results obtained by the two methods were in close agreement (Fig. 3). The regression coefficient scarcely diverged from the value of one and the regression constant was not significantly different from zero ($p > 0.1$).

4. Conclusion

On the basis of the results obtained in this study, it can be ascertained that the reliability of the gas chromatographic method developed meets practical requirements. The forte of this method is its high sensitivity, in consequence of which it is suitable for the establishment of even subclinical ketosis. The determination procedure is quite simple to perform, but necessitates a gas chromatograph equipped with an electron capture detector, together with distilled water of extremely high quality and very pure chemicals.

Abstract

Using three enzyme sensors (tyrosinase, catalase and glucose oxidase), capable of functioning also in non-aqueous solvents, we found new correlations between classical indicators, e.g. the log *P* value of several organic solvents and new empirical indicators such as 'maximum current variation' (MCV) and above all the 'current variation rate' (CVR), the values of which may be monitored with the biosensor considered dipping directly into the organic solvent. The trend of the immobilised specific activity of the tyrosinase enzyme dipping into different organic solvents was evaluated and compared with that determined by the spectrophotometric method. Lastly, an investigation was performed to experimentally verify the relation between hydrophobicity of the solvent and its ability to draw back the water from the enzyme microenvironment using the Karl Fischer method and thermogravimetric analysis to estimate the residual water in the enzyme microenvironment after having treated the enzyme with the organic solvent, then allowing it to dry. © 1998 Elsevier Science B.V. 1. Introduction

As the catalytic performance of an enzyme is strictly dependent on the characteristics of the solvent in which the enzyme operates, many attempts have been made in recent years to obtain empirical and theoretical rules for the optimization of the whole reaction system [1–11].

Authors such as Laane [4], Zacks [5], Klivanov [7], Dordick [8], and coworkers have repeatedly pointed to the correlation between enzymatic activity and dielectric constant, or log *P* values of the solvent considered. More recently, Cernia et al. [12] employed microbial immobilized lipase to catalyse the esterification of aromatic chiral alcohols, using organic solvents as reaction media. They reached very interesting conclusions regarding the correlation between the above cited indicators and enzyme activity and selectivity.

Our increased knowledge concerning the possible use of a large number of enzymes also in

* Corresponding author. Tel.: +39 6 49913744; +39 6 490375; e-mail: campanella@axrma.uniroma1.it

non-aqueous solvents recently encouraged the development of enzymatic sensors capable of operating in organic solvents. Several different authors, including Turner and coworkers and Wang et al., have published papers in this field [13–25].

In recent years we have carried out detailed studies into the correlation between the nature of the organic solvent used and the sensitivity of the response of an original tyrosinase enzymatic sensor dipping into this solvent [26,27]. What was really being looked for was a possible correlation between biosensor sensitivity (and, therefore, enzymatic activity) and indicators, such as the dielectric constant value (DEC), or the log P value of the solvent used; the results seemed to be of great interest [27].

Two different papers published last year [22,28] demonstrate the ability of catalase (from bovine liver) to operate in an organic phase. We, therefore, recently studied a new catalase biosensor, sensitive to hydrogen peroxide, capable of operating both in several non-aqueous anhydrous solvents [29] and in water saturated chloroform [30], employing the new catalase biosensor to continue the experimental research that our laboratory has been actively pursuing [26,27] into the dependence of biosensor sensitivity and lifetime (and ultimately also the greater or lesser activity displayed by the enzyme operating in organic solvents) on the different hydrophobicity and polarity of the solvent used. Results, obtained using the biosensor dipped in four different organic solvents, were excellent also in this case [29] and mostly confirmed what we expected to find on the basis of the previous experiments carried out using the tyrosinase sensor [27].

The aspect investigated in recent months and described in this paper, using catalase or tyrosinase biosensors dipping into several organic solvents, is the correlation between classical indicators such as the log P value of the solvent and empirical new indicators such as 'maximum current variation' (MCV) or 'current variation rate' (CVR) of the enzyme biosensor dipping into the solvent considered. The results discussed herein seem of particular interest as re-

gards the correlation between log P and the CVR.

The interest inherent in experimental investigations aimed at determining possible correlation among certain easily measurable indicators, using a biosensor, and chemical indicators such as the log P values (which is known to describe the hydrophobicity of the considered solvent [4,7,10]), derives from the fact that an enzyme, even when working in an organic solvent, needs a minimal quantity of water in order to carry out its catalytic activity [3,5,8]. The actual amount varies from enzyme to enzyme and depends also on the solvent used. Usually, enzymatic activity is related directly to hydrophobicity. On the other hand, hydrophobicity is measured using the value of log P (P is the distribution coefficient of the solvent used in a standard two-phase octanol/water system [4,7,10]). For instance, solvents with log P lower than 2 are strongly hydrophilic. They, thus, remove water needed by the enzyme and consequently tend to substantially enhance the structural rigidity of the latter's molecule, which results in a loss of catalytic activity. This removal of the water molecule from the enzymatic microenvironment has been both postulated and indirectly verified by various authors [3,5,6,8,31]. However, more direct experimental evidence in this connection is still needed. To achieve this it will nevertheless be necessary to develop specific, somewhat complex methods. The present paper represents also an attempt to make an experimental contribution to the study of this problem. We think that, although qualitative in nature, the results of studies can be of some interest also from the methodological point of view. In practice, it has been attempted to correlate the log P trend of the solvents considered with the percentage of water (as determined experimentally using two different analytical methods) still present in the microenvironment of the enzyme glucose oxidase chosen as an enzyme model, after the enzyme was treated with different organic solvents and then allowed to dry; the first data are reported and discussed in this paper.

2. Experimental

2.1. Materials

Catalase (EC 1.11.1.6) (from bovine liver, 11 000 U/mg), tyrosinase (EC 1.14.18.1) (from mushroom, 4400 U/mg), glucose oxidase (EC 1.1.3.4), (from *Aspergillus niger*, 150–203 U/mg) and the dialysis membrane (D-9777) were supplied by Sigma, St. Louis, MO, USA. The phenol and the κ -Carrageenan were purchased from Fluka AG, Buchs, Switzerland; n-heptane, n-hexane, n-pentane, toluene, acetonitrile and ethyl acetate (RPE ACS), hydrogen peroxide, glucose, phosphate (used for the buffer preparation) and all the other chemical reagents, of analytical reagent grade, were supplied by Carlo Erba, Milan, Italy; 1,4-dioxane (extra pure) was from Merck, Darmstadt, Germany; chlorobenzene (spectrophotometric grade) from Aldrich, Milan, Italy; chloroform (Chromasolv) was supplied by Riedel de Haen, Seelze-Hannover, Germany.

The reagent and solvent used for water content determination using the Karl Fischer method were supplied by Merck, Darmstadt, Germany, art. 9243 and art. 9241, respectively. Using this method the water content of the anhydrous solvents used is generally lower than 0.01–0.02% by weight [26,27].

2.2. Apparatus

The oxygen electrode was a mod. 4000-1 obtained from Universal Sensors Inc., New Orleans, USA, the original membrane of which was replaced by a Teflon one. The O-ring, as well as the external body of the electrode, was also custom made of Teflon [27].

Tyrosinase biosensor measurements were performed using a Digital pH meter multimeter apparatus, model 200, supplied by Bell Engineering, USA. A Metrohm (Switzerland) 641 VA-Detector was used as potentiostatic power supply and to transform the 'current' signal into a 'tension' signal.

For the catalase biosensor measurements an Amel mod. 551 potentiostat equipped with an Amel adapter mod. 551/R from Amel, Milan

Italy, and a digital multimeter Mitek-MK 5001 (Taiwan) were used.

Glucose biosensor measurements were carried out using an Amperometric Biosensor Detector supplied by Universal Sensors Inc., New Orleans, USA.

In all cases, the responses were recorded on an Amel (Italy) model 868 recorder and the tests were carried out at 25°C in a thermostatted glass cell equipped with a forced water circulation jacket coupled to a model VC 20B Julabo (Germany) thermostat. The solvents used in the tests were kept under constant magnetic stirring using a microstirrer from Velp Scientifica (Italy).

Measurements of the water content were performed using both a Karl Fischer automatic titrator, model DL18, supplied by Mettler (Switzerland) and a Mettler TG50 thermobalance, coupled with a Mettler TC10 A-TA processor system and a Swiss Dot-Matrix printer, all from Mettler (Switzerland).

2.3. Methods

2.3.1. Enzyme immobilization.

The same enzymatic immobilization method to make the biosensors was used throughout. It consisted essentially in the κ -Carrageenan gel immobilization method, which had proved very effective on previous occasions [27,29].

Briefly, a 2% (w/w) solution of κ -Carrageenan was prepared by dissolving 0.2 g of the polysaccharide in 10 ml of distilled water, gradually heating the solution and maintaining it under constant stirring. The warm solution was placed on a Petri dish and, after cooling, some disks (1 cm diameter) were cut from it. After drying at room temperature, the κ -Carrageenan disks can be stored as long as needed. To obtain the enzyme membrane, 25 μ l of the enzymatic solution was added to each disk, which was then stored overnight at 5°C. The concentrations of the enzymatic solutions (all in 1/15 M phosphate buffer, at pH 7) used to make the three different enzyme biosensors employed in this study, were about 55 000, 2000, 7500–10 000 U/ml, for tyrosinase, catalase and glucose oxidase, respectively.

2.3.2. Biosensors assembly

The κ -Carrageenan layer entrapping the enzyme, prepared as described above, was placed on the head of an amperometric gas diffusion electrode for oxygen, between the gas permeable membrane of the electrode and a dialysis membrane; the whole system was fixed to the Teflon cap by means of a Teflon O-ring (see the drawing of the biosensor assembly in a previous paper [27]).

Before use, the biosensor was immersed for about 15 min in phosphate buffer; after use it was first washed with the solvent used and then with phosphate buffer, before being stored at 5°C in a humid atmosphere.

If the dialysis membrane is deteriorated, the O-ring must be removed and the Teflon cap dipped into phosphate buffer for a short time, so that the dialysis membrane can easily be removed without disturbing the κ -Carrageenan layer containing the enzyme. A new dialysis membrane and the same enzyme-containing layer are then mounted on the cap using the Teflon O-ring.

2.3.3. Measurements

When the biosensor is dipped into 15 ml of the organic solvent, under stirring, and the substrate added, measurements are carried out by recording the signal variations related to the oxygen consumption, or production, in solution, due to one of the following enzymatic reactions:

For each biosensor and for each solvent, calibration curves were obtained by successive additions of small volumes (a few μl) of the non-aqueous standard solution of the substrate (i.e. phenol, hydrogen peroxide, or glucose) and

recording the signal variation between the two steady states before and after each addition of substrate. A procedure to obtain calibration curves using biosensors is reported in greater detail in previous papers [26,27,29,30]. Of course, the MCV was easily checked when the trend of the calibration curve reached the plateau (see example of graphical measurement of MCV in Fig. 1).

2.3.4. Measurement of the CVR and the immobilized specific activity using biosensors

To perform the measurements of CVR, the enzymatic sensor was immersed in 15 ml of non-aqueous solvent contained in a glass cell thermostatted at 25°C, under constant atmospheric pressure of 1013.1 (± 6.1) mbar and stirred magnetically, waiting until the signal became stable. With the onset of stabilization the measurement was performed by adding a fixed small volume (generally 25.0 μl) of the proper standard non-aqueous solution of the substrate [27,29], to bring the final concentration to 0.6 mM in hydrogen peroxide, or 1.0 mM in phenol, or 0.06 mM in glucose, respectively, and the signal variation (corresponding to the oxygen decrease, in the case of tyrosinase and glucose oxidase biosensors, or increase, for the catalase biosensor), was recorded until a new steady state was reached. The CVR value was obtained by plotting the recorded signal vs. the time, and calculating the value of the angular coefficient of the straight line portion of the recorded curve, see example in Fig. 3. To calculate the immobilized specific activity, the signal was converted into consumed or produced oxygen and, taking into account the stoichiometry of the enzymatic reaction, the number of μmol of substrate converted into the product per min was determined. Lastly, from the diameter (1.0 cm) of the κ -Carrageenan disk, it was possible to obtain the value of the immobilized specific activity (as described in greater detail in a previous paper [32]).

Because of the very low solubility of glucose in organic solvents, above all in non-polar solvents, the reaction rate measurements performed using the glucose oxidase sensor were performed only in saturated chloroform containing 0.09% (v/v) of

Fig. 1. Calibration graph obtained using the catalase biosensor with chloroform as organic solvent and graphical measurement of MCV indicator for catalase biosensor in chloroform.

water, as well as in ethyl acetate and in acetonitrile, 1.5 and 2.5% (v/v) in aqueous solution, respectively, (i.e. containing the minimum percentage of water below which no biosensor response could be observed). The small percentage of water contained in these solvents is, in fact, necessary to increase, albeit slightly, the solubility of the substrate in the solvent considered.

2.3.5. Measurement of the immobilized specific activity by the spectrophotometric method

In the case of the tyrosinase enzyme layer data on immobilized specific activity as a function of the organic solvent considered and determined using the tyrosinase biosensor were compared with analogous data obtained using a classical spectrophotometric method based on the use of Folin Ciocalteu reagent [33]. To this end a κ -

Carrageenan enzymatic layer was dipped in 25 ml of the non-aqueous solution 2.1 mM of phenol and thermostatted at 25°C. At different times a small volume of the solution was tested for phenol content by the following procedure: 0.5 ml of Folin Ciocalteu reagent, followed by 1.5 ml of 20% (w/v) sodium carbonate solution, were added to 1.0 ml of the above standard solution. The mixture was then diluted to 5 ml with water and heated in a water bath at 35°C for 20 min, to allow the colour to develop completely. The absorbance was measured at $\lambda = 760$ nm against a white reagent. Concentration values were obtained by the direct method using a calibration graph. It was, thus, possible to determine the decrease in concentration of the substrate (phenol) as a function of time, in practice, the reaction rate. Lastly, the immobilized specific activity was

obtained taking into account of the diameter of the κ -Carrageenan disk (generally 1.0 cm).

2.3.6. Treatment of the glucose oxidase enzyme with different organic solvents to check the solvent ability to draw the water from the enzyme microenvironment

About 200 mg of glucose oxidase were weighed out for each test. Four different procedures were preliminarily tested:

- a) The enzyme was placed in a glass Petri dish, about 20 ml of the organic solvent were added and then after stirring allowed to evaporate at constant humidity (25% RH), temperature (25°C) and atmospheric pressure (1013.1 mbar).
- b) The enzyme was placed in a dialysis tube filled with the solvent and closed at each end; the tube was then placed in about 20 ml of the same solvent; the latter was renewed three times and then the dialysis tube was opened and the solvent containing the enzyme allowed to dry at constant humidity (25% RH), temperature (25°C) and atmospheric pressure (1013.1 mbar).
- c) The enzyme was placed in a Gooch crucible incorporated in a filtering apparatus. The Gooch crucible was filled three times with volumes of about 20 ml of the organic solvent considered. The enzyme was then allowed to dry in a desiccator under a moderate vacuum.
- d) The enzyme was placed in a Gooch crucible in a filtering apparatus. The Gooch crucible was filled three times with volumes of about 20 ml of the organic solvent considered. The enzyme was then allowed to dry at constant humidity (25% RH), temperature (25°C) and atmospheric pressure (1013.1 mbar).

The determination of the water content after each of the above treatments, carried out using the methods described in the present paper, showed that treatment (a) is comparatively inefficient; in practice, the enzyme retains about the same water content as at the outset; treatments (b) and (d) are practically equivalent as far as the results are concerned, but treatment (b) is much slower, taking several days instead of several hours. Lastly, treatment (c), which differs from (d) only in the way the drying is performed, gives rise to a product (enzyme) that retains a smaller

quantity of water than in all other cases. Above all, however, this quantity remains practically constant whatever the method and solvent used. Using this method to dry the enzyme is practically the only drying treatment that affects the water retained by the enzyme, eliminating the differences due to treatment with the various solvents. In conclusion, taking these results into account, the treatment that was subsequently systematically adopted in all the experiments carried out using different solvents was the treatment (d). Probably, also in this way, the water content of the product is partially affected by the method used for drying (it is indeed possible that the enzyme is partially rehydrated). However, the differences in water content due to treatment with solvents at different degrees of hydrophilicity, may still be highlighted by means of careful determination of the water content, as the experimental results have shown.

2.3.7. Determination of the water content in the glucose oxidase enzyme whether treated or not by organic solvent

For measurements using the Karl Fischer method, 30–40 mg of the enzyme, treated or not treated with the organic solvent considered, were weighed and rapidly added to the Karl Fischer cell. Titration, performed by the automatic titrator, was started after 30 s of stirring at 25°C, in a nitrogen stream.

For the measurements of water content by thermogravimetry an amount of enzyme of the order of 10 mg was accurately weighed and analysed under the following experimental conditions: heating between 20 and 150°C at a rate of 5°C/min in an air stream at a flow rate of 50 cm³/min.

3. Results and discussion

As stated in the introduction of this paper, in recent work we investigated catalase biosensor response to hydrogen peroxide, which we studied in four different anhydrous organic solvents [29]. Fig. 1 shows the unpublished calibration graph in anhydrous chloroform. In the curve in Fig. 1, as well as in other similar curves, obtained using the

other solvents investigated (chlorobenzene, toluene, ethyl acetate), a fairly long straight line section is found, at the end of which the curve tends to flatten out rapidly. As observed in the case of the tyrosinase biosensor [27], also in this case it was possible to ascertain experimentally that a correlation existed between indicators, such as the slope of the straight line section of the calibration graph in the various solvents (in practice the biosensor's sensitivity) and the value of $\log P$ of the solvent considered. It is sufficient to compare the trends of the (a) and (b) series of histograms shown in Fig. 2 for this purpose. However, an improved correlation has now been found. In this case it should also be noted that, instead of biosensor sensitivity, in order to highlight another interesting correlation with $\log P$ value, it would also be possible to use the MCV of the enzyme sensors as a new empirical indicator, recorded for high concentrations of substrate, in practice when the calibration curve obtained using the catalase biosensor dipping in the organic solvent flattens out (see Fig. 1). With this purpose in mind a comparison should be made between the trends in the (a) and (c) series of histograms in Fig. 2.

Lastly, the histogram (b) of Fig. 4 also shows the trend of the value of the CVR of the catalase biosensor dipping into different organic solvents, as determined for high substrate concentrations (0.6 mM) and measured as shown in Fig. 3. Clearly, according to the common definition of enzymatic activity, the measured CVR, is related to the variation of the oxygen concentration in solution, due to the enzymatic reaction and therefore also to the reaction rate. CVR is thus essentially an empirical indicator that should correlate more closely with enzymatic activity than the previously [27,29] investigated indicators. Experimental tests actually also indicate a trend in perfect agreement with the value of $\log P$ (see Fig. 4(a)). On the other hand, in this connection, it is not surprising that the CVR trend is in perfect agreement with the value of $\log P$, if the latter is to be a truly realistic indicator of enzymatic activity in the solvent considered [11,13,27,29,31].

Furthermore, using the previous rate data, in order to calculate the reaction rate and thus the

immobilized specific activity of the enzyme in the various solvents, it is obvious that the plot obtained for the latter will be very similar to that of the CVR indicator and of course in good correlation with the trend of $\log P$ values (Fig. 4). It is equally obvious that, despite the objection that, since the classic operating conditions required for the activity measurement in aqueous solvent [20] were not fully achieved and so the 'absolute values' of the immobilized specific activity found

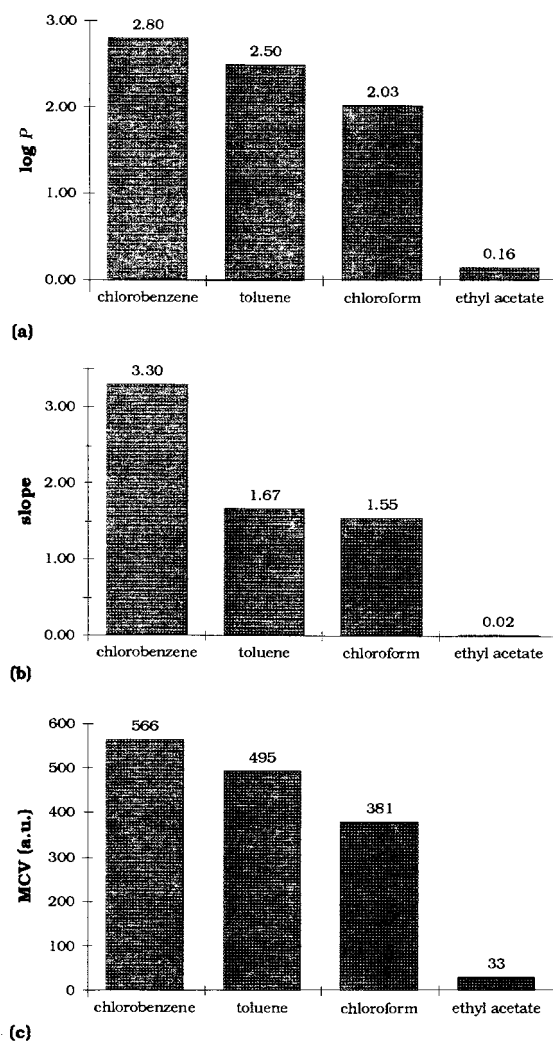

Fig. 2. Trend of: (a) $\log P$ values of several organic solvents; (b) the slope of the calibration graphs; (c) the MCV for the catalase biosensor as a function of the organic solvents considered.

Fig. 3. Response of catalase biosensor dipping into different solvents, as a function of time, recorded for a high value of the hydrogen peroxide concentration: 0.6 mM. The value of the angular coefficient of the straight line section of the recorded response curve of the biosensor allows the value of the CVR indicator to be checked.

might not be completely accurate, the histogram trends of the relative activity values, measured using the biosensor dipping into the different solvents, may certainly be considered reliable, as the operating conditions remained the same in spite of the change of solvent.

In view of the interest and satisfaction at having found this further correlation, we also set out to determine whether the highly significant correlation between $\log P$ values of different solvents and the CVR indicator (and therefore also the specific immobilized activity), or MCV indicator, could again be experimentally verified using another enzymatic sensor, i.e. the tyrosinase biosensor, which is also capable of being used in non-aqueous solution and was recently studied by us [26,27].

The experimental results of this investigation are shown graphically in Fig. 5 and Fig. 6. By means of the histograms in Fig. 5 a comparison was made of $\log P$ trends for the same solvents as were considered in a previous paper [27] and those of sensitivity values of the tyrosinase enzyme sensor (e.g. the slope values of the straight line section of the calibration curve obtained using the tyrosinase biosensor in the organic solvent considered), or else with those of the new indicator MCV. On the other hand, Fig. 6 shows the trend of CVR values of the tyrosinase biosensor response dipping into the different organic solvents considered, determined for a high substrate concentration (1.0 mM). It is interesting to note that the $\log P$ trend and that of the sensitivity values

are in good agreement when the following solvents are used: acetonitrile, chloroform, toluene and n-heptane, whereas, when n-hexane or n-pentane are used as solvent, the trend continues to rise if the sensitivity values are taken, while it is inverted and decreases if $\log P$ values are considered. Conversely, the same inversion is found in the trends of MCV values (Fig. 5) and in those of the CVR values (Fig. 6). However, while in the first case the MCV trend, although quite com-

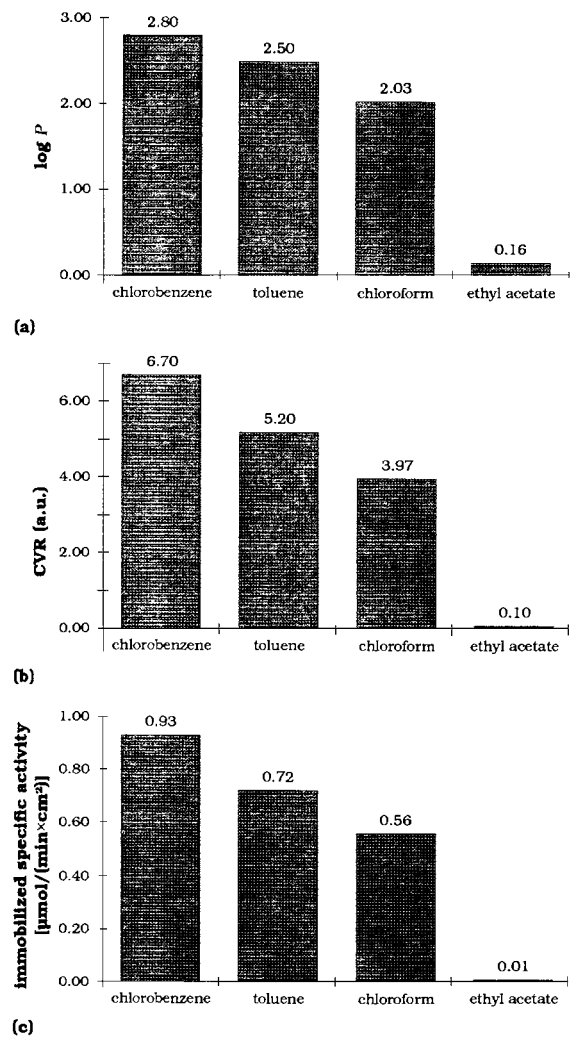

Fig. 4. Trend of: (a) $\log P$ values of several organic solvents; (b) the CVR; (c) the immobilized specific activity, for the catalase biosensor, as a function of the organic solvents considered.

parable to those of $\log P$, are not exactly the same, in the second case the CVR trend and that of $\log P$ are in almost perfect agreement.

Also in this case, as in that of the catalase electrode, it is obviously possible to estimate the values of the immobilized specific activity of the enzyme. Although also for these data the same reservations apply as for the accuracy of the

absolute value of the activities obtained using the enzyme sensor, it is nevertheless comforting to observe how the actual values of the activity, determined independently, also by means of the absorption spectrophotometry, not only obviously display an analogous trend regardless of the method used to obtain them, but the values are not in absolute terms much different from those determined using the biosensor immersed directly in the organic solvent (compare both the trends and the values of the histograms (b) and (c) in Fig. 6).

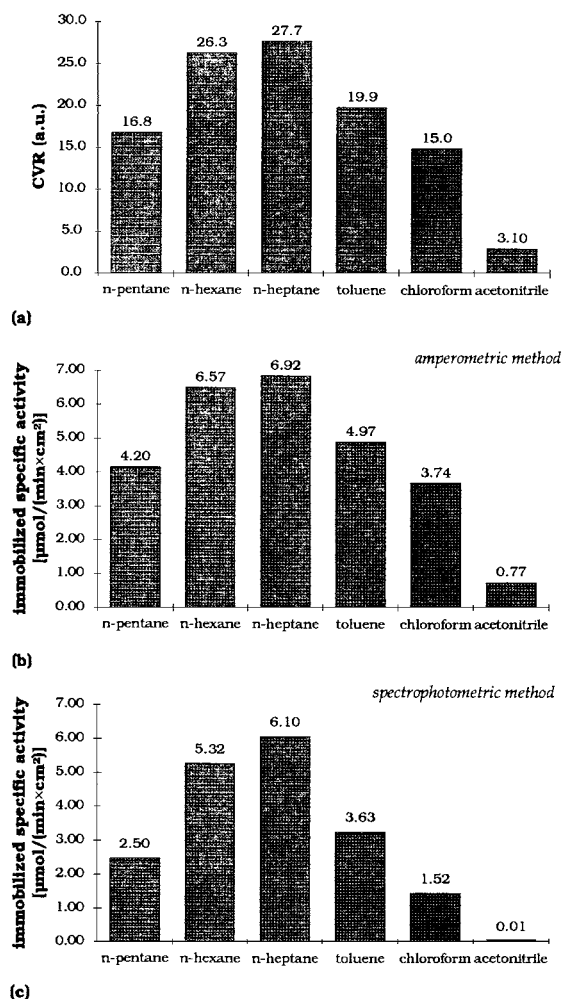

Fig. 6. Trend of: (a) the CVR; (b) the immobilized specific activity for the tyrosinase biosensor; (c) the immobilized specific activity measured using the spectrophotometric method, as a function of the organic solvents considered.

Lastly, as briefly stated in the introduction of this paper, the role played by the aqueous microenvironment constantly surrounding the enzyme is well known, and is thus a key factor in optimizing the enzymatic activity [3,5,8] and, thus, also the biosensor response [13,14,27,29]. Therefore, we carried out an experimental study to determine the water content of a typical common enzyme both in the lyophilized form and after treatment with an organic solvent and then allowing the organic solvent to evaporate. Taking into account that this study requires a large amount of enzyme, glucose oxidase was used as an enzyme model, even though it certainly does not represent one of the most interesting enzymatic systems from the point of view of possible uses in non-aqueous solvents. The main reason for this choice was the enzyme's relatively low cost and the fact that it was recently shown [34] to be capable of operating also in non-aqueous solvents, or mixtures of solvents. To this end several organic solvents with different hydrophobicity were employed; in practice a weighed amount of the lyophilized glucose oxidase enzyme was treated with each of the organic solvents considered in turn, according to the procedure described in Section 2 of this paper. Therefore, after allowing the organic solvent to evaporate, the water content that was still found to be held by the enzyme itself was determined. The techniques used for this study were thermogravimetric analysis and Karl Fischer titration. Although only in qualitative mode, the results seem to confirm the reverse correlation between the hydrophobicity of the solvents considered and their ability to withdraw water from the enzyme aqueous microenvironment. The data referring to the water content of the treated enzyme as determined independently using two different methods of analysis, confirm what we actually expected to find, namely that the enzyme treated with less hydrophilic solvent (i.e. with a higher $\log P$ value) retains a higher water content than the enzyme treated with a more hydrophilic solvent (i.e. with a low $\log P$ value) [11,13,27,29,31]. Clearly, for the reasons briefly set out in Section 2, in performing this kind of experiment, whatever the procedure adopted in treating

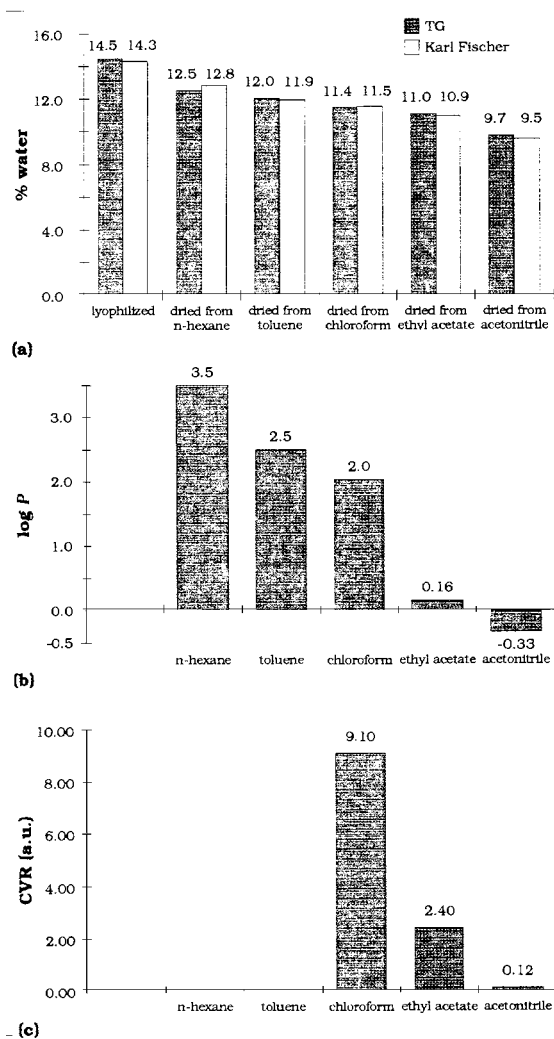

Fig. 7. (a) % Water content of glucose oxidase enzyme, either lyophilised or after treatment with the solvent considered, then allowed to dry, found using the thermogravimetric (TG) or Karl Fischer method; trend of: (b) $\log P$ values of the organic solvents considered; (c) the CVR measured using the glucose oxidase biosensor, as a function of the organic solvents considered.

the enzyme with the organic solvent and, to an even greater extent, that used to evaporate the organic solvent in the enzyme thus treated, inevitably had a systematic influence on the water content associated with the enzyme, thus determined using the above methods, nevertheless the trend that emerges from the histogram (a) in Fig.

7 shows that it still retains practically the original information; since by constantly operating in the same experimental conditions, the procedure adopted had only a systematic effect on the analytical data. Indeed an appreciable correlation was found between the $\log P$ trends of the solvents used and the water content retained by the glucose oxidase which was subjected to treatment using one of the organic solvents considered. Incidentally, it is interesting to observe the good agreement of the analytical results yielded by the two methods used to determine the water retained by the enzyme even though they are based on quite different principles.

Furthermore, some experiments using a glucose oxidase enzyme sensor dipping into an organic solvent yielded results in agreement with those found using two other catalase and tyrosinase biosensors. Indeed, the last set of histograms (c) in Fig. 7 clearly show how by considering the CVR indicator for the glucose oxidase enzyme sensor, working in different organic solvents, also in this case the value of this indicator increases with increasing $\log P$, i.e. with the degree of solvent hydrophobicity. Of course, in these experiments using the glucose oxidase biosensor, the investigation was limited to just three different organic solvents in view of the very low solubility of the substrate in organic solvents, above all in solvents that were more hydrophobic than those considered (e.g. toluene and n-hexane). In conclusion, even the limited experiments carried out using the glucose oxidase enzyme sensor confirm the more general results found in this research using the other two enzymatic biosensors.

In other words, we can conclude that a close correlation exists between the trend in the classic $\log P$ indicator and that of the CVR indicator proposed here. Subsequently, the latter indicator, also because it can be measured simply and rapidly by the enzyme sensor dipped directly into the organic solvent, may be used as an indicator of enzymatic activity in the organic solvent considered; in fact, its trend closely follows that of $\log P$, in many cases even more closely than the biosensor's sensitivity, which is the indicator that we have studied and proposed over the last 2 years in previous papers [27,29] and which itself

has often provided very good results in this connection.

Lastly, it must be pointed out that, in carrying out the research described, and in evaluating and discussing the results obtained, several reasonable assumptions were made: in the first place, that, as in all sensors of this kind (OPEEs), the enzyme molecules involved in the catalytic action are essentially those at the interface. Therefore, also in view of the considerable (albeit different) hydrophobicity of the organic solvents considered, it would appear legitimate, in discussing the results obtained, to neglect in the first instance, any diffusion phenomena in the κ -Carrageenan gel or any solvent effects on the gel itself (in any case, this assumption is supported by the long lifetime of the biosensors considered and the good reproducibility of their response [27,29,30]). Furthermore, the enzyme immobilized in the gel and certainly still completely surrounded by water molecules was considered as though it was practically free in an aqueous solution, so as to be able to discuss the effects of the solvent on the enzymatic microenvironment, using the same criteria and the same indicators as in the majority of literature articles on the subject, many of which are cited also in the references of the present paper [1–13,26–31]. The good agreement between the experimental results and what was reasonable to expect on the strength of the literature data [1–14,27,29,31], may in any case, be deemed to justify the assumptions made, albeit a posteriori.

Received 29 April 1997; received in revised form 22 August 1997; accepted 5 September 1997

Abstract

The voltammetric characteristics of lead(II) benzoylacetate in chloroform at the mercury electrode are investigated. The conditions for nearly reversible reduction of lead(II) were optimized. Anodic stripping voltammetry for the determination of trace-lead was developed using differential pulse technique to strip amalgamated lead from hanging mercury drop electrode. The experimental conditions, such as scanning rate of electrode potential and deposition time of lead were optimized. The calibration graph was linear over concentration range 5×10^{-8} – 10^{-6} M of lead(II). The detection limit was 2.5×10^{-9} and the relative standard deviation for the determination of 4×10^{-7} M Pb(II) was 2%. Preceded by decomposition of organolead compounds with concentrated nitric acid, then ashing at 300°C and a solvent extraction of Pb(II) benzoylacetate in chloroform, the suitability of the proposed method for the determination of lead in free-lead gasoline and gas oil was demonstrated as a typical example of application. © 1998 Elsevier Science B.V. 1. Introduction

Direct application of electroanalytical methods to the determination of analytes in pure extracts following solvent extraction seem to be simple and sensitive [1–7]. The previous studies revealed that a preliminary separation and preconcentration of some metal ion chelates by solvent extraction into chloroform and application of

electroanalytical methods for the determination of the analyte in pure extracts provide good selectivity and sensitivity [1,2]. Anodic stripping voltammetry (ASV) has always been regarded as one of the most sensitive technique for trace-metal analysis in water. A little works, exploiting non aqueous solvent for stripping techniques were reported [8,9]. To our knowledge, there are no reports on the use of stripping techniques in organic solvents of low dielectric constant, convenient for solvent extraction.

The present work deals with the study of polarographic characteristics of Pb(II) benzoylacetate in chloroform in the presence of a suitable supporting electrolyte. It was intended to investigate the suitability of the proposed method for the determination of lead in complex matrices, such as gasoline and gas oil, after its mineralization and extraction as lead(II) benzoylacetate in chloroform.

2. Experimental

2.1. Chemicals and reagents

Chloroform, perchloric acid, benzoylacetone (purified by recrystallization or sublimation), tetrabutylammonium chloride (TBACl) and piperidine were from E. Merck p.a grade. The supporting electrolytes used were 0.5 M tetrabutylammonium perchlorate (TBAP) or 0.75 M piperidinium perchlorate (PP) + 0.25 M piperidine (P). PP was prepared by gradual neutralization of a given volume of perchloric acid 1:1, with the required amount of piperidine while cooling the solution in iced water. PP formed in slightly acid solution was crystallized by successive concentration on the water bath and cooling at room temperature. The crystals formed were dried at 50°C.

2.2. Standard lead solutions

A 10^{-2} M aqueous solution of Pb(II) nitrate from E. Merck was prepared as a stock solution. The standard solutions were prepared by successive dilution of this stock solution.

2.3. Extraction solution

A 0.01 M chloroform solution of benzoylacetone was used. $\text{Pb}(\text{C}_2\text{H}_5)_4$, at least 99% purity, was from Octel (Manchester, UK) and gasoline sample with a certified amount of $\text{Pb}(\text{C}_2\text{H}_5)_4$ was obtained from Tabriz refinery. The free-lead gasoline sample (with no deliberate addition of $\text{Pb}(\text{C}_2\text{H}_5)_4$) was obtained from petroleum chemistry laboratory of our faculty.

2.4. Apparatus

All voltammograms were recorded with a three electrode system. A polarograph E 626 was used with a VA-Stand 663 and VA-controller E608 (from Metrohm) to plot the polarograms. A multipurpose instrument from EG and G including potentiostat/galvanostat model 273, electrochemical analysis software 300 model 270 coupled with an IBM personal computer and an Epson FX 850 printer was used to record the cyclic voltammograms with IR compensation.

2.5. Electrodes

The reference electrode Ag/AgCl (sat.), TBACl (sat.) and TBAP 0.5 M in chloroform in a separated compartment was directly immersed in the reaction cell. The working electrodes were DME and HMDE, the auxiliary electrode was a platinum wire.

2.6. Procedures

2.6.1. Extraction and polarography of Pb(II) benzoylacetate

A 1 ml portion of aqueous standard or sample solutions of Pb(II) was transferred into a 100 ml separating funnel, the pH of the solution was buffered with 10 ml of 0.1 M ammonia buffer at 9, at which the extraction of lead(II) benzoylacetate was complete, this solution was shaken with an equal volume of 0.01 M chloroform solution of benzoylacetone for 20 min on a mechanical shaker. The chloroform phase was separated and transferred into a polarographic cell and a required amount of supporting electrolyte (PP 0.75 + P 0.25 M) was added, the solution was deaerated for 20 min with the nitrogen gas (99.999) presaturated with chloroform. The polarograms were recorded by sweeping the potential from 0.4 to -0.6 V vs reference electrode (the potential range of electroactivity of Hg in chloroform is $+0.45$ – -0.70 V).

2.6.2. Anodic stripping voltammetry of Pb(II) benzoylacetate

A 10 ml portion of chloroform extract of 5×10^{-8} – 10^{-6} M Pb(II) benzoylacetate with 0.01 M benzoylacetone, obtained from the standard or sample solutions was transferred into an electrolysis cell and required amount of supporting electrolyte was added. The solution was deaerated by N_2 gas for 20 min. Metallic lead was deposited on a hanging mercury drop electrode at -0.5 V for 10 min, while stirring the solution. The amalgamated lead was stripped by differential pulse polarography by scanning of potential of the electrode between -0.5 and 0.0 V with scan rate of 5 mV s^{-1} and pulse amplitude of 50 mV .

2.6.3. Mineralization and anodic stripping voltammetry of free-lead gasoline and gas oil

An aliquot of the sample (2 ml) was transferred into a porcelain crucible and 1 ml of concentrated nitric acid (65%) was added. The mixture was heated on a hot plate at 90°C for about 15 min to form a viscous product, then the crucible was placed in a furnace at 300°C for 20 min. After cooling the crucible, the residue was taken with 5 ml water. Then lead(II) benzoylacetate was extracted into chloroform, as described, for pure lead(II). The standard addition procedure or calibration graph were used.

2.6.4. Spectrophotometric analysis of free-lead gasoline

An aliquot of the gasoline sample (2 ml) was shaken with 5 ml of 1 M aqueous solution of ICl [12] in a separating funnel for 2 min. The aqueous phase was separated and heated for 5 min to mineralize the organolead compounds, then a saturated solution of sodium sulfite was added until the aqueous phase become colourless. The mineralized Pb(II) was extracted by a 2.5% dithizone solution in chloroform. The absorbance was measured at 520 nm and the amount of Pb was determined via a calibration graph constructed by means of standard solutions of Pb(II) over a concentration range of 0 – 50 mg l^{-1} .

3. Results and discussion

3.1. Preliminary polarographic investigations.

Considering that the presence of β -diketones in chloroform do not restrict the potential range for mercury electrode and that Pb(II) may be extracted quantitatively into chloroform as benzoylacetates, we have first investigated the polarographic characteristics of lead(II) benzoylacetate in chloroform in the presence of two different supporting electrolytes.

In chloroform, in the presence of 0.5 M TBAP as supporting electrolyte, the lead(II) benzoylacetate did not reduce at mercury electrode, but with PP 0.75 + P 0.25 M merged as suitable electrolyte, the reduction of lead (II) benzoylacetate exhibited one cathodic wave with half-wave potential of -0.32 V. A plot of $\log[(i_d - i)/i]$ vs E for DC polarogram of lead(II) benzoylacetate gives a straight line with a slope of about 48 mV . A typical cyclic voltammogram monitored between 0.2 and -0.6 V is shown in Fig. 1. For all scan rates (20 – 2000 mV s^{-1}) one cathodic and corresponding anodic peaks were observed. The peak separation potential $\Delta E = E_p^a - E_p^c$ for scan rates less than 50 mV s^{-1} was 63 mV , the current

Fig. 1. Cyclic voltammograms of 1 mM Pb(II) benzoylacetate in the presence of 0.75 M PP/0.25 M P as supporting electrolyte, scan rate: 50 mV s^{-1} .

Fig. 2. Differential pulse polarograms of Pb(II) benzoylacetonate: (a) 0, (b) 5 μM , (c) 10 μM , (d) 20 μM , (e) 40 μM , (f) 60 μM in the presence of 0.75 M PP/0.25 M P as supporting electrolyte, scan rate: 5 mV s^{-1} . Pulse amplitude: 50 mV.

function ($i_p / V^{1/2}$) decreases with increasing scan rate. These confirmed that the reduction of Pb(II) benzoylacetonate was a two electron quasi-reversible process. On the other hand, the plot of i_p vs $V^{1/2}$ was linear, with a correlation coefficient better than 0.999, confirming the diffusion nature of the reduction current. The i_p^a/i_p^c ratio was about 1 for scan rate of 20–2000 mV s^{-1} . Differential pulse (DP) polarography presented well-defined peaks (Fig. 2) with E_p -0.31 V, very close to $E^{1/2}$. The calibration graph constructed with the aid of a 10^{-3} M Pb(II) benzoylacetonate solution in chloroform was linear over concentration range 5×10^{-6} – 10^{-4} M. The detection limit (LOD) of DP procedure ($\text{LOD} = y_B + 3S_{y/x}$) was suggested

5×10^{-7} M and the relative standard deviation for five replicate determinations of 2.5×10^{-5} M of Pb(II) was 1.2%.

3.2. Extraction efficiency of Pb(II) benzoylacetonate in chloroform

Quantitative extraction of Pb(II) benzoylacetonate from aqueous solution of pH 7–10, with a 0.1 M solution of benzoylacetonate in benzene was reported [10]. An extensive study showed that the Pb^{2+} ion may also be quantitatively extracted from a 0.1 M ammonia buffer solution of pH 8–9 by 0.01 M benzoylacetonate in chloroform. The optimum shaking time with a mechanical shaker was determined to be ~ 15 min. The average recovery of five replicate extractions of 10 ml 2×10^{-5} M aqueous solution of Pb^{2+} at the conditions mentioned above, was 98.5% ($\text{rsd} = 1.2\%$). The calibration graph, constructed by means of the chloroform extracts using various aqueous solutions of Pb^{2+} over concentration range 5×10^{-6} – 10^{-4} M, was linear. The slope (0.06 ± 0.008) was very close to that of calibration graph (0.062 ± 0.008) constructed by direct addition of Pb(II) benzoylacetonate in chloroform. This agreement confirmed the completeness of Pb(II) extraction into chloroform.

3.3. Anodic stripping voltammetry

On the basis of the results obtained from DP polarography of Pb(II) benzoylacetonate in chloroform, it can be concluded that the differential pulse anodic stripping voltammetry (DPASV) may be used for ultra-trace determinations of lead (10^{-7} – 10^{-10} M). The stripping voltammograms for lead deposited on the hanging mercury drop electrode (with the deposition potential and deposition duration of -0.5 V and 12 min, respectively), from the quiescent solutions of 4×10^{-7} – 10^{-6} M Pb(II) benzoylacetonate in the presence of 0.01 M benzoylacetonate and 0.75 M PP + 0.25 M P as supporting electrolyte, are shown in Fig. 3. In this experiment, the amalgamated lead is oxidized at -0.3 V followed by an unknown peak at -0.05 V. The peak at -0.05 V appeared to be a copper impurity, since it

increased in magnitude when Cu(II) was deliberately added to the solution. However, very sharp and reproducible lead stripping peaks were observed in all cases.

3.4. Effect of scan rate on the lead-stripping peak

On the basis of Randles-Sevcik equation, the anodic stripping peak current i_p increases with square root of scan rate $V^{1/2}$, while the charging current i_c increases with V . Therefore, an optimum scan rate providing a maximum 'analyt signal/residual current' ratio is desirable. For this purpose, the stripping voltammograms were recorded for the blank and 4×10^{-7} M Pb(II) benzoylacetate solutions with various electrode potential scan rates ranging from 2–50 mV s^{-1} . The deposition potential and deposition time were -0.5 V and 12 min, respectively.

On the basis of the results obtained, the maximum value of this ratio appeared at scan rate of 5 mV s^{-1} .

3.5. Effect of preconcentration time

Using three solutions of 0.1, 0.2 and 0.4 μM Pb(II) benzoylacetate, the effect of preconcentration time on lead stripping peak current has

Fig. 3. Anodic stripping voltammograms at the hanging mercury drop electrode of Pb(II) benzoylacetate (a) 0.1 (b) 0.2 (c) 0.3 (d) 0.4 (e) 0.5 μM in the presence of 0.01 M benzoylacetone and 0.75 M PP/0.25 M P as supporting electrolyte, preconcentration potential was -0.5 V and preconcentration time was 10 min, scan rate: 5 mV s^{-1} , pulse amplitude: 50 mV.

Fig. 4. Plot of average 'signal/noise' ratio of anodic stripping voltammograms of Pb vs deposition time, scan rate 5 mV s^{-1} . Deposition potential: -0.5 V, solutions concentration: 0.1, 0.2 and 0.4 μM of Pb(II) benzoylacetate.

also been studied. Preconcentration has been carried out at -0.5 V and the voltammograms have been simultaneously recorded for the blank and Pb(II) solutions, at a potential scan rate of 5 mV s^{-1} . The plot of average signal/noise ratio vs deposition time for the results obtained, is shown in Fig. 4. As seen in this figure, a preconcentration duration of 10 min may be suitable for this purpose.

3.6. Analytical performances

The calibration graph was constructed: (i) by direct addition of lead(II) benzoylacetate over concentration range 5×10^{-8} – 10^{-6} M in chloroform solution of 0.01 M benzoylacetone; and (ii) by means of chloroform extracts using the aqueous solutions of lead(II) nitrate over concentration range 5×10^{-8} – 10^{-6} M. The regression equations were $I(\mu\text{A}) = (0.013 \pm 0.004) + (0.015 \pm 0.0007) C$ (M) and $I(\mu\text{A}) = (0.0125 \pm 0.004) + (0.015 \pm 0.0007) C$ (M), respectively. These findings suggested that the two calibration graphs were nearly overlapped and therefore, the extraction efficiency of lead(II) benzoylacetate at low concentration range was $\sim 100\%$. The detection

limit of the method ($LOD = Y_B + 3S_{x/y}$) found to be 2.5×10^{-9} M of Pb(II). The standard deviation of three replicate determinations of 4×10^{-7} M lead(II) solution was $\sim 2\%$.

3.7. Interference study

Among the metal ions, Cd(II), Bi(III), Cu(II), Zn(II), Co(II), Ni(II), Mn(II), Ti(IV), Mo(VI), U(VI), La(III) and Be(II) are extractable with benzoylacetone in chloroform at pH 9 [10]. Cu(II), Bi(III), U(VI) and Mo(VI) seem to be electroreducible under the polarographic conditions for the determination of Pb(II) benzoylacetate in chloroform. We have demonstrated that the reduction potential of Cu(II) benzoylacetate is sufficiently different and did not interfere in the Pb(II) determination. We have also found that the presence of great amount of Mo(VI) and Bi(III) in aqueous solution of Pb(II) did not cause any serious interference. However U(VI) is undesirable [2], but natural occurrence of uranium in gasoline has not been reported. The presence of I⁻ ion in aqueous solution of Pb(II) masks it as PbI_4^{2-} and prevents the quantitative extraction of Pb(II) benzoylacetate into chloroform, therefore the mineralization of organolead compounds in petroleum product with ICl is undesirable.

3.8. Impurity and contamination effects

An extensive study in this area showed that a serious impurity problem appeared by benzoylacetone only (evaluated 5×10^{-8} M of Pb in voltammetric cell). This problem was solved by further purification of the commercial benzoylacetone and using its 0.01 M chloroform solution, instead of 0.1 M mentioned in Section 2.6.

3.9. Application to the analysis of gasoline and gas oil samples

The preliminary experiments showed that the alkyllead compounds are not reducible in chloroform in the polarographic conditions described above, therefore the mineralization of these compounds was required. The mineralization of organolead compounds in chloroform with a 1 M

iodine chloride (ICl) solution [11] in this solvent, seemed to be fast and suitable, but the experimental investigations showed that this procedure was unsuccessful.

Following a mineralization procedure in aqueous solution as described in [12], the alkyllead converted completely into an inorganic lead, the iodide ion formed in the solution however, was a interferent masking Pb(II) as PbI_4^{2-} and decreasing the extraction efficiency of lead(II) benzoylacetate into chloroform, therefore it was omitted in this work.

The mineralization of organolead compounds with nitric acid at convenient temperature and taking the residue in pure water [13] as described in Section 2, was found to be most suitable for the present extraction polarographic method in chloroform.

3.10. Optimization of mineralization temperature of gasoline

The ashing of gasoline–nitric acid mixture was performed at various temperature ranging from 200–600°C. Preceded by an ashing of gasoline–nitric acid mixture and solvent extraction of lead(II) benzoylacetate in chloroform, the pulse polarograms of Pb(II) were recorded and on the basis of the results, obtained the optimum temperature of 300°C.

Preceded by a mineralization process, as described above, the average recovery of lead (monitored by present extraction dp polarography) from five different tetraethyllead spiked free-lead gasoline samples ranging from 3×10^{-7} – 3×10^{-5} M was about 99%. The standard deviation in all cases was nearly 3% ($n = 3$).

3.11. Determination of lead in free-lead gasoline and gas oil

The free-lead gasoline and gas oil samples were mineralized according to procedure described in Section 2 and analyzed by anodic stripping voltammetry via a calibration graph. A typical stripping voltammogram is shown in Fig. 5 and the average amount of three replicate determinations are given in Table 1. The accuracy of the

Fig. 5. Anodic stripping voltammograms of Pb for (a) 2 ml free-lead gasoline, mineralized at 300°C (b) *a* + 0.6 ml and (c) *a* + 1.2 ml of 5 μ M Pb(II) benzoylacetate. Experimental conditions as Fig. 4.

proposed method was investigated: (i) By parallel analysis of the sample with the standard spectrophotometric method of ASTM [12]; and (ii) by recovery study of spiked samples. The results obtained from these studies are also given in Table 1. As can be seen from the results in Table 1, the agreement between the lead amount obtained by two methods is good and the recovery of spiked tetraethyllead is acceptable. Since a standard method for the determination of lead in gas oil was not reported in the literature, the

accuracy of gas oil analysis was confirmed by recovery study of spiked samples (Table 1).

4. Conclusion

The results obtained from DC polarography and cyclic voltammetry revealed that the Pb(II) benzoylacetate reduced according to a two electron quasi-reversible process at about -0.3 V in the presence of 0.75 M PP + 0.25 M P as suitable supporting electrolyte in chloroform. The mass transfer is controlled by diffusion. The Pb(II) benzoylacetate is extractable in chloroform at buffered pH 9 and extraction efficiency was $> 98.5\%$. The determination of Pb(II) in extracted phases was carried out by differential pulse polarography, the limit of detection (LOD) found is 5×10^{-7} M.

Differential pulse anodic stripping voltammetry can be successfully used for the determination of trace-lead in chloroform as an organic solvent of very low permittivity, after quantitative extraction of lead in chloroform as Pb(II) benzoylacetate. The calibration graph is linear over concentration range 5×10^{-8} – 10^{-6} M of lead at optimized conditions. The limit of detection is relatively low and found to be 2.5×10^{-9} M. The proposed stripping method is selective, precise, sensitive and usable for ultra-trace lead determination in complex matrices such as petroleum products. The reliability of the method was established by parallel determination of lead against the spectrophotometric standard method.

Table 1
Determination of lead in free-lead gasoline and gas oil samples

Pb added (mg l^{-1})	Pb found (mg l^{-1}) \pm SD*	
Free lead sample	Stripping method	Spectrophotometric method
Gasoline	—	0.078 ± 0.002
Gasoline	0.100	0.098 ± 0.003
Gas oil	—	0.062 ± 0.001
Gas oil	0.062	0.060 ± 0.002

Abstract

Infant formula and powdered milk samples were suspended in a medium containing 20% ethanol, 0.65% nitric acid, 6% hydrogen peroxide and 0.1% ammonium dihydrogenphosphate and directly introduced in the electrothermal atomizer. Liquid milk samples were diluted with this suspension solution. The build-up of carbonaceous residues inside the atomizer was avoided by using a combination of hydrogen peroxide and nitric acid. Fast programs were used to simplify the heating cycles. Calibration was carried out using aqueous standards and the detection limits for copper and zinc were found to be 70 and 15 pg, respectively. The metal contents of several milk samples obtained by direct introduction of the samples agree with those obtained by means of a conventional procedure based on the total dissolution of the samples. The reliability of the methods was also confirmed by analyzing three certified reference materials. The free and protein binding fractions were measured by ultrafiltration membrane permeability of the milk samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Atomic absorption spectrometry; Copper; Milk; Zinc

1. Introduction

Milk is an important food in the human diet, and the main source of metals for infants and children. Milk is considered a rich source of some essential trace metals such as zinc, but it is poor in

copper. A large amount of zinc in a diet interferes with the copper absorption system, resulting in copper deficiency. Hence, zinc antagonizes copper absorption. Zinc and copper have been associated with cholesterol metabolism and the maintenance of cardiovascular integrity. Hypercholesterolemia due to copper deficiency has been observed in humans and in a variety of animal species [1]. The improved availability of zinc in human milk over cow milk for infants has been explained by a

low-molecular-mass zinc-binding ligand [1] as well as by differences in protein composition. Cow milk has a low copper content and, therefore, infants provided solely with a milk diet may develop copper deficiency and anemia.

Electrothermal atomic absorption spectrometry (ETAAS) is a useful technique for the analysis of metals in milk and previous studies concerning determination of copper and zinc have been published [2–13]. However, such determinations are not without problems, since conventional acid-mineralization procedures are lengthy and there is a risk of contamination, which is particularly severe in the case of zinc. For this reason, some authors prefer to introduce the liquid samples directly into the electrothermal atomizer and, when dealing with powdered samples, to prepare a suspension [14,15], which is also analyzed without further treatment. Such procedures can also be problematic due to high background values and to the accumulation of carbonaceous residues inside the atomizer, both drawbacks being overcome by inclusion of an air or oxygen ashing step [16] in the heating program. Recently, it has been demonstrated [17–22] that the addition of hydrogen peroxide to the samples also alleviates these problems. The hydrogen peroxide decomposes during the heating cycle and the organic matter is partially destroyed with no apparent harmful effect on the pyrolytic graphite atomizers.

This paper describes procedures for the direct determination of copper and zinc in cow and human milk and infant formula samples using hydrogen peroxide as a chemical modifier. The removal of organic matter is very effective and allows fast-program methodology [23,24] to be used. The procedures, which were checked by analyzing three standard reference materials, are rapid and reliable, and were subsequently used to assess the fraction of the metal ions bound to milk proteins. For this purpose, various fractions of milk samples were separated using ultrafiltration membrane permeability, in which the solvents and solutes are forced through the membrane under centrifuge pressure while the movement of large molecules is restricted by the pore size [25].

2. Experimental

2.1. Instrumentation

A Perkin-Elmer Model 1100B atomic absorption spectrometer equipped with deuterium-arc background correction and a HGA-400 (Perkin-Elmer) graphite furnace atomizer were used. Pyrolytic graphite coated tubes (part number B013-5653) and pyrolytic graphite platforms (part number B012-1092) inserted into pyrolytic graphite coated tubes were obtained from Perkin-Elmer. Measurements were performed at 324.8 and 213.9 nm for copper and zinc, respectively, using hollow cathode lamps operated at 5 mA and bandwidths of 0.7 nm. Argon was used as the inert gas, the flow rate being 300 ml min⁻¹ during all stages, except during atomization, when the flow was stopped for copper or reduced to 150 ml min⁻¹ for zinc in order to adjust sensitivity. A Branson ultrasonic bath of 14 W constant power was used. Ultrafiltration of milk samples was carried out using a Centricon-SR3 filter system (3000 Da pore size) and an ultracentrifuge operated at 7500 × g.

2.2. Reagents

High-quality water, obtained using a Milli-Q system (Millipore), was used exclusively. Copper and zinc standard solutions (1000 µg ml⁻¹) were obtained from Panreac (Spain) and diluted as necessary to obtain working standards. High-quality ethanol (Riedel-deHaër), concentrated (65%) nitric acid (Merck), concentrated (30%) hydrogen peroxide (Fluka), concentrated acetic acid (Probus, Spain) and ammonium dihydrogenphosphate (Fluka) were also used.

2.3. Reference materials

Three reference materials were used. Non-fat milk powder SRM 1549 was obtained from NIST (USA); skim milk powder CRM 063 from BCR (Belgium) and whole milk powder 8435 from CLBRR (Canada).

Table 1
Heating furnace programs for copper and zinc

Step	Copper			Zinc		
	Temperature (°C)	Ramp (s)	Hold (s)	Temperature (°C)	Ramp (s)	Hold (s)
Dry	190	1	35	400	10	15
Atomize	2400	0	2 ^a	1600	0	3 ^b
Cleaning	2650	1	3	2600	1	3

^a Internal gas flow rate = 0 ml min⁻¹.

^b Internal gas flow rate = 150 ml min⁻¹.

2.4. Procedures

Infant formulas and powdered and liquid milk samples were purchased in specialized markets. Human milk samples were obtained from a volunteer. The samples of powdered milk were dried at 45°C. Homogeneous dispersions of dried milk were prepared by adding 25 ml of the suspension medium to an accurately weighed amount of sample (typical amounts ranged from 0.05 to 0.4 g for copper and from 12 to 50 mg for zinc). The suspensions were sonicated for a few minutes to ensure the absence of lumps and sampled while they were being continuously stirred with a magnetic stirrer. Liquid milk samples were diluted as necessary with the suspension medium and treated as mentioned for powdered milk. The suspension solution was prepared by mixing 0.1 g of ammonium dihydrogenphosphate, 20 ml of absolute ethanol, 20 ml of 30% hydrogen peroxide and 1 ml of 65% nitric acid in 100 ml deionised water, for both copper and zinc determinations. Aliquots of 20 µl were injected into the furnace. The heating programs given in Table 1 (where the quoted temperatures are values set on the HGA-400 power supply) were run and the background-corrected peak areas due to the analytes were obtained. Calibration was performed by injecting aqueous standards prepared in the suspension medium and using the same experimental conditions. Standard reference milk samples were analyzed in the same way.

The samples were previously analyzed for comparison purposes. Fractions of 0.5 ml or 0.1–0.5 g of liquid or powdered samples, respectively, were dried and then calcined at 450°C for 8 h. The

ashes were treated with 5 ml concentrated nitric acid and 2 ml concentrated hydrogen peroxide solution and heated to almost dryness; they were then diluted up to appropriate volumes with a solution containing 0.1% ammonium dihydrogenphosphate to analyze copper. A suitable dilution was used to analyze zinc by ETAAS.

2.5. Ultrafiltration of milk

A fraction of 2 ml milk was treated with 300 µl concentrated acetic acid, stirred and centrifuged at 3000 × *g* for 10 min. The two phases obtained were separated. The supernatant was filtered through a Centricon-SR3 filter system (3000 Da pore size) using an ultracentrifuge at 7500 × *g* for 1 h. The solid fraction remaining in the filter was resuspended with 2 ml suspension solution and sonicated for 5 min. Copper and zinc were measured in both the filtrated fraction (with proteins smaller than 3000 Da) and in the resuspended fraction (larger than 3000 Da). The metal contents in the fraction precipitated with acetic acid were determined by difference. The absence of membrane adsorption phenomena was studied using aqueous standards of Cu and Zn. No differences between the initial concentrations and the concentrations found in the ultrafiltrable were observed, thus discarding membrane adsorption. Contamination of the sample by the addition of acetic acid or by the micropartition process was evaluated by carrying out a blank using the suspension medium. This blank was repeated three times using different membranes and the results were reproducible.

3. Results and discussion

3.1. Optimization of the experimental conditions

Following the rules of analytical minimalism recently discussed by Halls [24], fast-program methodology, in which the conventional drying and ashing steps are replaced by a single modified drying step, was used throughout the work.

Preliminary experiments were carried out using 20 mg ml^{-1} suspensions prepared from a powdered milk sample in the presence of 0.65% nitric acid and 3% hydrogen peroxide. These experiments showed poor reproducibility, the relative standard deviation (R.S.D.) of copper being close to $\pm 20\%$. Consequently, to obtain a good dispersion and stabilization of the suspensions, the addition of different chemicals was tried. Addition of glycerol proved inadequate since abundant smoke was evolved during the atomization stage. Triton X-100 also proved problematic due to foam. Excellent results were obtained by adding ethanol to the suspensions. Fig. 1 shows that by increasing the ethanol percentage, the drying temperature could be increased without sputtering and, consequently, the hold time necessary for a totally dried sample to be obtained could be shortened and reproducibility improved due to a better homoge-

Fig. 1. Influence of ethanol percentage on the drying step (drying temperature and hold time) and the reproducibility of the analytical signal for copper. The bar graph represents the variation of the relative standard deviation for 10 identical injections.

Fig. 2. Effect of the hydrogen peroxide percentage on the drying temperature and the relative standard deviation of 10 successive injections of a 2% liquid cow milk sample for copper atomization.

nization. The bar graph in Fig. 1 shows the R.S.D.s obtained for 10 successive injections of milk. Thus, 20% ethanol was added to the suspensions in all the other samples considered in this work. Similar results were obtained for zinc. To ensure zinc stabilization and to avoid a premature signal during atomization, 1 mg ml^{-1} ammonium dihydrogenphosphate was routinely incorporated to all the samples [26].

The hydrogen peroxide percentage was optimized for the atomization of copper using a 20 mg ml^{-1} suspension prepared from powdered cow milk in the presence of 0.65% nitric acid. Fig. 2 shows the influence of this variable on the reproducibility and the drying temperature. The R.S.D. for 10 successive injections considerably decreased in the presence of the oxidant. The drying temperature was also slightly affected by the presence of hydrogen peroxide and percentages higher than 15% produced bubbling, it proving necessary to decrease the temperature to avoid sputtering of the sample. A concentration of 6% hydrogen peroxide was finally selected, which avoided the deposition of carbonaceous residues inside the atomizer even after a high number of firings. The influence of the addition of nitric acid was assayed in the 0–0.65% range. There was no

modification in the analytical peaks whereas an important decrease in the background values was observed in the presence of the acid [21,22]. Thus, a 0.65% nitric acid was added. These problems were not so important for zinc because the suspensions were prepared with lower amounts of solid matter.

Preliminary experiments for copper determination were carried out by using both platform and wall atomization. No advantages were observed when platform atomization was used. In addition, this atomization mode required lengthy times for the complete profile to be obtained. Thus, wall atomization was finally selected for copper, well defined atomization profiles being obtained by programming 2 s for the holding time of this stage. Following the guidelines of fast-program methodology, the drying temperatures and holding times to be used in the modified drying stage were studied in an attempt to find the highest temperature possible which did not produced sputtering. The optimal drying temperature for copper determination was found to be 190°C. A holding time of 35 s allowed the sample to be dried completely and smoke to be removed before atomization. The atomization temperature was varied between 1500 and 2400°C as shown in Fig. 3 and the best profile was found at 2400°C.

Fig. 3. Effect of atomization temperature on the integrated absorbance for the analytical signals for copper and zinc (—) and the backgrounds (---). Dilutions of 10 and 0.5% of liquid cow milk were used for copper and zinc atomization, respectively.

Although the analytical signal appeared very quickly, in non-isothermal conditions, both the reproducibility and results were excellent.

Platform atomization was used for zinc determination. The optimal drying temperature was found to be 400°C with a slow heating ramp (10 s) and a 15 s holding time. It is important to note that the temperatures and holding times here indicated are values programmed on the HGA-400 power supply although the actual temperature reached inside the atomizer and that programmed are not always identical [23]. So, these parameters must be taken as indicative rather than absolute and it is advisable to check and adapt them to the particular characteristics of the instrumentation used. The atomization temperature was varied in the 1400–2000°C range both for aqueous zinc and for milk samples, the maximum signal with a fully developed profile in 3 s being obtained at 1600°C. The optimized programs for copper and zinc are shown in Table 1.

It must be pointed out that the high sensitivity of zinc in ETAAS led to signals outside the linear response range being obtained, for which reason a small flow of argon was maintained during the atomization stage. This way of adjusting sensitivity can pose practical problems, since atomization takes place in a non-isothermal environment and, in addition, good reproducibility in the gas flow is necessary. Thus, the effect of the gas flow on both the slope of the calibration graph and the reproducibility of the analytical signal was studied. It was experimentally shown that a 150 ml min⁻¹ argon miniflow was suitable to obtain signals within the linear range when suspensions containing 0.5–2 mg ml⁻¹ powdered milk were used. In these conditions, the R.S.D. (10 measurements) was $\pm 3\%$.

3.2. Influence of the milk concentration, calibration and results

The variation of the atomic signal obtained for copper when varying the concentration of a powdered cow milk sample is shown in Fig. 4. Linearity was obtained up to 60 mg ml⁻¹. The precision of the method was demonstrated by repeated analyses calculating the R.S.D. for 10 replicate

Fig. 4. Influence of the slurry concentration on the copper and zinc signals using a cow milk sample ($n = 10$). The points joined to the x -axis by broken lines indicate the relative standard deviations for 10 successive injections at each concentration level.

determinations at each concentration level. The bars indicate the standard deviations and the points joined to the x -axis by broken lines indicate the R.S.D. values. A similar study was carried out for zinc using suspensions prepared from powdered milk in the $0.5\text{--}2\text{ mg ml}^{-1}$ concentration range. Values of R.S.D. were between $\pm 10\%$ for very diluted suspensions and $\pm 3\text{--}4\%$ for more concentrated suspensions, linearity being obtained between 0.5 and 2.0 mg ml^{-1} . It is important to note that, because the sensitivity is in this case adjusted by using a miniflow condition, this concentration range must be taken as orientative and adapted to the characteristics of the instrumentation used.

The standard additions method was used to investigate the possible interference caused by the matrix. Each graph was constructed from five points and each point was measured three times. The slopes obtained with aqueous standards were similar (95% confidence level) to those obtained

for the standard additions graphs (Table 2). In addition, the analyte contents obtained by extrapolation of the graphs agreed with those obtained by a conventional procedure involving the complete dissolution of the samples. Thus, calibration with aqueous standards was valid. The detection limits (DL) calculated by 10 repeated injections of the blank and using the 3σ criterion were 70 and 15 μg for Cu and Zn, respectively. The limits of detection could also be estimated using the regression line obtained for aqueous standards or a regression line obtained from a plot of the analytical signal against the milk concentration for a representative sample. The regression line should provide a more accurate estimation of the blank than the single measured blank value [27]. Using this approach, the DL for Cu and Zn were, respectively, 94 and 55 μg when using the regression lines from aqueous standards. When using the maximum recommended suspension concentration, DL was 60 ng g^{-1} for copper in the 60 mg ml^{-1} powdered cow milk suspension and 400 ng g^{-1} for zinc in the 2 mg ml^{-1} powdered cow milk suspension. It must be noted that the high values obtained in the detection limits for zinc are a consequence of the adjustment of the sensitivity needed to obtain signals within the linear response range.

Table 3 shows the results obtained when analyzing different types of milk using the proposed suspension procedure and another based on the total calcination of the milk samples. As can be seen, the results are in good agreement (95%

Table 2
Slopes of the standard additions calibration graphs

^b Certified values.

confidence level). The highest amounts of copper and zinc appeared in the infant formula and powdered cow milk. The methods were validated using three certified reference milk samples. The results are also included in Table 3.

3.3. Distribution of both copper and zinc free and protein binding

The main cow milk proteins are casein, lactalbumin, lactoferrin and lactoglobulin, the most important being casein. When milk is acidified with acetic acid, casein flocculates while the whey proteins remain in solution [28]. A distribution of the content of both free metals and protein binding in the milk samples was carried out. The study of speciation of copper and zinc in milk hardly depends on the method used [7,8]. The samples selected were human milk (collected 1 month after the birth), powdered fortified infant formula (60% casein and 40% lactalbumin) and whole bottled cow milk. Experiments were carried out in triplicate. After precipitation of the casein by means of acetic acid, the supernatant was ultrafiltered through a 3000 Da membrane. The degree to which individual proteins are filtered through the membrane is normally a function both of their molecular size and of their concentration. The low-molecular-mass proteins are forced into the filtrate while the high-molecular-mass proteins only appear in the filtrate in trace amounts.

It was found (Fig. 5) that the fractions containing higher concentrations of both metals were those having a particle size lower than 3000 Da (probably free copper or zinc) for the maternal milk and infant formula samples. For the non-fat cow milk, the fraction showing higher concentrations was that with a particle size greater than 3000 Da (probably proteins which are non-precipitable with acetic acid). These different distributions are in accordance with the literature, which cites a low-molecular-mass zinc-binding ligand

Fig. 5. Distribution of the free copper and zinc contents and protein binding in the milk samples ($n = 3$).

which facilitates zinc absorption as the explanation for the improved availability of zinc in human milk over cow milk, and the reported higher plasma zinc levels of breast-fed over bottle-fed infants [29]. It must be noted that the distribution of zinc and copper, as well as of other metals [30], is also influenced by the first step using acetic acid precipitation. Using acid could increase the ultrafiltrable part. Moreover, a prolonged storage at -20°C could also modify the distribution of copper and zinc.

4. Conclusion

The use of hydrogen peroxide is confirmed to be a useful way to decrease the background and to avoid the build-up of carbonaceous residues when concentrated milk suspensions are introduced into the electrothermal atomizer. The effect of such a modifier is so effective that fast-program methodology can be used. In this way, the sample manipulation is minimal and the risk of contamination is decreased.

Received 11 June 1997; received in revised form 9 September 1997; accepted 9 September 1997

Abstract

Voltammetric methods are very suitable, versatile and rapid techniques for the simultaneous metal determination in complex matrices. The work, regarding the determination of As(III), Se(IV) and Mn(II), is a very interesting example of the possibility for simultaneously determining each single element in real samples in a wide range of concentration ratios. The differential pulse (DPV) measurements were carried out using a conventional three-electrode cell, while ammonia–ammonium chloride buffer (pH 9.6) was employed as the supporting electrolyte. The analytical procedure was verified by the analyses of standard reference materials: estuarine sediment BCR-CRM 277 and river sediment BCR-CRM 320. Precision and accuracy, expressed as relative S.D. and relative error, respectively, were in all cases of the order of 3–5%, while the detection limit for each element was around 10^{-8} M. The standard addition technique improved the resolution of the voltammetric method, even in the case of very high element concentration ratios. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Toxic metals; Sediments; Simultaneous determination; Voltammetry

1. Introduction

The simultaneous determination of several elements at trace and ultratrace level concentration in real matrices is one of the main aims of an analytical procedure, which however must always have both good selectivity and very high sensitivity.

The accumulation of toxic and persistent substances in the environment continuously increases owing to anthropogenic activities. Particular at-

tention is being paid to the presence of heavy metals, because of their irreversible effects on man [1]. In fact such elements tend to concentrate in all aquatic environmental matrices [2,3], biota and sediment, and for this reason they are present in the aquatic food chain, becoming dangerous for humans too, as a consequence of the consumption of marine products.

In metal determination, several techniques are employed such as neutron activation analysis, atomic absorption spectrometry, atomic emission spectrometry with inductively coupled plasma excitation, and X-ray fluorescence. Usually such techniques need enrichment steps and, further-

* Corresponding author. Tel.: + 39 51 259534; fax: + 39 51 259456.

more, as regards selectivity and sensitivity, often favour only one of these two aspects. For these reasons, the voltammetric techniques are shown to be very suitable, versatile and rapid for multi-component determinations, having good selectivity and sensitivity without requiring metal enrichments before the analytical measurements [4–6].

In previous studies [7,8] sensitive and selective voltammetric methods were employed for the simultaneous determination of various elements in real matrices. The present study, regarding the simultaneous determination of arsenic(III), selenium(IV) and manganese(II), is the continuation of that endeavour. In fact the problem of selenium(IV) and arsenic(III) determination at trace level [9] has received much attention as a consequence of the biological importance of the former, in fact selenium(IV) is an essential nutrient at trace level, but toxic in excess [10,11]. Frequently they are simultaneously present in several matrices together with manganese(II), but such a simultaneous presence produces effects on the electrochemical behaviour of both elements [12]. Furthermore manganese(II) is an essential micronutrient: in fact it is very important in various biochemical cycles regarding man, animals and plants, and it is present in a great deal of inorganic matrices, in which arsenic(III) and selenium(IV) are also almost always present.

Adsorption stripping voltammetry was proposed for the determination of manganese(II) in the presence of several interferences [13] and in real samples [14]. Differential pulse anodic stripping voltammetry was also employed successfully for determining manganese(II) in natural water [15–17] and sea water [18,19].

Lastly, manganese(II) was also determined in real matrices by a potentiometric stripping technique [20], taking into account either interference problems [21] or batch and flow procedures [22–24].

For this reason it seems to be interesting to set up a new selective and sensitive analytical procedure for simultaneously determining arsenic(III), selenium(IV) and manganese(II) in the presence of each other in a wide range of concentration ratios in real samples, employing differential pulse

voltammetry (DPV) as the voltammetric technique.

2. Experimental

2.1. Apparatus

Voltammetric measurements were carried out with an AMEL Mod. 433 employing, as the working electrode, a hanging mercury drop electrode (HMDE), consisting of a glass capillary having an internal diameter of 0.1 mm and a cone-shaped tip. An Ag/AgCl, KCl sat. electrode and a platinum wire were used as the reference and the auxiliary electrode, respectively. The voltammetric cell was thermostated at $20.0 \pm 0.5^\circ\text{C}$. The solutions were deaerated with pure nitrogen for 5 min prior to measurements, while a nitrogen blanket was maintained above the solution during the analysis. The solutions were deaerated for 1 min after each standard addition.

2.2. Reagents and reference solutions

All solutions were prepared with deionized water (Millipore, Milli-Q). Suprapure grade acids, ammonia and sodium hydroxide were used. Ammonia–ammonium chloride buffer solution (pH 9.6) was prepared by mixing an appropriate amount of hydrochloric acid and ammonia solu-

tions. Aqueous stock solutions of arsenic(III), selenium(IV) and manganese(II) were prepared by dilution of the respective standard 1000 mg l⁻¹ (BDH, UK) solutions. The Teflon voltammetric cell was rinsed every day with suprapure concentrated nitric acid in order to prevent any contamination. Estuarine sediment BCR-CRM 277 and river sediment BCR-CRM 320 were chosen as standard reference materials for testing the accuracy and precision of the analytical procedure.

3. Results and discussion

3.1. Aqueous reference solutions

Prior to the analysis of the standard reference materials, a preliminary study was carried out employing aqueous reference solutions. The experimental conditions are reported in Table 1.

The standard addition method was used for the determination of the element analytical calibration functions (Table 2). The correlation coefficient was found to be satisfactory in all cases, while the precision of the technique, expressed in terms of the residual S.D. was good (s_r smaller than 5%). Table 2 also reports the detection limits for each element.

The simultaneous determination of arsenic(III), selenium(IV) and manganese(II) was studied in a large range of concentration ratios of the components. More precisely, employing the experimental conditions in Table 1, the element concentration ratios, within which each single element could be determined without mutual interference, were investigated. To a fixed, but very small concentration of the element of interest, standard additions of the interfering element were added in such a way as to change their concentration ratios. The peak current values of the former element were

Fig. 1. Differential pulse voltammogram of a mixture of As(III), Se(IV) and Mn(II) in ammonia–ammonium chloride buffer solution (pH 9.6) as supporting electrolyte. Peak 1, As(III); peak 2, Se(IV); peak 3, Mn(II). Concentrations: 2.6×10^{-7} M [As(III)]; 4.2×10^{-6} M [Se(IV)]; 6.6×10^{-6} M [Mn(II)]. For experimental conditions see Table 1.

then compared to those determined by using the analytical calibration function of the individual element (Table 2) and the relative errors were calculated.

The determination of the single metals is possible, within a maximum error of 5%, in the concentration ranges $49:1 > c_{\text{Se}}:c_{\text{As}} > 1:58$ and $77:1 > c_{\text{Se}}:c_{\text{Mn}} > 1:69$. Such concentration ratios have been confirmed also by mono- and bivariate [25–27] analysis. In all cases, within the considered concentration ratios interval, the slopes of the statistical functions were practically equal to

Fig. 2. Determination of 4.90×10^{-7} M Se(IV) in the presence of 6.96×10^{-4} M As(III) (concentration ratio $c_{\text{As}}:c_{\text{Se}} = 1420$). For experimental conditions see Table 1.

the analytical calibration function of the single element, and, moreover, the slope of the interfering element (bivariate analysis) was negligible (Table 2), thus indicating the non-interference between neighbouring species. Also, if the peak potential differences are of the order of 100 mV, the three metals, in the interval concentration ratios above, show well defined peaks. A typical voltammogram is shown in Fig. 1.

However the interesting aspect of this study is in regards to the determination of the metal with the lowest concentration and an unfavourable concentration ratio to the interferent species, that is outside the concentration ratios interval where the regression function obtained from bivariate analysis of the data was valid.

In this situation, bringing the concentration ratio within the interval valid for bivariate analysis by appropriate addition of the standard solution of the metal with the lowest concentration was enough to determine the metal itself. In fact, the I_p versus concentration plots showed a non linear behaviour. A linear section was obtained when the concentration ratios attain values within the validity of the bivariate analysis. An extrapolation of this linear section permitted the evaluation of the metal content in the mixture with acceptable accuracy. For example, Fig. 2 shows the fitting of the experimental data for the determination of selenium(IV) in the presence of a very high arsenic(III) concentration. The limit within which linearity prevails was well defined and statistically evaluated according to the method of Liteanu et al. [29] using the *t*-test criteria.

3.2. Standard reference materials

Once set up on the aqueous reference solutions, the method was transferred to the standard reference materials, in order to confirm and verify the applicability of the analytical procedure and to determine its accuracy and precision.

Estuarine Sediment BCR-CRM 277 and River Sediment BCR-CRM 320 were prepared as follows. Approximately 1.0 g, weighed accurately in a pyrex digestion tube, was dissolved in 15 ml 1:1 diluted 69% (m/m) nitric acid. The tube was inserted into the cold home-made block digester,

^a For r , s_r , e and D.L. see footnote in Table 2.

^b See Table 2.

which gradually increased the temperature up to 125°C and kept it there for all the mineralization time. A further two aliquots of concentrated nitric acid were added: 10 ml after 15 min and 5 ml after 30 min. At the end (after 45 min), 10 ml of 37% (m/m) hydrochloric acid were added, keeping the temperature at 125°C for a further 15 min. After light cooling, the solution was filtered through a Whatman No. 541 filter paper, evaporated almost to dryness, and then, again after cooling, the soluble salts were dissolved in 25.0 ml ammonia–ammonium buffer solution (pH 9.6).

The solutions were analyzed under the experimental conditions listed in Table 1. Table 3 shows the slopes and merits of the analytical calibration functions calculated in the standard reference materials for each element together with those determined in the aqueous reference solutions (Table 2). Their comparison emphasizes that, in all cases, no matrix interference was present, not showing analytical sensitivities of significant differences at the 5% error level. Furthermore, problems of possible hydrolysis of iron ions, present at a very low concentration level in the digested solution, were not found experimentally during the voltammetric measurements.

For both standard reference materials, the arsenic(III) and manganese(II) determinations (being the elements with higher concentrations) were possible by employing the respective calibration curves (Table 2).

On the contrary, the selenium(IV) determination was very difficult in both standard reference materials since the concentration ratios were $c_{\text{Mn}}:c_{\text{Se}} > 69$ in both cases ($c_{\text{Mn}}:c_{\text{Se}} = 1.6 \times 10^3:2.04 = 784.3$ for Estuarine Sediment BCR-CRM 277 and $c_{\text{Mn}}:c_{\text{Se}} = 0.8 \times 10^3:0.214 = 3738.3$ for River Sediment BCR-CRM 320) and $c_{\text{As}}:c_{\text{Se}} > 58$ in the case of the River Sediment BCR-CRM 320 ($c_{\text{As}}:c_{\text{Se}} = 76.7:0.214 = 358.4$). For this reason, being outside the non-interference concentration ratio intervals, selenium(IV) has been determined employing the standard addition method, extrapolating the linear section of the I_p versus metal concentration curve. The experimental data fall, at the 95% confidence level, in the interval of the certified values for each element of the standard reference materials (Table 4).

The precision, expressed as relative S.D., and accuracy, expressed as relative error, were good in all cases, thus confirming the validity of the proposed method.

3.3. Practical application

The analytical procedure, set up on the standard reference materials, was transferred to real samples: sediments sampled in the Marecchia River (Rimini, Italy), in the river-bed (Verucchio zone) and in the estuary (Rimini zone).

The sampling (May and October, 1996) was performed by means of a plexiglass device. Single samples of superficial sediment (height 5 cm) were

drawn out and put in polyethylene bottles, previously washed with a diluted 1:1 suprapure HNO₃ solution for 48 h, in order to avoid any contamination. The sample was dried at 60°C for 48 h and then passed through a 40 mesh sieve to eliminate coarse material and successively through a second 150 mesh sieve, and finally powdered by means of a corundum ball mill. The sediments were then mineralized with the HNO₃-HCl acidic mixture, following the same digestion procedure employed in the case of the standard reference materials.

The element concentration ratios, in almost all cases, were higher than the interference values ($c_{As}:c_{Se} = 58$ and $c_{Mn}:c_{Se} = 69$), notwithstanding this the metal analytical determinations have all been carried out employing the same standard

addition procedure described above (Table 5).

Also, though the environmental aspects are beyond the aim of this study, a comment can be made. Table 5 shows that the concentrations of the three elements change according either to the sampling time or the sampling site: higher in autumn, after the winter and spring floods followed by the summer dry weather, and in the vicinity of the estuary. However the concentrations in Table 5, if compared with those found in the sediments sampled in different ecosystems and with the native concentration level of each element [30], show substantial agreement, so indicating that, in the investigated area, no manifest pollution load seems to be present.

In conclusion, the present study confirms once more that the voltammetric techniques, together

Abstract

A cold trap system for the simultaneous determination of arsenic, antimony, selenium and tin by continuous hydride generation and gas phase molecular absorption spectrometry is described. The hydride generation is carried out in two steps; first, tin hydride is generated at low acidity and second, arsenic, antimony and selenium hydrides are formed at higher acidity. All the hydrides are collected in a liquid nitrogen cryogenic trap and transported to the flow cell of a diode array spectrophotometer, where molecular absorption spectra are obtained in the 190–250 nm range. Five calibration solutions containing arsenic, antimony, selenium and tin are solved using multiple linear regression analysis. Tests are performed in order to extend the same manifold to other hydrides but no signals are obtained for bismuth, cadmium, lead, tellurium and germanium. Under the optimum conditions found and using the wavelengths of maximum sensitivity (190, 198, 220 and 194 nm), the analytical characteristics of each element are calculated. The detection limits are 0.050, 0.020, 0.12 and 1.1 $\mu\text{g ml}^{-1}$ and the RSD values are 3.7, 3.1, 3.5 and 3.0% for As, Sb, Se and Sn, respectively. The method is applied to As, Sb, Se and Sn determination in natural spiked water samples. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Simultaneous determination; Gas phase molecular absorption spectrometry; Cryogenic preconcentration; Hydrides

1. Introduction

The adaptation of a preconcentration step to the hydride generation (HG) process has been

extensively developed. When acid–metal reducers were used initially, this step was necessary because hydride generation was slow; preconcentration is still used nowadays to improve sensitivity. Preconcentration can be performed at room temperature [1,2] or at low temperature (mainly using liquid nitrogen) [3–5]. Cryogenic traps are

now the most common. Very useful information about hydride generation and preconcentration in a cold trap is provided by Dedina [6,7].

A survey of the literature indicates that there are not many papers describing analytical methods to determine four or more hydride-forming elements simultaneously. The difficulties result from the interelement interferences and the different oxidation states involved, which affect the generation kinetic. One of the more widely used techniques for simultaneous determination (without the preconcentration step) is HG-Induced Coupled Plasma-Atomic Emission Spectrometry (HG-ICP-OES), which has been used for arsenic and antimony [8–10], arsenic and lead [11], arsenic, antimony and selenium [12–15], arsenic, antimony and bismuth [16] or arsenic, antimony, bismuth, selenium and tin [17]. Speciation analysis is also possible, for example, As(III) and As(V) [18]. Sensitivity is good, but the cost of such equipment compared with other techniques has prevented it from becoming commonplace in analytical laboratories. A preconcentration system can also be combined with HG-ICP-OES [19]. Atomic absorption spectrometry is another technique which is widely used for speciation analysis of hydride-forming elements, such as arsenic [20] or tin [21].

In the last few years, we have studied in depth the analytical possibilities of Gas Phase Molecular

Absorption Spectrometry (GPMAS) for the determination of 1, 2 or 3 compounds (which have been recently reviewed [22]), mainly hydride forming elements and as a detector in gas chromatography [23]. In all those previous papers, the volatilization conditions for all the elements composing the mixtures have been the same. In this paper, we have tried to approach a new problem: the simultaneous determination of a mixture of elements in which different volatilization conditions have to be used. As a result, we have solved mixtures of arsenic, antimony, selenium and tin by GPMAS combined with a robust direct multivariate calibration method.

2. Experimental

2.1. Apparatus

All measurements were performed by using a Hewlett-Packard model HP 8451A diode-array spectrophotometer furnished with a quartz flow cell of 1 cm path length (Hellma 174 QS) and equipped with a keyboard HP98155A (Hewlett-Packard), a floppy disk drive for bulk data storage (Hewlett-Packard HP9121) and a graphics plotter (HP7475A).

For mathematical treatment, a Hewlett-Packard Vectra microprocessor with Eureka[®] software was used.

Fig. 2. Molecular absorption spectra in the gas phase of As (a), Sb (b), Se (c) and Sn (d) hydrides.

Reagents were pumped using two Masterflex peristaltic pumps, models 7518-10 and 7016-20 (Cole Parmer, Chicago, IL 60648) and one peristaltic pump model MS-4 Reglo (Ismatec S.A., Spain).

2.2. Reagents

All reagents used were of analytical grade quality. Doubly distilled water was used.

- Stock arsenic solution, 1000 mg l⁻¹, prepared by dissolving As₂O₃ (Merck) in 5 M NaOH, neutralizing with 5 M HCl and diluting with 0.5 M HCl.
- Stock antimony solution, 1000 mg l⁻¹, prepared by dissolving potassium antimony (III) oxide tartrate hydrate extra pure (Merck) in water and acidifying to 0.5 M with respect to HCl.
- Stock selenium solution, 1000 mg l⁻¹, prepared by dissolving extra-pure selenium metal (Merck) (1 g) in the minimum volume of 60% (w/w) HNO₃ and evaporating the solution nearly to dryness. Doubly distilled water (2 ml)

was added and the solution evaporated nearly to dryness (this was repeated twice). The residue was subsequently diluted to 1 l with 10% (v/v) HCl.

- Stock tin solution, 1000 mg l⁻¹, prepared by dissolving SnCl₂ (Merck) in diluted HCl.
- Concentrated HCl 1.19 g ml⁻¹ and 35% (w/w) (Carlo Erba).

Working standards were prepared by serial dilution of the stock solutions with distilled water, immediately before use.

- Aqueous solutions of NaBH₄ (Merck) were prepared immediately before use. The same solution can be used for three or four measurements. By dissolving the NaBH₄ in water, the acidity can be controlled better than if dissolved in a basic medium.

2.3. System description. Recommended procedure

The system (Fig. 1) can be conveniently considered to consist of five sections: first generator (B), first gas-liquid separator (D), second generator (H), second gas-liquid separators (J and K), water

Fig. 3. Effect of HCl concentration on Sn hydride absorbance.

trap (an ice and salt bath at $\approx -10^{\circ}\text{C}$) (E) and the cryogenic trap (F). These components have been described previously [24].

The sample solution at 35 ml min^{-1} (A) containing arsenic, antimony, selenium and tin in 0.05 M HCl is mixed (B) with 4% NaBH_4 at 4 ml min^{-1} (C). All the tin hydride and a low amount (between 10 and 20%) of arsenic, antimony and selenium hydrides are generated. The resultant gas–liquid mixture enters the first gas–liquid separator (D); the hydrides are transported by a carrier gas stream of nitrogen (20 ml min^{-1}) to the water trap (E) and finally to the hydride trap (F).

The liquid remaining at D goes to a hermetically closed vessel (G). The liquid is pumped into a generator (H), where it comes together with a 2

Table 1
Optimization of HCl concentration for the hydride generation of As, Sb and Se in the second generator

HCl concentration (M)	Absorbance		
	As	Sb	Se
3	0.0091	0.0098	0.0088
2.5	0.0100	0.0128	0.0094
2	0.0103	0.0158	0.0105
1.5	0.0085	0.0105	0.0068
1	0.0064	0.0085	0.0043

M HCl solution at 4 ml min^{-1} (I); arsenic, antimony and selenium hydrides are generated. The gas–liquid mixture is then passed through two gas–liquid separators (J and K); in J, a carrier nitrogen flow of 20 ml min^{-1} is used and in K, nitrogen gas is bubbled at 20 ml min^{-1} . The volatiles generated are also transported to the water trap (E) and hydride trap (F) consecutively.

After 5 min of generation and retention, the hydride trap is removed from the liquid nitrogen and left at room temperature for 5 min. Finally, it is placed in hot water ($\approx 80^{\circ}\text{C}$) for 1 min (L). In this way, the hydrides are volatilized and are then transported to the flow cell, with a nitrogen flow of 2000 ml min^{-1} . Molecular absorption spectra of the hydrides in the $190\text{--}250\text{ nm}$ range are obtained, which are subjected to multiple linear regression analysis.

3. Results and discussion

3.1. Previous tests

As has been mentioned, we had previously carried out the simultaneous determination of arsenic, antimony and selenium using continuous hydride generation with cryogenic preconcentration [24]. According to other authors [7] and our previous experience [25], tin forms its hydride under similar generation conditions. Based on this, the system employed for arsenic, antimony and selenium determination was tested for the simultaneous determination of the four elements (including tin). Unexpectedly, the results obtained were not satisfactory and high concentrations of tin were necessary to obtain a good analytical signal. As a consequence, we reconsidered the generation and trapping conditions for tin hydride and later the manifold design for continuous generation.

3.2. Continuous tin hydride generation: Optimization

Tin hydride presents a molecular absorption spectrum with a maximum at 194 nm (Fig. 2). The main parameters affecting tin hydride genera-

Table 2
Analytical characteristics for the simultaneous determination of As, Sb, Se and Sn

Element	Sensitivity (ml μg^{-1})	Quantification limit ($\mu\text{g ml}^{-1}$)	LD ($\mu\text{g ml}^{-1}$)	RSD* (%)
As	0.0950	0.050	0.050	3.7
Sb	0.1510	0.050	0.020	3.1
Se	0.0195	0.20	0.12	3.5
Sn	0.0030	1.5	1.1	3.0

* Obtained for $n = 8$.

tion are the concentration of the reducing agent (NaBH_4) and the acidity of the medium. The NaBH_4 concentration is very important, not only for a quantitative tin hydride generation but also to get a good preconcentration in the cryogenic trap. Different NaBH_4 concentrations from 1 to 7% (w/v) were tested. By using low NaBH_4 concentrations, a low quantity of hydrogen is also generated and the total gas flow passing through cryogenic trap is low. Nitrogen gas therefore, becomes trapped also; when the trap is submitted to room temperature, the nitrogen suddenly escapes from the valve and allows the volatiles to escape. NaBH_4 concentrations equal to or above 4% w/v avoid this problem. From the GPMAS point of view, the optimum acidity for tin hydride generation in the batch method is about 0.6 M [25]; however, using this continuous method, the results were very different. Hydrochloric acid at various concentrations was used in order to look for the optimum acidity; as can be seen in Fig. 3, the higher the concentration, the lower the absorbance value obtained. In addition, it was necessary to employ a low concentration (0.05 M) to obtain a good generation yield. We also tried generating the tin hydride by mixing a basic solution (0.1 M NaOH) containing tin and NaBH_4 with different concentrations of HCl (0.5, 0.05 and 0.025 M), but we did not observe better absorbance values. Given these points, the optimum acidity for tin hydride generation in our system was set at HCl equal to 0.05 M.

3.3. Continuous As + Sb + Se + Sn hydride generation: Optimization

The main problem which appears when 0.05

M HCl is used, is that the arsenic, antimony and selenium hydrides are not generated quantitatively. Therefore, if simultaneous generation and determination of the four hydrides is required, it is necessary to modify the system in order to change the acidity of the medium during the generation process. A new system was therefore designed (Section 2.3). As can be seen, a two step generation process is proposed, first at low acidity (principally generating tin hydride) and second, at high acidity (arsenic, antimony and selenium hydrides are generated quantitatively). Several tests were also made using the contrary mode, with prior generation at high acidity and later alkalization, but the results were not satisfactory.

Considering 0.05 M HCl as optimum for the first step, optimization of the HCl concentration for the second step was then carried out. Since selenium is the element which shows the lowest sensitivity in GPMAS, the study was undertaken with this element, although it was later tested for As and Sb, also showing an agreement with the results for selenium. The results obtained are shown in Table 1; it can be seen that the optimum acidity is 2 M HCl.

In order to investigate if the acidity in the second generator (H) affects the tin hydride generation, some studies were made using tin solution in 0.05 M HCl (solution A) and modifying the HCl concentration in the second generator; different solutions were used as solution I: doubly distilled water, 0.05 M HCl, 0.5 M HCl and 2 M HCl. The results proved that the tin hydride signal is independent of the acidity of solution I, showing that tin hydride is generated quantitatively in the first generator.

Table 3
Results for simultaneous determination of As, Sb, Se and Sn

Mixture	Real concentration ($\mu\text{g ml}^{-1}$)				Found concentration ($\mu\text{g ml}^{-1}$)			
	As	Sb	Se	Sn	As	Sb	Se	Sn
1	0.10	0.10	1.0	10.0	0.09	0.08	1.1	11.0
2	0.10	1.0	1.0	10.0	0.08	0.86	0.93	11.3
3	1.0	0.10	1.0	10.0	1.2	0.12	1.0	9.2
4	0.10	0.10	1.0	40.0	0.12	0.10	0.90	42.0
5	0.10	0.10	5.0	10.0	0.11	0.12	4.8	8.6

3.4. Analytical characteristics

Fig. 2 shows the gas-phase molecular absorption spectra of As, Sb, Se and Sn hydrides. It can be seen that the maxima appear at 190, 198, 220 and 194 nm, respectively.

Under the optimum conditions found and using the wavelengths of maximum sensitivity, the analytical characteristics of each element were calculated. Table 2 shows the sensitivity (the slopes of the calibration graphs), detection limits (the concentration corresponding to a signal of twice the standard deviation of the blank¹ signal), reproducibility (expressed as Relative Standard Deviation) and quantification limits (obtained experimentally) for each element.

It is necessary to note that the analytical figures of merit obtained for As, Sb and Se were slightly worse; so when simultaneous determination of these three elements was carried out [24], detection limits of 0.022, 0.015 and 0.065 $\mu\text{g ml}^{-1}$ and quantification limits of 0.050, 0.030 and 0.200 $\mu\text{g ml}^{-1}$ were obtained for As, Sb and Se respectively. However, this is compensated for by the possibility of carrying out the simultaneous determination of four elements.

3.5. Simultaneous determination

Resolution of five calibration solutions containing As, Sb, Se and Sn was carried out by using multiple linear regression analysis (MLR), based on resolving a system of ' n ' equations with four

unknowns (n = number of wavelengths used). In all cases, all the absorbance values were experimentally obtained in the 190–250 nm range. The optimum wavelength range to be used for MLR resolution (190–220 nm) was obtained by testing empirically different ranges. Table 3 shows a matching of the real mixture concentrations and the results obtained. RSD was in all cases better than 4% ($n = 4$).

3.6. Application

The method was applied for As, Sb, Se and Sn determination in drinking water. Following the procedure described previously, the samples were analyzed and in all cases, the endogeneous amounts of the elements were below the detection limit, so these elements were added to the drinking water samples. After As, Sb, Se and Sn addition, the samples were analyzed in quadruplicate by the proposed method and the results obtained are shown in Table 4. In all cases, the RSD was better than 4%.

3.7. Incorporation of other hydride-forming elements

Once the new system had been prepared for the simultaneous determination of As, Sb, Se and Sn, the incorporation of other hydride-forming elements, such as Bi, Cd, Pb, Ge and Te was tested.

3.7.1. Bismuth

It was not possible to determine bismuth using this methodology because its hydride is very unstable and the preconcentration is not effective

¹ The blank signal is obtained following the procedure, but using 0.05 M HCl as solution (A).

Table 4
Results for simultaneous determination of As, Sb, Se and Sn in drinking water samples

Sample	Added concentration ($\mu\text{g ml}^{-1}$)				Found concentration ($\mu\text{g ml}^{-1}$)			
	As	Sb	Se	Sn	As	Sb	Se	Sn
1	0.30	0.52	1.0	10.4	0.26	0.48	1.2	11.0
2	0.15	0.26	2.0	20.8	0.11	0.23	2.1	19.3

[26]. This was checked by using both molecular absorption spectrometry and atomic absorption spectrometry techniques. The bismuth hydride signal was obtained just before the nitrogen liquid trap; the signal disappeared after trapping in the cryogenic trap.

3.7.2. Cadmium and lead

When simultaneous determination of As, Sb and Se was performed, cadmium and/or lead showed a positive interference (Cd and/or Pb increase the hydride absorbance) on the signal. However, it was not possible to obtain a signal from hydrides of these elements in the absence of As, Sb and Se.

3.7.3. Germanium and tellurium

Based on our own experience [27,28], hydrides of these elements using a batch method are better generated from a basic medium. Nevertheless, considering the results obtained for tin hydride generation (in the batch method the optimum acidity is ten times higher than in the continuous method), a complete study using different Ge and Te hydride generation conditions from acid media was made. Several tests were made modifying the concentrations of HCl (0.5–6 M) and NaBH_4 (2–6%), and no signal was found in any case for germanium or tellurium.

In conclusion, we think that it will be possible to obtain a GPMAS signal from these elements in a continuous flow system (by using a different manifold), but that this will not be possible at the same time as investigating As, Sb, Se and Sn.

Abstract

The application of differential electrolytic potentiometry as a detection system in flow injection analysis for precipitation reactions is described. Different combinations of electrodes were investigated. The optimum conditions for the current density and the flow rate were elucidated. In the case of chloride, an Ag/AgCl–Pt pair was found to be successful. For iodide a combination of Ag–Pt electrodes was found to give good results. The relation between the concentration of analyte and the measured signal was found to be linear. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Differential electrolytic potentiometry; Flow injection analysis; Chloride and iodide detection

1. Introduction

Differential electrolytic potentiometry (dc DEP) consists of polarising two identical electrodes with a stabilised current and measuring the potential difference (ΔE) between them. This method has been applied to various types of titrimetric reactions in both aqueous [1–4] and non-aqueous [5–9] media using different types of electrodes. In this technique the polarized electrodes respond faster, the apparatus is simple and the salt bridge problems of the reference cell are eliminated.

The determination of chloride by flow injection analysis has been based mainly on spectrophotometrical procedures where the reaction between thiocyanate and mercury complex leads to the

displacement of thiocyanate and the formation of an intensely colored complex of iron(III) [10–12]. This method has been found to suffer from poor detection limits, however, Slanina et al. [13] have improved the method and were able to detect chloride in the range of 0.2–15 ppm using both photometric and potentiometric detectors. Chloride was also determined by Cireloogamina and Brindle [14] using a UV-photometric flow injection method. Taylor and Grate [15] determined chloride by means of a flow injection technique with a reflectance detector for the determination of chloride.

The technique of differential electrolytic potentiometry has not as yet been applied as a detection system in flow injection analysis. This paper describes the application of this technique for certain precipitation reactions. The behaviours of different combinations of polarized electrodes

were investigated. Suitable combinations of electrodes for chloride and iodide determination is reported.

2. Experimental

2.1. Reagents

Chloride ion solutions were prepared using Thorn Smith Standard sodium chloride. Supporting electrolyte solutions were prepared from AnalaR sodium nitrate and potassium nitrate. Hydrochloric acid (Fisher) and Baker Analyzed nitric acid were used for the required purposes. Fluka iron(III) chloride was used for the preparation of the solution that is required in the plating of silver electrodes with silver chloride.

Fluka silver nitrate was used for the preparation of silver nitrate solution. Degussa mercury was used for the preparation of the amalgamated electrode. A stock solution of 0.01 M sodium chloride was prepared by dissolving 0.585 g of NaCl in distilled deionized water in 1000 ml volumetric flask. Working solutions were prepared by dilution. The same procedure was applied to prepare stock solutions of silver nitrate, sodium nitrate and potassium nitrate.

A solution of 0.5 M iron(III) chloride was prepared by dissolving the required weight of iron(III) chloride in 8.06 ml of concentrated hydrochloric acid and 50 ml of distilled deionized water in a 100 ml flask then completing to the mark with distilled deionised water.

Nitric acid solution (6 M) was prepared in the usual way from concentrated nitric acid. Fluka sodium iodide was used to prepare iodide solution. A standard solution of 0.01 M iodide was prepared in water.

Accumet Selective Ion Analyzer Model 750 for the other experiments.

A Cole Parmer chart recorder was used and the data was recorded with a speed of 0.3 cm/min .

The test solutions were propelled by a peristaltic pump of Alitea USA/ FIA laboratory for all experiments.

Gateway 2000 computer with RS 332-098 4 phase unipolar stepper motor drive board introduced into the hard disk was used for the injection of samples into carrier streams to provide highly precise and reproducible volume. The injector used was a plastic syringe with the metallic needle replaced by a plastic one to prevent corrosion.

A two line manifold system was used as shown in Fig. 1. Silver nitrate solution was passed from one line and the supporting electrolyte from the other. The reactor was made of a coiled tube formed from a plastic tube of 25 cm length and 1.14 mm inner diameter. This tube was mounted on a glass cylinder of diameter 0.7 cm. The detector was made of Teflon in the form of a cylinder 3 cm in length where the two electrodes were placed and this detector was connected to the reactor.

1	3.50	3.58	102.3
2	32.0	32.1	100.3

rsd, 0.2%

2.3. Electrodes

Silver wire electrodes were used in the first part of the chloride and iodide analysis. They were cleaned with 6 M nitric acid as a pretreatment before each experiment. The electrodes were then rinsed with distilled deionized water and placed in the cell.

The platinum electrodes were SargentWelch type 30-415 and 30-415 respectively. They were cleaned with concentrated sulfuric and/or nitric acid before each experiment as a pretreatment, rinsed with distilled deionized water and placed in the cell.

Platinum electrode were cleaned by dipping in boiling aqua regia and then rinsed with distilled deionized water. It was then immediately immersed into pure mercury for 30 s to prepare a Pt/Hg electrode.

Silver/silver chloride electrodes were prepared by surface oxidation of silver electrodes in a solution of 0.5 M Fe(III) chloride solution which was found to be more effective than the traditional anodic oxidation process [16]. The electrode was immersed in the solution, left overnight then rinsed with distilled deionized water and placed in the cell.

3. Results and discussion

Fig. 1 shows the manifold used in this study where silver nitrate was delivered as reactant from line I. The supporting electrolyte solution was passed through line II. At the start of this work, the proper current density was determined by injecting a volume of 140 μ l of 3.55 ppm chloride solution into a stream of 0.01 M KNO₃ and 10⁻³ M AgNO₃ as shown in Fig. 1. Different current

densities were employed to polarise two identical silver electrodes. Fig. 2a shows that the heights of the resulting peaks increased with the current densities employed. It was noted that at lower current densities, for instance 1.98 μ A cm⁻², the electrodes were found to have a slow response. This is reflected in the small heights of the resulting peaks. However, at current densities greater than 7.93 μ A cm⁻², the electrodes response becomes abnormal. Consequently the resulting peaks will show poor reproducibility as seen from peaks at d and f of Fig. 2. This abnormal behaviour is probably due to the fact that higher currents will increase the concentration overpotentials of both the anode and the cathode. Consequently the measured signal which is the difference between the potentials of these two electrodes will be affected. Fig. 2 shows that the three peaks at point (c) are symmetrical, reproducible and of a considerable height. These peaks were obtained at a current density of 5.95 μ A cm⁻², hence, this value is considered to be an optimum under the employed conditions. The relation between peak height and current density employed to polarise the silver electrodes is shown in table. 2.

The effect of flow rate on the produced signal was also studied and the results are depicted in Fig. 3. It is obvious from this figure that the peak height decreases with an increase in flow rate. The peaks of point b are symmetrical, having a reasonable width and they are considerably high, therefore, the flow rate at this point which is 0.93 ml min⁻¹ was considered to be appropriate for the experimental measurements.

A calibration curve was constructed by injecting standard chloride solutions of concentrations that range from 3.55–35.5 ppm. This calibration curve is shown in Fig. 4 and it has a regression

coefficient of 0.991. During the course of this work it was observed that the response of the silver electrodes became sluggish. This can be attributed to the fact that the resulting silver

Fig. 7. Current density–peak height relationship. Electrode pair, Ag/AgCl–Pt/Hg; flow rate, 0.93 ml min^{-1} , volume $100 \mu\text{l}$ of 4.5 ppm Cl^- ; (a) $0.99 \mu\text{A cm}^{-2}$; (b) $2.97 \mu\text{A cm}^{-2}$; (c) $11.89 \mu\text{A cm}^{-2}$; (d) $14.9 \mu\text{A cm}^{-2}$; (e) $19.8 \mu\text{A cm}^{-2}$.

	2.97	75
	11.89	141
	14.9	225
	19.8	500

Fig. 8. Calibration curve. Electrode pair, Ag/AgCl–Pt/Hg; current density, $19.8 \mu\text{A cm}^{-2}$; flow rate, 0.93 ml min^{-1} , volume, $100 \mu\text{l}$ of Cl^- ; (a) 1.8 ppm ; (b) 3.0 ppm ; (c) 18.2 ppm ; (d) 29.8 ppm ; (e) 42.7 ppm .

chloride dissociates and the ions formed will affect the behaviour of the polarised electrodes. A pair of Ag/AgCl electrodes has been used for the determination of chloride [17]. However, the use of Ag/AgCl electrode as a cathode in DEP will lead to the dissolution of AgCl coating and the electrode will eventually become a silver electrode. Consequently, the resulting signal will differ from the previous ones and abnormal behaviour becomes inevitable.

Polarised platinum electrodes have also been used for chloride analysis using silver nitrate as a titrant [18]. The response of the platinum electrode was attributed to the adsorption of silver chloride precipitate on the surface of the electrode. It was decided to make a combination of a platinum electrode with a Ag/AgCl electrode where the platinum electrode would act as cathode. This combination was employed for the determination of chloride by injecting the latter into a stream containing silver nitrate. When the sample is injected, a potential difference develops between the anode and the cathode, consequently, a peak is formed. The relation between the height of the peak and the current density was studied and the results are shown in Fig. 5 and Table 2. It

Fig. 9. Effect of change in the current density employed. Electrode pair, Ag–Ag; flow rate, 0.93 ml min^{-1} ; volume, $140 \mu\text{l}$ of 12.7 ppm I^{-} ; (a) $1.98 \mu\text{A cm}^{-2}$; (b) $3.96 \mu\text{A cm}^{-2}$; (c) $5.95 \mu\text{A cm}^{-2}$; (d) $9.91 \mu\text{A cm}^{-2}$.

is evident from this figure that the peak height increases with current density and the value of $19.82 \mu\text{A cm}^{-2}$ was chosen for experimental measurements because the resulting peaks are symmetrical and have similar heights.

A calibration curve was established by applying the above mentioned conditions. Standard chloride solutions of concentrations that range from $3.0\text{--}68 \text{ ppm}$ were injected. The resulting calibration curve is depicted in Fig. 6. This curve was found to be linear with $r = 0.997$ and can be applied to determine chloride in real water samples where the sulphate ion if exists is expected to pose no effect on the response of the indicating system. Fig. 6 shows the results of applying DEP in combination with Ag/AgCl–Pt as a detection system for the analysis of chloride in two samples of drinking water. Peaks (f) and (g) shown in Fig. 6 represent the signals for these two samples. Table 1 gives a comparison between the results obtained by this technique and that of standard precipitation titration. It is apparent from this table that DEP can be applied as a detector in FIA and better sensitivity is expected compared

with direct titration methods including the classical DEP technique. In this technique two identical electrodes are employed to obtain a symmetrical peak which gives the end point. The morphology of the peak depends on the completion of both anodic and cathodic reactions that take place on the two electrodes. However, the use of the DEP technique as a detector in flow injection analysis does not require the completion of the reaction. Therefore different combinations of electrodes can be employed to obtain a better signal. In this regard, a combination of Pt/Hg–Ag/AgCl electrodes was used for the determination of chloride. The proper conditions were found using the univariant method. Fig. 7 shows the effects of changing current density on the height of the signal and the optimum current density that gives the highest reproducible signal was found to be $19.82 \mu\text{A cm}^{-2}$. The relation between the peak height and the current density employed is shown in Table 2.

On applying these conditions, a calibration curve that covers a chloride concentration range between 1 and 45 ppm was constructed and is depicted in Fig. 8. It is apparent that this curve is

linear with $r = 0.996$. However when the combination of Pt/Hg–Ag/AgCl electrodes were used for the determination of chloride in real water samples, higher signals resulted. A similar observation

Fig. 12. Calibration curve. Electrode pair, Ag–Pt, current density, $35 \mu\text{A cm}^{-2}$, flow rate: 0.93 ml min^{-1} ; volume of I^- , 140 ml ; (a) 1.27 ppm; (b) 3.81 ppm; (c) 6.35 ppm; (d) 7.62 ppm; (e) 8.89 ppm; (f) 11.4 ppm; (g) 19.0 ppm; (h) 31.8 ppm.

was noted by others [19] where sulfate was found to interfere. Therefore the combination of Pt/Hg–Ag/AgCl is recommended for the determination of chloride in the absence of interfering ions such as sulphate.

The applicability of the DEP technique as a detector in FIA for precipitation reactions was extended to include iodide. Since the solubility of silver iodide is very low, a combination of two identical silver electrodes were expected to give satisfactory results. The appropriate current density gives symmetrical and reproducible peaks of considerable height which was found to be $5.95 \mu\text{A cm}^{-2}$ as shown in Fig. 9. The relation between peak height and current densities employed is shown in Table 3. A calibration curve was constructed for standard iodide solutions of concentrations from 12.7 to 127 ppm. Fig. 10 depicts this curve which has an excellent correlation coefficient of 0.998.

In order to examine the applicability of other combinations of electrodes, one silver electrode was replaced by a platinum electrode in iodide determination. The height of the signal was found to increase with an increase in current density employed as shown in Fig. 11. Its optimum value was chosen as $34.7 \mu\text{A cm}^{-2}$ and Table 3 shows the relation between the peak height and the current densities employed. A calibration curve was established for a concentration range of 1.27–31.8 ppm. This curve is shown in Fig. 12 and it has a correlation coefficient of 0.997 which indicates the applicability of the DEP technique as a detector in flow injection analysis.

4. Conclusion

The technique of DEP which depends on polarising two identical electrodes using a small current and measuring the potential difference between them can be used as a detector in FIA. A combi-

nation of Ag/AgCl–Pt electrodes can be applied for the determination of chloride. For iodide determination Ag–Pt combination was found to give acceptable results. The appropriate conditions of flow rate and current density were investigated.

Salting-out extraction technique for pretreatment in the liquid chromatographic determination of copper(II), aluminum(III), iron(III) and manganese(II) in biological samples

Y. Nagaosa *, K. Sakata

Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910, Japan

Received 5 February 1997; received in revised form 28 August 1997; accepted 12 September 1997

Abstract

A solvent extraction method for the simultaneous determination of Cu, Al, Fe and Mn by reversed phase liquid chromatography is presented. The metal chelates with 5-chloro-8-quinolinol are extracted into an acetonitrile phase with tetrabutylammonium perchlorate and ammonium sulfate as salting-out agents, followed by LC separation and determination using an ODS column. The experimental parameters such as the composition of mobile phase and concentration of the salting-out agent for phase separation have been investigated. The mobile phase is a mixture of 3:1 (v/v) acetonitrile-0.02 mol l⁻¹ sodium acetate solution containing 5 × 10⁻³ mol l⁻¹ 5-chloro-8-quinolinol. The proposed method has been applied to the trace analysis of Cu, Al, Fe and Al in bovine liver and citrus leaves. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Salting-out extraction; Liquid chromatography; 5-Chloro-8-quinolinol; Metal ions

1. Introduction

Trace metals like copper, zinc, manganese as well as iron are essential elements of plants and animals [1]. We need to develop simple and sensitive methods for analyzing these constituents in biological bodies—for human consumption of agricultural products and environmental conservation. Determination of metals in samples has usually been carried out using spectrometric and chromatographic methods [2,3].

Over the past decade, the simultaneous determination of metal ions in aqueous samples by liquid chromatography (LC) with spectrophotometric detection has received much more attention [4,5]. A number of papers have been published on the LC of metal complexes with various chelating agents such as dithiocarbamates [6,7], 8-quinolinol (8-HQ) [8] and 2-pyridylazo compounds [9,10] as derivatization agents.

In order to increase the selectivity and sensitivity of metal determinations, preconcentration methods using solvent extraction [11–13] and on-line enrichment system [14] has been developed. Direct injections of organic solvents into ODS

Fig. 1. Chromatograms obtained for metal complexes with 8-quinolinol (8-HQ) by reversed phase LC. The sample solution (A) was prepared by mixing 5.0 ml of a $0.1 \mu\text{g ml}^{-1}$ metal ion solution with 5.0 ml of a 0.02 mol l^{-1} 8-HQ solution in acetonitrile; the acetonitrile extract sample (B) was obtained by adding 2.0 g of ammonium sulfate to the sample (A); The sample (C) was obtained by dilution of the acetonitrile extract sample (B) (with water at a volume ratio of 1:1), the mobile phase was a mixture of 2:3 (v/v) acetonitrile- 0.02 mol l^{-1} acetate buffer (pH 5.9) containing $5.0 \times 10^{-3} \text{ mol l}^{-1}$ 8-HQ. Other conditions are described in Section 2 of the text.

columns often causes chromatographic distortions on the elution curves due to the solubility problem of the organic extract in the mobile phase [13,15]. Kaneko et al. [16] reported chloroform extraction followed by evaporation of the extract and addition of dimethylsulfoxide for sample preparation; the procedure was very tedious and time-consuming, and LC peaks obtained were quite sharp. Mueller et al. [11] used a salt-induced (salting-out) extraction technique using acetonitrile as a solvent to overcome this drawback. Sodium chloride as the salting-out agent, however, was inappropriate because an emulsion formed between the two phases.

Here we propose using tetrabutylammonium perchlorate (TBAP) for inorganic salt-induced extraction to achieve a simple and effective pretreatment method for LC analyses of complex samples like biological materials. This method is based on the extraction of metal complexes with 5-chloro-8-quinolinol (5-Cl-8-HQ) into an acetonitrile phase by using TBAP and ammonium sulfate as the composite salting-out agent, followed by direct injection of the extract into an ODS column. This

LC method has been applied to the determination of copper, aluminum, iron and manganese in bovine liver and citrus leaves.

2. Experimental

2.1. Reagents

Standard reference materials (citrus leaves 1572, bovine liver 1577a) were used to evaluate the proposed method. Tokyo Kasei supplied 8-HQ, 5-Cl-8-HQ and tetrabutylammonium perchlorate (TBAP). Metal ion standards (1000 ppm) for atomic absorption spectrometry and ammonium sulfate were from Wako Junyaku. All other chemicals and solvents were of analytical or HPLC grade. Water was purified with a Millipore Milli-Q water purification system after distillation.

2.2. Apparatus

The LC equipment comprised of the following components: Tosoh Model CCPD pump (Tokyo,

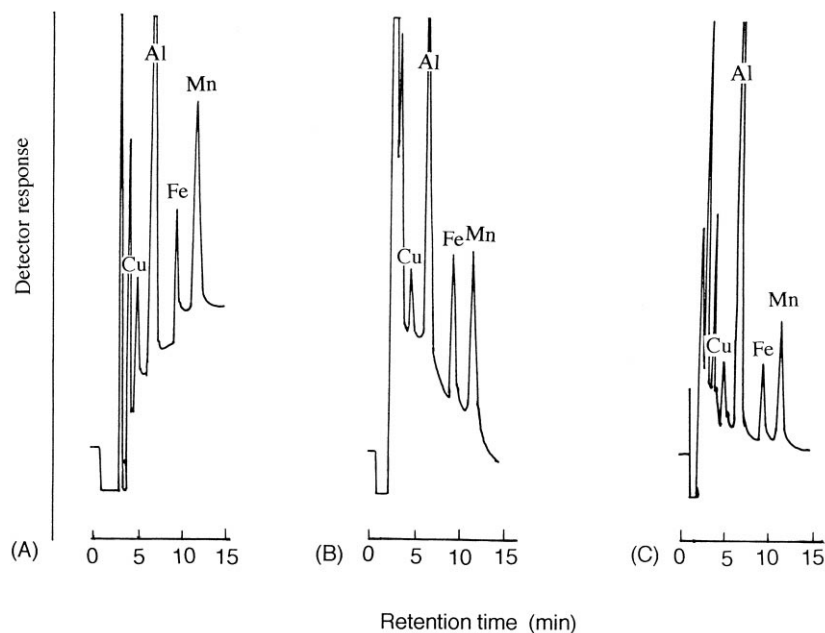

Fig. 2. Chromatograms obtained for metal complexes with 5-chloro-8-quinolinol (5-Cl-8-HQ) after sample treatment with various salting-out agents. The concentration of metal ions: $0.1 \mu\text{g ml}^{-1}$ of each of the extract samples (A), (B) and (C) were obtained by adding 1.0 g of ammonium sulfate, 1.0 mmol TBAP and a mixture of 1.0 g of ammonium sulfate and 0.5 mmol TBAP to a mixed solution of 2.0 ml of 0.02 mol l^{-1} 5-Cl-8-HQ in acetonitrile and 5.0 ml of metal ion solution; the mobile phase was a mixture of 3:1 (v/v) acetonitrile- 0.02 mol l^{-1} sodium acetate solution containing $5 \times 10^{-3} \text{ mol l}^{-1}$ 5-Cl-8-HQ.

Japan) and Reodyne Model 7125 injector valve with a $100 \mu\text{l}$ sample loop (Cotati, California); for UV detection at 390 nm, a Shimadzu Model SPD-6AV spectrophotometer (Kyoto, Japan). Data was processed using a Shimadzu Model CR-6A integrator/recorder. A Toa Denpa Model HM-30s pH meter was used to measure the pH of the solution. LC analyses were carried out on a Tosoh TSKGEL ODS column ($5 \mu\text{m}$, $4.6 \times 150 \text{ mm}$).

2.3. Procedures

5-Cl-8-HQ solution (2 ml of a 0.02 mol l^{-1}) in acetonitrile was added to 4.0 ml of a moderately acidic aqueous sample solution containing the metal ions. To the resultant solution, 1.0 ml

of a 2.0 mol l^{-1} sodium acetate solution was added. After complete complex formation, the metal complexes were extracted by adding a mixed salt of 2.5 g ammonium sulfate and 0.5 mmol (0.17 g) TBAP as the salting-out agent followed by vigorous shaking for about 1 min. The recovered volume of the acetonitrile phase was 2.0 ml under experimental conditions. A $100\text{-}\mu\text{l}$ portion of the acetonitrile extract was injected into the analytical column. The complexes were eluted with a 3:1 (v/v) acetonitrile- 0.02 mol l^{-1} sodium acetate solution containing $5 \times 10^{-3} \text{ mol l}^{-1}$ 5-Cl-8-HQ as the mobile phase. The flow rate was 1.0 ml min^{-1} , and the detector was operated at 390 nm.

About 1 g of the standard reference materials, citrus leaves (NBS, SRM 1572) and bovine liver

(NBS, SRM 1577a), was separately treated by the wet digestion method using a mixed acid of nitric acid–sulfuric acid–perchloric acid at about

200°C. The sample solutions were adjusted to about pH 2 with 2 mol l^{-1} sodium hydroxide and then diluted to 100 ml with water.

Table 1
Statistical analyses and detection limits

Metal ion	Regression line	Correlation coefficient	Detection limit (ng ml ⁻¹)
Cu(II)	$Y = 4.91 + 140X$	0.9966	3.1
Al(III)	$Y = 24.2 + 244X$	0.9972	4.8
Fe(III)	$Y = 1.46 + 94.6X$	0.9997	2.7
Mn(II)	$Y = 0.40 + 173X$	0.9952	3.3

X and Y are metal concentrations in $\mu\text{g ml}^{-1}$ and peak height in arbitrary unit, respectively.

3. Results and discussion

3.1. LC separation of metal complexes

Acetonitrile has been used as a modifier of mobile phases for the separation of a variety of compounds by the reversed phase LC method. Usually aqueous samples are injected into an ODS column and are then eluted with a mixture of acetonitrile and aqueous solution. Fig. 1(A) shows a typical chromatogram obtained for the separation of Al(III), Cu(II), Fe(III) and Mn(II) complexes with 8-HQ where the sample solution was a mixture of 1:1 (v/v) acetonitrile-0.02 mol l⁻¹ acetate buffer (pH 5.9) containing 5×10^{-3} mol l⁻¹ 8-HQ. Elution peaks were very sharp and good separation was achieved. When the acetonitrile extract obtained with the salt-induced phase separation was directly injected into the column, the peaks were broader and a little distorted, as shown in Fig. 1(B). This is probably because the sample was much different from the mobile phase in composition [17]: the acetonitrile extract was about 4:1 (v/v) acetonitrile-aqueous solution containing 0.25 mol l⁻¹ TBAP. A well-defined chromatogram illustrated in Fig. 1(C) was obtained when the acetonitrile extract was injected after diluting it (at a volume ratio of 1:1) with water. The injected sample was finally a mixture of 2:3 (v/v) acetonitrile–water; the experimental procedure is somewhat tedious and therefore seems inappropriate for LC analysis.

We have tried developing LC analysis using direct injections of the acetonitrile extract which can be obtained by the salting-out extraction with TBAP and/or ammonium sulfate. For the purpose

of this study, 5-Cl-8-HQ was selected as a derivatization agent for LC determination of metals. Fig. 2 shows typical chromatograms for Al(III), Cu(II), Fe(III) and Mn(II) complexes with the chelating agent, with a mobile phase of 3:1 (v/v) acetonitrile-0.02 mol l⁻¹ sodium acetate. In Fig. 2, the salting-out agents used were TBAP (A), ammonium sulfate (B) and their mixture (C), respectively. The metal complexes were found to be more strongly retained on the ODS column than the 8-HQ complexes. The volume ratio of acetonitrile/aqueous solution in the mobile phase was almost the same as that of the acetonitrile extract sample injected. The salting-out agent, however, affected the elution behavior as shown in Fig. 2; the baseline increased (A) and decreased (B) when TBAP and ammonium sulfate were used, respectively. This is because the two substances have opposite effects on the retention of 5-Cl-8-HQ in the reversed phase LC system. The mixture of both salts was chosen because the best result was obtained (C).

3.2. Phase separation with salting-out agents

The salt-induced phase separation between acetonitrile and aqueous solution was observed by addition of a variety of inorganic and organic electrolytes. Water-miscible organic solvents have drawbacks over water-immiscible ones in that the phase volumes depend on added amounts of the salting-out agent. A constant and possibly large amount of the salt must be added to get constant recovered-volumes of the two phases. In the present study, a relatively small amount of TBAP

Fig. 7. Determination of aluminum, copper, iron and manganese in biological samples. (A), $0.1 \mu\text{g ml}^{-1}$ of each metal ion solution; (B), citrus leaves; (C), bovine liver.

was added together with ammonium sulfate to achieve a rapid and clear phase separation between acetonitrile and aqueous solution. Fig. 3 shows a ternary phase-diagram expressed in weight percent for the water/salting-out agent/acetonitrile system. The lines indicate minimum amounts of the salt at which the two phases begin to separate, and no phase separation takes place under the lines.

3.3. Experimental conditions for LC determination of metals

The mobile phase was tested by changing the ratio of acetonitrile and 0.02 mol l^{-1} sodium acetate solution. The results shown in Fig. 4 indicate that the retention times gradually decreased as the acetonitrile content of the mobile phase increased. At an acetonitrile content of 80%, the peak-to-peak separation was incomplete. The mobile phase contained 75% acetonitrile, corresponding 3:1 (v/v) acetonitrile- 0.02 mol l^{-1} sodium acetate solution, was selected.

The effects of experimental parameters such as the amounts of TBAP and ammonium sulfate on the peak heights of the metals was investigated. Fig. 5 shows the relationship between the amount of TBAP and peak heights for Al(III), Cu(II) and Fe(III) and Mn(II). The recovered volume of the acetonitrile phase was also plotted against the amount of TBAP as the salting-out agent. It can be seen that all peaks gradually decreased in height as the amount of TBAP increased from 0.1 to 1.0 mmol. The recovered volume of acetonitrile phase increased from 1.71 to 2.04 ml without addition of ammonium sulfate. Fig. 6 shows the relationship between the amount of ammonium sulfate and peak heights for all metal ions investigated. It can be seen that the addition of ammonium sulfate ranging from 2.5 to 3.0 g gave approximately constant values in peak height even though an emulsion formed between the two phases. When 0.2–1.0 mmol TBAP and 2.5–3.0 g ammonium sulfate were added together as the salting-out agents, the recovered volume of the acetonitrile phase (2.0 ml) and the peak heights

Table 2
Analytical results for standard reference materials

Sample	Metal	Concentration found ($\mu\text{g g}^{-1}$)	Certified value ($\mu\text{g g}^{-1}$)
Bovine liver	Cu	157 ± 2	158 ± 2
	Al	- ^a	2
	Fe	190 ± 3	194 ± 20
	Mn	9.6 ± 0.7	9.9 ± 0.8
Citrus leaves	Cu	15.6 ± 0.7	16.5 ± 1
	Al	88.2 ± 1.1	92 ± 15
	Fe	91.6 ± 1.8	90 ± 10
	Mn	22.1 ± 0.5	23 ± 1

^a No detection

were kept almost constant. In the present study, 0.5 mmol (0.17 g) of TBAP and 2.5 g of ammonium sulfate were added because a rapid and clear separation of the two phases could also be achieved.

3.4. Calibration graphs and detection limits

From the results obtained using the procedures described above, calibration graphs of peak height (Y) and metal concentration (X) were constructed for the four metals. Linear relationships were obtained over the concentration of each metal up to $10 \mu\text{g ml}^{-1}$ for $100 \mu\text{l}$ injections. The equations of the graphs and their regression results are listed in Table 1, together with the detection limits defined as the metal concentration giving a signal-to-noise ratio of 3.

3.5. Analytical applications

In order to validate the proposed method, determination of Al, Cu, Fe and Mn in two biological samples were investigated. Fig. 7 shows the chromatograms obtained using the procedure described in Section 2.3. The analytical results (replicate five determinations) listed in Table 2 were in good agreement with the certified values, except for aluminum in bovine liver; the concentration of aluminum in bovine liver was too low to be determined. It can be concluded that the method is acceptable and seems very useful for the analysis of trace metals in biological materials. We expect that interference from matrices or large

amounts of foreign ions can be removed using the present method.

4. Conclusion

A salting-out extraction method as a pretreatment step is described for the liquid chromatographic determination of aluminum, copper, iron and manganese in biological samples of bovine liver and citrus leaves. The results indicate that the present LC method including the acetonitrile extraction gives a simple and rapid technique to eliminate interference due to matrix effect and coexisting constituents in biological samples. Moreover, effective preconcentration with higher enrichment factors can be achieved by changing the volume ratio of the two phases and the amount of salting-out agents.

Abstract

A highly selective, sensitive, and fairly rapid and economical differential pulse polarographic (DPP) method has been reported for the determination of trace amounts of vanadium and molybdenum in standard alloys and various environmental samples. The morpholine-4-carbodithioates of these metals were retained (> 99% recovery) quantitatively on microcrystalline naphthalene in the pH range 4.5–6.9 for vanadium and 1.5–4.5 for molybdenum. These metals were determined by DPP after desorption with 10 ml of 1 M HCl. Vanadium and molybdenum may also be preconcentrated by passing their aqueous solutions under similar conditions on morpholine-4-dithiocarbamate CTMAB-naphthalene adsorbent packed in a column at a flow rate of 1–5 ml min⁻¹ and determined similarly. The detection limits are 0.20 ppm for vanadium and 0.04 ppm for molybdenum at minimum instrumental settings (signal to noise ratio = 2). The linearity is maintained in the following concentration ranges, vanadium 0.50–10.0 and molybdenum 0.10–9.0 ppm, with a correlation factor of 0.9996 (confidence interval of 95%, slopes 0.0196 and 0.01497 $\mu\text{A } \mu\text{g}^{-1}$, intercepts 3.65×10^{-3} and -1.92×10^{-3} respectively) and relative standard deviation of 1.1% in the microcrystalline method, while in the column method, the linearity is maintained in the concentration ranges, 0.50–6.5 for vanadium and 0.10–5.5 ppm for molybdenum with correlation factor of 0.9994 (with confidence interval of 95%, slopes 0.0194, 0.015 $\mu\text{A } \mu\text{g}^{-1}$, intercepts 3.60×10^{-3} and -1.90×10^{-3} respectively) and relative standard deviation of 1.4%. Various parameters such as the effect of pH, reagent, naphthalene and CTMAB concentrations, volume of aqueous phase and interference of a large number of metal ions on the estimation of vanadium and molybdenum have been studied in detail to optimize the conditions for their voltammetric determination at trace level in various standard alloys and environmental samples. © 1998 Elsevier Science B.V. 1. Introduction

Vanadium and molybdenum are the most important elements which affect the physical properties of steel, alloys and high purity metals. Vanadium is widely distributed in the earth's crust, its compounds can be highly toxic to man and animals and cause environmental diseases when released in the atmosphere [1]. It has also been noted that the environmental background levels of vanadium have been slowly rising as a result of the combustion of fossil fuels which have high vanadium content [2]. Vanadium is therefore, important not only because of its toxicity at high levels but also because it is an environmental pollutant [3]. Occupational exposure to vanadium has been observed in several industrial processes, for example, in iron and steel production, in the manufacture of pigments, printing inks and paints, in the glass industry, in the cleaning and repairing of oil fired boilers, particularly in electricity power stations [4–6]. Molybdenum is an essential element to all living organisms. Its biological role is extremely important in the nitrogen metabolism of plants. However, an excess of this element becomes harmful to ruminants since the adsorption of copper by the liver is depressed [7]. Very low concentrations of molybdenum and vanadium are present in various matrices such as plants, soils, sea-water, etc. Therefore, it is very important from the analytical point of view to develop sensitive, selective, rapid and economical methods for their quantitative determination even when present in trace amounts. These metals may be determined spectrophotometrically after extraction of their metal complexes into suitable organic solvents, but these methods have a limited sensitivity and may have many types of interferences [8–12]. NAA, AAS, graphite furnace AAS, ICP-AES, ICP-MS may be used for the trace determination of metals in complex materials, but these instruments are highly expensive, their day to day maintenance cost is high and they are not free from various types of interferences [13–16].

Vanadium and molybdenum may also be determined polarographically after the extraction of their metal complexes into various organic solvents [17–23]. However, the method has poor

sensitivity since the organic phase has to be mixed with a solvent of high dielectric constant to obtain well defined polarograms, and is also time consuming as pure nitrogen gas has to be passed for 15–20 min, which may also result in partial evaporation of the organic solvent and thus effects the reproducibility of the method. Catalytic [24–26], adsorptive stripping voltammetric (AdSV) [27–29] and square wave adsorptive stripping voltammetry methods [30] are very sensitive for the determination of these metals, but in such cases the reproducibility depends upon a number of parameters like the rigid control of temperature, pH, reagent concentration, surface area of the electrode and the rate of formation of the film on the electrode. Adsorptive stripping voltammetry methods are also time consuming due to prolonged deposition and stripping steps and removal of oxygen with highly pure nitrogen gas and are not selective [27–30]. The preconcentration step proposed in the present method not only concentrates the sample from a large volume (300–350 ml) to a small volume (10–15 ml) to make the differential pulse polarography successful for the trace estimation of the metal ions, but also makes the method highly selective because different metal ions are adsorbed at different pH values. The various parameters developed are highly flexible and can be applied over a wide range while in the case of stripping voltammetric methods the various parameters related to them need rigid control to obtain reproducible results. The removal of oxygen hardly takes 2–5 min in the present method, while it takes 15–20 min in other electrochemical methods [17–30].

In the present work, we have developed a simple, rapid, economical, sensitive and selective method for the direct differential pulse polarographic determination of vanadium and molybdenum after adsorption of their morpholine-4-carbodithioates on microcrystalline naphthalene. Alternatively, these metal ions may be preconcentrated after passing their aqueous solutions over morpholine-4-dithiocarbamate CTMAB-naphthalene adsorbent placed in a column. The microcrystalline method is rapid but the column method gives a better preconcentration factor (2.5 times). This reagent is fairly sensitive,

selective, can be easily prepared in the laboratory and does not interfere in the polarographic determination of metals [31]. Various parameters have been evaluated and the procedure developed has been successfully employed for the determination of trace and ultratrace amounts of vanadium and molybdenum in various standard alloys and environmental samples.

2. Experimental

2.1. Apparatus

Polarograms were recorded with an Elico Model CL-90 three electrode polarograph. It was outfitted with a model LR-108 *X-Y* recorder. All atomic absorption measurements were made using a Varian Model 475 AAS. An Elico model LI-120 pH meter was used for pH measurements. A funnel tipped glass tube (60 × 6 mm i.d.) was used as a preconcentration column. It was plugged with poly(propylene) fibres and filled with the slurry (adsorbent) to a height of 1.0–1.2 cm after slightly pressing the adsorbent in the column with a flat glass rod.

2.2. Reagents

All reagents were of analytical grade and double distilled water was used whenever required. Molybdenum(VI) solution was prepared by dissolving 12.8800 g of $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}$ in water in the presence of a few millilitres of concentrated HCl, and made-up to 1000 ml in a calibrated flask with distilled water. Vanadium(V) solution was prepared by dissolving 2.3000 g of NH_4VO_3 in a few ml of 1 M NaOH, acidified with dilute HCl and then diluted to 1000 ml in a standard flask. Both solutions were standardized by known methods [32] and made 1000 ppm corresponding to pure metal by approximate dilution. Potassium morpholine-4-dithiocarbamate (MCDT) was prepared, by the method described in the literature [31]. Morpholine (17.5 g) in dry ether was placed in a 250 Erlenmeyer flask and to this solution, stoichiometric amounts of carbon disulphide (nearly 25 ml) was added dropwise

with constant stirring. The reaction mixture was cooled thoroughly in an ice-salt mixture and to this solution stoichiometric amount of potassium hydroxide ~12 g (dissolved in a minimum amount of water) was added dropwise with constant stirring. The addition was completed in about 3–4 h. The crude product was filtered over suction and washed several times with solvent ether. The residue was recrystallized twice from isopropyl alcohol. The pure product is white needle shaped crystals, highly soluble in water. The melting point 175°C was found to be the same as reported in the literature. A 0.2% aqueous solution of MCDT was prepared. For the preparation of MCDT CTMAB-naphthalene

Fig. 1. Effect of pH on adsorption/retention of molybdenum and vanadium complex; molybdenum, 100.0 µg; vanadium, 100.0 µg; reagent, 2.0 ml; (0.2%), naphthalene, 2.0 ml (20%), reference reagent blank, supporting electrolyte Mo: HCl, 10 ml (1 M), pyridine 2 ml (1 M), water 3 ml, (total 15 ml); V: HCl, 10 ml (1 M), pyridine 2 ml (1 M), NaOH, 3 ml (1 M), (total 15 ml); instrumental settings: scan rate = 12 mV s⁻¹, modulation amplitude = 50 mV and drop time = 0.5 s.

Fig. 2. Typical differential-pulse polarograms in a series of vanadium solutions (ppm). Conditions same as Fig. 1.

adsorbent, a solution of naphthalene was prepared by dissolving a 10 g sample in 100 ml of acetone followed by 1 l of distilled water containing 0.050 g cetyltrimethyl ammonium bromide. It was stirred at 25–30°C on a hot plate/stirrer, followed by 100 ml of 0.2% MCDT solution in distilled water. The mixture was stirred for 3 h and kept for 5 h at room temperature. The supernatant liquid was aspirated with a siphon and the residue was washed twice with double-distilled water. The final adsorbent was a slurry of MCDT CTMAB-naphthalene and stored in a bottle for subsequent use. Solutions of naphthalene in acetone (20%), pyridine 1 M, alkali metal salts (1%) and various metal salts (0.1%) in distilled water were used. Buffer solutions were prepared from 0.2 M acetic acid and 0.2 M ammonium acetate for pH 3–6.

2.3. Pretreatment of standard alloys and environmental samples

The solution of the standard alloys was prepared as described in the literature [31]. A 0.1–1.0 g sample of each of the standard alloy was dissolved in 30–60 ml of 6 M HCl by heating on a hot plate; then 3–5 ml of 30% hydrogen peroxide was added. The excess of peroxide was decomposed by heating. The solution was cooled, filtered if needed, and diluted to 100 ml with distilled water in a calibrated volumetric flask.

Solid environmental samples were oven dried at 200°C for 2 h. A 0.1–0.5 g sample of each was decomposed with 50–60 ml of 6 M HCl and 10 ml of concentrated HNO₃. The mixture was heated on a hot plate almost to dryness. The residue was then dissolved in 10 ml of 1 M HCl and diluted with 10 ml of distilled water and filtered if needed. Finally, the solution was made up to 100 ml with distilled water in a calibrated volumetric flask [31].

The liquid environmental sample (100–500 ml of each) was taken and 5 ml of concentrated nitric acid was added to it. The solution was heated

Fig. 3. Typical differential-pulse polarograms in a series of molybdenum solutions (ppm). Conditions same as Fig. 1.

almost to dryness on a hot plate, the residue was then dissolved in 5 ml of 1 M HCl and finally the solution was made up to 100 ml with distilled water in a calibrated volumetric flask [31]. The tap water samples may be analysed directly without the above treatment using the standard addition method. The recovery is more than 95% in each case.

2.4. General procedure

An aliquot of vanadium (V) or molybdenum (VI) (100 μg each) solution was taken individually in a 250 ml Erlenmeyer flask with a tightly fitting stopper. MCDT (2 ml of 0.2% reagent) was added and the solution was then diluted to 30–40 ml. The pH was adjusted with 2.0 ml of a buffer of pH 5.5 and 3.0, for vanadium and molybdenum, respectively. The solution was mixed well and allowed to stand for a few seconds. Then, 2.0 ml of a 20% solution of naphthalene in acetone was added to it while continuously shaking. The solid mass so formed was separated by filtration on a Whatman filter paper No. 1041. The residue was dried in the fold of a filter paper and transferred to an Erlenmeyer flask. It was shaken vigorously with 10 ml of 1 M HCl solution, and then transferred to the polarographic cell. In the column method, the adsorbent was conditioned to pH 5.5 for vanadium and 3.0 for molybdenum, with 5 ml of the buffer solutions, before passing the test solutions through the column at a flow rate of 1–5 ml min^{-1} . The column was finally washed with distilled water. Desorption of the metals was carried out by passing 10 ml of 1 M HCl at the same flow rate and the solution was transferred to the polarographic cell. Pyridine (2 ml of 1 M) was added to the polarographic cell. In case of vanadium, in addition to pyridine 3 ml of 1 M NaOH solution was also added. The total volume was made up to 15 ml with the addition of distilled water if needed. The differential pulse polarograms were recorded after oxygen was removed by passing nitrogen gas for 2–5 min.

3. Results and discussion

Preliminary observations indicated that vanadium(V) and molybdenum(VI) give well defined differential pulse polarograms with $E_p = -0.44$ V (pH ~ 1) and -0.68 V (pH ~ 1) vs. S.C.E. in pyridine–hydrochloric acid sodium chloride and pyridine–HCl solutions, respectively. The half peak width was 50 ± 3 for V(V) and 80 ± 1 mV for Mo(IV). Under these conditions, the cyclic voltammograms using mercury pool as the working electrode were recorded. In both cases only cathodic waves were obtained. It clearly indicates that these metal ions were reduced irreversibly under these conditions. The effect of the supporting electrolyte (1 M pyridine solution) concentration was studied on the polarograms of molybdenum and vanadium. The peak height and peak potential were almost constant in 1.0–6.0 ml of 1 M pyridine solution for molybdenum and 1.0–4.0 ml of 1 M pyridine solution for vanadium. Therefore, 2 ml of 1 M pyridine was used as the supporting electrolyte throughout this work.

3.1. Effect of pH on the differential pulse polarograms

The effect of pH was studied by adding a dilute solution of NaOH to the polarographic cell solution keeping other variables constant after the preconcentration step. In case of vanadium, two waves were obtained with peak potentials of (E_p) = -0.11 V and -0.44 V vs. S.C.E. The wave height of the first wave is very small as compared with the second wave. The shape and wave height of the second wave was found to be constant in the pH range of 1.0–4.0, however, E_p was shifted towards the more negative direction. The plot of E_p vs. pH was not linear indicating that protonation reaction is not taking part in the overall electrode process [33]. In case of molybdenum, the effect of pH could not be studied because the wave became ill-defined with the addition of NaOH.

Table 1
Effect of salts and metal ions

Salt or metal ion added	Tolerance Limit		Remarks

Mo: 100 µg, V: 100 µg, reagent (0.2%): 2 ml, naphthalene (20%): 2 ml, pH: Mo: 3.0, V: 5.5. E_p (V) vs. S.C.E.; Mo: -0.68 V, V: -0.44V.

3.2. Effect of pH on adsorption

The effect of pH on adsorption of the metal complex on naphthalene was studied at different pH values keeping other variables constant (Fig. 1). It was found that morpholine-4-carbodithioates of molybdenum and vanadium were quantitatively retained on naphthalene in the pH range 1.5–4.5 and 4.4–6.9 respectively. Analogous to the case in the column method. Addition of 1–5 ml of buffer did not have any effect on the adsorption, therefore, 2.0 ml of the buffer of respective pH was used in the subsequent studies.

3.3. Retention characteristics of MCDT.

The chelating agent has the functional groups

of the dithiocarbamate molecules which is coordinated with the metal. Hence, molybdenum and vanadium form chelates with four and two molecules of dithiocarbamate respectively [11]. The retention capacity of morpholine-4-dithiocarbamate supported on naphthalene was determined by the batch method. This experiment was carried out by taking a solution containing 5 mg each of

metal, 2.0 ml of required buffer solution, a suitable amount of the adsorbent in a 100 ml separatory funnel. The mixture was diluted to 30 ml. It was shaken for 30 min, and filtered through a filter paper. The amount of the metal ion in the filtrate was determined by AAS. The naphthalene-chelating agent material was dried on a filter paper, and the solid mass was weighed on a balance. The retention capacity of the metal ion for the adsorbent was found to depend on the amount of adsorbent. The maximum amount of retention per gram of the adsorbent was 1.3 mg of molybdenum and 1.6 mg for vanadium.

3.4. Reaction conditions

Reaction conditions were established using 100 μg of molybdenum or vanadium individually. The effect of HCl concentration on the desorption of metal complexes with 10 ml of 0.1–5.0 M HCl keeping other variables constant was studied. The peak height and shape of the differential pulse polarograms were found to be constant in the concentration range 0.5–2.0 M for molybdenum and 0.5–5.0 M for vanadium. Therefore, 10 ml of 1 M HCl was used throughout the present work. The reagent concentration was varied over a range of 0.1–7.0 ml (0.2%). It was found that adsorptions were quantitative and maximum for the concentration range, molybdenum 0.5–4.5 and vanadium 0.6–4.0 ml (0.2%). Therefore, 2.0 ml of 0.2% reagent solution was used in the subsequent studies. Various amounts of naphthalene (20% solution in acetone) was added to the sample solutions keeping other variables constant. It was found that 0.6–4.5 and 0.8–5.0 ml of 20% naphthalene solution was required for the quantitative retention of the molybdenum and vanadium complexes respectively. However, 2.0 ml of 20% naphthalene solution was used to be on the safe side. The effect of shaking time on the adsorption of the metal complexes on naphthalene indicates that the retention was constant and maximum over a range of 0.5–7.0 min and 1 min of shaking time was recommended. In case of the column method, the flow rate was varied from 0.5–8.0 ml min^{-1} . It was found that a flow rate of 0.5–5.0 ml min^{-1} in both cases did not effect the retention of the metal

complex on the adsorbent. Hence, a flow rate of 1–5 ml min^{-1} was recommended for the present work. The volume of the aqueous phase was varied—in the range of 10–700 ml under optimum conditions, keeping other variables constant. It was found that retention was almost constant up to 120 ml of the aqueous phase for molybdenum and vanadium (preconcentration factor 8) whereas in the case of the column method, the peak height was constant up to 350 ml for molybdenum (preconcentration factor ~ 23) and 300 ml for vanadium (preconcentration factor ~ 20). However, in both the cases, 40 ml of aqueous phase was maintained for convenience.

3.5. Calibration:

Calibration graphs for the determination of molybdenum and vanadium were prepared according to general procedure (Figs. 2 and 3). The detection limits were 0.04 ppm for molybdenum and 0.20 ppm for vanadium at the minimum instrumental settings (signal to noise ratio = 2). The linearities were maintained in the following concentration range, molybdenum 0.10–9.0 ppm and vanadium 0.50–10.0 ppm, with a correlation factor of 0.9996 (confidence interval of 95%, slopes 0.0196 and 0.1497 $\mu\text{A } \mu\text{g}^{-1}$, intercepts 3.65×10^{-3} and -1.92×10^{-3} respectively) and relative standard deviation of 1.1% in the microcrystalline method and molybdenum 0.10–5.5 ppm and vanadium 0.50–6.5 ppm with a correlation factor of 0.9994 (with confidence interval of 95%, slopes 0.194 and 0.015 $\mu\text{A } \mu\text{g}^{-1}$, intercepts 3.60×10^{-3} and -1.90×10^{-3} respectively) and relative standard deviation of 1.4% in the column methods.

3.6. Effect of diverse ions

The effect of various salts of anions and cations on the adsorption and subsequently on the differential pulse polarographic determination of 100 μg of molybdenum and vanadium taken individually was studied. Among the various ions examined (Table 1), many could be tolerated up to milligrams levels except EDTA. EDTA ($\sim 700 \mu\text{g}$) could be tolerated probably due to the high

In steel samples, Fe³⁺ was eliminated by pre-extraction as trifluoroethylxanthate.

In the case of Al–alloys, Cu²⁺ and Cd²⁺ were masked with 5 ml of 5% NaCN solutions, while Fe³⁺ with 5 ml of triethanolamine solution.

value of formation constants of these metals than their dithiocarbamates. In the case of metal ions, many did not interfere up to milligram levels. Fe(III), Cu(II) and Cd(II) interfered in both cases. Fe(III) was masked with 5 ml of 20% triethanolamine solution, while Cu(II) and Cd(II) with 5 ml of 5% solution of sodium cyanide during the preconcentration step. Tl(I) and Pb(II) interfered in the determination of vanadium only. Pb(II) could be masked with 0.5 mg of EDTA (0.5 ml of 1% EDTA solution) while 0.1 mg of Tl(I) could be tolerated by the controlling the pH. The concentration of Cu(II), Pb(II), Tl(I) and Cd(II) are higher than 5 mg in a sample, these could be easily removed by preextraction of their trifluoroethylxanthates into chloroform at pH 8.5–9.5 [11]. Thus the method is highly selective and has been applied safely in the estimation of these metals in various complex samples.

3.7. Application to the analysis of standard alloys and environmental samples

The accuracy and applicability of the proposed method was evaluated by its application on various standard alloys and environmental samples.

In the case of aluminium alloys and environmental sample, an aliquot of the sample (40–100 ml) was taken, 5 ml of 5% sodium cyanide and 5 ml of 20% solution of triethanolamine were added and then the general procedure was applied. For steel analysis, the excess of iron was removed by the preextraction of iron as trifluoroethylxanthate at pH 9 [11]. Relatively low results were obtained when Fe(III) was removed as hydroxide with NaOH solution [34] since iron oxide and iron hydroxides are well known adsorbents. After removal of Fe(III), molybdenum and vanadium were determined using the general procedure. In the case of environmental samples, the results were compared with atomic absorption spectrometry after the preconcentration step developed in the present method. The results are given in Tables 2 and 3.

4. Conclusion

Catalytic and stripping voltammetric methods are more time consuming and also depend on the rigid control of conditions. The proposed method has solved most of these problems and has been

successfully applied to the determination of molybdenum and vanadium in various complex materials. Atomic adsorption spectrometric method may be used following the preconcentration step after removal of naphthalene by filtration, but it is expensive, day to day maintenance is high and it is not free from matrix effect. The column method improves the preconcentration factor by 2.5 times that of the microcrystalline method but is relatively more time consuming as compared with the microcrystalline method. The developed procedure can also be employed for the determination of these metals in biological samples like bovine liver, human hair, nails and various vegetable products. Simultaneous determination of these metal ions is possible if the preconcentration is carried out at pH 4.5.

Abstract

A simple, accurate, rapid and sensitive spectrophotometric method has been developed for the assay of six phenothiazine derivatives in bulk drug and their pharmaceutical preparations. The method is based on ion-pair complex reaction of phenothiazines with bromocresol green in aqueous acidic buffer. The chromogen, being extractable with chloroform, could be measured quantitatively at 420 nm. All variables were studied in order to optimize the reaction conditions. The proposed method has been successfully applied to the analysis of the bulk drugs and their dosage forms, tablets and injections. No interference was observed from common pharmaceutical adjuvants. Statistical comparison of the results with those of an official method shows excellent agreement and indicates no significant difference in precision. © 1998 Elsevier Science B.V. Keywords: Phenothiazine derivatives; Pharmaceutical preparations; Spectrophotometric method

1. 1. Introduction

Phenothiazine derivatives make valuable pharmacological preparations. Owing to their relatively low toxicity, high physiological activity and versatile pharmacological action, they are widely used in therapeutics, particularly as psychotropic drugs. Over 30 phenothiazine drugs and 100 formulations are commercially available. The importance of these drugs prompted the development of many methods for their determination, reviewed by Blazek [1], Fairbrother [2] and Belikov and

Moiseeva [3]. Apart from official methods based on uv-spectrophotometry and non-aqueous titrimetry, two-phase, tetraphenylborate, ammonium reineckate, complexometric and oxidative titrations have also been used. A variety of spectrophotometric methods based on coloured complex formation or oxidative reactions have also been proposed, some lacking sensitivity and specificity [4–9] or requiring long heating times [10–13]. Some other spectrophotometric methods have very narrow limits of detection [14–16] and a few require the use of a very high concentration (50% v/v) of sulphuric acid [17,18].

Despite the large number of spectrophotometric methods available, the literature on extractive

spectrophotometric methods for the assay of phenothiazine drugs is scanty, although these methods are well suited for the determination of phenothiazine drugs in pharmaceutical formulations and body fluids.

In this paper, a study of the determination of six phenothiazine drugs is described. The proposed method is based on the formation of an ion-association complex between phenothiazines and the acid-dye, bromocresol green in acidic buffer. The reaction conditions were thoroughly studied and the molar-ratio was also calculated. The procedure provides a highly sensitive method for the determination of phenothiazine drugs.

2. Experimental

2.1. Apparatus

A Systronics Model 106 spectrophotometer with 1-cm matched glass cells was used for all absorbance measurements. pH measurements were made with an Elico Model LI-120 digital pH-meter.

2.2. Reagents

All chemicals were of analytical reagent grade and solvents were of spectroscopic grade. Buffer solutions of required pH were prepared by mixing appropriate volumes of 0.2 M KCl and 0.2 M HCl. A 0.04% (m/v) bromocresol green (BDH) solution was prepared in buffer solutions.

2.3. Standard solutions of phenothiazines

Aqueous solutions of chlorpromazine hydrochloride (CPH; British Pharma., India), thioridazine hydrochloride (TH; Sandoz, India) trifluoperazine dihydrochloride (TFPH; SmithKline Beecham, India) triflupromazine hydrochloride (TPH; Sarabhai Chemicals, India), prochlorperazine dimaleate (PCPM; Rhône-Poulenc, India) and thioproperazine mesylate (TPPM; Rhône-Poulenc, India) were prepared by dissolving the requisite amount of the samples in distilled water. Insoluble PCPM was dissolved in a few

drops of dilute hydrochloric acid. Working solutions were prepared as required by dilution.

2.4. Standard procedure for the determination of phenothiazines

Accurately measured volumes of drug solutions equivalent to 2–8, 2–18, 2–12, 2–10, 2–10 and 2–12 $\mu\text{g ml}^{-1}$ final solution of CPH, TH, TFPH, TPH, PCPM and TPPM respectively, were transferred into a series of 125-ml separating funnels. Buffer (5 ml) of recommended pH (Table 1) and of bromocresol green solution (2 ml) were added to each separating funnel. The total volume was adjusted to 15 ml by adding distilled water. Chloroform (10 ml) was added to each separating funnel and the contents were shaken for exactly 1 min. The two phases were allowed to separate and the chloroform layer was passed through anhydrous sodium sulphate. The absorbance was measured at 420 nm against a reagent blank. A calibration graph was drawn or regression equation calculated.

2.5. Procedure for pharmaceutical formulations

Twenty tablets were weighed and powdered. An accurately weighed portion of the powder, equivalent to 20 mg of active ingredient, was transferred into a 100 ml calibrated flask and diluted to volume with water. Using a mechanical stirrer, the powder was completely disintegrated and the solution was filtered. An aliquot of this solution was further diluted with distilled water to obtain a concentration of calibration graph and assayed as

Table 1
Optimum reaction conditions

Phenothiazine	pH range	Stoichiometry (drug:dye)
CPH	1.0–1.8 (1.4)	1:1
TH	1.0–2.2 (1.6)	1:1
TFPH	1.0–2.0 (1.6)	1:2
TPH	1.2–2.2 (1.6)	1:1
PCPM	1.4–1.8 (1.4)	1:2
TPPM	1.2–2.0 (1.6)	1:2

Working pH values are shown in parentheses.

described under standard procedure (for dissolving PCPM a few drops of dilute HCl were used).

For the determination of the drug in injectable dosage form, the mass of the drug per ml was determined. A quantity of injectable dosage form equivalent to 20 mg of drug was transferred to a 100 ml volumetric flask and diluted to the mark with distilled water. This solution was further diluted with distilled water so that the final solution contained about $20 \mu\text{g ml}^{-1}$ of drug, before analysis using the described procedure. The results of the analysis are given in Table 3.

3. Results and Discussion

Ion-pair extractive spectrophotometry has received considerable attention for quantitative estimation of many pharmaceutical compounds [19–24]. Phenothiazines were previously determined by colorimetric methods [25] based on yellow or blue colour formed, using buffered orange II ($\lambda_{\text{max}} = 495 \text{ nm}$) or brilliant blue ($\lambda_{\text{max}} = 620 \text{ nm}$). In the present investigation, bromocresol green being an anionic dye, forms with phenothiazines, in acidic pH, a yellow coloured ion-pair complex which is soluble in chloroform and can be measured at 420 nm.

3.1. Optimization of conditions

The optimum conditions for quantitative estimation of the associated ion-pair formed were established via a number of preliminary experiments. The effect of pH was studied by extracting the coloured complex formed in the presence of various buffers of different acidic pH values. Of the various buffers tried, Clark and Lubs (pH 1.0–2.2) was found to be more suitable compared to Walpole or Sorenson buffer. Table 1 shows the pH range over which the absorbances were constant for the drugs studied. Complexation was found to be unaffected when 0.5–12.5 ml of buffer of selected pH was used. Hence, 5 ml of buffer was used in all the cases in a total volume of 15 ml. A 2.0-ml addition of

0.04% bromocresol green solution was found to be optimal for complexation, since the absorbance was practically constant in the range of 1–5 ml of 0.04% dye solution.

A number of immiscible organic solvents were tested in order to provide an applicable extraction procedure. Chloroform was preferred for its selective extraction of the drug–dye complex from the aqueous phase. A ratio of 3:2 of aqueous to chloroform phases was required for efficient extraction of the coloured species. Shaking times of 0.5–4 min produced a constant absorbance, hence a shaking time of 1 min was used throughout. Only one extraction was adequate to achieve a quantitative recovery of the complex. Absorbances of the separated extracts were stable for more than 1 h. The blanks did not absorb at λ_{max} .

The phenothiazines being basic in nature, form an ion-association complex with the acidic dye, bromocresol green, which is extractable into chloroform from the aqueous phase. The stoichiometric ratio of phenothiazine to bromocresol green was determined by the mole–ratio method [26] and the findings are presented in Table 1.

3.2. Linearity of calibration graphs.

The Beer's law limits, molar absorptivity and Sandell's sensitivity values, regression equations and correlation coefficients found for various phenothiazine drugs are given in Table 2. A linear relationship was found between absorbance at λ_{max} and the concentration of drugs in the range 2–18 $\mu\text{g. ml}^{-1}$ in the final measured solutions (10 ml.). Regression analysis of the Beer's law plots at λ_{max} reveal a good correlation ($r = 0.9289$ – 0.9986). The graphs show negligible or zero intercept except for CPH and TH and are described by the regression equation, $Y = a + bx$ (where Y is the absorbance of a 1-cm. Layer, b is the slope, a is the intercept and x the concentration of the measured solution in $\mu\text{g. ml}^{-1}$) obtained by the least-squares method [27]. The apparent molar absorptivities of the resulting coloured products range from 1.74×10^4 to $2.65 \times 10^4 \text{ l. mol.}^{-1} \text{ cm.}^{-1}$ and indicate the high sensitivity of the proposed procedure.

3.3. Quantification, accuracy and precision

The validity of the proposed procedure for the determination of the studied drugs in their pure state and in their pharmaceutical formulations, was tested by analysing these products using the proposed procedure and the official method [28]. The results obtained for pure drugs (Table 2) were reproducible with low relative standard deviations (0.28–0.48%) and the mean recoveries were comparable to those obtained using the official method (Table 4) for each of the studied drugs. The results of analysis for dosage forms obtained by the proposed and the official methods are in good agreement (Table 3).

3.4. Statistical analysis of the results in comparison with the BP method

The performance of the proposed method was judged by calculating the student's *t*- and *F*-values. At 95% confidence level, the calculated *t*- and *F*-values do not exceed the theoretical values (Table 5). Therefore, there is no significant difference between the proposed method and the official method, indicating that the proposed method is as accurate and precise as the official method.

3.5. Application

The applicability of the method to the assay of sample dosage forms was examined by analysing

various formulations. Table 3 shows the quantities obtained by the proposed method and labelled amount. The percent recoveries (97.20–101.24%) indicate good accuracy and the independence of the matrix effect over the absorbance measurements.

4. Conclusion

The proposed method is advantageous when compared to many of the reported methods in having higher sensitivity [29,30] and stability [31,32] of the coloured species. The method is sufficiently sensitive to permit determination even up to $2 \mu\text{g ml}^{-1}$. A significant advantage of the extractive spectrophotometric method is that it can be applied to the determination of individual components in a multicomponent mixture. This aspect of spectrophotometric analysis is of major interest in analytical pharmacy, since it offers distinct possibilities in the assay of a particular component in a complex dosage formulation. In the present study, some phenothiazine drugs were estimated successfully as pure compounds, as well as components in representatives dosage formulations. The commonly used additives and excipients in the dosage forms of phenothiazines, such as starch, lactose, galactose, glucose, sugar, talc, gelatin, magnesium stearate, sodium lauryl sulphate, sodium sulphite, sodium chloride, calcium chloride, ethanol, formaldehyde and sodium salt

Spectrophotometric determination of nitrate and nitrite in water and some fruit samples using column preconcentration

G.F. Wang, M. Satake, K. Horita *

Faculty of Engineering, Fukui University, Fukui 910, Japan

Received 4 April 1997; received in revised form 15 September 1997; accepted 16 September 1997

Abstract

A sensitive analytical method for the simultaneous assay of nitrate and nitrite in water and some fruit samples is presented. The method is based on nitrite determination using the diazotization-coupling reaction by column preconcentration and on the reduction of nitrate to nitrite using the Cd–Cu reductor column. Nitrite is diazotized with sulfanilamide (SAM) in the pH range 2.0–5.0, sulfamethizole (SM) in pH 1.8–5.6 and sulfadimidine (SD) in pH 1.8–4.0 in a hydrochloric acid medium to form water-soluble colourless diazonium cations. These cations were coupled with sodium 1-naphthol-4-sulfonate (NS) in the pH range 9.0–12.0 for the SAM–NS system, pH 8.6–12.0 for the SM–NS system and pH 9.4–12.0 for the SD–NS system to be retained on naphthalene-tetradecyldimethylbenzylammonium (TDBA)–iodide (I) adsorbent packed in a column. The solid mass is dissolved out from the column with 5 ml of dimethylformamide (DMF) and the absorbance is measured by a spectrophotometer at 543 nm for SAM–NS, 537 nm for SM–NS and 530 nm for SD–NS. The calibration graph was linear over 30–600 ng NO₂-N and 22–450 ng NO₃-N in 15 ml of final aqueous solution (i.e. 2–40 ng NO₂-N ml⁻¹ and 1.5–30 ng NO₃-N ml⁻¹ in aqueous sample) for three systems. The detection limits were 1.4 ng NO₂-N ml⁻¹ and 1.1 ng NO₃-N ml⁻¹ for SAM–NS, 1.2 ng NO₂-N ml⁻¹ and 0.89 ng NO₃-N ml⁻¹ for SM–NS, 1.0 ng NO₂-N ml⁻¹ and 0.75 ng NO₃-N ml⁻¹ for SD–NS, respectively. The concentration factor is eight for SAM–NS and SM–NS, and 12 for SD–NS. Interferences from various foreign ions have been examined and the method was successfully applied to the determination of low levels of nitrate and nitrite in water and some fruit samples. © 1998 Elsevier Science B.V. 1. Introduction

Nitrate and nitrite are commonly monitored for environmental protection purposes in agriculture and food control. Owing to the formation of carcinogenic *N*-nitrosamines [1] and being also

essential to indicate organic pollution in water [2], the determination of the exact concentration of nitrate and nitrite is desirable. In recent years, an increasing interest in the determination of nitrate levels in food products has been observed, essentially due to the potential reduction of nitrate to nitrite, which is known to have adverse effects on human and animal health. Nitrite and nitrate are intermediate states in the nitrogen cycle, and the high concentration of nitrite in water generally indicates poor quality [3]. From these points of view, the determination of nitrate and nitrite in water, fruit samples is of vital importance. Numerous methods for the determination of nitrate and nitrite in mixtures are based on the reduction of nitrate to nitrite by reducing agents, such as zinc [4], cadmium [5], amalgamated [6] or copperized cadmium [7], and on the reaction of nitrite with various aromatic amines in acidic medium to form a diazonium salt coupled with an aromatic amine to produce a highly coloured azo dye com-

pound which is subsequently determined colorimetrically [8].

Based on considerations of simplicity, rapidity, colour stability, adherence to Beer's law and sensitivity, we propose a simple and convenient pre-concentration method of the azo dye made from nitrite with the diazotizable and coupling reagents and TDBA-I ion-pair loaded on naphthalene. Preliminary observations revealed that the nitrite ion is quantitatively retained as the azo dye on naphthalene. The adsorbed mixture was dissolved out from the column with 5 ml DMF solution and the trace nitrite was estimated spectrophotometrically. The same reaction is used to determine nitrate using the Cd-Cu column which converts nitrate to nitrite. When the sample was not passed through the Cd-Cu column, the only response was due to nitrite present in the sample. Nitrate can therefore be determined by measuring the difference between responses with and without the converter. For nitrite analysis of natural waters,

diazotization-coupling reaction with sulfanilamide and *N*-(1-naphthyl) ethylenediamine is recommended as the official standard method by the Japanese Industrial Standard (JIS) [9], but the sensitivity of the method is not sufficient to permit the direct colorimetric measurement of nitrite in unpolluted natural water samples. In such cases, the preconcentration techniques such as solvent extraction or adsorption are required for the analysis of water samples. The conditions have been optimized and the method has been used for analysis of low levels of nitrate and nitrite in water and some fruit samples without prior separation.

2. Experimental

2.1. Reagents and apparatus

Standard nitrate solution, 1 mg l^{-1} , was prepared by diluting 1000 mg l^{-1} standard nitrate solution (Wako, Osaka, Japan) with oxygen-free water. Standard nitrite solution, 1 mg l^{-1} , was prepared by diluting 1000 mg l^{-1} standard nitrite solution (Wako, Osaka, Japan) with oxygen-free water. The working solutions containing 1 ml of chloroform were stored in a brown bottle. Solutions (0.1% m/v) of SAM, SM and SD were prepared by dissolving 0.2 g of the reagent in 2 ml of 6 mol l^{-1} hydrochloric acid and diluting to 200 ml with water. A solution of NS (0.1% m/v) was prepared by dissolving 0.3 g of the reagent in 300 ml of water. Buffer solution was prepared by

mixing an appropriate ratio of 0.5 mol l^{-1} ammonium acetate and 0.5 mol l^{-1} acetic acid or 0.5 mol l^{-1} aqueous ammonia. All chemicals used were of analytical-reagent grade or the highest purity available. Doubly distilled water was used throughout.

A Hitachi Model 200-20 spectrometer and a Toa-Dempa HM-6A pH meter were used. A glass tube ($5 \text{ cm} \times 6 \text{ mm i.d.}$) with a tapered end was used as a simple separatory column. The column was plugged with polypropylene fibres and then slurry-packed with the naphthalene material to a height of 1.0–1.5 cm, pushing it with a flat-topped glass rod. The Cu–Cd reductor column was made from a glass funnel ($12 \text{ cm} \times 6 \text{ mm i.d.}$) filled with the copperized cadmium (particle size: 0.5–1.0 mm, Wako, Osaka, Japan).

2.2. Preparation of naphthalene-TDBA-I adsorbent

A solution of naphthalene (20 g) was prepared by dissolution in acetone (40 ml) on a stirring-hot plate at 35°C . This solution was added to water (1500 ml) containing TDBA (2 g) with constant stirring, and then KI (6 g) in 500 ml water was slowly added. The naphthalene, coprecipitated with TDBA^+ and I^- , and stirred for 2 h. The supernatant solution was drained off by decantation and the mixture was washed twice with water. The slurry of naphthalene–TDBA–I adsorbent in water was stored in a bottle.

The preparation of adsorbent is very simple and is completed by mixing the acetonetic solution

of naphthalene with water. The naphthalene adsorbent, stored in aqueous solution, is very stable and has no effect on the adsorption of the azo dye for over a year.

2.3. General procedure

An aliquot (10 ml) of sample solution containing 30–600 ng $\text{NO}_2\text{-N}$ for the three systems was transferred to a 20 ml beaker, 1.0 ml of 0.1% SAM, SM or SD solution was added as the diazotizable reagent. The solution was adjusted to pH 3.5 for SAM–NS system, pH 3.0 for SM–NS system and pH 2.8 for SD–NS system with 1 mol l^{-1} HCl and allowed to stand for 10 min for complete diazotization. To each solution 5.0 ml of 0.1% NS was added to the three systems as a coupling agent and the volume made up to 15 ml with water. Then the pH was adjusted to 10.5 with ammonia buffer solution, leaving it to stand for 10 min allowing the complete coupling reaction for the three systems. The mixture was passed through a column packed with the adsorbent at the natural flow rate of 1 ml min^{-1} . The packing was washed with small volumes of water and aspirated for a few seconds to eliminate excess water attached to naphthalene. The azo dye along with naphthalene was dissolved out from the column with 5 ml of DMF. The absorbance of the solution was measured at 543 nm for SAM–NS, 537 nm for SM–NS and 530 nm for SD–NS against a reagent blank. An aliquot of aqueous solution containing 11–230 ng $\text{NO}_3\text{-N}$ solution for the three systems was passed through the Cd–Cu column, then reduced nitrite was determined using the same method.

3. Results and discussion

3.1. Diazotization-coupling reaction and adsorption characteristics

The diazotization-coupling reaction and adsorption reaction of the azo dye are depicted as follows Scheme 1. Nitrite ion reacts with diazotizable aromatic amines such as SAM, SM and SD in a hydrochloric acid medium to form colourless

diazonium ions. These ions produce the coloured azo dyes with NS. Among the ion-pair adsorbents i.e. TDBA-I, CTMA (cetyltrimethylammonium bromide)-I, CTMA–SCN, CPA (cetylpyridiniumammonium chloride)–SCN and CTMA– ClO_4 , only naphthalene–TDBA–I adsorbed the azo dyes completely for the three systems because the exchange reaction of azo dye with the TDBA–I adsorbent occurs easily.

3.2. Optimum experimental conditions for NO_2^-

Table 1 presents the optimum experimental conditions for NO_2^- . Fig. 1 shows the absorption spectra of the reagent blanks and azo dyes in the naphthalene–DMF solution, measured against DMF. It was observed that the absorption spectra of azo dyes shifts slightly to the longer wavelength side in the order SD–NS (λ_{max} 530 nm) < SM–NS (λ_{max} 537 nm) < SAM–NS (λ_{max} 543 nm). All absorbance measurements were made at 530 nm for SD–NS, 537 nm for SM–NS and 543 nm for SAM–NS. Figs. 2 and 3 shows the effect of pH

on diazotization and coupling reactions, respectively. The pH range of diazotization decreases in the order SM–NS (pH 1.8–5.6) > SAM–NS (pH 2.0–5.0) > SD–NS (pH 1.8–4.0). The coupling reactions for the three systems were in a pH 8.6–12.0 medium.

3.3. Choice of solvent and colour stability

Various solvents were tried to dissolve out the azo dye along with naphthalene from the column. The solid material is soluble in solvents such as DMF, acetonitrile, dimethyl sulfoxide, propylene carbonate, ethanol and 1,4-dioxane. As these solvents are miscible with water, there is no need to remove excess water attached to the naphthalene, unlike non-polar solvents such as benzene or chloroform. Since the solid mass is also dissolved in a small volume of solvent, it is necessary to select a solvent in which the compound is highly soluble. In the three systems, DMF was the most suitable and sensitive solvent. The azo dyes in the DMF solution were very stable, even after standing for more than 90 min, the relative changes of the absorbance with time being < 0.2%.

3.4. Linearity, sensitivity and precision

Under optimal conditions, the absorbance of various concentrations of nitrite were measured at 543 nm for SAM–NS, 537 nm for SM–NS and 530 nm for SD–NS. Beer's law holds well in the concentration range 2–40 ng $\text{NO}_2\text{-N ml}^{-1}$ and 1.5–30 ng $\text{NO}_3\text{-N ml}^{-1}$ in the sample solution for the three systems. The replicate determinations of seven sample solutions containing 0.067 mg l^{-1} of nitrite for SAM–NS, 0.06 mg l^{-1} of nitrite for SM–NS and 0.053 mg l^{-1} of nitrite for SD–NS gave mean absorbances of 0.439, 0.407 and 0.359 with relative standard deviations of 0.48, 0.35 and 0.47%, respectively. The molar absorptivity was 10^5 order, estimated to be $1.01 \times 10^5 \text{ l}^{-1} \text{ mol}^{-1} \text{ cm}^{-1}$ for SAM–NS, $1.04 \times 10^5 \text{ l}^{-1} \text{ mol}^{-1} \text{ cm}^{-1}$ for SM–NS and $1.03 \times 10^5 \text{ l}^{-1} \text{ mol}^{-1} \text{ cm}^{-1}$ for SD–NS. The detection limits, calculated as three times the standard deviation ($n = 10$) of the reagent blanks, were 1.4 ng $\text{NO}_2\text{-N ml}^{-1}$ and 1.1 ng $\text{NO}_3\text{-N ml}^{-1}$ for SAM–NS, 1.2 ng $\text{NO}_2\text{-N}$

Table 2

ml⁻¹ and 0.89 ng NO₃-N ml⁻¹ for SM–NS, 1.0 ng NO₂-N ml⁻¹ and 0.75 ng NO₃-N ml⁻¹ for SD–NS, respectively.

3.5. Effect of diverse ions

Possible interferences of various ions were examined in the determination of nitrite. Various amounts of alkali metal salts and metal ions were added individually to a solution containing 1.0, 0.9 and 0.8 µg of nitrite for SAM–NS, SM–NS and SD–NS systems, respectively and the procedure applied. The tolerance limit was taken as the amount causing a change of ± 3% in the absorbance. The results obtained are given in Table 2. The same procedure was also carried out for the determination of NO₃⁻. Differences were not observed in the tolerance limit between NO₂⁻ and NO₃⁻. Hence, the proposed method is considerably selective and has been applied to the determination of trace nitrate and nitrite in unpolluted water and some fruit samples without any previous separation.

3.6. Determination of nitrite and nitrate in water and some fruit samples

Water samples from various sources were col-

lected and analysed within 1 h after sampling because nitrite is potentially unstable, and all food and water samples should be analyzed as soon as possible after collection [10]. The sample collected was filtered through a filter paper (No. 5C, Toyo Roshi, Japan). An aliquot (10 ml) of the filtrate was taken in a beaker and the general procedure applied. The fruit sample was chopped and 5.0 g of the slurry was transferred to a 150 ml beaker, with 100 ml of distilled water. After shaking for 60 min and filtering through a membrane filter (pore size 0.45 µm), the nitrite it was diluted in a 100 ml standard flask and nitrite was analyzed using the general procedure outlined above. From the calibration curve, the nitrite content in some fruit samples was determined and calculated. The results given in Table 3 agreed reasonably with alternative methods [11]. The recovery test was carried out for spiked water and pear samples. The recovery of the obtained nitrite was good.

For the analysis of nitrate, an aliquot (10 ml) of the filtrate was taken in a beaker, passed through the Cd–Cu column, and the nitrate content was determined in the same manner as nitrite (Table 3). These results indicate that this analytical method can be successfully applied to determine low levels (ng ml⁻¹) of nitrite and nitrate which are

normally present in water and some fruit samples.

4. Conclusions

The proposed method is the first attempt at separating and preconcentrating trace nitrite and nitrate using diazotization-coupling reaction and ion-pair loaded on naphthalene-TDBA-I adsorbent. Nitrate was reduced 100% through the Cd-Cu column. Since the method requires only simple glassware, such as glass tubes, small volume beakers, and a small volume of organic solvent, it is very economical. As the procedure is free from the interference of diverse alkali salts and metal ions, it has been applied to analyzed lower concentrations of nitrite and nitrate in water and some fruit samples. The primary purpose of the present study is to develop various adsorbents for the preconcentration of trace nitrite and nitrate using conventional instruments, which are available in all laboratories. The proposed method is

characterized by the fact that the solid adsorbent in the column can only be used once, instead of being re-usable as in ion-exchange resin and chelex-100 methods. The method may be improved further by using ion-exchange resin and the adsorbent supported with an ion-pair on silica combined with optical analytical techniques like flow injection and/or fluorimetry.

Abstract

A new copolymer made of 8-quinolyl methacrylate, methyl methacrylate and *n*-butyl acrylate (PQMB) has been used as a solid substrate for the preparation of an optical fiber berberine sensor. The sensing is based on the fluorescence of 1,4-bis(naphth[2,1-d]oxazole-2-yl)benzene (BNOB) immobilized in the copolymer quenched by berberine with the formation of 1:1 complex between them. The membrane composition was optimized using the orthogonal experimental design. Using the sensor described above, berberine in a sample solution from $4.02 \times 10^{-7} \text{ mol l}^{-1}$ to $2.82 \times 10^{-4} \text{ mol l}^{-1}$ can be detected. The sensor has satisfactory reversibility and a short response time of less than 30 s. The relative standard deviations for repeated measurements ($n = 15$) of $8.05 \times 10^{-6} \text{ mol l}^{-1}$ and $4.02 \times 10^{-5} \text{ mol l}^{-1}$ berberine are 0.43% and 0.33%, respectively. The sensor shows good selectivity over alkali and alkali-earth metal salts and some common pharmaceutical species and can be used for the determination of berberine in pharmaceutical preparations. © 1998 Elsevier Science B.V. 1. Introduction

A fluorescence optical fiber sensor can be prepared by immobilizing a fluorophore on a solid substrate and monitoring the change in optical properties of the sensing layer upon interaction with the analyte. Various methods of immobilizing fluorophores such as adsorption [1,2], entrapment [3–5], and covalent bonding [6,7] have been used for this purpose. The fluorophores without suitable bonding groups attached to polymers are

often trapped in plasticized poly(vinyl chloride) (PVC) membranes [8–10]. The PVC type polymeric membrane material has numerous disadvantages such as dye leaching and poor adhesion of the membrane on quartz glass located at the distal end of the optical fiber. Finding new membrane materials with reduced dye leaching and improved adhesion characteristics is of considerable interest.

Methacrylate–acrylate based polymers are a class of promising membrane materials for chemical sensor design [11,12] with fine adhesion abilities on ceramics, silicon and quartz glass. In this

* Corresponding author.

paper, we describe a new methacrylate–acrylate based copolymer prepared from 8-quinolyl methacrylate, methyl methacrylate and *n*-butyl acrylate (PQMB) for trapping 1,4-bis(naphth[2,1-d]oxazole-2-yl)benzene (BNOB) to prepare an optical fiber sensor for berberine.

Berberine, being a quaternary ammonium salt, has been used as a medicine for stomach and intestinal disorders. For analytical determination of berberine, a number of methods have been proposed including extraction spectrophotometry [13,14], high performance liquid chromatography [15], ion-selective electrodes [16,17], flow-injection [18], and fluorometry [19]. Most of these methods demand a cumbersome sample pretreatment and suffer from interference of many co-existing species. We report on a fluorescence sensor for detection of berberine, which was based on fluorescence quenching of 1,4-bis(1,3-benzoxazolyl-2-yl)benzene (BBOB) immobilized on a plasticized PVC membrane [20]. This method's response is quick and has good reversibility, though BBOB tends to leach from the PVC membrane. In this study, we report on a new optical fiber sensor for berberine based on immobilizing BNOB on a new membrane material. This membrane material has good adhesion properties on quartz glass and fair compatibility with BNOB because of the existence of quinolyl groups in PQMB copolymer which reduces the BNOB leaching from the membrane phase. Furthermore, the sensor made of PQMB exhibits a fast response time, high sensitivity, good reversibility and durability. The newly proposed sensor can be used in the determination of berberine in commercial pharmaceutical preparations.

2. Experimental

2.1. Apparatus

Fluorescence measurements were conducted on a Hitachi M-850 spectrofluorimeter with both excitation and emission bandpasses set at 5.0 nm. Berberine sensing measurements were carried out using a home-made poly(tetrafluoroethylene) (PTFE) flow-through cell (Fig. 1). A randomly

distributed bifurcated bundle (30 + 30 quartz fibers, length 1 m, 6 mm in diameter at the common end) from Glass Institute of Beijing, was sealed into a mounting screw nut (26 mm in length, 32 mm in outer diameter and 26 mm in inner diameter) to carry the light to and from the cell. A quartz glass plate (12 mm in diameter) covered with the sensing membrane was positioned on the top of the flow chamber (ca. 75 μ l) and fixed by the mounting screw nut. The solution inlet and outlet channels were drilled through the cell body (28 mm in length, 20 mm in diame-

ter) to the flow chamber and connected to two 2 mm Teflon tubes. The sample solution was continuously circulated in and out of the cell at a flow rate of 1.2 ml min^{-1} with a peristaltic pump (Guokang Instruments, Zhejiang, People's Republic of China). In order to avoid ambient light penetrating the sensing membrane, the flow-through cell was covered with black cloth during measurements. Measurements of pH were performed using a Model PH-3C pH meter equipped with a combination electrode calibrated using two standards.

2.2. Chemicals

The copolymer PQMB was synthesized from 8-quinolyl methacrylate, methyl methacrylate and *n*-butyl acrylate by free-radical polymerization. A detailed description is presented in other studies [21]. BNOB was obtained by a condensation reaction of 1-amino-2-naphthol hydrochloride with *p*-phthalic acid [22], tetrahydrofuran (THF) and dinonyl sebacate (DNS) were from Changsha Chemical Reagents. Berberine was used as received from Shanghai Pharmaceutical.

A stock standard aqueous berberine solution of $2.012 \times 10^{-3} \text{ mol l}^{-1}$ was prepared. The working solutions were obtained by serial dilutions of this stock with chloroacetic acid buffer prepared by dissolving 24 g of chloroacetic acid in 500 ml of water and adjusting it to pH 2.16 with 6 mol l^{-1} NaOH solution. All reagents were of analytical grade, and freshly redistilled water was used in all experiments.

2.3. Preparation of optode membrane

A membrane cocktail was obtained by dissolving 40 mg of PQMB and 80 mg of DNS in 0.8 ml of THF saturated with BNOB and 0.2 ml of THF without BNOB. With the help of a spin-on device [3], a membrane of approximately $4 \mu\text{m}$ in thickness was cast on a quartz glass (12 mm in diameter).

2.4. Fluorescence measurement

The membrane was positioned on the top of a

flow chamber (Fig. 1). The detection of membrane fluorescence quenched by berberine was made under batch conditions at the maximum excitation wavelength of 380.0 nm and the maximum emission wavelength of 435.0 nm using an emission filter of 390 nm. Berberine solution was pumped through the flow cell at a rate of 1.2 ml min^{-1} . The sensor was allowed to equilibrate with the sample solution, so that a stable fluorescence signal could be recorded. The fluorescence reading of the optode membrane was recovered by flowing the blank buffer solution prior to the next measurement.

2.5. Sample preparation

The powder (50 mg) of ground berberine tablets was dissolved in boiling water, and the cooled solution together with the residue was diluted to a final volume of 100 ml. With the initial portion discarded, the filtrate was collected and used for analytical determination.

3. Results and discussion

3.1. Principle of operation

The lipophilic fluorophore BNOB newly synthesized in our laboratory has a large conjugated double bond system and exhibits strong fluorescence emission. Benzoxazole compounds were referred to as good charge-donors [23] capable of forming charge-transfer complexes with charge-acceptor molecules. Fig. 2 shows the fluorescence excitation and emission spectra of the optode membrane containing BNOB on exposure to the blank and berberine solutions of different concentrations. It is evident from Fig. 2 that berberine can strongly quench the fluorescence of the membrane, accompanied by the formation of a possible charge-transfer complex. The process can be expressed as follows:

Fig. 3. A plot of $\log(\Delta F/F)$ as a function of the logarithm of berberine concentration.

Fig. 4. Relative fluorescence intensity (α) as a function of $\log[\text{berberine}]$. The curves fitting the experimental data were calculated from Eq. (4). The circles are experimentally observed data points. (1), $m:n = 1:1$ $K = 1.67 \times 10^4$; (2), $m:n = 1:2$ $K = 2.72 \times 10^6$; (3), $m:n = 1:3$ $K = 4.87 \times 10^8$; (4), $m:n = 1:4$ $K = 9.49 \times 10^{10}$.

where A and B represent berberine and BNOB, respectively; m/n are the complexing ratio of berberine and BNOB; k_d is the distribution coefficient of berberine between aqueous and membrane phases; β is the formation constant of the complex of berberine with BNOB in PQMB membrane and K is the equilibrium constant of Eq. (1). The relationship between fluorescence signal

changes, berberine concentration and the amount of BNOB can be expressed as:

$$\frac{F_0 - F}{F} = K[B]_{(\text{mem})}^{n-1}[A]_{(\text{aq})}^m$$

$$\log\left(\frac{\Delta F}{F}\right)$$

$$= \log K + (n-1) \log[B]_{(\text{mem})} + m \log[A]_{(\text{aq})}$$

$$\Delta F = F_0 - F \quad (2)$$

where F_0 and F denote the fluorescence intensities of the optode membrane in the absence and presence of berberine, respectively; $[A]_{(\text{aq})}$ is the total concentration of berberine in aqueous phase and $[B]_{(\text{mem})}$ is the total concentration of BNOB in the membrane phase. It is obvious from Eq. (2) that m is the slope of the plot of $\log(\Delta F/F)$ versus $\log[A]_{(\text{aq})}$ (Fig. 3), which was calculated to be 1 from Fig. 3.

Relative fluorescence intensity α is defined as the ratio of free BNOB, $[B]_f$, and the total amount of BNOB, $[B]_{(\text{mem})}$ in the membrane which can be determined experimentally by measuring the fluorescence intensity of the optode membrane:

$$\alpha = \frac{[B]_f}{[B]_{(\text{mem})}} = \frac{F_2 - F_{(\text{limit})}}{F_1 - F_{(\text{limit})}} \quad (3)$$

where F_1 is the fluorescence intensity of the optode membrane in the blank solution, and $F_{(\text{limit})}$ is the fluorescence intensity when BNOB in the membrane is completely complexed with berberine, F_2 is the fluorescence intensity of the

Fig. 5. Fluorescence intensity, response and recovery times of berberine sensor operated at different pH. (1), pH 2.65; (2), pH 5.01; (3), pH 6.92; (4), pH 8.29.

^a Volume of THF solution saturated with BNOB.

optode membrane actually measured when in contact with berberine solutions of different concentrations. The relationship between the fluorescence signal and berberine concentration $[A]_{(aq)}$ can be expressed by as:

$$\frac{\alpha^n}{1 - \alpha} = \frac{1}{nK[B]_{(mem)}^{n-1}[A]_{(aq)}^m} \quad (4)$$

It is noticed that $m = 1$. The functional relationship between α and the concentration of berberine is governed by different n and K . Fig. 4 shows the theoretical curves calculated by Eq. (4). Obviously, only curve 1 of 1:1 complex ratio and a reasonable $K = 1.66 \times 10^4$ is the best fit for the experimental data.

Based on the formation of the 1:1 complex, the quenching efficiency as a function of the berberine concentration is given by the Stern–Volmer equation:

$$\frac{F_0}{F} = 1 + K[A]_{(aq)} \quad (5)$$

In subsequent experiments, Eq. (5) is employed to evaluate the analytical performance of the sensor and is used as the basis of quantitative analysis.

3.2. Effect of acidity

In order to determine the optimum experimental conditions, the suitable pH range was investigated by recording fluorescence intensity, response and recovery times of the sensor. The fluorescence quenching efficiency (F_0/F) and the response time of the sensor are almost independent of pH, while the recovery time is affected by the acidity of solutions. Fig. 5 shows the response curves of the berberine sensor operated at different pH. A pH of 2.16 chloroacetic acid buffer solution was selected as the working buffer in the following experiments.

Fig. 6. Response of the sensor membranes exposed to $6.03 \times 10^{-5} \text{ mol l}^{-1}$ (left) and $2.01 \times 10^{-4} \text{ mol l}^{-1}$ (right) berberine: (a), DNS plasticized PQMB membrane; (b), PQMB membrane; (c), PQM membrane.

3.3. Optimization of membrane composition

For optimization of the optode membrane composition, a membrane cocktail containing PQMB, BNOB and DNS was prepared, approximately 0.1 ml of the solution was used for the preparation of the optode membrane. The optimization of the optode membrane composition including PQMB, BNOB and DNS was performed using the $L_9(3^4)$ orthogonal experimental table. The solubility of BNOB in THF solution is rather low owing to the presence of a large conjugated system in the molecule. THF solution saturated with BNOB was used instead of the weighting of BNOB in optimization experiments.

As described above, the response of the sensor is based on the fact that berberine can quench the membrane fluorescence. The sensing performance is determined by the quenching curve and the quenching constant in Stern–Volmer Eq. (5). The analytical range and the slope of the Stern–Volmer curve were employed in the evaluation of optode membrane optimization. The experimental results are showed in Table 1. Relatively narrow linear ranges were obtained from membranes without DNS or with small amounts of DNS. No

distinct effects of the amount of PQMB and DNS on the linear ranges and response slopes were observed, though fluorescence intensities increased with increasing amounts of PQMB and DNS in the membranes. A membrane cocktail containing 80 mg of DNS, 40 mg of PQMB and 0.8 ml of THF saturated with BNOB and 0.2 ml of THF without BNOB was selected for the optode membrane preparation.

3.4. Response time and possible response mechanism

The response time of a polymer membrane based optical sensor is closely related to the diffusion of the analyte within the membrane phase and its extraction from the sample solution [24]. Usually, an appropriate plasticizer should be added to the membrane phase to facilitate the diffusion and extraction processes. In our experiments, however, the response time of a DNS-free PQMB membrane was actually the same as that of a DNS-plasticized PQMB membrane (Fig. 6). A new copolymer of 8-quinolyl methacrylate and methyl methacrylate (PQM) was prepared to test whether the *n*-butyl group in PQMB has a func-

tion as ‘internal’ plasticizer. It turned out that the response time of the PQM based sensor was quite similar to that of the two PQMB based sensors (Fig. 6). It seems that the diffusion of berberine within the membrane and the extraction of berberine from the aqueous phase into the membrane phase are not substantially affected by the presence of plasticizer or some functional groups acting as ‘internal’ plasticizer. On exposure to water the PQM and PQMB based membranes would undergo swelling as a result of the slight hydrophilicity of the quinolyl group in the copolymer. This might facilitate the diffusion and extraction of hydrophilic berberine in the membrane phase and results in the fast response of the berberine sensor.

The aforementioned reasoning should not be applicable to lipophilic analytes. Nitrobenzene is a lipophilic molecule, it can quench the fluorescence of BNOB. A comparison was made for PQMB, DNS-plasticized PQMB and PQM mem-

branes for sensing nitrobenzene. Among these membranes, one would expect that membranes with the addition of a plasticizer (PQMB/DNS) or ‘internal’ plasticizer (PQMB) should have shorter response times in comparison with the PQM membrane. This was in agreement with experimental observations (Fig. 7). The response times of the PQMB membrane and the DNS plasticized PQMB membrane exposed to nitrobenzene solu-

^a F_1 and F_2 are the fluorescence intensities of the optode membrane in contact with 4.02×10^{-5} mol l⁻¹ berberine solution without and with the interferant, respectively.

tions are nearly the same as those membranes in contact with the berberine samples. Here the role of DNS as a plasticizer or, *n*-butyl group as 'internal' plasticizer seems to facilitate the extraction of nitrobenzene from sample solution into these membranes and the quick diffusion of nitrobenzene within them. The unplasticized PQM membrane has a substantially longer response time for nitrobenzene than for berberine as a result of the difficult extraction of nitrobenzene from the water phase into the unplasticized membrane phase and a slower diffusion of nitrobenzene within it.

3.5. Reversibility, reproducibility, short-time stability and life time

The sensor was successively exposed to a series of berberine solutions of different concentrations, with the blank buffer in-between. By recording the fluorescence intensity changes vs. time, the

reversibility of the sensors was evaluated. The result is shown in Fig. 8. It can be seen that the sensor is completely reversible. The relative standard deviations in fluorescence intensities recorded from 15 consecutive measurements of 8.05×10^{-6} mol l⁻¹ and 4.02×10^{-5} mol l⁻¹ berberine with the blank in between were 0.43% and 0.33%, respectively. The sensor shows good reproducibility in the detection of berberine.

For the evaluation of short-term stability of the sensor, experiments were carried out by dipping two similar sensors into a blank buffer and 8.05×10^{-6} mol l⁻¹ berberine solution, respectively. Fluorescence intensities of these sensors were recorded over a period of 12 h at intervals of 1 h (Fig. 9). The relative standard deviations was calculated as 0.33% and 0.29%. In order to monitor BNOB leakage from the membrane into the sample, the fluorescence intensity changes of the optode membrane were recorded. The fluorescence intensity of the sensor dropped ca. 6.5%

Table 3
Response characteristics of the berberine sensors

Sensor characteristics	Sensor	
	BNOB trapped in PQMB membrane	BBOB trapped in PVC membrane ^a
Complexing ratio	1:1	1:1
Response time (s)	< 30	< 30
Linear range (mol l ⁻¹)	4.02 × 10 ⁻⁷ ~ 2.82 × 10 ⁻⁴	1.62 × 10 ⁻⁵ ~ 6.76 × 10 ⁻⁴
Response slope (mol ⁻¹ l)	1.35 × 10 ⁴	1.00 × 10 ³
Detection limit (mol l ⁻¹)	2 × 10 ⁻⁷	—
Relative standard deviation for repeated measurements	0.43 (n = 15, [HB] = 8.05 × 10 ⁻⁶ mol ⁻¹ l) 0.33 (n = 15, [HB] = 4.02 × 10 ⁻⁵ mol ⁻¹ l)	1.67 (n = 12, [HB] = 8.05 × 10 ⁻⁶ mol ⁻¹ l)
Dye leaching	Slight	Serious

^a Data from literature [20]

from the initial value, after 200 measuring cycles (sensing and regeneration). The existence of the quinolyl group in the PQMB copolymer (having good compatibility with BNOB), seems beneficial in reducing the leakage of BNOB from the membrane phase. The optode membrane can be stored in wet conditions without losing its sensitivity for at least one month.

3.6. Interference

The effect of interferants on the fluorescence intensity of the proposed sensor was tested. Alkali and alkali earth metal salts as well as many

common pharmaceutical species do not have a substantial effect on the fluorescence intensity (Table 2). The sensor has sufficient selectivity towards berberine, making it feasible for practical applications in pharmaceutical analysis.

3.7. Comparison of the berberine sensors

The sensor response characteristics including complexing ratio, response time, linear range, response slope, detection limit, etc. are summarized in Table 3 and compared with a berberine sensor reported earlier [20]. The proposed sensor in this paper has a wider linear range, higher sensitivity and better reproducibility. Moreover, one can expect the PQMB based sensor to have a longer life time owing to the reduced dye leaching from the membrane phase.

3.8. Preliminary application

The proposed sensor was used for the direct determination of berberine in pharmaceutical preparations. The sample solutions as prepared according to the Section 2 were diluted with buffer solution at pH 2.16 analyzed by the calibration curve method using the BNOB sensor. The results are in agreement with those obtained using the pharmacopoeia method [25] (Table 4).

Table 4
Results for berberine in commercial tablets using the proposed method and the pharmacopoeial method

Sample	Berberine content (%)

Abstract

UV-visible absorption spectra of uranium(VI)-tributylphosphate (U(VI)-TBP) complex dissolved in supercritical CO₂ at 40–60°C and 100–250 kg cm⁻² were recorded. Wavelengths and molar extinction coefficients for the absorption peaks of U(VI)-TBP were determined and confirmed to be in good agreement with those of UO₂(NO₃)₂(TBP)₂ complex dissolved in organic solvents such as *n*-hexane. The absorbance at a given wavelength was proportional to the concentration of U(VI) species in supercritical CO₂, indicating a feasibility of in-situ determination of U(VI) concentration in CO₂ phase. A lower detection limit of U(VI)-TBP complex was estimated to be ca. 1×10^{-3} M. The molar extinction coefficient of U(VI)-TBP in supercritical CO₂ decreased slightly with an increase of the density of CO₂ medium, suggesting that the solute–solvent interaction of U(VI)-TBP complex with CO₂ was affected by the density. On the basis of the spectra obtained, phase behavior and solubility of UO₂(NO₃)₂(TBP)₂ + H(NO₃)(TBP) + TBP in supercritical CO₂ were elucidated. © 1998 Elsevier Science B.V. All rights reserved.

Keywords: Spectrophotometry; Uranium(VI); Tributylphosphate; Supercritical carbon dioxide; Density; Solubility; Phase behavior

1. Introduction

A supercritical CO₂ fluid is one promising substitute for metal-extraction media because of its potential for minimizing the amount of solvent waste and for simplifying the process. It is also attractive in that CO₂ is easily recyclable, non toxic, chemically and radiochemically stable and

less expensive[1,2]. We have been developing the supercritical fluid extraction (SFE) method for the separation of U(VI), Pu(IV) and fission product elements in nitric acid solution using supercritical CO₂ containing relatively low concentrations of tributylphosphate (TBP) and have demonstrated a high feasibility of SFE in a metal-separation processes, in particular to such nuclear technology fields as the reprocessing of nuclear spent-fuel [3–5]. Although continuous and in-situ measurement of the concentration of U(VI) and/or Pu(IV)

* Corresponding author. Tel.: +81 292 825532; fax: +81 292 825927; e-mail: sas@analchem.tokai.jaeri.go.jp

extracted in the SF-CO₂ phase is indispensable to attain normal operation of the SFE process, an analytical method applicable to this purpose is very limited.

Absorption spectrophotometry of a solute in dissolving supercritical fluids provides information on the concentration of the solute [6,7], which implies the feasibility of spectrophotometry for monitoring the metal concentration in SF-CO₂. UV absorption spectrometry was employed for direct measurement of the concentration of the uranium/ β -diketone complex extracted into SF-CO₂ [8]. In addition, spectrophotometric measurement has been used as a very powerful means for the observation of the solute–solvent or solute–solute interactions of organic dye dissolved in supercritical fluid [9–11]. The distribution and solvation behaviors of the extracted species in SFE can be elucidated by measuring the absorption characteristics of the extracts.

In the present study, we measured the UV-visible spectrum of uranium(VI)-tributylphosphate (U(VI)-TBP) complex, which was involved in the SFE of U(VI) from nitric acid solution [3–5], dissolved in SF-CO₂ under different conditions of pressure and temperature. The feasibility of spectrophotometry for analytical application will be evaluated. A phase behavior and solubility of U(VI)-TBP/SF-CO₂ system will be discussed.

2. Experimental

2.1. Apparatus

A stainless steel cell (JASCO), of 2.35 ml inner volume, consisting of a pair of sapphire windows of 10 mm diameter and 6 mm thickness, was installed in a UV-visible spectrophotometer (JASCO, Ubest-30). The light path was calibrated to be 0.992 cm by measuring the absorption spectra of a standard solution of potassium dichromate [12]. The cell was maintained at a given temperature using a water-jacket type thermostat with a water circulator, (THOMAS TRL-108H) and was connected to a syringe pump (ISCO, series D). A stainless steel capillary of 0.1 mm ϕ i.d. and 20 cm in length was used as a restrictor (ISCO).

2.2. Measurement of spectra

An aliquot of U(VI)-TBP solution, prepared as described below, was taken in the cell. Carbon dioxide fluid was introduced into the cell using the syringe pump and the pressure and the temperature inside the cell were maintained at P higher than the critical pressure, P_c , of CO₂ (75.2 kg cm⁻²) and at T higher than the critical temperature, T_c , of CO₂ (31.2°C). The mixture of the sample and CO₂ was stirred using a magnetic stirrer for 5 min. The mixture was allowed to stand for 5 min after stirring, following which the absorption spectrum was measured. The pressure was varied stepwise from the lower to the higher pressure, after which the procedure of stirring followed by spectrum-measurement at a given pressure was repeated. After the experiment, the sample–CO₂ mixture was allowed to flow through the restrictor into the collection vessel containing ca. 100 ml of 0.1 mol dm⁻³ (M) HNO₃ where U(VI) and TBP were recovered from the CO₂ medium being gasified under atmospheric pressure and temperature.

2.3. Chemicals

Uranium(VI) stock solution: uranium metal, JAERI U-4, 99.99% purity, was dissolved with 7 M HNO₃ in the presence of hydrogen peroxide. After the solution was heated to near dryness, the residue was dissolved in 1 M HNO₃ to prepare a 0.10 M U(VI) solution.

U(VI)-TBP solution: aqueous solution, 100 ml of 7 M HNO₃ + 0.10 M U(VI), was mixed with 10 ml of TBP of $\geq 97\%$ purity. Uranium(VI) and H⁺ were extracted into the TBP phase as UO₂(NO₃)₂(TBP)₂ and H(NO₃)(TBP), resulting in a mixture of U(VI)-TBP, H⁺-TBP and uncombined TBP. The composition of the mixture prepared was confirmed to be 0.991 M U(VI) + 1 M H⁺ + 0.7 M free TBP from analytical results of U(VI) by inductively coupled plasma atomic emission spectrometry and H⁺ by alkali titration, as well as by subtracting the combined TBP from total TBP concentration, i.e. 3.7 M. The solution obtained was dehydrated in contact with molecular sieves for 30 min and then stored in a desiccator with silica-gel.

Fig. 1. Absorption spectra of U(VI)-TBP complex in supercritical CO_2 . Sample: 4.55×10^{-2} M $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2 + 5 \times 10^{-2}$ M $\text{H}(\text{NO}_3)(\text{TBP}) + 3.5 \times 10^{-2}$ M free TBP in CO_2 . Pressure (kg cm^{-2}): (1) 100; (2) 125; (3) 150; (4) 151; (5) 152; (6) 153; (7) 154; (8) 155; (9) 175; (10) 250.

All chemicals used were of reagent grade. Liquid CO_2 cylinder of 99.99% purity supplied by Shin Tokyo, Teisan, was used.

3. Results and discussion

An aliquot of U(VI)-TBP solution was taken in the cell to which CO_2 was added in order to obtain a mixture of 4.55×10^{-2} M U(VI)-TBP + 5×10^{-2} M H^+ -TBP + 3.5×10^{-2} M free TBP and supercritical CO_2 at 50°C and 100 kg cm^{-2} . Since the mixture prepared was slightly turbid initially, the measurement of the spectrum was performed after the mixture was stirred for 5 min and then allowed to stand for 5 min. The result thus obtained is shown by spectrum 1 in Fig. 1. A slight positive shift of

baseline absorbance over a wide range of wavelength is observed, which shows that the mixture is still turbid at $P = 100 \text{ kg cm}^{-2}$. No characteristic absorption peak due to U(VI) in the CO_2 phase is detected in spectrum 1. Spectra 2–10 were recorded identically to spectrum 1, but at different pressures, which were varied stepwise from 125 kg cm^{-2} to 250 kg cm^{-2} . In these spectra, 11 clear peaks are observed at wavelengths specific to absorption of U(VI), indicating distinct aspects as follows.

(i) Spectra 2 and 3 measured at $P = 125$ and 150 kg cm^{-2} respectively, show a slight increase of absorbance of U(VI), although the absorption intensity is not so strong and is hardly dependent on the pressure. It is noteworthy that a turbid characteristic of the mixture observed in spectrum 1 completely disappears in spectra 2 and 3.

(ii) Spectra 4–6 measured in very narrow pressure range, $P = 151–153 \text{ kg cm}^{-2}$, show the most remarkable variation. The absorption intensity of U(VI) starts to increase rapidly, indicating the sudden enhancement of the dissolution of U(VI)-TBP in the CO_2 phase with an increase in pressure greater than 151 kg cm^{-2} . Coincidentally, with the steep rise in the U(VI) absorption intensity, the positive shift of the baseline is again noted, as shown typically by spectra 4 and 5. The shift is assumed to be due to a formation of suspension under such transient conditions of the mixture of U(VI)-TBP, H^+ -TBP, free TBP and CO_2 from heterogeneous to homogeneous phases, although this is not yet fully understood.

(iii) Spectra 7–10 measured at $P = 154–250 \text{ kg cm}^{-2}$ indicate the complete dissolution of U(VI)-TBP complex over this pressure range resulting in a homogeneous supercritical CO_2 phase containing $4.55 \times 10^{-2} \text{ M U(VI)-TBP}$.

The wavelengths of 11 absorption peaks of U(VI)-TBP complex in supercritical CO_2 at 50°C and 200 kg cm^{-2} are listed in Table 1. All wavelengths determined agree well with those of U(VI)-TBP complex dissolved in neat TBP at 25°C and atmospheric pressure; the results are given in the last column of the table. From these results, it is confirmed that the chemical form of U(VI)-TBP complex dissolved in CO_2 is $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2$ as expected.

Table 1
Wavelengths λ and molar extinction coefficients ϵ of absorption bands of U(VI)-TBP complex in (1) supercritical CO_2 (50°C , 200 kg cm^{-2}) and (2) tributylphosphate (25°C , 1 kg cm^{-2}) media.

10	367.3	2.67 ± 0.07	368.5
11	357.0	3.49 ± 0.08	358.5

A small discrepancy (1.2–2.6 nm) in wavelengths between the U(VI)-TBP complex in CO_2 and that in neat TBP is attributable to the difference in solvation behavior of the complex with the TBP and CO_2 molecules. In regard to this, a slight temperature-dependence of wavelength was observed, e.g. the highest peak was at 412.6 nm (40°C), 412.7 nm (50°C), or 412.9 nm (60°C). Similar temperature-dependence was reported by Bell et al.[13] in the absorption spectra of U(VI) in aqueous perchlorate media. This temperature-dependence of the wavelength, i.e. 0.02 nm longer shift per 1°C increase, does not coincide with the shorter shift as shown in Table 1. The effect of temperature on the peak position is so small that the measurement of the absorbance at a given wavelength is not disturbed by the variation of temperature over the range from 40 to 60°C , or even higher.

Fig. 2a shows the plot of absorption intensity at 412.7 nm, at which the highest U(VI) absorption peak appears, against the pressure. The absorption intensity after subtracting the baseline is shown in this figure. Plots 1, 2 and 3 correspond to results at 40, 50 and 60°C , respectively. From these results, one can recognize a sudden increase of the absorption with increasing pressure. The absorbance decreases slightly and gradually, with an increase of the pressure in the higher pressure range even where the complete dissolution of U(VI)-TBP is achieved. It is evident from the plots in Fig. 2(a) that the minimum pressure for achieving complete dissolution of U(VI)-TBP complex is lower at lower temperatures.

In Fig. 2(b), the results are reproduced as the plot of absorbance against the density of CO_2 [14–16]. It can be concluded that the complete dissolution of U(VI)-TBP complex is achieved more effectively, i.e. with CO_2 of the lower density, when the dissolving temperature is at its highest. There has been a suggestion that the solubility, S , of a solute in supercritical CO_2 can be expressed using the density, ρ , of CO_2 and S increases with an increase of ρ , as given by Eq. (1) [17]:

$$\ln S = a \ln \rho + b \quad (1)$$

where constant a is assumed to be an indication of the solvation of the solute in the supercritical

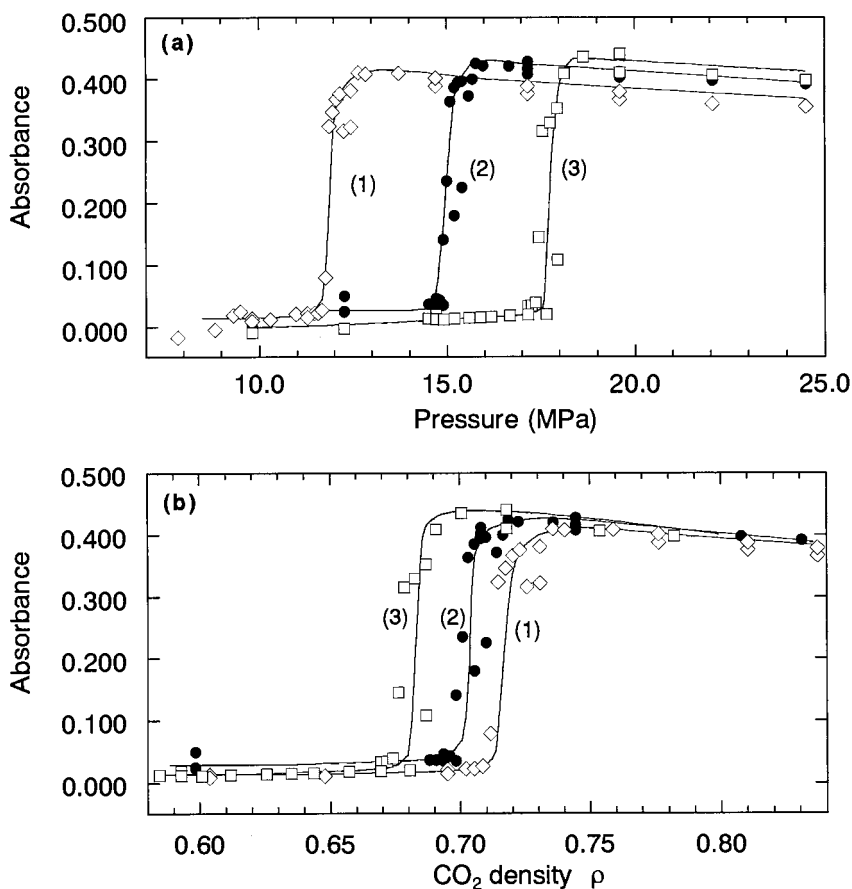

Fig. 2. Relation between U(VI)-absorbance at 412.7 nm and (a) pressure or (b) density of supercritical CO₂. Sample: identical as that in Fig. 1, temperature (°C): (1) 40; (2) 50; (3) 60.

CO₂ and b is a temperature-dependent constant correlated to the volatility of the solute. The temperature effect is attributable to the contribution of the constant b to the overall solubility, as shown in Fig. 2(b), the solubility of U(VI)-TBP complex in CO₂ of a given density is higher at higher temperatures.

The low absorbance of less than 0.02 which is observed at the lower pressure in Fig. 2(a) and in the lower CO₂-density region in Fig. 2(b), (see also spectra 2 and 3 in Fig. 1) hardly depends on the pressure, i.e. the density of the CO₂ medium. Simple solubility theory expressed by Eq. (1), cannot be applied to simulate the dissolution behavior of U(VI)-TBP complex in such a lower solubility region. One difficulty in the simulation

may arise from the variation of the composition of U(VI)-TBP + H⁺-TBP + free TBP mixture, depending strongly on the experimental conditions.

Molar extinction coefficients for absorption peaks of U(VI)-TBP spectra in supercritical CO₂ (50°C, 200 kg cm⁻²) are summarized in Table 1, calculated from results obtained with a supercritical CO₂ phase containing 2.28×10^{-2} , 4.55×10^{-2} and 6.83×10^{-2} M U(VI)-TBP. No appreciable change in the molar extinction coefficients was observed, even when the contents of H⁺-TBP complex or of free TBP in the sample were increased in the concentration range of 5×10^{-2} – 2×10^{-1} M or 3×10^{-2} – 8×10^{-2} M, respectively. The calibration curves representing the

linear relation between absorption intensity at 412.7 nm and the concentration of U(VI)-TBP complex in supercritical CO₂ are illustrated in Fig. 3. The slope of the linearity decreases slightly with increase of the pressure.

A lower detection limit, which is estimated as the concentration giving an absorption intensity of 0.01 with a cell of 1 cm light path, is ca. 1×10^{-3} M of U(VI)-TBP complex in CO₂, if the absorption at 412 nm is employed (Fig. 3). High reproducibility was obtained in the measurement of the absorption intensity, since peak position was almost independent of pressure, temperature and the concentration of coexisting free TBP and nitric acid species. A relative standard deviation (%) in the measurements (repeated six times) of a given sample of 4.55×10^{-2} M U(VI)-TBP + 5×10^{-2} M H⁺-TBP + 3.5×10^{-2} M free TBP in SF-CO₂ is less than $\pm 1\%$. Pu(IV) species extracted together with U(VI) gives a positive error in the measurement of absorption of U(VI) at 412.7 nm. The concentration of U(VI) in the presence of Pu(IV) can be determined by correcting the Pu(IV) contribution estimated from the absorbance of Pu(IV) at the other wavelength.

Fig. 3. Relation between U(VI)-absorbance at 412.7 nm and the concentration of U(VI)-TBP complex dissolved in supercritical CO₂. Pressure (kg cm⁻²): (1) 175; (2) 200; (3) 225; (4) 250.

4. Conclusion
