PREFERRED ENDO-ATTACK ON HEXAMETHYLDEWARBENZENE BY PROTONS KINETIC VS. THERMODYNAMIC CONTROL

H. Hogeveen and P.W. Kwant Department of Organic Chemistry, The University, Zernikelaan, Groningen, The Netherlands. (Received in UK 8 June 1972; accepted for publication 22 June 1972)

HexamethylDewarbenzene  $(\underline{1})$  is attacked by various reagents from the <u>exo</u> side of the molecule.<sup>1</sup> Only recently<sup>2</sup> has an unambiguous example of <u>endo</u> attack been presented. Another example of <u>endo</u> attack is claimed<sup>3</sup>, but it is doubtful whether this is correct, because it is possible, as shown in analogous cases<sup>4,5</sup>, that intermediates of the type <u>2a</u> and <u>2b</u> occur, which interconvert rapidly thereby destroying information about the orientation of the initial attack.

We wish to report here the protonation of <u>1</u> by HCl under conditions wherein interconversion of the intermediate bicyclic [2.1.1.] ions occurs only for a minor part. The data show that the protonation occurs for at least 80% from the <u>endo</u> side. It will further be shown that the initially formed bicyclic [2.1.1.] addition products of <u>1</u> and HCl undergo a number of reactions depending on the experimental conditions, such as temperature and acidity.

Ions <u>2a</u> and <u>2b</u> are formed by dissolving <u>1</u> in an excess of an equimolar mixture of HCl and methylene chloride in the temperature range of  $-50^{\circ}$  to  $-100^{\circ}$ C.<sup>6</sup> The NMR-spectra of the ions were identical (within 0,05 ppm) to those reported in strong acids<sup>5,7</sup> and the same ratio of the ions <u>2a:2b</u> = 3:1 was found. When quenched with cold (-60°) sodium methoxide/methanol the ethers 4a and 4b were formed in a ratio of 3:1.<sup>7</sup>

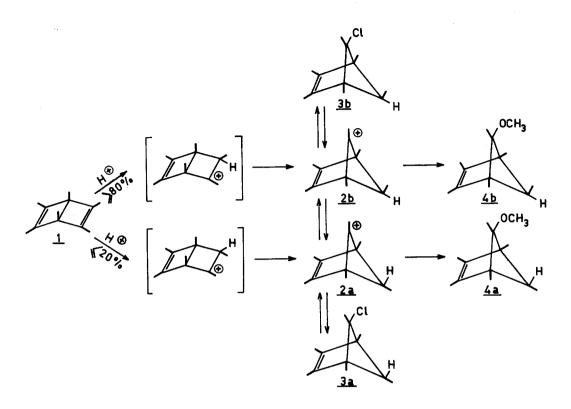

In case the amount of HCl in the methylene chloride solution was <u>decreased</u> to about the same concentration as <u>1</u>, the NMR-spectra of the ions <u>2a</u> and <u>2b</u> and the chloride <u>3a</u> were observed at  $-80^{\circ}$ . Warming up to  $-50^{\circ}$  resulted in an increase in chloride <u>3a</u> at the expense of the ions. The reverse reaction was not observed upon cooling to  $-80^{\circ}$ , but this occurred on addition of more HCl. Structure <u>3a</u> was assigned on the basis of the experiments mentioned above,

3197

the NMR-spectrum and a quenching experiment. The NMR-spectrum in methylene chloride showed peaks at  $2.62^8$  (q, J = 7 cps, 1H) 1,04 (d, J = 7 cps, 1CH<sub>3</sub>) ca. 1,03 (two overlapping s, 3CH<sub>3</sub>) and 1,43 (s, 2CH<sub>3</sub>). Pouring out a solution of <u>3a</u> in sodium methoxide/methanol at  $-80^\circ$  gave the ether <u>4a</u> besides about 5% of <u>4b</u>. Compound <u>3a</u> could be isolated by evaporating the solvent after adding LiAlH<sub>4</sub> at  $-70^\circ$  to the solution in order to destroy any excess acid. Purification was unsuccessful because <u>3a</u> completely rearranged to <u>10</u> in a couple of hours at room temperature.

On further <u>decreasing</u> the amount of HCl in the methylene chloride solution to about half the concentration of <u>1</u> and carrying out the reaction at lower temperature (-95°, part of the solution became solid) the NMR-spectrum at -80° showed besides <u>1</u> the presence of <u>3a</u> and the isomeric chloride <u>3b</u>, whereas ions <u>2a</u> and <u>2b</u> were absent. The ratios <u>3a</u> and <u>3b</u> varied between 3:10 and 4:10. Repeating this experiment in vinyl chloride at -115° and measuring the spectrum at -80° gave a ratio of 2,5:10 to 3:10. Warming up the solution to  $-30^{\circ}$  gave an increase in <u>3a</u> at the expense of <u>3b</u>. Addition of HCl resulted in the formation of ions <u>2a</u> and <u>2b</u> in a ratio <u>3:1</u> from any mixture of <u>3a</u> and <u>3b</u>. Structure <u>3b</u> was assigned on the basis of the experiments mentioned above, the NMR-spectra and a quenching experiment. The NMR-spectrum of <u>2b</u> showed peaks at  $3,22^{\circ}$  (q, J = 6 cps, 1H) 0,72 (d, J = 6 cps, 1CH<sub>3</sub>) 1,67 and 0,95 (s, 2CH<sub>3</sub> each) 1,39 (s, 1CH<sub>3</sub>). Pouring out mixtures of <u>1</u>, <u>3a</u> and <u>3b</u>, prepared at -115° to -60°, in sodium methoxide/methanol of -90° gave besides <u>1</u>, the ethers <u>4a</u> and <u>4b</u> in ratios varying from 10:1 to 10:7.

From the literature<sup>5a</sup> the kinetics of the interconversion of <u>2a</u> and <u>2b</u> are known. At temperatures of about  $-90^{\circ}$  the half-life for the interconversion is about half an hour. Ions formed at this or lower temperature will partially conserve their configuration, when the reaction with a negative ion is faster than the interconversion. This is the case in the reaction of HCl with excess <u>1</u> at very low temperature, described above. In an NMR-spectrum, recorded within half an hour after preparation, no ions were observed demonstrating that the reaction of the ions with chloride ion is faster than the interconversion of the ions at these temperatures. Hence the stereochemistry of the chlorides observed gives information about the stereochemistry of the ions initially formed. From the observation that <u>3b</u> is formed predominantly we conclude that the proton attacks <u>1</u> for at least 80% from the <u>endo</u> side. The observed amount of <u>3a</u> can be explained either by an <u>exo</u> attack or by partial isomerization of the ion <u>2b</u>.

The experiments described above show that increasing the reaction temperature gives the same effect as increasing the HCl concentration, namely an increase of compound <u>Ja</u>. At higher temperature the interconversion of <u>Za</u> and <u>Zb</u> is faster and at a higher HCl concentration the concentration of the ions is larger and thus the rate of interconversion of <u>Za</u> and <u>Zb</u> is larger. These conditions allow equilibrium to be established and as a result only chloride <u>Ja</u> is observed. Chloride <u>Jb</u> is presumed to be thermodynamically less favoured, due to steric hindrance between the <u>exo</u> CH<sub>3</sub> group and the chlorine atom in this compound.<sup>8</sup>

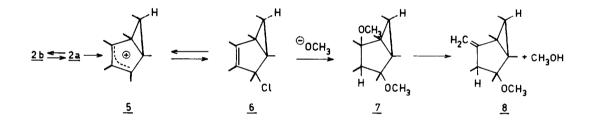

Also during the quenching of chlorides  $\underline{3a}$  and  $\underline{3b}$  to form the ethers  $\underline{4a}$  and  $\underline{4b}$ , interconversion of the intermediate ions  $\underline{2a}$  and  $\underline{2b}$  is likely to change the ratio of <u>endo</u> and <u>exo</u> compounds.

When the reaction between <u>1</u> and one equivalent HCl was performed at temperatures of  $-60^{\circ}$  to  $0^{\circ}$ , a new bicyclic[3.1.0]chloride <u>6</u> was formed; at the lowest temperature compound <u>3a</u> was observed also. Warming up the reaction mixture gave more <u>6</u> at the expense of <u>3a</u> and at  $-30^{\circ}$  about 90% of <u>6</u> was formed. This reaction was enhanced by increasing the HCl concentration.

No. 31

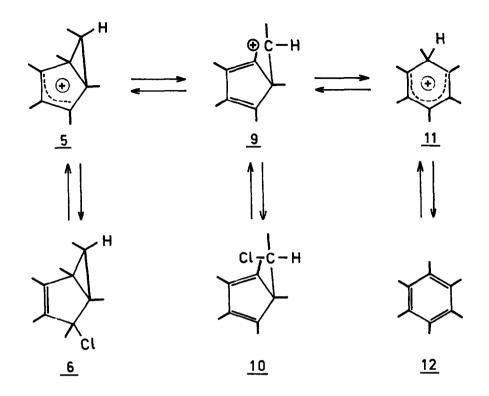

Isolation of <u>6</u> was possible by adding  $\text{LiAlH}_4$  to these mixtures, so that any excess acid was destroyed. Washing with water and evaporating the solvent gave the crude product. Structure <u>6</u> was assigned on the basis of the experiments mentioned above, the NMR-spectrum and a quenching experiment. The NMR-spectrum in methylene chloride showed peaks at 2.18 (q, J = 6.5 cps, 1H), 1.10 (d, J = 6.5 cps, 1CH<sub>3</sub>), 1.54, 1.45, 1.11, 1.04, 1.01 (s, each 1CH<sub>3</sub>). From the value of the chemical shift of the doublet and the quartet the conclusion can be made that the methyl group is oriented <u>endo.</u><sup>9</sup> This is confirmed by the fact that <u>6</u> rearranges at 0<sup>°</sup>.<sup>10</sup>

Pouring out a solution containing <u>6</u> in sodium methoxide/methanol afforded compound <u>7</u> in nearly quantitative yield. Structure <u>7</u> was supported by the following data: the NMR-spectrum showed peaks at 1.02 (d, J = 7 cps,  $1\text{CH}_3$ ), 0.78 (d, J = 7 cps,  $1\text{CH}_3$ ), 3.14, 1.00 and 0.88 (s, each 2CH<sub>3</sub>). This is consistent with structure <u>7</u> with the methoxy groups arranged <u>cis</u>. On standing at room temperature <u>7</u> decomposed in a week's time into one equivalent methanol and one equivalent <u>8</u>. <u>8</u> was characterised by its NMR, IR and Mass spectra.<sup>5a</sup>

On standing at  $0^{\circ}$  or at room temperature <u>6</u> completely isomerised to <u>10</u> within a week. Identification of <u>10</u> was possible by comparing spectra of the isomerisation product with spectra of authentic material.<sup>11</sup> The rate of isomerisation increased upon adding acid and prolonged contact with acid resulted in the formation of hexamethylbenzene (12).

That <u>12</u> can be obtained from [3.1.0.] structures is well known. Hogeveen and Volger<sup>5</sup> proposed a [3.1.0.] ion as an intermediate in the formation of <u>11</u> from <u>2a</u> and <u>2b</u>. Childs and Winstein<sup>12</sup> observed the isomerisation of <u>5</u> (the structure was established later as <u>endo</u>  $CH_{\overline{5}}^{10}$ ) to the hexamethylbenzeniumion (<u>11</u>) at  $-34^{\circ}$ , the half-life being about 10 minutes. This observation suggests a mechanism in which <u>9</u> is an intermediate:

The possibility of a rearrangement of 5 and 2 is proposed by Schäfer and Hellmann<sup>13</sup> and the observed rearrangement <u>6</u> to <u>10</u> obviously occurred via <u>5</u> and <u>9</u>. It remained to be shown that in strong acids <u>10</u> can be converted into <u>11</u>. Abstraction of Cl<sup>-</sup> by SbF<sub>5</sub> in SO<sub>2</sub> gave <u>11</u> only, within 8 minutes at -60°. The half-life of <u>9</u> therefore certainly is less than 1 minute at -60°. This makes clear why Childs and Winstein did not observe this intermediate in their experiment, performed at -34°. It is likely therefore, that in contrast to the symmetry-allowed, concerted photochemical ring closure of <u>11</u> into <u>5</u><sup>12</sup>, the reverse thermal reaction is a stepwise reaction rather than a symmetry-forbidden concerted reaction.
