An Analysis of Consecutive First-Order Reactions: Protodeacetylation of Diacetylmesitylene

Jameel Farooqi and Peter H. Gore School of Chemistry, Brunel University, Kingston Lane, Uxbridge, Middlesex UB8 3PH, U.K.

(Received in UK 14 June 1977; accepted for publication 29 June 1977)

<u>Abstract</u> In 89.8% sulphuric acid 1,3-diacetyl-2,4,6-trimethylbenzene undergoes two successive protodeacetylation stages and a final sulphonation to give 2,4,6-trimethylbenzenesulphonic acid. A kinetic analysis of the component reactions has been realised.

There have been many theoretical studies¹⁻⁴ of the model kinetic system of consecutive, irreversible, first-order reactions. Few actual examples have been investigated, however, because complete analysis for the components of such a mixture is normally very difficult. We have now found a system of this type, which can be examined experimentally. The kinetic analysis is made possible because the component reactions could be studied individually.

In 89.8% sulphuric acid 1,3-diacetyl-2,4,6-trimethylbenzene (diacetylmesitylene) (<u>A</u>) is smoothly converted into 2,4,6-trimethylbenzenesulphonic acid (<u>D</u>)(see Figure 1). The reaction was followed spectrophotometrically at 315 nm; there was no spectroscopic evidence

of the presence in the medium of the presumed intermediates 2,4,6-trimethylacetophenone $(acetylmesitylene)(\underline{B})$ or 1,3,5-trimethylbenzene $(mesitylene)(\underline{C})$. The kinetic data are presented in the Table. These reactions are characterized by high enthalpies of activation $(\Delta \underline{H}^{\ddagger})$ and high entropies of activation $(\Delta \underline{S}^{\ddagger})$, unusual for aromatic substitutions. The former accounts for the comparatively low reaction rates. High $\Delta \underline{S}^{\ddagger}$ values can be explained as a gain in degrees of freedom (e.g. rotational) in proceeding from a highly strained initial state^{5,6} to a less strained transition state.

The sulphonation of mesitylene in 89.8% sulphuric acid could be estimated to have a high rate constant, $\underline{k}_{3} = 1.05 \text{ sec}^{-1}$ at 25° C.⁷

The stages involved, then, in the overall deacetylprotosulphonation, $(\underline{A}) \longrightarrow (\underline{D})$, consist of three reactions, each being much slower than the subsequent one. Therefore, the chemical change as observed spectrophotometrically was essentially the formation of the acid (\underline{D}) from the diketone (\underline{A}) . The only previously analysed cases of sequential first-order

reactions with increasing rate constants have been successive alkylations of alkylbenzenes, and these were complicated by the invariable formation of isomers. 3,4,10

	Table				
Protodeacylations of	Mesityl Keto	nes in 89.8	8% Sulphuric	Acid	
Substrate	<u>k</u> at 298.2K	∆н≠ .	∆ <u>s</u> ≠	∆ <u>6</u> ≠	
	(sec ⁻¹)	<u>(kJmol⁻¹)</u>	(JK ⁻¹ mol ⁻¹)	<u>(kJmol⁻¹)</u>	
etylmesitylene (<u>B</u>)	4.68 X 10 ⁻³	82.0	- 14	86.3	
acetylmesitylene (\underline{A})	9.88 X 10 ⁻⁶	102	+ 2.0	101.5	
nzoylmesitylene	1.92 X 10 ⁻⁵	107	+ 23	99.9	

* Values of \underline{E}_{Arr} are higher by 2.5 kJmol⁻¹

The concentrations of the components (\underline{A}) , (\underline{B}) , (\underline{C}) , and (\underline{D}) , relative to the initial concentration $[\underline{A}]_0$, could be determined ^{11,12} as a function of time, \underline{t} , from the known rate constants of the component reactions, viz. \underline{k}_1 , \underline{k}_2 , and \underline{k}_3 :

It follows from the mechanism that:

$$\frac{-d[\underline{A}]}{dt} = \underline{k}_{1}[\underline{A}] - \underline{k}_{2}[\underline{B}]$$

$$\frac{-d[\underline{B}]}{dt} = \underline{k}_{1}[\underline{A}] - \underline{k}_{2}[\underline{B}]$$

$$\frac{-d[\underline{C}]}{dt} = \underline{k}_{2}[\underline{B}] - \underline{k}_{3}[\underline{C}]$$

$$\frac{d[\underline{D}]}{dt} = \underline{k}_{3}[\underline{C}].$$
Thus there exists an idle follow that:

From these equations it will follow that:

$$\frac{\begin{bmatrix} \underline{B} \\ \underline{A} \end{bmatrix}_{0}}{\begin{bmatrix} \underline{A} \end{bmatrix}_{0}} = \frac{\underline{k}_{1}}{\underline{k}_{2} - \underline{k}_{1}} \begin{bmatrix} e^{-\underline{k}_{1} \underline{t}} - e^{-\underline{k}_{2} \underline{t}} \end{bmatrix}$$

$$\frac{\begin{bmatrix} \underline{C} \\ \underline{A} \end{bmatrix}_{0}}{\begin{bmatrix} \underline{A} \end{bmatrix}_{0}} = \frac{\underline{k}_{1} \underline{k}_{2}}{(\underline{k}_{2} - \underline{k}_{1})(\underline{k}_{3} - \underline{k}_{1})} e^{-\underline{k}_{1} \underline{t}} + \frac{\underline{k}_{1} \underline{k}_{2}}{(\underline{k}_{1} - \underline{k}_{2})(\underline{k}_{3} - \underline{k}_{2})} e^{-\underline{k}_{2} \underline{t}} + \frac{\underline{k}_{1} \underline{k}_{2}}{(\underline{k}_{1} - \underline{k}_{3})(\underline{k}_{2} - \underline{k}_{3})} e^{-\underline{k}_{3} \underline{t}}$$

$$\frac{\begin{bmatrix} \underline{D} \\ \underline{A} \end{bmatrix}_{0}}{\begin{bmatrix} \underline{A} \end{bmatrix}_{0}} = 1 - \frac{\underline{k}_{2} \underline{k}_{3} e^{-\underline{k}_{1} \underline{t}}}{(\underline{k}_{2} - \underline{k}_{1})(\underline{k}_{3} - \underline{k}_{1})} + \frac{\underline{k}_{1} \underline{k}_{3} e^{-\underline{k}_{2} \underline{t}}}{(\underline{k}_{1} - \underline{k}_{2})(\underline{k}_{3} - \underline{k}_{2})} + \frac{\underline{k}_{1} \underline{k}_{2} e^{-\underline{k}_{3} \underline{t}}}{(\underline{k}_{1} - \underline{k}_{3})(\underline{k}_{2} - \underline{k}_{3})}$$

From these equations it was calculated that maximal concentrations are present for $[\underline{B}]/[\underline{A}]_{0} = 2.1 \times 10^{-3}$ and for $[\underline{C}]/[\underline{A}]_{0} = 9.3 \times 10^{-6}$, both at $\underline{t} = 22$ min. The sum of concentrations $[\underline{A}] + [\underline{D}]$ are therefore > 99.7% throughout the sequence of reactions, and this explains why good rate constants were here obtainable for the conversion of $\underline{A} \rightarrow \underline{D}$ by the spectrokinetic technique.
