Report

NF1 Gene Mutations Represent the Major Molecular Event Underlying Neurofibromatosis-Noonan Syndrome

Neurofibromatosis type 1 (NF1) demonstrates phenotypic overlap with Noonan syndrome (NS) in some patients, which results in the so-called neurofibromatosis-Noonan syndrome (NFNS). From a genetic point of view, NFNS is a poorly understood condition, and controversy remains as to whether it represents a variable manifestation of either NF1 or NS or is a distinct clinical entity. To answer this question, we screened a cohort with clinically well-characterized NFNS for mutations in the entire coding sequence of the *NF1* and *PTPN11* genes. Heterozygous *NF1* defects were identified in 16 of the 17 unrelated subjects included in the study, which provides evidence that mutations in *NF1* represent the major molecular event underlying this condition. Lesions included nonsense mutations, out-of-frame deletions, missense changes, small inframe deletions, and one large multiexon deletion. Remarkably, a high prevalence of inframe defects affecting exons 24 and 25, which encode a portion of the GAP-related domain of the protein, was observed. On the other hand, no defect in *PTPN11* was observed, and no lesion affecting exons 11–27 of the *NF1* gene was identified in 100 *PTPN11* mutation-negative subjects with NS, which provides further evidence that NFNS and NS are genetically distinct disorders. These results support the view that NFNS represents a variant of NF1 and is caused by mutations of the *NF1* gene, some of which have been demonstrated to cause classic NF1 in other individuals.

The so-called neurofibromatosis-Noonan syndrome (NFNS [MIM 601321]) is a peculiar clinical association, first noted in 1985 by Allanson and colleagues (1985), who described subjects with features of both neurofibromatosis type 1 (NF1 [MIM 162200]) and Noonan syndrome (NS [MIM 163950]) (Opitz and Weaver 1985). Since that report, a number of NFNS cases, including a few families transmitting the trait, have been documented (Kaplan and Rosenblatt 1985; Mendez 1985; Saul 1985; Meinecke 1987; Quattrin et al. 1987; Shuper et al. 1987; Abuelo and Meryash 1988; Stern et al. 1992; Colley et al. 1996).

It has been long speculated whether NFNS is a variant of either NF1 (Riccardi 1992) or NS (Allanson 1987), there is a chance association, or they are distinct disorders (Opitz and Weaver 1985; Colley et al. 1996; Carey 1998). Colley et al. (1996) and Bahuau et al. (1996, 1998) documented independent segregation of NF1 and NS traits in two families. Stern et al. (1992) and Colley et al. (1996) reported a few families in which only a fraction of affected members with NF1 exhibited some NS features. Carey et al. (1997) first reported a two-generation family in which the NFNS trait cosegregated with a mutation within the *NF1* gene, the gene responsible for all cases of NF1 (Xu et al. 1990). Subsequently, Baralle et al. (2003) examined the *NF1* gene in six subjects with NFNS and found mutations in two cases. Very

Note.—S = sporadic; FA = familial; a plus sign (+) = present; a minus sign (−) = absent; NE = not evaluated; NV = not evaluable; BIL = bilateral; MON = monolateral. Craniofacial features: HP = high arched palate; MO = malocclusion; TL = thick lips; FNB = flat nasal bridge; LE = large ears. Ectodermal features: KP = keratosis pilaris (face); HN = hairy nevus; E = eczema; SLE = sparse lateral eyebrows. Cardiac defects: ASD = atrial septal defect (ostium secundum); A = arrhythmia (right-branch block); MVT = mitral valve thickening; MVP = mitral valve prolapse. Other features: an asterisk (*) = mild thickening of the optic nerves; SM = thoracic syringomyelia; NBL = neuroblastoma; SD = sensorineural deafness; CD = conductive deafness, SE = seizures; RBA = retarded bone age; HYP = hypotonia; HJ = hyperextensible joints; H = hyperactivity; PPD = postaxial polydactyly of hands; MS = macrostomia; RC = renal cyst; RK = Rokitansky.

[a] With dysplastic leaflets.

recently, Bertola et al. (2005) reported a patient with NF1 and NS features who carried a heterozygous mutation in both *NF1* and *PTPN11* (MIM 176876), the latter of which is responsible for half of the cases of NS (Tartaglia et al. 2001), providing the molecular evidence for concurrence of both disorders in one individual. However, from a genetic point of view, NFNS still remains a poorly understood disorder.

To delineate the genetic cause of NFNS, we screened a well-characterized NFNS cohort for mutations affecting the *NF1* and *PTPN11* genes. Included in the study were 14 unrelated Italians with sporadic NFNS and three families transmitting the trait. All subjects were evaluated by clinical dysmorphologists experienced with both NF1 and NS (G.Z., A.B., C.D., and B.D.). For each patient, clinical assessment included family history; physical, anthropometric, neurological, and cardiac evaluation (including chest x-ray, electrocardiogram, and 2-dimensional and color Doppler echocardiography); renal ultrasonography; and radiological and magnetic resonance imaging (MRI) studies. The phenotype was evaluated through accurate clinical examination for NS facial and other dysmorphisms, such as hypertelorism (interpupillary distance >2 SD), ptosis (abnormally low lid position), downslanting palpebral fissures, low-set and posteriorly rotated ears, short neck, low posterior hair line, and thoracic and other skeletal anomalies. NF1 was diagnosed on the presence of features fitting the NF1 diagnostic criteria (Stumpf et al. 1988; Gutmann et al. 1997), whereas, for diagnosis of NS, the criteria introduced by van der Burgt et al. (1994) and discussed by Jongmans et al. (2005) were used. The clinical features

of the study population are summarized in table 1 and are shown in figure 1. Café-au-lait spots (CLSs) and low-set posteriorly rotated ears were observed in all subjects. CLSs were numerous and stochastically dispersed but variable in number (from 15 to 59) and size (from pointlike to 8 × 2.5 cm) among different-aged patients. Among the NF1 features, a variable number (1–30) of neurofibromas and Crowe sign (freckling of axillary and inguinal regions) were present in 41% and 73% of subjects, respectively. Lisch nodules were detected in 60% of patients, whereas optic gliomas or other MRI findings, such as unidentified bright objects (UBOs), were found in 28% and 69%, respectively. A single plexiform neurofibroma was observed in one patient. Among the NS features, a variable combination of facial dysmorphisms was observed in all subjects. Short stature and congenital heart defect (CHD) were present in 45% and 32% of the subjects, respectively. In the latter, pulmonary valve stenosis (PVS) was the prevailing defect (50% of cases). Short and/or webbed neck and thoracic abnormalities were also common, present in 64% and 50% of subjects, respectively. Among the features common to both conditions, macrocephaly and scoliosis were observed in 64% and 41% of patients, respectively, whereas mental retardation or learning difficulties were documented in half of all patients. All patients fulfilled the National Institutes of Health Consensus Criteria for the diagnosis of NF1, except for the four youngest patients (individuals NFNS-3, NFNS-4, NFNS-8, and NFNS-10), who presented with only one NF1 criteria, almost certainly because of their young age. In particular, patient NFNS-3, aged 6 years, showed >60 CLSs and mild thickening of the optic nerves on MRI investigation; patient NFNS-4, aged 2.2 years, presented with >20 CLSs and UBOs; whereas patients NFNS-8 and NFNS-10 presented with >15 CLSs at age 2.2 and 4 years, respectively.

Genomic DNA was isolated from peripheral-blood lymphocytes by phenolchloroform extraction and ethanol precipitation. The entire coding sequence and flanking intronic portions of the *NF1* and *PTPN11* genes were screened by denaturing high-performance liquid chromatography (DHPLC) analysis, by use of a 3100 or

Figure 1 Facial characteristics and other clinical features of study individuals with NFNS

3500HT WAVE DNA fragment analysis system (Transgenomic). PCR settings, amplicons length, and resolution temperatures for DHPLC analysis were reported elsewhere (Tartaglia et al. 2002, 2004*a*; De Luca et al. 2003, 2004). Bidirectional sequencing of purified PCR products (Qiagen) was performed using the ABI BigDye Terminator Sequencing Kit v.1.1 (Applied Biosystems) and an ABI 3700 Capillary Array Sequencer or ABI Prism 3100 Genetic Analyzer (Applied Biosystems).

No sequence variation affecting the coding sequence of *PTPN11* (exons 1–15 and their flanking intronic stretches) was observed. On the contrary, 15 different *NF1* defects were identified in 16 of the 17 unrelated subjects (table 2). Mutations cosegregated with the disease in the three families transmitting NFNS. Consistently, none of the three lesions was observed in >200 Italian control individuals. For sporadic cases with mutations, parental DNA was available for patients NFNS-1, NFNS-9, NFNS-10, and 128; no parent was identified as carrying the mutation. A large deletion involving a portion of the *NF1* gene was observed in one subject (NFNS-16). The deletion was suspected because of lack of heterozygosity along the entire *NF1* gene. Patient NFNS-16 and both his parents were genotyped using a battery of STR markers, either intragenic to *NF1* or flanking the gene (see table 3), and loss of heterozygosity due to loss of the maternal allele of marker *3′-NF1-1* (López Correa et al. 1999), which is located 200 kb downstream of the gene, was documented. STR results were compatible with a partial deletion of ⩽1.7 Mb of the maternal chromosome, between markers *D17S1849* (telomeric to exon 23-1) and *D17S798* (telomeric to *NF1*). The deletion was confirmed by quantitative real-time PCR performed on exon 25 of the gene (data not shown; primers, probe, and experimental procedure are available on request). In the remaining patient (NFNS-17), no intragenic defect was identified. This individual exhibited a heterozygous condition for five exonic and intronic polymorphisms (IVS3, 288+41G→A; Ex5, 702A→G; IVS10b, 1528-29insA; IVS29, 5547+19T→A;

NOTE.—Mutations affecting residues located within the GAP-related domain are shown in bold italics.

[a] From a family with three affected members.

[b] Mutations found to recur in NFNS.

[c] From a family with two affected members.

[d] Centromeric breakpoint maps between marker *D17S1849* (intron 23-1) and exon 25, and telomeric breakpoint localizes between markers *3′-NF1* (200 kb downstream of the *NF1* gene) and *D17S798* (1.6 Mb downstream of the *NF1* gene).

and IVS41, 7395-29G→A), which would not support occurrence of a deletion involving the entire *NF1* gene. On the whole, *NF1* gene defects accounted for 16 (94.1%) of the 17 NFNS cases included in the study.

NF1 intragenic lesions included nonsense and frameshift mutations as well as missense mutations and small inframe deletions. According to the Human Gene Mutation Database, 8 of the 15 defects were novel, whereas the remaining 7 had been documented in patients with NF1, either with or without NS features. Eight defects, including four small out-of-frame deletions and two splice-site and two nonsense mutations, were predicted to result in a truncated protein. Five mutations of this group—1721+3A→G, 1756delACTA, 1862delC, 2153delA, and 4243G→T—would result in a protein missing a portion of or the entire GAP-related domain, which has a major role in controlling RAS function by promoting conversion of active guanosine triphosphate (GTP)–binding RAS to inactive guanosine diphosphate (GDP)–binding RAS (Martin et al. 1990). Of note, four of these mutations had been reported elsewhere in patients with NF1, none of whom exhibited features of the NFNS condition. Six different missense mutations or small inframe deletions were identified in seven probands. Remarkably, these lesions were not randomly distributed; the majority involved portions of the gene coding for two functional domains of the protein. Specifically, five defects affected the GAP-related domain (exons 21–27a), the majority clustering in a short amino acid stretch (residues 1423–1438) of this domain, whereas the single-residue deletion affecting codon 991 was located within the putative cysteine/serine–rich domain (exons 11–17). Comparison with *NF1* orthologs demonstrated that all the affected residues were highly conserved among vertebrates. Three of these mutations—991delM, K1423E, and 1438delE—were reported elsewhere (Li et al. 1992; Carey et al. 1997; Baralle et al. 2003). Among them, 991delM and 1438delE had been documented in patients with NFNS (Carey et al. 1997; Baralle et al. 2003), which indicates a genotype-phenotype correlation.

Because of relevant clustering of inframe mutations within a small portion of the GAP-related domain, the predicted spatial location and function of four affected residues—K1423, N1430, V1432, and E1438—were analyzed. To model the structure of the neurofibromin/RAS complex, RAS was docked to the structure of the neurofibromin GAP-related domain (Protein Data Bank [PDB] code 1NF1), according to the experimental topology of binding between the homologous p120GAP and HRAS (PDB code 1WQ1). This model is in agreement with the model of the neurofibromin GRD/RAS complex described by Scheffzek et al. (1998). As shown in figure 2, all the affected residues lie at the interface

Table 3

Markers on Chromosome 17q11.2

The table is available in its entirety in the online edition of *The American Journal of Human Genetics*.

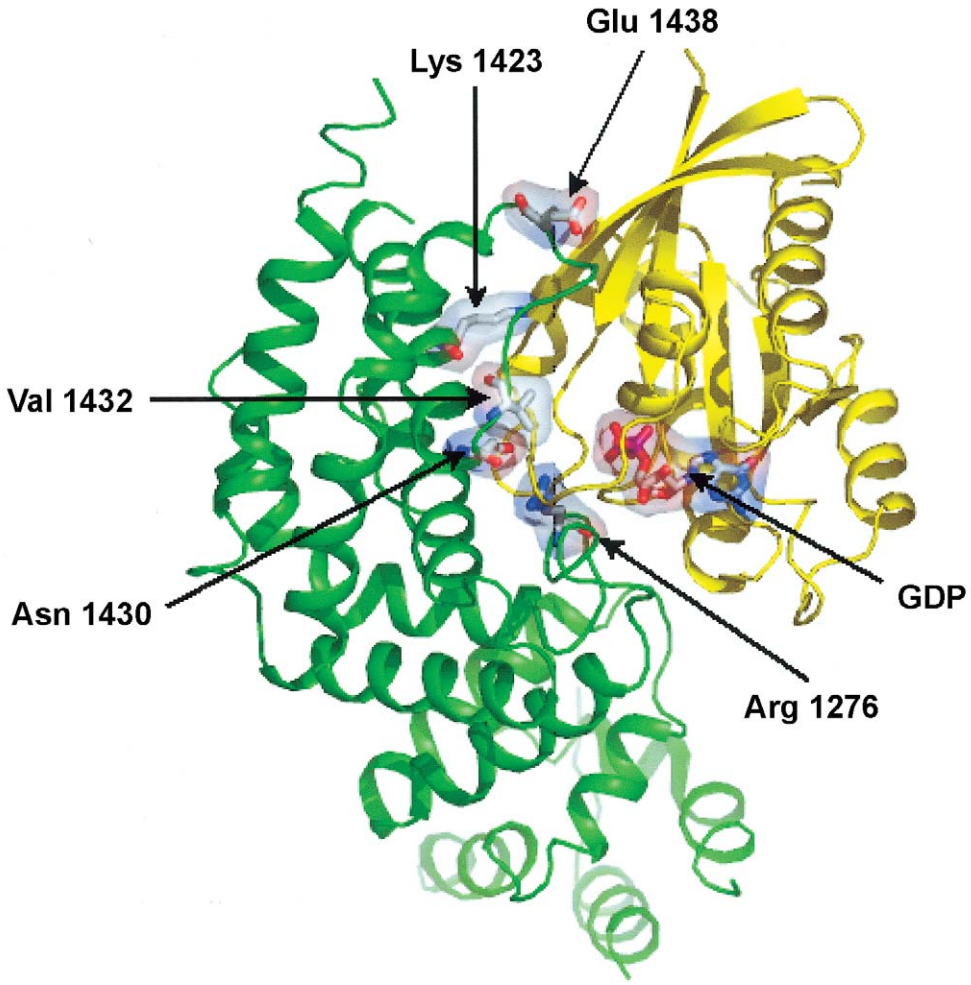

Figure 2 Three-dimensional model showing location of residues affected by mutations in the neurofibromin GAP-related domain/RAS complex. Ribbon-like structures of neurofibromin GAP-related domain and RAS are shown in green and yellow, respectively. The mutated residues (Lys1423, Asn1430, Val1432, and Glu1438), the catalytic arginine finger (Arg1276), and GDP are represented by sticks and transparent surfaces. Molecular alignment and representation were made with the programs SwissPdb Viewer v. 3.7 (Guex and Peitsch 1997) and PyMOL (DeLano 2002), respectively.

of interaction between the GAP-related domain of neurofibromin and RAS, close to the catalytic site of the former. Such impressive clustering suggests that mutations affecting these residues might impair the ability of the neurofibromin GAP-related domain in stimulation of the GTPase activity of RAS, affecting either stability of the neurofibromin/RAS complex or neurofibromin catalytic activity. Structural data indicate that K1423 is directly involved in the intermolecular interaction, since it forms a salt bridge with residue D38 of RAS. Such interaction is lost in the K1423E mutant, since the positive charge of the lysine is replaced with the negative charge of a glutamic acid residue. Because of the electrostatic repulsion between the two negatively charged residues E1423 and D38, this mutation causes further destabilization of the neurofibromin/RAS complex. It has been consistently demonstrated that the K1423E mutation results in a dramatic reduction of GAP activity (Poullet et al. 1994). The structural reorganization caused by the N1430T mutation might affect the local environment in proximity to residue R1276, which is known as the arginine finger of the GAP-related domain and therefore might perturb the catalytic activity of the protein. Disruptive effects on both substrate binding and catalysis can also be expected for the substitution of V1432, which lies on the surface of the GAP-related domain in proximity to the arginine finger. In regard to the 1438delE mutation, E1438 is located in a region of the domain with local negative electrostatic potential. Loss of this ionizable negative group is predicted to cause decreased repulsion to the negative surface of RAS, which promotes an increased stability of the neurofibromin/RAS complex. Other mutations (R1413G/K1436R, N1430H, R1491K, and R1276G) with a similar per-

turbing role on neurofibromin binding to RAS were described elsewhere (Morcos et al. 1996). Such an abnormally increased stability of the complex would result in the saturation of the GAP active site by lower RAS concentrations and, as a consequence, in decreased availability of the protein for stimulation of the GTPase activity of further incoming RAS molecules.

Because of the wide clinical spectrum associated with different *NF1* mutations, we investigated possible genotype-phenotype relationships. Comparison with the data reported by Fahsold et al. (2000) demonstrated a significantly higher prevalence of missense mutations and inframe deletions among patients with NFNS than among individuals with NF1 (7/16 vs. 28/278; $\chi^2 = 13.31$; $P = .0003$). Within the NFNS cohort, comparison of the clinical features between patients carrying missense mutations or inframe deletions and those with truncating mutations showed a preferential but not significant association, with a slightly increased risk of CHD (odds ratio [OR] = 2.40; 95% CI 0.27–23.27; Fisher's exact test one-tailed $P = .32$). Among the families transmitting the trait, intrafamilial phenotypic variability was evident. Patient NFNS-17, who apparently did not carry any *NF1* gene mutation or deletion, fulfilled the NF1 diagnostic criteria and presented with CLSs, axillary freckling, learning difficulties, and the typical NS-associated facial dysmorphisms, short stature, webbed neck, and thoracic abnormality.

Because of the clinical overlap between NFNS and NS, as well as the antagonistic modulatory function of neurofibromin and SHP-2 in RAS signaling, we also investigated the possible contribution of *NF1* gene lesions to NS. One hundred unrelated patients with NS but no symptoms of NF1 were screened for those exons (exons 11–27) and flanking intronic sequences that represent the major hotspot regions in patients with NFNS. All subjects had been documented elsewhere to be negative for mutations affecting the *PTPN11* coding sequence (Sarkozy et al. 2003; M.T., unpublished data). No *NF1* pathogenetic mutation was detected.

As discussed elsewhere by Carey (1998), despite the amount of work done and number of cases documented, including a few families transmitting the trait, debate still continues about the genetic cause and nosologic entity of NFNS. It has been suggested that the NFNS phenotype might represent the result of a chance association of two common autosomal dominant disorders—NF1 and NS—or that certain NF1 features in subjects with NFNS might occur as a component of NS. In NS, a similar association was documented for the occurrence of bony and soft-tissue giant cell lesions or CLSs, as observed, respectively, in Noonan-like/multiple giant cell lesion syndrome (NL/MGCLS [MIM 163955]) and LEOPARD syndrome (LS [MIM 151100]). Indeed, both NL/MGCLS and LS are caused by missense mutations in the *PTPN11* gene (Digilio et al. 2002; Legius et al. 2002; Tartaglia et al. 2002; Sarkozy et al. 2004; Lee et al. 2005), which is mutated in a large percentage of subjects with NS (Tartaglia and Gelb 2005). These conditions can now be viewed as either a part of the NS phenotypic spectrum (NL/MGCLS) or an allelic variant of NS (LS).

In contrast, with one exception, no mutation affecting *PTPN11* has been identified in NFNS thus far (Baralle et al. 2003; Bertola et al. 2005; present study), which strongly supports the hypothesis that *PTPN11* is not a major disease gene contributing to or causing NFNS and that NFNS and NS are distinct genetic disorders. Accordingly, large clinical studies of NS make no reference to patients with neurofibromas, which suggests that NF1 features do not occur frequently in classic NS (Sharland et al. 1992). Coexistence of NS and NF1 features has also been explained by consideration of certain NS signs in subjects with NFNS as part of the phenotypic variability of NF1 or as a distinct and well-delineated condition. Both these possibilities imply mutations in *NF1* as a common molecular event underlying the condition. However, in the former, one would expect both a number of mutations shared with NF1 and a similar distribution. In the latter, specific mutations not occurring (or rare) in patients with NF1 would be expected. The identification of *NF1* lesions in 16 of 17 subjects in the present cohort provides evidence of a major role of *NF1* in NFNS. With combination of the present and previous data, 18 distinct *NF1* gene mutations have been described in 22 unrelated patients with NFNS (Carey et al. 1997; Baralle et al. 2003; Castle et al. 2003; Bertola et al. 2005; present study). These lesions include nonsense mutations, out-of-frame deletions, insertions, or splicing mutations, as well as missense mutations and small inframe deletions. Among them, a statistically significant incidence (42%) of missense mutations and small inframe deletions is observed. Remarkably, inframe defects account for a considerably lower percentage (10%) of *NF1* lesions among patients with NF1 than among those with NFNS (10/24 patients with NFNS studied [Carey et al. 1997; Baralle et al. 2003; Castle et al. 2003; Bertola et al. 2005; present study] vs. 28/278 patients with NF1 [Fahsold et al. 2000]; $\chi^2 = 17.28$; $P = .00003$). In NFNS, most (60%) of these inframe mutations cluster to the GAP-related domain, which does not represent the major (25%) mutational hotspot region for missense mutations in patients with NF1 (6/10 patients with NFNS [Carey et al. 1997; Baralle et al. 2003; Castle et al. 2003; Bertola et al. 2005; present study] vs. 7/28 patients with NF1 [Fahsold et al. 2000]; Fisher's exact test one-tailed $P = .055$).

A nonsignificant trend of association between inframe mutations and CHD was also observed. Of note, two of the mutations (991delM and 1438delE) we docu-

mented in subjects with CHD had been associated with CHD elsewhere (Carey et al. 1997; Castle et al. 2003). In particular, 991delM had been associated with PVS in patients with NFNS (Carey et al. 1997; present study) and in patients with Watson syndrome, a condition characterized by PVS, CLSs, and mental retardation and caused by *NF1* gene mutations (Tassabehji et al. 1993; Castle et al. 2003), thus suggesting an independent relationship between 991delM and PVS by the associated phenotype

Remarkably, the clinical phenotype of patients reported here is characterized by a peculiar presentation of NF1 and NS features. Specifically, whereas plexiform neurofibroma was found only in a single patient, neither pseudoarthrosis of the tibia nor *NF1* gene mutation–related tumors—other than neurofibromas, optic gliomas, and one neuroblastoma—occurred, either in pediatric or in adult patients. These findings partly overlap with the conclusions of Carey (1998), who reported the absence of Lisch nodules, the small number of dermal neurofibromas, and the lack of internal tumors as distinct features of NFNS. Among NS features, typical dysmorphisms were hypertelorism, ptosis, and low-set ears, whereas short neck and stature and thoracic anomalies were present in only half of the patients. The identification of specific *NF1* alleles recurring in NFNS, the evidence that these alleles cosegregate with the condition in families, and the observation of a peculiar mutational spectrum strongly suggest that the term "NFNS" does characterize a phenotypic variant of NF1, which manifests with a low incidence of plexiform neurofibromas, skeletal anomalies, and internal tumors, in association with hypertelorism, ptosis, low-set ears, and CHDs. However, it should be noted that some of the mutations identified in patients with NFNS have also been reported in NF1 without any feature suggestive of NS. From a molecular point of view, the clinical overlap between NFNS and NS is not surprising. Increasing evidence supports the hypothesis that *NF1* and *PTPN11* gene products—neurofibromin and SHP-2 (a cytoplasmic protein tyrosine phosphatase functioning as a transducer)—elicit their modulatory role through a common pathway. Indeed, whereas neurofibromin stimulates the intrinsic GTP hydrolysis of RAS proteins required for their functional silencing, SHP-2 promotes their sustained activation. The antagonistic function of neurofibromin and SHP-2 on RAS-mediated transduction cascades modulates cell response to several growth-factor and cytokine receptors, which control a number of developmental processes (Dasgupta and Gutmann 2003; Neel et al. 2003; Arun and Gutmann 2004; Tartaglia et al. 2004*b*). Consistent with the crucial role of neurofibromin and SHP-2 in modulating cell proliferation, children with NF1 or NS are predisposed to distinct but overlapping spectra of hematologic malignancies (Shannon et al. 1994; Side et al. 1998; Tartaglia et al. 2003, 2004*a,* 2005). For both NF1 and NS, deregulation of RAS signaling appears to occur in a ligand-dependent manner, which suggests that the differential contribution of these proteins to modulation of transduction pathways elicited by distinct signals might account for the phenotypic differences observed in NF1/NFNS and NS.

On the whole, the present study provides the first molecular evidence of a major role of *NF1* mutations in NFNS, emphasizing the extreme phenotypic variability associated with lesions in the *NF1* gene. We hypothesize that mutations affecting regulatory portions of the gene might also have a pathogenetic role in NFNS. Although mutations affecting the *NF1* promoter have not been reported to date (Horan et al. 2000), lesions in other noncoding portions are to be expected. Gross rearrangements consistently comprise up to 5% of all *NF1* mutations documented in NF1 (Korf 1998; Upadhyaya and Cooper 1998; Kluwe et al. 2004). Even though the present data do not allow exclusion of the possibility that NFNS is genetically heterogeneous, they definitely exclude defects in the coding sequence of the *PTPN11* gene as a recurrent molecular event underlying NFNS. Similarly, the recently reported chance occurrence of mutations in both *NF1* and *PTPN11* represent a rare event in NFNS, probably accounting for a minority of these cases (Bertola et al. 2005). Finally, mutations in *NF1* are unlikely to play an important role in NS, which further supports the view that NFNS is genetically distinct from NS.

Acknowledgments

We thank the patients and families who participated in this study and the physicians who referred the subjects. This work was supported in part by grants from the Italian Ministry of Health (RC 2004 and RC 2005) and the Italian Ministry of Education, University and Research (to B.D.) and Telethon-Italy (GGP04172) and Programma di Collaborazione Italia-USA/malattie rare (to M.T.).
