**Abstract.** We report a measurement of the  $B_s^0$  meson lifetime from  $B_s^0 \rightarrow D_s^- X$  decays, where  $D_s^-$  mesons are reconstructed in the  $D_s^- \rightarrow \phi\pi^-$  and  $D_s^- \rightarrow K^{*0}K^-$  decay channels. From approximately 3.7 million hadronic  $Z^0$  decays recorded by the OPAL detector at LEP a sample is selected containing  $911 \pm 83$  candidates, of which  $519 \pm 136$  are estimated to be from  $B_s^0$  meson decays. Fitting the distribution of the distance from the beam spot to the decay vertex of the  $D_s^-$  candidates with an unbinned likelihood function we measure

$$\tau(B_s^0) = 1.72_{-0.19}^{+0.20+0.18}_{-0.17} \text{ ps},$$

where the errors are statistical and systematic, respectively.

## 1 Introduction

The lifetimes of b-flavored hadrons are related to both the strength of the b quark coupling to c and u quarks, and to the dynamics of b hadron decay. The spectator model assumes that the light quarks in b and c hadrons do not affect the decay of the heavy quark, and thus predicts the lifetimes of all b-hadrons to be equal. For charm hadrons this prediction is inaccurate; the measured  $D^+$  lifetime is approximately 2.5 times that of the  $D^0$  and more than

twice that of the  $D_s^-$  [1]. More sophisticated models predict that the differences among b-hadron lifetimes should be much smaller than those in the charm system, because of the larger mass of the b quark [2–4]. Bigi et al. [3] predict a difference in lifetime between the  $B^+$  and  $B^0$  meson of several percent, and between the  $B_s^0$  and  $B^0$  mesons of about 1%. Although some assumptions in [3] have been questioned by Neubert and Sachrajda [4], there is agreement that the models predict a difference between the  $B_s^0$  and  $B^0$  lifetimes of the order of  $\pm 1\%$ .

The first measurements of the  $B_s^0$  lifetime [5–9] were made using correlated  $D_s^-$ -lepton pairs that primarily result from the semileptonic decay of the  $B_s^0$ . However, the small  $B_s^0$  semileptonic branching ratio limits the statistical power of this channel. More inclusive techniques, which do not require that the  $B_s^0$  decay semileptonically, have been used to circumvent this limitation [7, 9].

We present a measurement of the lifetime of the  $B_s^0$  meson in which only the  $D_s^-$  mesons are reconstructed. The two decay channels used are:<sup>1</sup>

$$B_s^0 \rightarrow D_s^- X \quad \text{and} \quad B_s^0 \rightarrow D_s^- X$$

$$\begin{array}{l} \searrow \text{K}^{*0} \text{K}^- \\ \searrow \text{K}^+ \pi^- \end{array} \quad \begin{array}{l} \searrow \phi \pi^- \\ \searrow \text{K}^+ \text{K}^- \end{array}$$

The  $B_s^0$  meson is not the only source of  $D_s^-$  mesons. Significant numbers of  $D_s^-$  mesons are produced in the decays of other b-hadrons as well as in  $Z^0 \rightarrow c\bar{c}$  events. The level and shape of this background is evaluated using Monte Carlo data and measured branching fractions. The background from random track combinations is evaluated using the side band technique.

To measure the  $B_s^0$  lifetime, we reconstruct the decay vertex of the  $D_s^-$  and determine the distance from the beam spot to this point. For  $D_s^-$  mesons that result from the decay of b-hadrons, this “decay length” has contributions both from the b-hadron and  $D_s^-$  decay lengths. The bias arising from the angle between the  $B_s^0$  meson and the  $D_s^-$  meson direction is very small and does not affect the result of this analysis. An unbinned maximum likelihood fit is performed using the reconstructed decay lengths, their errors and the  $D_s^-$  momentum to extract the mean  $B_s^0$  lifetime. The following sections describe the OPAL detector, the selection of  $D_s^-$  candidates, the vertex topology of the events, the determination of the  $B_s^0$  decay length, the estimation of the  $B_s^0$  energy, the lifetime fit, the results, and the systematic errors.

## 2 The OPAL detector

The OPAL detector is described in [10]. The central tracking system is composed of a silicon microvertex detector, a precision vertex drift chamber and a large volume jet chamber surrounded by a set of chambers to measure the  $z$ -coordinate of tracks ( $z$ -chambers)<sup>2</sup>. These detectors are located inside a solenoid. The detectors outside the solenoid consist of a time-of-flight scintillator array and a lead glass electromagnetic calorimeter with a presampler, followed by a hadron calorimeter consisting of the instrumented return yoke of the magnet, and several layers of muon chambers. Charged particle types are identified by their specific energy loss,  $dE/dx$ , in the jet chamber. Further information on the performance of the tracking and  $dE/dx$  measurements can be found in [11].

<sup>1</sup> Charge conjugate modes are always implied. Also, unless otherwise noted, K and  $\pi$  always refer to charged particles

<sup>2</sup> The coordinate system is defined such that the  $z$ -axis follows the electron beam direction and the  $x$ - $y$  plane is perpendicular to it with the  $x$ -axis lying horizontally. The polar angle  $\theta$  is defined relative to the  $+z$ -axis, and the azimuthal angle  $\phi$  is defined relative to the  $+x$ -axis

## 3 $D_s^-$ candidate selection

This analysis uses data collected during the 1991–1995 LEP running periods at center-of-mass energies within  $\pm 3$  GeV of the  $Z^0$  mass. After the standard hadronic event selection [12] and detector performance requirements, a sample of 3.7 million events is selected. Charged tracks and electromagnetic clusters not associated with a charged track are grouped into jets using the JADE E0 recombination scheme [13] with a  $y_{\text{cut}}$  value of 0.04. Tracks from identified secondary vertices,  $\Lambda$  and  $K_S^0$  decays or  $\gamma$  conversions, are excluded from the  $B_s^0$  candidate selection.

Simulated event samples were generated using the JETSET 7.4 Monte Carlo program [14], together with a program to simulate the response of the OPAL detector [15]. The Monte Carlo sample includes approximately 4 million simulated multihadronic  $Z^0$  decays and one million  $Z^0 \rightarrow b\bar{b}$  decays (the equivalent of about 4.5 million multihadronic decays). In addition, three special Monte Carlo samples were generated in which each event contains at least one  $D_s^-$  decaying in the channels of interest. The parameter optimisation used in this simulation is described in [14]. For each of the following decay channels, 20000 events were generated:  $B_s^0 \rightarrow D_s^- X$ ,  $D_s^-$  from b-hadrons other than  $B_s^0$  decays and  $D_s^-$  from  $Z^0 \rightarrow c\bar{c}$ .

### 3.1 $D_s^- \rightarrow K^+ K^- \pi^-$ selection

The  $D_s^-$  meson is reconstructed in the decay chains  $D_s^- \rightarrow K^{*0} K^-$  in which the  $K^{*0}$  decays into a  $K^+ \pi^-$ , and  $D_s^- \rightarrow \phi \pi^-$  where the  $\phi$  subsequently decays into  $K^+ K^-$ .

Tracks forming the  $D_s^-$  candidates are required to be in the same jet and to have the appropriate charge combination. At least two of the three candidate tracks are required to have good  $\theta$  measurements either from the  $z$ -chambers or from a measurement of the track endpoint as it exits the main jet chamber. Similarly, to reject poorly reconstructed candidates, at least two of the three tracks are required to have hits in the silicon microvertex detector.

To reduce the combinatorial background, the tracks forming the  $D_s^-$  are subject to particle identification requirements. For candidate pion tracks, the probability for the measured  $dE/dx$  value to be consistent with the pion hypothesis is required to be greater than 1%. For candidate kaon tracks, if the observed energy loss of a kaon candidate is less than the mean  $dE/dx$  expected for a kaon, the probability of consistency with the kaon hypothesis is required to be greater than 1%, and greater than 3% otherwise. If both kaon candidates have energy losses greater than the mean  $dE/dx$  expected for a kaon, the product of the two  $dE/dx$  probabilities is required to be greater than 0.02. These tighter requirements reduce the background from pion tracks, for which the mean  $dE/dx$  value is above that of kaons. Furthermore, one of the kaon candidates must satisfy a pion-rejection criterion by having an observed  $dE/dx$  less than that expected for a pion, and a probability of less than 10% that the  $dE/dx$  is consistent with a pion hypothesis.

For the  $K^{*0}K^-$  mode, the invariant mass of the  $K\pi$  combination is required to satisfy  $0.865 < m_{K\pi} < 0.925$  GeV. In the  $\phi\pi$  mode, the width of the  $K^+K^-$  peak is dominated by detector resolution and the  $K^+K^-$  invariant mass is required to satisfy  $1.010 < m_{KK} < 1.030$  GeV. The momenta of the kaons are required to be greater than 2 GeV and that of the pion must exceed 1 GeV.

To reduce further the  $D^- \rightarrow K^{*0}\pi^-$  background in the  $K^{*0}K^-$  mode, the kaon candidate originating directly from the  $D_s^-$  decay is subject to a tighter, 5%,  $dE/dx$  requirement. Also, in this mode both kaons must meet the pion-rejection criterion described above.

We require that the  $D_s^-$  momentum divided by the beam energy,  $x_{D_s^-}$ , is greater than 0.20 to reduce random track combinations, and less than 0.60 to reduce the  $D_s^-$  contribution from  $Z^0 \rightarrow c\bar{c}$  events.

The differences between the angular distributions of  $D_s^-$  decays and those of combinatorial background are exploited to enhance the signal purity as follow. The  $D_s^-$  is a spin-0 meson and the final states of both decay modes consist of a spin-1 ( $\phi$  or  $K^{*0}$ ) meson and a spin-0 ( $\pi^-$  or  $K^-$ ) meson. The  $D_s^-$  signal is expected to have no dependence on  $\cos\theta_p$ , where  $\theta_p$  is the angle in the rest frame of the  $D_s^-$  between the spin-0 meson direction and the  $D_s^-$  direction in the lab frame. However, the  $\cos\theta_p$  distribution of random combinations peaks in the forward and backward directions. It is therefore required that  $|\cos\theta_p| < 0.8$  for both modes. The distribution of  $\cos\theta_v$ , the angle in the rest frame of the spin-1 meson between the direction of the final state kaon from the decay of the spin-1 meson and the  $D_s^-$  direction, is proportional to  $\cos^2\theta_v$  for  $D_s^-$  decays. The  $\cos\theta_v$  distribution of the random  $K^+K^-\pi^-$  combinations in the data is, however, approximately uniform. Therefore it is required that  $|\cos\theta_v| > 0.6$  (0.4) for the  $K^*K$  ( $\phi\pi$ ) mode.

### 3.2 Decay length determination

The  $D_s^-$  decay vertex is reconstructed in the  $x$ - $y$  plane by fitting the  $D_s^-$  candidate tracks to a vertex. To reject random combinations of tracks, the probability of the tracks to have arisen from a common vertex is required to exceed 1%.

The beam spot position is measured using charged tracks in the OPAL data with a technique that follows any significant shifts in the position during a LEP fill [16]. The intrinsic width of the beam spot in the  $y$  direction is about  $8\mu\text{m}$ . The width in the  $x$  direction is directly measured using  $\mu^+\mu^-$  events and varies between  $100\mu\text{m}$  and  $160\mu\text{m}$ , depending on the LEP optics.

The distance from the  $D_s^-$  decay vertex to the beam spot is determined in the  $x$ - $y$  plane. This distance is converted into three dimensions using the polar angle of the  $K^+K^-\pi^-$  momentum vector. Typical decay length errors are about  $300\mu\text{m}$ , with only a small contribution coming from uncertainties in the position of the interaction point within the beam spot. Rejecting candidates with decay length errors greater than 3 mm helps to reduce the effects of poorly measured tracks.

**Fig. 1.** Results of the standard selection. *Top:*  $K^+K^-\pi^-$  invariant mass distribution for  $\phi\pi$  combinations along with the fitted distribution. *Bottom:*  $K^+K^-\pi^-$  invariant mass distribution for  $K^*K$  candidates, along with the fitted distribution. The *dotted lines* indicate the region within which candidates are used in the lifetime fit. The *arrow* indicates the  $D^-$  peak position

### 3.3 $D_s^-$ selection results

The  $K^+K^-\pi^-$  invariant mass distribution for all candidates that pass the selection is shown in Fig. 1. A likelihood fit to the measured  $K^+K^-\pi^-$  invariant mass of the  $D_s^-$  candidates is performed separately for the two decay channels. The  $K^+K^-\pi^-$  mass distribution is parameterized as the sum of a quadratic term to account for random combinatorial background (which also is observed to describe accurately the background in the simulated data samples), a Gaussian function which describes the mass peak of the reconstructed  $D_s^-$  signal, and another Gaussian to account for a  $D^- \rightarrow K^+K^-\pi^-$  contribution. This last term has a mean fixed to the  $D^-$  mass of 1869.3 MeV [1] and the width constrained to be the same as that of the  $D_s^-$  signal. This second Gaussian is included to avoid biasing the estimate of the combinatorial background. The results of this fit to the  $K^+K^-\pi^-$  invariant mass spectra are shown in Table 1. A total of  $911 \pm 83$   $D_s^-$  candidates are found.

### 3.4 Composition of the $D_s^-$ signal

The  $B_s^0$  meson is not the only source of  $D_s^-$  mesons. Significant numbers of  $D_s^-$  mesons are produced in other b-hadron decays as well as in  $Z^0 \rightarrow c\bar{c}$  events, collectively referred to as ‘physics background’. In what follows, the contributions of these three components to the observed  $D_s^-$  spectra are estimated.

The fractions of  $D_s^-$  mesons produced from each of these sources are extracted using the results in [17]. The measured  $D_s^-$  production rates separated into flavour are  $f_b = \Gamma_{b\bar{b}}/\Gamma_{\text{had}} \cdot f(b \rightarrow D_s^-) \cdot Br(D_s^- \rightarrow \phi\pi^-) = (0.166 \pm$

**Table 1.**  $K^+K^-\pi^-$  invariant mass spectra fitting results. The fitted mass is in agreement with the value of  $1.9685 \pm 0.0006\text{MeV}$  from [1]. The “background fraction” is defined as the fitted number of combinatorial background candidates divided by the total number of candidates within  $2\sigma$  of the fitted  $D_s^-$  mass

source	$\phi\pi$	$K^*K$
number of $D_s^-$ candidates	$629 \pm 64$	$282 \pm 53$
fitted $D_s^-$ mass	$1.966 \pm 0.002\text{ GeV}$	$1.959 \pm 0.004\text{ GeV}$
fitted $D_s^-$ sigma	$18 \pm 2\text{ MeV}$	$21 \pm 3\text{ MeV}$
background fraction	0.75	0.86
total $\chi^2$ over 80 bins	90.0	80.0

$0.018 \pm 0.016\%$  and  $f_c = \Gamma_{c\bar{c}}/\Gamma_{\text{had}} \cdot f(c \rightarrow D_s^-) \cdot Br(D_s^- \rightarrow \phi\pi^-) = (0.056 \pm 0.015 \pm 0.007)\%$ . Thus,  $f_b/(f_c + f_b) = (75 \pm 9)\%$  of produced  $D_s^-$  mesons are from  $Z^0 \rightarrow b\bar{b}$  events and the remaining  $(25 \pm 9)\%$  are from  $Z^0 \rightarrow c\bar{c}$  events.

The fraction of  $D_s^-$  mesons from b-hadrons in our signal is estimated using the following production rates:  $f(b \rightarrow B_s^0) = 0.112^{+0.018}_{-0.019}$  [1] and  $f(b \rightarrow B) = 0.378 \pm 0.022$  [1] (where ‘B’ is either  $B^+$  or  $B^0$ ). Assuming that b-baryons decay to  $D_s^-$  mesons with the same branching fractions as the non-strange b-mesons ( $0.086 \pm 0.016$  [1]) and using the inclusive branching ratio of  $B_s^0$  to  $D_s^-$ , measured to be  $0.87 \pm 0.31$  [1], we estimate that  $(56 \pm 11)\%$  of  $D_s^-$  mesons from b-hadron decay are from  $B_s^0$ . Thus,  $(42 \pm 10)\%$  of the  $D_s^-$  mesons come from  $B_s^0$  decays,  $(33 \pm 9)\%$  come from other b-hadron decays and  $(25 \pm 9)\%$  from  $Z^0 \rightarrow c\bar{c}$  events. Assuming the production rates of  $B^+$  and  $B^0$  are the same and that they have equal branching ratios to  $D_s^-$ , each of these non-strange b-mesons accounts for  $(14 \pm 4)\%$  of the  $D_s^-$  production with the remaining  $(5 \pm 2)\%$  of  $D_s^-$  produced from b-baryons.

The special Monte Carlo samples described above were used to determine the contribution of each of these channels in the reconstructed sample. The ratio of the efficiency to reconstruct a  $D_s^-$  meson from b-hadron decay other than  $B_s^0$ , divided by the efficiency to reconstruct a  $D_s^-$  meson from a  $B_s^0$  decay is  $0.82 \pm 0.02$ , where the error is due to the limited statistics of the simulated data samples. The principal reason that this ratio is less than unity is that the momentum spectrum of  $D_s^-$  mesons from the decay of b-hadrons other than  $B_s^0$  is softer than that of  $D_s^-$  mesons from  $B_s^0$  decay. The ratio of the efficiency to reconstruct a  $D_s^-$  meson from a  $Z^0 \rightarrow c\bar{c}$  event divided by the efficiency to reconstruct a  $D_s^-$  from a  $B_s^0$  decay is  $0.67 \pm 0.01$ . The upper cut on the scaled energy of the  $D_s^-$  ( $x_{D_s^-} < 0.6$ ) preferentially rejects  $D_s^-$  from  $Z^0 \rightarrow c\bar{c}$ , which tend to have higher momentum. The sources of  $D_s^-$  production are summarized in Table 2.

Monte Carlo events were used to study the background from events where the three  $K^+K^-\pi^-$  candidate tracks come either from the same fully reconstructed charm hadron for which a pion or a proton has been mis-identified as a kaon, or from a partially reconstructed charm hadron.

**Table 2.** Estimated  $D_s^-$  signal composition. The errors include those from the measured branching ratios and the statistical uncertainty from the Monte Carlo samples used to estimate the relative reconstruction efficiencies

source	percentage of produced $D_s^-$	percentage of reconstructed $D_s^-$
$Z^0 \rightarrow c\bar{c}$	$25 \pm 9$	$17 \pm 6$
$B^+$	$14 \pm 4$	$11 \pm 3$
$B^0$	$14 \pm 4$	$11 \pm 3$
b-baryons	$5 \pm 2$	$4 \pm 2$
$B_s^0$	$42 \pm 10$	$57 \pm 14$

The resulting  $K^+K^-\pi^-$  invariant mass distribution in the region around the  $D_s^-$  mass is similar to that of the combinatorial background. Such events are therefore, considered to contribute to the combinatorial background.

Since  $(57 \pm 14)\%$  of the reconstructed  $D_s^-$  meson decays are calculated to be from  $B_s^0$  decays,  $519 \pm 136$   $D_s^-$  candidates are attributed to  $B_s^0$  decay from the  $911 \pm 83$  candidates resulting from the fits to the  $K^+K^-\pi^-$  invariant spectra.

## 4 The $B_s^0$ lifetime fit

To extract the  $B_s^0$  lifetime from the measured decay lengths, an unbinned maximum likelihood fit is performed using a function that accounts for both the  $D_s^-$  signal and the background components of the sample. In the part of the likelihood function describing events from b-hadron decays, the observed decay lengths depend on the  $B_s^0$  lifetime.

The form of the likelihood function for the candidates in the  $D_s^-$  signal from  $B_s^0$  decays is described in terms of the probability for observing a combined  $D_s^-$  and  $B_s^0$  decay length,  $L^i$ , given a measurement error  $\sigma_L^i$ , the momenta of the  $D_s^-$  and  $B_s^0$ , and the mean lifetimes of these mesons.

The likelihood function has components which describe the different sources of  $D_s^-$  mesons in the signal and in the combinatorial background. This follows closely the method used in previous opal  $B_s^0$  lifetime analyses [5].

The likelihood function which accounts for  $D_s^-$  mesons from  $B_s^0$  decays is constructed as a convolution of two exponential functions to describe the  $D_s^-$  and  $B_s^0$  decay lengths, convoluted with a function to describe the probability of having a particular  $B_s^0$  momentum ( $p_{B_s}$ ) and Gaussian functions to describe the measured decay length resolution. This can be expressed as:

$$\begin{aligned} \mathcal{L}_i^{B_s^0}(L^i | \tau_{B_s^0}, \sigma_L^i, p_{D_s}^i, s_1, s_2, f_2) \\ = \int_0^\infty dl \int_0^{p_{B_s}(max)} dp_{B_s} \mathcal{R}(L^i | l, \sigma_L^i, s_1, s_2, f_2) \\ \times \mathcal{B}(p_{B_s} | p_{D_s}^i) \mathcal{P}(l | \tau_{B_s^0}, \tau_{D_s^-}, p_{B_s}, p_{D_s}^i) \end{aligned} \quad (1)$$

where  $p_{B_s}(max) = 45\text{GeV}$  and  $\mathcal{R}$  is given by

$$\mathcal{R}(L^i | l, \sigma_L^i, s_1, s_2, f_2) = (1 - f_2) \mathcal{G}(L^i | l, \sigma_L^i, s_1)$$

$$+f_2 \mathcal{G}(L^i | l, \sigma_L^i, s_2) . \quad (2)$$

The function  $\mathcal{G}$  is a Gaussian function which describes the probability to observe a decay length,  $L^i$ , given a true decay length  $l$  and the measurement uncertainty  $\sigma_L^i$  and scale factors on this error,  $s_1$  and  $s_2$ . Two scale factors are employed to describe both the majority of tracks for which the measured decay length uncertainty is a good estimate and the small fraction,  $f_2$ , of mis-measured candidates in which the measured decay length uncertainty is an underestimate. The scale factors  $s_1$  and  $s_2$ , as well as the fraction of mis-measured candidates,  $f_2$ , are free parameters in the lifetime fit.  $\mathcal{B}$  is the probability of a particular  $B_s^0$  momentum for an observed  $D_s^-$  momentum,  $p_{D_s^-}$ . This probability is determined from Monte Carlo events by forming distributions of the ratio  $p_{B_s^0}/p_{D_s^-}$ . Six such distributions are formed, depending on the value of  $p_{D_s^-}$ , since at higher values of  $p_{D_s^-}$  the range of potential values of  $p_{B_s^0}$  is more tightly constrained than for lower  $p_{D_s^-}$  candidates.  $\mathcal{P}$  is the probability for the  $D_s^-$  to decay at a distance  $l$  from the  $e^+e^-$  interaction point, given  $B_s^0$  and  $D_s^-$  lifetimes  $\tau_{B_s^0}$  and  $\tau_{D_s^-}$  and momenta  $p_{B_s^0}$  and  $p_{D_s^-}^i$ . This function is constructed as:

$$\begin{aligned} & \mathcal{P}(l | \tau_{B_s^0}, p_{B_s^0}, p_{D_s^-}, s_1, s_2, f_2) \\ &= \frac{m_{D_s^-}}{\tau_{D_s^-} p_{D_s^-}} \frac{m_{B_s^0}}{\tau_{B_s^0} p_{B_s^0}} \int_0^l \exp \left[ \frac{-l' \cdot m_{B_s^0}}{\tau_{B_s^0} p_{B_s^0}} \right] \\ & \quad \times \exp \left[ \frac{-(l-l') \cdot m_{D_s^-}}{\tau_{D_s^-} p_{D_s^-}} \right] dl' \end{aligned} \quad (3)$$

where  $\tau_{B_s^0} p_{B_s^0}/m_{B_s^0}$  and  $\tau_{D_s^-} p_{D_s^-}/m_{D_s^-}$  are the mean decay lengths for the given momenta ( $p_{B_s^0}$  and  $p_{D_s^-}$ ) mean lifetimes ( $\tau_{B_s^0}$  and  $\tau_{D_s^-}$ ) and masses ( $m_{B_s^0}$  and  $m_{D_s^-}$ ).

Similar functions are employed for the other  $D_s^-$  meson sources. For  $D_s^-$  mesons from other b-hadron decays ( $B^+$ ,  $B^0$  and b-baryons), the world average lifetime for each species of b-hadron [1] is used in the likelihood function and a slightly different boost function,  $\mathcal{B}$ , is employed. For  $D_s^-$  mesons produced in  $Z^0 \rightarrow c\bar{c}$  events, the function  $\mathcal{P}$  is a single exponential function with the decay constant  $\tau_{D_s^-} p_{D_s^-}/m_{D_s^-}$ . The total likelihood function containing the contributions for all sources of  $D_s^-$  mesons, is formed by combining the likelihood functions for each of the sources of  $D_s^-$  mesons with the fixed fractions listed in Table 2.<sup>3</sup> This likelihood is written as:

$$\begin{aligned} & \mathcal{L}_i^{D_s^-}(L^i | \tau_{B_s^0}, \sigma_L^i, p_{D_s^-}^i) \\ &= (1 - f_{c\bar{c}} - f_{B^+} - f_{B^0} - f_{A_b}) \mathcal{L}_i^{B_s^0} + \\ & \quad f_{c\bar{c}} \cdot \mathcal{L}_i^{c\bar{c}} + f_{B^+} \cdot \mathcal{L}_i^{B^+} + f_{B^0} \cdot \mathcal{L}_i^{B^0} + f_{A_b} \cdot \mathcal{L}_i^{A_b} . \end{aligned} \quad (4)$$

The functional form of the likelihood function,  $\mathcal{L}^{\text{comb}}$ , used empirically to parameterize the combinatorial background, is composed of an exponential convolved with the

<sup>3</sup> The  $D_s^-$  momentum dependence on The fractions  $f_{c\bar{c}}$ ,  $f_{B^+}$ ,  $f_{B^0}$  and  $f_{A_b}$  has been neglected. This omission was studied in simulated data and found not to produce a noticeable bias in the resulting lifetime

$B_s^0$  boost function,  $\mathcal{B}$ , a fraction with no lifetime and the same double-Gaussian resolution function as the signal. This is expressed as:

$$\begin{aligned} & \mathcal{L}_i^{\text{comb}}(L^i | \tau_{bg}, f^0, \sigma_L^i, p_{D_s^-}^i, s_1, s_2, f_2) \\ &= \int_0^\infty dl \int_0^{p_{B_s^0}(\text{max})} dp_{B_s^0} \mathcal{R}(L^i | l, \sigma_L^i, s_1, s_2, f_2) \\ & \quad \times \mathcal{B}(p_{B_s^0} | p_{D_s^-}^i) \mathcal{P}_{bg}(L | \tau_{bg}, f^0, p_{B_s^0}) , \end{aligned} \quad (5)$$

where the parameters describing the resolution,  $s_1$ ,  $s_2$  and  $f_2$ , are the same as used in the likelihood terms that describe the  $D_s^-$  signal and

$$\begin{aligned} & \mathcal{P}_{bg}(l | \tau_{bg}, f^0, p_{B_s^0}) \\ &= (1 - f^0) \frac{m_{B_s^0}}{\tau_{bg} p_{B_s^0}} \exp \left[ \frac{-l \cdot m_{B_s^0}}{\tau_{bg} p_{B_s^0}} \right] + f^0 \delta(l) . \end{aligned} \quad (6)$$

The fraction of background with no lifetime,  $f^0$ , as well as the characteristic lifetime of the background,  $\tau_{bg}$ , are free parameters in the fit. This term makes no attempt to extract a physically meaningful quantity for the background lifetime. It characterizes the background lifetime behavior and it should not be interpreted as a measurement of the average b lifetime.

The combinatorial background in the event sample is taken into account by fitting for it simultaneously with the  $D_s^-$  signal. The probability that a candidate has arisen from a combination of background tracks,  $\mathcal{F}^{\text{comb}}(m_i)$ , is determined as a function of the  $K^+K^-\pi^-$  invariant mass of each candidate,  $m_i$ , using the results of the fit to the  $K^+K^-\pi^-$  invariant mass spectrum.

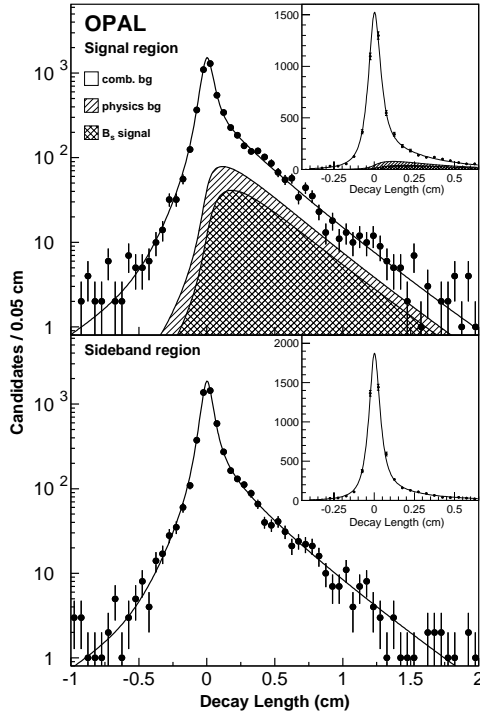

Thus, the full likelihood for candidate  $i$  is:

$$\begin{aligned} & \mathcal{L}_i(L^i | \tau_{B_s^0}, \sigma_L^i, p_{D_s^-}^i, m_i) \\ &= [1 - \mathcal{F}^{\text{comb}}(m_i)] \cdot \mathcal{L}_i^{D_s^-} + \mathcal{F}^{\text{comb}}(m_i) \cdot \mathcal{L}_i^{\text{comb}} \end{aligned} \quad (7)$$

In total six parameters are free in the fit: the  $B_s^0$  lifetime, the parameters describing possible scale factors on the decay length error ( $s_1$ ,  $s_2$  and  $f_2$ ) and the parameters describing the combinatorial background ( $f^0$  and  $\tau_{bg}$ ).

The lifetime fit uses the 10633 events found in the region from 50 MeV below the fitted  $D_s^-$  mass to 200 MeV above it (see Fig. 1). From studies on simulated data, it is found that the lifetime properties of the combinatorial background in this region accurately reflect the combinatorial background around the  $D_s^-$  mass. Furthermore, this avoids the region below the  $D_s^-$  mass in which the number of  $K^+K^-\pi^-$  candidates from  $D^-$  decays and contributions from other D meson decays (e.g. reflections and partially reconstructed decays) are potentially significant. This fit finds  $\tau(B_s^0) = 1.72_{-0.19}^{+0.20}$  ps, where the error is statistical only, the values of the other free parameters of the fit are in Table 3.

The fitted values of the parameters describing the decay length resolution are consistent with the understanding of the OPAL tracking performance. Also, note that the likelihood function describing the background is an empirical one, and as such, the parameters describing the

**Fig. 2.** *Top:* decay length distribution within a  $D_s^-$  mass region of  $\pm 50$  MeV around the fitted  $D_s^-$  mass (signal region). The *single-hatched area* represents the contribution from physics background, the *unhatched area* the combinatorial background and the *cross-hatched area* is the contribution from  $B_s^0$  decays. *Bottom:* decay length distribution for events outside the  $D_s^-$  mass region (sideband region), namely from 50 to 200 MeV above the  $D_s^-$  mass

**Table 3.** Final values of the free parameters in the fit

parameter	fit results
$f_2$	$0.07 \pm 0.01$
$s_1$	$0.88 \pm 0.01$
$s_2$	$4.69 \pm 0.26$
$f^0$	$0.77 \pm 0.01$
$\tau_{bg}$	$1.61 \pm 0.07$

background (e.g.  $\tau_{bg}$ ) have no straightforward physical interpretation. The decay length distributions are shown in Fig. 2 separately for candidates with  $K^+K^-\pi^-$  invariant mass within 50 MeV of the fitted  $D_s^-$  mass (the “signal region”), and for those candidates outside this mass window (the “sideband region”). These illustrate the quality of the fit in regions dominated by  $D_s^-$  signal events and by combinatorial background, respectively. The curves in Fig. 2 represent the sum of the decay length probability distributions for each event. Using the 42 bins that are expected to contain at least five candidates (as predicted by the lifetime fit), a total  $\chi^2$  of 54.7 is found for the sum of the signal and sideband decay length distributions. For the positive decay length bins, a total  $\chi^2$  of 24.0 for 29 bins is observed. These  $\chi^2$  values and plots shown in Fig. 2

indicate that the fitted functional forms provide a good description of the data for both signal and background. It should be stressed that the fit is to the unbinned data.

## 5 Checks of the method

A number of different checks have been made to investigate potential biases in the method of selecting and fitting the signal.

### 5.1 Potential bias in the selection and fitting procedure

Tests were performed on several samples of simulated data to check for biases in the selection and fitting procedures. The first tests involved a toy Monte Carlo program which generated decay length data for the signal  $D_s^-$  decays and combinatorial background. For each  $D_s^-$  signal candidate from a  $B_s^0$  decay, this simulation generated  $B_s^0$  and  $D_s^-$  decay times from exponential distributions with the means set to known values. The  $B_s^0$  and  $D_s^-$  momenta were chosen from a spectrum based on the full Monte Carlo simulation. The  $B_s^0$  and  $D_s^-$  decay lengths were then calculated and combined to give the true candidate decay length, which was then smeared by a resolution function. physics and combinatorial backgrounds were generated through a similar procedure. Many fits were conducted over wide ranges of  $B_s^0$  lifetimes with different levels and parameterizations of the backgrounds. The result of these studies shows that any bias in the fitted  $B_s^0$  lifetime is less than 0.5% and that the statistical precision of the fit to data is consistent with the sample size and composition.

To verify that the  $D_s^-$  selection does not bias the reconstructed sample, a lifetime measurement was made from 20000  $B_s^0 \rightarrow D_s^- X$  Monte Carlo decays into the two channels of this analysis, using a  $B_s^0$  lifetime of 1.60 ps. The mean lifetime of the selected  $D_s^-$  sample was  $1.64 \pm 0.04$  ps, consistent with the expectation that there is no bias from the selection procedure. The lifetime obtained by fitting this same sample was  $1.65 \pm 0.05$  ps.

To investigate the effects of the combinatorial background on the lifetime fit, the same selection and fitting procedure has been applied on a Monte Carlo sample of 4 million multihadronic  $Z^0$  decays. Due to the choice of branching ratios used to produce this sample of simulated events, there are fewer reconstructed  $D_s^-$  signal candidates than we observe in the data. The fitted lifetime has been found to be  $1.73 \pm 0.29$  ps, which is consistent with the generated  $B_s^0$  lifetime of 1.6 ps within the statistical power of this sample. If the signal events from the 20000  $B_s^0 \rightarrow D_s^- X$  decays described above are added to the simulated data, the resulting sample is of similar purity to that found by the tight neural net selection. The fitted lifetime of this pure sample is  $1.65 \pm 0.07$  ps, again in good agreement with the true lifetime of the sample.

The lifetime fit has also been repeated as for the standard result, except that the  $\phi\pi$  and  $K^*K$  channels are fitted separately. The results are  $1.53 \pm 0.23$  ps and  $2.14 \pm$

**Fig. 3.** Results of the tight (neural network) selection, used as a cross-check of the analysis. *Top:*  $K^+K^-\pi^-$  invariant mass distribution for  $\phi\pi$  combinations along with the fitted distribution. *Bottom:*  $K^+K^-\pi^-$  invariant mass distribution for  $K^*K$  candidates, along with the fitted distribution. The dotted lines indicate the region within which candidates are used in the lifetime fit for the check. The arrow indicates the  $D_s^-$  peak position

0.40 ps, respectively, consistent at the level of 1.3 standard deviations.

## 5.2 Use of the tight (neural network) selection

As a check, a much tighter selection was developed which employs a neural network to reject significantly more combinatorial background, thereby producing a much purer  $D_s^-$  signal. However, this also results in a rather significant loss of signal, and as such is not as statistically powerful for the  $B_s^0$  lifetime determination. This artificial neural network uses 16 kinematic and particle-identification quantities, including b-tagging information in the hemisphere opposite to the  $D_s^-$  candidate. The  $K^+K^-\pi^-$  invariant mass distributions for all candidates which pass this selection are shown in Fig. 3. The likelihood fit to the measured  $K^+K^-\pi^-$  invariant mass of the  $D_s^-$  candidates is performed as above, resulting in a smaller signal of  $232 \pm 29$  ( $104 \pm 17$ ) candidates with a much reduced background fraction of 0.54(0.61) for the  $\phi\pi$  ( $K^*K$ ) mode.

The sample of  $D_s^-$  candidates found by the tighter neural network selection has also been used to fit for the  $B_s^0$  lifetime. This sample gives a value of  $1.69 \pm 0.27$  ps for the  $B_s^0$  lifetime and is consistent with the more precise result from the analysis of Sect. 4. The difference in statistical precision between the two fits is in agreement with expectation from toy Monte Carlo studies, given the relative size of the  $D_s^-$  signal and the level of combinatorial background in each sample.

The results of all of the tests show no indication of a significant bias in the selection and fitting procedures.

## 6 Evaluation of systematic errors

Systematic errors arise from the level, parameterization and source of the background, the potential bias from the selection and fitting procedure, the boost estimation method, the beam spot determination and possible tracking errors. The systematic errors are summarized in Table 4.

### Combinatorial background

We consider the effects of both the level of the combinatorial background, as determined by a fit to the  $K^+K^-\pi^-$  mass spectrum, and the effective lifetime of this background, as estimated from the candidates in the sideband region. The systematic error due to the level of this background is determined by repeating the calculation of the event-by-event probability that an event is combinatorial background by changing the estimated size of the  $D_s^-$  signal by the statistical uncertainty from the fit to the invariant mass spectrum. This yields a variation in the  $B_s^0$  lifetime of  $\pm 0.08$  ps. The width of the  $K^+K^-\pi^-$  mass region from which candidates are selected for use in the lifetime fit has also been varied. This was done by selecting candidates in regions extending from 150 to 350 MeV above, and from 25 to 75 MeV below, the  $D_s^-$  mass. Another check included using a sideband from 200 to 350 MeV above the  $D_s^-$  mass in place of the standard sideband from 50 to 200 MeV. These change the fitted  $B_s^0$  lifetime by  $\pm 0.07$  ps which is assigned as a systematic error. Tests were also conducted using the toy Monte Carlo which indicated that the level of these observed changes is consistent with the expected 0.05 ps uncertainty due to statistical fluctuations in the sideband sample; however we conservatively retain the observed variation as a systematic uncertainty.

Several alternative parameterizations describing of the decay length distributions of the combinatorial background have been investigated. For example, we have included an exponential on the negative decay length side, in place of the second Gaussian function, to describe those events that are significantly mis-measured. The resulting  $B_s^0$  lifetime is +0.02 ps higher than the standard result. In another check the second wider Gaussian was used only for the combinatorial background term in the likelihood function, changing the lifetime by +0.05 ps. Leaving out this second Gaussian altogether decreased the lifetime by 0.10 ps, although the quality of this fit is significantly worse, as illustrated by an increase in  $\chi^2$  of about 300 for 40 bins, c.f. 54.7 for 42 bins with the default parameterization. Consequently this last case is not considered as a systematic error. In no case do these alternative parameterizations significantly improve the quality of the  $B_s^0$  lifetime fit, and an error of  $\pm 0.05$  ps was assigned to cover such effects.

We assign a total systematic error due to the combinatorial background, parameterization and source, of  $\pm 0.12$  ps.

### Physics background: sources of $D_s^-$ mesons

The physics background composition has already been discussed. Varying the fraction of  $D_s^-$  mesons from  $Z^0 \rightarrow c\bar{c}$

events over the range given in Table 2 produces a change of  $^{+0.12}_{-0.11}$  ps in the  $B_s^0$  lifetime. The uncertainty due to the  $D_s^-$  fraction from b-hadrons other than  $B_s^0$  is evaluated in the same way. The observed change on the  $B_s^0$  lifetime is  $^{+0.04}_{-0.03}$  ps. These variations also change the statistical error on the fitted  $B_s^0$  lifetime by up to  $\pm 0.03$  ps, and this systematic effect is not considered further.

The  $B_s^0$  lifetime dependence on the uncertainty of the b-hadron lifetimes has been measured by varying the b-hadron lifetimes within the errors quoted in [1], assuming, conservatively, that the individual lifetimes are fully correlated with each other. The  $B_s^0$  lifetime changed by  $\pm 0.02$  ps, which is included as a systematic error. The  $D_s^-$  lifetime has also been varied in the fit, within the errors quoted in [1]. The effect on the measured  $B_s^0$  lifetime is  $\pm 0.01$  ps. This variation is also taken as a contribution to the systematic error.

The  $D_s^-$  momentum spectrum also depends on the fragmentation in  $Z^0 \rightarrow c\bar{c}$  and  $Z^0 \rightarrow b\bar{b}$  events. Changes in the fragmentation affect the composition of the  $D_s^-$  signal through changes in the efficiencies for the charm and bottom contributions to the  $D_s^-$  signal (the effect of the momentum spectrum of the  $D_s^-$  in  $Z^0 \rightarrow b\bar{b}$  events on the estimation of the  $B_s^0$  momentum in the lifetime fit is discussed below). In  $Z^0 \rightarrow c\bar{c}$  events, we have varied the average b hadron energy by the measurement errors [18] to yield a variation in the observed lifetime of  $\pm 0.01$  ps. Similarly, the momenta of the  $D_s^-$  mesons produced in  $Z^0 \rightarrow c\bar{c}$  events was varied according to the average energy measured for non-strange mesons in  $Z^0 \rightarrow c\bar{c}$  events (on the assumption that there is little difference in fragmentation amongst the various charm mesons) [17], producing a variation of  $\pm 0.01$  ps in  $\tau(B_s^0)$ .

In the case of  $D_s^-$  mesons coming from the decay of b-hadrons other than  $B_s^0$ , the  $D_s^-$  may be produced in either a two-body mode (e.g.  $B \rightarrow D_s^- D$ ) or a multi-body final state where one or more light particles are produced. The two-body decay fraction of  $B \rightarrow D_s^- X$  has been measured to be  $0.56 \pm 0.10$  [19, 20]. In determining the relative efficiency of these  $D_s^-$  mesons from b-hadrons other than  $B_s^0$ , we have already corrected our simulation to this two-body fraction. Assuming b-baryons decaying to  $D_s^-$  mesons in two- or multi-body states have the same fractions as  $B^+$  and  $B^0$  mesons, the efficiency of selecting  $D_s^-$  mesons from these decays has been evaluated by varying the two-body fraction over the range 0.46 to 0.66 and re-evaluating the relative efficiency of this source of  $D_s^-$  with respect to the  $D_s^-$  which arise from a  $B_s^0$  decay. This produces a variation of  $\pm 0.01$  ps in the fitted  $B_s^0$  lifetime.

Thus we assign a total error due to these other sources of  $D_s^-$  mesons of  $^{+0.13}_{-0.12}$  ps.

### $B_s^0 \rightarrow D_s^- X$ decay modelling

The systematic error on the  $B_s^0$  lifetime from  $B_s^0 \rightarrow D_s^- X$  decay modelling has also been taken into account. Since the properties of the  $B_{u,d}$  system are measured much more accurately than in the  $B_s^0$  system, the first comparison made was of momentum spectra of D mesons from  $B_{u,d}$  decays (in the  $B_{u,d}$  rest frame) predicted by our Monte Carlo with that measured by CLEO [20]. It is found that

the means of the Monte Carlo and CLEO spectra within the measurement error of the latter. In our simulation, the spectrum of  $D_s^-$  momentum in the  $B_s^0$  rest frame can be reweighted such that the mean is shifted by the difference observed in the non-strange B mesons above. Doing so produces a shift of 0.02 ps in the  $B_s^0$  lifetime.

Since our simulation reproduces the  $B_{u,d}$  decays reasonably well, in what follows, comparisons are made between the properties of the  $B_{u,d}$  and  $B_s^0$  decays within the simulated data, to further evaluate the uncertainties in the lifetime due  $B_s^0 \rightarrow D_s^- X$  decay modelling. This is done by dividing the  $B_s^0 \rightarrow D_s^- X$  Monte Carlo sample into two-body decays and decays with more than two bodies. In our simulation, the two-body  $B_s^0$  decays are described with similar branching ratios as those in  $B_{u,d}$  decays. If we vary the fraction of two-body decays that are double-charm decays (e.g.  $B_s^0 \rightarrow D_s^- D_s^+$ ) from zero to 100%, the  $B_s^0$  lifetime varies by  $\pm 0.01$  ps. For decays which yield more than two-bodies, our Monte Carlo predicts that the momentum spectra of  $B_s^0$  decays agrees with the one from  $B_{u,d}$  decays, when the events are separated into single- and double-charm decays. The least certain parameter is the fraction of double-charm decays in the  $B_s^0$  decays into more than two particles. Varying this fraction from zero to twice that predicted the Monte Carlo, produces a change of  $\pm 0.02$  ps on the  $B_s^0$  lifetime. Combining these two uncertainties resulting from our imperfect knowledge of  $B_s^0 \rightarrow D_s^- X$  decay kinematics, a systematic error of  $\pm 0.02$  ps is assigned.

### Boost estimation

The energy spectrum of the Monte Carlo  $B_s^0$  events used to estimate the momentum of the  $B_s^0$ , given the observed  $D_s^-$  momentum, can also affect the resulting lifetime. This effect is not large because the scaling used to estimate the  $B_s^0$  momentum from the measured  $D_s^-$  momentum is correlated with the  $D_s^-$  momentum itself. We have varied the average  $B_s^0$  energy by the measured errors on the average b-hadron energy [18] to yield a variation in the  $B_s^0$  lifetime of  $\pm 0.01$  ps.<sup>4</sup> The effect of a 2.0 MeV uncertainty in the mass of the  $B_s^0$  [1] was found to produce a change of less than 0.01 ps in the  $B_s^0$  lifetime.

### Beam position and size

The average intersection point of the LEP beams in OPAL is used to estimate the production vertex of the  $B_s^0$  candidates. The sensitivity of  $\tau(B_s^0)$  to the assumed position and size of the beam spot has been evaluated as in [5], resulting in a variation in the fitted lifetime of no more than 0.01 ps, which has been assigned as a systematic error.

### Detector alignment

The effects of alignment and calibration uncertainties on the  $B_s^0$  lifetime are estimated from a detailed study of 3-prong  $\tau$  decays [16]. These uncertainties lead to an uncertainty of 0.01 ps on  $\tau(B_s^0)$ .

Combining the systematic errors in Table 4, we find  $\tau(B_s^0) = 1.72^{+0.20}_{-0.19}(\text{stat})^{+0.18}_{-0.17}(\text{syst})$  ps.

<sup>4</sup> Note that the uncertainty due to the bottom and charm hadron energy spectra affects the  $B_s^0$  lifetime both through the boost estimation and through the  $D_s^-$  sample composition. When combined, these two contributions are added linearly

**Table 4.** Summary of systematic errors on the  $B_s^0$  lifetime

source	uncertainty (ps)
combinatorial background	$\pm 0.12$
physics background	$^{+0.13}_{-0.12}$
$B_s^0 \rightarrow D_s^- X$ decay modelling	$\pm 0.02$
uncertainty in boost	$\pm 0.01$
beam spot	$\pm 0.01$
alignment errors	$\pm 0.01$
total	$^{+0.18}_{-0.17}$

## 7 Conclusion

A sample of  $D_s^-$  decays has been reconstructed in which the  $D_s^-$  has decayed into  $K^+K^-\pi^-$  through either the  $\phi\pi^-$  or  $K^{*0}K^-$  channels. From 3.7 million hadronic  $Z^0$  events recorded by OPAL from 1991 to 1995, a total of  $911 \pm 83$  such candidate decays have been found, of which about 57% are expected to be from  $B_s^0$  decay. The  $B_s^0$  lifetime is found to be

$$\tau(B_s^0) = 1.72^{+0.20}_{-0.19}(\text{stat})^{+0.18}_{-0.17}(\text{syst}) \text{ ps},$$

a result consistent with the measured  $B^0$  lifetime and other  $B_s^0$  measurements [1]. This result is also in agreement with current theoretical expectations [3,4].

*Acknowledgements.* We particularly wish to thank the SL Division for the efficient operation of the LEP accelerator at all energies and for their continuing close cooperation with our experimental group. We thank our colleagues from CEA, DAPNIA/SPP, CE-Saclay for their efforts over the years on the time-of-flight and trigger systems which we continue to use. In addition to the support staff at our own institutions we are pleased to acknowledge the Department of Energy, USA, National Science Foundation, USA, Particle Physics and Astronomy Research Council, UK, Natural Sciences and Engineering Research Council, Canada, Israel Science Foundation, administered by the Israel Academy of Science and Humanities, Minerva Gesellschaft, Benozziyo Center for High Energy Physics, Japanese Ministry of Education, Science and Culture (the Monbusho) and a grant under the Monbusho International Science Research Program, German Israeli Bi-national Science Foundation (GIF), Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, Germany, National Research Council of Canada, Hungarian Foundation for Scientific Research, OTKA T-016660, T023793 and OTKA F-023259.
