Received: 25 March 1998 / Revised version: 3 August 1998 / Published online: 29 October 1998

Abstract. The determination of the centre-of-mass energies from the LEP1 data for 1993, 1994 and 1995 is presented. Accurate knowledge of these energies is crucial in the measurement of the Z resonance parameters. The improved understanding of the LEP energy behaviour accumulated during the 1995 energy scan is detailed, while the 1993 and 1994 measurements are revised. For 1993 these supersede the previously published values. Additional instrumentation has allowed the detection of an unexpectedly large energy rise during physics fills. This new effect is accommodated in the modelling of the beam-energy in 1995 and propagated to the 1993 and 1994 energies. New results are reported on the magnet temperature behaviour which constitutes one of the major corrections to the average LEP energy.

The 1995 energy scan took place in conditions very different from the previous years. In particular the interaction-point specific corrections to the centre-of-mass energy in 1995 are more complicated than previously: these arise from the modified radiofrequency-system configuration and from opposite-sign vertical dispersion induced by the bunch-train mode of LEP operation.

Finally an improved evaluation of the LEP centre-of-mass energy spread is presented. This significantly improves the precision on the Z width.

1 Overview

The mass, m_Z , and the width, Γ_Z , of the neutral weak boson Z are fundamental parameters of nature, and the large electron-positron collider, LEP, at CERN near Geneva, Switzerland is the ideal place to measure them precisely. The first phase of operation of the collider, from 1989 until 1995, known as LEP1, was devoted to the study of the characteristics of the Z resonance. This paper concerns the LEP1 data delivered after 1992.

^g Present address: Fermilab, PO Box 500, Batavia, IL 60510, USA

In 1993 and 1995 energy scans of the Z resonance were performed at LEP in order to determine its mass and width. In both scans luminosity was delivered at the peak of the resonance, i.e. 91.2 GeV centre-of-mass, and two points approximately 1.8 GeV above and below the peak. In 1994 a large amount of data was collected at an energy close to the Z peak. These three datasets provide the largest part of the LEP data used to determine the parameters of the Z resonance, and, when the results of all experiments are combined, yield a statistical precision of about 1.3 MeV on m_Z and 2.0 MeV on Γ_Z .

The natural polarization of the LEP beams [1] allows a determination of the beam energy by resonant depolarization [2] (RD) with a precision of 200 keV [3]. A model to interpolate between RD measurements to determine the centre-of-mass energy (E_{CM}), at a level of accuracy comparable with the statistical precision, has been developed. The error contributions from the LEP energy uncertainties on the determination of m_Z and Γ_Z are approximately given by

$$\Delta m_Z \approx 0.5 \Delta(E_{P+2} + E_{P-2}) \quad (1)$$

$$\begin{aligned} \Delta \Gamma_Z &\approx \frac{\Gamma_Z}{(E_{P+2} - E_{P-2})} \Delta(E_{P+2} - E_{P-2}) \\ &= 0.71 \Delta(E_{P+2} - E_{P-2}) \end{aligned} \quad (2)$$

where E_{P-2} and E_{P+2} are the luminosity-weighted centre-of-mass energies at the two off-peak points.

The details of the calibration data collected during the scan in 1993 are described in [4]. The 1995 energy scan was performed at approximately the same energies and gave similar integrated luminosities to those of the 1993 scan. However, several additional measurements were made: Nuclear Magnetic Resonance (NMR) probes were placed directly inside LEP dipole magnets, providing considerable new insight into their behaviour; more frequent calibrations by RD were performed usually at the end of fills¹ and six times also at the beginning, whereas in 1993 all RD calibrations during physics fills were made at the end. Some problems specific to the 1995 scan, namely the operation with bunch-trains and the use of a large number of superconducting cavities which were being commissioned for the LEP2 programme, required specific measurements. This report describes the determination of the LEP centre-of-mass energies for the 1995 scan, and, applying the further understanding gained from these measurements, a revision of the 1993 and 1994 energies is given.

The model of the accelerator energy behaviour (Sect. 3) has to track the two basic quantities which could cause variation of the beam-energy: the magnetic dipole field

¹ The operation of LEP is subdivided into *fills*. A fill, identified by a sequential number, consists, in simplified terms, of injection of the beams at 20–22 GeV and acceleration to the final energy. A successful fill is one where, after the final tuning, the accelerated beams are put into collision mode, delivering physics events to the four experiments. A typical LEP1 fill lasts 6–10 hours. Fills are eventually dumped or switched to *calibration* mode when the experimental luminosities, which decrease steadily during a fill owing to particle losses, become too low

component perpendicular to the beam trajectory (Sects. 6, 8) and the circumference of the accelerator (Sect. 7). The model has been significantly improved over the one described in an earlier publication [4]. In particular the thermal behaviour of the LEP dipole magnets has been studied in great detail (Sect. 5). Unsuspected phenomena causing drifts of the magnetic fields have been discovered and understood. The leakage currents from the Swiss–French railway power system, referred to as *parasitic currents* in this paper², perturb the field of the LEP dipoles and are the cause of the systematic drift of the accelerator dipole magnetic field. The evidence for these drifts is discussed, and the inclusion of this effect in the model is described (Sect. 4).

As a result of the discovery of these effects, the 1993 and 1994 energies are revised. It is explained how the parametrization of 1995 can be applied to the earlier years, and what data exist from these years to support this treatment (Sect. 6.1).

To obtain the centre-of-mass energy for each of the four LEP experiments requires additional corrections specific to each interaction point³ (IP). These arise from the status of the LEP radiofrequency (RF) system (Sect. 10.1), and from the effect of opposite-sign vertical dispersion induced by the bunch-train operation in 1995 (Sect. 10.3).

The systematic errors on the centre-of-mass energy are given, together with their correlation between experiments and energy points (Sect. 11).

Finally, the knowledge of the beam-energy spread in 1993, 1994 and 1995 is summarized (Sect. 12). This is an important correction to Γ_Z and to the peak cross-section. A direct measurement of the incoherent synchrotron tune has allowed a reduction of the associated systematic error by a factor of four compared to the previous determination [4].

The data collected prior to 1993 have not been re-analysed, as most of the critical monitoring information was not available or was of lower quality. The LEP energy working group considers the published analysis [6] of these data to be adequate for the determination of the centre-of-mass energies (see Sect. 11.2) while the determination of the centre-of-mass energy spread has been revised (see Sect. 12.5).

2 The 1993, 1994 and 1995 LEP runs

2.1 The datasets

In 1993 and 1995 energy scans of the Z resonance were made at three energy points: peak ('P'), at a centre-of-mass energy of 91.2 GeV, close to the peak of the Z resonance, and two points approximately 1.8 GeV either side

² These leakage currents are a well documented source of electrical nuisance and electro-chemical corrosion and are known technically as *vagabond currents* [5]

³ LEP has eight straight sections numbered from 1 to 8 where only the even ones house an experiment (IP2: L3, IP4: ALEPH, IP6: OPAL, IP8: DELPHI)

Table 1. Dataset statistics per year and per energy point. The two values in the calibrated fills columns express the number of fills with at least one successful calibration divided by the total number of fills, and the percentage of integrated luminosity collected in calibrated fills

Year	P-2		P		P+2	
	\int Ldt	cal. fills	\int Ldt	cal. fills	\int Ldt	cal. fills
1993	$\sim 10 \text{ pb}^{-1}$	13/38(35%)	$\sim 20 \text{ pb}^{-1}$	1/57(2%)	$\sim 10 \text{ pb}^{-1}$	11/31(45%)
1994			$\sim 60 \text{ pb}^{-1}$	11/167(8%)		
1995	$\sim 10 \text{ pb}^{-1}$	14/22(69%)	$\sim 20 \text{ pb}^{-1}$	1/14(6%)	$\sim 10 \text{ pb}^{-1}$	13/23(65%)

of the peak (‘P+2’ and ‘P-2’). P-2 and P+2 are close to the energies of optimal sensitivity for the measurement of Γ_Z .

The cross sections at the two off-peak points were typically measured in adjacent fills, interspersed with measurements at the peak. This reduces any systematic biases to m_Z and Γ_Z resulting from changes in LEP operating conditions or in experimental efficiencies during the course of each year of data taking.

In 1994 LEP ran only at the peak energy. The delivered integrated luminosities and other information relevant to the energy determination are given in Table 1.

In 1996 the LEP2 programme started, with LEP operating at energies above the W pair production threshold. The data collected during 1996, with improved instrumentation, have been used to confirm the observations of the previous years.

2.2 Resonant depolarizations

The best determination of the beam-energy at a particular time during a fill is by means of RD of the beams. At LEP the beam can build up a non-negligible transverse polarization through the Sokolov-Ternov mechanism [7]. The degree of polarization can be measured by the angular distribution of Compton-scattered polarized laser light. By exciting the beam with a transverse oscillating magnetic field, the transverse polarization can be destroyed when the excitation frequency matches the spin precession frequency. Determining the resonant depolarization frequency⁴ allows a precise determination of the beam-energy E_b through

$$E_b = \frac{\nu_s \cdot m_e c^2}{(g_e - 2)/2} \quad (3)$$

$$= \nu_s \cdot 440.6486(1) [\text{MeV}]$$

where m_e is the electron mass, c the speed of light and $(g_e - 2)/2$ the magnetic-moment anomaly of the electron. Here E_b is the average over the ring, weighted by the vertical magnetic field, and over the beam particles. A

⁴ The resonant condition happens when the excitation RF frequency divided by the LEP orbit frequency matches the non-integer part of the spin tune ν_s . In practice the frequency domain is swept in intervals corresponding to 0.8 MeV

depolarization takes place over many thousand turns of the beams, given that a frequency sweep lasts at least 12 seconds. The precision achievable is 200 keV [3]. The three energies used to scan the Z resonance correspond to spin tunes ν_s (number of electron-spin precessions per turn of LEP) of 101.5 (P-2), 103.5 (P) and 105.5 (P+2). The choice of the off-peak energies derives from the fact that half-integer spin tunes ensure that the beam polarization is sufficient to allow RD calibration. It is fortunate that the Z peak corresponds to a half-integer spin tune.

RD calibration [3] has been a regular operational tool since 1993 and this measurement has become routinely possible with separated beams. Transverse polarization with colliding beams was obtained only in special conditions, far from the physics operation mode. This limitation implies that a precise determination of the LEP average beam-energy can only be made outside physics conditions.

The time necessary to perform the measurement was considerably reduced in 1994 and 1995 as more experience was gained. In 1995 calibration was attempted at the end of each off-peak physics fill (End Of Fill – EOF – calibrations). The number of successful calibrations was larger than in 1993 and the time spent in individual calibrations was significantly reduced. Since one important component of the final error stems from the uncertainty in absolute beam energy for those physics fills without an energy calibration, this results in a significantly smaller uncertainty due to these fills. The improved operational control also allowed the successful calibration of several fills before the beams were put into collision. The six special fills in 1995, with RD both at the beginning and at the end of the fill, will be referred to as BOF-fills in the following.

Typically the RD was performed on the electron beam. From time to time (once or twice per year) the positron energy was also checked.

Table 1 shows the statistics of the calibrated physics fills for the three datasets. As explained later, special Machine Development (MD) studies, where the beam-energy is measured at different times in the same fill, played an essential role and Table 2 lists the details of such fills.

2.3 Monitoring of the dipole magnetic field

The method used to monitor the magnetic field in the LEP dipoles has evolved over the years. The current, which is typically 2000 A at peak energy, providing a field of

Fig. 1. Diagram of a concrete-reinforced dipole cross-section. The approximate positioning of the NMR probe is also shown

≈ 0.05 T, is distributed serially to the dipoles of the ring⁵. It was monitored in 1993 via a DC Current Transformer (DCCT) installed close to the power-supplies in IP2. In 1995 an additional DCCT was installed on the return lead close to IP6 to check for possible leakage to ground at the level of the coil windings along the ring. The current was measured every 15 minutes. In 1995 a special device was installed which allowed the monitoring of the current every second, for short periods of time. Short time structures have been observed at the level of 0.01 A (that is well below the power-supply specification of stability at the 10^{-5} level). There is no evidence that such structures in the main power-supply currents cause detectable short-term fluctuations nor long-term rises of the magnetic field [8].

The only measurement of the dipole field in 1993 was provided by a special reference magnet connected in series with the LEP dipoles. The reference magnet is different from the LEP dipoles: it is a high precision iron-core magnet as opposed to the cheaper concrete-reinforced dipoles used in the tunnel; it is installed in a thermally controlled environment in a surface building. To monitor changes of the field this reference magnet houses a flip-coil device and an NMR probe, which are both recorded every eight minutes. In 1994 a short section of vacuum-chamber was mounted in the magnet and a new NMR probe positioned in the middle of it to measure the field in conditions closer to those experienced by the beam.

In 1995, direct measurements of the dipole field were provided by two additional NMR probes which were installed on top of the vacuum-chamber in two dipoles located in the LEP tunnel near IP4 (NMR4) and near IP8 (NMR8) as sketched in Fig. 1. In 1996 14 additional NMR probes were installed: in this configuration all eight of the LEP octants had a probe and in two octants strings of ad-

acent magnets were monitored. The measurements from 1996 are used to verify the observations made in 1995.

2.4 Flux-loop calibrations of the field

A loop covering the cross-section of the dipole field [9] has been placed inside the LEP dipoles (see Fig. 1). The voltage induced in this loop while cycling the magnets provides a measurement of the field integral produced by the LEP dipoles. It is performed without beams and was repeated regularly (typically once every two weeks) to follow the overall behaviour of the accelerator field in 1993. Given the confidence in the more precise NMR measurements, and the fact that the extended magnetic cycle for the flux loop measurement was clearly affecting the magnetic history of the magnets and complicating the accelerator operation, it was decided to perform only two such measurements in 1995, at the beginning and at the end of the running period.

2.5 Magnet cycling

Before each physics fill the magnets are cycled at least five times (*demagnetization cycle*), between +300 A and +2900 A to reproduce the initial magnetic conditions, after which the accelerator is injected with positrons and electrons at 20–22 GeV. Ramping to the final energy was performed differently for different years. In 1993 the accelerator was ramped to 44.12 GeV and then ramped, after a pause, to the final energy. In 1994 LEP was ramped directly to the peak energy. In 1995 the first ramp was directly to P–2 and, when needed, a second ramp was made to P or P+2. There is no evidence that this slight variation of the magnet cycles affects the energy model. In 1993 (and in 1995) a small and unexplained drift of the field of the reference magnet was measured by the NMR probe. A few erratic field jumps (believed to be caused by power-supply spikes) were also observed. Thinking that a possible cause for both these effects could be related to the fact that the dipoles work far from saturation (0.05 T vs. 1 T) and that some additional conditioning could help reduce this effect, a special magnet cycle was developed (referred to in the following as *bending modulation*). It consisted in modulating the main dipole current by a sequence of, typically, seven square pulses (of amplitude equivalent to roughly 10 MeV) over a time of two minutes, after the operational energy had been reached and before colliding the beams [8]. The bending modulation was commissioned in the first part of the 1995 run and used regularly from fill 2953 onwards (53% of the 1995 data was delivered after bending modulation).

2.6 Magnet temperature

Each accelerator octant is structured in 60 ‘half-cells’, each comprising six dipoles, a quadrupole and a sextupole. Each octant has an independent cooling circuit. The

⁵ LEP comprises 3280 concrete-reinforced dipoles, 32 weak dipoles for special sections of the accelerator and 24 injection dipoles, providing respectively 98.37%, 0.19% and 1.44% of the total transverse magnetic field

Fig. 2. Schematic diagram of the RF distribution around the LEP ring during the LEP1 phase. The shaded modules show the superconducting cavities which were installed and commissioned during the 1995 energy scan. Additional superconducting cavities were installed around IP8 and IP4 only after LEP1

chilled water is supplied in parallel to each half-cell where a local manifold distributes it to the dipoles, quadrupole, sextupole and vacuum-chamber circuit. The temperature of the incoming and outgoing water is logged for each octant. The actual temperature of the accelerator is estimated from a set of high precision (0.1°C) resistive platinum temperature probes inserted in the cores of 32 dipoles uniformly distributed (four per octant) around the ring. In 1993 and 1994 the temperature of the chilled water was kept constant in each octant. In 1995 a new control regulation was introduced aiming to maintain the core temperature as constant as possible. The reason for this was to reduce the related variations of magnetic field, leading to more stable accelerator conditions, and smaller energy corrections. The new system changes the chilled water temperature in each octant (in steps of 0.1°C per hour) based on the feedback of four temperature probes inserted in the dipole cores in order to maintain a preset average core temperature.

2.7 Quadrupole-current imbalance compensation

A different phase advance in the horizontal and vertical planes of the LEP optics means that in the quadrupole power bars running around the LEP ring at a distance of roughly 1 m from the vacuum-chamber, there is a current difference between the circuit feeding the focusing (QF) and defocusing (QD) quadrupoles which run respectively clockwise and anticlockwise around the ring.

For the datasets considered here, LEP was operated with an optics based on a phase advance in the vertical plane (60 degrees) different from the one in the horizontal plane (90 degrees). The net current difference amounts to 33 A, which produces a field of $6.6\ \mu\text{T}$ at the position of the beam in the vacuum-chamber. A compensation circuit, known as the QFQD compensation loop, has been

installed around the ring in order to eliminate the effects of this stray field. This compensation circuit was used in 1993 and 1994. The control system of the power-supply for this compensation circuit proved rather unreliable, so in 1995 it was decided not to use it and instead to cope with the small additional constant component of the field.

2.8 Radiofrequency distribution

In 1993 and 1994 the power lost by the beam due to bremsstrahlung, about 125 MeV per turn, was provided by the original set of copper cavities (CU-RF) distributed symmetrically along the straight sections close to IP2 and IP6. In 1993, during the energy scan, a precondition for running off-peak was to have a stable and symmetrical RF configuration: this stability requirement minimized the spread of the IP-dependent RF corrections and allowed for interpolation when RF system data were missing. In 1995 the energy scan was performed concurrently with the commissioning of the first set of superconducting RF cavities (SC-RF) to be used in preparation for LEP2. Two SC-RF units were installed for testing in 1994, but were not used extensively, and had negligible effect on the 1994 beam-energy.

New cavities were installed around IP2 and IP6 (see Fig. 2). Most of the power was available at IP6 and the accelerator was operated for a large fraction of time with a highly asymmetric and somewhat unstable RF configuration. The recording of the RF data became essential to the calculation of the IP-dependent corrections and having the recording system fully working became a precondition for running off-peak. Additional measurements were made at later dates to determine parameters for the new cavities and reduce the associated errors.

2.9 Effects related to the LEP mode of operation

LEP operated in 1993 and 1994 in ‘pretzel’ mode. Eight equally spaced bunches of electrons and positrons collided at each of the four experimental IPs. The unwanted encounters at mid-arc were avoided by causing a pretzel-like oscillation of the two beams in the horizontal plane, which provided the necessary separation where the beams crossed. The pretzel oscillation was not large enough to provide enough separation in the odd IPs so additional vertical separators were available to prevent unwanted collisions. No significant side-effect on the average centre-of-mass energy determination has been seen from this mode of operation.

In 1995 LEP was operated in ‘bunch-train’ mode. Four equally spaced trains of up to four bunches (separated by 247 ns) crossed at each IP. All bunches in the same relative position within a train belonged to a *family*: the first bunch on the train belongs to family A while the fourth belongs to family D. In practice LEP operated for most of the time with only three families or less. A rearrangement of the available electrostatic separators provided a vertical separation *bump* around each IP to prevent unwanted

collisions outside the experimental areas. The vertical separation bumps cause a non-negligible vertical dispersion at each IP⁶ which has a different sign between positrons and electrons. This effect could have been a serious problem for the determination of the centre-of-mass energy at a given IP. Having anticipated the problem, the LEP energy team was successful in maintaining it at a negligible level, mostly through a careful control of the collision offsets (Sect. 10.3).

2.10 Beam position monitors and orbit correcting coils

For a large number of quadrupoles there is a Beam Orbit Measurement (BOM) [10] monitor made of four capacitive electrodes able to measure with a precision of a few microns the relative position of the beam with respect to the centre of the quadrupole. In total there are 504 BOMs around the ring that sense the transverse position of the beam. In particular they can be used to track the average orbit deviation in any octant of LEP. The change of the average beam orbit radius (ΔR) is related to the relative change of LEP energy (ΔE) through

$$\Delta R = D_x^{\text{BOM}} \cdot \frac{\Delta E}{E_0} \quad (4)$$

where D_x^{BOM} is the horizontal beam dispersion at the BOM and E_0 the average beam-energy. The horizontal dispersion is significant only in the curved sections of LEP (arcs) and hence the 240 BOMs in the arcs are important to monitor radial changes of LEP. The measurements from all of the BOM stations are logged whenever the accelerator operator monitors the beam trajectories (*orbits*), which occurs every 10 minutes or less. These sets of data are analysed to reject monitors that are not working properly for the complete data sample and that might bias the results for some orbits: typically 50 BOMs are rejected for a given year. The reproducibility of the ΔR measurement is estimated from the 1993 and 1994 datasets to be $8 \mu\text{m}$ within a fill and $15 \mu\text{m}$ between fills. This precision permits the use of the radial changes to monitor long-term trends (see Sect. 7).

For most quadrupoles there is also one correcting coil (corrector) used to steer the beam vertically or horizontally through the centre of the quadrupole. The correctors are weak dipole windings mounted next to the quadrupole. The changes of current in each corrector are logged for off-line analysis (see Sect. 8.1).

2.11 The ISR test facility

In 1996 a laboratory was established in the tunnel formerly housing the Intersecting Storage Ring (ISR) accelerator

⁶ The *dispersion* of a beam at a given point of the orbit is the parameter describing the level of spatial ordering of particles of different momentum $D_x = \frac{\partial x}{\partial E} \cdot E_0$ where x is a spatial coordinate transverse to the direction of motion and E_0 is the mean (central orbit) energy. It varies along the orbit and depends on the accelerator optics configuration

in order to investigate the behaviour of the magnetic field of the LEP dipoles. Particular importance was given to studies of temperature dependence and to an accurate reproduction of the LEP configuration. In this laboratory one of the LEP concrete dipoles was assembled around a replica of the LEP beam pipe with a cooling system similar to that of LEP. The dipole excitation bars and cooling circuit could be operated to reproduce any phase of a LEP fill. A special device allowed the ‘play back’ of parasitic currents recorded during LEP operation.

The results of the measurements at this test facility have been essential to the understanding the detailed thermal behaviour of the LEP dipoles.

3 The LEP energy model

As stated earlier, precise beam-energy measurements by RD can be performed only with separated beams. A model of the accelerator behaviour is needed to correct for the differences in the beam energy between physics and RD conditions. In addition, the model is used to predict variations of beam energy with time throughout data-taking. The absolute scale of the predictions of such a model is determined by the RD measurements.

The average beam energy (as measured by RD) is determined by the integral around the ring of the vertical component of the magnetic field seen by the beam. There are several contributions to this field integral: the main one comes from the field produced by the LEP dipoles which is sensitive to temperature and parasitic currents; the second is the bending field from off-centred quadrupoles which is affected by variations in the LEP circumference, in particular changes due to terrestrial tides; and finally, the additional fields generated by the quadrupole-current imbalance compensation loop and horizontal-orbit correctors must be taken into account.

Determining the parameters which can influence the field integral for a ring of 27 km circumference has proven to be a formidable task. New understanding has been accumulated over the years about the behaviour of the dipoles, of the geology of the Geneva area and the LEP civil engineering structures. In this section the various contributions to the determination of the experimental average beam energy are discussed. The model parametrization is introduced, followed by a detailed discussion of the various model components: the thermal behaviour of the LEP dipoles, a discussion of the evidence for unforeseen field drifts and the details of how they have been parametrized, the tidal and hydrogeological effects influencing the accelerator size and the variation of the accelerator lattice.

The LEP beam-energy variation, as a function of the time t , is computed every 15 minutes according to the following formula:

$$E_b(t) = E_{\text{norm}}(\text{fill}) \cdot (1 + C_{\text{rise}}(t_{\text{day}}, t_{\text{fill}})) \cdot (1 + C_{\text{T-dipole}}(t)) \cdot (1 + C_{\text{tide}}(t)) \cdot (1 + C_{\text{orbit}}(\text{fill})) \cdot (1 + C_{\text{h.corr.}}(t)) \cdot (1 + C_{\text{QFQD}}(t)) \quad (5)$$

In this equation E_{norm} is used for absolute normalization, whereas all other terms follow the relative energy changes. The individual effects are discussed in the following Sections and the meaning of each of the terms is explained below.

- E_{norm} is different depending on whether or not the fill in question was calibrated using the RD method. If it was, then this normalization factor ensures that the energy of the model at the moment of the calibration equals the value of the calibration for this fill. If it was not, this term is equal to the mean normalization factor of all the calibrated fills at that energy point (Sect. 6.1.2).
- $C_{\text{rise}}(t_{\text{day}}, t_{\text{fill}})$ is the term accounting for the rise of the bending field due to the parasitic currents flowing along the beam-pipe. It is parametrized as a function of the time-of-day, t_{day} , and time since the magnet reached the final field, t_{fill} (Sect. 6.1). This term is new in the analysis.
- $C_{\text{T-dipole}}$ is the temperature correction for the ensemble of ring dipole magnets (Sect. 5). The understanding of this term is substantially improved in this analysis.
- C_{tide} is the correction due to the effect of the Earth tides [11] [12] (Sect. 7.1).
- C_{orbit} is the correction for the deviation of the horizontal position of the orbit from a *central orbit* with no quadrupole bending component. This effect is calculated using an average orbit position for each fill after the expected variations for tide have been removed (Sect. 7.2).
- $C_{\text{h.corr.}}$ is the correction due to the setting of the horizontal correctors (Sect. 8.1). This term is new in the analysis.
- C_{QFQD} is the correction for current in the QFQD compensation loop (Sect. 8.2).

The actual centre-of-mass energy for a given IP is computed from

$$E_{\text{CM}}^{\text{IP}}(t) = 2 \cdot E_{\text{b}}(t) + \Delta E_{\text{RF}}(t) + \Delta E_{\text{disp}}(t) + \Delta E_{\text{e}^+} \quad (6)$$

where

- ΔE_{RF} is the correction, different for each IP, due to the RF system (Sect. 10.1).
- ΔE_{disp} is the correction (only for 1995), different for each IP, due to the combined effect of opposite-sign vertical dispersion and beam offsets (Sect. 10.3).
- ΔE_{e^+} accounts for the possible difference of positron and electron average energies (constant for each year).

All the corrections, with the exception of E_{norm} and C_{orbit} , are applied according to the conditions at that particular time, whereas E_{norm} and C_{orbit} are applied on a fill-by-fill basis. The information is given to each experiment in the form of a file containing the modelled centre-of-mass energy at the given IP for every 15 minutes. These files are used in convolution with the experimental data to arrive at the luminosity-weighted mean energies and rms scatters which are used to determine the Z resonance parameters.

4 Field rise in a fill and related observations

In 1995, both the six BOF-fills and the tunnel NMRs indicated that, rather than remaining constant, the field of the LEP dipoles rose throughout a fill. This rise was significantly larger than that previously observed in the reference magnet.

The BOF-fills exhibited a rise in the beam-energy. The mean rise between first and last depolarization was 3.9 MeV. This mean has a significant rms scatter of 2.6 MeV as can be seen from Table 2. Some of this scatter can be attributed to the variation in the length of the fills (between 6 and 20 hours), but the rate of energy change was not identical in all fills. Part, but not all, of this rise can be attributed to temperature effects, as detailed in Sect. 5, which can lead to significant drifts of the dipole field.

Throughout 1995, the NMRs also recorded an increase in the dipole field over the fills. Assuming that this can be related to the beam-energy, the field change is equivalent to a rise of a few MeV over a typical fill. The field change observed was not necessarily the same in NMR4 and NMR8; the relative rises in both varied from fill to fill, as did the absolute size of the increase.

In addition to revealing a field rise, the NMRs displayed significant short term fluctuations with typical frequencies of around 1 Hz. This noise was found to be strongly anticorrelated between NMR4 and NMR8; this is shown in Fig. 3a. Occasionally, sudden field jumps could be observed with magnitude equivalent to an energy change of up to a few MeV.

The fluctuations in the NMRs were found to have an unexpected dependence on time of day. Much quieter behaviour was observed between midnight and about 05:00, at which point the noise resumed.

Averaged over many fills however, the behaviour was distinctive, as can be seen from the solid circles in Fig. 3d, which shows the relative rise seen by the NMR probes since the beginning of the fill. The rise is at first steep, but after about 10 hours tends to saturate. The rate of field increase per hour as a function of time into a fill is shown in Fig. 3c. The field rise was also studied as a function of time of day: the rise was found to be much smaller in the ‘quiet period’ than in the remainder of the day. The rise as a function of time of day is shown in Fig. 3b.

Eventually the NMR noise was correlated with the measurement of a current flowing on the LEP beam-pipe. This current fluctuates in amplitude with time and position around the LEP ring, with a typical magnitude of about 1 A. It enters close to the beam-injection lines at IP1 and flows in both directions around LEP, exiting near the Versoix river at IP6 (Fig. 4). The current’s behaviour in the regions of NMR4 and NMR8 is consistent with the anticorrelated noise seen in these devices.

These observations led to the definition of the pseudo-device NMR48, where

$$\text{NMR48} \equiv \frac{5}{8}\text{NMR4} + \frac{3}{8}\text{NMR8} \quad (7)$$

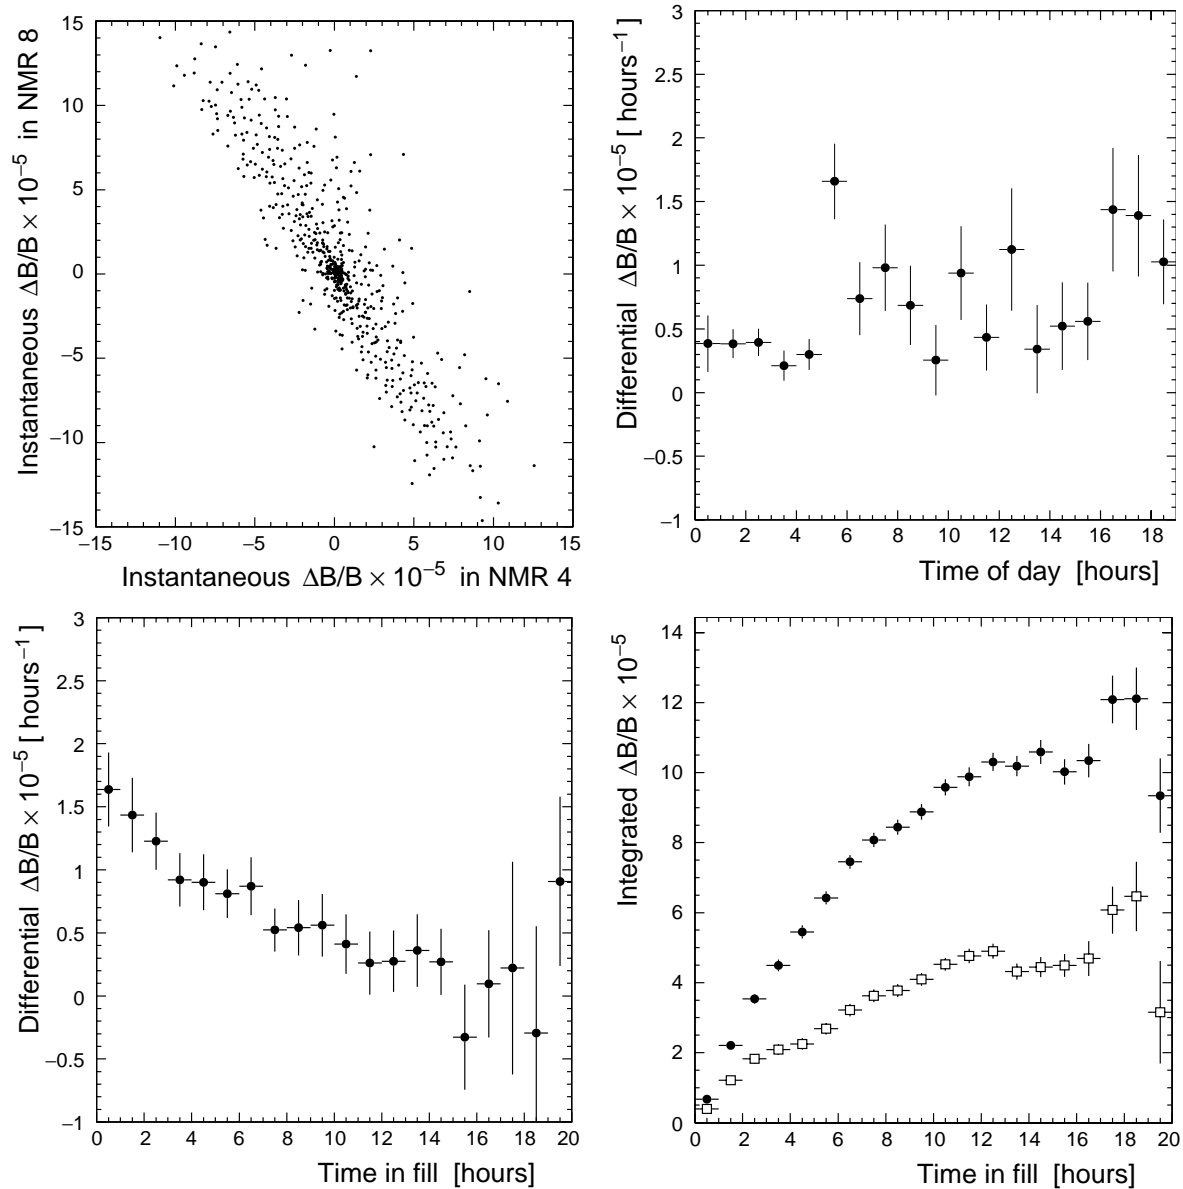

Fig. 3a–d. NMR behaviour in 1995: b, c, d are obtained using NMR48 as defined in (7). **a** Noise in NMR4 vs NMR8, **b** Differential field rise vs. time in day, **c** Differential field rise vs. time in fill, **d** Integrated field rise in fill: The black dots show the total rise, the open squares are after the subtraction of temperature effects

yields an ‘average NMR’ sampling the field at both positions around the ring, eliminating almost completely the anticorrelated noise.

The choice of coefficients in (7), defining NMR48, was based on the assumption that each NMR represents the average behaviour of, respectively, the three or five octants between IP1 and IP6. This assumption is confirmed by the detailed measurements of the amplitude of the parasitic current flowing along the beam-pipe.

The current arises from electrical trains passing along the Geneva–Bellegarde railway line [13]. A fraction of the direct current powering the trains leaks to Earth when returning to the generator station, and this leakage current passes through the Earth and on to the LEP beam-pipe.

The quiet period between midnight and 05:00 is a consequence of there being no trains running in the area at this time. A dedicated experiment monitoring the voltage between the train rails and Earth recorded a signal clearly correlated with the variations in the beam-pipe current and the NMR field (see Fig. 5).

The currents flowing on the beam-pipe perturb the magnetization status of the iron. The tendency to saturate apparent in Fig. 3d is due to the finite amplitude of the current spikes. The level of saturation depends on the combined effect of temperature and current peak patterns (see Fig. 6 and Sect. 5).

For the 1996 high energy running, in addition to NMR4 and NMR8, probes were installed in the other octants

Table 2. Fills with multiple RD calibrations, i.e. fills where the first RD and last RD were separated by at least two hours. t_f is the time of the first calibration after the start of the fill, Δt denotes the time between the first and the last calibration, ΔE_b^{raw} denotes the measured beam-energy difference between the last and the first calibration, ΔE_b^{corr} is the beam-energy difference corrected for the effects of the tide, horizontal correctors, QFQD loop compensation and ring deformation (see Sects. 7 and 8). ΔE_b^{corr} shows clear evidence for additional sources of energy increase

Year	Fill number	Energy	t_f	Δt	ΔE_b^{raw} (MeV)	ΔE_b^{corr} (MeV)
1993	1636	P-2	2h	3.5h	6.1	1.3
1993	1734	P-2	2h	4h	0.6	1.7

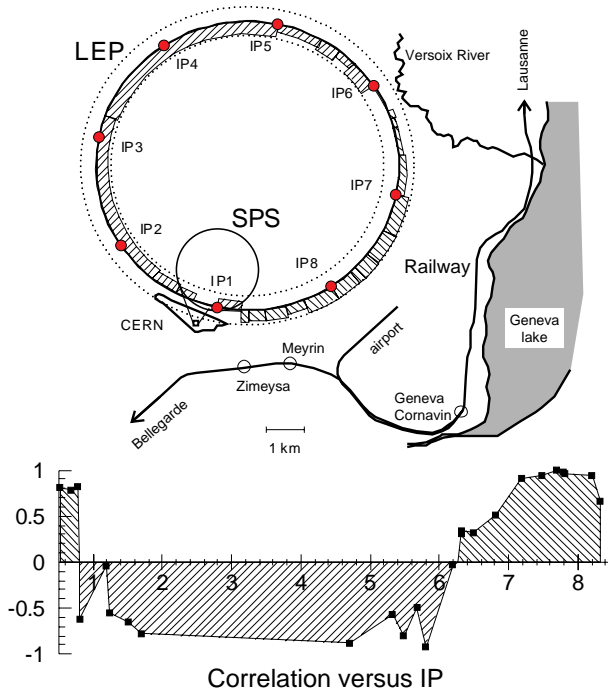

Fig. 4. Diagram of CERN accelerators and surroundings. The measured correlation pattern of the parasitic currents along the ring is shown, proving that they enter and leave LEP near IP6 and IP1

to provide additional sampling of the magnets around the ring. Two octants were instrumented with five probes each, giving a total of 16 NMRs. The data from these devices enabled a cross-check of the behaviour observed in 1995 to be made with a larger sample of magnets. In comparing the data of the two years, certain differences in operating conditions had to be taken into account. In particular, in 1996 the magnets were run at approximately twice the field and had a more significant temperature excursion. In addition, no bending modulation was performed prior to the start of a fill.

The 1996 NMR data indicated a field rise in all octants. The three octants between IP1 and IP6 behaved in a similar manner to that seen in NMR8, with sudden steps in field, while the smoother field evolution in the remaining five octants was similar to that seen by NMR4 (see Fig. 7). The short-term noise was anticorrelated around the ring in a manner expected from the measurements of the current on the beam-pipe as shown in Fig. 4. This supports the choice of coefficients in (7). The variation of the short-term noise and of the field rise itself with time of day and time into fill confirmed that observed in 1995. The rise averaged over all the octants was compatible with that seen in the weighted mean of octants 4 and 8. This demonstrates that the pseudo-device NMR48 is representative of the LEP ring as a whole. Further discussion of these phenomena can be found in [8, 13, 14].

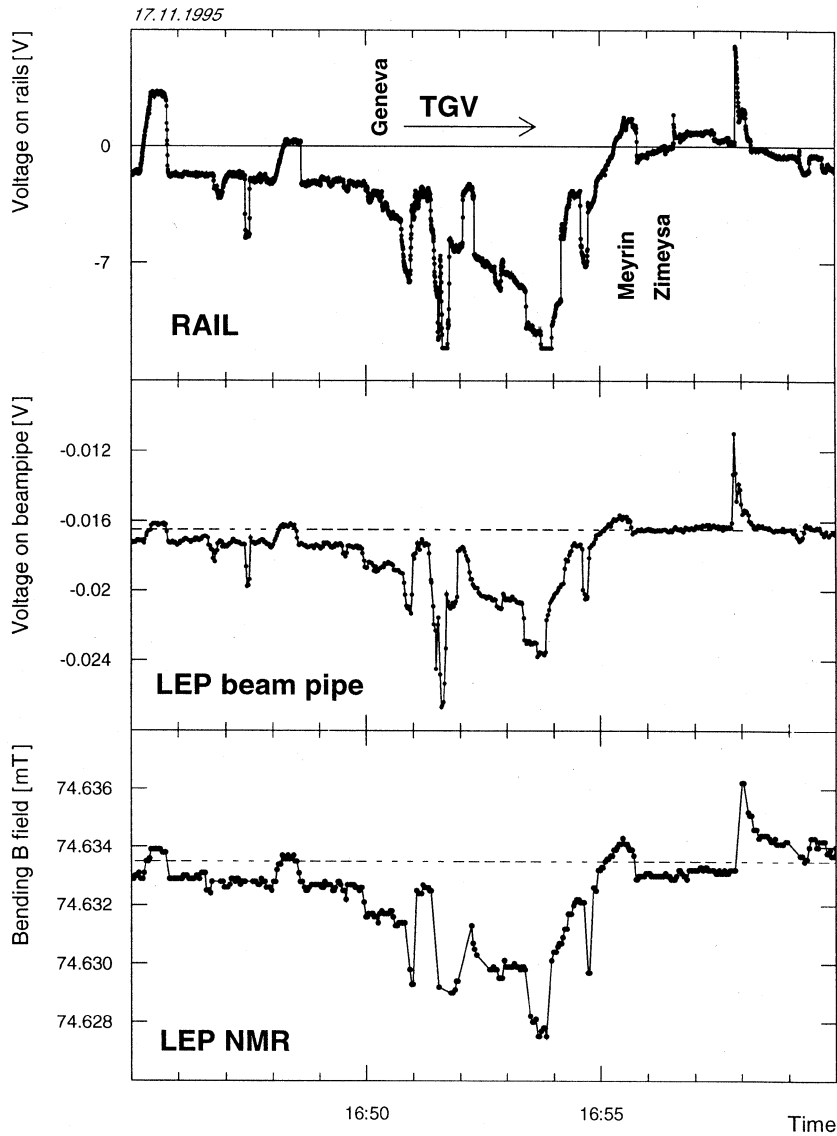

Fig. 5. The synchronous measurement of the voltage difference between ground and the train rails (*top*), the voltage difference between the LEP beam pipe and ground (*middle*) and the NMR readings (*bottom*). The correlation is obvious. The label ‘Geneva’ marks the time of the departure of the TGV (‘Train à Grande Vitesse’) from Geneva central station. The label ‘Zimeysa’ indicates the time when the TGV went past the measuring device

5 The temperature behaviour of a LEP dipole

The thermal behaviour of the LEP magnet cores is driven by several heat sources, sinks and the resulting temperature gradients. The major power sources are resistive-loss heating of the excitation bars, synchrotron radiation on the beam-pipe and the cooling water which circulates along both the beam-pipe and the excitation bars. The power transfer to the air happens mostly by radiation exchange as the small temperature difference between the air and the magnets is not sufficient to drive a strong convective motion.

The temperature variations induced by all of these effects produce distortions of the geometry of the LEP dipoles.

- The C-shaped dipole cores (see Fig. 1), and thus the gap between the poles, tend to expand due to the average temperature variation and to open or close depending on the temperature gradients around the magnet excitation bars.

- The thermal expansion of material leads to variation of the pole area.
- Thermally induced stresses arise at the contact interface between the soft iron slabs and the concrete. These result in a change of pressure propagating to the centre of the slabs which modifies the relative permeability coefficient of the iron [15] and introduces thermal hysteresis effects in the field. This is the dominant thermal effect influencing the magnetic field.

From the test laboratory (see Sect. 2.11) the dependence of the field on measurable quantities such as the core and cooling-water temperature could be derived experimentally.

5.1 Experimental results

Figure 8 shows the result of a particular experiment used to determine the thermal model for the LEP dipoles. This experiment, which lasted over eight days, consisted of five

Fig. 6. The NMR recording from one of the LEP dipoles (*top figure*) is compared with the NMR readings from the test dipole in the laboratory (*middle figure*) when the parasitic current recorded from the LEP beam-pipe (*bottom figure*) is ‘played back’ on the section of beam-pipe inserted in the laboratory dipole

periods. Each of these starts with a *demagnetization cycle*, described in Sect. 2.5. The current is then set to 2000 A, which is the value used to run LEP at the Z peak energy.

In the following period (varying from 10 to 40 h) the temperature of the cooling water is changed in a controlled way. The core temperature follows these changes with a time constant of 5.5 h. Unexpectedly the first period shows a monotonic rise of the field for both increasing and *decreasing* core temperature. The second and the third are partial repetitions. The fourth and the fifth show both increase and decrease of the magnetic field by applying the reverse temperature variation pattern with respect to the first.

The agreement between experiments sharing the same conditions and history is quite good, while applying a different history or simply reversing the time order of the temperature variations produces different results.

The model used previously [4], where the field changes were simply proportional to the temperature variations ($\Delta B = C_T \cdot \Delta T$), cannot reproduce these observations.

5.2 The thermal model

The model developed to describe the thermal behaviour of LEP dipole magnets includes five temperature param-

eters:

$$B = B_0 \cdot [1 + C_{T_i} \cdot (T_i - T_0) + C_T \cdot (T - T_i) + C_{T_{\text{GRAD}}} \cdot (T - T_W) + C_{T_{\text{MAX}}} \cdot (T_{\text{MAX}} - T_i) + C_{T_{\text{MIN}}} \cdot (T_{\text{MIN}} - T_i)] \quad (8)$$

where T_0 is the reference temperature, T_i is the core temperature at the beginning of the period, T is the dipole core temperature, T_W is the cooling-water temperature, T_{MAX} and T_{MIN} are respectively the maximum and minimum core temperatures since the beginning of the period, B is the corrected magnetic field and B_0 is the magnetic field at $T_i, T, T_W, T_{\text{MAX}}, T_{\text{MIN}} = T_0$.

From experience accumulated at the test facility, the phenomenological description of the parameters is as follows:

- C_{T_i} : this term accounts for changes in the geometry of the magnets as well as stresses in the iron.
- C_T : this term arises mainly from bulk change of size of the cores without stress variation in the interface region.
- $C_{T_{\text{GRAD}}}$: the temperature gradient across the section of the magnet changes the size of the air gap. The temperature difference between the core and the cooling-water is taken as an estimate of this gradient since the thermal conductivity of the aluminium (coil) is much larger than that of the concrete.
- $C_{T_{\text{MAX}}}, C_{T_{\text{MIN}}}$: the underlying explanation for these parameters is not fully understood. Large variation of the stress status in the interface region seems to be the main cause.

The values of the five coefficients measured for the test magnet were:

$$\begin{aligned} C_{T_i} &= (6.4 \pm 0.6) \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1} \\ C_T &= (-3.3 \pm 0.3) \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1} \\ C_{T_{\text{GRAD}}} &= (0.4 \pm 0.04) \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1} \\ C_{T_{\text{MAX}}} &= (12.0 \pm 1.2) \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1} \\ C_{T_{\text{MIN}}} &= (-4.2 \pm 0.4) \cdot 10^{-5} \text{ } ^\circ\text{C}^{-1} \end{aligned}$$

The most important parameter is $C_{T_{\text{MAX}}}$ since it is the largest one and T_{MAX} has the greatest variation during LEP physics fills. The 10% relative error on the determination of these parameters is assigned based on the quality of the fits and the reproducibility of the experimental determinations. The uncertainties on these parameters for the well known and controlled test magnet are, in any case, smaller than the final error on the same parameters for LEP due to the spread of characteristics of the 3336 LEP dipoles.

5.3 Application to the LEP environment

The cooling system of LEP is operated in such a way that the gradient term $C_{T_{\text{GRAD}}} \cdot (T - T_W)$ is always negligible.

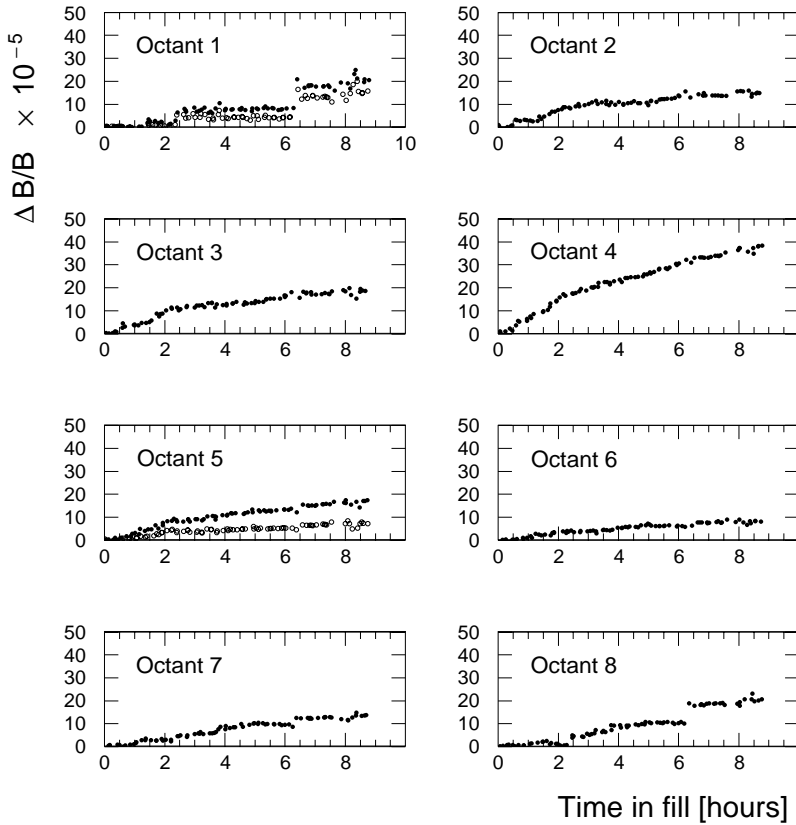

Fig. 7. The fractional field rise observed by the NMR probes in each of the LEP octants for a typical fill in 1996 at a beam-energy of 86 GeV. Octants 1 and 5 are equipped with five probes, of which the two exhibiting the minimum and maximum rise are displayed. Each dipole has experienced a different temperature excursion; for instance the temperature rise for the instrumented magnet in octant 4 is three times that for octant 6. The nonlinear behaviour caused by parasitic currents on the beam-pipe is evident in octants 1, 7 and 8

The term $C_{T_i} \cdot (T_i - T_0)$ is constant within a fill by definition since T_i can vary only from fill to fill: most of its effect is absorbed into the overall offset for a fill (E_{norm} in (5)) and for simplicity this term was ignored. Checks were performed by including this term in the model: the largest observed change in the mean energy of any energy point was 0.03 MeV, and is thus negligible.

The typical temperature profile for the 1993 and 1994 physics fills is monotonically increasing (Fig. 9, left). In this case the $C_{T_{\text{MIN}}}$ term is always zero and the use of a single parameter equal to $C_{T_{\text{MAX}}} + C_T$ is sufficient to parametrize the field variation, proportional to $T - T_i$.

In 1995 the situation was different, since the cooling regulation was changed to reduce temperature excursions in the magnets (see Sect. 2.6). In this case the profile was of rising temperature for the first few hours and then a partial decrease (Fig. 9, right). Even in 1995 the temperature of the magnets rarely decreased below the initial temperature, T_i , making the $C_{T_{\text{MIN}}}$ term irrelevant.

The model can then be simplified and reduced to only two parameters, one to be used during increases and one during decreases of the mean temperature of the magnet cores.

$$\frac{1}{B_0} \frac{dB}{dT} = \begin{cases} C_{T_{\text{MAX}}} + C_T \equiv C_{\text{eff}} & \text{if } \frac{dT}{dt} > 0 \\ C_T & \text{if } \frac{dT}{dt} < 0 \end{cases} \quad (9)$$

Since $C_{\text{eff}} > 0$. and $C_T < 0$., the application of this model to all periods of LEP operation results in a monotonic increase of the magnetic field.

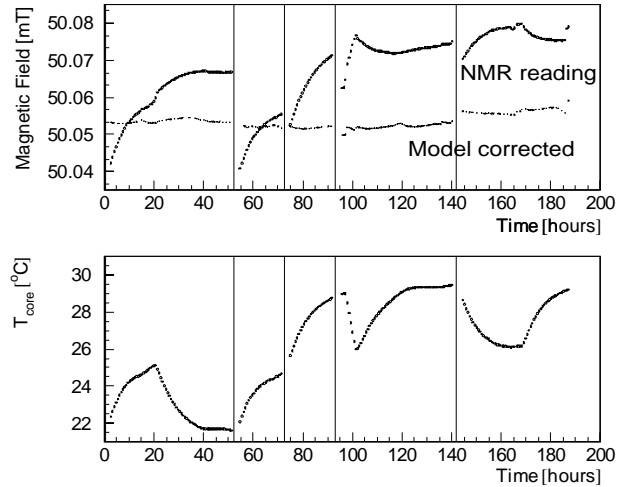

Fig. 8. Temperature experiment performed at the ISR test facility. The two lines in the top figure represent the raw magnetic field and that which is obtained after subtraction of the contribution due to temperature effects. The lower figure shows the mean temperature of the magnet. Vertical bars mark each demagnetization cycle

5.3.1 Interplay between temperature and parasitic-current effects

Because both temperature changes and parasitic currents on the beam-pipe (see Sect. 4) generate field rises, it is difficult to disentangle the two contributions. Moreover,

Fig. 9. Average temperature profiles during 1993 and 1995 LEP physics fills. For 1994 the temperature profile is the same as in 1993

the way these two effects combine is not straightforward: studies performed at the test facility have shown that the two sources of drift compete to determine the saturation level of the dipole field. The dipole-field rise is described as a superposition of the effect of temperature and of the instantaneous current flowing on the beam-pipe. Any current spike has an effect only if, when added to the underlying drift due to temperature, its amplitude exceeds that of any of the preceding spikes. From the laboratory measurements it is seen that only approximately 65% of the instantaneous field due to these spikes is left as permanent magnetization of the dipole. A given field can be reached either by a temperature variation or by means of a current spike, whichever comes first. For example, when a large current spike causes a jump in the field, the field will stay constant until either the temperature-induced variations reach an equivalent level or a larger spike happens. The saturation effects are explained both by the stabilization of the dipole temperatures and by the finite amplitudes of the current spikes. In fact, the random time distribution of the largest current spike explains, at least qualitatively, the variation on a fill-by-fill basis of the time evolution of the field drifts. The magnet is reset only after a demagnetization cycle. An empirical model including these features has been developed which predicts quite well the field variations [16]. The model demands the knowledge of the current flowing on the beam-pipe. As this input parameter was not generally available, an approximated version has been developed to cross check the LEP field model used to deliver the experimental energies (see Sect. 6.2).

5.4 Determination of LEP temperature coefficients

The parameters shown in (9) have been determined from the LEP dipoles themselves using the data of 1996. The 16 dipoles equipped with NMR and temperature probes enabled a better sampling of the average ring behaviour than the two dipoles, NMR4 and NMR8, which had been equipped in this manner during 1995. Furthermore, the large temperature excursions of about 1°C during the high-energy running of 1996 produced a suitable data set to study the temperature behaviour of the magnets. This is

to be compared with 1995, where the short-term temperature variations were only about 0.2°C and similar to the precision of the measurements. In the determination of C_{eff} of (9) all high-energy physics running in 1996 was analysed.

Successive recordings at intervals of six minutes were considered, and the relative field change $\Delta B/B$ was plotted against the absolute temperature change ΔT . This was done for the first eight hours of fills, during which the temperature was continuing to rise. Intervals with large field jumps, presumably induced by stimulation from parasitic currents, were discarded.

A linear fit was made in $\Delta B/B$ against ΔT for the region $\Delta T > 0$. This fit was made both for the mean behaviour of all the instrumented dipoles, to represent the ring, and for the weighted mean of NMR4 and NMR8 using the coefficients of (7), to represent the pseudo-device NMR48 used in the energy-rise modelling. To assess systematic stability, the analysis was restricted to the period $0 < t_{\text{day}} < 5$ hours, the definition of ‘large field jump’ was varied and the fit range and the bin width were changed. In addition, complementary analyses were performed where the temperature coefficient was fitted simultaneously with terms representing independent field variation caused by the beam-pipe current (Sect. 5.4.1).

The results of the various fits showed a significant variation, indicating the presence of systematic effects and the difficulty of separating the parasitic current and temperature-driven behaviour. An effective coefficient C_{eff} , of $10 \cdot 10^{-5}/^\circ\text{C}$ was found to describe both the ring and NMR48 data, with uncertainties of $\pm 30\%$ and $\pm 60\%$ respectively. Example fits to $C_{\text{eff}}^{\text{ring}}$ and C_{eff}^{48} for the ring and NMR48, are shown in Figs. 10a and b respectively. The NMR jumps are bigger and more frequent in octant 8 than elsewhere in the ring, leading to the larger error for C_{eff}^{48} .

To determine the effective coefficient C_T for periods in which the dipole temperature decreases, a dedicated experiment was performed during fill 3822 in 1996. Without beam in the machine the dipoles were ramped to 45 GeV with the cooling system inhibited. This provoked a steady rise in core temperature. At about 02:00 the cooling was re-enabled, and a decrease in core temperature of about 1°C was observed in the next three hours. As expected

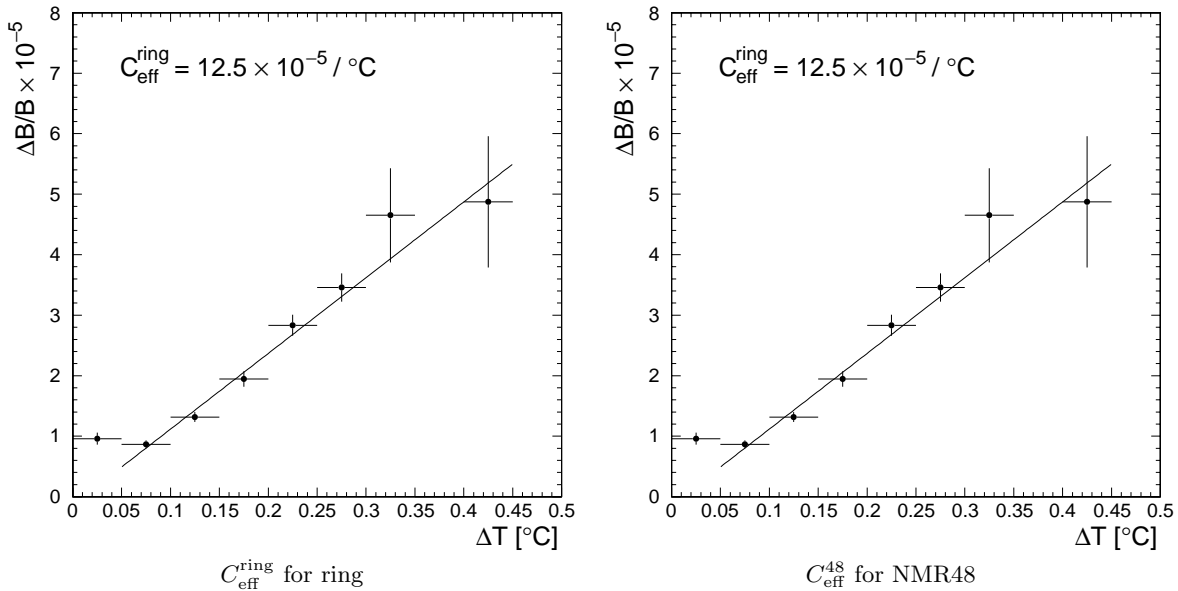

Fig. 10. Example fits to the coefficient $C_{\text{eff}}^{\text{ring}}$ for the ring and C_{eff}^{48} for NMR48. These data are restricted to the period $00:00 < t_{\text{day}} < 05:00$, and yield the fits with the maximum deviations from the estimated central values for these coefficients

from the laboratory temperature model, the temperature decrease was accompanied by a rise in the field of the dipoles, as monitored by the NMR devices. The relative change in the temperature and dipole field with respect to the reading at midnight is shown in Fig. 11.

Because the field rise occurred during the period in which noise currents are at a minimum, it can be attributed directly to the change in temperature. In extracting the temperature coefficient C_T from these data, the full temperature model must be invoked, taking account of the terms involving $C_{T_{\text{GRAD}}}$ and $C_{T_{\text{MIN}}}$ in expression (8), as the conditions of the experiment are sufficiently extreme as to render these effects significant. The values of $C_{T_{\text{GRAD}}}$ and $C_{T_{\text{MIN}}}$ were fixed to those measured for the laboratory dipole, and C_T determined for each instrumented dipole. The results obtained were similar in magnitude to the coefficients found for the laboratory dipole. A value of $C_T = (-5.0 \pm 2.5) \cdot 10^{-5} / ^{\circ}\text{C}$ was adopted, for both the ring as a whole and the pseudo-device NMR48. The error covers the variation seen between the dipoles and also accounts for the systematic uncertainties in subtracting the other terms in the temperature model.

5.4.1 Additional checks on the BOF-fills

The six BOF-fills in 1995, together with the long-term calibration machine development measurements made in 1993 and 1994, allow various cross-checks to be performed on the parameters of the model for the LEP energy. These data are sensitive to the tide-model parameters (see Sect. 7.1), the temperature coefficient of the ring and to variations during a fill from other effects.

A model was used to make a fit to these RD data which took into account the variation due to tides, the ring

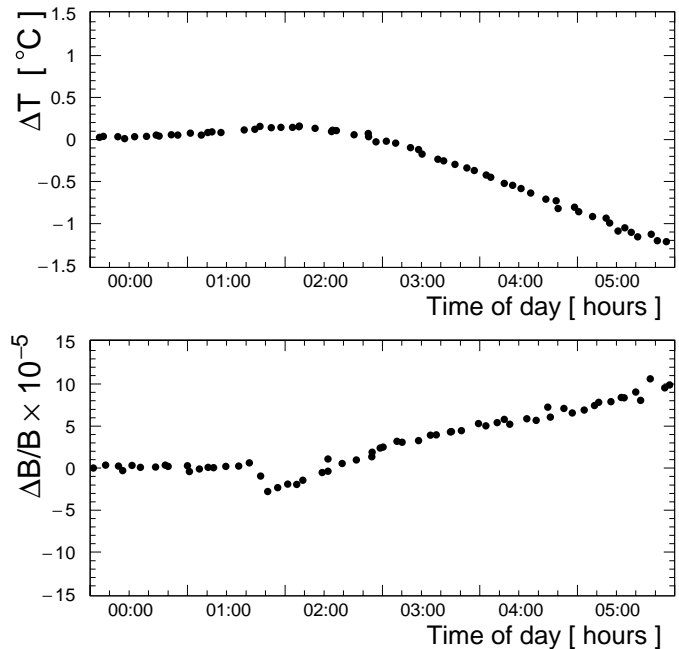

Fig. 11. Variation in temperature and dipole field during the temperature experiment, fill 3822. Both quantities are shown relative to their value at midnight, and are averaged over all instrumented dipoles. The dip at 1.6 h coincides with the abrupt turn off of the LEP quadrupoles, done in order to speed the cooling of the refrigeration water. This manipulation is never done during physics conditions

temperature coefficient, $C_{\text{eff}}^{\text{ring}}$, and a functional form for the rise during a fill as a function of time of day and time into fill. For the fills used in the fit the temperature was almost always increasing, so that there is no sensitivity

to the coefficient C_T in (9). The value for $C_{\text{eff}}^{\text{ring}}$ is found to be $(10 \pm 2) \cdot 10^{-5}/^\circ\text{C}$, where the error is the statistical uncertainty from the fit. This is in good agreement with that determined from the 1996 data.

6 Modelling the energy rise in the fill

Since more than half of the data at the Z resonance were collected prior to 1995, the model for the dipole field drifts must be independent of the direct NMR readings in order that it can be applied to the 1993 and 1994 datasets. The dipole drifts depend on the temperature changes of the dipole cores and on the parasitic currents flowing on the beam-pipe, which are related to the railway traffic and depend on the time of day. Moreover, the way the magnets react to these stimulations depends on the time elapsed since the last cycling of the field, the time into the fill.

The model chosen is based on straightforward two-dimensional binning against time of day and time into fill of the available NMR data after subtraction of the temperature effects (*phenomenological model*). Other treatments of these data were explored in order to gauge the systematic stability of this method. In addition, another (*deterministic*) model has been developed based on the experiments with the dipole in the ISR facility and the recording of beam-pipe currents in a typical week.

The *phenomenological model* treats the temperature and current effects independently; the comparison with the *deterministic model* allows a cross-check of this assumption. Both models necessarily assume the daily behaviour of the parasitic currents to be essentially the same throughout all LEP operation.

6.1 Model based on NMR readings (phenomenological)

The model used for the determination of the central values is based on the assumption that the NMR48 readings are representative of the magnetic behaviour of the whole of the ring. The data collected in 1996 from additional NMR probes have shown this to be a good approximation.

The model takes the rise seen in the combination of the two devices, subtracts the effect of temperature and parametrizes the resulting rise as a function of two parameters: the time of day, and the elapsed time in the fill. The temperature model used to subtract the effect of the temperature is the one described in Sect. 5. When this is done the residual rise, attributable to parasitic currents, is about half that of the total rise as can be seen in Fig. 3d. The time of day correlation comes from the train schedules, whereas the elapsed time in the fill determines the saturation behaviour seen in the energy rise. No assumption on the functional form for the two rises is made. The NMR data, after rudimentary quality cuts (both devices working; no bending modulation happening at that instant), are simply represented in a two-dimensional histogram with 10 time-into-fill bins, of two hours each, and 5 time-of-day bins (one bin between midnight and 05:00 and

four equal bins for the rest of the day). The mean value of each bin is then used to obtain the energy correction at any specific instant.

The model implicitly assumes that the effects of temperature and noise currents can be added linearly. This model, developed from the 1995 data, can then be applied to the 1993 and 1994 data with no modifications, under the assumption that the average effects of the parasitic currents are the same over the years. The only difference is the assumed beam-energy at the start of a fill.

6.1.1 Effect of bending modulations

Since bending modulations have an important effect on the subsequent dipole energy rise, their consequence is taken into account by treating all data taken before (i.e. without) and after a bending modulation as separate samples, and filling a histogram for each as a function of time into fill. In the model a bending modulation causes a rise of 2.5 ± 1.0 MeV where this value was derived from all the available NMR data.

6.1.2 Beam-energy at the start of a fill

For fills calibrated at EOF, the initial energy is fixed by extrapolating backwards in time from the RD measurement using the model. For uncalibrated fills a nominal value is used which is normalized to the mean of the calibrated fills.

This nominal value is assumed to be the same for all fills at the same energy point in 1995. During 1994 a drifting dipole-magnet power supply does not permit the same treatment: the energy is taken to follow the dipole supply current variations during the year. For 1993, due to the frequent flux-loop calibrations which have an important effect on the demagnetization of the dipoles, the starting field of the reference magnet was used instead.

6.2 Model based on parasitic currents (deterministic)

It has been demonstrated in the laboratory that the dipole field rise is a function of two quantities: the parasitic currents flowing on the LEP beam-pipe, and the temperature evolution of the magnet [16]. The reproducibility of the field rise is very good. Replaying the current recorded on the actual LEP beam-pipe and following a similar temperature history, a test magnet can accurately reproduce the rise seen in one of the tunnel magnets equipped with an NMR (see Fig. 6). The deterministic model estimates the beam-energy changes directly from these quantities (see Sect. 5.3.1 for a description of the interplay between temperature and current-spike effects).

To use such a model in practice the LEP ring is subdivided into eight octants and it is assumed that within an octant all currents and temperatures are the same. Another input is the temperature profile per octant, available for every year, and the current flowing on the beam-pipe

Fig. 12. Average rise per hour as a function of time since the beginning of the fill. The full line represents the recorded NMR48 values averaged over the LEP runs without bending modulation in 1995. The dotted line represents the prediction for the same quantity by the deterministic model

per octant. The latter was recorded for a week during 1995 close to IP5, while the noise current correlation factors between octants were also measured [8] (see Fig. 4).

In Fig. 12 the average rise per hour during a fill, as measured by the NMR48 pseudo-device and the prediction of the model, are shown. The influence of the small variation of the train schedule from day to day has been computed and found to be small. The conversion factor between parasitic current and dipole field is obtained by tuning the model on the NMR data so that the measured energy rise is obtained. The model can be used on all years and NMR information is used only for the normalization.

This model was used to assess the interplay between temperature and parasitic current effects, but the simpler phenomenological model was preferred to determine the central values.

6.3 Field-rise model error

The understanding of the field variations during a fill is very different for the various years. The real relevance of these effects was realized only in 1995 with the installation of the NMR probes in the tunnel and the possibility to compare the BOF and EOF energy calibrations. This is reflected in the estimation of the error on this energy correction for each dataset.

The correlation between energy points and years has been estimated by changing the model parameters and observing the resulting energy variations. When this was not possible the error estimation has been driven by the final use of the errors: the direct influence on the determination of the mass and width of the Z resonance has been studied and then converted back to a centre-of-mass energy error and a corresponding correlation coefficient. If the correlation coefficient could not be precisely determined a value has been adopted which shares the uncertainty between mass and width. In such cases it has been verified that the final m_Z and Γ_Z errors, from the systematic study in question, have less than 10% sensitivity to the choice of

correlation coefficients. It should be noted that whenever a monotonic variation over the full length of a fill is converted into an error on the average energy, a reduction of roughly a factor of two has to be applied on the change induced by the variation to reflect the luminosity-weighting.

The most important tool to estimate the error on the field rise model is the set of BOF-fills. The comparison of field drift predicted by the model with the direct measurement is used to set a limit on the error from any unknown effects.

In addition the model uncertainties have been evaluated by varying the parameters of the phenomenological model (temperature coefficients and binning of distribution) within their errors. Checks have also been performed using the deterministic model and the direct distribution of the NMR48 readings.

6.3.1 Rise scatter and model variations

The comparison of the phenomenological model prediction with the 6 BOF-fills (Fig. 13) yields an average offset [rise(model predicted) – rise(measured)] of 0.0 MeV with a scatter of 0.4 MeV (beam-energy). Studies performed by selecting at random sets of six fills in 1995 and using the NMR48 data as an estimate of the ‘true’ rise, show that the expected average scatter of the offset is 1.2 MeV, suggesting that the actual scatter between model and measurement for the six BOF-fills was fortuitously small. A value larger than 0.4 MeV, around or exceeding 1 MeV, is indicated also by the comparison with other models such as the deterministic model or the use of the NMR48 data directly. The value of 1.2 MeV (beam-energy) has been chosen for the 1995 dataset as representative of the rms of the offset between the modelled and measured rise. Taking account of the sample size and the necessary conversion to go to the luminosity-weighted centre-of-mass energy, this translates into an error of 0.5 MeV on the absolute centre-of-mass energy scale.

For the 1993 energy scan and the 1994 peak runs the amount of information available is reduced and it has been

Fig. 13. The estimate of the beam-energy rise from the phenomenological model versus the actual one for the six BOF fills of 1995. The rms of the difference is 0.4 MeV. Temperature effects have been subtracted

assumed that the error is equal to the rise predicted by the model, that is 2.6 MeV for 1993, correlated between energy points, and 3.3 MeV for 1994. The inter-year correlations are taken to be at the 50% level. For 1993 and 1994 a few fills were available where, during Machine Development (MD) studies, RD measurements were performed over several hours (see Table 2). These sets of measurements are not representative of the typical physics fill as in most cases the first RD happened at the end of a physics fill and the last one several hours later, that is in a regime where only small field drifts are expected. Nevertheless, with these reservations, the comparison of the model with these fills supports the above error assignments.

To estimate the uncorrelated part of the error, i.e. that which mostly affects the Z width, the systematic differences between the P-2 and the P+2 sample have been studied.

For 1995 three different checks have been performed:

- Determining the change in the average energy at each off-peak point when using alternative models such as the deterministic model or functional fits to the RD data.
- Tuning the phenomenological model using only the P-2 (P+2) fills and applying it to the P+2 (P-2) fills to check the changes in average energy.
- Using the NMR48 data directly and checking the change in the average energy with respect to the phenomenological model.

From the observed energy dependence of the changes an error contribution equivalent to 0.4 MeV on ΔI_Z was assigned.

For 1993 the variations with different models were used as an estimate of the uncorrelated energy errors: the various models give differences ranging from 0.9 to 1.2 MeV.

Table 3. The difference of the average fill centre-of-mass energy computed with the phenomenological model and with the deterministic model for the off-peak datasets

Year	ΔE_{CM} (MeV)	
	P-2	P+2
1993	0.0	-1.8
1995	-0.4	-0.2

In particular the error due to the approximate assumption that temperature and parasitic-current contributions to the field drift are independent is monitored by the comparison with the deterministic model (see Table 3). From these sources, a contribution equivalent to an error on the width of 1 MeV was taken. The larger error in 1993 can be partially accounted for by the observation that the average length of a P+2 fill was significantly longer than the average length of the fills at P-2 and that the P+2 calibrations occurred correspondingly later in the fill.

The model depends on the number of bins and bin-size for time of day and time into fill: these have been varied between 1 and 10 bins and the largest deviation was 0.3 MeV for the peak energy and less than 0.1 MeV for the off-peak points.

6.3.2 Uncertainties in temperature coefficients

The temperature coefficients of the NMR48 pseudo-device affect the model as they are used to subtract the part of the measured field variation which is due to temperature effects at a given time-of-day and time-into-fill, and thereby determine the residual effect due to the parasitic currents. The associated variations are studied by changing C_{eff}^{48} and C_T^{48} within the limits described in Sect. 5.4. The changes due to the variation of the two coefficients are added in quadrature and shown in Table 4. The larger shift in 1995 is partially understood as an effect related to a greater sensitivity to the temperature coefficients for the fills with an initial bending modulation. The level of correlation is taken to be 75% between energy points and between years. The uncertainty on the energy rise deriving from the imprecision in the modelling of the ring temperature coefficients is accounted for separately. The energy changes due to variations of the ring coefficients $C_{\text{eff}}^{\text{ring}}$ and C_T^{ring} , within the limits described in Sect. 5.4, are added in quadrature. To be conservative, the uncertainties of the ring and NMR48 temperature coefficients have been assumed to be uncorrelated. It is worth noting that the error is dominated by the uncertainty on C_{eff} and not by the error on C_T . These variations, shown in Table 5, are taken as the size of the error with 75% correlations between years and energy points.

6.3.3 Bending modulations

An error component relevant only for the 1995 datasets is the uncertainty on the modelling of the bending modula-

Table 4. The variations in centre-of-mass energy for the three years for extreme variations of the temperature coefficients of the NMR48 pseudo-device: C_{eff}^{48} varied by $\pm 60\%$ and C_T^{48} varied by $\pm 50\%$. The shifts from C_{eff}^{48} and C_T^{48} are then added in quadrature with appropriate luminosity weighting

Year	ΔE_{CM} (MeV)		
	P-2	P	P+2
1993	0.6	0.3	0.6
1994		0.5	
1995	1.0	1.0	1.1

Table 5. The variations in centre-of-mass energy for the three years for extreme variations of the temperature coefficients of the ring: $C_{\text{eff}}^{\text{ring}}$ varied by $\pm 30\%$ and C_T^{ring} varied by $\pm 50\%$. The shifts from $C_{\text{eff}}^{\text{ring}}$ and C_T^{ring} are then added in quadrature with appropriate luminosity weighting

Year	ΔE_{CM} (MeV)		
	P-2	P	P+2
1993	0.1	0.4	0.4
1994		0.2	
1995	0.4	0.3	0.4

tion. The effect of varying the jump induced by a bending modulation by ± 1.0 MeV around the central value of 2.5 MeV induces a change of 0.0, 1.4, 0.3 MeV (centre-of-mass energy) for P-2, P, P+2 respectively. The whole variation is taken as the error with 75% correlation between energy points.

6.3.4 Summary

In addition to studying the effect of parameter variations and alternative models on the central values of the energies themselves, the compatibility of each variant with the 1995 BOF-fills was checked. In general good agreement was observed. The largest discrepancy, $\Delta E_{\text{CM}} = 1.4$ MeV i.e. slightly above two standard deviations, was observed when allowing the NMR48 temperature coefficients to span their allowed range. Such discrepancies indicate that there are anticorrelations between the error sources considered. The error assignment is conservative in the sense that these anticorrelations have been ignored.

Table 6 summarises the different components of the field rise error assignment, expressed in terms of m_Z (or E_{CM} for 1994) and I_Z . The equivalent uncertainties on each energy point and accompanying correlations are given in Table 19. The main impact of the uncertainty of the field rise is on m_Z .

7 The accelerator size

The LEP storage ring is based on a ‘strong focusing lattice’ which keeps the particles oscillating on stable orbits

around the ring. The particular orbit passing on average through the centre of all quadrupoles is called the *central orbit*. Particles moving on this orbit sense the magnetic field of only the bending dipoles and corrector coils because there is no field on the quadrupole axis. At LEP the particles are ultra-relativistic and they circulate on a stable orbit synchronous with the frequency of the accelerating RF fields, which is a multiple of the revolution frequency. Since the speed of the particles is constant to a very high degree, the length of their orbits is fixed by the RF frequency⁷. If the positions of the magnetic elements change, for example due to movements of the tunnel structure, then, given that the length of the actual orbit is fixed, the particles will move away from the centre of the quadrupoles. Hence they will sense an additional magnetic field which attempts to restore the particle trajectory to the central orbit. This extra deflection will affect the average beam-energy of the particles. Quantitatively the energy change as a function of time $\Delta E(t)$ is related to the change of ‘ring circumference’ (C) by

$$\frac{\Delta E(t)}{E_0} = -\frac{1}{\alpha} \frac{\Delta C(t)}{C_0}. \quad (10)$$

The change of circumference, relative to the length of the central orbit (C_0), is related to the change of energy, relative to the energy defined by the dipole-field (E_0), through the momentum compaction factor⁸ $\alpha = (1.86 \pm 0.02) \cdot 10^{-4}$ [17]. Therefore, small changes of the LEP circumference are amplified by four orders of magnitude into measurable changes of the average beam-energy.

7.1 Gravitational deformation of LEP

The concrete LEP tunnel is distorted by the effects of local deformations of the surrounding geological formations. In particular, tidal effects, due to the combined gravitational attraction of the Sun and the Moon, which can cause, at Geneva latitudes, distortions of up to 10^{-8} of the local Earth radius, change the size of LEP in an appreciable way. The change in beam-energy due to gravitational effects can be parametrized as

$$\frac{\Delta E}{E} = k_G \Delta g_m \quad (11)$$

where Δg_m ⁹ is the correction to be applied to the measured local acceleration due to gravity [11] and $k_G = (-82 \pm 4)/(\text{ms}^{-2})$ is a coefficient estimated from the measured deformation of the LEP ring as detected by the Beam Orbit Measurement system [18]. The reliability of

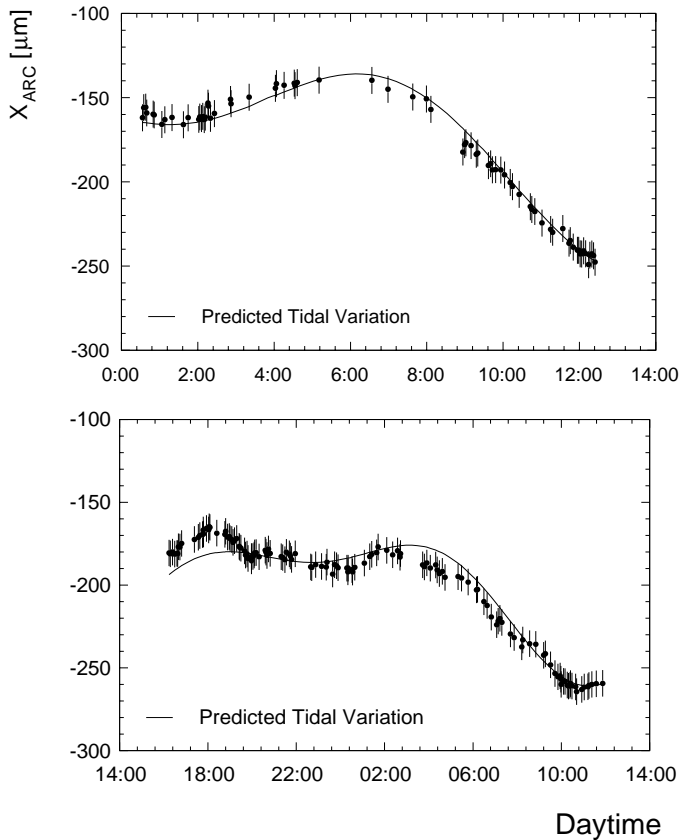

⁷ At LEP1 the RF frequency was kept constant during physics fills

⁸ The momentum compaction factor depends on the optics used, which was the same for 1993, 1994 and 1995. The relatively large amplification is mostly due to the strong focusing of the LEP optics

⁹ At high tide Δg_m reaches $\pm 1.2 \cdot 10^{-6} \text{ms}^{-2}$

Table 6. The contribution of the various components of the magnetic field rise error to the final error on the Z mass and width, and the absolute energy scale in 1994

Component	How assigned	1993		1994		1995	
		Δm_Z (MeV)	$\Delta \Gamma_Z$	ΔE_{CM} (MeV)	Δm_Z (MeV)	$\Delta \Gamma_Z$ (MeV)

Total		2.7	1.1	3.3	1.2	0.7	

**Fig. 14.** Evolution of the horizontal orbit position for two LEP fills. The predicted tidal variations are indicated by the solid lines. In the top figure (fill 1694) the agreement is excellent. In the bottom figure (fill 2260) the tidal effects cannot explain all the orbit movements. The errors on each point are estimates

the modelling of such deformation has been proven in dedicated experiments, by comparison with energy changes as measured by the RD technique [12].

To evaluate the effect of a possible phase-shift of the model (due for example to the finite binning in time) the changes in the energy due to a relative change of ± 7.5 minutes, corresponding to half of the recording interval,

have been modelled: the largest change on the average centre-of-mass energy is 0.2 MeV. The effect of the uncertainty on k_G is determined by changing the parameter by one standard deviation and re-evaluating the average energies. The observed difference is assigned as an error (see Table 19 for the results for every energy point).

7.1.1 Additional checks on the BOF-fills

Using fills with multiple RD measurements, a fit similar to the one detailed in Sect. 5.4.1 was used to cross-check the value of the amplitude of the tide parameter k_G . With k_G left as a free parameter in the fit, a value of $(0.96 \pm 0.03) \cdot k_G^{\text{std}}$ was obtained, where k_G^{std} is the value used in the model; again confirming the value determined in Sect. 7.1.

7.2 Hydrogeological deformation of LEP

In 1993 it was realized that, on top of the well-established tidal effects, some additional long-term phenomena were taking place. Over periods of weeks, changes in the average LEP radius of up to several hundred microns could be detected after correcting for tidal effects. This observation was made possible by the improved reliability of the BOM electronics. While this precise monitoring of the relative orbit deviations cross-checked the expected deformations due to tidal effects, it also made it clear that there were additional contributions (see Fig. 14). In 1994, it was realized that such changes could be qualitatively correlated with the pressure of the watertable under the nearby Jura mountains and with the level of water in the lake of Geneva.

The model of the average LEP beam-energy factorizes into a correction for tidal effects and an overall correction for each fill which accounts for the measured remaining changes of the average LEP radius. The correction is

$$\Delta E = K_{\text{radius}} \Delta R \quad (12)$$

where ΔR is the measured variation of the radial beam position at the BOMs. It is proportional to the variation

of the radius of LEP. The coefficient K_{radius} follows from the definition of the horizontal dispersion and is given by $K_{\text{radius}} = E/D_x = (0.077 \pm 0.002) \text{ MeV}/\mu\text{m}$ (at 45 GeV), where D_x is the horizontal dispersion at the BOMs. Its accuracy is limited to 2% by systematic effects.

The fill-to-fill error on the LEP radius change ΔR has been estimated to be $15 \mu\text{m}$, which contributes a negligible error to the average energy considering that several hundred fills are used in the analysis.

8 Additional contributions to the dipole fields

Besides the dominant effect of the dipoles and quadrupoles, two effects have been found to influence the total bending field around the LEP ring: the field of the horizontal corrector coils used to perform fine steering of the particle orbits, and the stray field of the power-bars distributing the current to the quadrupoles of the machine. These effects are significant and need to be taken into account. The influence of the corrector coils, in particular, can be very important as often the corrector configuration used during RD calibration is different from the one used in physics conditions.

8.1 Horizontal-corrector effects

Around LEP there are several hundred small dipole corrector magnets used to modify the beam orbit in both planes. Horizontal correctors can affect the beam-energy either by contributing directly to the field integral or by modifying the orbit. In this respect, simulations show that the horizontal corrector magnets can affect the beam-energy significantly through a change in path length if the fields add up coherently. This change is proportional to the product of the corrector deflection angle and the horizontal dispersion at its location. Since the orbit length is fixed by the RF frequency, the change in path induced by a corrector forces the beam to change its radial position in the quadrupoles. The additional fields seen by the beam in the quadrupoles lead to a change in energy.

The LEP vertical and horizontal betatron tunes are slightly different in physics and in calibration modes, requiring in general different corrector settings. Modelling of the effect of correctors on the beam-energy is therefore necessary.

A controlled experiment during an RD measurement proved that the modelling of the effect on the beam-energy of changing the corrector settings is reasonably accurate [19] as can be seen in Fig. 15. The effects of varying corrector strength and distribution are included in the model as relative changes within a fill while the systematic tracking of the absolute value of the beam energy is done by using the average orbit deformations described in Sect. 7.2.

Since the effect of correctors remains rather uncertain, the systematic error was calculated by assuming that horizontal correctors affect the energy either by their field contribution or by their influence on the orbit length. The

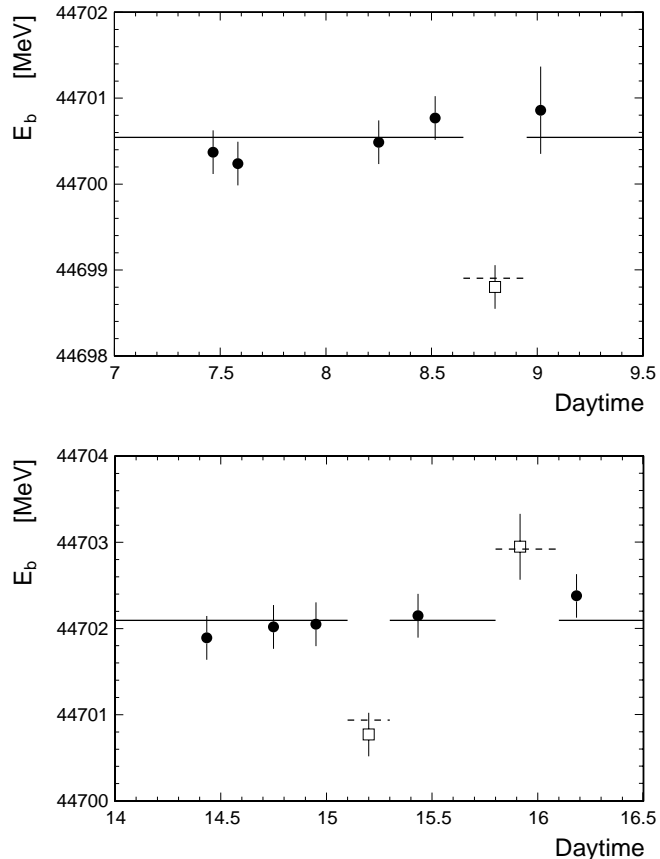

Fig. 15. Evolution of the beam-energy E_b as a function of time in LEP fills 3702 (*top*) and 3719 (*bottom*). E_b is corrected for tides and magnet temperature. All RD measurements plotted as circles correspond to the reference orbit with a fixed corrector pattern. The solid lines indicate the average energy on the reference orbit. RD measurements performed with different corrector settings are indicated by squares. The dashed lines represent the energy shifts predicted from the orbit lengthening due to the change of corrector patterns with respect to the reference orbit

Table 7. Average difference of centre-of-mass energy values assuming that the horizontal-corrector settings affect the beam-energy either via the orbit lengthening or via the beam deflection. The values are luminosity weighted and for all the physics fills

Year	ΔE_{CM} (MeV)		
	P-2	P	P+2
1993	+0.0	+0.4	-0.4
1994		+0.2	
1995	-0.2	-0.5	-0.2

results shown in Table 7 are taken as the error. The values are uncorrelated between years and 75% correlated between energy points where the sign of the correlation is taken from the relative signs of the shifts of Table 7.

8.2 QFQD compensation-loop effects

The QFQD compensation loop (see Sect. 2.7) was used in 1993 and in 1994 (although it was not always on), and was turned off in 1995. For 1995 the effect of the stray field is constant and therefore absorbed in the overall normalization. For 1993 and 1994 the beam energy is corrected for the current, I_{QFQD} , flowing in the QFQD compensation loop using

$$\Delta E_b = k_{\text{QFQD}} \cdot \Delta I_{\text{QFQD}}. \quad (13)$$

The coefficient k_{QFQD} , determined in dedicated experiments [3], has been revised in the light of the improved modelling of the LEP energy and it agrees with the theoretical prediction. The value used here is 0.04 ± 0.01 MeV/A where the error is determined from the spread of the experimental results.

9 Uncalibrated fills

A number of fills ended by loss of beam before calibration could be performed. For these uncalibrated fills, the absolute energy is fixed to the average energy obtained from the calibrated ones. This leads to an additional uncertainty, arising from two types of fluctuations.

First the statistical error on the mean energy estimated from the finite number, N_{cal} , is equal to $\sigma_{\text{cal}}/\sqrt{N_{\text{cal}}}$, where σ_{cal} is the rms scatter of the differences ($E_{\text{model}} - E_{\text{polarization}}$). Here $E_{\text{polarization}}$ is the end-of-fill calibration measurement and E_{model} is computed from the model of (5), with a constant normalization factor E_{norm} equal to the nominal value defined in Sect. 6.1.2. The distributions of these differences for the calibrated fills in 1993, 1994 and 1995 are shown in Fig. 16.

Secondly, the mean energy of the uncalibrated fills (N_{uncal}) can also fluctuate with an error of $\sigma_{\text{cal}}/\sqrt{N_{\text{uncal}}}$. When combined to form the resulting error on the average energy of all fills, this gives the *normalization* error

$$\begin{aligned} \Delta E_{\text{CM}}^{\text{norm}} &= \frac{N_{\text{uncal}}}{N_{\text{total}}} \left(\frac{\sigma_{\text{cal}}}{\sqrt{N_{\text{cal}}}} \oplus \frac{\sigma_{\text{cal}}}{\sqrt{N_{\text{uncal}}}} \right) \\ &= \frac{\sigma_{\text{cal}} \sqrt{N_{\text{uncal}}}}{\sqrt{N_{\text{total}}} \sqrt{N_{\text{cal}}}}. \end{aligned} \quad (14)$$

where $N_{\text{total}} = N_{\text{uncal}} + N_{\text{cal}}$ is the total number of fills. The equations above are for illustration purposes only as they neglect the effect of luminosity weighting, which is taken into account in practice. The normalization errors including the effects of luminosity weighting, are shown in Table 8.

10 Centre-of-mass energy corrections

The centre-of-mass energy at each IP is not simply twice the average beam energy for two main reasons. The first arises from the asymmetry in the distribution of the RF

Table 8. The normalization error for each centre-of-mass energy and each year. For the peak points of 1993 and 1995 the rms of all the P−2 and P+2 fills has been used

Year	$\Delta E_{\text{CM}}^{\text{norm}}$ (MeV)		
	P−2	P	P+2
1993	1.7	5.9	0.9
1994	–	1.1	–
1995	0.8	5.0	0.5

power which compensates for the energy lost by the beams due to synchrotron radiation. Specifically, the centre-of-mass energy can be shifted differently at each IP depending on the relative misalignments of the RF cavities in use, the phase errors on these cavities, and the disposition of RF cavities around LEP. These considerations were particularly important in 1995, when the commissioning of a large number of the SC-RF cavities needed for LEP2 operation led at times to a very asymmetric distribution of the accelerating voltage around the ring.

In 1995, the new bunch-train mode of operation introduced the second possible source of IP-specific systematic shifts in E_{CM} . To avoid unwanted encounters between the bunches in the counter-rotating bunch-trains, the beams were separated electrostatically in the vertical plane as they passed through the straight sections of LEP. As a consequence of passing off-axis through the quadrupoles near the IP, a non-negligible vertical ‘dispersion’ (a momentum ordering of the particles in the vertical plane) is induced. If the bunches within the train do not collide head-on, significant shifts in E_{CM} can occur because the sum of the energies of the colliding particles will not be equal to the average E_{CM} . This effect was anticipated and minimized by the use of a separation scan technique to centre the beams (see Sect. 10.3).

As only the electron energy is routinely monitored by RD an additional correction or uncertainty common to all four IPs arises from a possible difference in energy between electrons and positrons. The measurements of this difference over the years are described in Sect. 10.5.

10.1 Centre-of-mass energy corrections from the RF system

This section presents the ingredients of the simulation used to calculate for each IP the shift in E_{CM} due to the interaction of the LEP beams with the RF system and other LEP components. The previously published analysis of the 1993 data [4] is summarized along with the new results from 1994 and 1995.

Until October 1995 the beam-energy loss due to synchrotron radiation (approximately 125 MeV per turn) was compensated for by acceleration provided by RF cavities placed symmetrically at IP2 and IP6 at diametrically opposite points on the LEP ring (see Fig. 2). Each of the groups of RF cavities was placed so that its centre lies an integral number of RF wavelengths, λ_{RF} , from the IP; the

Fig. 16. Differences between the beam energies measured by RD and those predicted by the model with a constant normalization factor. The error bar attached to each point is of 1 MeV. Open squares: P+2, open triangles: P, black circles: P-2

RF wavelength is given by $\lambda_{\text{RF}} = c/f_{\text{RF}} \simeq 85$ cm, where c is the speed of light and f_{RF} is the LEP RF frequency, $f_{\text{RF}} = 352209188.1$ Hz. However, to reduce the operating power the CU-RF system includes a supplementary storage cavity driven by an independent klystron operating at a slightly different frequency, $f_2 = 352299152.2$ Hz, such that the RF power oscillates between the storage and the accelerating cavity with a frequency $(f_2 - f_{\text{RF}})/2$. This configuration results in the CU RF system providing an accelerating voltage with a frequency $(f_2 + f_{\text{RF}})/2$, rather than f_{RF} . Since the cavities were placed an integral number of λ_{RF} from each IP, they are longitudinally *misaligned* with respect to their operating frequency. The misalignment $\Delta\ell$ is given by

$$\Delta\ell = c \cdot d_{\text{IP}} \left[\frac{1}{f_{\text{RF}}} - \frac{2}{f_{\text{RF}} + f_2} \right] \approx 2.1 \text{ cm} \quad (15)$$

where $d_{\text{IP}} \approx 196$ m is the effective distance from the IP to the centre of the CU cavities. Since $\lambda_{\text{RF}} > 2c/(f_{\text{RF}} + f_2)$, the cavities are too far away from the IP. The effect on the beam energies is that the incoming beam on each side of the IP will gain too much energy from the RF (about 10 MeV extra) such that E_{CM} will be approximately 20 MeV higher than the average LEP centre-of-mass energy. This effect is essentially exactly compensated for as the beams leave the IP, so that there is on average no energy offset outside IP2 and IP6. A schematic representation of this effect is shown in Fig. 17. This cancellation is not necessarily exact, however: other geometrical effects, such as a non-zero path difference in the lengths of the LEP

half-arcs IP2-IP4-IP6 and IP2-IP8-IP6 (defined as $\Delta\ell_{26}$), or an asymmetric distribution of RF power around LEP, can result in non-zero corrections at IP4 and IP8 as well.

To calculate the corrections to E_{CM} at each IP, a detailed simulation of the energy losses and gains of the beams as they travel around LEP is necessary. The modelling of the corrections is carried out by the iterative calculation of the stable RF phase angle ϕ_s ¹⁰ which proceeds by setting the energy gains of the beams in the RF cavities equal to all of the known energy losses. These losses include synchrotron radiation in the bending magnets, radiation in the wiggler magnets used to control beam emittances, and beam-energy loss in unused RF cavities. In addition, beam-loading effects, changes in the RF voltage distribution, phase errors and cavity misalignments are included.

The 1995 RF model includes several updates specific to the new running conditions experienced during the 1995 scan:

- The introduction of the bunch-train running has necessitated the independent simulation of ϕ_s for each bunch in the bunch trains, which takes into account the details of interbunch spacing and the different bunch positions on the RF wave.
- The first series of high-gradient, SC cavities, which are needed for LEP2 running, has been added, including all of their alignment, phase, and voltage calibration.

¹⁰ The energy gain of the beams is given by $V_{\text{RF}} \cdot \sin \phi_s$, where V_{RF} is the total RF accelerating voltage

Fig. 17. The effects of misalignment of the RF cavities on the LEP beam-energy. In this drawing, the amplitude of the accelerating voltage (V_{RF}) is represented by the curved line on which the particle bunches are sitting. The top half of both figures shows the acceleration experienced by the incoming bunch, here shown as the e^+ bunch, whereas the bottom half of the figures shows the acceleration of the outgoing (e^-) bunch at the same cavity but at a later time, after the bunches have crossed at the IP. The left figure shows the ideal situation, where the cavity sits at an integer number of RF wavelengths from the IP. Here, both bunches are given the same acceleration by the cavity. The right figure shows the situation if the cavity is moved a distance $\Delta\ell$ away from the IP but the timing of the RF accelerating voltage is kept constant. In this case, the incoming bunch arrives earlier than is optimal, and thus sees a larger accelerating field and gains a larger amount of energy E_{gain} . The outgoing bunch e^- arrives later than is optimal, and thus sees a smaller accelerating field and has a smaller E_{gain} . If the misalignment were the same on both sides of the IP (as it is for the CU cavities in LEP), E_{CM} at this IP would be higher than expected from this effect

tion information. These cavities do not suffer from the longitudinal misalignment problems of the CU-RF as they operate with a single frequency.

- The use of a small number of high-gradient cavities to provide the necessary acceleration resulted in many of the CU cavities being unused during 1995. Thus, a means of describing the interaction of the beams with the unused cavities had to be added to the model. The best description was achieved if the bunches deposit energy in the unused cavities equivalent to the measured peak induced voltage, but do not, on average, interact with the stored energy.
- A new diagnostic tool, R_{BOM} , combines the measured size of the electron-positron difference orbit Δ^{+-} on both sides of IP2 and IP6 into a ratio which is sensitive to the phasing of both individual RF units and the relative phase of the RF between IP2 and IP6. The orbit difference is directly proportional to the difference in energy of the two beams. An example of the energy difference as the beams travel around LEP is shown in Fig. 18. The definition is:

$$R_{\text{BOM}} = \frac{|\Delta_{\text{IP2 Left}}^{+-}| + |\Delta_{\text{IP2 Right}}^{+-}|}{|\Delta_{\text{IP6 Left}}^{+-}| + |\Delta_{\text{IP6 Right}}^{+-}|}. \quad (16)$$

where $\Delta^{+-} = r_{e^+} - r_{e^-}$ with r being the radial displacement at the end of the LEP curved section measured by the BOM sensors. Based on the modelled energy loss and the known horizontal dispersion at the BOM position, this quantity can also be calculated in the RF model. Comparison with the measured values places powerful constraints on potential phase errors within the RF system.

Some of the model parameters are known with only limited precision, and, in addition, varied with time. To control these, the measured value of the electron and positron synchrotron tunes¹¹ Q_s^\pm are compared with the value from the model, calculated from the phase angles, ϕ_i^\pm , in each cavity i , for each bunch, and the derivatives of the energy gain, E_i , at each cavity with reference to the phase angle, $dE_i/d\phi_i^\pm$:

$$Q_s^\pm = \sqrt{-\frac{h_f \alpha}{2\pi E_b} \sum_i \frac{dE_i}{d\phi_i^\pm}}. \quad (17)$$

Here, h_f is the LEP harmonic number (the ratio of the RF frequency to the revolution frequency, 31324) and α is the momentum compaction factor (see Sect. 7). Deviations between the measured and the calculated Q_s were taken as an indication of inconsistencies between input parameters, in particular the individual time-dependent unit phases.

Longitudinal shifts of the collision point in the IPs occur if the stable phase angles of the electron and positron bunches become different and vary with time. Such shifts were observed in all experiments and could be compared with the model prediction, providing another cross-check of the model's validity.

The calculations of the RF corrections use a database of patched and corrected input values where any necessary information that was not available from the variety of logging sources has been interpolated. Uncertainties arising from this can be controlled by comparison of distributions for complete and interpolated database records.

After the tuning of the RF model parameters, which required the input of time-dependent misphasing and volt-

¹¹ The synchrotron tune is the number of longitudinal, or energy, oscillation per turn of LEP

Fig. 18. The evolution of the energy of each of the counter-rotating beams as they circulate in LEP, the so called *energy sawtooth*. The electron beam is represented by the left-going dotted line, the positron beam by the right-going solid line. The light grey lines mark the positions of the IPs. $\Delta E = 0$ denotes the average energy of LEP, i.e. that given by the rest of the energy model. The orbit differences Δ^{+-} used in R_{BOM} are measured at the points marked by a \star , just outside the RF sections around IP2 and IP6. The energy gains provided by the RF are clearly visible. This configuration represents a typical RF complement and centre-of-mass energy corrections for the 1995 running

age calibrations, the difference between the measured and calculated values of Q_s is finally adjusted to be zero by the application of a small voltage scaling to all of the RF voltages. Its value of 1.5% to 2.0% is consistent with the precision expected from the original voltage calibration. The rms of the difference between calculated and measured Q_s is larger in 1995 (0.0008) and 1994 (0.0006) than it was in 1993 (0.0004): this is due to the instability of the RF configuration during the 1995 scan and the poor logging quality of the 1994 running.

For the 1995 data, the mean of the distribution $R_{BOM}(\text{calc})/R_{BOM}(\text{meas})$ is 1.009, with an rms of 0.077. Assuming a resolution of $20 \mu\text{m}$ on each of the quantities Δ^{+-} in (16), the width of the $[R_{BOM}(\text{calc.}) - R_{BOM}(\text{meas.})]/\sigma(R_{BOM})$ distribution is 2.1. This implies that the phasing of the machine is understood to a level of approximately twice the resolution achievable from R_{BOM} .

The average corrections for the off-peak and peak points from 1993, 1994 and 1995 are shown in Table 9. The average bunch-specific corrections for each IP show only small bunch-to-bunch variations (≤ 0.2 MeV), and therefore the average over the bunches in a train is used in the energy determination.

10.2 Evaluation of errors for the RF corrections

The constituent errors on the 1994 and 1995 analyses are discussed below. Unless explicitly mentioned, nothing is

Table 9. The corrections to E_{CM} for each LEP IP and each energy point from the RF model

LEP IP	Corrections to E_{CM} (MeV)						
	1993		1994		1995		
	P-2	P	P+2	P	P-2	P	P+2
2	19.0	18.8	19.9	19.1	14.7	15.0	14.8
4	0.0	-0.3	0.0	-0.2	0.9	1.7	1.4
6	19.5	19.6	20.1	18.9	4.4	4.6	4.6
8	0.0	0.3	0.0	0.0	-1.0	-1.8	-1.5

changed for 1993 from the published results [4]. The 1994 and 1995 errors are summarized in Table 10.

The largest systematic error on the RF corrections arises from the uncertainties on the positions of the RF cavities. The uncertainty on the alignment of the CUCavities is taken to be ± 1 mm, where the most conservative estimate of the effect is to assume that the total uncertainty on the difference in cavity positions is 2 mm, moving the cavities coherently towards or away from the IP to calculate the effect. This led to shifts of 0.4 MeV at IP2 and IP6 in 1994, and 0.6 MeV at IP2 and 0.2 MeV at IP6 in 1995. In 1995, alignment uncertainties of about 1.4 mm (obtained from repeated measurements of the cavity positions) on the superconducting cavities are also important and amount to 0.1 MeV at IP2 and 0.5 MeV at IP6, leading to a total systematic error arising from RF

cavity misalignment of 0.6 and 0.5 MeV for IP2 and IP6, respectively. The corresponding error for the 1994 running is negligible because the total accelerating voltage provided by superconducting cavities was small. Since the source of this error is geometrical, it is taken to be 100% correlated between energy points and years of running.

A very important systematic uncertainty in 1995 results from the discrepancy between the observed and predicted longitudinal movements of the collision point and the difference in collision points between bunches. The measurements by the LEP experiments of the position of the average interaction point measured along the beam axis (z coordinate) show good agreement except for a small period at the end of the scan, when all CU cavities around IP6 were unused and new superconducting RF cavities were operated instead. The model also predicts smaller differences between the individual bunch collision points, about 0.5 mm between the first and the last bunch in a train, than are measured from the data, where differences up to 1 mm are observed. The average energy of the various bunches was shown to be equal to within 0.1 MeV, with an rms of 0.3 MeV, by means of RD measurements. This, however, does not exclude local effects due to the RF system. Limits on the possible shifts in collision energy arising from collective and bunch-to-bunch shifts in stable phase are obtained by using the measured vertex positions as an input to the RF model to constrain the bunches to sit at a ϕ_s which identically reproduces the observed collision positions [20]. The systematic errors due to this effect are 0.8, 0.6, 0.1, and 0.6 MeV for IPs 2, 4, 6, and 8, respectively. These errors include small discrepancies in the Q_s values of the individual bunches in a train. The errors are assumed to be 100% correlated between IPs and 50% correlated between energy points.

The residual rms spread of ($Q_s(\text{calc.}) - Q_s(\text{meas.})$) was larger in 1994 and 1995 by 50% and 100% respectively compared to 1993. This, and the need to re-scale the RF voltages to obtain agreement between the average measured and calculated Q_s , indicates an uncertainty in the RF voltages and phases, which is taken into account by assuming the full normalization correction as the error on the voltages. This resulted in errors on centre-of-mass energy of 0.4 MeV at IP2 for both years, 0.4 and 0.1 MeV at IP6 in 1994 and 1995 respectively, and much smaller errors (< 0.1 MeV) at IP4 and IP8. These errors are 100% correlated between energy points and IPs, but are taken to be uncorrelated between years. Separate studies of the agreement between measured and modelled Q_s at the various energy points showed no significant differences.

Measurements made in 1996 during the high-energy running of LEP have revealed a potential discrepancy between the modelled and actual energy loss by the circulating beams. In particular, a difference of approximately 5% was observed between the energy loss calculated from the size of the horizontal orbit excursions measured by the BOM system and that assumed from the optical modelling of LEP. To estimate the effect of a global change in the rate of energy loss on the RF corrections to E_{CM} , the loss was changed in the simulation by 5% and the full shifts in

E_{CM} taken as the uncertainty from this effect. This results in an additional error of 0.3 MeV at IP2 for 1995, and 0.6 MeV errors at IP2 and IP6 for 1993 and 1994 which are correlated between these two IPs for these years.

For 1995, the measured quantity R_{BOM} provides a stringent constraint on possible phase errors between and within the RF at IP2 and IP6. To estimate the possible energy errors due to misphasing, the relative phases of the CU cavities at IP2 and IP6 were shifted in a way to move R_{BOM} to two standard deviations from its central value. The size of the effect is a negligible 0.1 MeV at IP2 and 0.0 MeV at IP6. For 1994, however, the R_{BOM} information is not available, and a 5° shift in the relative phases between the two IPs is used to estimate the error due to misphasing. In this case, the error is 0.5 MeV at IP2 and IP6, anticorrelated between the two. Possible errors due to misphasing are not correlated between years.

The recent measurement of cavity positions [21] also includes an estimation of the possible path-length difference of the two half-arcs of LEP, from IP2 to IP6 via IP4 or IP8 ($\Delta\ell_{26}$). The difference in path length was measured to be zero, with an error of 1 mm. This result can be applied retrospectively to the 1993 analysis, such that the resulting error on the centre-of-mass energy is reduced from 1 MeV to 0.1 MeV for IP4 and IP8. The error is anticorrelated between the two IPs, and is 100% correlated between energy points and years.

Additional small errors arise from missing input data, from a small difference in average Q_s of electrons and positrons, and from the errors on model input parameters. These are quantified in Table 10.

10.3 Centre-of-mass energy corrections from dispersion effects

The bunch-train mode of operation used for the 1995 energy scan required the control of a new effect. The beam-orbit deflections induced by the electrostatic separators to avoid unwanted collisions, hereafter called ‘bunch-train bumps’, generate vertical dispersion of opposite-sign for the two beams at the IPs. If the beams collide with a vertical offset, the centre-of-mass energy is shifted from the nominal by an amount ΔE_{CM} [22]:

$$\Delta E_{\text{CM}} = -\frac{1}{2} \cdot \frac{\delta y}{\sigma_y^2} \cdot \frac{\sigma_{E_b^2}}{E_b} \cdot \Delta D_y^* \quad (18)$$

where δy , the collision offset, is the vertical distance between the centre of the positron bunch and the electron bunch in collision at the IP, σ_y is the individual beam size, ΔD_y^* is the difference in the vertical dispersion ($D_{e^+}^* - D_{e^-}^*$) and E_b , σ_{E_b} are the beam-energy and spread respectively.

As ΔD_y^* is a characteristic of the bunch-train bumps and σ_E is set by the beam-energy and optics, the only feasible control of this effect is to reduce δy . In the 1995 energy scan, LEP was operated with four trains of three bunches per beam. Under such circumstances it is not possible to collide all bunches with zero δy since the residual

Table 10. A summary of the systematic errors for the 1994 and 1995 analyses of the RF corrections. Errors not listed for a given IP are negligible (< 0.1 MeV). The values for 1994 are given in square brackets, and are zero if not listed. The column labelled ‘ $P \pm 2$ Corr.’ gives the correlation of the errors between energy points in 1995. The correlations between years of LEP running are given in the text

Error		ΔE_{CM} (MeV)	$P \pm 2$ Corr.	Comments
RF misalignment	IP2	0.6 [0.4]	100%	
	IP6	0.5 [0.4]	100%	uncorrelated
Bunch $\langle z_0 \rangle$ shifts within a train	IP4, 8	0.6	50%	
	IP2	0.8	50%	all IPs correlated
	IP6	0.1	50%	
Voltage scale	IP2	0.4 [0.4]	100%	
	IP6	0.1 [0.4]	100%	IP2 and IP6 corr.
Energy loss	IP2	0.3 [0.6]	100%

Fig. 19. Typical online display of a separator scan taken at IP6. The three different sets of points correspond to the three families. The lines are Gaussian fits to the data

beam–beam kicks generate transverse distortions of the train [23]. It is shown in [22] that optimization of the total luminosity results in a cancellation of the individual ΔE_{CM} of each collision within a train, provided that the dispersion differences are the same for each bunch.

The strategy adopted for controlling collision offsets was based on luminosity optimization using vertical separator scans [24]. From these separator scans are obtained:

- The electrostatic-separator setting giving maximum luminosity, at the time of the scan, for the given IP (*optimal setting*), globally and for each family.

- The vertical beam size, σ_y .
- The collision offset, δy , by comparing the setting of the separator before the scan to the optimal setting.
- The opposite-sign vertical dispersion was measured by repeating the separator scans for different RF frequencies, i.e. different beam energies.

With the knowledge of the energy spread measured as described in Sect. 12, these measurements are sufficient to determine the energy shifts of (18). More details of this analysis can be found in [25].

10.3.1 Separator scans

A separator scan consists of moving the beams vertically in opposite directions by varying the voltage of the electrostatic separators. Separator scans were performed once or twice in a fill. After a scan was completed, the separator setting was adjusted to the optimal position, that is the one maximizing the total luminosity, given by an online fit.

Figure 19 shows a typical separator scan. The three different sets of points correspond to the three families. The shift of the maximum for family B with respect to families A and C is in agreement with theoretical predictions [23].

The separator-scan data were re-analysed offline to study quality, stability and other characteristics of the scans. The Gaussian fits were found to be good with a mean $\chi^2/D.O.F.$ of $\simeq 1.2$. The typical statistical error on the optimal separator scan position per family is 0.2–0.3 μm . There were about 35 scans taken at each IP and at each off-peak energy point for the purpose of controlling the collision offsets.

As an example, the stability of the optimal position is shown in Fig. 20 for IP2 as a function of time into the 1995

Fig. 20. The stability of the optimal separator setting for IP2 during the 1995 energy scan for P-2

Table 11. The rms variation of the optimal separator-setting position (using a Gaussian fit) for each IP

	rms separator setting (μm)			
	IP2	IP4	IP6	IP8
P-2	1.07 ± 0.13	0.86 ± 0.11	1.41 ± 0.18	0.98 ± 0.12
P+2	0.97 ± 0.11	1.11 ± 0.13	1.50 ± 0.18	1.24 ± 0.14

Table 12. The mean vertical beam size $\bar{\sigma}_y$. The errors shown are statistical only: the overall absolute scale at each IP is uncertain by up to 15%

	$\bar{\sigma}_y$ (μm)			
	IP2	IP4	IP6	IP8
P-2	3.84 ± 0.12	5.20 ± 0.08	4.75 ± 0.11	4.08 ± 0.13
P+2	3.93 ± 0.07	5.39 ± 0.10	4.76 ± 0.07	4.10 ± 0.06

energy-scan running period (time since 1 Aug., 1995) for P-2. The rms variation of the optimal position for each IP and each energy is given in Table 11.

10.3.2 Vertical beam sizes

Ideally the vertical beam size can be extracted directly from the width of the luminosity curve in a separator scan. The beam size itself varies during the separator scan due to increased beam-beam forces when the collisions are not perfectly head-on at the IP being scanned. This effect was corrected for using the luminosity measured at the same time in the other IPs, resulting in much improved fits to the luminosity curves. The luminosity-weighted average of the vertical beam size, $\bar{\sigma}_y$, determined in this way is used in (18) to define the scale of the energy shifts. Table 12 shows the average vertical beam size, $\bar{\sigma}_y$, for each IP and energy point in 1995. The significant differences in the vertical beam sizes at different IPs are likely due to the overall separator-setting scale, i.e. to the conversion of separator voltages to microns of deflection at the IP, which can differ by up to 15% between IPs. An overall difference in the separator-setting scale drops out of (18) since the collision offset, δy , and the dispersion difference, ΔD_y^* , are also subject to the same scale differences.

10.3.3 Collision offsets

In practice, the LEP operators set the separators for each IP to the optimal setting determined from the online fit after a separator scan at that IP. For data taken before a separator scan had been performed, the settings determined from the previous fill were used. These actual settings were logged continuously. They are close, but not identical, to the true optimal settings, the differences leading to potentially dangerous collision offsets.

In order to evaluate the collision offsets and resulting energy corrections, a model of the optimal settings as a function of time is required, and was estimated as described below. Since optimal settings are known only at the time of a separator scan, this involves interpolation in time, with some uncertainty.

First the separator scans were refitted offline in order to take into account such effects as variation of beam size and online data truncation. Then, for fills with two separator scans available (50% of the data), the value given by the first scan was used for the first part of the fill, a linear interpolation was used between the two scans, and the value given by the second scan was used for the last part of the fill. For fills with only one scan, its value was used throughout. For fills with no scan (less than 10% of the data), the yearly average of optimal settings for the IP and energy considered was used. Uncertainties in this procedure were evaluated by using the last available optimal setting instead of these interpolations.

The luminosity-weighted collision offsets at the four IPs are shown in Table 13. The errors are calculated from the rms variation of the optimal settings. The stability of the optimal settings with time and the large number of scans performed, about 35 scans at each energy point for each IP with an rms of about 1 micron over the 1995 running period, ensure that the resulting errors are small. The optimal settings were found to be different for the two off-peak energies. Since this was not anticipated, the separator settings at the beginning of fills, being taken from the previous fill with a different energy, were systematically offset from the optimum during the first part of the 1995 running period. This was corrected for the later part of that period. The resulting corrections to the energies of the off-peak points lead to corrections to the Z width, determined from the 1995 data, of up to 0.6 MeV for each experiment. The corrections have different signs for the different IPs and are correlated so that the effect for the LEP average Z width is smaller than 0.2 MeV.

Table 13. The luminosity-weighted collision offsets $\langle\delta y\rangle_{\text{lum}}$

	$\langle\delta y\rangle_{\text{lum}}$ (μm)			
	IP2	IP4	IP6	IP8

Theoretical prediction	1.8	-2.8	1.9	-1.9

10.3.4 Dispersion measurements

The LEP beam-energy is changed by changing the RF frequency. Each beam moves by an amount proportional to the beam energy shift. Measurements of the optimal vertical separator settings before and after the RF frequency shift allow the determination of the difference ΔD_y^* in the dispersion of the two beams from the relation

$$\Delta D_y^* = -\frac{\alpha \cdot f_{\text{RF}}}{\Delta f_{\text{RF}}} \cdot \Delta y_{\text{opt}} \quad (19)$$

where Δy_{opt} is the observed shift in the optimal separator setting when the RF frequency, f_{RF} , is shifted by Δf_{RF} . The momentum compaction factor (see Sect. 7) is denoted by α .

An example of a dispersion measurement at IP2 is given in Fig. 21, where the offsets measured for each family are displayed for three beam energies. The dispersion is proportional to the offset difference between both off-energy measurements. The dispersion value retained is the average over the three families. The three separator scans done at nominal frequency before and after each off-frequency scan are used as a consistency check.

Dispersion measurements were made for each IP at each energy. The results (see Table 14) were averaged over the families and the energies. The fluctuations of the different measurements are much larger than their statistical error and are quite different from one IP to another. The error quoted in Table 14 is the sum of all the systematic effects investigated in [25]. The theoretical expectations coming from the accelerator simulation code MAD [26] are also given. The agreement between these predictions and the measurements ensures that the effect is well under control.

10.3.5 Energy shift

Using the results from the previous sections for beam size and dispersion difference, the sensitivity to collision offsets

Table 15. The centre-of-mass energy correction ΔE_{CM} due to dispersion effects. The error is due to the error on the determination of the collision offset δy

	ΔE_{CM} (MeV)			
	IP2	IP4	IP6	IP8
P-2	-0.99±0.39	0.69±0.24	-0.48±0.33	0.29±0.25
P+2	0.12±0.39	-0.47±0.24	-0.21±0.41	-0.26±0.38

Table 16. Mean global errors on ΔE_{CM} for each IP. The systematic errors are labelled uncorrelated and correlated

	Errors on ΔE_{CM} (MeV)		
	Statistical	Uncorrelated	Correlated
IP2	0.39	0.46	0.31
IP4	0.24	0.35	0.18
IP6	0.37	0.34	0.20
IP8	0.32	0.36	0.24

at each IP is determined from (18) to be -2.3 , 1.3 , -1.4 and 1.6 MeV/ μm for IP2, 4, 6 and 8 respectively.

This sensitivity can be combined with the collision offsets given in Table 13 to obtain an estimate of the luminosity-weighted centre-of-mass energy shifts at each IP and energy point. This is shown in Table 15. The error is due to the statistical error on the collision offset, δy , from Table 13.

10.4 Evaluation of errors for the dispersion corrections

In addition to the statistical errors given in Table 15, the following systematic error sources were considered. A first set of errors is uncorrelated between IPs and energies, either because they stem from luminosity statistics in the separator scans, or because they produce effects with no obvious pattern between energies and experiments:

- The errors on the measurement of ΔD_y^*
- The error on the measurement of the vertical beam size (except the overall scale error, which drops out). This is obtained by comparing the results obtained with and without the correction for beam size variation during the separator scans. Also, the difference in results obtained when using a time-averaged beam size for the whole running period or that measured as function of time is taken as a systematic error.
- The results from the Gaussian fit have been compared to the results of the beam size corrected fit, as well as to those of another fit (and model) which uses the LEP BEUV [27] instrument to estimate the beam size.
- Equation (18) gives the energy shift assuming the opposite sign vertical dispersion is the same for all bunches in a train. Possible deviations from this assumption were evaluated using the experimental errors on the family-by-family dispersion measurements.

The following errors are considered fully correlated between energies and experiments:

Fig. 21. Example of a dispersion measurement at IP2 for the three families. The offsets for the three energies are displayed (\circ for the nominal energy, \blacktriangle and \blacktriangledown for $\Delta f_{RF} = +50$ and -50 Hz respectively)

- A possible bias resulting from the direction in which the separator voltages are scanned. This effect was studied by performing separator scans where voltages were varied in the direction opposite to the usual one.
- Variations in the method used to interpolate the optimal settings between separator scans (see Sect. 10.3.3). This effect is found to be similar at P-2 and P+2 and for each IP presumably because the drift of optimal settings during a fill is due to variations in the beam-current intensity.

The off-peak averages of these errors, as well as the statistical errors are given in Table 16 for each IP. In all cases, the systematic errors are larger than the statistical ones. The resulting errors on the energy shifts are between 0.5 and 0.7 MeV, in good agreement with design expectations [24].

10.4.1 Dispersion effects in 1993 and 1994

During the LEP pretzel running in 1993 and 1994, the beams were separated in the odd IPs with short vertical-separation bumps similar to the bunch-train bumps. The opposite-sign dispersion expected at the even points due to these bumps is smaller than 0.1 mm. An unknown fraction of horizontal-dispersion difference created by the pretzel separators may also couple into the vertical plane. An estimate of the opposite-sign dispersion at the collision points was obtained from dispersion measurements made with the beam position monitors. An extrapolation of the difference dispersion measured at monitors located around

the collision points indicated the presence of opposite-sign vertical dispersion of between 0.2 and 0.6 mm. The measurement accuracy is about ± 0.3 mm. No precise figures are available in 1993 and 1994 for the collision offsets since the separator settings were optimized manually by the operators to tune the performance. No systematic separator scans were performed at that time. By comparing the results of empirical optimisation of the collision offsets by the accelerator operators with the separator scan results from 1995 it was concluded that any possible vertical collision offset in 1993 and 1994 would be smaller than 1 μm . This yields systematic errors on the centre-of-mass energy of 0.4 MeV for 1993 and 0.7 MeV for 1994. The correlations between the interaction points and the two running periods are unknown: 75% correlation between energy points in 1993 and 50% correlation between years has been assumed, with no correlation between IPs.

10.5 Positron beam-energy

Imperfections in the LEP lattice such as misalignments of quadrupoles, imperfections in the quadrupole and sextupole fields or asymmetries in the optical sequences combined with the energy sawtooth (see Fig. 18) can cause horizontal deviations from the ideal orbit which are different for positrons and electrons. Theoretical calculations and detailed simulations of imperfect accelerator layout lead to an upper limit of 0.3 MeV on the maximum energy difference between the two beams (see [14], p. 119 and references therein). In 1994 a positron polarimeter was installed in LEP, while in 1993 the electron polarimeter was

Table 17. Difference in energy between positron and electron beam as measured during the various years. In 1994 a dedicated positron polarimeter was installed, while in 1993 the measurement was performed with a modification of the electron polarimeter

Year	Date	$E_{e^+} - E_{e^-}$ (MeV)	LEP operation

slightly modified in order to attempt a measurement of the positron energy which was carried out at the very end of the running period. To maximize the physics time the calibration of the positron beam-energy was performed only once or twice per year, while the RD measurements were performed routinely on the electron beam. A summary of the various measurements performed is given in Table 17. The 1993 experiment performed with the pretzel optics shows an unexpectedly large deviation which contradicts any expectation and was not confirmed in 1994 with the improved polarimeter when running in the same conditions. As all subsequent measurements showed differences compatible with zero it was decided to use, for 1993 and 1994, the largest possible estimated deviation as the correction with an error equal to the correction (0.3 MeV on centre-of-mass energy). Without pretzel the expected possible deviation is negligible and for 1995 the error has been correspondingly reduced to 0.25 MeV on the centre-of-mass energy and the correction set to zero.

11 Summary of the systematic errors on the 1993, 1994 and 1995 LEP centre-of-mass energies

The luminosity-weighted energies at each IP are affected by a number of possible systematic error types.

There is an uncertainty in the average beam-energy determination at a given time arising from the accuracy with which the energy is tracked during a fill and from the precision in the definition of the absolute beam-energy for a given fill. The known contributions to the errors due to the tracking of the energy during a fill have been described in the preceding sections and the unknown ones estimated using the comparison of the model prediction with the measured changes during fills which had multiple calibrations.

In addition there are uncertainties from the RD measurement technique (see [3]) and errors on the corrections to convert the average beam-energy to the energy at the interaction points (see Sect. 10).

The full list of error components is summarized in Table 19. Note that for 1993 these supersede those given in [4] (in Appendix A the changes between the earlier model and the one described in this paper are quantified in detail). In the same table an indication is also given of the

contribution of each component to the error on the m_Z and Γ_Z measurements assuming a similar dataset for each experiment and an equal weight for the 1993 and 1995 energy scans; as this is only an approximation the final errors might differ slightly from those indicated.

The dominant error on m_Z arises from the uncertainty in the dipole-field rise. The Z width is less sensitive to these uncertainties: the largest error contribution to Γ_Z is the statistical contribution from uncalibrated fills.

The systematic uncertainties have correlations between energy points, between IPs and between years. A 7×7 matrix was constructed which held the correlations between the P-2, P and P+2 energy points in 1993, 1994 and 1995 (see Table 18). This matrix takes into account the correlations between IPs in a manner which is correct if it is used to combine the data from the four LEP experiments. The full 28×28 matrix which contains the information about the errors and correlations between IP, years and energy points is given in Appendix B.

11.1 Periods with less precise energy calibration

In 1993 and 1995, prior to the energy scans and in preparation for them, a substantial amount of data was collected at peak energies in conditions which were far from ideal from the point of view of controlling the systematics related to the LEP energy. In 1994, at the end of the year, a special accelerator configuration was tested in order to prepare for the bunch-train running scheme of 1995: LEP had for part of the time a special separation bump in IP4 and IP8. At the same time the existing superconducting RF cavities were also switched on to be tested. During these periods the recording of the RF status was erratic. The same model used to derive the energy for the other fills was used as much as possible for these fills.

For the 1993 pre-scan period (fills 1527 to 1624) the analysis described in [4] is still valid and hence a centre-of-mass energy error of ± 18 MeV is retained. For the 1995 pre-scan period (fills 2614 to 2832) the accelerator parameters were better controlled than in 1993 and the main uncertainty stems from the evidence that one superconducting RF module voltage was not correctly logged. A centre-of-mass energy error of ± 10 MeV is assigned for this period.

For the bunch-train test period, at the end of 1994, estimates of potential luminosity loss due to a vertical offset between the colliding beams, together with the theoretical upper limits on the vertical dispersion at the IPs, and the effects of missing RF records, lead to an error on the centre-of-mass energy of ± 20 MeV (fills 2493 to 2551).

These error assignments are conservative: with such large values the correlations between years can safely be neglected. It is worth mentioning that within these special periods some physics fills were at energies significantly different (up to 500 MeV in centre-of-mass) from the standard ones.

Table 18. LEP energy common error matrix for the scan points of 1993, 1994 and 1995. The values are for centre-of-mass energy in units of MeV²

	93 P-2	93 P	93 P+2	94 P	95 P-2	95 P	95 P+2

95 P+2							2.83

11.2 Energies for the LEP runs before 1993

The model of LEP used for determining the energies from 1993 onwards cannot be applied to the earlier datasets as some of the basic information was not logged and the quality of the accelerator diagnostic tools was lower. Systematic cross checks have been made to ensure that the times at which RD calibrations were performed in 1991 and 1992 were uniformly spread and therefore not biased in a significant way by the tidal and geological deformation cycles and by the field rise effects. The conclusion is that the published analysis had correctly evaluated the errors and is still adequate [6]. Given the large errors the year-to-year correlation can be neglected.

12 Energy spread

The LEP centre-of-mass energy spread σ_{ECM} induces a shift $\delta\sigma$ in the measured cross section (σ) proportional to its second derivative with respect to energy:

$$\delta\sigma = -0.5 \frac{d^2\sigma}{dE^2} \sigma_{ECM}^2 \quad (20)$$

This in turn affects the measured width of the Z resonance. A spread of 55 MeV requires a correction to the measured Z width of about -4 MeV. This correction is essentially the same for all four LEP experiments and the corresponding error is fully correlated. Because the energy scans were approximately symmetric around the resonance peak, the effect on m_Z is negligible.

For the 1993 scan, σ_{ECM} was evaluated with a 10% uncertainty, from measurements of the length of the luminous region in the LEP experiments. The resulting error of 1.0 MeV on Γ_Z was the single largest systematic error on this quantity. The main systematic error originated from the uncertainty in the incoherent synchrotron tune $Q_s^{inc.}$.

The precision has been improved by a factor four for the 1995 scan, and retroactively for data taken in 1993 and 1994. This improvement comes from a direct measurement of $Q_s^{inc.}$ from the synchrotron side-bands of the depolarizing resonance and an improved theoretical calculation of the expected beam-energy spread. In addition, the relationship between beam-energy spread and centre-of-mass energy spread in the presence of opposite-sign vertical dispersion has been investigated and corrected for. Full details of the analysis can be found in [28].

12.1 Beam-energy spread calculations

The rms beam-energy spread σ_{E_b} can be calculated for electrons in equilibrium between the radiation losses in the ring and the energy gain in the cavities [29]:

$$\left(\frac{\sigma_{E_b}}{E_b}\right)^2 = \frac{55}{32\sqrt{3}} \frac{\hbar}{m_e c} \gamma^2 \frac{I_3}{J_e I_2} \quad (21)$$

where E_b is the beam energy, \hbar the reduced Planck constant, m_e the electron mass, c the speed of light, γ the relativistic factor, J_e the energy damping partition number, $I_2 = \oint G^2 ds$ and $I_3 = \oint |G|^3 ds$ are the integrals around LEP (s being the local variable along the beam orbit) of $G(s) = eB(s)/p_b c$, where $B(s)$ is the magnetic field, p_b the beam momentum and e the electron charge.

The largest source of variation in σ_{E_b} comes from the excitation of the emittance wigglers. They are continuously trimmed to control the horizontal emittance and optimize the luminosity. Additional variations of J_e , due to geometrical effects, were controlled with the beam-orbit-measurement system with a relative precision of 1%. Variation of σ_{E_b} with wiggler current and J_e have been parametrised [30], allowing evaluation of σ_{E_b} as a function of time with an estimated precision of 2%.

12.2 Beam-energy spread from bunch-length measurements

Another method to evaluate σ_{E_b} is to relate it to the rms longitudinal size (σ_z) of the interaction region in the experiments. This quantity has the advantage of being continuously measured from the distribution of event vertices and is automatically luminosity-weighted. The relation between σ_{E_b} and σ_z is [29],

$$\sigma_{E_b} = \frac{\sqrt{2}E_b}{\alpha R_{LEP}} Q_s^{inc.} \sigma_z \quad (22)$$

where α is the LEP momentum compaction factor (see Sect. 7), R_{LEP} is the average LEP accelerator radius (i.e. the LEP circumference divided by 2π) and $Q_s^{inc.}$ is the incoherent synchrotron tune. The factor $\sqrt{2}$ relates the longitudinal size of the interaction region to that of the individual bunches.

Table 19. Summary of errors (MeV) on the centre-of-mass energy determination. These are selected numbers shown for illustration, the exact errors are determined using the correlation matrix formalism. The energy correlation coefficients between energy points and between years are shown. Whenever the year-to-year or the energy-to-energy correlation coefficient is not fixed the range is indicated. The relative sign of the energy correlation coefficient is given by the relative sign of the error. The last two rows give average errors due to RF and dispersion effects when combining the 4 IPs with the respective correlation coefficients. The last two columns give estimates of the error contributions to the determination of m_Z and Γ_Z in MeV: the actual errors depend on the details of experimental samples

Energy spread											0.2

The main uncertainty in this determination of σ_{E_b} comes from $Q_s^{\text{inc.}}$. The incoherent synchrotron tune is the number of energy oscillations per turn for individual beam particles. What is operationally measured are the longitudinal oscillations of full particle bunches, giving the coherent synchrotron tune, $Q_s^{\text{coh.}}$. Equation (22) is written in terms of $Q_s^{\text{inc.}}$. The relation between $Q_s^{\text{coh.}}$ and $Q_s^{\text{inc.}}$ is parametrized as

$$\frac{Q_s^{\text{coh.}}}{Q_s^{\text{inc.}}} = 1 - \kappa \frac{I}{I_0}, \quad (I_0 = 300 \mu\text{A}) \quad (23)$$

where I is the bunch current and κ is a complicated function of the longitudinal impedances of the machine elements which is difficult to evaluate analytically.

The incoherent synchrotron tune was measured in a dedicated experiment carried out at P+2 in 1995 during an RD calibration. Depolarization was observed at the main resonance and at spin tunes different from the main one by $\pm Q_s$, identified as synchrotron sidebands. From the precisely determined position of these sidebands, the value of $Q_s^{\text{inc.}}$ was measured. By comparing these values of $Q_s^{\text{inc.}}$ with the value of $Q_s^{\text{coh.}}$ simultaneously determined by the RF system, a value of κ could be extracted using (23). The sidebands were determined for bunches with currents of 50 and 180 μA , showing agreement with (23) for a value of $\kappa = 0.045 \pm 0.022$. The error is assigned from the frequency sweep interval (see Sect. 2.2) used in the RD measurements and the time variations of $Q_s^{\text{coh.}}$ during the experiment.

For each year of data-taking and each energy point, the beam-energy spread (luminosity-weighted) was computed

according to (22) using the rms of the z distribution in ALEPH, the measured bunch currents and $Q_s^{\text{coh.}}$, and $\kappa = 0.045$. For 1995 data, no difference between the different bunch families was observed.

Consistency checks of the two determinations of energy spread could be performed as a function of time for groups of events recorded in the ALEPH detector, showing consistency at the level of $\pm 2\%$. The comparison is shown in Fig. 22 as a function of the most sensitive parameter, the wiggler current, showing again consistency at that level of precision.

12.3 From beam-energy to centre-of-mass energy spread

The centre-of-mass energy spread $\sigma_{E_{CM}}$ is related to the beam-energy spread σ_{E_b} by the simple formula:

$$\sigma_{E_{CM}} = \sqrt{2} \sigma_{E_b} C, \quad (0 \leq C \leq 1) \quad (24)$$

For colliding beams having no or identical energy dispersion (as in 1993 and 1994) the *monochromatization* factor C is equal to 1 [22]. This is not the case for data taken in 1995 with the bunch train operation mode, where beams had opposite sign vertical energy dispersion leading to a more complicated relation between σ_{E_b} and $\sigma_{E_{CM}}$ [25]. This relation can be simplified to:

$$\sigma_{E_{CM}}^2 = 2 \sigma_{E_b}^2 \left[1 + \left(\frac{D_y \frac{\sigma_{E_b}}{E_b}}{2\sigma_y} \right)^2 \right]^{-1} \quad (25)$$

Table 20. Centre-of-mass energy spread for the different years and interaction points. The numbers in brackets are the average $\sigma_{E_{CM}}^2$ including the effect of varying energy spread during a fill due to changes in the wiggler magnets currents. These are the numbers needed since the cross-section correction depends at leading order on $\sigma_{E_{CM}}^2$

	$\sigma_{E_{CM}} (\sigma_{E_{CM}}^2)$ in MeV (MeV ²)

P	55.4 (3108)	54.9 (3044)	55.6 (3128)	56.2 (3198)	56.2 (3199)	56.3 (3204)
P+2	55.6 (3120)		56.0 (3196)	56.6 (3269)	56.7 (3269)	56.7 (3274)

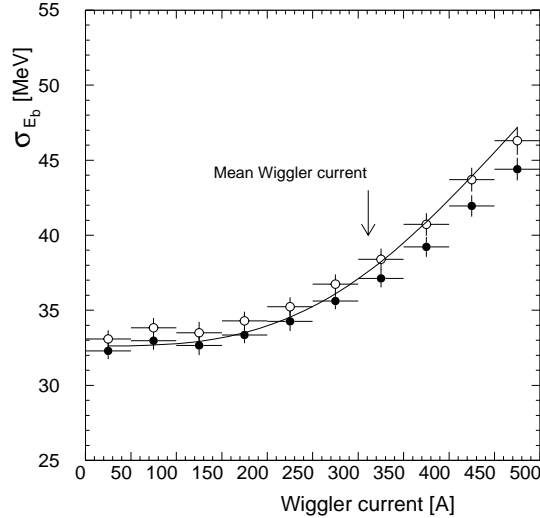

Fig. 22. 1994 data. Comparison of the two evaluations of σ_{E_b} as a function of wiggler current. The ‘theoretical’ prediction (full line); σ_{E_b} computed from σ_z using Q_s^{coh} . (black dots); σ_{E_b} computed using Q_s^{inc} . with a κ value of 0.045 (open dots)

where D_y is the opposite sign vertical energy dispersion and σ_y is the vertical beam size.

The possible beam dispersion differences at the IP for the 1993 and 1994 running periods have been evaluated [31]. The reduction on the centre-of-mass energy spread is estimated to be less than 0.2%. This corresponds to a change of 0.1 MeV on $\sigma_{E_{CM}}$, and is therefore neglected. For the 1995 running period this correction amounts to about 2% and is different for each IP. This was calculated using the measurements of dispersions [25] described in Sect. 10.3.

The LEP centre-of-mass energy spread is given in Table 20 for the different years where also the luminosity-weighted average squares, which are needed in (20), are shown. The measured energy spread increases with energy, as expected.

LEP centre-of-mass energy variations increase the centre-of-mass energy spread. The rms of the LEP centre-of-mass energy distribution for each year, experiment and energy point has to be added in quadrature to the numbers given in Table 20.

12.4 Systematic errors on the LEP centre-of-mass energy spread

A full estimate of systematic errors was performed for the determination using bunch length as follows. The resulting evaluation of $\pm 2\%$ is similar to the quality of the consistency with the theoretical calculation. The following parameters contribute to the systematic error on the LEP centre-of-mass energy spread.

- The LEP momentum compaction factor α , was measured to be $(1.86 \pm 0.02) \cdot 10^{-4}$. The 1% error on this parameter directly translates into a 1% error on σ_{E_b} : 0.4 MeV.
- The difference between the measured and the computed Q_s^{coh} . is -0.00034 for the 1995 scan [20] and 0.0001 for the 1993 scan [32]. It is a 10^{-3} effect at maximum (mean value of $Q_s = 0.065$) and therefore can be neglected.
- The beam-energy variations within a fill have not been included in the above calculations. However it is less than a 10^{-3} effect and can be neglected.
- The error on κ is the dominant error, resulting in an error of 0.7 MeV on σ_{E_b} and of 1.1 MeV on $\sigma_{E_{CM}}$.
- The errors on the opposite-sign vertical dispersion, described in Sect. 10.3, yield an error of the order of 0.01 on the *monochromatization* factor C , which leads to a 0.6 MeV error on $\sigma_{E_{CM}}$, for 1995 data. This uncertainty is negligible for earlier years.

From the above discussion, the error on the LEP centre-of-mass energy spread is 1.1 MeV for 1993 and 1994. For 1995 this error is increased to 1.3 MeV due to vertical beam-energy dispersion. These numbers are correlated between years and experiments. The contribution to the corresponding error on I_Z is $\Delta I_Z \approx 0.2$ MeV.

12.5 Energy spread for LEP runs before 1993

To insure a consistent set of values for the analysis of LEP data taken before 1993, the values of the energy spread to be used for the years previous to 1993 are presented here. These values supersede those given in [33]. The Table 21 summarizes the results for the years 1990, 1991 and 1992. The values from 1989 are the same as 1990. Since no data

Table 21. Centre-of-mass energy spread for the years 1990, 1991, 1992. To be noted that the Z scans before 1993 consisted of 6 off-peak points: here ± 1 and ± 3 means respectively ± 0.9 GeV and $\pm 3 \cdot 0.9$ GeV on either side of the Z peak for 1991 and 1992, while for 1990 the step is an integer number of GeV

	σ_{ECM} in MeV		
	1990	1991	1992
P-3	47.	43.	
P-2	48.	44.	
P-1	49.	45.	
P	50.	46.	51.
P+1	51.	47.	
P+2	52.	48.	
P+3	53.	49.	

on the time-dependence of the energy spread exists, the quantity σ_{ECM}^2 is assumed to be equal to $(\sigma_{ECM})^2$, where σ_{ECM} is taken from Table 21.

The difference in values between 1990 and 1991 is a result of the beams being more centered in the LEP quadrupoles during 1991. In 1992, wiggler magnets were used in LEP to increase the beam size in order to maintain a higher luminosity, which also increased the energy spread.

Owing to the less accurate logging of vital information, the error the center-of-mass energy spread is taken to be 3 MeV for all years prior to 1993.

13 Conclusions

The 1995 energy scan and the improved accelerator instrumentation have allowed a significant advance in the understanding of the energy of the LEP beams. The improved understanding of the thermal behaviour of the LEP dipoles and newly discovered effects of parasitic currents flowing on the LEP beam-pipe have improved the modelling of the LEP energies. All the datasets since 1993 have been analysed and the final LEP energies determined with small, but significant, changes with respect to the published 1993 results.

The precision of the centre-of-mass energy spread determination has been improved by more than a factor of four reducing significantly what used to be one of the dominant sources of error in the Z width.

The overall contribution of the energy uncertainties to the combined LEP m_Z and Γ_Z measurement can be estimated to be $\Delta m_Z \approx 1.9$ MeV and $\Delta \Gamma_Z \approx 1.2$ MeV on the assumption that datasets from all experiments and both scans enter with equal weight. A full fit to the experimental cross-sections using the error matrix of Appendix B is expected to yield different errors.

Acknowledgements. We thank the SL Division of CERN for the excellent performance of the LEP collider. The careful work and assistance of many technical groups in the AS, MT and ST Divisions has been essential to reach the performance described in this paper. We acknowledge many useful discussions with J. Jowett, E. Keil, W. Herr and S. Myers. We also acknowledge the support of the Particle Physics and Astronomy Research Council, UK.

Appendices

A Comparison between the present and original 1993 energy Idetermination

There are several differences between the present determination of the 1993 scan energies and the previously published analysis [4]. These differences are summarised in Table 22. Certain components of the model have been wholly revised, namely the treatment of the dipole temperature behaviour and the B field rise within a fill, and new ingredients have been introduced concerning the effects of horizontal correctors. Small modifications to the modelling of other corrections have resulted in further changes in the central values. These include re-evaluated values of the fill-by-fill ring deformation ('BOM file'), a new procedure for averaging groups of RD measurements to obtain a mean value for the calibration ('RD file'), and changes of coefficients for the tide and QFQD corrections. A possible difference in energy between the electron and positron beams, not propagated to the final energies in the original analysis, has now been included (e^+ vs e^-). Table 22 lists how these changes have affected the two off-peak energy points and the resulting shifts in m_Z and Γ_Z . Note that because of correlations, the exact values of the shifts for the mean beam energy, component by component, have some dependence on the order in which they are applied. The given values of the energy shifts correspond to the order in which the components are listed. Also shown is the effect of the re-evaluated centre-of-mass energy spread, whose central value has changed by -0.4 MeV at P-2, 0.4 MeV at P and 0.6 MeV at P+2. It can be seen that the major effect comes from the dipole field rise. In total the measured value of m_Z has decreased by ~ 1.6 MeV and that of Γ_Z has increased by ~ 0.6 MeV. Table 23 lists the assigned errors in both analyses. The large dipole field rise in the present model is accompanied by a significant uncertainty which dominates for m_Z and inflates the final error. The dipole field rise also induces a larger uncertainty on Γ_Z , although the degradation from this and other effects is partially compensated for by the improved knowledge of the beam energy spread.

Table 22. Shifts in 1993 off-peak centre-of-mass energies of the present analysis with respect to the old analysis for each component of the model and for the model as a whole. Only components which have changed or were not present in the earlier analysis are listed. In the earlier publication ‘B rise’ was referred to as ‘NMR uncertainty’. Approximate shifts in m_Z and Γ_Z are also given, with the contribution from the re-evaluated energy spread included
