Abstract. An optimization of the CERN SPL beam line has been performed guided by the sensitivities to the θ_{13} mixing angle and to the δ_{CP} Dirac CP violating phase. A UNO-like 440 ktons water Čerenkov detector located at 130 km from the target in a new foreseen Fréjus laboratory has been used as a generic detector. Concerning the δ_{CP} independent θ_{13} sensitivity, a gain of about 20% may be reached using a 3.5 GeV proton beam with a 40 m long, 2 m radius decay tunnel compared to the up to now considered 2.2 GeV beam energy and 20 m long, 1 m radius decay tunnel. This may motivate new machine developments to upgrade the nominal SPL proton beam energy.

1 Introduction

The very near future of the neutrino long baseline experiments is devoted to the study of the oscillation mechanism in the range of $\Delta m^2 = \Delta m_{atm}^2 \approx 2.4 \times 10^{-3} \text{eV}^2$ [1, 2] using conventional ν_μ beams. The current K2K experiment in Japan [2], and the forthcoming MINOS in the USA [3] take benefit of low energy beam to measure the Δm^2 parameter using the disappearance mode $\nu_\mu \rightarrow \nu_\mu$, while OPERA/ICARUS experiments [4, 5] using the high energy CNGS beam [6] will be able to detect ν_τ appearance. If we do not consider the LSND anomaly [7] that will be further studied soon by MiniBooNE experiment [8], the three flavor family scenario will be confirmed and accommodated by a 3×3 Pontecorvo-Maki-Nakagawa-Sakata (PMNS) mixing matrix [9] with three angles ($\theta_{12}, \theta_{13}, \theta_{23}$) and one Dirac CP phase δ_{CP} .

Beyond this medium term plan, two of the next future tasks of neutrino physics are to improve the sensitivity of the last unknown mixing angle parameter, the so-called θ_{13} , and to explore the CP violation mechanism in the leptonic sector. The present upper bound on θ_{13} is $\sin^2 2\theta_{13} < 0.14$ for $\Delta m^2 = \Delta m_{atm}^2$ (90% CL) [10]. This sensitivity can be improved using reactor and accelerator experiments. In reactor experiments, one uses $\bar{\nu}_e$ in disappearance mode and may reach $\sin^2 2\theta_{13} < 0.024$ for $\Delta m^2 = \Delta m_{atm}^2$ (90%CL) [11]. In accelerator experiments, one can use ν_e and $\bar{\nu}_e$ from β beams [12] in both disappearance and appearance modes (i.e. $\bar{\nu}_e \rightarrow \bar{\nu}_\mu$), and also $\bar{\nu}_\mu$ in appearance mode (i.e. $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$) with conventional beams either with sub-mega watt proton drivers [13, 14] or with multi-mega watt proton drivers [14–16]. The later neutrino beam type, called Superbeam, is foreseen to be extended to produce ν_μ beam and $\bar{\nu}_\mu$ beam from muon

decays, the so-called Neutrino Factory, in order to study the eventual leptonic CP violation. Such Neutrino Complex is under study in Japan, in USA and also in Europe at CERN and details may be found in [16]. A comparison of the performances of β beam and Superbeam may be found for instance in [17]. The reactor experiment result on θ_{13} is straight forward as compared to Superbeam and Neutrino Factory results that are on one hand reacher but in an other hand more complex to analyse due to the interplay between the different physics factors $\theta_{13}, \delta_{CP}, \text{sign}(\Delta m_{23}^2), \text{sign}(\tan(2\theta_{23}))$ [17, 18].

This paper presents results of a new simulation of the SPL (Super Proton Linac) Superbeam that could take place at CERN [19], using for definitiveness a UNO-like 440kT fiducial water Čerenkov detector [20] located in a new enlarged underground laboratory under study in the Fréjus tunnel, 130 km away from CERN [21]. The SPL neutrino beam is created by decays of pions, muons and kaons produced by the interactions of a 4 MW proton beam impinging a liquid mercury jet [16]. Pions, muons and kaons are collected using two concentric electromagnetic lenses (horns), the inner one and the outer one are hereafter called “Horn” and “Reflector” respectively [22]. The horns are followed by a decay tunnel where most of the neutrinos are produced. A sketch of the beam line is shown on Fig. 1.

The analysis chain consists of different stages: the simulation of the interactions between the proton beam and the mercury target, the propagation of the resulting secondary particles through the magnetic field and the materials of the horns, the tracking of $\pi^\pm, K^{\pm,0}$ and μ^\pm until they decay, the computation of the neutrino flux at the detector site, and finally the statistical analysis. A part of the simulation chain has already been described in [23, 24].

Compared to recent papers on the same subject [17, 25, 26], we have reoptimized the Horn and Reflector shapes [27], and introduced the kaon background simulation which al-

allows us to update the SPL beam energy. The organization of this document follows the simulation chain: the interaction between the proton beam and the mercury target is presented in the second section. The kaon production is detailed in the third section. The simulation of the horns is described in the fourth section, while the algorithms used to compute the neutrino fluxes are explained in the fifth section. Then, the sensitivities to θ_{13} and δ_{CP} are revisited with new studies about the optimization of the proton beam energy, the pion collection and the decay tunnel geometry.

2 Target simulation

Since hadronic processes are crucial to describe the interactions of the proton beam on the target, the FLUKA simulator [28] has been chosen for this first step of the simulation. The target used in the present study is a mercury liquid jet [16] simulated for a sake of simplicity by a cylinder 30 cm long (representing two hadronic lengths) and 1.5 cm diameter (see Table 1) [25]. Other types of target are under study [16]. The pencil like simulated proton beam is composed with 10^6 mono-energetic protons, and no beam-

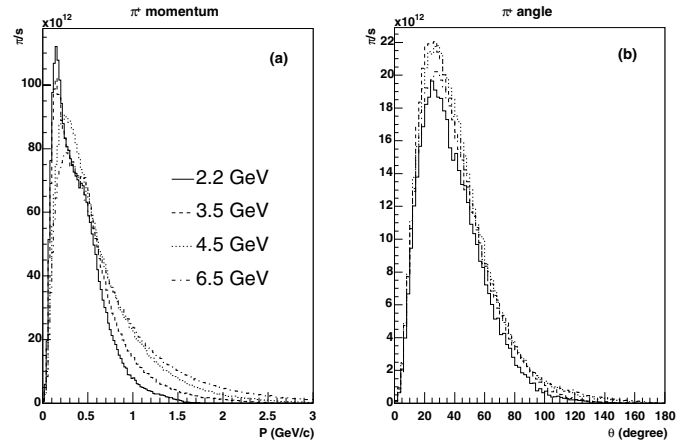

Fig. 2. **a** π^+ momentum distribution per second at the exit of the target for the different proton beam energies studied, simulated with FLUKA, and **b** π^+ angle with respect to the beam axis of the pion having a momentum between 0.5 GeV/c and 0.7 GeV/c. The different SPL beam kinetic energies presented are (—) 2.2 GeV, (----) 3.5 GeV, (····) 4.5 GeV and (---) 6.5 GeV

target dynamical effects are taken into account. The beam axis is also the symmetry axis of the target and the horns and the decay tunnel. Simulations have been performed for 2.2 GeV proton kinetic energy, the up to now nominal design [19], as well as for 3.5 GeV, 4.5 GeV, 6.5 GeV and 8 GeV according to possible new designs [29].

Particle production yields are summarized in Table 2. The pion momentum spectra obtained at different energies and normalized to a 4 MW SPL beam power are presented in Fig. 2a. At low energy, pions come from Δ decays while the high energy part is dominated with multi pion production. At very low energy, for $P < 200$ MeV/c, pions come from Δ produced by protons of the target excited by the beam interactions, while for higher energy, pion production is due to transformation of protons of the beam into Δ .

The horns are designed to focus the 600 MeV/c pions (see Sect. 4) and the variation of the number of such pions is rather smooth with respect to the beam energy considering a 4 MW fixed beam power: $4.19 \times 10^{13} \pi/s$ for the 2.2 GeV beam, $4.91 \times 10^{13} \pi/s$ for the 3.5 GeV beam, $5.14 \times 10^{13} \pi/s$ for the 4.5 GeV beam, and $4.92 \times 10^{13} \pi/s$ for the 6.5 GeV beam. The main difference is made by the angular distribution. Figure 2b shows this distribution for the π^+ exiting the target with a momentum between 500 MeV/c and 700 MeV/c. The acceptance of the horns is limited to

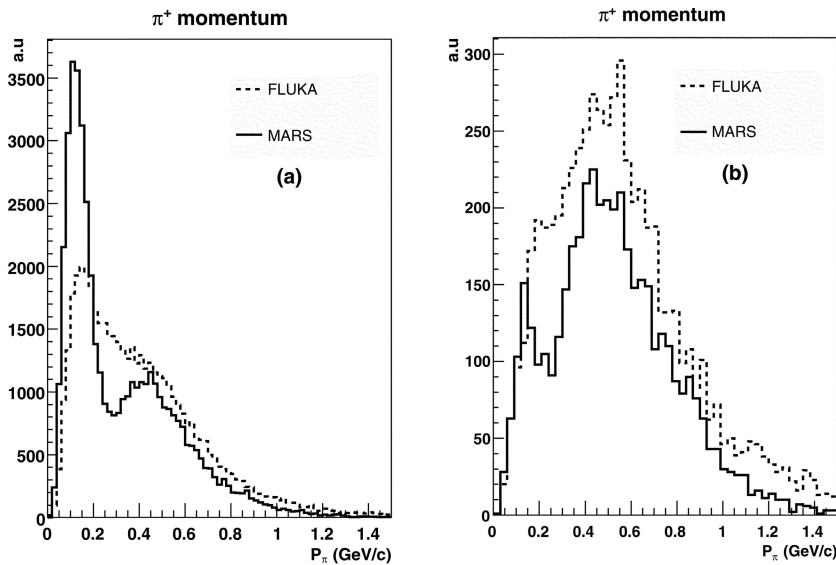

Fig. 3. π^+ momentum distribution at the exit of the target **a** and at the exit of the horns **b**, simulated by FLUKA (---) and by MARS (—)

the pion below 25° , and we see that more pions are accepted by the horns for the 3.5 GeV and 4.5 GeV proton beams compared to other beam energies.

The secondary proton and neutron rates induce important radiation damages and power dissipation in the horns which have been addressed in [23], and which will require specific R&D effort. At 2.2 GeV, kaon yields are very low, but it has a dramatic energy dependence as further studied in Sect. 3. It is worth to mention that the numbers in Table 2 are not to be taken as face values, because the cross sections of pion and kaon productions using proton beam are still under studies as for instance by the HARP experiment [30]. The cross section uncertainties are the main source of discrepancy between simulator programs. Some comparisons between FLUKA and MARS [32] have already been presented in the same context [23]. The energy distribution of the pions exiting the target, computed with the two simulator programs FLUKA and MARS, is shown on Fig. 3a. The discrepancy is quite large for the low energy part. However, the horns are designed to focus the high energy part of the spectrum (see Sect. 4), and therefore, MARS and FLUKA are in better agreement for the energy spectrum computed at the entrance of the decay tunnel, as shows Fig. 3b. For a 2.2 GeV beam and a positive focusing, 27% more ν_μ and 6% more ν_e neutrinos are produced around the oscillation probability maximum with the FLUKA generator. It turns out that a sensitivity 10% better for FLUKA compared to MARS has been found for the $\sin^2(2\theta_{13})$ sensitivity (see Sect. 7). So, the discrepancy at low energy between MARS and FLUKA does not matter too much for the present application, and the sensitivity difference can be taken as a systematic error.

3 Kaon production

The possibility to increase the SPL energy in order to study the optimization of the physics program has been recently pointed out [29]. Then, the kaon production should

be clearly addressed because it is a source of ν_e and $\bar{\nu}_e$ background events. The kaon decay channels and branching ratios are presented in Table 13 in Appendix A.3.

The target simulation described in Sect. 2 has been used with 10^6 p.o.t with kinetic energy uniformly distributed between 2.2 GeV and 5 GeV. The momentum of outgoing pions and kaons are recorded when they exit the target. The number of produced $K^{0,\pm}$ at different proton beam energies are presented on Fig. 4 (left). In one hand the K^0 production rate is similar to the K^+ production rate, but in an other hand the K^- production rate is almost forty times smaller. For comparison, the numbers of π^+ and π^- produced in the same conditions are presented on Fig. 4 (right). Pion production rate is about two orders of magnitude greater than the kaon production rate. The behavior of the two pion and kaon production rates are quite different. The π^+ yield grows smoothly with the proton energy while the production of kaons seems to have two origins, which has been confirmed by FLUKA's authors [33]. For beam energy below approximately 4 GeV, the resonance production model is used, and one notices a low production rate with a maximum at about 3.4 GeV. For beam energy above 4 GeV, the dual parton model is used, and the production rate experiences a threshold effect with a rapid rise. The ratio between positive kaon and pion production rates is about 0.5% between 2.2 GeV and 4 GeV and grow up to 2.3% at 5 GeV. One notices that the transition between the two kaon production models may not be optimal.

4 Horns simulation

The simulation code of the electromagnetic horns is written using GEANT 3.2.1 [34] for convenience and since electromagnetic processes are dominant, FLUKA has not been considered as mandatory, but this may be revised in a future work. The geometry of the horns has been inspired by an existing CERN prototype and a Reflector design proposed in [35]. Depending of the current injection, only

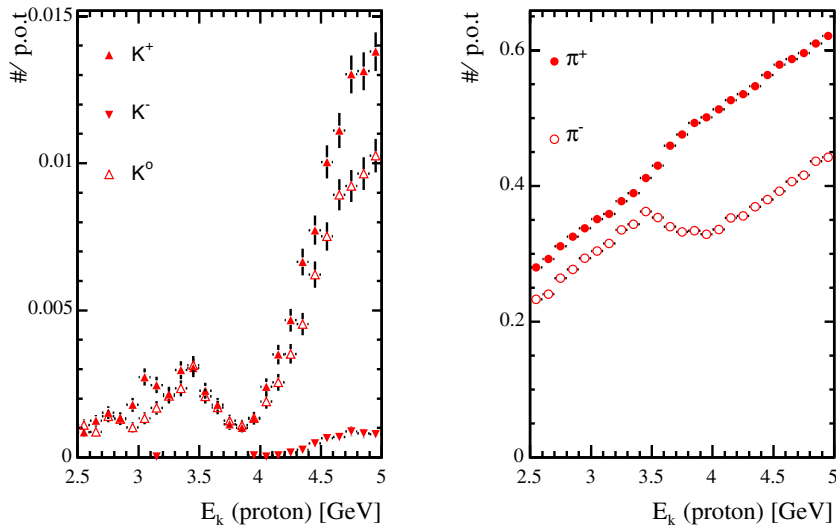

Fig. 4. Kaon production (left panel) and pion production (right panel) defined as number of particle produced per proton on target (p.o.t) as function of the kinetic energy of the incident proton (E_k)

positive secondary particles or negative secondary particles are focused. The relevant parameters are detailed in Table 3.

The shape of the horn conductors is a crucial point since it determines the energy spectrum of the neutrino at

Table 3. Relevant parameters of the horns in case of the generation of a 260 MeV neutrino beam (or 350 MeV in parenthesis). The shapes of the conductors are independent of the proton beam energy, as the focusing has been optimized for a 600 MeV/c (or 800 MeV/c) pion momentum

	Horn	Reflector
neck inner radius	3.7 cm	20.3 cm
neck length	40 cm	120(140) cm
end cone inner radius	16 cm	35.7 cm
outer radius	20.3 cm	40 cm
total length	120(140) cm	190(220) cm
Alu thickness	3 mm	3 mm
Peak current	300 kA	600 kA
Frequency	50 Hz	50 Hz

the detector site. The details of the conductor shape optimization for the present context may be found in [27]. We just recall here some ingredients. For a θ_{13} driven $\nu_\mu \rightarrow \nu_e$ oscillation, a Δm_{23}^2 parameter value of $2.4 \times 10^{-3} \text{eV}^2$, and a baseline distance of 130 km, the first oscillation maximum occurs for a neutrino energy of 260 MeV. The optimization of the physics potential depends at first approximation on the pion neutrino characteristics, which energy is fully determined by the pion 2-body decay and boost. To reach an energy of 260 MeV, the pion needs a $\beta = 0.97$, which in turn induces a pion momentum of 600 MeV/c. Then, the shape of the conic part of the horns is determined such that these 600 MeV/c pions exit parallel to the beam axis.

The mercury target is localized inside the Horn because of the low energy and the large emittance of the secondary pions produced:

$$\langle P_{\pi T} \rangle / \langle P_\pi \rangle \approx 240 \text{ MeV} / 400 \text{ MeV}$$

(2.2 GeV proton beam energy). This explains the Horn design (Fig. 5), with a cylindrical part around the target, called the neck, which is larger than the transversal size of the target to simulate the room for target handling, and a

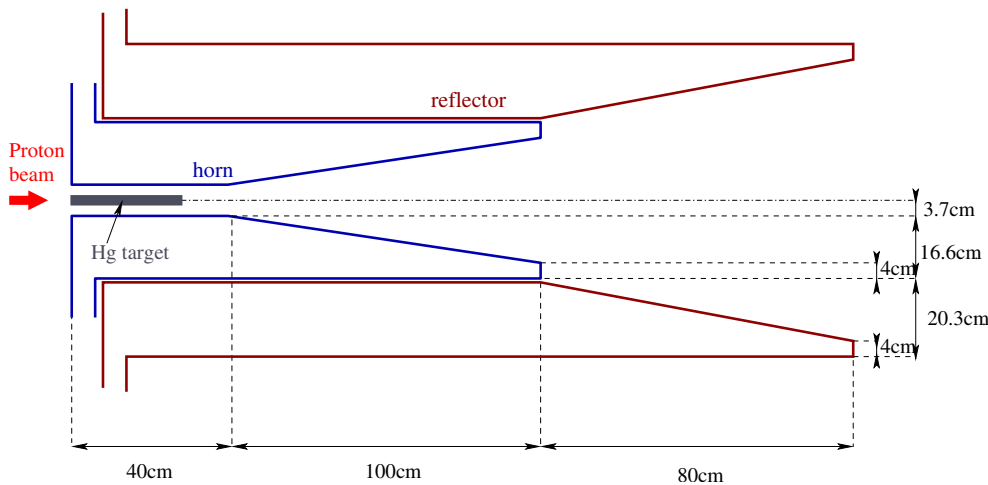

Fig. 5. Design of the Horn and the Reflector conductors implemented in the GEANT simulation in case of the generation of a 350 MeV neutrino beam. The Hg target is located inside the cylindrical part of the Horn

conic part designed such that the relevant pions are focused as much as possible to exit the magnetic field parallel to the beam axis.

Another shape of the horn conductors has been used to produce a 350 MeV neutrino beam to compare the sensitivity potential (see Sect. 7). In that case, keeping the current intensity unchanged (300/600 kA), the lengths of the Horn and the Reflector should be increased by 16% and 18.5%, respectively (see Table 3).

Before closing this section, it is worth to quote that the Horn/Reflector conductor shapes optimized in the present study to focus a given pion momentum value, is not affected at first order by a proton beam energy change. What is affected is the production rate of the relevant pions. This Horn/Reflector design consideration would be different if one wishes to focus as much as possible all the pions produced for which the mean energy is of course affected by a proton beam energy change.

5 Particle decay treatment and flux calculation

The decay tunnel representation is a simple cylinder with variable length (L_T) and radius (R_T) filled with “vacuum” and located right after the horns. The default design is a 20 m long and 1 m radius cylinder, but simulations have also been conducted with lengths of 10 m, 40 m and 60 m, and radius of 1.5 m and 2 m in the spirit of [36]. In the GEANT simulation, to gain in CPU time, only pions, muons and kaons are tracked in the volume of the tunnel, and all particles exiting this volume are discarded.

Beyond the $1/L^2$ solid angle factor due to the source-detector distance (L) which decreases dramatically the fluxes, the neutrino beam focusing is very limited due to the small pion boost factor (≈ 4). Therefore, computational algorithms have been used to avoid a too prohibitive CPU time resulting from the simulation of each secondary particle decay. Otherwise, about 10^{15} p.o.t would have been necessary to obtain reliable statistics for the estimation of the $\bar{\nu}_e$ flux for instance.

It is worth to mention that the particle decays occurring before the entrance of the decay tunnel are also taken into account and treated in the same manner, which is not the case in [36].

5.1 Algorithm description

The decay code has been included in the GEANT code. The basic idea of this algorithm is to compute the neutrino fluxes using the probability of reaching the detector for each neutrino produced by a π or a K or a μ particle (on-axis neutrino beam). This method has already been used in [36] and has been modified and extended to the kaon decay chain for the present study.

Muon neutrino comes mostly from pion decay. In a first stage, each pion is tracked by GEANT until it decays. Then, the probability for the produced muon neutrino to reach the detector is computed. The flux is obtained applying the probability as a weight for each neutrino. All the pions

produced in the simulation are therefore useful to compute the flux, and this allows to reduce the number of events in the simulation to 10^6 p.o.t. In this computation, the decay region (horns and tunnel) is considered as point like compared to the source-detector distance.

The same method is applied for neutrino coming from muons and kaons with some modifications because most of the muons do not decay, and there are very few kaons produced (see Table 2). The probability computation is presented in Appendix A.

5.2 Validation of the algorithm

The validity of the method presented in the previous section have been tested against a straight forward algorithm consisting of decaying each pion N times ($N \approx 10^6$) in a full GEANT simulation of the event (decays included). Such method presents the advantage to keep all the information of the neutrino available for further studies. It can be a good approach to compute the muon neutrino flux coming from pion decays. It can also provide the beam profile, but it shows its limits for the muon induced fluxes, especially the $\bar{\nu}_e$ flux. Indeed, this means that each muon is duplicated N times and when a muon decays, it must decay N times again. For $N \approx 10^6$, this is a prohibitive CPU time consuming. The ν_μ and $\bar{\nu}_\mu$ fluxes are displayed on Fig. 12 for both methods. The two spectra shows a clear agreement, and this makes confidence on the probability method.

5.3 Simulated fluxes

The fluxes are computed at a distance of 100 km from the source by convention and can be rescaled at any desired distance. They provide the number of the four neutrino species (ν_μ , $\bar{\nu}_\mu$, ν_e , $\bar{\nu}_e$) passing through a 100 m^2 fiducial area during 1 year.

In practice, the fluxes are given as a function of the neutrino energy via histograms composed of 20 MeV bin width. These histograms are filled with the energy of each neutrino weighted by the probability to reach the detector (Sect. 5.1). To obtain the fluxes, the histograms are rescaled to the number of p.o.t per year depending on the beam energy. Table 4 reports on the number of p.o.t per year for the different energies studied using the definition of one year being 10^7 s and keeping the beam power constant (i.e. 4 MW).

Table 4. Number of protons on target for different beam energy at 4 MW constant power. One year is defined as 10^7 s

Beam energy (GeV)	Number of proton per year (10^{23} p.o.t/y)
2.2	1.10
3.5	0.70
4.5	0.56
6.5	0.40
8.0	0.30

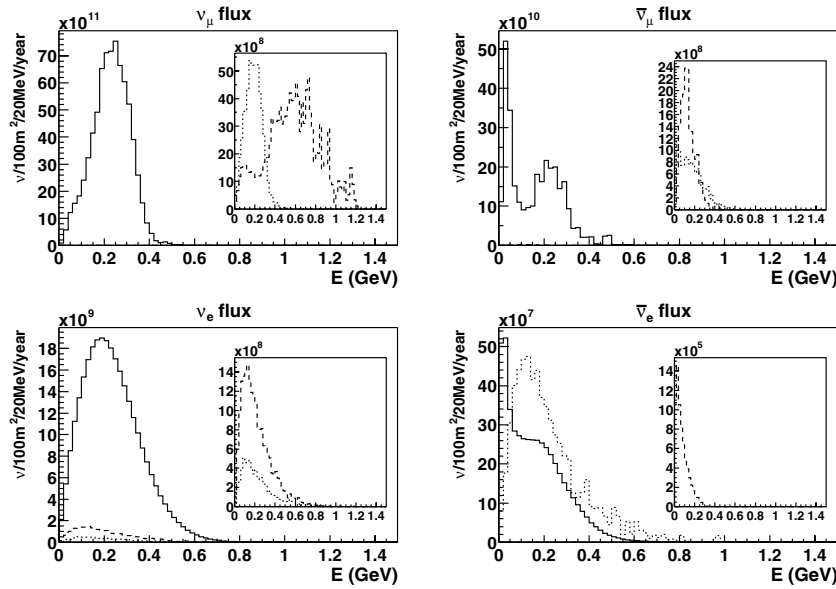

Fig. 6. Neutrino fluxes, 100 km from the target and with the horns focusing the positive particles. The fluxes are computed for a SPL proton beam of 2.2 GeV (4 MW), a decay tunnel with a length of 20 m and a radius of 1 m. The top left panel contains the ν_μ fluxes, and the top right panel shows the $\bar{\nu}_\mu$ fluxes. The bottom left panel presents the ν_e fluxes while the bottom right panel displays the $\bar{\nu}_e$ fluxes. The (—) curve is the contribution from primary pions and the daughter muons, and from primary muons. The (---) curve is the contribution from the charged kaon decay chain, and the (⋯⋯) curve is the contribution from the K^0 decay chain. An insert has been added to the plots to highlight when needed the contribution of charged and neutral kaons

Three origins are identified in the composition of each neutrino flux:

- neutrinos from pions, which includes neutrinos created by primary pion decays and neutrinos coming from the muons produced by pion decays or muons directly exiting the target. This is the component studied in [36] but with different settings and event generator;
- neutrinos emitted during the decay chain of the charged kaons, either by direct production, or produced by the daughter pions and muons;
- neutrinos coming from the decay chain of the neutral kaons.

The three components of the fluxes for the four neutrino species are presented on Fig. 6 for positive particle focusing and a proton beam kinetic energy of 2.2 GeV. The ν_μ flux is dominated by the neutrinos of pion decays, but a tail above 500 MeV (insert on the top left part) is created by

the $K^+ \rightarrow \mu^+ \nu_\mu$ channel, which is anyway at least three orders of magnitude below the flux maximum. The $\bar{\nu}_\mu$ flux is mostly due to the decays of π^- that are not defocused by the horns, but the higher energy part comes from μ^+ decays. It is noticeable that the ν_e and $\bar{\nu}_e$ fluxes are respectively more than 200 and more than 7000 times smaller than the ν_μ flux. The $\bar{\nu}_e$ are produced in a large part by the $K_L^0 \rightarrow \pi^+ e^- \bar{\nu}_e$ decay channel and by μ^- decays, while the ν_e flux is dominated by the μ^+ decays.

On Fig. 7, the horns are set to focus negative particles keeping other parameters identical. By comparison with positive focusing, one can at first approximation translate the results by exchanging particles and anti-particles, except that the K^+/K^- ratio is about 50 in the beam-target interactions (see Table 2).

On Figs. 8 and 10, one observes the evolution of Fig. 6 when the proton beam kinetic energy increases to 3.5 GeV and 8 GeV, respectively. Correspondingly, the results for

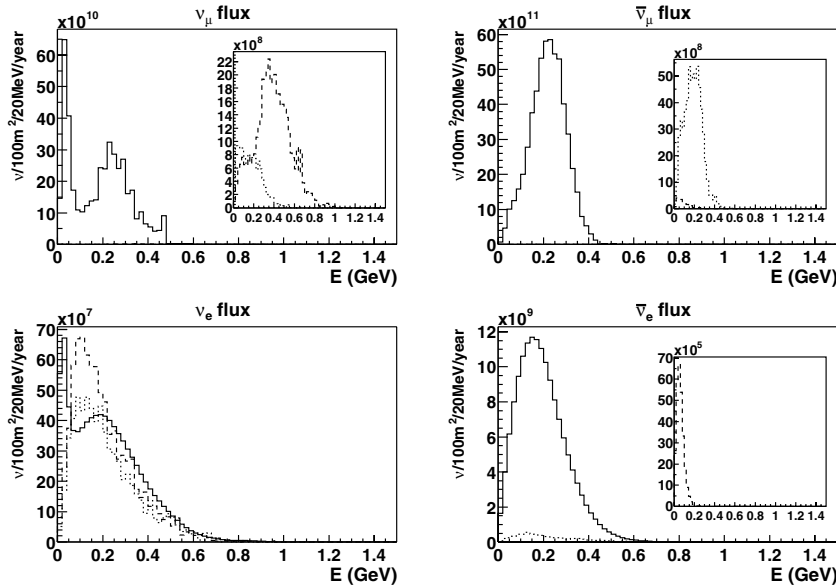

Fig. 7. Same legend as for Fig. 6 but the horns are focusing negative particles

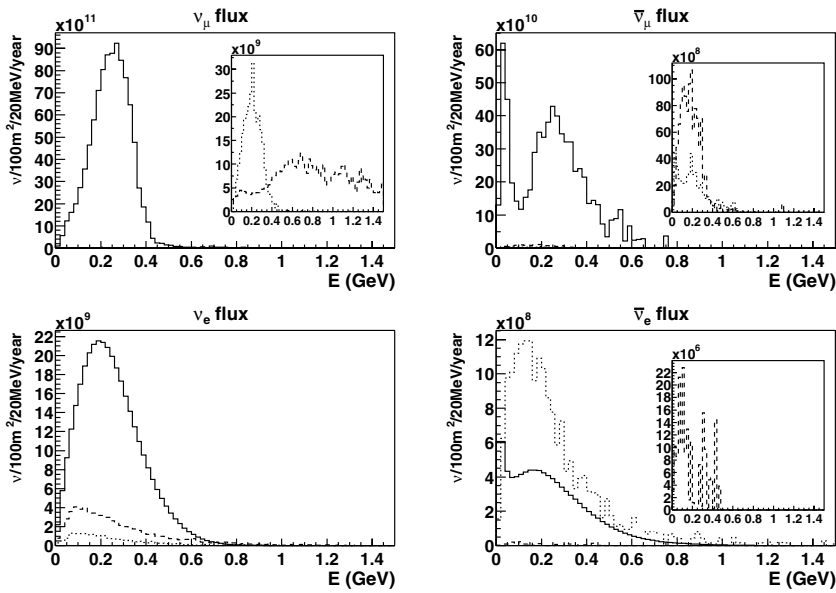

Fig. 8. Same legend as for Fig. 6 but for proton beam kinetic energy of 3.5 GeV (4 MW)

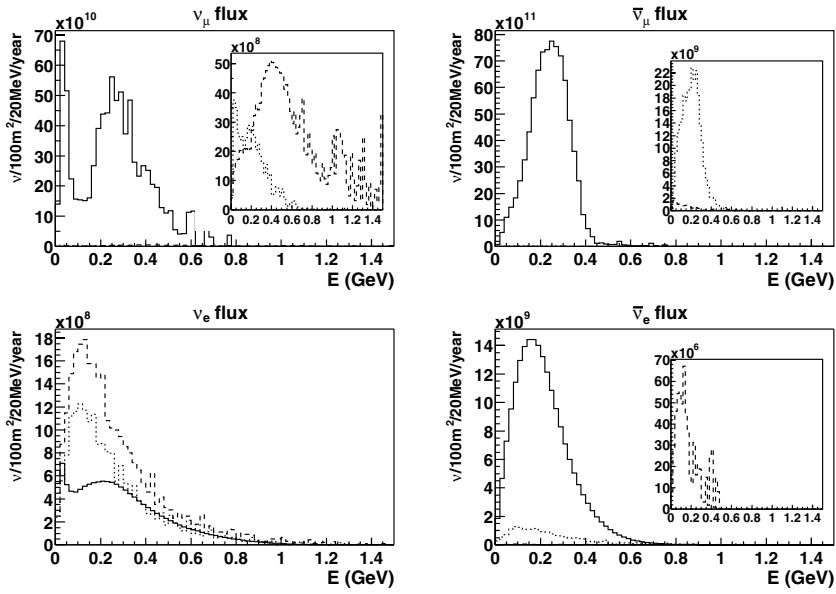

Fig. 9. Same legend as for Fig. 7 but for proton beam kinetic energy of 3.5 GeV (4 MW)

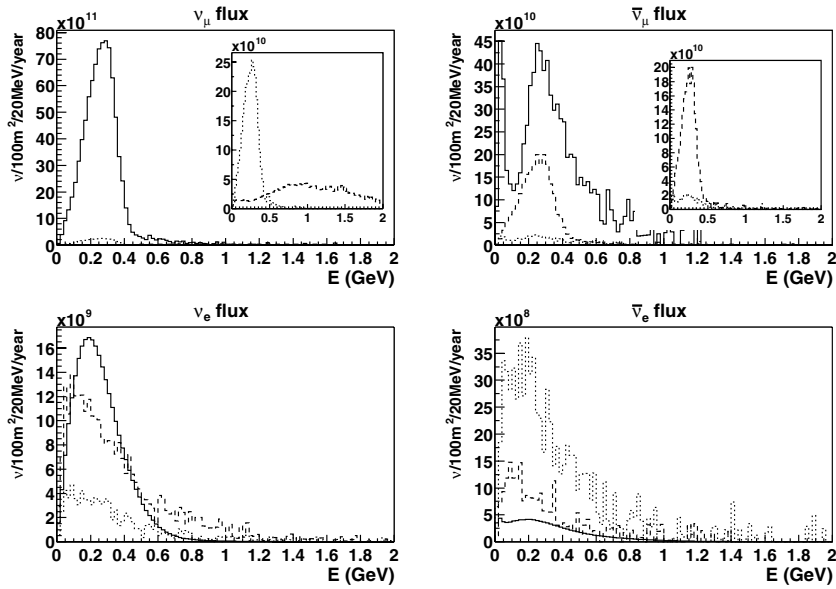

Fig. 10. Same legend as for Fig. 6 but for proton beam kinetic energy of 8 GeV (4 MW)

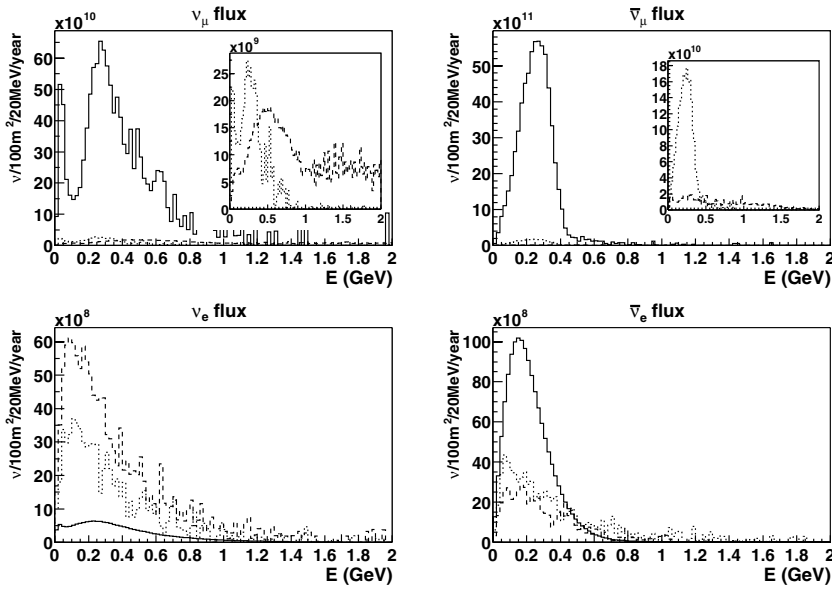

Fig. 11. Same legend as for Fig. 7 but for proton beam kinetic energy of 8 GeV (4 MW)

negative particle focusing are presented on Figs. 9 and 11. One clearly notices the increase of the kaon induced neutrino contents as the beam energy grows. On Table 5 are reported the integral of the fluxes when one modifies the decay tunnel length and radius, as well as the beam kinetic energy. Changing the length from 10 m to 40 m will increase the ν_μ flux by 50% to 70% and in the same time, the number of ν_e will be multiply by a factor 1.5 to 2. One can notice that going from 40 m to 60 m does not increase the signal-like events but increase the background-like events. For a 40 m length of the decay tunnel, the increase of the radius improve the number of signal-like events by 50%, and the background increase by 70% to 100%. Notice that the $\nu_\mu/\bar{\nu}_\mu$ flux ratio is rather insensitive to the decay tunnel length. The feeling that $L_T = 40$ m and $R_T = 2$ m is a good signal over background compromise is confirmed by sensitivity quantitative studies reported in Sect. 7.

Looking at the evolution of ν_μ flux with respect to the beam energy, one notices that a maximum is reached around 4.5 GeV. This is due to the competition between the cross section rise with respect to the energy and the decrease of the number of p.o.t due to the constant SPL power (4 MW).

6 Sensitivity computation ingredients

The sensitivity to θ_{13} and δ_{CP} is computed for a $\nu_\mu \rightarrow \nu_e$ appearance experiment. The detector considered for definitiveness is similar to the UNO detector, i.e. a 440 kt fiducial water Čerenkov detector [20]. The detector simulation has been presented in [25] and the analysis program described in [37] has been used for sensitivity computation following previous work of [26]. See Table 6 for the default use r

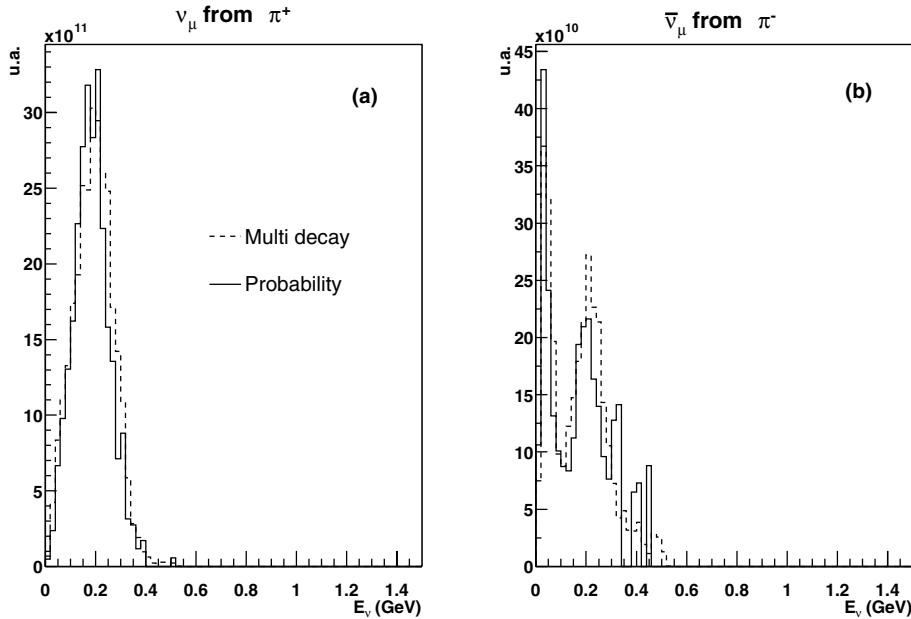

Fig. 12. Comparison between the probability method, (—) curve, and the full GEANT simulation method, (---) curve, for the ν_μ from π^+ flux **a** and the $\bar{\nu}_\mu$ from π^- flux **b**. The horns are set to focus positive particles. It should be stressed that the full GEANT simulation has taken roughly 13 times more CPU time than the probability method with the same number of protons on target, and the later simulation is able to produce as well the ν_e and $\bar{\nu}_e$ fluxes contrary to the former simulation

Table 5. Integral of the total flux of the different species with different settings. The ν_μ and $\bar{\nu}_\mu$ fluxes are expressed in $10^{13}/100\text{m}^2/\text{y}$ unit while the ν_e and $\bar{\nu}_e$ fluxes are expressed in $10^{11}/100\text{m}^2/\text{y}$ unit. The positive focusing and negative focusing are distinguished by a (+) sign and a (-) sign, respectively. The settings used corresponds to different values of L_T and R_T , the length and radius of the decay tunnel

Settings			ν_μ		ν_e		$\bar{\nu}_\mu$		$\bar{\nu}_e$

parameter values used in this paper. We just remind here some key points of the sensitivity analysis program.

It is included a full 3-flavors oscillation probability computation with matter effects, but no ambiguities are taken into account. This latest point may be revisited in a future work using [38]. Concerning the background events, the $\nu_e/\bar{\nu}_e$ from the beam, the $\nu_\mu e^-$ elastic scattering process, the π^0 production as well as the μ/e misidentification are taken into account. The cross-sections from the NUANCE program are used [39]. The systematics error on the total ν_e and $\bar{\nu}_e$ fluxes determination is a user parameter and we have used the 2% value considered as a final goal, but also 5% and 10% [37]. The detector is located at $L = 130$ km from CERN, in the foreseen new Fréjus laboratory [21]. It is worth to mention that if one wants to evaluate the influence of L on the sensitivity, it would mean a re-optimization of the horns for each L envisaged (see Sect. 4). The running time scenario has been fixed either by focusing positive

Table 6. Default parameters used to compute the sensitivity curves [37]. The quoted errors in parenthesis for the (12) and the (23) parameters (absolute value for the masse square differences and relative value for the angles) are coming respectively from the up to date combined Solar and KamLAND results [40] and from a 200 ktons-years SPL disappearance exposure [25]

$\Delta m_{12}^2 = 8.2(0.5) \times 10^{-5} \text{ eV}^2$	$\sin^2 2\theta_{12} = 0.82(9\%)$
$\Delta m_{23}^2 = 2.5(0.1) \times 10^{-3} \text{ eV}^2$	$\sin^2 2\theta_{23} = 1.0(1\%)$
$L_T = 20 \text{ m}$	$R_T = 1 \text{ m}$
$M = 440 \text{ kT}$	$\epsilon_{\text{syst}} = 2\%$

7 Results

7.1 The positive only focusing scenario

The θ_{13} and δ_{CP} sensitivities are computed with $\theta_{13} = 0^\circ$ and $\delta_{CP} = 0^\circ$ if not explicitly mentioned. It is worth to stress that the default parameters of Table 6 are used if not contrary mentioned, in particular, the decay tunnel geometry parameters ($L_T = 20$ m and $R_T = 1$ m), and the horn design to generate a 260 MeV neutrino beam.

Table 7 presents the number of signal and background events for a 5 years positive focusing experiment, but with different beam energy settings. The contours at 90%, 95% and 99% CL of the θ_{13} sensitivity are presented in the $(\sin^2 2\theta_{13}, \Delta m_{23}^2)$ plane on Fig. 13 for 3.5 GeV proton beam kinetic energy. The comparison between the contours at 90% CL with 2.2 GeV, 3.5 GeV, 4.5 GeV and 8 GeV beam energies is shown on Fig. 14. One notices in this scenario a better performance reached with a 4.5 GeV energy beam. But, in fact there is not much visual difference between a sensitivity obtained with 3.5 GeV and 4.5 GeV, even if one should keep in mind that kaon production models are different at these two energies (see Sect. 3). These two energy settings have been studied with different decay tunnel geometries and minimum values of $\sin^2 2\theta_{13}$ observable at 90% CL are reported on Table 9. One notice that similar results can be reached with a 3.5 GeV beam, compared to a 4.5 GeV beam.

Quantitative studies of the minimum $\sin^2 2\theta_{13}$ with respect to the kinetic beam energy $E_k(\text{proton})$, and the decay length L_T , and the systematics ϵ_{sys} are presented in Tables 8 and 10. One notices that for $\epsilon_{\text{sys}} = 5\%$ there is no difference between a 3.5 GeV and a 4.5 GeV beam. We have also considered the 3.5 GeV and 4.5 GeV beam energies with the tunnel geometry parameters $L_T = 40$ m and $R_T = 2$ m, and the horn design producing a 350 MeV neutrino beam (see Sect. 4). In Table 9 are reported numerical

Table 8. Minimum $\sin^2 2\theta_{13} \times 10^3$ in the $(\sin^2 2\theta_{13}, \Delta m_{23}^2)$ plane observable at 90% CL computed for different decay tunnel length (L_T) and kinetic beam energy ($E_k(\text{proton})$) and 5 year of positive focusing. Other parameters are fixed to default values (Table 6)

	2.2 GeV	3.5 GeV	4.5 GeV	6.5 GeV	8 GeV
10 m	1.10	0.92	1.04	1.07	1.16
20 m	1.16	0.92	0.89	1.01	1.12
40 m	1.23	1.00	0.99	1.08	1.19

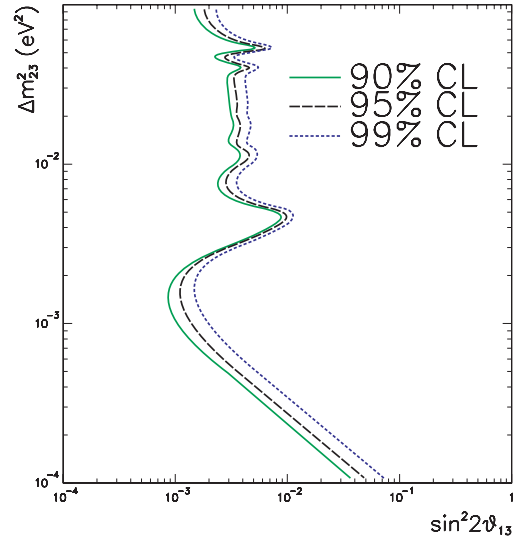

Fig. 13. Sensitivity contours obtained with a SPL energy of 3.5 GeV and default parameters of Table 6. In particular, it is reminded that the tunnel geometry parameters are $L_T = 20$ m and $R_T = 1$ m. (—), (---) and (···) curves stand for 90%, 95% and 99% confidence level, respectively

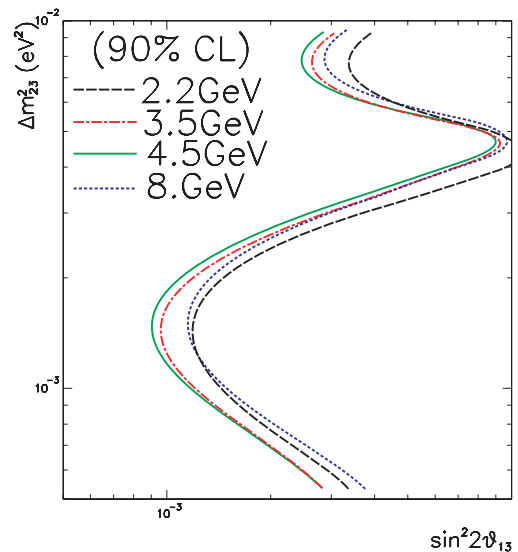

Fig. 14. Comparison of 90% CL sensitivity contours obtained with SPL energies of 2.2 GeV (---), 3.5 GeV (-·-·), 4.5 GeV (—) and 8 GeV (···) and default parameters of Table 6. In particular, it is reminded that the tunnel geometry parameters are $L_T = 20$ m and $R_T = 1$ m

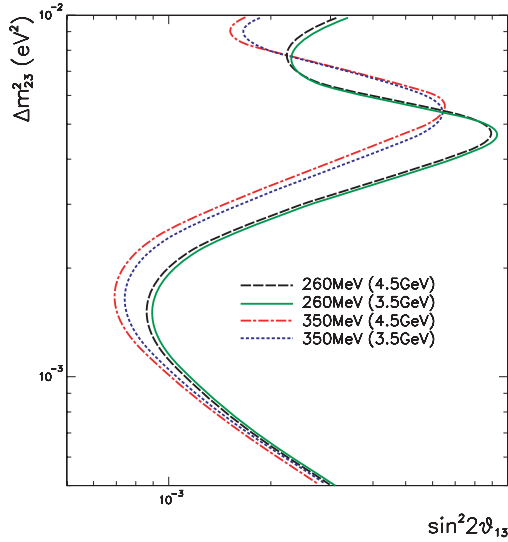

Fig. 15. Comparison of 90% CL sensitivity contours obtained with SPL energies of 3.5 GeV or 4.5 GeV, and either a 260 MeV (default) neutrino beam or a 350 MeV neutrino beam. The tunnel geometry parameters are $L_T = 40$ m and $R_T = 2$ m. The (---) curve corresponds to a 350 MeV/4.5 GeV (neutrino beam/SPL beam energy) setting; the (····) curve corresponds to a 350 MeV/3.5 GeV setting; the (----) curve corresponds to a 260 MeV/4.5 GeV setting and the (—) curve corresponds to a 260 MeV/3.5 GeV setting

values, and on Fig. 15 are shown the 90% CL sensitivity contours. With the 350 MeV neutrino beam, one can expect a 16% improvement with respect to the 260 MeV neutrino beam. One notices also that there is marginal gain to increase the beam energy from 3.5 GeV to 4.5 GeV, as already mentioned.

There are also variations on the minimum $\sin^2 2\theta_{13}$ value that may be reached in a $\nu_\mu \rightarrow \nu_e$ experiment which are due to the $\text{sign}(\Delta m_{23}^2)$ ambiguity and the δ_{CP} value. On Table 11 are presented these kind of variations. Other ambiguities coming from the $\text{sign}(\tan(2\theta_{23}))$ ignorance also take place as studied in [17]. From Fig. 9 of this, we estimate a 30% effect on $\sin^2(2\theta_{13})$ sensitivity due to these ambiguities.

7.2 Mixed positive/negative focusing scenario

The combined $\sin^2 2\theta_{13}$ and δ_{CP} sensitivity for the 5 years positive focusing scenario and the default parameters of Table 6 is presented on Fig. 16a. The results obtained with a 3.5 GeV and 4.5 GeV SPL beam are similar and better than with the other energy settings. On Fig. 17a the results obtained with a 260 MeV neutrino beam and a 350 MeV neutrino beam are presented with a 40 m long, 2 m radius decay tunnel. With the 350 MeV neutrino beam, one can reach better sensitivity results in the range $|\delta_{CP}| < 120^\circ$, and comparatively the gain obtained when switching from a 3.5 GeV proton beam to a 4.5 GeV proton beam is marginal. To improve the δ_{CP} -independent limit on $\sin^2 2\theta_{13}$, especially around $\delta_{CP} = 90^\circ$, one may envisaged a combination of 2 years with positive focusing and 8 years negative focusing as in [17, 25, 26]. The comparison of the results obtained

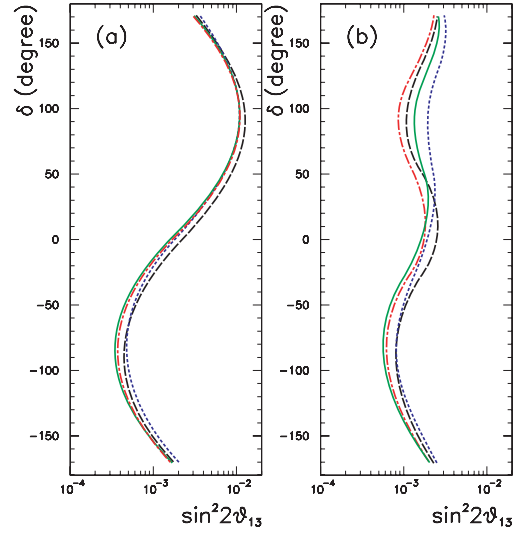

Fig. 16. 90% sensitivity contours obtained with SPL beam energy of 2.2 GeV (----), 3.5 GeV (---), 4.5 GeV (—) and 8 GeV (····) at 90% CL. Default parameters of Table 6 are used either with a 5 years positive focusing scenario **a** or a mixed scenario of 2 years positive focusing and 8 years of negative focusing **b**. In particular, it is reminded that the tunnel geometry parameters are $L_T = 20$ m and $R_T = 1$ m

with different SPL beam energies on the combined sensitivity contours are presented in Fig. 16b. Sensitivities to $\sin^2 2\theta_{13}$ observable at 90% CL in the worse δ_{CP} case are reported Table 9 for this kind of mixed focusing scenario. One generally gets 10% to 20% better limit on $\sin^2 2\theta_{13}$ independently of δ_{CP} with a 3.5 GeV kinetic energy beam compare to a 2.2 GeV beam. Doubling the length and the radius of the decay tunnel allows to reach a 10% better limit.

On Fig. 17b are presented the results considering the effects of a 350 MeV neutrino beam obtained either with a 3.5 GeV proton beam or a 4.5 GeV proton beam compared to a 260 MeV neutrino beam obtained with a 4.5 GeV proton beam. The tunnel geometry parameters are $L_T = 40$ m and $R_T = 2$ m (other tunnel geometry have been studied but the results are worse and so are not reported). Except in the region $|\delta_{CP}| > 150^\circ$, the results obtained with the 350 MeV neutrino beam (3.5 GeV proton beam) are somewhat better, even if a 11% improvement of the δ_{CP} -independent $\sin^2 2\theta_{13}$ limit can be reached with the 260 MeV neutrino beam obtained with the 3.5 GeV proton beam.

8 Summary and outlook

A complete chain of simulation has been set up for the SPL-Fréjus project. The neutrino production has been extended to the kaon decay contribution, which is important to test SPL energy scenario above 2.2 GeV. The beam line optimization has been performed using the sensitivity to $\sin^2 2\theta_{13}$ and δ_{CP} . The shape of the focusing system has been updated to obtain a neutrino beam energy around 260 MeV or 350 MeV.

Table 9. Study of the sensitivity of different beam energy, decay tunnel length (L_T) at and radius (R_T), and horn design in two different scenarios. First scenario is 5 years of positive focusing, in which sensitivity is given as the minimum of $\sin^2 2\theta_{13} \times 10^3$ in the $(\sin^2 2\theta_{13}, \Delta m_{23}^2)$ plane observable at 90% CL ($\delta_{CP} = 0$). Second scenario is 2 years of positive focusing plus 8 years of negative focusing, in which sensitivity is given as the minimum $\sin^2 2\theta_{13} \times 10^3$ observable at 90% CL computed for the worse δ_{CP} case. A star (*) indicates the use of the the horn geometry producing a 350 MeV neutrino beam. Other parameters are fixed to default values (Table 6)

setting	L_T	10 m	20 m	20 m	30 m	40 m	40 m	40 m	40 m(*)	60 m	60 m
		R_T	1 m	1 m	1.5 m	1 m	1 m	1.5 m	2 m	2 m(*)	1 m
5 years of positive focusing scenario	3.5 GeV	0.92	0.92	0.83	0.98	1.00	0.93	0.91	0.76	1.05	1.01
	4.5 GeV	1.04	0.89	0.82	0.94	0.99	0.92	0.87	0.71	1.03	1.00
2 years of positive focusing + 8 years of negative focusing scenario	2.2 GeV		2.52			2.58		2.30			
	3.5 GeV	2.34	2.22	2.10	2.13	2.09	2.08	2.02	2.28	2.16	2.09
	4.5 GeV	2.91	2.60	2.43	2.48	2.52	2.39	2.34	2.55	2.53	2.47

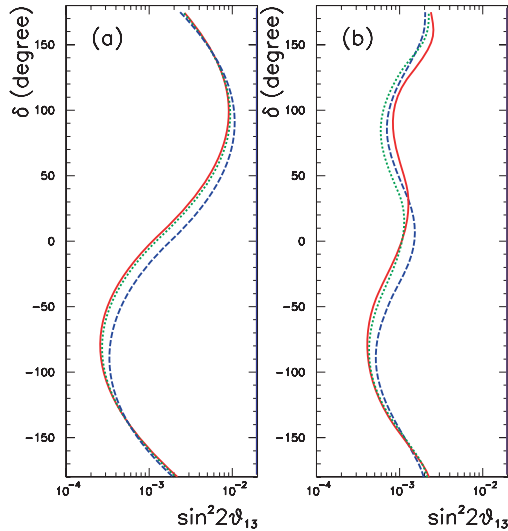

Fig. 17. 90% CL sensitivity contours obtained with the decay tunnel geometry parameters $L_T = 40$ m and $R_T = 2$ m and different SPL beam energies (3.5 GeV or 4.5 GeV) and different horn designs (260 MeV or 350 MeV neutrino beams): (—) curve for a 350 MeV/4.5 GeV setting, (⋯⋯) curve for a 350 MeV/3.5 GeV setting, (---) curve for a 260 MeV/3.5 GeV setting. Other default parameters of Table 6 are used either with a 5 years positive focusing scenario **a** or a mixed scenario of 2 years positive focusing and 8 years of negative focusing **b**

In a positive only focusing scenario, the best limit on $\sin^2 2\theta_{13}$ is 0.82×10^{-3} (90% CL, $\delta_{CP} = 0$), with a 4.5 GeV beam energy and a 20 m long, 1.5 m radius decay tunnel. However, the 3.5 GeV beam may also obtain rather similar limit with 0.83×10^{-3} (90% CL) with the same tunnel parameters. The δ_{CP} independent $\sin^2 2\theta_{13}$ sensitivity is limited to $\approx 10^{-2}$ due to the $\delta_{CP} \approx 90^\circ$ region.

In a mixed focusing scenario, the best limit on $\sin^2 2\theta_{13}$ independent of δ_{CP} is 2.02×10^{-3} (90% CL) obtained with a 3.5 GeV beam energy and a 40 m long, 2 m radius decay tunnel.

The comparison of the optimization presented in this paper with the results obtained by other projects is displayed on Fig. 18. It is presented the 5 years positive focusing scenario, and two versions of a mixed scenario using

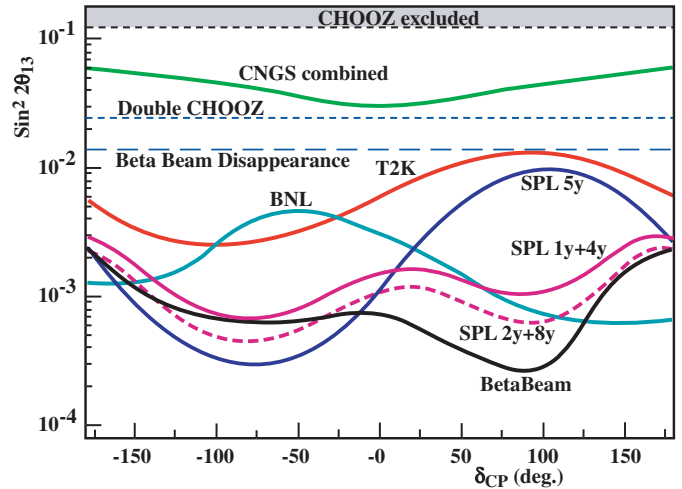

Fig. 18. 90%CL sensitivity contours labeled by the project or experiment involved. The “CHOOZ excluded” dashed curve comes from the exclusion obtained from [10] with $\Delta m^2 = \Delta m_{atm}^2$; in the same conditions is given the sensitivity foreseen for the “Double-CHOOZ” project [11]. The “CNGS combined” has been obtained combining the results from OPERA and ICARUS [41]. The T2K contour has been derived from [42]. The BNL contour has been obtained from [43]. The “Beta Beam” contour has been computed with 5 years running with both ν_e and $\bar{\nu}_e$ neutrino beams in an appearance mode, while the dashed “Beta Beam disappearance” has been obtained as if the β beam was analysed like a reactor experiment with 1% systematic error [44]. The “SPL 5y” and “SPL 2y+8y” and “SPL 1y+4y” curves have been obtained from the optimisation described in this paper (“5y”: positive only focusing scenario; “1y+4y”: 1 year of positive focusing and 4 years of negative focusing scenario; “2y+8y”: 2 years of positive focusing and 8 years of negative focusing scenario) using a 3.5 GeV beam and a decay tunnel of 40 m length, and 2 m radius

positive and negative focusing: one scenario duration is 5 years in total and the other one is 10 years running in total and has been used in the previous section. It shows the complementarity of the SPL-Fréjus project with the beta beam-Fréjus project. Especially when considering the sensitivity to $\sin^2 2\theta_{13}$ for $\delta_{CP} < 0$.

Table 10. Minimum $\sin^2 2\theta_{13} \times 10^3$ in the $(\sin^2 2\theta_{13}, \Delta m_{23}^2)$ plane observable at 90% CL computed for different level of systematics (ϵ_{syst}) and kinetic beam energy ($E_k(\text{proton})$) and 5 years of positive focusing. Other parameters are fixed to default values (Table 6)

	2.2 GeV	3.5 GeV	4.5 GeV	6.5 GeV	8 GeV

10%	2.40	2.14	2.21	2.72	3.09

Table 11. Minimum $\sin^2 2\theta_{13} \times 10^3$ in the $(\sin^2 2\theta_{13}, \Delta m_{23}^2)$ plane observable at 90% CL computed for a 2.2 GeV kinetic energy proton beam, and for different values of $\text{sign}(\Delta m_{23}^2)$ and δ_{CP} and 5 years of positive focusing. Other parameters are fixed to default values (Table 6)

	-180°	-90°	0°	90°	180°
+	1.40	0.43	1.16	11.48	1.40
-	1.45	11.75	1.11	0.43	1.45

The authors think that the present study may be extended in many respects. The beam line simulation part may be performed with a single simulator as FLUKA (or GEANT4 [45] for comparison). Other targets may be envisaged (tantalum, carbon) as well as other detector types as a Large Liquid Argon detector [46]. The baseline length may also be revisited as well as the off axis option. The sensitivity analysis may be deeper investigated using the complete set of possible ambiguities as in *iteDONINI*, and the θ_{13} or δ_{CP} measurement accuracy with new beam energy scenario may be investigated too.

Acknowledgements. The authors would like to thank M. Mezzetto to have expressed his interest since the early stage of this work and to have provided us with his sensitivity computation program. Also the authors thank S. Gilardoni for fruitful discussions.

Appendix A: Decay probability computations

This appendix contains the probability formulas and the algorithms used in the flux computation (see Sect. 5.1).

A.1 Pion neutrino probability computation

Pions decay only as $\pi^+ \rightarrow \mu^+ + \nu_\mu$ or $\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$ and the neutrinos are emitted isotropically in the pion rest frame, with an energy of about 30 MeV given by the 2-body decay kinematics. Applying a Lorentz boost knowing the pion momentum and direction, it is possible to compute the probability to reach the detector for the neutrinos. Only neutrino parallel to the beam axis are supposed to pass through the detector fiducial area, and therefore, the neutrino must be emitted by the pion with an angle opposite to the angle between the pion and the beam axis (see

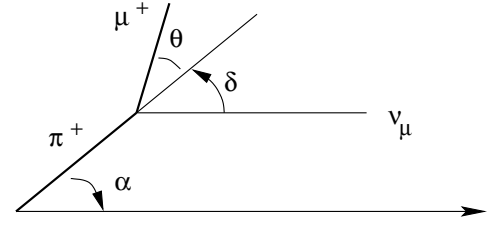

Fig. 19. Pion decay in the tunnel frame. To reach the detector, $\delta = -\alpha$ is needed

Fig. 19). This gives:

$$\mathcal{P}_\pi = \frac{1}{4\pi} \frac{A}{L^2} \frac{1 - \beta^2}{(\beta \cos \alpha - 1)^2} \quad (\text{A.1})$$

where β is the velocity of the pion in the tunnel frame, A is the fiducial detector surface, L the distance between the neutrino source and the detector, and α the angle between the pion direction and the beam axis in the laboratory frame.

A.2 Muon neutrino probability computation

Muons decay only as $\mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$ or $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$, and will produce background events. The mean decay length of the muons is 2 km, therefore, most of them do not decay in the tunnel. This induces a lack of statistics to estimate the corresponding level of background. This problem has been solved using each muon appearing in the simulation in the following steps:

1. the probability for the muon to decay into the tunnel has been computed using a straight line propagation;
2. the available energy for the neutrino in the tunnel frame has been divided in 20 MeV energy bins;
3. one ν_e and one ν_μ have been simulated in each of the energy bins (step 2). Then, the probability to reach the detector has been computed, and multiplied by the probability computed at step (1).

After the probability computation, the non useful muon is discarded by GEANT to gain in CPU time.

The probability for the muon neutrino and the electron neutrino to be emitted parallel to the beam axis is [36]:

$$\frac{d\mathcal{P}_\mu}{dE_\nu} = \frac{1}{4\pi} \frac{A}{L^2} \frac{2}{m_\mu} \frac{1}{\gamma_\mu (1 + \beta_\mu \cos \theta^*)} \times \frac{1 - \beta_\mu^2}{(\beta_\mu \cos \rho - 1)^2} [f_0(x) \mp \Pi_\mu^L f_1(x) \cos \theta^*] \quad (\text{A.2})$$

where β_μ and γ_μ are the velocity and the Lorentz boost of the muon in the tunnel frame, θ^* is the angle with respect to the beam axis of the muon in the muon rest frame, ρ is the corresponding angle in the tunnel frame. Like in the pion case, this angle appears because the neutrino must be parallel to the beam axis. Π_μ^L is the muon longitudinal polarization, the parameter x is defined as $x = 2E_\nu^*/m_\mu$ where E_ν^* is the neutrino energy in the muon rest frame,

Table 12. Flux function in the muon rest frame [47]

	$f_0(x)$	$f_1(x)$
ν_μ	$2x^2(3-2x)$	$2x^2(1-2x)$
ν_e	$12x^2(1-x)$	$12x^2(1-x)$

and the function $f_0(x)$ and $f_1(x)$ coming from the matrix element of the muon decay are given in Table 12. The sign in front of Π_μ^L in equation A.2 is $(-)$ for the μ^+ decays and $(+)$ for the μ^- decays, respectively.

Muon polarization is computed using the conservation of the transverse component of the velocity four-vector $\gamma(1, \beta)$ between the muon rest frame (where the polarization is computed) and the pion rest frame, where the muon helicity is -1 , due to the parity non conservation. It yields [48]:

$$\Pi_\mu^T = \frac{\gamma_\pi \beta_\pi}{\gamma_\mu \beta_\mu} \sin \theta^* \quad \text{and} \quad \Pi_\mu^L = \sqrt{1 - \Pi_\mu^T{}^2} \quad (\text{A.3})$$

where γ_π , β_π , γ_μ , and β_μ are the Lorentz boost and velocity of the pion and of the muon in the tunnel frame, and θ^* the angle with respect to the beam axis of the muon in the pion rest frame.

A.3 The treatment of the kaons

Contrary to pions and muons, kaons have many decay channels. They are summarized in Table 13.

Table 13. Charged and neutral kaon decay channels [49]

K^\pm	K_L^0	K_S^0
$\mu^\pm \nu_\mu$	$\pi^- e^+ \nu_e$	$\pi^+ \pi^-$
$\pi^\pm \pi^0$	$\pi^+ e^- \bar{\nu}_e$	$\pi^0 \pi^0$
$\pi^\pm \pi^+ \pi^-$	$\pi^- \mu^+ \nu_\mu$	
$e^\pm \nu_e \pi^0$	$\pi^+ \mu^- \bar{\nu}_\mu$	
$\mu^\pm \nu_\mu \pi^0$	$\pi^0 \pi^0 \pi^0$	
$\pi^\pm \pi^0 \pi^0$	$\pi^+ \pi^- \pi^0$	

There is a very small amount of kaons produced (Sect. A.3), and this number has been artificially increased in order to obtain statistically significant results. The multiplicity of decay channels makes impossible the method used for the muon case (A.2). The method chosen for the good compromise between the gain in CPU and the statistical uncertainty of the results, is to duplicate many times each kaon exiting the target. The number of duplication varies between 10 and 300. It depends on the initial kaon rate and therefore on the beam energy.

All the kaons daughter particles are tracked by GEANT until they decay. Three different types of daughter particles are identified in the kaon decays. The first type corresponds to primary neutrinos, the second type concerns charged pions and muons, and the neutral pions are left for the last type.

In the $K^\pm \rightarrow \mu^\pm \nu_\mu (\bar{\nu}_\mu)$ decay modes, the computation of the probability for a neutrino to reach the detector is

the same than the 2-body decay formula used to in the pion decay (A.1), where β is now the kaon velocity, and α the angle of the kaon with respect to the beam axis.

When a neutrino is produced by a kaon 3-body decay, the probability to reach the detector is computed using a pure phase space formula. It yields:

$$\mathcal{P}_K = \frac{1}{4\pi} \frac{A}{L^2} \frac{1}{m_K - m_\pi - m_l} \times \frac{1}{\gamma_K(1 + \beta_K \cos \theta^*)} \frac{1 - \beta_K^2}{(\beta_K \cos \delta - 1)^2} \quad (\text{A.4})$$

where m_K is the kaon mass (charged or neutral), m_π is the pion mass (π^0 mass in K^\pm decays and π^\pm mass in K_L^0 decays), and m_l is the mass of the lepton associated with the neutrino. The β_K and γ_K are the velocity and the Lorentz boost of the kaon, θ^* is the angle between the neutrino direction and the kaon direction, in the kaon rest frame. Finally, δ is the angle between the kaon direction and the beam axis in the tunnel frame.

When a π^\pm is produced in the kaon decay chain, it is tracked by GEANT until it decays, and the probability of (A.1) is applied to the produced neutrino. In case of a muon, it is treated as explained in Appendix A.2. The muon polarization is computed this time using the kaon decay informations. Finally, when a π^0 is produced, as it cannot create neutrinos, it is simply discarded.
